a. Antimicrobial therapy

- (1) **Urethritis alone.** The approach to and treatment of this problem is discussed in Chapter 16 under Urethritis.
- (2) **Prostatitis** therapy is discussed in section III.
- (3) **Initial therapy** in the adult man who presents with his first UTI believed to be **unrelated to a prostatic focus** is uncertain. (This may be a particular problem in the young or middle-aged man compared with the older man, who is more likely to have a prostatic focus.) A subclinical prostatic focus still is possible, as is an occult genitourinary structural problem. With **recurrent UTI**, the prostatic localization test (see section III.B) sometimes is performed to help localize the problem. It is reasonable to use TMP-SMX (which penetrates the prostate well) because of the possibility of a prostatic focus in all men with UTI. Alternatively, one may use TMP alone in the sulfa-allergic patient or a fluoroquinolone because these agents also penetrate the prostate well (see Chapter 27).
- (4) For that subgroup of sexually active young males (see section 2.c) a 7-day course of TMP-SMX, TMP, or fluoroquinolone is suggested [2] once urethritis is excluded. Failure of this regimen necessitates more careful evaluation, including consideration of a prostatic focus [2].

- b. **Urologic evaluation.** In addition to antimicrobial therapy, urologic evaluation to determine whether a urinary tract abnormality exists should be considered. It is reasonable to treat a first UTI in a man who has no history of prior genitourinary abnormalities, then watch closely, and eventually proceed with a urologic workup when and if a second UTI or relapse occurs. Cystoscopy usually is indicated in patients with recurrent infections. **In patients with a typical initial episode of cystitis or acute prostatitis responding to antibiotics, a complete urologic evaluation is not necessary.** The approach to patients with an enlarged prostate (compatible with benign prostate hypertrophy) is an evolving area, with the increased availability of medical therapy for some forms of benign prostate hypertrophy. Also, stents can be inserted in the prostatic urethra segment (instead of conventional prostatic surgery) only in carefully selected patients. Urologic consultation is therefore important [15].

III. Bacterial prostatitis [10,43,46] can present as either an acute or a chronic disease. It has been estimated that prostatitis constitutes approximately 25% of annual office visits for genitourinary complaints by men. Unfortunately, many aspects of prostatitis have been poorly understood, and both patients and clinicians often become confused and frustrated in dealing with this condition [10].

The common forms of prostatitis are summarized in Table 15.4. Bacterial prostatitis is associated with a UTI, positive cultures localizing the bacterial pathogen to the prostatic fluid, and excessive numbers of inflammatory cells (WBCs and macrophages containing fat) in the prostatic secretion [10,46]. **Studies suggest that nearly 90% of patients with prostatitis symptoms have nonbacterial prostatitis or prostatodynia [10,47].**

A. Acute bacterial prostatitis is an abrupt febrile illness. Symptoms include fever, chills, and low back and acute perineal pain and discomfort. In addition, symptoms of acute lower UTI such as dysuria, frequency, and urgency usually are present.

1. **Diagnosis.** The signs and symptoms are sufficiently abrupt, severe, and typical that the clinician seldom has difficulty in making the diagnosis [10].

- a. **Rectal examination** often is not necessary, thereby avoiding the discomfort and potential risk of prostate massage, because symptoms and urinalysis usually support the diagnosis of acute bacterial prostatitis. If a single gentle rectal examination is performed, it reveals a swollen prostate that often is exquisitely tender on palpation.

- b. **Urinalysis** usually demonstrates pyuria and bacteriuria.

- c. **Prostatic localization studies**, as discussed later, require prostatic massage and are **unnecessary** to support the clinical diagnosis in patients with acute prostatitis. Massage may precipitate bacteremia and causes considerable patient discomfort.

Table 15.4. Clinical Features of Common Prostatitis Syndromes

Syndrome	History of Confirmed UTI	Prostate Abnormal on Rectal Examination	Excessive WBCs in EPS	Positive Culture of EPS	Common Causative Agents	Response to Antimicrobial Treatment	Impaired Urinary Flow Rate
Acute bacterial prostatitis	Yes	Yes	Yes	Yes	Coliform bacteria	Yes	Yes
Chronic bacterial prostatitis	Yes	±	Yes	Yes	Coliform bacteria	Yes	±
Nonbacterial prostatitis	No	±	Yes	No	None ? <i>Chlamydia</i> ? <i>Ureaplasma</i>	Usually no	±
Prostatodynia	No	No	No	No	None	No	Yes

UTI, urinary tract infection; WBCs, white blood cells; EPS, expressed prostatic secretions. From Meares EM Jr. Prostatitis. *Med Clin North Am* 1991;75:497; with permission.

- d. Clean-catch urine culture.** Because acute cystitis usually is associated with acute prostatitis, **the infecting pathogen generally can be identified by routine culture of a clean-catch urine specimen.** Data suggest a clean-catch culture may not be necessary in men. Neither meatal cleansing nor mid-stream sampling generally is needed to obtain urine for culture [43].
- 2. Therapy.** The inflammation of acute bacterial prostatitis allows most antibiotics to achieve high prostatic concentration, and patients generally respond rapidly to antibiotic therapy. Most infections are caused by enteric gram-negative bacilli (75%), particularly *E. coli* (25%), although gram-positive infections occur in the other 25% [10,43].
- a. Antibiotic choice.** Currently, **TMP-SMX, or TMP alone, is the treatment of choice** for acute bacterial prostatitis because of cost and the good penetration of prostatic tissue by TMP (Table 15.3) [10,48]. TMP alone may be administered in the sulfa-allergic patient. Comparable results have been published with the fluoroquinolones, and these agents are the drugs of choice for TMP-SMX-resistant organisms or as another alternative in sulfa-allergic patients (see Chapter 27). There are few data to support the use of oral carbenicillin indanyl.
- b. Other antibiotics.** Some patients with acute prostatitis are systemically ill and may require therapy with parenteral antibiotics initially. Ampicillin and aminoglycosides have commonly been used in combination while awaiting cultures, especially if enterococci are a concern. Broad-spectrum penicillins, cephalosporins, and aminoglycosides are effective in many patients with acute prostatitis, even though these drugs are generally not believed to penetrate the prostate well. The inflammation in acute prostatitis allows these drugs to penetrate the prostate to a greater extent in acute infections than in chronic prostatitis.
- c. Duration of therapy.** The optimal duration of therapy is not well defined. Conventionally, treatment spans a minimum of 14 days. However, continuing therapy for prolonged durations in an attempt to treat a focus of chronic prostatitis has often been advocated [10,44]. If the antibiotic is well tolerated, we tend to treat acute infection for a 4-week course, and chronic infection for 6 to 12 weeks.
- 3. Prognosis.** Most patients recover from acute prostatitis with appropriate treatment. Relapse may occur in some cases, or the prostate may remain a persistent source of infection, as discussed next.
- B. Chronic bacterial prostatitis** is a more subtle condition than acute prostatitis. Bacterial organisms in this disease are **difficult to eradicate** despite antibiotic therapy, and the prostate can remain a persistent source of UTI. The prostatic focus can repeatedly infect the bladder urine and is believed to be responsible for most relapsing lower UTIs in men. Infection usually is due to gram-negative bacilli but occasionally may be due to gram-positive organisms (e.g., enterococci). The role of other gram-positive bacteria is unclear. *S. aureus* at times may be a pathogen, but *S. epidermidis*, micrococci, and diphtheroids probably are not pathogens [10].
- Infected prostate calculi that cannot be appreciated by rectal examination or simple plain-film radiographic studies may function as infected foreign bodies, explaining in part why it may be difficult to eradicate infection in chronic bacterial prostatitis.
- 1. Symptoms** are highly variable, and some patients are detected because of asymptomatic bacteriuria. Many patients may not have a history of acute prostatitis. Some complain of perineal or low back discomfort. Periodic episodes of cystitis symptoms or irritative voiding dysfunction, such as urgency, frequency, nocturia, and dysuria, may occur. **The best clue to this diagnosis is that prostatitis is the most common cause of relapsing UTIs (with the same pathogen) in men.** Because many antibiotics penetrate the prostate poorly, the pathogen remains viable in the prostatic tissue. Some antibiotic regimens will eradicate concomitant cystitis and sterilize the patient's urine, temporarily providing relief of symptoms, but symptoms return when the antibiotic is discontinued, because the prostatic infection persists.

2. Diagnosis

a. Rectal examination reveals no characteristic findings on prostatic palpation. An enlarged or slightly boggy prostate is a nonspecific finding.

b. Localization studies. The historical method of diagnosis was to perform prostatic localization studies, with **careful microscopic and culture examination of the segmented urine and the prostatic fluid. Localization studies are now regarded as seldom if ever necessary**; the procedure is time-consuming, fairly expensive, and uncomfortable for patients and therefore is infrequently performed [49]. **They should not be performed in bacteriuric patients in whom the causative agent is already identified.** A justifiable alternative to performing prostatic localization studies is to treat bacteriuric men with prolonged courses of antibiotics known to penetrate the prostate. Studies may be useful in the patient who is not bacteriuric, to distinguish bacterial from nonbacterial prostatitis, to confirm a prostatic focus of infection for patients in whom prostatic surgery is contemplated because of recurrent UTI, or to help confirm the diagnosis in patients with recurrent symptoms.

The prostatic localization method requires that the patient is well hydrated and has a full bladder before starting. The glans must be cleaned as previously noted, and the foreskin must be fully retracted during the procedure. The specimens collected usually are examined microscopically and cultured immediately after collection, using methods that allow quantitation of small numbers of bacteria. **Careful microscopic examination alone can provide useful information** (see section (6)).

(1) The patient first voids 20 mL urine (VB₁) into one container.

(2) A midstream specimen then is obtained in a second container (VB₂).

(3) During prostatic massage, expressed prostatic secretions (EPS) are collected.

(4) Finally, 10 mL of urine is collected after prostatic massage (VB₃).

(5) **Interpretation.** Meares [10] reviewed the interpretation of this technique in detail, including illustrative cases. Briefly, if colony counts in specimen VB₁ exceed those in VB₃, the bacteria are localized to the anterior urethra. If VB₁ and VB₂ are negative or have low counts of bacteria and the EPS and VB₃ have larger numbers of bacteria, bacterial prostatitis must be considered. If the specimens all yield more than 10⁵ CFU/mL, interpreting the test is not possible. In this instance, the patient should be treated with a 2- to 3-day course of nitrofurantoin, which will eradicate bladder bacteriuria but will not penetrate the chronically inflamed prostate; then the four-specimen test should be repeated.

(6) **In chronic prostatitis, the prostatic fluid (EPS) should reveal more than 15 WBCs per high power field.** Culture of prostatic fluid should reveal the offending organism. Colony counts of fewer than 100,000 CFU/mL generally are seen, with counts of 1,000 CFU/mL or fewer on occasion.

Provided that the urethral and midstream specimens show insignificant pyuria, more than 15 WBCs per high power field in the prostate expressate is diagnostic of prostatic inflammation. The most convincing sign of prostatitis is the finding of both excessive WBCs and macrophages containing fat droplets (ovoid fat bodies) in EPS.

3. Treatment. Eradication of a persistent prostatic focus of infection often is difficult. Except for TMP (alone or in combination with SMX), erythromycin (for gram-positive bacteria), and the quinolones, most antibiotics useful against gram-negative bacteria diffuse poorly into the prostatic fluid. Therefore, despite prolonged 6- to 12-week courses of appropriate antibiotics, cure rates of only about 30% to 40% are reported [10], but these rates are better than those for short-course regimens.

a. TMP-SMX or a quinolone (Table 15.3) has been reported to be most successful for chronic prostatitis when used for prolonged periods. Therapy with TMP-SMX (one double-strength tablet twice daily) should be continued for a minimum of 6 weeks and preferably for 12 weeks. Optimal duration of therapy with the quinolones awaits further study. Ciprofloxacin (500 mg twice a day),

norfloxacin (400 mg twice a day), or ofloxacin (300 mg twice a day) for 30 days has been suggested [10].

- b. Even prolonged courses of antibiotics may be unsuccessful, particularly if there are prostatic calculi. Further urologic evaluation and partial prostatectomy may be indicated in refractory cases. Complete prostatectomy may result in incontinence or sexual impotency and therefore is contraindicated. Chronic suppressive therapy with TMP-SMX (one tablet daily) or TMP alone is appropriate in patients who continue to relapse after a 12-week course of full-dose therapy. Nitrofurantoin (100 mg/day) has been used [10]. The quinolones also are used for chronic suppression, but these agents are far more expensive than TMP or TMP-SMX (see Chapter 27).

C. Nonbacterial prostatitis is far **more common than chronic bacterial prostatitis**. It is defined as symptomatic prostatic inflammation with negative culture of urine and prostatic secretions. It has also been referred to as **prostatosis** [50]. Some authorities believe that prostatosis is merely bacterial prostatitis caused by small numbers of organisms. The etiology remains unclear; it is an inflammatory condition of unknown cause [10]. Systematic reviews have recently questioned the methodologic quality of historical diagnostic standards for chronic abacterial prostatitis [51].

1. **Symptoms.** Complaints are similar to those of patients with chronic bacterial prostatitis. The patient often has no prior history of a UTI.
2. **Diagnosis.** Physical examination generally is unremarkable, although some patients may complain of prostatic tenderness on palpation. **EPSs show more than 10 to 15 WBCs per high power field**, but routine urine cultures and prostatic localization cultures show no bacterial etiology.
3. **Treatment.** There is **no accepted approach** to therapy because the etiology of this disease is unknown. Empiric treatment directed toward chlamydiae, with a 2-week trial of tetracycline (500 mg four times a day), doxycycline (100 mg twice a day), or erythromycin (250–500 mg four times a day), may provide symptomatic relief, and a partial response in some patients may justify longer therapy with these agents (e.g., 4–6 weeks).

Other antibacterial agents are neither effective nor indicated [10,52]. Sitz baths, therapy with nonsteroidal antiinflammatory agents, and, in some patients, prostatic massage also may provide symptomatic relief. Surgical intervention is not indicated. Some patients have greater relief from aspirin than from nonsteroidal antiinflammatory agents, which may aggravate the problem.

D. Prostatodynia. Patients with this condition have no associated UTI, noninflammatory prostatic secretions with negative cultures of EPS, and no excessive inflammatory cells in their prostatic secretions. This is a common condition [10].

1. **The typical patient** is a young to middle-aged man with irritative voiding symptoms (frequency, urgency, and nocturia) and symptoms of abnormal urinary flow (hesitancy, diminution of stream force and size, postvoid dribbling).
2. General physical and neurologic examinations are normal except that many patients have “tight” anal sphincters and tender prostates and paraprostate tissues on rectal examination [10].
3. Cystoscopic examination often suggests mild to moderate bladder neck obstruction and variable bladder trabeculation. Meares [10] believed that these patients have “spastic” dysfunction of the bladder neck and prostate urethra and therefore called this the **bladder neck-urethral spasm syndrome**.

Smooth-muscle spasm and high prostatic urethral pressures during voiding probably lead to intraprostatic reflux of urine and an associated chemical prostatitis. α -Blocking agents are beneficial in some patients [10,52].

4. Most men with this syndrome admit to stress and emotional tension. Whether stress is a cause or merely an effect of prostatodynia is unclear [10].

IV. Epididymitis. This condition is diagnosed readily by physical examination. Most infections in sexually active men are caused by *C. trachomatis* and *N. gonorrhoeae*; urethritis and prostatitis may occur concurrently [53,54]. Infection in older men is caused by the usual uropathogens, gram-negative bacilli, and, infrequently, enterococci; infection may occur as a complication of concurrent prostatitis. Etiologic agents generally are recovered from culture of the urethra, urine, or prostatic secretions; alternatively,

direct aspiration of the epididymis may be required. Therapy is directed at the etiologic agent and, if present, concurrent sites of infections.

- V. Upper UTI.** The approach to pyelonephritis in the normal man does not differ from that in the normal woman. See section III under Urinary Tract Infection in Women, above.
- VI. Recurrent infections.** The **definition** of recurrent UTIs in men differs from that used for women. The defining, but arbitrary, time limit set for repeated infections in women is 6 months. For men, because UTIs are much less common and less likely to occur as a sporadic event, **two or more UTIs at any time within a 3-year period** has been used to define the syndrome [44].
- A. Predisposing factors.** The association of prostatitis and recurrent UTIs is even stronger than for sporadic lower UTIs. Unlike women, men with recurrent UTIs almost always have evidence of tissue-invasive disease. **Most men with recurrent UTIs will be found to have structural defects of the urinary tract.** In those without structural defects, most will be found to have chronic bacterial prostatitis. **Urologic evaluation is essential** in these patients.
- B. Therapy**
1. The ideal antimicrobial agent is one that penetrates the prostate–blood barrier. TMP and TMP-SMX are agents with an appropriate antimicrobial spectrum. The dosages given in Table 15.3 are appropriate for recurrent infection. The best chance for cure is with 6 weeks of therapy. The quinolones are other commonly used agents (see Chapter 27).
 2. If recurrences are frequent and severe, it may be appropriate to give chronic suppressive therapy, as discussed in section III.D under General Management Principles of Urinary Tract Infections. Treatment should be with full therapeutic dosages (not the low-dose suppressive regimens used in women) in an attempt to eradicate the focus of tissue infection and, therefore, cause cessation of symptomatic episodes.

URINARY TRACT INFECTION IN THE ELDERLY

Although many of the basic principles in the understanding and treatment of UTI in the elderly are similar to those for younger patients, several differences are noted in the elderly, and these deserve emphasis [55–63].

- I. Asymptomatic bacteriuria** is much more common in the geriatric population than in younger patients [55–58]. Among young to middle-aged women, the prevalence of bacteriuria is less than 5% and, among young to middle-aged men, less than 0.1%. By contrast at least 20% of women and 10% of men who are older than 65 years and are living at home have bacteriuria. Some, but not all, studies suggest the incidence of bacteriuria in the elderly rises with increasing age [56].
- A. Factors** [56–58]
1. The **place of residence** is a major factor in determining the prevalence of bacteriuria. Approximately 25% of women and 20% of men living in nursing homes or extended-care facilities have bacteriuria; even higher percentages of hospitalized elderly patients have bacteriuria.
 2. **Debilitated state** (i.e., the frail elderly). The higher rates of bacteriuria are related to the more debilitated state of patients (e.g., after cerebrovascular accidents, presence of decreased functional status), perineal soiling, poor hygiene, less complete bladder emptying, and more frequent catheterization.
- B.** Serial studies show that although at one point in time an elderly patient may not have bacteriuria, at another point in time he or she will. It seems likely that most elderly persons experience episodes of asymptomatic bacteriuria at some time [56].
- C. Significance of asymptomatic bacteriuria** [56–58]
1. **Therapy of asymptomatic bacteriuria in the elderly to prevent renal insufficiency is not justified.** No causal relationship between uncomplicated UTI and worsening of renal function has been shown.
 2. Therapy of asymptomatic bacteriuria is unlikely to result in improvement of incontinence when present; asymptomatic bacteriuria rarely, if ever, causes incontinence.

3. Bacteriuria and mortality. Although it has been suggested that the elderly with asymptomatic bacteriuria die earlier than their noninfected cohorts, randomized controlled trials have shown that therapy does not provide a permanently sterile urine and has no effect on mortality [57–63].

D. Treatment. In recent reviews, the authors conclude that the treatment of asymptomatic bacteriuria is best avoided because the bacteriuria cannot usually be eradicated, therapy is associated with side effects, and treatment is not cost effective [56–58].

Available data do not support routinely treating asymptomatic bacteriuria in the frail elderly [58,63]. Asymptomatic bacteriuria may be treated, however, before perioperative urethral catheterization or genitourinary instrumentation.

II. Pathogenesis. The same principles for UTI in adults apply to the elderly. A few points warrant special emphasis. Most UTIs in the elderly follow invasion of the urinary tract with bacteria by the **ascending route**. The inoculum size probably is increased by a shift of the normal vaginal flora toward coliforms, by soiling of the perineum from fecal incontinence in women, and by catheterization. Lack of estrogen effect may be important in elderly women (see section II.C under General Approach to Urinary Tract Infections). Prostatitis is a very important cause of recurrent UTI in men.

Micturition with complete emptying of the bladder often is impaired in the elderly due to prostate disease in men, bladder prolapse in women, and neurogenic bladder in either gender.

III. Microbiologic features [56–58]

A. *E. coli* is still the **most common** pathogen infecting the elderly.

B. *S. saprophyticus* is **uncommon** in the elderly compared with its incidence in young women.

C. Elderly men have a higher incidence of gram-positive isolates (e.g., enterococci) for unclear reasons.

D. Elderly patients have often had prior therapy for UTI or other infections and often are infected with other gram-negative bacteria (e.g., *Proteus*, *Klebsiella*, *Enterobacter*, *Pseudomonas* species). Frequently, these bacteria are more resistant to antibiotics than bacteria isolated from younger patients.

E. The frequency of true polymicrobial infections is unclear.

IV. Clinical presentation. Catheter-related infections are discussed separately later in this chapter under Catheter-associated Urinary Tract Infection.

A. Lower UTIs. These usually are easy to recognize if patients are capable of expressing complaints of dysuria, frequency, and urgency [58].

B. Upper UTIs. Acute pyelonephritis in the frail elderly, like other intraabdominal processes, may present in an atypical fashion. Elderly patients may not have the classic presentation of high fever, chills, flank pain, and symptoms of lower UTI. At times, gastrointestinal (nausea or vomiting, abdominal tenderness) or respiratory symptoms may be the patients' initial complaint, even though they do not have another underlying gastrointestinal or respiratory infection. **Clinicians must always exclude UTIs in the differential diagnosis of disease in septic-appearing elderly patients.** Because of the nonspecificity of pyuria in this age group and the coexistence of asymptomatic bacteriuria with other causes of sepsis, some ambiguity will always have to be accepted. The criteria for diagnosis, however, do not differ from those described earlier (see section V).

Absence of fever in the elderly does not exclude upper UTI because elderly patients may have difficulty mounting a fever. Peripheral leukocytosis may also be absent. Bacteremia and shock are more common in the elderly with pyelonephritis than in young adults [56]. Blood cultures should be routinely obtained.

V. Diagnosis. In general, the same diagnostic principles that apply to younger patients apply also to the elderly, with a few noteworthy differences [56–58].

A. Urine collection. It may be difficult to obtain a reliable midstream clean-catch urine sample for culture in the elderly woman. A single straight-catheter sample is a reasonable approach in symptomatic patients.

B. Significant urine culture colony counts (midstream collections)

1. For symptomatic infections, Enterobacteriaceae in at least 10^5 CFU/mL, and probably more than 10^2 CFU/mL, are significant [58].
 2. For asymptomatic bacteriuria, more than 10^5 CFU/mL of the same organism in two sequential specimens are needed [58].
- C. Nonspecificity of pyuria** [58]. Unlike younger people, in the elderly the presence of pyuria does not correlate highly with bacteriuria. In a population-based study in Finland, 47% of residents had pyuria, but only half of those had bacteriuria [59]. Other studies have shown even higher rates of pyuria in elderly women.
- The presence of pyuria is a poor predictor of the presence of bacteriuria, but the **absence of pyuria is a good indicator of the absence of bacteriuria**.
- D. Necessity of routine urine culture** [56–58]
1. For **elderly women** with typical symptoms of lower UTI, urine **culture at the time of first presentation is suggested but not mandatory** [57]. If pyuria is present, empiric therapy is rational; if the patient does not respond, a urine culture should be done as an aid to future antibiotic choices. However, **urine culture is recommended in the frail elderly prior to therapy for UTI** [57,58].
 2. In recurrent UTI in the elderly woman, urine cultures are advisable to help guide antibiotic therapy choices.
 3. **In men, routine cultures are advised** [58].
- E. Blood cultures.** Obtain blood cultures in febrile patients or in any elderly patient who may have pyelonephritis because bacteremia is relatively common in the elderly with upper urinary tract disease.
- F. Urologic evaluation.** Consider urologic evaluation in
1. **Men** to help assess for obstructive uropathy. (A residual urine volume or bladder sonogram is a useful screen.)
 2. **Women** with bacteremia or pyelonephritis that does not respond well to antibiotics.
- VI. Therapy.** Asymptomatic bacteriuria should not be treated, as previously discussed.
- A. Lower UTI**
1. **Women.** Although some experts recommend that elderly women are treated initially with 3-day regimens, a more conventional 7-day regimen is favored [57,58]. Anyone who fails a 3-day regimen should be tried on a 2-week course for presumed upper UTI. Because of the drug's spectrum of activity and low toxicity, TMP alone, norfloxacin, or ciprofloxacin is favored by Baldassarre and Kaye [56]; a more recent review suggests TMP-SMX or nitrofurantoin [57]. For elderly women with recurrent UTI, a trial of local vaginal topical estrogen therapy may be beneficial by normalizing vaginal flora (see section IV.C.1 under Urinary Tract Infection in Women, above).
 2. **Men** deserve at least the conventional duration of therapy (e.g., 10–14 days) and consideration of underlying structural abnormality or prostatitis, which may warrant protracted therapy, especially if recurrent infections occur [58].
 3. Long-term suppressive therapy may be indicated for patients with frequently recurring symptomatic infections.
- B. Upper UTI.** Elderly patients with pyelonephritis are more likely to have bacteremia and hypotension, and hospitalization usually is indicated [56].
- Although *E. coli* remains the most common bacterium, more resistant bacteria are more often found in the frail elderly. For those patients who have acquired their infection in a long-term care facility, the likelihood of a multiple antibiotic-resistant bacterium is appreciable [57,58].
- A **Gram stain of the unspun urine** will help guide therapy, in part by helping to determine whether enterococci are a concern. This is more likely in men.
1. **Empiric choice of an agent.** Most frail elderly will have some degree of renal impairment, whether recognized or covert (see Chapter 27). If an aminoglycoside is used in a very ill patient, careful serum level monitoring is advised. Once susceptibility data are available, alternative safer agents may often be selected. Alternatives are indicated in Table 15.3. Careful attention to dosage modification of antibiotics for renal impairment is important (see Chapter 27).

For empiric therapy of pyelonephritis with or without urosepsis, intravenous ampicillin and gentamicin have commonly been used, especially if enterococci are suggested on the Gram stain of an unspun urine or if urine Gram staining has not been performed. If only gram-negative bacilli are seen on a Gram stain, an aminoglycoside or a third-generation cephalosporin alone is a rational choice. If *P. aeruginosa* or a multiresistant gram-negative organism is a concern, an aminoglycoside can be used with another agent while awaiting culture data.

2. **Definitive therapy.** Once the bacterium is isolated, therapy can be modified based on the susceptibility data of the causative agent. Complete eradication of bacteriuria often is not a reasonable goal for the frail elderly, and in the absence of bacteremia, we sometimes use a shorter course of therapy—that is, 3 days beyond the time the patient has become afebrile if the patient has responded well to therapy. Otherwise, a routine 10- to 14-day course of therapy seems prudent [57,58].

C. Urologic evaluation. An evaluation for the exclusion of obstructive disease is important for men but is not cost effective for frail elderly women responding to therapy. However, in both men and women, if the patient is not clinically responding after 72 hours of appropriate antibiotic therapy, renal ultrasonography is suggested to help rule out an obstructive uropathy (see under Urinary Tract Infection in Men, above). A CT is indicated if renal abscess is a concern.

VII. Recurrent infections. Because they have not been studied in a focused manner, recurrent infections in the frail elderly should be managed as described in section VI under Urinary Tract Infection in Men and in section IV under Urinary Tract Infection in Women (see above).

VIII. Foley catheter-related infections. These are discussed separately later in this chapter under Catheter-associated Urinary Tract Infection.

URINARY TRACT INFECTION IN CHILDREN

Neonatal UTIs are discussed in Chapter 3 under Selected Specific Infections in the Newborn. Both acute and chronic UTIs in children are relatively common. Several points deserve special emphasis [64–66].

- I. **Incidence.** UTI occurs in as many as 5% of female and 1% to 2% of male children [64].
- II. **Pathogenesis.** Hematogenous spread of infection to the kidney is the most common mode of infection in neonates. In older children, the ascending route of infection is most common.
 - A. **Obstruction with urinary stasis predisposes to UTI.** Posterior urethral valve, obstruction at the ureteropelvic junction or ureterovesical junction, and ectopic ureterocele are the main causes of anatomic obstruction in children [64].
 - B. **Vesicoureteral reflux is the most common underlying abnormality.** The likelihood of parenchymal scarring and renal damage is related to the severity of vesicoureteral reflux.
 - C. **Risk groups. Children who are at increased risk for bacteriuria or symptomatic UTI with subsequent renal damage include**
 1. Premature infants discharged from neonatal intensive care units (see Chapter 3).
 2. Children with systemic or immunologic diseases.
 3. Children with urinary tract abnormalities, renal calculi, neurogenic bladder, voiding dysfunction, constipation, or a family history of UTI with anomalies such as reflux.
 4. Girls younger than 5 years with a previous history of UTI.
 5. **Uncircumcised males** [15].
- III. **Etiology** is essentially the same as in adults, with at least 80% of infections due to *E. coli*. Patients with underlying structural abnormalities and recurrent infections are more likely to demonstrate other pathogens (*Klebsiella*, *Proteus*, and *Pseudomonas* species) over time.
- IV. **Asymptomatic bacteriuria**
 - A. **Incidence.** Approximately 1% of preschool children, 1.2% to 1.8% of school-aged girls, and 0.03% of school-aged boys have asymptomatic bacteriuria [64].

- B. Diagnosis** is made when, in an asymptomatic child, cultures of two properly obtained, clean-voided, midstream urine specimens grow at least 10^5 organisms (of one bacterial type)/mL.
- C. Implications** [64]. Asymptomatic bacteriuria in children is associated with increased risk of recurrent symptomatic infections that may result in renal scarring. Hypertension or renal insufficiency, however, is unusual.
- 1. In 20% to 30% of school-aged girls with asymptomatic bacteriuria**, radiographic investigation will reveal upper tract damage, vesicoureteral reflux, or both. **Most of the kidney damage occurs before 5 years of age.**
 - 2.** Most prospective studies of school-aged girls older than 5 years with asymptomatic bacteriuria have failed to demonstrate decreased glomerular filtration rates, impaired renal growth, or progressive parenchymal damage in kidneys that are normal at the start, even if the bacteriuria is left untreated.
 - 3.** Bacteriuria in neonates and infants, and in boys beyond infancy, is associated with a high incidence of urinary tract abnormalities and necessitates prompt diagnosis and early treatment.
- D. Screening** neonates and infants for asymptomatic bacteriuria is not practical because of the difficulties of obtaining a clean urine specimen in this age group. **The only children who should definitely be screened at 6- to 12-month intervals are those at high risk for bacteriuria and subsequent renal damage** (see section II.B).
- E. Radiographic studies.** Appropriate imaging studies should be performed in boys of any age with bacteriuria, in girls younger than 5 years, and in older girls with recurrent episodes of bacteriuria. (See detailed discussion of this in section V.E.)
- F. Treatment of asymptomatic bacteriuria.** Some have argued that therapy of asymptomatic bacteriuria may eradicate organisms of low virulence and facilitate UTI with more resistant bacteria or, alternatively, may be associated with unnecessary antibiotic side effects. Although this remains a controversial area, **we agree with recent reviewers who suggest the use of antibiotic therapy in children** younger than 5 years, with underlying structural abnormalities, and who progress to symptomatic UTI. A 7- to 10-day course of therapy is suggested, and failure to respond suggests noncompliance, improper antibiotic therapy, or underlying structural defect requiring radiographic evaluation [64].
- V. Symptomatic bacteriuria**
- A. Clinical manifestations.** The usual signs and symptoms of lower UTIs in adults (e.g., dysuria and frequency) often are not present, and patients may have a variety of symptoms depending on their age. Fever may not be present, and by history, examination, and routine tests, it often is difficult to distinguish upper from lower UTI in children.
- 1. See Table 15.5.**

Table 15.5. Signs and Symptoms of Urinary Tract Infections in Different Age Groups

Age	Presentation
Neonate and infant	Hypothermia, hyperthermia, failure to thrive, vomiting, diarrhea, sepsis, irritability, lethargy, jaundice, malodorous urine
Toddler	Abdominal pain, vomiting, diarrhea, constipation, abnormal voiding pattern, malodorous urine, fever, poor growth
School-aged child	Dysuria, frequency, urgency, abdominal pain, abnormal voiding pattern (including incontinence or secondary enuresis), constipation, malodorous urine, fever
Adolescent	Dysuria, frequency, urgency, abdominal discomfort, malodorous urine, fever

From Sherbotic JR, Cornfeld D. Management of urinary tract infections in children. *Med Clin North Am* 1991;75:328; with permission.

2. When fever is present in a child, the diagnosis of UTI should routinely be considered [66].
 3. **Dysuria, especially without bacteriuria**, when present may be attributable to other causes such as vaginitis, local perineal irritation, use of bubble baths, masturbation, and pinworm infections. At times, it may be a clue to sexual molestation [64,66].
- B. Physical examination.** A careful abdominal examination, gentle rectal examination, and inspection of the genitals are suggested [64]. Growth failure or hypertension may be present in a child with renal insufficiency.
- C. Diagnosis. A positive urine culture** that is properly obtained **is essential** for the diagnosis [64,65].
1. **Pyuria** (≥ 5 WBCs per high power field) may be absent in centrifuged urine sediment in 30% to 50% of children with UTI [64,66]. If pyuria is present, it is strong supportive evidence of a UTI.
 2. The **leukocyte esterase** and **nitrite tests** on a urinalysis may be falsely negative or positive in 15% to 30% of childhood cases [64].
 3. **Urine culture** is advised. A properly collected sample may be difficult to obtain but is essential.
 - a. **For neonates**, see Chapter 3.
 - b. **For infants and toddlers**, either urethral catheterization (growth of $\geq 1,000$ CFU/mL is significant) or suprapubic bladder aspiration (any growth on culture is significant) is suggested.

“Bagged” urine specimens frequently are contaminated and, when positive for growth, are difficult to interpret. A negative urine culture from a bagged sample is useful in ruling out a UTI [64].
 - c. **For older and cooperative children**, clean-voided midstream collection for urinalysis, Gram stain, and culture is suggested. Significant colony counts have already been reviewed under Urinary Tract Infection in Men and Urinary Tract Infection in Women and in section IV.B.2 under General Approach to Urinary Tract Infections (see above).
 4. **Gram stain (or unstained examination) of unspun urine under a 40-power microscope lens.** If bacteria and leukocytes are seen, UTI is likely [64,66].
- D. Antimicrobial therapy.** In general, children who appear ill or who are at significant risk of becoming seriously ill because of their age (e.g., young infants) or who have urinary tract abnormalities should be admitted to the hospital and treated aggressively.
1. **Neonates.** See Chapter 3.
 2. **Infants** are at risk for serious sequelae of UTI (e.g., sepsis) and so should be treated with intravenous antibiotics. Initial therapy with intravenous ampicillin plus gentamicin or a third-generation cephalosporin alone is appropriate (Table 15.6).
 - a. A repeat urine culture 48 hours after starting therapy is advised. It should be negative.
 - b. Intravenous antibiotics are continued until there is clinical improvement and consistent oral intake [65]. If the patient improves rapidly, a switch may be made to oral antibiotics after 24 to 48 hours; a total course of 7 to 14 days of antibiotics (intravenous plus oral) is advised [65].
 - c. Radiographic evaluation is advised, as below.
 - d. A repeat urine culture 1 week after completion of therapy is suggested.
- 3. Children**
- a. **Uncomplicated UTI.** Children older than 6 to 12 months of age with normal urinary tracts who are not toxic can be treated with oral outpatient regimens.
 - (1) Ideally, a urine culture at 48 hours is suggested to ensure that the urine has become sterile.
 - (2) A conventional 7- to 14-day course of therapy is advised [64–66] (Table 15.6). Ampicillin or amoxicillin still is commonly used in children with

Table 15.6. Suggested Antimicrobial Therapy for Urinary Tract Infections: Dosages and Alternatives

Parenteral therapy (suspected upper UTI or sepsis)	
Neonates and infants <4–6 mo old	
Ampicillin, 75–200 mg/kg/d divided into 4 doses	
	<i>plus</i>
Gentamicin, 5–7.5 mg/kg/d divided into 2–3 doses	
Older children	
Ampicillin, 100 mg/kg/d divided into 4 doses	
	<i>plus</i>
Gentamicin, 7.5 mg/kg/d divided into 3 doses	
	<i>or</i>
A third-generation cephalosporin alone (e.g., cefotaxime, 100–200 mg/kg/d divided into 3–4 doses)	
Oral therapy (acute cystitis, resolving upper UTI)	
Neonates and infants <4–6 mo old	
Amoxicillin, 40 mg/kg/d divided into 3 doses	
	<i>or</i>
TMP-SMX, ^a 6–12 mg/kg/d TMP with 30–60 mg/kg/d SMX, divided into 2 doses	
	<i>or</i>
Cephalexin, 50 mg/kg/d divided into 3 doses	
Older children	
TMP-SMX, 6–12 mg/kg/d TMP with 30–60 mg/kg/d SMX, divided into 2 doses	
	<i>or</i>
Amoxicillin, 40 mg/kg/d divided into 3 doses	
Prophylaxis (for recurrent infections)	
TMP-SMX, based on 2 mg/kg/d of TMP as a single nighttime dose	
	<i>or</i>
Nitrofurantoin, 2 mg/kg/d as a single nighttime dose	

^aSulfonamide agents (e.g., TMP-SMX) should not be used in children younger than 6 weeks. Antibiotic dosages should be adjusted for the level of renal function, and serum levels should be followed where appropriate.

UTI, urinary tract infection; TMP, trimethoprim; SMX, sulfamethoxazole.

Modified from Sherbotic JR, Cornfeld D. Management of urinary tract infections in children. *Med Clin North Am* 1991;75:335; with permission.

initial uncomplicated UTI, because resistance to *E. coli* occurs less in childhood UTI than in adult UTI.

- (3) Single-dose regimens are not advised in children.
 - (4) The use of short-course therapy for UTI in children remains controversial. Until further data are available, 3-day regimens should be reserved only for selected patients with asymptomatic bacteriuria and girls older than 5 years with clinical findings of lower UTI, a documented normal genitourinary tract, and poor compliance (in which case a short course would be beneficial) [64].
- b. Complicated UTI.** For patients with fever, chills, CVA tenderness, or gastrointestinal upset (i.e., presumed pyelonephritis); those who have undergone recent instrumentation; or those with significant anatomic abnormalities, aggressive intravenous antibiotics are suggested [64,66].
- (1) Empiric therapy with ampicillin and gentamicin or a third-generation cephalosporin can be started (Table 15.6). Regimens can be revised after susceptibility data are available.
 - (2) Clinical improvement with a decrease in the fever usually begins within 48 hours. If this does not occur, obstruction or a resistant pathogen should be sought [65].

- (3) Intravenous therapy is continued until the patient improves clinically, with completion of treatment orally based on susceptibility studies [64,65].
- (4) A follow-up urine culture is advised 1 week after therapy and, when possible, 4 to 6 weeks after therapy.

E. Radiographic evaluation. In children with UTI, radiographic evaluation of the urinary tract is indicated to identify vesicoureteral reflux, obstruction, or other urinary tract abnormalities. In approximately 30% to 50% of young children with their first symptomatic UTI, a structural abnormality will be found. Most commonly this is vesicoureteral reflux, which is rare in children without UTI.

1. Indications [64–66]

- a. Any male or female child younger than 5 years** with asymptomatic UTI or asymptomatic bacteriuria.
- b. Any male child** with a first episode of UTI or asymptomatic bacteriuria.
- c. Recurrent UTI or recurrent asymptomatic bacteriuria in female children older than 5 years** who have not been previously evaluated. A sexually active adolescent girl with recurrent lower UTI does not need radiographic evaluation.
- d. A child with his or her first UTI and a family history of urinary tract abnormalities** (e.g., reflux) or recurrent UTI and abnormal voiding pattern, poor growth, or hypertension.

Data suggest that siblings of patients with known vesicoureteral reflux should have a screening study done for early detection of reflux, which may be found in as many as 45% of these children. This is a somewhat controversial recommendation [64].

- e. Any child with pyelonephritis.**

2. The choice of radiographic examinations depends on the facilities available, the skills and experience of the radiologist, and clinical findings [64–66]. The clinician should review options and plan studies after discussion with the radiologist.

- a. Voiding cystourethrography** will detect vesicoureteral reflux, grade the severity of reflux, and provide anatomic and functional information of the lower urinary tract.
- b. Intravenous urogram** has been the time-honored method to evaluate upper tract abnormalities but exposes the patient to more radiation than other options. Sonography and radionuclide scintigraphy provides similar data more safely.
- c. Renal ultrasonography** is noninvasive and free of ionizing radiation. It can reveal obstruction, renal size and contour, stones, size of the collecting system, and bladder anatomy. Upper tract infection may be associated with increases of renal volume of more than 30%. Ultrasonography provides anatomic information only, and often must be combined with a functional study.

d. Radionuclide scans

- (1) **Direct radionuclide voiding cystography** will detect reflux with a 50- to 100-fold decrease in gonadal radiation exposure when compared with voiding cystourethrography, but anatomic detail is not sufficient enough to grade the severity of reflux [64]. **If this test is used as a screen and is abnormal, then a more definitive voiding cystourethrography can be done.** Periodic radionuclide cystography examinations can be performed to assess the degree of reflux over time.
- (2) **Technetium succimer (Tc-99m dimercaptosuccinic acid [DMSA])** accumulates in functional renal cortex and provides exquisite renal images. When available, **this test is preferred over intravenous urography.** It is useful in demonstrating acute pyelonephritis and evaluating focal parenchymal scarring.

- e. A reasonable approach** for the radiographic evaluation of UTI in children is shown in Figure 15.1 [64].

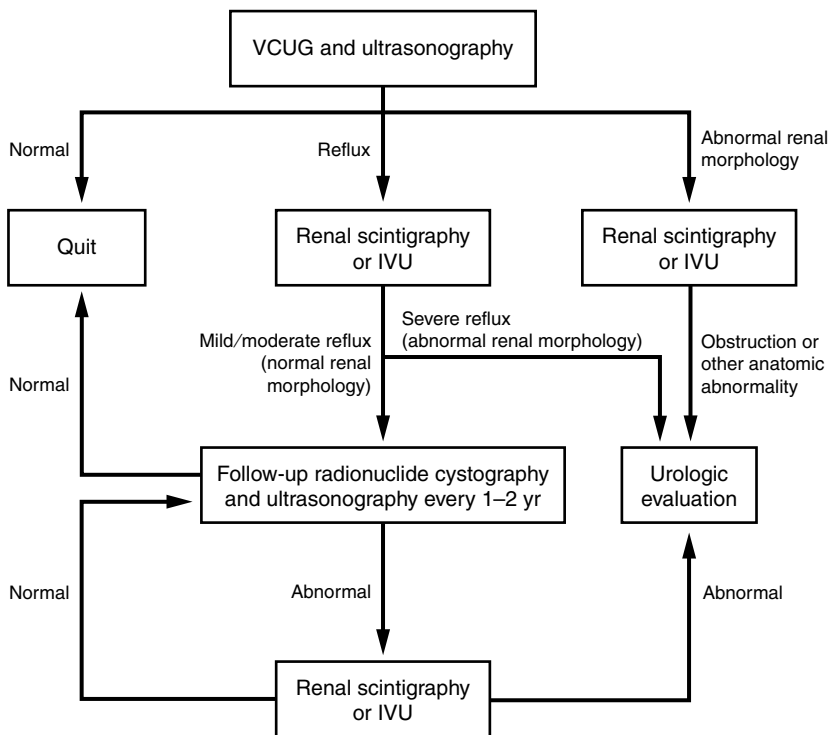

FIG. 15.1 The protocol for radiologic evaluation of urinary tract infection in children. IVU, intravenous urography; VCUG, voiding cystourethrography. (From Zelikovic I, et al. Urinary tract infections in children: an update. *West J Med* 1992;157:558; with permission.)

- (1) Immediate sonography can be done in the acutely ill child to exclude obstruction [64,65].
- (2) **The optimal timing of radiographic studies.** Because transient reflux can be masked or overestimated during an acute UTI, it was previously believed that the ideal time for imaging studies was 4 to 6 weeks after antibiotic therapy. However, it is now recommended that radiographic studies should be done when infection is controlled and there is no longer evidence of bladder irritability [65]. If radiographic studies are delayed, it is prudent to continue low dose prophylactic agents until the urinary tract anatomy has been defined [65,66].
- (3) Patients with abnormalities deserve careful evaluation by a specialist in this area.

3. Follow-up studies. Mild to moderate reflux usually disappears with increasing age. The goal of management of reflux is to prevent recurrent UTI and the resultant potential for renal scarring. In patients with documented reflux, repeated ultrasonography every 1 to 2 years is indicated to follow renal growth, and radionuclide cystograms should be used (e.g., every 1–2 years) serially to determine the resolution of reflux so that antimicrobial prophylaxis can be discontinued when appropriate [66].

VI. Sequelae [64,66]

A. As many as 80% of children with uncomplicated UTI will have **recurrences**.

- B. Renal parenchymal infection and renal scarring are well-established complications of UTI in children.** Parenchymal scarring is found in 10% to 15% of children with UTIs. It has been estimated that nearly 10% may develop hypertension and a smaller percent renal insufficiency [64]. **The risk is especially great in infants and neonates.** To reduce the risk of renal damage, the diagnosis and therapy of UTI must be prompt. Most of the damage to the kidney caused by vesicoureteral reflux occurs in infancy and early childhood, and therefore careful workup to prevent sequelae in this age group is essential.
- C. Recurrent infections.** The approach to these patients depends on whether there is an underlying structural abnormality and on the degree of symptomatology.
- 1. Patients with normal urinary tract anatomy and recurrent UTI.** Usually, three documented UTIs in a 1-year period indicate the need for prophylactic therapy. After a conventional course of antibiotics aimed at the susceptible pathogen, either TMP-SMX (10 mg/kg/day of the SMX component, given nightly or every other night) or nitrofurantoin (1–2 mg/kg/day, given nightly) is administered [64]. These agents are very effective and have few side effects. Usually prophylactic antibiotics are given for 6 to 24 months and are discontinued if the patient remains free of infection.
 - 2. Children with structural abnormalities,** especially vesicoureteral reflux, are best managed with continuous use of prophylactic antibiotics after the urine has been successfully sterilized with a conventional course of antibiotics. Antibiotic regimens similar to those listed in section C.1 can be used. A prophylactic antibiotic is used to prevent UTIs and possible renal damage secondary to reflux of infected urine.

Prophylaxis often is continued for 12 to 24 months or longer while waiting for mild to moderate reflux to resolve spontaneously. Serial ultrasonography and scanning studies will help determine optimum duration of prophylactic antibiotics for patients with vesicoureteral reflux.

VII. Surgical intervention

- A.** Mild to moderate vesicoureteral reflux will resolve spontaneously with growth of the child in most patients [64,66].
- B.** High-grade vesicoureteral reflux, nonresolving vesicoureteral reflux, or reflux in those children unable to take prophylactic antibiotic therapy may require surgical intervention. These patients should be carefully followed by an experienced pediatric urologist and pediatric nephrologist with a special interest and expertise in these problems.

Even in patients with high-grade vesicoureteral reflux, conservative management with prophylactic antibiotics often is attempted and frequently is successful. Overall, in approximately 70% of patients with vesicoureteral reflux that is managed conservatively, the condition resolves spontaneously.

CATHETER-ASSOCIATED URINARY TRACT INFECTION

The most common nosocomial infections are of the urinary tract, accounting for approximately 40% of all nosocomial infections [67–72]. Most patients with nosocomial UTI have had genitourinary manipulation, usually urethral catheterization (approximately 80%) or urologic manipulation (about 20%) [71]. Foley catheters are commonly used in hospitalized patients and in aged nursing home residents.

I. Methods of catheterization and risk of UTI

- A. Single (straight) catheterization.** After this procedure, bacteriuria develops in approximately 1% to 5% or more (up to 20%) of patients. The risk of infection is lowest in healthy outpatients and greatest in certain high risk patients such as diabetics, prepartum or postpartum patients, and especially in the elderly, debilitated, hospitalized patient [71].

Indications for single catheterization include (a) providing relief of temporary obstruction or inability to void; (b) obtaining urine from patients who are unable to provide a clean specimen because of weakness, debility, or other medical problems; (c) determining the amount of residual urine; and (d) conducting a urologic study of urethral anatomy.

B. Intermittent catheterization. This method has been helpful in avoiding long-term catheterization, **especially in young patients with spinal cord injuries** [73,74]. The technique, as originally described after World War II, was a “no-touch” technique performed by a nurse or urologic technician wearing mask, sterile gown, and gloves. Using this technique, approximately 65% of male patients and 50% of female patients were discharged from the hospital with sterile urine [73]. In recent years, a “clean” (as opposed to “sterile”) technique has been taught to paraplegic patients who have been able to learn the procedure rather easily. Quadriplegics have been successfully catheterized by a caregiver using a similar technique. This has become a very useful approach for treating spinal cord-injured patients [73,74]. Intermittent catheterization might also be useful in the postoperative patient who is unable to void.

Intermittent catheterization should not be used in circumstances in which traumatic catheterization may be a problem, such as in obstruction of the urinary tract due to benign prostatic hypertrophy or carcinoma of the prostate. In these cases, an indwelling urethral or suprapubic catheter generally is indicated.

There is little, if any, role of prophylactic antibiotics in this setting. An attempt to use TMP-SMX in patients with spinal cord injuries demonstrated little benefit [75]; likewise, although limited published data suggest that fluoroquinolones might be effective, this is not an established practice. This approach is likely only to delay episodes of bacteriuria and pose a concern for selecting resistant pathogens.

C. Short-term catheterization. This may be necessary for monitoring acutely ill patients who are unable to void or who are incontinent and in whom measurement of urine output is mandatory (e.g., postoperative patients or selected patients in intensive care areas). The catheter should be removed as soon as possible to avoid increasing the risks of nosocomial UTI.

1. Risk factors associated with catheter-related infection [71]

a. Unalterable factors that increase the risk of infection include female gender, older or debilitated patients, and patients with meatal colonization.

b. Potentially alterable factors, such as duration of catheterization, catheter care techniques, type of drainage system (a closed system is preferred), and whether the patient is receiving systemic antibiotics or not affect infection rates.

2. The per-day risk of developing bacteriuria is approximately 3% to 6%, and the cumulative risk increases with duration of catheterization. Therefore, **nearly 50% of hospitalized patients catheterized for longer than 7 to 10 days develop bacteriuria** [71].

D. Chronic catheterization. The patient with a long-term indwelling catheter is at high risk of morbidity due to this procedure. The risk of bacteriuria increases with the duration of catheterization, at a rate of approximately 5% per day. **With protracted catheterization (>30 days) bacteriuria** with at least one bacterial strain **is universal**, and many patients have at least two bacterial strains [58,67].

1. Indications for long-term bladder catheterization

a. Patients with atonic bladders, such as those with diabetes or other chronic neurologic disorders.

b. Patients with obstructive uropathy preoperatively, or patients who are not surgical candidates but who have benign prostatic hypertrophy, prostatic carcinoma, and the like.

2. Chronic catheterization should be avoided in the chronically ill incontinent patient if at all possible. When other methods of incontinent management such as nursing care, behavioral modification, medication, special clothes, and special bed linens are not successful, there may be no alternative to long-term urethral catheterization in an attempt to prevent skin maceration and resultant decubitus ulcers. Condom catheters are an option for the incontinent male patient.

II. Pathogenesis of catheter-associated UTI. Bacteria can enter the urinary tract by either the periurethral or the intraluminal route [67,70,72].

A. Periurethral or transurethral route. This route of entry is especially important in catheterized women, probably accounting for 70% of episodes of bacteriuria. Bacteria involved in UTI emanate from the rectal flora and organisms colonize the

periurethral zone. Then organisms enter the urinary tract via the external surface of the catheter in the mucous sheath between the catheter and urethral mucosa, similar to the pathogenesis of UTI in noncatheterized women [67,70,71]. This route may be less important in men.

B. Intraluminal route. Microorganisms can ascend through the lumen of the urinary catheter into the bladder.

1. In approximately 15% to 20% of infected patients, the infecting organism appears in the collecting bag before entry into the bladder, which occurs 24 to 48 hours later.

2. Once in the bladder, small numbers of microorganisms (e.g., 100 organisms/mL) can increase to large numbers (e.g., $>10^5$) in 24 to 48 hours.

3. **Two populations of bacteria** exist in the catheterized urinary tract.

a. **Planktonic growth** (bacteria growing in the urine itself). Particularly adherent strains of *E. coli* (to uroepithelial cells) may be more likely to cause UTI.

b. **Biofilm growth** (those bacteria growing on the surface of the catheter). The growth of a bacterial biofilm progresses in an orderly fashion: Bacteria attach to the catheter and initiate a biofilm form of growth in which organisms coat the catheter and secrete an extracellular matrix of bacterial glycolocalyxes in which they become embedded. Host urinary proteins such as Tamm-Horsfall protein and urinary salts can be incorporated into this biofilm growth, which eventually leads to encrustation of the inner surface of the catheter [66–72].

(1) Certain bacteria (e.g., *Proteus* and *Pseudomonas* species) appear especially to contribute to biofilm growth.

(2) In general, biofilm seen on the inner surface of the catheter is much thicker and of a different nature than that seen on the external surface [67–72].

(3) **Implications of the biofilm** [67]

(a) **To retard bacterial growth within the catheter biofilm, silver and silver alloy coated catheters** have been developed. Such catheters have been effective in decreasing the frequency of bacteriuria and symptomatic UTIs [68]. However, because of the greater acquisition costs, it is not clear whether routine use of silver coated catheters is cost effective [69].

(b) **Urine cultures** obtained from the catheter may not reflect bladder bacteriuria in patients who have organisms in a biofilm on the inner surface of the catheter. Bladder urine could be sterile, but organisms from the catheter biofilm may contaminate the aspirated urine culture.

(c) Biofilms have been demonstrated to retard the activity of antimicrobials. **Therefore, if bacteriuria is treated in a given patient, it may be prudent to replace the catheter.**

4. Breaking the connection at the junction of the catheter and drainage tube or contamination by improper manipulation of the collection bag may facilitate retrograde migration.

C. Catheter insertion. Only occasionally do nosocomial UTIs result from direct introduction of urethral microorganisms at the time of catheter insertion, assuming proper technique is used [71].

III. Complications arising in use of urinary catheters. Before using indwelling catheters in a patient, one should be thoroughly familiar with the complications associated with their use. Whenever possible, an indwelling catheter should be avoided, and when used it should be left in place for the shortest time possible.

A. Bacteriuria. The incidence of bacteriuria with a bladder catheter depends on the host and the method and duration of catheterization, as discussed previously [71].

1. Most episodes of bacteriuria are asymptomatic. Criteria have not been established for differentiating asymptomatic colonization of the urinary tract from symptomatic infection [67,71].

2. Pyuria accompanies most episodes of symptomatic infection, and its presence suggests host invasion rather than simple bladder colonization.

- B. Pyelonephritis.** The association between bacteriuria and subsequent pyelonephritis is well documented in both clinical and research settings.
1. The incidence of bacteriuria associated with upper tract disease has not been well defined or studied.
 2. In studies using the antibody-coated bacterial test, as many as 25% of episodes of catheter-associated bacteriuria were positive, suggesting upper UTI [71]. Fever, flank pain, or other symptoms of pyelonephritis are uncommon in these patients.
 3. Patients with prolonged use of catheters (>10 days) are at increased risk.
- C. Bacteremia or gram-negative sepsis.** In hospitalized patients, approximately 30% to 40% of all nosocomial gram-negative bacteremias originate from a UTI, usually catheter associated [71]. It is estimated that 30,000 deaths per year occur as a result of catheter-related sepsis due to gram-negative bacilli [71].
- D. Increased mortality.** Epidemiologic studies have related nosocomial bacteriuria to an approximate threefold relative increase in death. The exact explanation for this is not known but may involve unrecognized episodes of bacteremia [67,71].
- E. Other complications** of prolonged urinary catheterization include urinary stones, vesicoureteral reflux, and local periurethral complications such as prostatitis, prostatic abscesses, epididymitis, and scrotal abscesses. The frequency of these infections remains ill defined.
- IV. Catheter care.** Once the decision to use a catheter has been made, the following guidelines may be useful in decreasing or minimizing the risk of infection. **Catheters should be used only when absolutely necessary and then for the shortest time possible.**
- A.** For short-term use, two or three single straight catheterizations (every 6 hours) over a 24- to 72-hour period may be preferable to an indwelling catheter because of the lower risk of infection. Repeated straight catheterizations are not advisable in the patient who may be difficult to catheterize (e.g., patients with prostatic hypertrophy, prostatic cancer, or urethral strictures).
 - B. Insertion** of the catheter should be **performed under aseptic conditions**, with the use of sterile gloves, sterile catheter, liquid antiseptic soap or an iodophor for perineal cleaning, and sterile water-soluble lubricating jelly for the catheter. Studies of siliconized or silver ion-coated catheters in comparison with latex catheters have given mixed results. We believe that the limited value, if any, of newer catheters does not warrant their added cost.
 - C. A sterile closed drainage system** with a disposable plastic bag and connecting tubes should be used. The **junction of the catheter and drainage tube should not be disconnected** unless irrigation of an obstructed catheter is necessary, and irrigation should be done with sterile technique. Urine for culture should be aspirated from the aspiration port or distal-most portion of the catheter.
 - D. Maintain adequate urine flow** at all times. Ideally, sufficient fluid to maintain a urine output of greater than 100 mL/h should be given if it is not contraindicated by the patient's clinical condition. Such a urine flow may prevent the ascent of bacteria through the collecting system.
 - E. Gravity drainage** should be maintained, with the collection bag lower than the level of the bladder at all times. The bag should never touch the floor and should have a valve adequate to prevent reflux of urine into the bladder if the bag is accidentally raised above the level of the bladder. Urine in the collection bag may have very high bacterial colony counts. The downward drainage will help prevent retrograde spread of bacteria to the patient's bladder. The catheter should not be clamped except when the patient must be separate from his or her drainage bag or temporarily when a culture specimen is being collected.
 - F.** Although some have suggested routine catheter change every 2 to 3 weeks [2], we concur with other experts [15] who suggest that a chronic catheter should **not be changed on a routine schedule. Indications for catheter change include** (a) malfunction or leakage; (b) obstruction of the catheter; (c) contamination of the system (e.g., breaking the connection between catheter and drainage tube); (d) concretions felt in the catheter lumen, which may precede obstruction of the catheter; (e) bacteriuria requiring antibiotic therapy as previously discussed in

section II.B.3; and (f) in candiduria, catheter-change may be associated with clearing of the candiduria [15] (see Chapter 17).

- G. To minimize the risks of cross-contamination, **a patient with an indwelling catheter should not be placed in the same room** as another patient with an indwelling catheter. Likewise, it is important that **hospital personnel wash their hands** before and after handling any portion of the collection system. Gloves should be used whenever the collection bag is handled, because the bag may be contaminated.
 - H. After the catheter has been removed, a follow-up urine culture should be done. Symptomatic or persistent bacteriuria should be treated.
 - I. **Urinary catheters should not be used as a matter of convenience** for the nursing staff or physician.
 - J. Cleansing the periurethral area with povidone-iodine solution or daily cleansing with soap and water are not recommended. These forms of **meatal care** may, in fact, cause meatal irritation and increase the risk for retrograde extraluminal bacterial migration. In addition, they are expensive.
 - K. **Additional measures** have been used. Attempts to prevent collection bag-related infection using a variety of bag antibacterial substances (e.g., hydrogen peroxide) have demonstrated no difference in the incidence of bacteriuria among patients whose bags were treated and those whose bags were not. Attempts to modify the catheter by incorporating a vent or by coating the catheter with various antibacterial substances require further study before they can be recommended for routine use.
 - L. **Condom catheters** are a preferred alternative in selected alert cooperative patients who can receive meticulous skin care to prevent meatal ulceration. See discussion in section VI.
 - M. **Chronic catheterization.** Prevention of infection is very difficult in these patients, who universally develop bacteriuria over time.
- V. **Management of catheter-associated bacteriuria.** While the catheter is in place, systemic antimicrobial **treatment of asymptomatic catheter-associated bacteriuria is not recommended** [58,67,71]. Because complications of long-term catheterization are primarily infectious in nature, there is a temptation to treat all patients with catheter-associated bacteriuria; such treatment during catheterization is not helpful in eradicating infection for prolonged periods of time and serves only to select populations of organisms that are resistant to the antibiotics being used. Therefore, **while the catheter is in place, antibiotic treatment is recommended only for symptomatic infection** (i.e., bacteremia, pyelonephritis, epididymitis) [58,67,71].
- A. **Short-term catheterization.** Not all patients who have been catheterized for short periods of time require a urine culture after the catheter is removed. Most patients who have bacteriuria immediately after catheter removal are asymptomatic and many patients, especially younger women, will have cleared the bacteria on repeat culture 1 to 2 weeks later. If symptomatic bacteriuria is present or if the patient is at high risk for symptomatic infection (pregnancy, diabetes, age over 65, or prolonged catheterization over 10 days), a urine culture should be obtained and appropriate antibiotic treatment based on susceptibility data should be instituted. The optimal antibiotic regimen in this setting is unclear. In one study of women, persistent bacteriuria after short-term catheterization (e.g., 4–6 days) that was asymptomatic or associated with lower UTI symptoms only was treated as effectively with single doses of TMP-SMX (320–1,600 mg) as with a 10-day course of TMP-SMX (160–800 mg twice a day) in women younger than 65 years old [76]. For older women, patients with upper tract symptoms, and males (with possible prostatic involvement), we favor conventional therapy (i.e., 10–14 days of antibiotic therapy based on susceptibility studies).
 - B. **Long-term catheterization.** Certain guidelines are helpful in monitoring and managing these patients.
 - 1. **Urine cultures** in patients with chronic indwelling catheters often reveal multiple species of organisms, frequently with counts of 100,000 CFU/mL or more. These results are difficult to interpret and frequently change over short periods

of time. **Routine urine cultures are not recommended if the catheter is draining properly.**

2. **Antibiotic irrigation** of the catheter and bladder is of no advantage. Although bacteria can be suppressed, the beneficial effect is canceled by the contamination that occurs by periodically opening the collecting system.
3. **Asymptomatic bacteriuria should not routinely be treated.** This condition is very common, as was indicated previously. Because of the presence of a foreign body (i.e., the catheter), one cannot sterilize the bladder for prolonged periods of time. Unnecessary or prolonged use of antibiotics will only increase the likelihood of selecting out more resistant organisms.
4. **Systemic antibiotics should be used for catheterized patients who are febrile and ill-appearing, presumably from a UTI, with signs or symptoms suggesting a possible UTI-related bacteremia or pyelonephritis. Causes of fever other than a urinary tract source should be evaluated,** the catheter should be assessed for partial or complete obstruction, the patient should be examined for periurethral complication of urethral catheterization, and a urine culture should be aseptically obtained. **Because these are hospital-acquired infections, relatively resistant bacteria should be anticipated when selecting empiric antibiotic therapy.** Definitive antibiotic therapy should be adjusted based on susceptibility studies once they are available.
 - a. **Bacteremic patients.** If bacteremia is suspected or known, broad-spectrum antibiotics are indicated while one is awaiting results of urine and blood cultures. For the hospitalized patient, enterococcal bacteremia would be uncommon and could, for all practical purposes, be excluded if an unspun urine Gram stain showed no gram-positive cocci. While awaiting cultures, an aminoglycoside, extended-spectrum penicillin or cephalosporin, or a fluoroquinolone alone could then be chosen on the basis of local antibiotic susceptibility patterns.

These patients usually require a full 10- to 14-day course of antibiotics because of the associated bacteremia. Once culture data are available, initial empiric therapy can be tailored based on susceptibility data.
 - b. **Nonbacteremic UTI.** If no bacteremia is suspected or documented, these patients should be treated with less than 10 days of antibiotics, and shorter courses (e.g., 5–7 days) are suggested [58]. This will usually sterilize the urine without selecting out more resistant bacteria. The optimal duration of therapy for a UTI in a male with a chronic catheter is not established. Prolonged therapy may only select out resistant organisms. However, a 3- to 5-day course may allow a prostatic focus to persist. While awaiting further guidelines in this setting, a 7-day course may be a reasonable compromise.

For a patient who has just a low-grade temperature and is clinically stable, observation may be reasonable as the low-grade temperature may be transient.
 - c. **Catheter change.** When antibiotics are to be given for catheter-related infections, the catheter should be changed and the urine cultured from the new catheter, as discussed in section II.B.3.
5. **Chronic antibiotic suppressive therapy is not effective** in these patients. Because the catheter acts as a foreign body, the urine of these patients cannot be sterilized for a prolonged period. Therefore, there are no data to support the use of daily TMP-SMX, quinolones, or other antibiotics in this group of patients. In addition, chronic use of methenamine and ascorbic acid is not effective in these patients. Methenamine requires 30 to 90 minutes to form formaldehyde, the active urinary suppressant. If the catheter is providing adequate drainage, the necessary “contact time” is not provided in the catheterized patient. (See methenamine discussion in Chapter 27.)
6. **Follow-up therapy.** When the catheter is discontinued, the urine should be cultured and persistent or symptomatic bacteriuria should be treated (see section V.A).

VI. Condom catheters. To obtain adequate urinary outputs, to maintain dryness of the patient with urinary incontinence, or to prevent soiling of an adjacent wound of the sacrum or perineum, a condom catheter system is an excellent alternative to indwelling urethral catheters in the male patient without outlet obstruction. This avoids problems

associated with having a catheter within the bladder; however, bladder bacteriuria may still develop in condom-catheterized patients [77].

- A. The **risk for bladder bacteriuria** in condom-catheterized patients is increased in uncooperative patients who frequently manipulate their condom drainage system.
- B. Other **complications** of condom catheterization include local skin maceration, breakdown, and ulceration.
- C. These problems should not occur if (a) constriction by the condom roller ring is avoided; (b) kinking of the collection roller ring or the collection system, which would result in urine retention, is prevented; and (c) the condom is removed once or twice daily to wash and dry the skin. Circumcision may be necessary if the prepuce is macerated and inflamed.
- D. Physicians should be aware of the potential for bladder distention and vesicoureteral reflux in some patients with neurogenic bladders, including spine-injured patients.

FUNGAL URINARY TRACT INFECTIONS

The presence of fungi in the urine often presents a diagnostic dilemma. *C. albicans* and other *Candida* species in the urine are seen most frequently in diabetics, in patients with indwelling bladder catheters, in patients receiving antibiotics, and occasionally in patients who have had previous instrumentation of the urinary tract.

The presence of fungi in the urine is most often due to colonization of the bladder and does not represent true infection. This topic is discussed in Chapter 17.

INTRARENAL AND PERINEPHRIC ABSCESS

Intrarenal abscess occurs either as an uncommon consequence of ascending UTI, usually in patients with pyelonephritis and underlying obstructive urinary tract abnormalities; diabetes [9]; or hematogenous spread of bacteria from an extrarenal primary focus of infection [78]. Intrarenal abscess also may result from spontaneous infection of preexisting renal cysts. Perinephric abscess usually is the result of rupture of an intrarenal abscess into the perinephric space [78]. These are uncommon complications of UTI, and because the onset of symptoms is **characteristically insidious**, they may be overlooked as a cause of fever and flank or abdominal pain.

I. Clinical manifestations

- A. **Setting.** Intrarenal and perinephric abscesses are most frequently associated with pyelonephritis in patients with underlying obstructive urinary tract abnormalities. Sometimes, intrarenal abscess is caused by *S. aureus*. Although one-third of patients with hematogenously derived *S. aureus* intrarenal abscesses will have no discernible primary focus of infection, most will have clinically apparent skin and soft tissue infections due to *S. aureus*; predisposing conditions are those that increase the risk for *S. aureus* bacteremia, including hemodialysis, intravenous drug abuse, and diabetes mellitus. Renal cyst infection in patients with polycystic kidney disease usually follows ascending UTI; however, on occasion, infection may be iatrogenic after cyst instrumentation.
- B. **Signs and symptoms.** Intrarenal and perinephric abscesses usually present with fever, chills, and flank or abdominal pain [78]. Confusion and resultant delay in diagnosis occur when no localized signs or symptoms are present; when nausea, vomiting, or abdominal symptoms predominate; and because of the usual insidious nature of the onset of symptoms. Flank and CVA tenderness are the most common physical findings, with some patients demonstrating a tender flank or abdominal mass. Dysuria may or may not be present.

II. Diagnosis

- A. **Signs and symptoms.** Clinical findings of fever, chills, and back pain are nonspecific and may be seen with pyelonephritis, renal and perirenal abscesses, and, occasionally, with renal tumor. An abscess or other space-occupying lesion and pyelonephritis complicated by obstruction **should be considered in the patient with UTI when fever persists beyond 48 to 72 hours despite appropriate antimicrobial therapy.**
- B. **Urinalysis.** Pyuria, proteinuria, bacteriuria, or hematuria usually are present in patients whose infections originate from ascending infection; however, **in one-third**

of patients, abscess collections will not be in communication with the collecting system and urinalysis will be normal [78]. Patients with intrarenal abscesses due to *S. aureus* bacteremia and those with infected cysts often will have a normal urinalysis.

- C. Urine culture.** Two-thirds of patients will have urine cultures positive for aerobic gram-negative bacilli, most commonly *E. coli*, *Klebsiella* species, and *Proteus* species. **However, urine cultures frequently are sterile in patients with infected renal cysts.** Low colony counts (10^2 to 10^4 CFU/mL) of *S. aureus* are present in one-half of patients with bacteremic intrarenal abscesses; **urine cultures positive for *S. aureus* in patients who have neither been catheterized nor treated by instrumentation should suggest an underlying *S. aureus* bacteremia** and, if clinical manifestations are present, possible secondary intrarenal abscess [78].
- D. Blood cultures.** Bacteremia is confirmed in fewer than one-third of patients [78]. Sustained *S. aureus* bacteremia suggests concurrent endocarditis (see Chapter 12).
- E. Radiographic studies. Ultrasonography and CT** are the imaging tests preferred for definite diagnosis. **Ultrasonography** can identify associated urinary obstruction, and **CT** allows precise anatomic information on the extent of extrarenal soft tissue extension. Both imaging procedures provide guidance for percutaneous aspiration and drainage. Infected intrarenal cysts may be identified by gallium scanning. Scan-guided percutaneous cyst aspiration and culture provide the definite diagnosis. Excretory urography is used less frequently today for diagnosis; abnormalities suggestive of intrarenal or perinephric abscess include decreased renal mobility, diminished renal function, calyceal abnormalities, and displacement of the kidney or ureter.

III. Therapy

- A. Intrarenal abscesses** often respond to antimicrobial therapy alone, and surgical intervention generally is not required. Empiric antimicrobial therapy should be directed against aerobic gram-negative bacilli and *S. aureus*. An aminoglycoside (gentamicin or tobramycin) or aztreonam in combination with a semisynthetic penicillinase-resistant penicillin (nafcillin or oxacillin) or a first-generation cephalosporin (cephalothin, cephapirin, or cefazolin) provide appropriate therapy pending the results of culture and susceptibility testing. Intravenous antibiotics are suggested in doses used for bacteremic patients, because high renal and extrarenal tissue levels of antibiotics are desirable.

Once susceptibility data are available, a conservative course of therapy of 6 to 8 weeks usually is begun; however, longer term therapy may be necessary based on the clinical response. Treatment of patients with polycystic disease is complicated by the unpredictable penetration of antibiotics into infected cysts [79], and infectious disease consultation is advised. Percutaneous drainage is indicated in a patient with a large intrarenal abscess, persistent fever, and no clinical improvement after 5 to 7 days of appropriate antimicrobial therapy. Prompt percutaneous nephrostomy drainage of obstructive lesions should be performed acutely, with delayed permanent corrective surgery.

- B. Perinephric abscesses** usually require percutaneous or open drainage, and frequently nephrectomy is necessary for definitive therapy. Along with early drainage, empiric antibiotic therapy, as stated in section A, should be instituted. Despite improved diagnostic and surgical techniques, the mortality for perinephric abscesses remains high [78]. Early urologic and infectious disease consultations are advised.

GENITOURINARY TUBERCULOSIS

- I. Renal tuberculosis.** As in most forms of extrapulmonary tuberculosis, renal tuberculosis is the result of blood-borne dissemination from a primary focus elsewhere in the body, usually the lung but occasionally the gastrointestinal tract. The tubercle bacilli may be dormant for many years and may reactivate at a later time, with subsequent formation of caseous and cavitary necrosis of the kidney, prostate, or other genitourinary organs [80–82]. Tuberculosis is discussed in detail in Chapter 11.

A. Clinical presentation

1. Symptoms of dysuria, frequency, nocturia or urgency, and flank or back pain are frequently reported, but fever and constitutional symptoms generally are absent.
2. Approximately one-third of patients with renal tuberculosis have a history of tuberculosis elsewhere in the body that occurred many years previously. Sites of concurrent infection include the lung, bones, joints, other genitourinary organs, and adrenal glands.

B. The tuberculin skin test generally is positive in these patients.

C. The urinalysis frequently is abnormal, demonstrating the presence of pyuria or hematuria or both. Proteinuria also may be present. Routine bacterial cultures of urine are characteristically negative—hence, the so-called sterile pyuria that often is associated with renal tuberculosis.

D. Abnormal chest roentgenograms may be obtained in as many as 75% of such patients, most of whom have inactive pulmonary disease. Some patients have active pulmonary tuberculous infection concurrently.

E. Special studies

1. Smears. Urine smears for acid-fast bacilli may have false-positive results because of saprophytic mycobacteria present in the urine of healthy patients.

2. PCR is a sensitive and specific rapid diagnostic test [83]. However, it may not be widely available.

3. Acid-fast bacilli cultures. Three first-morning clean-catch specimens of urine are preferred over 24-hour collections, which often are contaminated samples. The urine culture will be positive in as many as 90% of patients.

4. Intravenous pyelogram. The radiographic appearance may support the diagnosis but is nonspecific. In addition, autonephrectomy is common in renal tuberculosis, and often there is secondary calcification.

F. Therapy. Extrapulmonary tuberculosis is treated in a manner similar to pulmonary tuberculosis if isoniazid and rifampin can be used for sensitive isolates, with 6 to 9 months of therapy sufficient for most patients. If isoniazid and rifampin cannot be used together, more protracted therapy (18–24 months) is indicated (see Chapter 11).

Surgery was the mainstay of treatment before the advent of antituberculous chemotherapy. At present, surgery generally is reserved for complications of renal tuberculosis, such as hemorrhage, sepsis, pain, inability to sterilize the urine, or ureteral stricture [84].

G. Prognosis with chemotherapy is good, with few relapses occurring in patients completing a full course of chemotherapy. Complications may result even though bacteriologic cure has been achieved. Hypertension, bacterial UTI, and ureteral obstruction may be seen.

II. Male genital tuberculosis. Tuberculosis of other portions of the male genitourinary tract may be present concurrently with renal tuberculosis. This suggests that infection may occur directly from the urine itself, although hematogenous spread can occur. Epididymitis is the most common form of male genital tuberculosis. A palpable painful lesion is characteristic of this disease, and the tuberculin skin test generally is positive. Diagnosis is made by biopsy and culture of the mass.

III. Female genital tuberculosis. Tuberculosis of the female genital tract is the result of hematogenous spread of tubercle bacilli. The **fallopian tubes** are most commonly involved. Common complaints are chronic pelvic and abdominal pain, menstrual disorders, and infertility. The tuberculin skin test generally is positive, and constitutional symptoms and fever are absent. The demonstration of tubercle bacilli is necessary for diagnosis. Endometrial curettage may reveal granulomas in half the patients with tuberculous **endometritis**. However, monthly sloughing of the endometrium in the menstruating patient may make histologic diagnosis difficult. Culdoscopy, laparoscopy, and laparotomy ultimately may be required to establish the diagnosis.

16. SEXUALLY TRANSMITTED DISEASES AND OBSTETRIC AND GYNECOLOGIC INFECTIONS

Eric R. Houpt and Michael F. Rein

GENERAL PRINCIPLES IN MANAGEMENT

- I. **Definition.** The sexually transmitted diseases (STDs) are grouped together because sexual contact is epidemiologically significant, although it is not the only mechanism through which the diseases are acquired.
- II. **Consequences**
 - A. Sexual partners of patients with STDs are at high risk of infection and must be evaluated. The risk of infection may be so high that such partners are treated when first evaluated, even if their infection has not yet been confirmed. This is termed **epidemiologic treatment and is a cornerstone of STD management** [1].
 - B. **Coprevalence**
 1. **Patients with one STD are significantly likely to have others.** A patient in whom one STD has been diagnosed should be carefully evaluated for others that may be clinically silent but of much greater eventual medical consequence (e.g., human immunodeficiency virus [HIV]) [2].
 2. **Patient education regarding risk reduction** is an important aspect of management.
 - C. **Management of an STD always involves dealing with more than one patient.**
 1. All patients must have completed treatment before resuming unprotected sexual contact.
 2. Several STDs (syphilis, gonorrhea, chancroid, lymphogranuloma venereum, acquired immunodeficiency syndrome [AIDS], and, in some states, asymptomatic HIV infection) must be reported to local health departments.
- III. A careful and complete **sexual history** must be obtained from each patient.
 - A. The history must be taken in terms understandable to the patient. Thus, the examiner must become desensitized to using street terms (e.g., “Do you take your partner’s penis into your mouth?” or “Do you give head?”) rather than technical jargon (e.g., “Do you practice fellatio?”).
 - B. **Never make assumptions regarding your patient’s sexual orientation.** Obtain a sexual history in gender-neutral terms (e.g., “Have you had sex with any new partners in the past month?” rather than “Have you had sex with any new women [men] in the past month?”) until the patient’s sexual preferences have been defined explicitly.
- IV. A **history of recent antibiotic use** is critical, because antibiotics may mask clinical features of disease without producing a cure.

URETHRITIS

Urethritis is a common presenting syndrome. Initial evaluation requires differentiating gonococcal from nongonococcal urethritis.

- I. **Epidemiology.** The major single specific etiology of acute urethritis is *Neisseria gonorrhoeae*, producing **gonococcal urethritis** (GCU). Urethritis of all other etiologies is collectively referred to as **nongonococcal urethritis** (NGU).
 - A. NGU is twice as common as GCU in the United States, especially among higher socioeconomic groups [3].
 - B. GCU is relatively more common among homosexual than heterosexual men with acute urethritis [4].
- II. **Clinical features in men. GCU and NGU cannot be differentiated reliably on clinical features alone.** A significant proportion of men with GCU or NGU may be asymptomatic [5–7].
 - A. **Incubation period** can sometimes be assessed if the patient has had a single sexual exposure or sex with a new partner within the preceding several weeks.
 1. Seventy-five percent of symptomatic men with GCU develop symptoms within 4 days and 80% to 90% within 2 weeks [7].

2. Fifty percent of symptomatic men with NGU develop symptoms within 4 days, but the incubation period ranges from 2 to 35 days [7].
 3. An incubation period of less than 1 week has no differential diagnostic significance.
 4. Incubation periods can be prolonged by subcurative doses of antibiotics.
- B. Urethral discharge.** Discharge is described by 75% of men with GCU but by only 11% to 33% of men with NGU [7].
1. Discharge present at the meatus without stripping suggests GCU.
 2. Mucopurulent discharge (purulent flecks in a mucoid matrix) is seen in 50% of cases of NGU but also in 25% of cases of GCU.
 3. A completely clear urethral discharge suggests NGU.
 4. The discharge in NGU may be so slight as to be present only as a meatal bead or a crust noted when the patient first arises.
- C. Dysuria** is common in both GCU and NGU.
1. Urethral discomfort may occur at other times and be described as itching or irritation.
 2. Urethral symptoms may mimic those of cystitis, particularly in women.
- D. Onset.** Symptoms usually begin fairly abruptly with GCU, whereas the onset of NGU may be less acute.
- E. Natural history.** The clinical features of acute urethritis will eventually resolve without treatment.
1. Ninety-five percent of patients with GCU will become asymptomatic within 6 months.
 2. Chronic gonorrhea sometimes manifests as gleet, a thin discharge containing only small numbers of gonococci.
 3. Of patients with NGU, 30% to 70% become asymptomatic over 1 to 3 months [7].

III. Diagnosis and differential diagnosis in men

- A. Examination of the patient.** Men should stand before the seated examiner, and the entire genital area should be examined.
1. It is preferable that the patient be examined at least 2 hours after micturition.
 2. The underwear may reveal stains of discharge.
 3. Erythema around the meatus may indicate urethritis, but some degree of perimeatal blush is often a normal finding.
 4. If discharge is not spontaneously present, the urethra should be gently stripped by placing the gloved thumb along the ventral surface of the penis with the fingers above, applying gentle pressure, and moving the thumb forward to deliver discharge.
- B. Examination of the urethral specimen**
1. If no discharge is expressed from the meatus, urethral material must be recovered by inserting a small swab into the urethra.
 - a. The patient should be warned about the brief discomfort that will result.
 - b. A 1- to 2-mm calcium alginate or rayon swab on a metal shaft is inserted approximately 1.5 to 2.0 inches into the urethra and removed while the shaft is being rotated.
 2. The swab is rolled across a microscope slide and then rolled across a plate of medium selective for *N. gonorrhoeae*.
 3. The slide is fixed and Gram stained using standard methods.
 4. The slide is examined using the oil-immersion objective (950–1,000 × X).
 - a. The proximal urethra has cuboidal epithelium.
 - b. The distal urethra supports a **normal bacterial flora** consisting primarily of gram-positive cocci and rods, which have no clinical significance.
 - c. **Spermatozoa** sometimes are present in physiologic secretions. The heads are gram-positive and characteristically fade out toward the acrosomal cap. Gram-negative tails are sometimes observed.
 - d. The diagnostic criterion of five polymorphonuclear neutrophils (PMNs) per oil-immersion field is insensitive, and 16% to 50% of men with acute urethritis will fail to show this number of PMNs in the densest portion of the slide [7]. The number of PMNs observed is reduced by recent micturition. **Even**

the presence of a few PMNs on a urethral smear provides objective evidence of urethritis.

- e. The **complete absence of PMNs** argues against urethritis. The discomfort of symptomatic patients may persist from adequately treated urethritis or reflect psychosomatic symptoms or perhaps discomfort resulting from excessive consumption of urethral irritants such as caffeine or alcohol. Such patients are best managed with reassurance and reexamination if symptoms persist.
 - f. The presence of PMNs supports the diagnosis of urethritis. If, in addition, one sees characteristic **gram-negative, intracellular diplococci**, the diagnosis of gonorrhea is established. If such organisms are not observed, the patient is said to have NGU. This test is more than 95% accurate in men with symptomatic acute urethritis. The presence of extracellular organisms with the same morphology has no diagnostic significance [7,8].
5. **One cannot diagnose concurrent NGU by Gram staining in the presence of gonorrhea. Thus, one should assume that patients with gonorrhea are coinfecting with nongonococcal pathogens.**

IV. Microbiologic features in men

A. Gonorrhea

1. *N. gonorrhoeae* is a gram-negative kidney-shaped diplococcus with flattened opposed margins. Some strains of *N. gonorrhoeae* are susceptible to the vancomycin contained in selective media and will not grow thereon. **A negative culture in the face of a positive Gram stain does not rule out GCU.**
2. **Nonculture diagnostic techniques.** Newer techniques have supplanted the culture in many clinical settings.
 - a. **Ligase chain reaction** has a sensitivity of 99% and a specificity of 98% [9].
 - b. **Nonamplified DNA probe** has a sensitivity of 96% and a specificity of 98% [10].
 - c. Antigen detection tests are insensitive compared with culture and genetic probes.
3. **Antimicrobial susceptibility.** The gonococcus has developed resistance to antimicrobial agents by two mechanisms.
 - a. **Chromosomal mutations.** are additive, and strains with relatively high resistance to many classes of antibiotics, including fluoroquinolones, are now widely observed [11–13].
 - b. **Plasmids.** Gonococci bearing plasmids coding for **penicillinase production and tetracycline resistance** are prevalent in the United States [11].

B. NGU

1. NGU is caused by any of several organisms. The cause of perhaps 20% of cases has not been identified.
2. *Chlamydia trachomatis* causes 15% to 50% of cases of NGU in various studies [3,4,7].
 - a. The organism is an obligate intracellular parasite, which possesses both DNA and RNA; replicates by binary fission, like bacteria; and is **sensitive to a variety of antimicrobials** [3,13,14].
 - b. The organism can be grown only in tissue culture, but its presence in urogenital specimens can be detected with new techniques, such as the polymerase chain reaction (PCR) and the ligase chain reaction, both of which will detect 95% of cases from urethral swabs or from urine specimens [15–17].
 - c. The spectrum of diseases caused by *C. trachomatis* closely parallels that caused by *N. gonorrhoeae*. **Coinfection with these two organisms is very common and affects management strategies.**
3. *Ureaplasma urealyticum* causes about 15% to 30% of NGU [3,7,18,19].
 - a. *Ureaplasmas* are free-living agents that can be grown in broth or on culture plates, although cultures are rarely performed in clinical practice.
 - b. Some ureaplasmas are resistant to the tetracyclines and must be treated with a macrolide or a fluoroquinolone [20–22].
4. *Mycoplasma genitalium* is a recently characterized mycoplasma, which appears to be associated with up to 30% of NGU. Although its precise contribution

remains to be defined, it may be more strongly associated with chronic or recurrent than with acute urethritis. It is sensitive to the tetracyclines [23–26].

5. *Trichomonas vaginalis* usually is carried asymptotically by men but may cause NGU that fails to respond to standard antibacterial treatment [27–29].
6. **Herpes simplex virus (HSV)** can infect the urethra and cause dysuria, which is usually far more severe than the amount of discharge would suggest [30]. The urethritis usually occurs in the setting of external lesions.
7. **Other organisms**, such as Enterobacteriaceae, adenovirus, *Neisseria meningitidis*, *Streptococcus pneumoniae*, microsporidia (in AIDS), and possibly *Staphylococcus saprophyticus*, *Haemophilus species*, and *Bacteroides* are rare causes of NGU but are not sexually transmitted [7].

V. Treatment in men

- A. **Gonorrhea.** Because of increasing resistance of *N. gonorrhoeae* to antimicrobials, the treatment for uncomplicated anogenital gonorrhea has changed. Examples of currently acceptable regimens include
 1. Ceftriaxone 125 mg intramuscularly (i.m.) made up in 1% lidocaine as a single dose.
 2. Ciprofloxacin, 500 mg orally as a single dose.
 3. Ofloxacin, 400 mg orally as a single dose.
 4. Cefixime, 400 mg orally as a single dose.
 5. Cefpodoxime, 200 mg orally as a single dose.
 6. Azithromycin 2 g orally as a single dose. Although this regimen will cure coincident chlamydial infection, it is very costly, and resistance is developing rapidly in several parts of the country.
 7. Gatifloxacin, 400 mg orally as a single dose.
 - B. **Because 10% to 30% of heterosexual men and 40% to 60% of women with gonorrhea (in STD clinics) are also infected with *Chlamydia*, treatment for gonorrhea should include a second regimen effective against this organism.**
 - C. **NGU.** Because it is impossible to differentiate among the common etiologies of NGU, the condition is treated syndromically, including in the initial treatment regimen those drugs effective against the common causative agents. There is no advantage to extending the initial regimen beyond 7 days [31]. Examples of regimens useful in the treatment of NGU include the following:
 1. Azithromycin 1 g orally provides the only single dose regimen for chlamydial infections [32,33].
 2. Doxycycline 100 mg orally twice a day for 7 days.
 3. Tetracycline hydrochloride 500 mg orally four times a day for 7 days.
 4. Erythromycin 500 mg orally four times a day for 7 days or, if the larger dose is not tolerated, 250 mg orally four times a day for 7 days.
 5. Ofloxacin 300 mg orally twice a day for 7 days. One may use equivalent (approximately half) doses of levofloxacin.
 6. Minocycline 100 mg orally at bed time (qhs) for 7 days [34].
 - D. **The following additional regimens may be used if the infection is known to be chlamydial.** These regimens are not active against mycoplasmas.
 1. Clindamycin, 450 mg orally three times a day for 10 days [35].
 2. Amoxicillin 500 mg orally three times a day for 7 days [36].
 3. Sulfisoxazole, 500 mg orally four times a day for 10 days. Trimethoprim-sulfamethoxazole has no greater efficacy.
 - E. **Epidemiologic treatment** of sexual partners of men with urethritis is essential. The practice of testing such partners for chlamydial infection and basing therapy on the result is erroneous, because NGU is very likely to be nonchlamydial [7,37].
- VI. Management of recurrent disease.** A careful sexual history regarding reexposure and adequate treatment of sexual partners is critical, because **reinfection is the most common cause of recurrence**. The pattern of recurrence of NGU can be of great value in deciding further management.
- A. **Response, reexposure, recurrence.** Initial response suggests infection with a sensitive agent. Reexposure followed by recurrence strongly suggests reinfection,

supports retreatment with an effective regimen, and demands careful investigation of possible sources of reinfection.

- B. Failure to respond.** Lack of response to **doxycycline** suggests infection with a tetracycline-resistant agent (see section IV.B.3–5) such as *U. urealyticum* or *T. vaginalis*.
1. The persistence of urethritis is documented by observing PMNs on a urethral smear. The absence of PMNs suggests resolution of the infectious process with a persistent pain syndrome that does not require further treatment with antimicrobials.
 2. Patients with documented persistent urethritis should be empirically treated for both organisms with metronidazole, 2 g orally as a single dose, and erythromycin, azithromycin, or an appropriate fluoroquinolone.
- C. Response with relapse** in the absence of reinfection is poorly understood. Such patients are disproportionately those men who are initially culture negative for chlamydiae and ureaplasmas [22]. Appropriate treatment is not clearly defined.
1. Of such patients, 50% to 75% may respond to a 3- to 6-week course of erythromycin or a tetracycline [38,39].
 2. Patients relapsing after this treatment should probably be referred for urologic evaluation [40].
 3. These patients do not develop complications, and their sexual partners have no clinical evidence of infection.
 4. Patients who relapse after an initial 3- to 6-week treatment course may be rendered asymptomatic with a standard regimen and then placed on long-term suppressive doses of a tetracycline [7,39]. Tetracycline hydrochloride is preferred because it is more economical, and one should use the lowest dose that keeps the patient free of symptoms, often 500 mg orally once daily. Treatment for 6 to 12 months is well tolerated and might be followed by discontinuation of the drug and reevaluation [7,39].

VII. Urethritis in women

A. Clinical features

1. **Women are usually unaware of urethral discharge, and urethritis presents as dysuria and frequency.**
2. Women with dysuria should be asked whether it is external or internal. Internal dysuria is associated with urethritis or cystitis, whereas external dysuria is more frequently associated with vulvovaginitis.
3. Infected women usually manifest **pyuria**.
4. If routine urine cultures are negative, affected women are said to have the **acute urethral syndrome** [41,42].

B. Etiology

1. Some women have cystitis caused by small numbers of Enterobacteriaceae [41] or urethritis caused by Enterobacteriaceae [43].
2. Some patients have GCU or NGU [41,42], which may respond initially to standard urinary tract treatments. Recurrence of such an apparently culture-negative urinary tract infection may result from reinfection with sexually transmitted urethritis.

C. Treatment of GCU or NGU in women is the same as treatment in men. Treatment in pregnancy involves the following [35–37]:

1. **Tetracyclines and fluoroquinolones are contraindicated.**
2. Gonorrhea can be treated with a cephalosporin or, in the setting of β -lactam allergy, with 2 g of azithromycin; the latter is followed by a test-of-cure 1 to 2 weeks later.
3. Chlamydial infection can be treated with erythromycin, azithromycin, amoxicillin, or clindamycin.

VIII. Asymptomatic urethritis

A. GCU or NGU can occur without symptoms [5,6].

B. Asymptomatic urethritis is prevalent among the male partners of women whose gonococcal or chlamydial infections are detected on routine screening or who present with symptoms or complications [6,44]. **Asymptomatic male partners of infected women should be treated on initial presentation.**

- C. Many men with asymptomatic urethritis have PMNs on a Gram-stained smear of a urethral specimen [5,6,44]; thus, a urethral smear should be part of the workup of asymptomatic men.
- D. The sensitivity of the urethral smear for gonococci in asymptomatic GCU is probably only 70% [6].
- E. Most men harboring trichomonads are asymptomatic [27].

CERVICITIS

- I. **Etiology.** Major pathogens include *N. gonorrhoeae*, *C. trachomatis*, and herpes simplex. However, most infected women do not have mucopurulent cervicitis (MPC) [13,45].
 - A. *N. gonorrhoeae* is most frequently isolated from the endocervix of infected women.
 - B. *C. trachomatis* can be recovered from the endocervix of 60% to 90% of the sexual partners of men with chlamydial urethritis, and cervical abnormalities, often subtle, have been observed in 80% to 90% of infected women [45–49].
 - C. **HSV** is isolated from the cervix in 88% of women with primary infection but from only 12% of women with recurrent herpetic infection [30,50]. **Herpetic cervicitis may be present without external lesions.**
 - D. Certain types of **human papillomavirus (HPV)** preferentially infect the cervix [51].
 1. Several lines of evidence support the contention that certain types of HPV cause cervical cancer [16,18,31,33,35,39,45,51,52].
 - a. Cervical cancer behaves epidemiologically as an STD [52].
 - b. HPV DNA, particularly types 16 and 18, is found in more than 90% of cervical cancers [53].
 - c. Prospective data indicate that acquisition of cervical HPV confers a high risk of premalignant lesions developing within 1 to 2 years [54].
 - d. A molecular mechanism for malignant transformation is currently being defined [55].
 2. Cervical carriage of HPV is, however, self-limited, with a median persistence of about 8 to 10 months [56–60].
 - E. **Other organisms** [45] that occasionally cause cervicitis include adenovirus, measles virus, cytomegalovirus, *Enterobius vermicularis*, amoebae, *Mycobacterium tuberculosis*, group B streptococci, *Neisseria meningitidis*, and actinomycetes, the last usually in association with the use of intrauterine contraceptive devices.
- II. **Diagnosis.** The clinical features of specific cervical infections overlap too much to permit an accurate etiologic diagnosis without laboratory assistance [46,47]. **Multiple infections are common** [48].
 - A. **Clinical features.** About one-third of infected women note a discharge from the vagina that actually originates in the inflamed cervix. Inguinal adenopathy is rare unless the disease is accompanied by lesions of the external genitalia, because lymphatic drainage of the cervix involves the external iliac rather than the inguinofemoral nodes.
 - B. **Examination**
 1. **Erythema around the cervical os may indicate infection or may merely represent cervical ectropion**, migration of endocervical epithelium over the surface of the cervix, which is symmetric about the os and is not particularly friable. It is often impossible on clinical grounds alone to differentiate ectropion from true infection. Normal cervical discharge is clear and mucoid. Purulent or mucopurulent discharge (MPC) is associated with gonococcal, chlamydial, or, less frequently, herpetic infection [46–49].
 2. **Chlamydiae** have been isolated from 50% to 90% of sexually active patients with hypertrophic cervicitis. Only 19% to 32% of women with chlamydial cervical infection manifest hypertrophic cervicitis, an intensely erythematous, raised, irregular lesion that bleeds easily [45–49], and only 30% or so have a mucopurulent or purulent cervical discharge [45–49,61]. On examination, **20% to 70% of infected women have a completely normal cervix [62–65]. Therefore, physical examination never adequately excludes chlamydial or gonococcal cervicitis.**

- 3. Cervicitis is seen on physical examination** in approximately 90% of women whose cervical cultures are positive for **HSV** [30,50]. Cervical discharge is usually mucoid but is occasionally mucopurulent, and in one series herpetic cervical infection caused 8% of cases of MPC [46].

C. Laboratory tests

1. Microscopy

- a.** Observation of 10 to 30 PMNs per oil-immersion field in the densest portion of a Gram-stained specimen of cervical discharge correlates statistically with the presence of gonococci or chlamydiae [46,63,66–69], but the sensitivity and positive predictive value of the observation (both 25%–45% in a high risk population) are far too low for a definitive diagnosis.
- b.** In the setting of MPC, a Gram stain diagnosis of gonorrhea mandates treatment for both gonococci and chlamydiae. A Gram stain negative for gonococci rules out the infection with a sensitivity of only 50%, and so such patients must still be treated for both gonococcal and nongonococcal cervicitis. **The cervical Gram stain has very limited utility in the management of MPC.**

2. Culture and other tests

- a. Gonorrhea.** The standard method for detecting *N. gonorrhoeae* is culture (sensitivity approximately 90%). The organism can also be detected by DNA hybridization (sensitivity approximately 92%) and the ligase chain reaction (sensitivity approximately 97%) [70–72].
- b. C. trachomatis.** Culture of the organism is an expensive and time-consuming procedure. Chlamydiae can be identified in cervical specimens using immunofluorescence microscopy (sensitivity 75%–95%), enzyme immunoassays (sensitivity 65%–95%), DNA probes (sensitivity 60%–80%), PCR (sensitivity approximately 88%) or ligase chain reaction (sensitivity approximately 93%) [15,73–75].
- c. HSV.** The sensitivity of diagnostic tests is poorly defined, but all are relatively specific. The diagnosis may be made by observing multinucleate giant cells, often with intranuclear inclusions on Papanicolaou (Pap) smear; by recovering the virus in tissue culture; by immunofluorescent staining; or by PCR [76,77].

III. Therapeutic approach

- A.** Specifically diagnosed gonococcal or chlamydial cervicitis should be treated in the same manner as gonococcal and chlamydial urethritis.
- B.** Mucopurulent cervicitis in patients at risk for STD should be treated with a regimen that is effective against both *N. gonorrhoeae* and *C. trachomatis*. In a patient whose history suggests she is at very low risk for STD and in whom compliance is good, one could await the results of the screening tests.
- C. Female partners of men with NGU and male partners of women with MPC should be treated epidemiologically.**
- D. HSV.** Management of cervicitis due to HSV is identical to that of other genital herpes infections.

PHARYNGEAL INFECTIONS AND SEXUALLY TRANSMITTED PHARYNGITIS

The oropharynx can be infected by *N. gonorrhoeae*, *C. trachomatis*, *Treponema pallidum*, HSV, or HPV.

I. Gonococcal pharyngeal infection [78]

- A. Epidemiology.** The major risk factor is fellatio. Cunnilingus is less likely to transmit infection, and transmission by kissing is very rare.
- B. Most infected patients are asymptomatic**, although erythematous and exudative gonococcal pharyngitis does occur.
- C.** The identity of *N. gonorrhoeae* on culture must be confirmed by biochemical or immunologic testing because *N. meningitidis*, will also grow on selective media and resembles gonococcus.
- D.** Workup for disseminated gonococcal infection should include pharyngeal cultures.

E. Treatment

1. Ceftriaxone, 125 to 250 mg i.m. as a single dose
2. Cefixime 400 mg orally as a single dose
3. For β -lactam–allergic patients in whom fluoroquinolones are not contraindicated: ciprofloxacin 500 mg, ofloxacin 400 mg, or levofloxacin 400 mg orally as a single dose

II. Chlamydial pharyngeal infection

- A. *C. trachomatis* is occasionally isolated from the pharynx of the patient who practices fellatio [79].
- B. Such infection is usually but not always asymptomatic.
- C. Treat with those regimens effective for genital chlamydial infection.

III. Pharyngeal herpetic infection [30,50]

- A. **Epidemiology.** In adults, this syndrome generally is associated with primary genital infection.
- B. **Clinical features.** Patients usually are symptomatic, and one may see erythema or frank ulcers on the oropharynx. Fever and anterior cervical adenopathy are common.
- C. **Treatment** is the same as for genital lesions.
- D. Herpetic pharyngitis **may recur** and be particularly severe in immunocompromised patients, in whom extension to the esophagus is frequent.

GENITAL LESIONS

- I. **Significance.** Genital lesions present problems in differential diagnosis because of clinical overlaps in presentation. The issue is further complicated by the frequency with which different infections coexist. Ulcerative genital lesions probably predispose to the transmission of HIV infection by acting as the portal of exit or entry for the virus [2]. The morphology of genital lesions may be greatly modified in AIDS [2].

II. Initial approach. The initial approach to genital lesions in the sexually active patient involves taking a careful history, including the following information [80–82].

- A. The **incubation period** can be assessed by inquiring about new or recent sexual contacts.
 1. A very short incubation period of minutes to hours suggests trauma or an allergic reaction to a topical chemical used by a partner. Infectious diseases do not have such short incubation periods.
 2. An incubation period of 2 to 5 days is seen with most cases of chancroid or HSV infection, although the mean incubation period for the latter is approximately 6 days [30,50,76,77].
 3. Longer incubation periods of 1 to 3 weeks are seen with syphilis, 4 to 12 weeks with venereal warts, and approximately 4 weeks for pubic lice and scabies.
 4. The incubation periods for some conditions such as molluscum contagiosum [83] and donovanosis [84] are poorly defined, but the latter may be 1 to 12 weeks.
- B. A **travel history** influences the likelihood of various etiologies. Lymphogranuloma venereum is far more common in Africa and the Far East than in the United States. Donovanosis is endemic in India, New Guinea, the West Indies, and some parts of Africa and South America, but it is distinctly rare in the United States. Chancroid has become more common in the United States, particularly in major metropolitan areas.
- C. **Pain** usually accompanies the lesions of herpes and chancroid. Although not classically painful, the lesions of primary syphilis cause some discomfort in up to 30% of patients [85]. Intense **pruritus** is characteristic of crabs and scabies.
- D. A **history of STD in a partner** is an important clue to the differential diagnosis.
- E. **Recurrence** at intervals is characteristic and highly suggestive of herpes.
- F. The **morphologic features of the lesions** are key to the differential diagnosis.
- G. **Recent use of antimicrobials** or other drugs may dramatically modify the morphology of lesions, and drugs may cause **fixed drug eruptions**, which are commonly limited to the genitals.

III. Ulcerative lesions**A. General principles**

1. A clinical differential diagnosis of genital ulcers is the most challenging aspect of venereal dermatology [80–82].

2. Chancroid has become more common in the United States and must be considered in differential diagnosis [86].
3. Rare causes of genital ulceration include tuberculosis, amebiasis, and histoplasmosis.
4. Although the classic descriptions of lesions have high specificity, only about one-third of patients present with “classic” lesions [82].

B. Genital herpes simplex infection

1. Epidemiologic considerations

- a. Approximately 70% to 95% of genital herpes infections are caused by HSV type 2 [30]. Type 1 genital infections may result from orogenital sexual contact.
- b. Serologic studies suggest that 20% of young adults in the United States are infected with HSV type 2 [87,88].
- c. Initial infections are classified as **primary** if the patient has had no prior exposure to HSV (either type 1 or type 2); otherwise the episode is referred to as **nonprimary initial infection**. Patients with prior exposure to HSV have milder initial episodes than do those patients suffering true primary genital infection.
- d. **Approximately 70% to 90% of patients have asymptomatic initial and recurrent genital infections** [89–94]. Most infections appear to have been contracted from sexual partners who are asymptomatic shedders of virus. Because asymptomatic shedding only occurs about 3% to 7% of the time, an asymptotically infected individual may transmit infection to a sexual partner only after years of regular contact.
- e. The rate of recurrence decreases over time [95].
- f. The rate of transmission of HSV type 2 from symptomatic to uninfected partners who have been advised not to have unprotected intercourse when the infected partner is symptomatic is approximately 10% per year [96].

2. Clinical features. Because only about 20% of infected patients present with typical clinical features, standard clinical evaluation can never rule out genital herpes [91].

- a. Lesions appear 2 to 20 days after exposure, but the mean incubation period is approximately 6 days. Classical lesions are initially **vesicular**, grouped, sometimes umbilicated, and surmount an erythematous base. Particularly in women, the vesicles quickly rupture to form clean, shallow, markedly painful **ulcers**, which are usually all about the same size and are not indurated. Ulcers may coalesce.
- b. Lesions are usually located on the penis or on the labia or vulva. The adult vagina is involved in only about 5% or so of cases and the cervix in nearly 90% of primary infections [30].
- c. Involvement of the urethra is common.
- d. **Regional lymphadenopathy**, usually tender, generally develops toward the end of the first week of illness.
- e. Lesions heal by **crusting** over. Primary disease often lasts 3 weeks.
- f. **Extragenital manifestations. Fever, malaise, and anorexia** are common in primary infection. A true **aseptic meningitis** without encephalitis accompanies some primary infections with HSV type 2. These manifestations are rare in recurrent disease [30].
- g. Within the first year after infection, **recurrent disease** is seen in approximately 90% of symptomatic patients with HSV type 2 genital infections but in only about 25% to 50% of those infected with HSV type 1 [94,95]. Recurrences with HSV type 2 appear four to eight times per year, whereas recurrences with HSV type 1 are, on average, nearly 10 times less frequent. The rate of recurrence varies dramatically from patient to patient. Many patients give a history of recurrences triggered by stress.
 - (1) Recurrent disease may be preceded by a prodrome of itching, tingling, or burning that begins 6 to 24 hours before lesions appear [30].
 - (2) Recurrences generally last 7 to 10 days and proceed through the same stages as primary disease.

3. **Direct diagnosis** can usually be made clinically in classic cases, but most cases are not classic.
 - a. A **dark-field examination** may be performed **if syphilis is suspected**. Multiple chancres may be seen in almost half of patients with primary syphilis [85,97].
 - b. The **Tzanck smear** is prepared by making a smear of a fresh **vesicular** lesion, which then is stained with Wright or Giemsa stain and examined for the presence of characteristic multinucleated giant cells. The sensitivity of the test is only 40% for ulcers, for which clinical differential diagnosis is more difficult [81,90].
 - c. **HSV antigen detection tests**, such as direct immunofluorescence and ELISA, vary in sensitivity and specificity from about 70% to 90% [90,98].
 - d. **Viral DNA** can be detected by PCR with 100% specificity and sensitivity, which is higher than any other direct technique [90,99,100].
 - e. **Culture has been the gold standard for diagnosis**, but its sensitivity rapidly diminishes in recurrent disease, and it is often negative if taken from lesions that are just a few days old [91]. DNA amplification techniques are more sensitive.
4. **Serologic diagnosis** has been used in many epidemiologic studies but is of limited clinical utility.
 - a. Older tests do not reliably differentiate between type 1 and type 2 virus. **Even with type-specific tests, many sexually active patients are HSV 1 antibody positive, and HSV 1 genital infection cannot be excluded in these patients.**
 - b. An ELISA based on glycoprotein gG can differentiate between HSV types and is about 95% sensitive [101,102].
 - c. A Western blot assay, also capable of differentiating among HSV types, is highly sensitive and specific but is available only from research centers [90].
 - d. A new commercially available ELISA specific for HSV 2, the POckit HSV-2 Rapid Test [103], can be performed in the clinic and becomes positive in 80% of infected patients after 4 weeks [104].
5. **Treatment. Oral antiherpetic agents** are the treatment of choice. Topical therapy is far less effective [13,105,106], and occlusive topical treatment increases the risk of maceration and delays healing. The lesions should be kept clean and dry. Valacyclovir is a prodrug of acyclovir and is therefore a more convenient but more expensive means of administration of acyclovir. Famciclovir is a prodrug of penciclovir. Various **clinically equivalent oral regimens** include the following:
 - a. **Initial infection:** 7 to 10 days of oral therapy with one of the following: 400 mg acyclovir three times a day, 200 mg acyclovir five times daily, 250 mg famciclovir three times a day, or 1 g valacyclovir twice a day.
 - b. **Recurrent episodes** may be treated with one of the following 5-day oral regimens: 400 mg acyclovir twice a day, 200 mg acyclovir five times per day, acyclovir 800 mg twice a day, famciclovir 125 mg twice a day, or valacyclovir 500 mg twice a day. **The effect on recurrent disease is substantially less than that observed with initial infection**, and its value depends on starting the drug early in the course of the relapse, preferably during the prodrome. In this setting, the patient should keep a supply of the drug at home so that therapy can be started immediately.
 - c. **Frequently recurring disease** can be controlled with long-term **suppressive oral therapy** consisting of acyclovir 400 mg twice a day; famciclovir 250 mg twice a day; or valacyclovir 250 mg twice a day, 500 mg/day, or 1,000 mg/day [13,106–108]. After 1 year of continuous daily therapy, the drug should be discontinued and the frequency and severity of recurrences should be reassessed. Approximately 75% of patients will remain free of symptomatic recurrences. **Such suppressive therapy prevents symptomatic recurrences and reduces but does not eliminate viral shedding.** Patients should be warned that they may still be contagious.

6. Special considerations

- a. **Intravenous (i.v.) acyclovir** is used for serious infection, in immunocompromised patients, or when accompanying clinical problems make oral administration inadvisable. The drug is given as 5 to 10 mg/kg i.v. every 8 hours for 5 to 7 days or until clinical resolution occurs [13]. Adequate hydration reduces the risk of nephrotoxicity caused by tubular precipitation.
 - b. **AIDS** patients suffer from chronic necrotizing herpetic infection, and infection may disseminate. Longer term, higher dose, or i.v. therapy may be required. Resistance has developed and should be suspected if lesions persist among patients undergoing acyclovir therapy. An alternative regimen for resistant infections is foscarnet, 40 mg/kg body weight i.v. every 8 hours until clinical resolution is obtained [13].
 - c. **Pregnancy** poses problems for mother and baby, and **management remains controversial** [109]. The risk to the newborn is highest among women with their first episode of genital herpes near the time of delivery and is lower among women with recurrent herpes. The likelihood that a completely asymptomatic individual is shedding virus at the time of delivery is probably as low as 1%. Antepartum cultures are not useful, but women should be carefully examined for the presence of active lesions, which are considered by many to be an indication for cesarean section. The safety of acyclovir in pregnancy has not been completely defined, and its use should probably be restricted to treatment of initial genital herpes in this setting [13,106].
- C. Syphilis in the United States** is now at its lowest levels in the history of reporting [110].
1. **Microbiologic features.** *T. pallidum* is a spirochete 5 to 15 μm long and less than 0.5 μm wide. Living organisms are visualized by reflected light using **dark-field** microscopy. The organism can also be identified by silver staining or by direct immunofluorescence [111].
 2. **Epidemiology**
 - a. From 1986 to 1990, an epidemic of syphilis occurred in the United States. However, in 1991 the number of reported cases of primary and secondary syphilis declined for the first time since 1985 and has declined yearly since that time [112,113]. The reasons are uncertain but may include the use of ceftriaxone for treatment of gonorrhea, HIV prevention education with personal protection measures being followed (e.g., condom use), or HIV partner notification (which may allow for early therapy of new cases of contacts).
 - b. Rates of infection remain highest in the rural South [114] and among lower socioeconomic inner-city populations. Several studies have found a strong epidemiologic association between syphilis and crack cocaine use, probably due to crack cocaine-associated changes in sexual behavior, such as sex-for-drugs prostitution [115–117].
 - c. After an initial drop, syphilis has reappeared among some groups of gay men [118].
 - d. Sexual transmission occurs by direct contact with a moist lesion, and transplacental transmission is the second major route of acquisition. Transfusion syphilis is no longer a problem.
 3. **Clinical manifestations.** Syphilis is a chronic infection, usually latent, the course of which is punctuated by clinically apparent stages.
 - a. The **incubation period** averages approximately 3 weeks but is said to range from 10 to 90 days. During this interval, infected patients have, by definition, neither clinical nor serologic evidence of disease.
 - b. **Primary syphilis** consists of one or more **ulcerated lesions, called chancres**, which appear at the site of initial infection and multiplication by the spirochetes [85]. There are multiple lesions in many cases. Chancres usually are minimally painful or tender (compared, most dramatically, with chancroid or herpes, both of which produce tender ulcers) and are usually clean ulcerations with distinctly indurated edges. Regional **adenopathy** develops within the first week and usually consists of several discrete nodes that are relatively nontender and rubbery. Inguinal adenopathy generally is bilateral. The

cervix, proximal third of the vagina, and the glans penis are drained by deep iliac nodes, and regional lymphadenopathy is not detected on physical examination of patients infected at these sites. Although most chancres occur on the genitalia, the examiner must maintain a high index of suspicion for lesions about the mouth or anus as well. Untreated, the manifestations of primary syphilis usually resolve in 3 to 6 weeks. **Nontreponemal serologic tests for syphilis are positive in only approximately 50% of patients at the time the chancre first appears.** A nonreactive test does not rule out syphilis in such patients.

- c. **Secondary syphilis.** *T. pallidum* disseminates throughout the body even before the appearance of the chancre. Approximately 3 to 6 weeks after the appearance of the chancre (indeed, often after its resolution) this dissemination manifests as a generalized rash, commonly involving the palms and soles and almost always involving the oral mucous membranes and the genitalia. The rash is highly variable, and differential diagnosis is often challenging [119,120]. **The rash generally is maculopapular, bilaterally symmetric, and nonpruritic or minimally pruritic and is described classically as having a “sinister” coppery or boiled-ham color [121].** It may, however, be papular or, rarely, papulopustular. The rash may resemble pityriasis rosea. The dry lesions of secondary syphilis are not contagious, because they contain very few organisms. Arguing against secondary syphilis in the adult is sparing of the mouth and genitalia, a markedly pruritic eruption, or bullous lesions [121].
- (1) Secondary syphilis generally begins with a nonspecific constitutional illness that commonly includes a sore throat and myalgias.
 - (2) Patchy alopecia is frequent.
 - (3) Generalized lymphadenopathy is observed in approximately 75% of patients.
 - (4) *Condylomata lata* are hypertrophic lesions, resembling flat warts, that occur in moist areas (e.g., around the anus) and are highly contagious.
 - (5) Painless shallow ulcers of the mucous membranes—**mucous patches—are highly contagious.**
 - (6) **Serologic tests are almost always reactive in secondary syphilis,** usually in high titer. Therefore, a negative test can be used to rule out secondary syphilis. Rarely, patients have such high levels of antibody that the nontreponemal tests are falsely negative, a so-called **prozone phenomenon.** One can avoid this by performing quantitative nontreponemal tests, in which serial dilutions of serum are examined.
 - (7) The manifestations of secondary syphilis resolve without treatment.
 - (8) Nearly 25% of patients will again develop the manifestations of secondary syphilis, termed **mucocutaneous relapse,** during the first year of infection. Such patients are again contagious to sexual partners.
- d. **Latent syphilis** is clinically silent, and diagnosis can be made only on the basis of serologic tests.
- e. **Late (tertiary) syphilis** eventually develops in approximately one-third of infected patients. A discussion of late syphilis is beyond the scope of this chapter, but good descriptions are available elsewhere [122]. Briefly, tertiary syphilis should be suspected in the following clinical settings:
- (1) **Lymphocytic meningitis** may be a manifestation of secondary syphilis or may appear somewhat later as **meningovascular syphilis.** A cerebrovascular accident without other cause in a young person should raise suspicion. See further related discussions in Chapter 6.
 - (2) **Destructive lesions of skin and bones** may represent so-called **late benign syphilis.**
 - (3) **Dementia** may be due to **general paresis.**
 - (4) **Posterior column disease** may result from **tabes dorsalis.** Stabbing (lightning) pains are suggestive.
 - (5) Disease of the **aorta or incompetence of the aortic valve** for which other etiologies are not documented may represent **cardiovascular syphilis.**

- (6) The diagnosis of late syphilis is confounded by the lack of sensitivity of the nontreponemal tests in these conditions. **A nonreactive nontreponemal test should be confirmed with a treponemal test in the workup of patients with suspected late syphilis.**
- f. Approximately one-third of patients will remain seroreactive but will not develop late manifestations of syphilis. Nearly one-third remain well and become nonreactive on nontreponemal testing.
- 4. Diagnosis of syphilis is undergoing a true revolution, as newer molecular techniques are applied.**
- a. Syphilis can be diagnosed by identifying *T. pallidum* in lesions. The traditional method is the **dark-field examination** in which material from a lesion is examined using a microscope that sends light rays obliquely through the specimen, illuminating the organism by reflected light against a dark background. Obtaining the specimen and interpreting the test require experience and are more difficult in areas such as the mouth, where other spirochetes may be part of the normal flora. **Direct immunofluorescence** has the same sensitivity, but specimens may be sent to a central laboratory [123]. Silver staining is less sensitive and specific. PCR methods are far more sensitive and are available in a research setting [124,125]. Because syphilis is subclinical for much of its course, we have come to rely heavily on **serologic diagnosis. Potential pitfalls in serodiagnosis must be recognized** [123,124,126].
- b. **Nontreponemal tests. Screening tests for syphilis** exploit the observation that patients with syphilis develop IgG antibodies, traditionally termed **reagin**, reactive with a variety of poorly defined lipids. Classical tests include the **VDRL** (Venereal Disease Research Laboratory), **RPR** (rapid plasma reagin), **ART** (automated reagin test), and **TRUST** (toluidine red unheated serologic test), among others. An ELISA for antiphospholipid antibody, the Spirotek Reagin II, is about 95% sensitive in early syphilis [127].
- (1) **Nontreponemal tests are nonspecific**, reacting in a variety of acute and chronic conditions such as acute viral illnesses, collagen vascular disease, pregnancy, i.v. drug use, old age, and leprosy. A nontreponemal test is diagnostic in the setting of a highly suggestive clinical syndrome (e.g., chancre) but cannot be used to diagnose latent syphilis without confirmation by a treponemal test.
 - (2) The tests **often are quantitated** and reported as the highest twofold dilution of serum eliciting a positive reaction. Titers of 1:8 or higher are unusual among false positives. The highest titers (1:128) may be seen in secondary syphilis.
 - (3) The tests are **relatively insensitive in primary and late syphilis**, and here it may be prudent to order a treponemal test even when the nontreponemal test is nonreactive.
 - (4) **The titer of the test diminishes after adequate treatment of syphilis. A fourfold drop in titer is considered evidence of adequate treatment** [127–130] and should occur within 3 months of treatment of early syphilis and within 6 months of treatment of latent syphilis.
 - (5) **After treatment, one should follow serologic tests at 3 and 6 months and then every 6 months thereafter until titers stabilize or disappear.**
 - (6) The RPR converts to nonreactive within 2 years in only 72% or so of patients treated for primary syphilis and approximately 56% of patients treated for secondary syphilis [129]. The VDRL is more likely to revert to nonreactive after treatment.
 - (7) The failure of the nontreponemal test titer to drop fourfold requires careful follow-up but is not associated with clinical relapse within 12 months [130].
 - (8) A subsequent reappearance or fourfold rise in titer of nontreponemal tests is considered evidence of relapse or reinfection.
 - (9) **It is essential that the same nontreponemal tests are used in follow-up as were used for the original testing, because the RPR**

can yield two- to eightfold higher titers on the same specimen than does the VDRL. Switching between tests invites confusion.

- c. Treponemal tests.** Confirmatory tests for syphilis use *T. pallidum*, or fractions thereof, as antigen. The treponemal tests are **more specific and more sensitive** than the nontreponemal tests, **particularly in very early primary and late syphilis**. They are not quantitated but are reported as reactive or nonreactive.
- (1) The fluorescent treponemal antibody absorption test has been regarded as the most sensitive test for syphilis, but it is less sensitive than the newer DNA-based tests.
 - (2) The microhemagglutination test for *T. pallidum* has been superseded by tests using particulate gelatin or latex, such as the **Serodia TP-PA** and the **PK-TP**, which are suitable as screening tests and now used extensively by blood banks [124,131–134]. They are not subject to misreading due to heterophile antibodies and are about 97% specific.
 - (3) Several **treponemal ELISA tests** are now available, the most commonly used being the **Captia syphilis G test**, [132,134], which is 98% sensitive and about 100% specific. Several ELISA tests use cloned *T. pallidum* antigens and have high sensitivity and specificity [135–137].
 - (4) **Western blot tests** have very high specificity and may be used in problem cases [124,138].
 - (5) **Treponemal tests may be used to confirm a diagnosis of past or present treponemal infection in patients with reactive nontreponemal tests.**
 - (6) **The treponemal tests remain positive for extended periods, probably for life, even after adequate treatment of syphilis in most (but not all) patients. A persistently reactive treponemal test does not indicate inadequate treatment, relapse, or reinfection [119].**
 - (7) Although they are highly specific, **the treponemal tests are reactive in other treponemal diseases** (e.g., yaws, pinta, bejel) and **in some other spirochetal diseases (e.g., Lyme disease)** [139].
- 5. Treatment. Penicillin remains the drug of choice for all stages of syphilis**, unless the patient is hypersensitive [13,140,141]. **All patients being treated for syphilis should be strongly advised to undergo testing for HIV antibody.**
- a. Contact to syphilis** (epidemiologic treatment, incubating syphilis). Infection is present in 25% to 50% of the sexual partners of patients with syphilitic lesions. Syphilis may take up to 90 days to become clinically or serologically manifest. Thus, **all patients presenting as contacts to syphilis within the past 90 days (the so-called critical period) are treated with a regimen effective for early syphilis**. Patients whose exposure was more than 90 days previously may be evaluated serologically to determine whether they need treatment.
- b. Early syphilis** (primary, secondary, and latent syphilis of <1 year's duration)
- (1) **Recommended:** benzathine penicillin G, 2.4 million units i.m., in one treatment.
 - (2) **In penicillin allergy:** doxycycline, 100 mg orally twice a day for 2 weeks, or tetracycline, 500 mg orally four times a day for 2 weeks.
 - (3) **The pregnant woman with severe penicillin allergy** ideally should be desensitized to penicillin so she can receive penicillin, because tetracyclines are contraindicated in pregnancy and erythromycin should not be used because it cannot be relied on to cure an infected fetus (see Chapter 24).
 - (4) Ceftriaxone may be a suitable alternative in patients whose allergy to penicillin is not manifested by anaphylaxis [140,141]. It is not advised in pregnancy [13].

c. Latent syphilis of unknown duration or of more than 1 year's duration, late benign syphilis, or cardiovascular syphilis

- (1) **Recommended:** benzathine penicillin G, 7.2 million units total, administered as three doses of 2.4 million units i.m., given 1 week apart for 3 consecutive weeks.
- (2) Alternatively **for penicillin-allergic nonpregnant patients:** doxycycline, 100 mg orally twice a day for 4 weeks, or tetracycline, 500 mg orally four times a day for 4 weeks.
- (3) Management of the **penicillin-allergic pregnant woman** is uncertain and should probably involve desensitization to penicillin.
- (4) **Examination of cerebrospinal fluid is recommended in the following situations** [141]:
 - (a) Neurologic signs or symptoms;
 - (b) Treatment failure;
 - (c) Other evidence of active syphilis (e.g., aortitis, gumma, iritis);
 - (d) Nonpenicillin therapy planned;
 - (e) Concurrent HIV infection.

d. Neurosyphilis (see related discussion in Chapter 6)

- (1) **Recommended:** aqueous crystalline penicillin G, 12 to 24 million units/day i.v. for 10 to 14 days, administered 2 to 4 million units every 4 hours or by continuous drip. In the HIV-positive patient, neurosyphilis may be particularly difficult to treat, and failures of therapy can occur despite optimal therapy with high dose i.v. aqueous penicillin [141–143].
- (2) Alternatively, procaine penicillin G, 2.4 million units/day i.m., and probenecid, 500 mg orally four times a day, both for 10 to 14 days.
- (3) An alternative for which data are limited: ceftriaxone, 1 g/day i.m. for 14 days [143]. This might be used in patients whose allergy to penicillin is not manifested by anaphylaxis.
- (4) **It is believed by many workers that the benzathine penicillin G regimen formerly recommended for neurosyphilis is inadequate.** Because the currently recommended regimen is shorter than that recommended for late syphilis in the absence of neurosyphilis, **some experts administer one or more doses of benzathine penicillin, 2.4 million units i.m., after completion of regimen (1) or (2) [13].**

e. The Jarisch-Herxheimer reaction occurs 1 to 6 hours after beginning treatment for syphilis and is seen in approximately 50% of patients with primary syphilis and in most patients with secondary syphilis. It manifests as fever, increased rash, adenopathy, and sometimes hypotension. The mechanism is not fully defined, but it probably results from the release of treponemal antigens on lysis of the organisms. The Jarisch-Herxheimer reaction is self-limited and usually requires only treatment with antipyretics, but patients should be warned of the likelihood of its occurrence.

f. Serologic follow-up (see section 4.b)

g. Syphilis in pregnancy should be managed according to the maternal stage of syphilis. Monthly serologic follow-up is required to ensure that treatment has been effective and reinfection has not occurred. The tetracyclines are to be avoided in pregnancy [144].

h. The effect of HIV infection on the clinical course of syphilis is incompletely defined. Such patients may present with multiple and persistent chancres [2,145]. It is unclear whether HIV infection affects the serologic manifestations, the natural history, or the response to therapy in patients coinfecting with *T. pallidum* [146,147]. However, many clinicians remain particularly concerned about reports suggesting that neurosyphilis may occur more rapidly in patients with HIV [148,149]. **Some experts recommend that cerebrospinal fluid examination be performed on all HIV-infected patients with syphilis, regardless of clinical stage.**

D. Chancroid is an infection with the gram-negative rod *Hemophilus ducreyi*. The incidence of chancroid has increased in the United States, and small epidemics have

occurred, usually associated with prostitutes [150–152]. Chancroid is a major public health problem in the developing world, and its significance is compounded by its striking **association with HIV infection** [2,153]. **Patients should be tested for HIV at the time of diagnosis.**

1. Clinical manifestations [82,151,152,154]

- a. The incubation period is 4 to 7 days.
- b. Presents as painful ragged ulcers on the genitalia. The ulcers often are dirty or appear necrotic, are not indurated, and may vary in size. So-called **kissing lesions** of the thighs may occur by autoinoculation. Painful inguinal adenopathy occurs in more than 50% of patients, and the nodes may become fluctuant and rupture. Occasionally, one sees superinfection with mixed anaerobic organisms.

2. Diagnosis. The major differential diagnoses are herpes simplex genital infection and syphilis. Clinical differential diagnosis is notoriously unreliable [81,82,154].

- a. **Dark-field examination helps to rule out syphilis.** Serology is less helpful because the diseases may coexist, and nontreponemal tests are insensitive early in primary syphilis.
- b. **Gram staining of the lesions** may reveal chains of gram-negative streptobacilli, but the technique is insensitive and nonspecific and **is not recommended** [155].
- c. **Culture** of the organism is definitive but difficult [155,156] and, at best, is only 80% sensitive.
- d. **Newer tests** under development include **PCR** (sensitivity approximately 90%) and **antigen detection** (sensitivity approximately 90%) and will become the tests of choice [155–157]. Multiplex PCR can be used to diagnose simultaneous infections, which are not rare.

3. Treatment [158] is complicated by recent development of resistance to traditional agents.

- a. Uniformly effective in the United States are (a) ciprofloxacin, 500 mg orally twice a day for 3 days; (b) ceftriaxone, 250 mg i.m. as a single dose; (c) erythromycin, 500 mg orally four times a day for 7 days; and (d) azithromycin, 1 g orally as a single dose. Trimethoprim-sulfamethoxazole should not be used [159].
- b. Cure rates in other parts of the world, such as Africa, may be somewhat lower [160], and single-dose thiamphenicol, 5 g orally, appears to remain effective in South America.
- c. Patients coinfecting with HIV may require longer courses of therapy [2].

E. Donovanosis (*granuloma inguinale*) is very rare in the United States, although it is far more common in other parts of the world, including India and Latin America. Caused by an intracellular gram-negative rod, *Calymmatobacterium granulomatis*, which is related to *Klebsiella*, it manifests as **painless destructive ulcers** characterized by exuberant tissue formation and healing with scarring. Diagnosis is made by biopsy of involved tissue. Treatment with azithromycin 1 g orally weekly appears effective [161] and may replace older regimens [13,162].

IV. Papular lesions

A. Pearly penile papules are regular white papules that form in one to five rows on the penile corona or in the coronal sulcus. They have no pathologic significance but sometimes precipitate a consultation.

B. Molluscum contagiosum is seen frequently in children, among whom it is spread by nonvenereal contact. After 2 to 8 weeks, infected adults usually develop 1- to 5-mm lesions around the genitalia, thighs, and buttocks. The infection is caused by a poxvirus that has not been cultured. The **painless papules** are easily identified clinically by their **central umbilications**. Treatment is by curettage, cryotherapy, or laser ablation. Patients should be warned to avoid squeezing the lesions and touching other areas of the body, which presents the risk of autoinoculation. Disseminated cutaneous disease, seen in AIDS [163], must be differentiated from disseminated cryptococcosis and may be treated with cidofovir [164].

C. Venereal warts (*condylomata acuminata*)

1. **Etiology.** Warts are **caused by HPV**, double-stranded DNA viruses that have not been cultured. Nearly 90 types have been identified. Types 6 and 11 cause benign genital warts, but **types 16, 18, 31, 33, and 35, among others, cause cervical cancer** [51–55]. Gestational HPV infection is associated with laryngeal lesions in vaginally delivered offspring.
2. **Natural history.** **Cervical HPV is self-limited in women with normal immune systems, with a median duration of about 8 to 10 months** [56–60]. Premalignant lesions often develop within 1 to 2 years of infection [54] and invasive carcinoma of the cervix within about 10 years [2].
3. **Clinical features.** The incubation period probably is approximately 4 to 6 weeks. Lesions are soft papules with irregular verrucous surfaces. They are usually located around the external genitalia or inside the urethra or vagina and on the cervix. Perianal warts in women may result from spread from a primary genital focus, but perianal warts in men strongly suggest receptive anal intercourse. Daughter lesions appear near older lesions. **Subclinical infection** is extremely important, with most infected patients having papillomavirus DNA identified in normal epithelium near visible lesions.
4. **Diagnosis of overt external lesions usually is made clinically. Warts in other locations**, including flat warts of the cervix, may require **biopsy**, which reveals characteristic koilocytosis, clear zones around the nuclei of infected cells. Subclinical infections may be suspected by swabbing the vagina, cervix, or penis [165] with 3% to 5% **acetic acid**, which turns infected areas white. This test is nonspecific and requires histologic confirmation. **DNA hybridization** kits are now commercially available and can supplement or replace standard cervical cytology [166,167].
5. **Treatment** is largely unsatisfactory and generally **controversial**. The benefit of treating subclinical infection has not been demonstrated [13]. Thus, the goal of therapy is the elimination of overt warts.
 - a. **Cryotherapy** with liquid nitrogen or cryoprobe is **preferred** because of its lack of toxicity, its usefulness in pregnancy, and its destruction of warts with a single treatment.
 - b. **Podofilox 0.5% solution** is applied by the patient twice daily for 3 days followed by a 4-day rest interval. The cycle may be repeated up to four times. The response rate is essentially identical to that with podophyllin, but podofilox is much more expensive [168].
 - c. **Trichloroacetic acid, 80% to 90%**, can be applied carefully to warts, followed by an application of sodium bicarbonate. Treatment can be repeated at weekly intervals. This regimen is safe in pregnancy.
 - d. **Podophyllin, 10% to 25% in tincture of benzoin**, is widely used. It is applied directly to the warts at weekly intervals and washed off after about 6 hours. **Absorption occurs, and so the regimen is contraindicated in pregnancy.**
 - e. **Imiquimod 5% cream (Aldara)**, an immunostimulator, can be applied by the patient three times weekly. The response rate is the same as with podophyllin, but it is far more costly [169].
 - f. **Intralesional interferon** has been used to treat warts [170], but the technique is expensive and time consuming and is inapplicable to patients with many warts.
 - g. The **relapse rate** with the treatments listed in this section approaches 75%.
 - h. The cervix should not be treated before cytologic studies have ruled out malignancy.

V. Pustular lesions (*disseminated gonococcal infection*). Dissemination is reported to occur in approximately 1% to 3% of patients infected with gonococci and manifests most commonly as a rash and arthritis or tenosynovitis [171,172].

A. Epidemiology

1. **Deficiency in the terminal components of complement**, most frequently of C8, predisposes to disseminated gonococcal infection and disseminated meningococcal infection.

2. The organism resists killing by serum [171–173].

B. Clinical features [171,172]

1. Bacteremia usually manifests as **fever**, accompanied by **pustular or hemorrhagic skin lesions**, usually distributed primarily **on the distal portions of the extremities**.

- a. The classic lesion is a tiny pustule, sometimes with a central eschar, surmounting a hemorrhagic base.
- b. Vesicular lesions sometimes are observed.
- c. Although most patients have few lesions, some have hundreds [173].
- d. **Differential diagnosis** includes meningococcemia [173], staphylococcal endocarditis, Rocky Mountain spotted fever, or dengue.

2. **Arthritis**

- a. Most patients, particularly early in their course, will have a **polyarthritis**, often accompanied by prominent tenosynovitis. Effusion usually is absent. Skin lesions are common and may continue to form.
- b. Some patients present with one or very few joints manifesting effusion, a septic joint picture. Skin lesions are no longer forming at this stage.
- c. Differential diagnosis includes septic arthritis of other etiologies. One must consider **Reiter syndrome**, which consists of urethritis, arthritis (usually asymmetric), dermatitis, and conjunctivitis.

C. Diagnosis is initially made clinically.

1. **Cultures for *N. gonorrhoeae* should be obtained for all sites used for sexual contact** (urethra, anorectum, cervix, pharynx) even if asymptomatic.
2. **Blood cultures** are positive in only approximately 40% of patients.
3. **Joint effusions should be cultured** but will be positive in only approximately 20% of cases.
4. Skin lesions are rarely positive by culture or by Gram stain. Direct fluorescent antibody staining may be useful.
5. In many patients, all cultures are negative, and diagnosis depends on clinical impression and response to therapy.

D. Treatment must take into account new patterns of gonococcal resistance [13].

1. **Initial therapy** should consist of **any of the following**:

- a. Ceftriaxone, 1 g i.m. or i.v. every 24 hours.
- b. Ceftizoxime, 1 g i.v. every 8 hours.
- c. Cefotaxime, 1 g i.v. every 8 hours.
- d. In β -lactam allergy, use ciprofloxacin, 500 mg orally or i.v. every 2 hours or an equivalent newer fluoroquinolone.

2. **Intravenous therapy may be discontinued 24 to 48 hours after symptoms resolve, and 1 week of total therapy may be completed with:**

- a. Cefixime, 400 mg orally twice a day, or
- b. Ciprofloxacin, 500 mg orally twice a day (**contraindicated in pregnancy and in children younger than 16 years**).

3. **Special considerations**

- a. **Sexual partners** must be evaluated and treated, even if asymptomatic.
- b. Patients with disseminated gonococcal infection should also be treated for chlamydial infection.
- c. **Meningitis or endocarditis** rarely complicates this infection. These conditions require longer duration treatment [13,171,172].

VI. Ectoparasites. Infected patients should be evaluated for other STDs. Sexual partners should be treated.

A. Pubic (crab) lice (*Phthirus pubis*) infestation is markedly pruritic and has an incubation period of approximately 4 weeks [174,175]. Signs include observation of the **lice**, 1- to 2-mm-long gray-brown organisms; **nits**, 0.5-mm brown or white ovoids attached to the hair shafts; **excreta**, tiny red dots on the skin among the hair; or rarely, **maculae ceruleae**, blue-gray macules [176]. Infestation may include the pubic and perianal, abdominal, chest, axillary, and superciliary hair.

1. Various **treatment regimens** are equally effective [13,175,177,178].

- a. Permethrin (e.g., Nix) 1% creme rinse, applied to affected areas and washed off after 10 minutes.

- b. Pyrethrins and piperonyl butoxide (e.g., RID) applied to affected areas and washed off after 10 minutes.
 - c. Lindane (γ -benzene hexachloride) (e.g., Kwell) 1% shampoo applied for 4 minutes and then washed off.
2. **Additional measures.** Clothing or bed linen contaminated within the past 48 hours should be washed before reuse. The eyelids should be carefully examined.
3. **Follow-up.** Patients should be reevaluated after 1 week if they remain symptomatic. The presence of **any lice** or the presence of **nits at the base of the hair shafts is an indication for retreatment.**
- B. Scabies** is caused by infestation with the itch mite, *Sarcoptes scabiei* [175]. After an incubation period of approximately 4 weeks, most patients develop severe pruritus of the infected areas, usually worse at night or after bathing.
1. **Diagnosis** is confirmed by **demonstrating the mite** in unexcoriated papules or burrows. The mites often are difficult to demonstrate. The female adult has a rounded body with four pairs of legs and is less than 0.5 mm long.
- a. A hand lens is used to identify suspicious lesions. The classic linear burrows, occurring most frequently in the interdigital spaces and on the penis, are the best sites from which to take the scrapings.
 - b. With a needle or a scalpel blade, a superficial epidermal shave biopsy is performed.
 - c. The specimen is suspended in immersion oil and covered with a glass coverslip.
 - d. The mite or its products will, one hopes, be visible under the high dry lens of a light microscope.
2. **Treatment for adults**
- a. **Recommended** [13,175,177–180]. **Permethrin 5% cream** applied to all areas of the body below the chin and washed off after 8 to 14 hours; **or**
 - b. **Lindane (γ -benzene hexachloride) 1% lotion or cream** applied to all areas of the body below the chin and washed off after 8 hours. **Application must be complete, including the interdigital spaces. Patients should be cautioned not to wash their hands after applying the medication.** Avoid in pregnant or lactating women, people with dermatitis, or in children under the age of 2.
 - c. **Alternatively**, one can use **crotamiton 10%**, applied to all areas of the body below the chin for two successive nights and washed off thoroughly 24 hours after the second application. This regimen appears less effective than those above [181].
 - d. **Ivermectin** as a single oral dose of 200 $\mu\text{g}/\text{kg}$ has been used successfully in patients with standard and severe crusted scabies [182–184]. The drug has been used topically in a small number of cases [185].
3. **Additional measures**
- a. Clothing or bed linens contaminated within the previous 48 hours should be washed before reuse.
 - b. Sexual and close household contacts should be treated.
4. **Follow-up.** Pruritus may persist for several weeks after adequate treatment. A single retreatment may be indicated if pruritus is not *improved* after 1 week.
5. **HIV-infected patients**, especially those with advanced HIV disease, may present with **atypical and severe forms** of scabies that may not respond to first-line agents [186,187]. Management may include repeated applications and should be done in consultation with a dermatologist.

VULVOVAGINITIS

Vulvovaginitis is a common clinical syndrome and is diagnosed in more than one-fourth of women attending STD clinics (Table 16.1) [188].

I. Differential diagnosis of vulvovaginitis

A. Candidiasis

1. Epidemiology

Table 16.1. Typical Features of Common Vaginal Infections

	Trichomoniasis	Candidiasis	Bacterial Vaginosis
Epidemiology			
Sexual transmission	Yes	Very rarely, if ever	Often but not always
Symptoms			
Relation to menses	Often postmenstrual	Often premenstrual	None
Vulvar irritation	Mild to marked	Mild to marked	Absent to mild
Dysuria	Internal and external	External	Absent
Odor	Sometimes	Absent	Fishy, aminelike
Signs			
Labial erythema	Variable	Variable	No
Satellite lesions	No	Yes	No
Vaginal tenderness	Yes	Yes	No
Rugal hypertrophy	Yes	Sometimes	No
Adnexal tenderness	Occasionally	No	No
Discharge			
Consistency	Frothy 25%	Sometimes curdy	Homogeneous, frothy
Color	Yellow-green (25%)	White	Gray, white
Adherent to vaginal walls	No	Yes	Yes
PH	Usually ≥ 4.7	≤ 4.5	≥ 4.7
Microscopy			
Epithelial cells	Normal	Normal	Studded with coccobacilli (clue cells)
Polymorphonuclear neutrophils	Usually increased	Variable	Not increased
Bacteria	Gram-positive rods	Gram-positive rods	Gram-variable coccobacilli
Pathogens	Trichomonads (70%)	Yeasts or pseudohyphae (50%)	Coccobacilli and short motile rods

- a. Vulvovaginal candidiasis (VC) accounts for approximately one-third of the vaginitis cases seen in private practice. It is estimated that 75% of adult women suffer at least one episode of VC during their lifetimes [189].
- b. *Candida albicans* is isolated from nearly 80% to 90% of cases of VC, but infection due to other species (*C. glabrata* approximately 10%, *C. tropicalis* approximately 1%–5%) is apparently increasing and is associated with higher failure and relapse rates [190–193].
- c. Inhibition of normal bacterial flora by **broad-spectrum antibiotics** favors the growth of yeasts and predisposes to the development of VC.
- d. **Overgrowth of yeast is favored by high estrogen levels** [194]. This may explain the observation that VC is more common in **pregnancy**. Some nonpregnant women note recurrent or increasing symptoms **preceding each menstrual period**. The prevalence of vaginal carriage of *Candida* is higher among women using **oral contraceptives** compared with those using other methods of birth control [195].
- e. There is some evidence that tight, insulating clothing predisposes to VCiasis by increasing vulvar warmth and moisture [196].
- f. **Patients with AIDS** often experience severe and recalcitrant disease [2,197].

2. Clinical features

- a. **Symptoms.** Patients generally complain of **perivaginal pruritus**, often with little or no discharge. Dysuria, if noted, is likely to be vulvar rather than urethral.
- b. **Physical findings.** The labia may be pale, erythematous, or excoriated. **Shallow linear fissures**, especially on the posterior portion of the introitus, are common. Tiny **satellite papules** or papulopustules just beyond the main area of erythema are helpful diagnostically. The vaginal walls may be erythematous. Candidal discharge may be thick, adherent, and curdy or thin and loose.

3. Diagnosis

- a. A **wet mount** to which 10% to 20% KOH is added will reveal fungi in 50% to 70% of infected women. If negative, a presumptive diagnosis must be made on the basis of clinical features, pH, “whiff test,” and microscopy negative for other pathogens.
 - b. The **vaginal pH** generally is **normal** (approximately 4.5) in women with VC, in contrast to trichomoniasis and bacterial vaginosis (BV), in which it is characteristically elevated.
 - c. The **whiff test** (see section II.B.2.b) is characteristically **negative** in VC.
 - d. The discharge usually contains relatively few PMNs.
 - e. A commercially available latex agglutination test has a limited sensitivity of approximately 60% [198].
- B. Trichomoniasis.** *Trichomonas vaginalis* is an anaerobic, flagellated, motile protozoan, approximately the size of a polymorphonuclear leukocyte.

1. Epidemiology

- a. An estimated 3 million American women contract trichomoniasis every year. Its incidence has declined, possibly because of the widespread use of metronidazole for BV, but it remains common in populations at risk for other STD [199–201].
- b. Trichomoniasis is only rarely acquired nonvenereally. Sexual partners should be treated and infected patients should be evaluated for other STD [201].

2. Clinical features

- a. **History.** The incubation period in women is 5 to 28 days [202]. Infected women usually note **vaginal discharge and vulvovaginal soreness or irritation**. **Dysuria and dyspareunia** are common. Although up to two-thirds of infected women complain of a disagreeable **odor**, this symptom may actually be more suggestive of BV. Symptoms often begin or exacerbate during the menstrual period. **Abdominal discomfort** is described by only 5% to 12% of infected women and should prompt careful evaluation for a second process, such as pelvic inflammatory disease (PID). Approximately 10% to 50% of infected women attending STD clinics carry the organism asymptotically.

Most men infected with *T. vaginalis* are asymptomatic [29].

b. Physical findings

- (1) Examination usually reveals a copious rather loose **discharge** pooling in the posterior vaginal fornix, often yellow or green. Bubbles are observed in 10% to 33% of cases, and as many as half have a relatively thick discharge that may be confused with VC.
 - (2) There is usually **inflammation of the vaginal walls** and the exocervix. Punctate hemorrhages (colpitis macularis), including the so-called **strawberry cervix**, are observed colposcopically in 45% of infected women but in only 2% by visual inspection alone [202].
 - (3) Vaginal discharge from 90% of women with trichomoniasis has a **pH level elevated above the normal value of 4.5**.
- c. **Diagnosis.** The accurate diagnosis of trichomoniasis depends on **demonstrating the organism** in genital specimens.
 - (1) **Trichomonads may be identified** in vaginal secretions using the **wet-mount** technique, which will detect their **characteristic movements** in nearly 60% of infected women [203]. The wet mount generally also reveals large numbers of **white blood cells**, although asymptomatic women may have very few.

- (2) Direct fluorescent antibody staining [203], latex agglutination [204], and ELISA techniques [205] are more sensitive than a wet mount (80%–90%) but less sensitive than culture. More sensitive, however, are newly developed DNA probes [206] and PCR [207,208] that are becoming available.
- (3) **Culture remains the most sensitive technique**, and commercially available kits have increased the ease with which the organism can be cultured [209].
- (4) **Serologic testing has no current role in the evaluation of the individual patient.**
- (5) The Pap smear is specific but insensitive.

C. BV is the most common vaginal infection in the United States. Seen primarily in sexually active women, it is characterized by a **nonirritating malodorous vaginal discharge**. Though previously called *nonspecific vaginitis* and originally attributed to infection with *Gardnerella vaginalis*, there is now considerable evidence that BV is actually a **synergistic infection** involving not only *G. vaginalis* but also certain anaerobic bacteria [210,211]. Loss of hydrogen peroxide-producing lactobacilli, possibly through the action of a recently described bacteriophage [212], probably sets the stage for this infection [210,211].

1. Epidemiology

- a. BV is common in populations with a high prevalence of STDs. **The precise contribution of sexual transmission to the overall epidemiology of the condition remains controversial.**
- b. Recurrence in the absence of sexual reexposure is well described. **It is not demonstrably necessary to treat male sexual partners** initially, but some women with frequent recurrences will benefit if sexual partners are treated well [213].

2. Clinical features

- a. **History.** Affected women usually are sexually active and often **complain predominantly of vaginal odor**. Approximately 90% of patients also notice a **mild to moderate discharge**. If present, inflammation and perivaginal irritation are mild. Dysuria and dyspareunia are rare. Abdominal discomfort, if present, is usually mild and should prompt evaluation for coincident infections including salpingitis.
- b. **Physical findings. Discharge** often is present at the introitus and is visible on the labia minora. The labia and vulva generally are not erythematous or edematous. On speculum examination, the vaginal walls are uninflamed. The vagina often contains a grayish-white, thin, homogeneous discharge manifesting **small bubbles**. This discharge differs from normal physiologic discharge in that the latter has a floccular appearance, and bubbles are absent. Because it is **relatively thin but adherent to the vaginal walls**, this discharge is often apparent only as an increased light reflex. The endocervix is unaffected by the process.

3. Diagnosis. BV is perhaps most easily differentiated from trichomoniasis on the basis of direct microscopic examination of vaginal discharge.

- a. A **wet mount** of the discharge reveals **clue cells**, which are vaginal epithelial cells studded with tiny coccobacilli. **Some clue cells are seen in more than 90% of patients with BV.**
- b. The **pH of vaginal discharge is elevated** above the normal of 4.5 in approximately 90% of cases.
- c. A **positive whiff test** is found in nearly 70% of cases.
- d. Bacterial flora can also be assessed on a wet-mount slide. In healthy women, the predominant morphotype is a large rod (presumably *Lactobacillus* species). In the discharge from a patient with BV, these rods have been completely supplanted by **clumps of coccobacilli**.
- e. Discharge in BV contains **few PMNs**.
- f. It has been suggested [214] that the clinician **look for (a) a pH greater than 4.5; (b2) homogeneous, white, adherent vaginal discharge; (c) a positive whiff test; and (d) clue cells. Finding any three of these four**

signs strongly supports the diagnosis of BV; the finding of clue cells is the most specific of the criteria [214].

- g. Culture for *G. vaginalis* does not prove that the patient has BV or suggest a need for treatment.
 - 4. **BV and pregnancy.** BV has been associated with adverse outcomes of pregnancy (e.g., preterm labor, preterm delivery, premature rupture of membranes, postpartum endometritis) [215]. Treatment of BV in pregnant women apparently reduces the risk of adverse pregnancy outcomes [216,217].
 - 5. BV is associated with an increased risk of PID [218,219].
 - D. **Other vaginal conditions** to consider include vaginitis due to foreign bodies, HSV, HPV, and, much less commonly, *Mycobacterium tuberculosis*, salmonellae, actinomycetes, schistosomes, and pinworms. ***N. gonorrhoeae* and *C. trachomatis* can cause true vaginitis in prepubescent girls** [45].
 - E. **Noninfectious causes** of vulvovaginal complaints include genital neoplasms, chemical irritation, or focal vulvitis. Physiologic vaginal fluid can sometimes be perceived by the patient as vaginal discharge.
- II. **Approach to the patient with vaginal complaints** [45]

A. Historical features

- 1. **Mode of onset.** An abrupt and identifiable time of onset of symptoms suggests infection. Symptoms beginning during or immediately after the menstrual period are somewhat suggestive of trichomoniasis, whereas a premenstrual onset more frequently accompanies VC.
- 2. **Perineal irritation.** Pruritus with a scanty or absent discharge frequently is seen in VC and is less common with trichomoniasis. Perineal discomfort is an infrequent complaint in BV. Severe episodic perineal pain sometimes preventing urination strongly suggests herpes genitalis, which affects the labia but usually spares the vagina *per se*. **Chronic discomfort, often interfering with sexual activity, should prompt consideration of focal vulvitis.**
- 3. **Abdominal pain.** Abdominal discomfort is rare in uncomplicated vulvovaginitis except for occasional cases of trichomoniasis. Women complaining of abdominal pain should be examined carefully for evidence of coincidental cystitis or PID.
- 4. **Medication. Use of antibiotics, corticosteroids, or oral contraceptives** predisposes to VC.
- 5. **New or multiple sexual contacts** increases the risk of trichomoniasis or BV.

B. Examination of the female genitalia

- 1. A **complete pelvic examination** should be performed.
- 2. **Other bedside evaluation**
 - a. After the speculum is withdrawn, the **pH of vaginal secretions** can be determined by inserting a strip of indicator paper into the material collected in the lower lip of the speculum. A normal pH of 4.5 is seen in most patients with VC, whereas a pH elevated to 5.0 or higher is associated with BV or trichomoniasis.
 - b. Several drops of 10% KOH are then added to the material on the speculum. A resultant pungent, fishy, aminelike odor constitutes a positive **whiff test**. The whiff test is positive in more than 90% of patients with BV and in many patients with trichomoniasis. This test may also be evaluated on a slide that has been prepared for KOH microscopic examination.

C. Laboratory examination

- 1. A **wet mount is of greatest value in the differential diagnosis of a vaginal discharge**, and the specimen may be prepared in several ways. A swab of vaginal discharge may be agitated in a tube containing approximately 0.5 mL of normal saline. One drop of the resulting suspension is put on a microscope slide, and a coverslip is applied. Alternatively, the examiner may place a drop of saline on the slide and mix in a loopful of vaginal material, after which a coverslip is applied. The slide is examined at 400 × with the substage condenser racked down and with the substage diaphragm closed. Phase-contrast microscopy is an excellent means of evaluating vaginal wet mounts.

- a. **The relative numbers of epithelial cells and PMNs should be noted.** Finding more than one PMN per epithelial cell should raise the examiner's suspicion of cervical or vaginal inflammation. The relative absence of PMNs is characteristic of the discharge of BV.
 - b. The wet preparation should be **scanned for motile trichomonads**. Trichomonads are best recognized by their characteristic twitching motility. Trichomonad motility is improved by gently warming the preparation. Unfortunately, the wet mount is negative in approximately 30% of the women with trichomoniasis, and a negative wet mount does not rule out this infection, particularly in relatively asymptomatic women.
 - c. Normal squamous epithelial cells have transparent cytoplasm and small nuclei. Epithelial cells covered with tiny coccobacillary forms are **clue cells** and are associated with BV. Clue cells are best recognized by observing the edges of epithelial cells, which may be obscured by the adherent coccobacilli.
 - d. The **bacterial flora can be assessed** on the wet mount. Normal vaginal flora consists primarily of rods. In BV, the predominant flora is tiny coccobacilli.
 - e. Combining a drop of 10% or 20% **KOH** with the vaginal material on a microscope slide, applying a coverslip, and gently heating will destroy cellular elements but leave the bacteria and fungi unscathed.
2. A **Gram stain of vaginal material can be used for the diagnosis of BV** [220], but trichomonads are very difficult to identify.

III. Treatment

A. Candidiasis

1. **Topical therapy.** VC usually is treated with the topical application of an antifungal agent. Commercially available preparations are characterized by high patient acceptability and safety in pregnancy. The choice of an agent is based primarily on cost, the patient's preference for cream versus suppository, and the availability of agents. We prefer 3- or 7-day regimens.
 - a. **One 14-day regimen** is nystatin, a 100,000-unit suppository at bedtime. The cure rate exceeds 90%.
 - b. **Seven days of treatment with an imidazole** yields cure rates ranging from 80% to 94% [45].
 - (1) Miconazole 2% cream, 5 g daily at bedtime
 - (2) Miconazole, 100-mg vaginal suppository daily at bedtime
 - (3) Clotrimazole, 100-mg vaginal suppository daily at bedtime
 - (4) Clotrimazole 1% cream, 5 g daily at bedtime
 - (5) Terconazole 0.4% cream, 5 g daily at bedtime
 - (6) Fenticonazole 2% cream, 5 g daily at bedtime
 - c. **Three-day regimens.** Some reviews suggest marginally better results with 7 days of therapy [221]. Patient compliance is likely to be better [222].
 - (1) Miconazole, 200-mg vaginal suppository daily at bedtime
 - (2) Clotrimazole, 200-mg suppository daily at bedtime
 - (3) Butoconazole 2% cream, 5 g daily at bedtime
 - (4) Tioconazole 2% cream, 5 g daily at bedtime
 - (5) Econazole, 150-mg suppository daily at bedtime
 - (6) Terconazole 0.8% cream, 5 g daily at bedtime
 - (7) Terconazole, 80-mg suppository daily at bedtime
 - d. **Single-dose regimens** with large amounts of imidazoles may be preferred for the sake of convenience in the treatment of mild infections, but cure rates obtained in some of these studies have not quite matched those obtained with longer courses. Treatment in pregnancy is more often unsuccessful, and so the longer course regimens may be preferred in this setting [223].
 - (1) Clotrimazole, 500-mg vaginal tablet at bedtime (single dose)
 - (2) Tioconazole 6.5% ointment, 4.6 g at bedtime (single application)
 - (3) Miconazole 1200 mg suppository at bedtime (single administration)
2. **Oral therapy.** Considerable data support the value of oral imidazoles and triazoles in treating VC [45]. **Results do not appear to be substantially superior to those obtained with topical regimens, and the clinician must consider**

carefully the need for systemic therapy for VC in view of the potential toxicities and possible teratogenicity of the drugs. Only the fluconazole single-dose regimen is approved for this use by the U.S. Food and Drug Administration.

- a. **Single-dose fluconazole**, 150-mg single oral dose, is at least as effective as intravaginal treatment of VC, and many patients may prefer the convenience of a single-dose oral regimen.
 - b. Other oral regimens (**not U.S. Food and Drug Administration approved**) with very limited clinical data include (a) ketoconazole, 200 mg orally twice a day for 3 to 5 days; (b) ketoconazole, 200 mg orally every day for 3 days; (c) itraconazole, 200 mg orally twice a day for 1 day; and (d) itraconazole, 200 mg orally every day for 3 days.
- 3. Recurrent infection. The optimal therapy for recurrent VC has not been defined.** Several approaches have been tried with limited success in individual cases.
- a. **Replacement of lactobacillary flora by diet.** This is ineffective. Vaginal lactobacilli are not *Lactobacillus acidophilus*, women with recurrent candidiasis do not lack vaginal lactobacilli, and a double-blind trial of live versus killed yogurt failed to show any differences in recurrences [224,225].
 - b. **Monthly premenstrual treatment with an antifungal.** Although this is effective, many women with somewhat less frequent symptoms prefer to use therapy only when they become symptomatic, and efficacy disappears when the regimen is discontinued [226,227].
 - c. **Treatment of sexual partners.** This too is ineffective in most cases [228,229].
 - d. **Elimination of a rectal focus.** This is ineffective. Note the large number of studies of the new oral regimens, which would eliminate a rectal focus but are not associated with a delay in next recurrence [229,230].
 - e. **Higher dose or alternative treatment for *Candida* species other than *C. albicans*,** many of which are resistant to the imidazole/triazoles. Note that *C. glabrata* may require treatment with fluconazole 150 mg orally on days 1 and 4 or may be better treated with 7 days of a topical imidazole. Boric acid powder, 600 mg in a gelatin capsule *per vaginum* daily for 14 days, is effective against highly resistant yeasts [231,232].
 - f. **Long-term, continuous, suppressive therapy for 6 months** [223,233]. This is effective for the duration of suppression and in some women for the long term. This approach may work by allowing women to become desensitized to yeast products. Regimens tested include ketoconazole 100 mg orally daily; itraconazole 50 to 100 mg orally daily; **fluconazole 150 mg orally weekly**; and clotrimazole suppositories 500 mg *per vaginum* once per week. **Because of its potential toxicity, the ketoconazole regimen is not recommended. The fluconazole regimen is the most convenient. Cost of any of these regimens is a major consideration.**
- B. Trichomoniasis.** The index case and all sex partners should be treated. Cure rates of 95% have been achieved when recommended metronidazole regimens are used [13,201].
1. **The standard treatment is metronidazole, 2 g, as a single oral dose.**
 2. An **alternative regimen** is metronidazole, 250 mg orally three times a day or 500 mg orally twice a day for 7 days. **Note:** Metronidazole gel has been approved for treatment of BV but it is ineffective for trichomoniasis.
 3. **Metronidazole may be used in pregnancy.**
 4. **Metronidazole resistance is increasing** in prevalence. Treating metronidazole-resistant trichomoniasis usually involves the administration of high doses of metronidazole, which can be associated with toxicity [201]. Usually, retreatment with metronidazole, 500 mg twice a day for 7 days, is tried. If repeated failure occurs, the patient can be treated with a single 2-g dose of metronidazole once daily for 3 to 5 days. Patients with culture-documented infection who do not respond to these regimens and in whom reinfection has been excluded should be referred for consultation with an expert, so that susceptibility of the *T. vaginalis* to metronidazole can be determined.

- C. **BV.** Successful regimens have been aimed at the anaerobic bacteria that participate in the infection. Male sexual contacts do not require therapy [13] for the initial episode. In women with recurrent episodes of BV, it would be prudent also to treat sexual contacts.
1. **Oral regimens**
 - a. Metronidazole, 500 mg orally twice a day for 7 days.
 - b. Metronidazole, 250 mg orally three times a day for 7 days.
 - c. Clindamycin, 300 mg orally twice a day for 7 days. This regimen has the advantage of being safe in pregnancy [234].
 - d. Cefadroxil, 500 mg orally twice a day for 7 days. This regimen is safe in pregnancy but is supported by very limited data [235].
 2. **Topical regimens** appear to have acceptable cure rates, although data are limited.
 - a. Clindamycin 2% vaginal cream, 5 g (one full applicator) vaginally at bedtime for 7 days [236–238]. **This regimen should not be used in pregnancy because it is less effective than metronidazole in preventing gestational complications** [13,239,240].
 - b. Metronidazole 0.75% vaginal gel, 5 g (one full applicator) vaginally twice a day or qhs for 5 days [237,241–243].

SEXUALLY TRANSMITTED INTESTINAL INFECTIONS

Sexually transmitted intestinal infections (e.g., due to *Salmonella* species, *Campylobacter jejuni*, *Shigella* species, *Cryptosporidium* species) are discussed in Chapters 13 and 18.

OBSTETRIC/GYNECOLOGIC INFECTIONS

I. Basic concepts

- A. The **lower genital tract** (cervix and vagina) contains a complex flora of more than 100 species of bacteria, viruses, and fungi.
- B. The **upper genital tract** (uterus, fallopian tubes, ovaries, pelvic peritoneum) is normally sterile.
- C. When the upper genital tract is anatomically disrupted (e.g., by STDs, surgery, or the trauma of delivery) and local defense mechanisms are impaired, the “normal flora” of the lower genital tract can ascend and cause disease [244]. **Accordingly, most gynecologic and obstetric infections are polymicrobial with these normal flora** (Table 16.2). Conversely, some “**pathogens**” are readily isolated from the healthy woman’s vagina [245].

II. Bacteria

- A. There are 10^8 to 10^9 **colony-forming units** of bacteria per milliliter of vaginal secretions.
- B. **Anaerobes** predominate over aerobes by a ratio of approximately 10:1.
- C. *Staphylococcus aureus* and *Streptococcus pyogenes* (group A streptococcus) are rarely found in normal flora; thus, their presence in the setting of toxic shock syndrome is important.
- D. *Mycoplasma hominis* and *U. urealyticum* are frequently found in the vaginas of sexually active women. In the absence of illness they do not warrant therapy, but there is speculation as to their role in the development of PID.

III. Fungi

- A. Yeasts are the only fungi of importance regularly isolated from the normal genital tract.
- B. *C. albicans* is the most common species, although *C. glabrata* may be found.

IV. Viruses

- A. **Cytomegalovirus** has been recovered in the healthy lower genital tract, particularly in highly sexually active individuals [246].

PELVIC INFLAMMATORY DISEASE

- I. **Definition.** PID refers to infection of the upper female genital tract, anywhere from the endometrium to the fallopian tubes to the ovaries to the peritoneum. **Various combinations of *C. trachomatis*, *N. gonorrhoeae*, and mixed bacteria of the lower genital tract are the causal organisms.**

Table 16.2. Normal Flora of the Lower Female Genital Tract

Isolate	Approximate % of Normal Carriage
<i>Lactobacillus</i>	~45
Anaerobic gram-positive cocci	~25
<i>Prevotella</i> species	~20
<i>Ureaplasma urealyticum</i>	~18
<i>Gardnerella vaginalis</i>	~12
<i>Streptococcus agalactiae</i> (group B streptococcus)	~11
<i>Escherichia coli</i>	~7
Anaerobic gram-negative rods	~5
<i>Candida</i> species	~5
<i>Mycoplasma hominis</i>	~3
<i>Bacteroides fragilis</i>	~3
Other gram-negative rods	~1

Note: The compendium of “normal flora” changes dramatically with menses, postoperatively, with tampon usage, with bacterial vaginosis, and with other sexually transmitted diseases.

From Eschenbach DA, Thwin SS, Patton DL, et al. Influence of the normal menstrual cycle on vaginal tissue, discharge, and microflora. *Clin Infect Dis* 2000;30:901–907, with permission [245].

II. Risk factors

- A. Heterosexual activity (young at first intercourse, multiple partners, recent new sexual partner, frequency of intercourse, etc.)
- B. Prior STD (gonorrhea, *Chlamydia*, probably BV)
- C. Age: incidence peaks among 15 to 24 year olds.
- D. Intrauterine device (IUD, especially the Dalkon shield) or no contraception greater than barrier methods or oral contraceptives
- E. Invasive gynecologic procedures
- F. Menstruating women (PID is rare during pregnancy and after menopause)

III. Diagnosis

- A. **Gold standards** for diagnosis are often impractical to achieve in the outpatient setting [13].
 1. Endometrial biopsy showing changes consistent with PID
 2. Transvaginal ultrasound showing thickened fluid-filled tubes
 3. Laparoscopic evidence of PID
- B. **Clinical diagnosis**
 1. **Symptoms** classically include fever (temperature > 101°F) and lower abdominal or adnexal tenderness.
 2. **Examination** may reveal cervical motion tenderness or abnormal cervical discharge.
 3. **Laboratory values** may include elevated C-reactive protein or erythrocyte sedimentation rate and cervical culture of *N. gonorrhoeae* or *C. trachomatis*.
 4. **Clinical diagnosis is insensitive and nonspecific.** Many patients with these findings will not have true PID [247], and likewise many patients without such findings will have PID. Sole endometritis can have particularly mild symptoms [248].
 5. **Gonococcal PID** is usually relatively acute with significant symptoms, high fever, peritoneal signs, and vaginal discharge.
 6. **Chlamydial PID** usually displays mild to moderate symptoms (e.g., chronic pain, irregular bleeding) but severe inflammation on laparoscopy.
 7. **Nongonococcal/nonchlamydial PID** is often marked by abscess formation.

IV. Therapy. The Centers for Disease Control and Prevention (CDC) recommend empirical treatment for all sexually active women with lower

abdominal/adnexal tenderness and cervical motion tenderness on examination with no other explanation [13].

- A. There are no large-scale trials that support one therapeutic regimen over another.**
- B.** All treatment regimens should be effective against **gonorrhea, chlamydia, and anaerobes**, regardless of endocervical or other cultures. The rationale is that negative endocervical cultures for *N. gonorrhoeae* and *C. trachomatis* do not preclude upper tract infection and anaerobes are likely pathogenic and therefore also should be treated [249].
- C.** Failure rates of 15% to 20% are documented for single drug regimens; thus, most authorities recommend **multiple-drug regimens**. These provide clinical and microbiologic cure rates of approximately 90%.
- D. Whether to hospitalize** and use i.v. therapy relies on clinical judgment, but most authorities suggest hospitalization in the following scenarios:
1. Tubo-ovarian abscess (see below)
 2. Peritonitis (cannot rule out other abdominal processes)
 3. Pregnant patients (because of high rates of preterm labor, stillbirths, and maternal morbidity)
 4. Immunosuppressed patients (including HIV patients, who often have more severe presentations)
 5. The patient cannot tolerate oral medications
 6. Possibly in young adolescents when compliance is in question
- E.** The CDC recommends any of the following **parenteral** regimens:
1. **Cefotetan** 2 g i.v. every 12h + **doxycycline** 100 mg orally every 12h
 2. **Cefoxitin** 2 g i.v. every 6 hours + **doxycycline** 100 mg orally every 12 hours
 3. **Clindamycin** 900 mg i.v. every 8 hours + **gentamicin** 2 mg/kg i.v. loading dose, then 1.5 mg/kg every 8 hours
- Note:** Limited trials also suggest that parenteral ofloxacin + metronidazole, ampicillin/sulbactam + doxycycline, or ciprofloxacin + doxycycline + metronidazole are effective.
- F. Duration of i.v. therapy.** Most trials on inpatients have used parenteral treatment for at least 48 hours, after which the patient is switched to oral doxycycline 100 mg twice a day to complete a 14-day course.
- G. Stable patients who do not require hospitalization can be managed with outpatient therapy with any of the following regimens:**
1. **Ofloxacin** 400 mg orally twice a day + **metronidazole** 500 mg orally twice a day for 14 days
 2. **Ceftriaxone** 250 mg i.m. \times 1 + **doxycycline** 100 mg orally twice a day for 14 days
 3. **Cefoxitin** 2 g i.m. + probenecid 1 g orally once + **doxycycline** 100 mg orally twice a day for 14 days
 4. **Ceftizoxime** or cefotaxime i.m. once + **doxycycline** 100 mg orally twice a day for 14 days
- Note:** Amoxicillin/clavulanate plus doxycycline may also be effective. There are no data on oral cephalosporins nor azithromycin (instead of doxycycline) in the treatment of PID.
- H. IUD-associated PID.** The need to remove an IUD has not been proven, but clinical response seems to be faster with removal. It is recommended for mild IUD-associated PID that oral antibiotics are started before removal to reduce the likelihood of bacteremia upon instrumentation. IUDs are also associated with *Actinomyces israelii* colonization and infection (see below).
- V. Follow-up.** All patients with PID whether given i.v. or oral therapy should have a **follow-up examination in 2 to 3 days**. **Male partners** who have had sexual contact with the PID patient in the preceding 60 days should be **seen and treated** empirically for both *C. trachomatis* and *N. gonorrhoeae*.
- VI. PID sequelae:**
- A.** Disease recurrence (approximately 43%).
 - B.** Chronic pelvic pain (approximately 24%) [250].
 - C.** Infertility (20%–40% in some series of PID patients).

- D. Ectopic pregnancy (2.5%–10%) [251].
- E. PID is also associated with premature rupture of membranes, preterm delivery, and amnionitis [252].

VII. Prevention. Strategies revolve around aggressive screening for chlamydial infection [253].

VIII. Tubo-ovarian abscess

A. Epidemiology. Tubo-ovarian abscess is a major complication of PID and occurs in up to one-third of hospitalized PID patients. The microbiology is generally the same as for PID.

B. Clinical presentation. Like PID, symptoms are insensitive and nonspecific. In a large review 89% of tubo-ovarian abscess patients had abdominal pain, 50% a history of fever/chills, 28% vaginal discharge, 26% nausea, and 21% abnormal vaginal bleeding. Fever may be present in only 60% and leukocytosis in only 70% [254].

C. Diagnosis requires demonstration of an inflammatory mass on imaging (usually ultrasound or computed tomography [CT]).

D. Management

1. Antibiotics. Approximately 75% to 80% of tubo-ovarian abscesses respond to antibiotic therapy alone, especially when small (<7 cm) [255].

- a. The i.v. clindamycin + gentamicin regimen detailed above for PID has commonly been used.
- b. In retrospective reviews, many patients receive 7 to 10 days of i.v. antibiotics before switching to oral therapy. Oral clindamycin or metronidazole is often added to the oral doxycycline to complete the 14-day PID treatment course.

2. Surgery is required for tubo-ovarian abscesses that rupture (approximately 3%).

3. Surgery is usually performed for

- a. Poor response despite i.v. antibiotics
- b. In the setting of an enlarging abscess
- c. With bilateral tubo-ovarian abscess
- d. In cases of chronic pain

4. Unilateral adnexectomy, often under laparoscopy, with continued antibiotics is accepted treatment (vs. total abdominal hysterectomy/bilateral salpingo-oophorectomy)[256]. Percutaneous and endovaginal ultrasound-guided **drainage** are also used.

IX. Actinomycotic salpingitis [257]

A. *Actinomyces israelii* is an anaerobic, gram-positive, branching, non-acid-fast rod.

B. Colonization of the lower genital tract occurs most often in the setting of IUDs (especially in long-time users) and colonization **portends an increased risk of PID.**

1. Colonization is usually diagnosed by Pap smears showing characteristic “sulfur granules.”

2. Colonization management. Patients either can be followed expectantly with repeat Pap smears or treated for 10 to 14 days with oral penicillin. Rarely does the IUD need to be removed for colonization [257].

C. Infection ensues in a small percentage of colonized women.

- 1. Clinical presentation** may be irregular vaginal bleeding or mild pelvic discomfort.
- 2. Pathology** can reveal significant destruction, fibrosis, and stricturing of pelvic/retroperitoneal structures.
- 3. Management.** If there is a concern of active actinomycotic endometritis/salpingitis in an IUD user, the patient should receive i.v. penicillin (plus the i.v. therapy for PID), the IUD should be removed, and surgery may be required.
- 4. Note:** The tetracyclines, erythromycin, and clindamycin are also effective against *Actinomyces*.

X. Genital tract tuberculosis

A. Most common in developing countries.

B. Usually results from **hematogenous spread** from pulmonary infection, rarely from contiguous intraperitoneal disease or direct sexual inoculation.

- C. **Clinically**, an indolent infection. Chief presentation is infertility and also vaginal bleeding or chronic pelvic pain.
- D. **Diagnosis:** Hysterosalpingogram may show characteristic changes; however, endometrial or fallopian tube histology, which demonstrates granulomas, positive acid-fast stains, or positive culture of endometrial aspirates, is required.
- E. **Therapy.** Antibiotics (see Chapter 27) and surgery (often TAH/BSO) if symptoms persist.

INFECTIONS AFTER GYNECOLOGIC SURGERY OR PROCEDURES

It is helpful to realize that animal models of intraabdominal infection reveal an early and late-onset clinical pattern with **early** infection marked by **gram-negative** peritonitis with **sepsis** and **late** infection marked by **abscess** formation caused by **anaerobes**.

- I. **Risk factors** for postgynecologic surgical infections
 - A. Hysterectomy, especially vaginal
 - B. Lower socioeconomic status
 - C. Duration of surgery
 - D. BV at the time of surgery
 - E. Increased age
- II. **Pelvic cellulitis** is the most common infection after hysterectomy.
 - A. **Clinical presentation.** Fever and abdominal and pelvic pain (usually more severe on one side), typically on postoperative days 2 to 3, with parametrial tenderness on bimanual examination.
 - B. **Diagnosis** is clinical. The value of obtaining cultures is controversial.
 - C. **Therapy:** cefotetan, cefoxitin, ampicillin/sulbactam, ticarcillin/clavulanate. An alternate regimen is clindamycin plus gentamicin. Intravenous therapy is typically continued until the patient is afebrile for 24 to 36 hours and then stopped.
- III. **Pelvic abscess.** This occurs rarely but is the most serious postoperative complication.
 - A. **Epidemiology.** Risk is greatest after hysterectomy, particularly vaginal hysterectomy. There need not be preceding pelvic cellulitis. It is most common in premenopausal women.
 - B. **Clinical presentation:** May present weeks after surgery (average 18 to 20 days) with high fever (usually late in the afternoon), leukocytosis, elevated erythrocyte sedimentation rate, and often a palpable mass high in the pelvis.
 - C. **Diagnosis.** Ultrasound or CT to confirm presence of the mass/loculations/relationship to bowel.
 - D. **Microbiology.** Abscess pus and abscess tissue should be inoculated into anaerobic transport vials for culture. Such anaerobic cultures will be adequate for aerobes, fungi, and mycobacteria as well.
 - E. **Therapy**
 - 1. **Antibiotic therapy alone is often successful.**
 - 2. Surgery should be considered because of the high mortality of abscess rupture.
 - 3. *Bacteroides fragilis* is most frequently isolated; thus, anaerobic coverage with **i.v. clindamycin or metronidazole** is recommended. Failure to respond to antibiotics usually attests to the need for surgical **drainage** and not antibiotic resistance.
 - 4. **Drainage** can be performed percutaneously or via colpotomy or laparotomy. There are numerous reports of ultrasound-guided drainage procedures. The abscess should be completely evacuated and a pigtail or equivalent catheter left in place until drainage ceases, usually 4 to 8 days.
 - 5. **Duration.** Intravenous antibiotics should be administered until temperature, white blood cell count, and symptoms normalize. Some clinicians treat these patients for 7 days after discharge with oral **amoxicillin/clavulanate** or **metronidazole**.
 - 6. **Follow-up.** Patients are often reexamined at 2 weeks.
- IV. **Vaginal cuff cellulitis.** Inflammation at the vaginal cuff incision is normal after hysterectomy, but frank infection at this site is relatively rare.

- A. Clinical presentation:** Usually presents after discharge from the hospital with lower abdominal/pelvic pain, increased vaginal discharge, and low-grade fever. On bimanual examination only the superior vaginal surgical area is tender.
- B. Therapy.** Oral therapy such as amoxicillin/clavulanate is usually effective within 72 hours.
- V. Vaginal cuff abscess**
- A. Clinical presentation.** Cuff abscess generally presents acutely on postoperative days 2 to 3 with fullness in the lower abdomen, often pain with defecation, and a well-localized collection above the vaginal cuff.
- B. Management.** Therapy requires surgical drainage, which can usually be accomplished through the vagina, and i.v. antibiotics (e.g., clindamycin + gentamicin) until the patient is afebrile for 24 to 36 hours.
- VI. Osteomyelitis pubis.** A rare infection that usually results from contiguous extension after urethral suspension, radical vulvectomy, pelvic exenteration, or, rarely, hematogenous seeding.
- A. Clinical presentation.** Patients usually present approximately 8 weeks after the operation with pubic bone pain, avoidance of ambulation, and pain on abduction. Wound drainage, low fever, and elevated erythrocyte sedimentation rate and alkaline phosphatase may be present.
- B. Diagnosis.** Plain films, bone scans, CT, or magnetic resonance imaging can confirm the presence of osteomyelitis.
- C. Therapy.** Intravenous coverage for both *S. aureus* and gram-negative rods should be started **after** surgical debridement is performed. Coverage can then be narrowed based on operative cultures. Duration of therapy is 6 weeks.

MATERNAL INFECTIONS AFTER DELIVERY

- I. Postpartum fever.** Fever (oral temperature $>38.0^{\circ}\text{C}$) in the first 24 hours after delivery is common but usually due to breast engorgement, atelectasis, aspiration pneumonia (particularly after cesarean section), or urinary tract infection. In the setting of vaginal delivery, only approximately 20% of fevers **on** postdelivery day 1 are due to pelvic infection; in the setting of cesarean section, the percentage rises to approximately 70%. Fever **after** postdelivery day 1 is then generally due to pelvic infection. Such infections are an important cause of maternal death, accounting for between 8% and 13% of maternal deaths.
- II. Episiotomy infections**
- A. Epidemiology.** Only 0.1% to 0.3% of episiotomies become infected overall, highest for third- or fourth-degree tears (1%–2%).
- B. Risk factors:** Cigarette smoking, coagulation disorders, HPV infection.
- C. Classification**
1. Simple episiotomy infection
 2. Infection of the superficial fascia without necrosis
 3. Infection of the superficial fascia with necrosis
 4. Myonecrosis, most commonly caused by *Clostridium perfringens*
- D. Clinically presents** as a wound with red swollen edges, often with dysuria.
- E. Management** includes opening and exploration of the wound with adjunctive antibiotics for the usual vaginal flora.
- III. Postcesarean section wound infections**
- A. Epidemiology.** Incidence averages approximately 6%, with prophylactic antibiotics 2%.
- B. Risk factors:** obesity, diabetes mellitus, corticosteroid therapy, immunosuppression, or hematoma formation.
- C. Clinical presentation.** Fever on about postoperative day 4, often preceded by endometritis. Erythema and drainage are found on examination.
- D. Diagnosis.** Wound cultures are almost always positive, and the organisms are usually the same as those that cause endometritis. Hospital-acquired gram-negative pathogens may be considered, however.
- E. Therapy.** Surgical drainage and antibiotics; if fascia not intact (i.e., wound dehiscence), secondary closure.

IV. Postpartum endometritis. “Postpartum endometritis” technically involves not only the endometrium but also the myometrium and parametrium.

A. Risk factors [258]

1. Cesarean delivery
2. Poor socioeconomic status
3. Prolonged rupture of membranes
4. Prolonged labor
5. Multiple cervical examination
6. Internal fetal monitoring
7. Midforceps delivery
8. Vaginal colonization with certain organisms (group B streptococcus, *C. trachomatis*, *M. hominis*, *G. vaginalis*, *U. urealyticum*)
9. Chorioamnionitis

B. Clinical presentation. Any postpartum fever should be evaluated for endometritis. Classically entails fever on postpartum days 1 to 2 (temperature $>38\text{--}39^\circ\text{C}$), chills (may suggest bacteremia), abdominal pain, fundal tenderness, parametrial tenderness, foul-smelling lochia, and leukocytosis.

C. Microbiology. Typically multiple organisms of the normal vaginal flora are isolated from the endometrium (approximately 2.5 on average), including

1. Anaerobes: *Peptostreptococcus*, *Peptococcus*, *Bacteroides*, *Clostridium*.
2. Aerobes: *Enterococcus*, group B streptococcus, *E. coli*.
3. *Gardnerella vaginalis*.
4. *M. hominis*.
5. *U. urealyticum*.

6. **Note:** The utility of endometrial cultures in routine cases is controversial, because results will not likely affect antibiotic choice.

7. An estimated 10% to 20% will have documentable bacteremia, often with group B streptococcus or *G. vaginalis*. Bacteremia does not predict the severity of illness.

D. Special pathogens to consider

1. *C. trachomatis*: implicated as a cause of late-onset (2–6 days postpartum), indolent, postpartum endometritis.
2. Group A streptococcus causes severe presentation with high fever, erythroderma, desquamation, and sepsis (“toxic shock”) and carries a more than 55% mortality. Organisms are often associated with transmission from a caregiver, and the CDC recommends screening caregivers. Consider i.v. immunoglobulin.

E. Therapy. An antimicrobial regimen effective for all putative pathogens is impractical, but empirical therapy against a broad range of anaerobes and aerobes tends to be effective.

1. **After vaginal delivery:** i.v. clindamycin + gentamicin is effective in 95%.
2. If fever persists at 48 to 72 hours, most add ampicillin as enterococcus has been implicated in this setting.
3. **After cesarean section:** Many include ampicillin along with clindamycin and gentamicin.
4. β -Lactams have less of a track record, but extended-spectrum penicillins with β -lactamase inhibitors such as ampicillin/sulbactam or piperacillin/tazobactam could be considered.

F. Duration of therapy. Typically antibiotics are stopped after the patient is afebrile for 24 hours. Improvement should follow in 48 to 72 hours in 90%. Bacterial resistance and drug fever are extremely rare in this population, and persistence of fever after 72 hours should prompt a search for complications such as parametrial phlegmons, incisional or pelvic abscesses, infected hematomas, and septic pelvic thrombophlebitis.

G. Prevention. Prophylactic antibiotics decrease the postcesarean endometritis rate.

1. For routine cesarean section: cefazolin 1 g for one dose after cord-clamp
2. For cesarean section plus chorioamnionitis: clindamycin plus gentamicin (every 8 hours for three doses postoperatively)

V. Phlegmon is an extensive induration of the parametrium within the leaves of the broad ligament.

- A. Presentation.** Should be considered when fever persists after 72 hours despite standard antibiotic therapy. Usually unilateral, may stay limited to the base of the broad ligament or extend laterally or posteriorly.
- B. Therapy** is with i.v. antibiotics; fever may persist for more than 7 days; surgery is reserved for women in whom uterine incisional necrosis is suspected. Surgery usually requires hysterectomy and debridement is difficult.

VI. Necrotizing fasciitis

- A. Epidemiology.** Extremely rare but may complicate episiotomy incisions and perineal lacerations
- B. Risk factors:** diabetes mellitus, obesity, hypertension
- C. Clinically.** Symptoms usually begin at 3 to 5 days.
- D. Diagnosis.** Histopathology consistently reveals panniculitis and can help confirm the diagnosis [259].
- E. Microbiology:** polymicrobial with streptococci, coliforms, and anaerobes or monomicrobial with group A streptococci.
- F. Therapy.** Prompt wide debridement in the operating room and antibiotics, usually clindamycin plus a β -lactam. High mortality (approximately 100% without surgical treatment, 50% with aggressive excision), particularly in obstetric/gynecologic patients [260].

INTRAPARTUM INFECTIONS

- I. Chorioamnionitis**, also known as **intraamniotic infection syndrome**, is an ascending infection of the uterus and its contents (placenta, amniotic membranes, umbilical cord) during pregnancy. It occurs in 1% to 2% of women with full-term pregnancies but increases to over 25% with the following **risk factors**.

A. Risk factors

1. Prolonged rupture of membranes
2. Prolonged labor with multiple vaginal examinations
3. Preterm labor
4. Meconium staining of amniotic fluid
5. Obstetric procedures (cervical cerclage, amniocentesis, cordocentesis)
6. Young age
7. Low socioeconomic class
8. Nulliparity
9. Preexisting BV

- B. Clinically:** maternal fever, tachycardia, uterine tenderness. Occasionally foul or purulent amniotic fluid. Fetal heart rate abnormalities.

- C. Diagnosis:** based largely on clinical findings, especially tachycardia. Amniotic fluid obtained in the setting of intact membranes (e.g., preterm labor unresponsive to tocolytics) that reveals a positive Gram stain, positive leukocyte esterase, or low glucose is suggestive.

- D. Microbiology.** With the rare exception of hematogenous listerial amnionitis, this ascending infection is polymicrobial with organisms similar to other gynecologic infections: anaerobes, streptococci (group B streptococcus, viridans group), *E. coli*, *Gardnerella*, *Mycoplasma*, and so on.

- E. Management** is antibiotic therapy with the understanding that delivery is required for cure. Antibiotics seek to prevent neonatal pneumonia and therefore antibiotics which target group B streptococcus and *E. coli* (such as ampicillin plus gentamicin) are common initial regimens. Antibiotics provide a better cure rate when given immediately upon diagnosis of chorioamnionitis rather than postpartum. With **cesarean delivery**, clindamycin should be added after cord clamping because 20% to 30% of these patients will fail ampicillin plus gentamicin. Cephalosporins and β -lactam/ β -lactamase inhibitor combinations may also be successful.

II. Postabortion infections

Maternal mortality from septic abortion is a huge problem worldwide, annually accounting for over 100,000 deaths [261].

A. Risk factors

1. Increased gestational age

2. Method of termination (intraamniotic injection or hysterotomy higher risk than suction curettage)
 3. Untreated gonorrhea or chlamydial cervicitis, possibly BV
 4. IUDs
- B. Clinical.** Typical symptoms of fever, chills, tachycardia, and lower abdominal/pelvic pain develop within 4 days of the procedure. Exceptions are *S. aureus* or group A streptococcal infections, which typically present within 24 hours. Examination may reveal an enlarged uterus, foul-smelling exudate, and an open or bleeding os (indicating retained products). Septic shock occurs in 5% to 15%, usually in the setting of delayed treatment.
- C. Diagnosis.** A positive pregnancy test will rule in a recent (4–6 week) pregnancy. Gram stains of endometrial smears may be useful in fulminant cases, if gram-positive cocci, suggestive of staphylococcus or streptococci, or Gram-positive rods, suggestive of *Clostridium*, are present. Cultures should be performed. Abdominal plain films are used to exclude intraperitoneal air or (rarely) gas in the myometrium. Massive hemolysis is a clue to infection with *C. perfringens*.
- D. Microbiology.** As with PID, usually a polymicrobial infection consisting of lower genital tract flora +/- gonococci or chlamydia [261].
- E. Management:** Except for rare instances, patients should be admitted for
1. **Intravenous antibiotics**
 - a. In mild to moderate infection, therapy with cefoxitin, cefotetan, or ampicillin/sulbactam can be adequate.
 - b. In severe infection with septic shock, clindamycin or metronidazole + gentamicin + ampicillin has commonly been used. Depending on local methicillin-resistant *S. aureus* (MRSA) rates, vancomycin may be substituted for ampicillin. A third-generation cephalosporin + metronidazole or imipenem alone are other options. Penicillin has the largest track record for known clostridial infection.
 2. **Evacuation of the uterus.** Evacuation should ideally be performed by suction curettage after adequate serum levels of antibiotics are obtained. Laparotomy is required with free intraperitoneal air, failure to respond to uterine evacuation, or myometritis and often entails hysterectomy.

SEPTIC PELVIC THROMBOPHLEBITIS

Septic pelvic thrombophlebitis is a complication of postpartum or postoperative infections, occurring in about 0% to 2% of cases. Heparin alone is often not successful for therapy, and bacteria can be demonstrated in resected thrombi. Septic pulmonary emboli complicate up to 30% of untreated cases.

- I. **Postpartum septic pelvic thrombophlebitis** can be due to superficial, deep pelvic, or ovarian vein thrombophlebitis, but **ovarian vein thrombophlebitis** is the “classic” obstetric infection. It occurs in 1 in 2,000 deliveries, most commonly in the setting of postcesarean endometritis.
 - A. **Clinically.** Patients can be well or ill appearing with fever, tachycardia, and lower abdominal pain. Patients classically have a “ropelike” abdominal mass on examination.
 - B. **Diagnosis.** Doppler ultrasonography, CT, or magnetic resonance imaging can make the diagnosis, visualizing clot extending to one or both ovarian vein plexi or the inferior vena cava (occurs in one-fourth). Blood cultures are usually negative.
 - C. **Therapy** consists of antibiotics against the common pelvic pathogens (third-generation cephalosporin plus clindamycin or metronidazole; clindamycin plus gentamicin) and, historically, heparin anticoagulation. A recent large study, however, showed no benefit in women treated with heparin plus antibiotics over antibiotics alone [262]. Most clinicians use a course of 7 to 10 days of both antibiotics with or without heparin.
 - D. **Surgery** is reserved for persistent fever or persistent pulmonary emboli to remove the associated infected area.
- II. **Postoperative septic pelvic thrombophlebitis**
 - A. **Clinical.** Generally develops 4 to 8 days after gynecologic surgery, almost always with an operative site infection. The typical presentation is when the patient with

an operative infection improves clinically on antibiotic therapy but fever persists (“**enigmatic fever**”). Physical findings are minimal.

- B. Diagnosis.** Blood cultures are positive in 35%. The diagnosis is supported by deferescence after anticoagulation with heparin.

MATERNAL INFECTIONS DURING PREGNANCY

Though pregnancy is often considered a semi-immunosuppressed state due to maternal tolerance to the allogeneic fetal “graft,” significant changes in maternal immunoglobulin, cell-mediated immunity, and polymorphonuclear cell function are difficult to demonstrate. Nonetheless, certain viral, bacterial, and protozoal infections are particularly severe in pregnancy and bear mentioning.

I. Varicella-zoster virus

A. Clinical. Varicella infection is severe in adults and probably even more severe in pregnancy. Approximately 10% of varicella-zoster virus–infected pregnant women develop **pneumonitis**.

B. Prevention. Varicella-zoster immune globulin can prevent or attenuate infection in nonimmune individuals upon exposure to varicella-zoster virus if administered within 96 hours. Most individuals (90%) who report never having had chickenpox are seropositive (i.e., immune) upon testing. Many authors recommend varicella-zoster immune globulin administration for all nonimmune pregnant women if exposed to chickenpox. An ideal preventive strategy would be to screen women of childbearing age for a history of varicella and administer the vaccine before pregnancy.

II. Influenza

A. Clinical. Influenza infection is common in pregnancy and **may** be associated with pregnancy complications [263].

B. Prevention. Vaccination against influenza is recommended by the CDC for all pregnant women after the first trimester. There is no evidence of teratogenicity.

III. Parvovirus

A. Epidemiology. Approximately 50% of pregnant women are seropositive (immune) for parvovirus; the remainder are at risk. The virus is associated with outbreaks, during which the attack rate is 20% to 30%, often asymptomatic. In infected pregnant women, the fetal loss rate is approximately 5% to 10%, due to miscarriage or hydrops fetalis. Term infants appear to develop normally [264].

B. Management. For women with positive IgM, ultrasound examination is indicated. If there is hydrops, fetal transfusion is recommended by some.

IV. Rubella

A. Epidemiology. Despite widespread immunization in the United States, 6% to 25% of women are susceptible.

B. Clinically. Maternal rubella infection is asymptomatic in about 25%; in the 75% of symptomatic infections, viremia precedes symptoms (usually a rash) by about 1 week.

C. Management. Given the profound teratogenicity of rubella, preconception vaccination is a priority. The use of immunoglobulin is not recommended for exposure.

V. Cytomegalovirus

A. Epidemiology. Cytomegalovirus is the most common perinatal infection, usually acquired from reactivated (not primary) infection in the mother.

B. Clinically. There is no evidence that pregnancy increases the risk or severity of maternal cytomegalovirus infection.

C. Management. Serologic screening is not recommended by the American College of Obstetrics and Gynecology, there is no effective preventive strategy, and there is no vaccine.

VI. Group B streptococcus

A. Epidemiology. Asymptomatic vaginal carriage of group B streptococcus is common, occurring in 15% to 20% of pregnant women. The organism has been implicated in preterm labor, premature rupture of membranes, chorioamnionitis, postpartum sepsis, and severe fetal/neonatal infections.

B. Management. Guidelines for prevention are published by the American College of Obstetrics and Gynecology, the CDC, and the Association of American Physicians using either a risk-based (treat the high-risk mother intrapartum) or screening-based (treat colonized mothers intrapartum) strategy. Implementation of either protocol diminishes group B streptococcus neonatal sepsis from 1.5 to 0.2 per 1,000.

VII. Listeria

A. Epidemiology. Infection with *L. monocytogenes* is uncommon, with approximately 2,500 infections in the United States annually, but over one-third occur in pregnant women.

B. Clinically. Infection in the pregnant woman may be asymptomatic or a nonspecific febrile illness. Maternal listeremia causes amnionitis/fetal infection, and neonatal mortality approaches 50%.

C. Management. Therapy is with ampicillin.

VIII. Toxoplasmosis

A. Epidemiology. Maternal infection occurs through ingestion of infected raw or undercooked meat, through ingestion of toxoplasma oocysts, and transplacentally. Prior infection confers immunity, so maternal infection must be primary for fetal infection. About one-third of American women have preexisting immunity, and the CDC estimates that 0.1% to 0.5% of pregnancies are complicated by acute toxoplasmosis.

B. Clinical. Maternal infection is usually asymptomatic but can include fatigue, muscle pains, and lymphadenopathy. Maternal infection in the first trimester leads to a severe infection in 10% of infants, whereas infection in the third trimester leads to a milder infection in 60% of infants.

C. Management. The American College of Obstetrics and Gynecology does not recommend routine prenatal screening except with concurrent HIV infection. For the woman with active disease (diagnosed by a rise in IgG titer or PCR), treatment is with pyrimethamine plus sulfadiazine or with spiramycin.

MASTITIS

I. Postpartum mastitis may or may not be infectious. Bacteria enter through fissures and cracks in the nipple and cause infection in the setting of an inflamed breast.

A. Clinical presentation. Typically begins weeks to months after delivery (average 5.5 weeks) with abrupt fever, chills, and breast soreness. Usually a cellulitis is visible, classically V-shaped, extending from the nipple.

B. Diagnosis. Samples of breast milk may be obtained for leukocyte count and culture. Leukocyte count more than 10^6 /mL of milk **plus high bacterial counts** in milk confirms infectious mastitis. If pus can be expressed, it should be cultured and Gram stained. Blood cultures may be obtained if the patient appears systemically ill. The neonate should also be examined for evidence of infection.

C. Microbiology. *S. aureus* is the most common organism. Less common organisms include *S. epidermidis*, β -hemolytic streptococci, enterococci, and *E. coli*.

D. Therapy. Infectious mastitis may resolve with simple emptying of the breast, but antibiotics are recommended to prevent abscesses that otherwise develop in 11% of patients. Most patients are managed with **oral** antistaphylococcal antibiotics such as **dicloxacillin** (250–500 mg orally four times a day) or a first-generation cephalosporin such as **cephalexin** (500 mg orally four times a day). In severe cases or with systemic toxicity, i.v. **oxacillin** or **nafcillin** (1–1.5 g every 4 hours) or **cefazolin** (1 g every 8 hours) can be used. In the penicillin-allergic patient, **erythromycin**, **clarithromycin**, or **clindamycin** is acceptable. Adjunctive measures such as breast emptying (continued nursing is not problematic [265]) and anti-inflammatories are important.

E. Duration of therapy is usually 10 days.

F. Abscess. In the unusual scenario when an abscess develops, nursing should be interrupted. In addition to therapy with parenteral antibiotics, prompt incision and drainage should be performed.

II. Mastitis in the nonlactating breast is uncommon.

A. Breast abscess may rarely occur in premenopausal and postmenopausal women and is often polymicrobial, including anaerobes.

Treatment consists of surgical incision or excision, in conjunction with antimicrobial therapy based on culture results.

- B. Granulomatous mastitis** presents as firm hard masses and may mimic carcinoma. This condition has been attributed to chronic bacterial abscess, tuberculous disease, or fungi but may be idiopathic. **Diagnosis** requires biopsy and culture.

17. INFECTIONS DUE TO FUNGI, *ACTINOMYCES*, AND *NOCARDIA*

Harold M. Henderson and Stanley W. Chapman

An organized approach to fungal infections is outlined in this chapter, which is divided into sections that describe each mycosis. The epidemiologic settings, host status, skin tests, and serologic information associated with the major fungal diseases are listed in Table 17.1 and should assist the reader in narrowing down the diagnostic possibilities in a given patient. The decision to initiate systemic antifungal chemotherapy may be difficult, and infectious disease consultation is strongly recommended to help determine the indications for the potentially toxic antifungal agents and to assist in their administration. Actinomycosis and nocardiosis are caused by organisms that are no longer classified as fungi. They are discussed separately at the end of this chapter.

CANDIDIASIS

***Candida* species are normal inhabitants of mucocutaneous body surfaces** and commonly cause superficial skin disease and vaginitis. Under certain circumstances, they may **cause invasive disease if alterations in host defenses occur**. The incidence of *Candida* infections has increased markedly with the widespread use of antibiotics and immunosuppressive therapy, increased numbers of patients in critical care settings, and infection with human immunodeficiency virus (HIV) [1].

I. Growth and identification characteristics. Many *Candida* species cause infection in humans, including *C. tropicalis*, *C. krusei*, *C. parapsilosis*, and *C. glabrata*, but the most common cause of clinical infection is *C. albicans*. *Candida* species are yeasts and can be cultured easily on blood agar and Sabouraud dextrose agar in 24 to 48 hours. Presumptive identification of *C. albicans* can be made in 2 to 3 hours by a positive germ tube test (i.e., characteristic morphologic change seen on incubation of the yeast colony in serum). Definite species identification requires an additional 2 to 8 days.

II. Epidemiologic and host factors. *Candida* species are found worldwide and are normal commensals of humans.

A. Colonization. *Candida* is commonly cultured from the female genital tract, gastrointestinal (GI) tract, diseased skin, and from the urine of patients with indwelling Foley catheters. Colonization is more prevalent in hospitalized patients than in healthy individuals and is promoted by antibiotics that suppress normal bacterial growth.

B. Host defense. Intact skin, phagocytic cells such as neutrophils and monocytes, and the cell-mediated immune system are all important components of the host's resistance to infection by *Candida* species. **Alterations in host defenses** may lead to a change in the organism's normal commensal status, with subsequent tissue invasion and clinical disease. These alterations may be naturally occurring as in the cases of **diabetes mellitus** and **acquired immunodeficiency syndrome (AIDS)**. More often, **iatrogenic factors** predispose to invasive candidiasis. The use of broad-spectrum antibiotics and corticosteroids, mucosal damage from instrumentation or chemotherapeutic agents, or a breach in the integrity of the skin by intravenous catheters or pressure-monitoring devices increases the risk of invasive disease.

III. Clinical aspects

A. Cutaneous infections. *Candida* commonly causes infection in warm moist areas of the skin such as the axillary, inguinal, and intergluteal regions. Perineal infection with involvement of the perianal area, thighs, scrotum, and penis (balanitis) is common. Diaper rash in infants often is caused by *Candida*, and angular cheilitis at the corners of the mouth may be caused by the organism as well. Each of these conditions is characterized by **erythematous papules or macules that may be confluent and are very pruritic**. Infection tends to be more extensive in the presence of immunosuppression. The diagnosis can be made by wet-mount examination of scrapings from the infected area with 10% to 20% KOH. *Candida* may also cause nail infection in the forms of paronychia or onychomycosis. Persons who frequently immerse their hands in water or wear occlusive gloves are particularly susceptible,

Table 17.1. Summary of Major Fungal Infections

Fungus	Epidemiologic Features	Major Clinical Entities	Host/Setting	Skin Test	Immunologic Test	Value of Immunologic Studies
<i>Candida</i>	Worldwide	Cervical; vaginal Oropharyngeal	Normal; antibiotic use Normal; antibiotic use; steroid inhalers; immunocompromised	Not helpful		
		Gastrointestinal; disseminated; isolated fungemia	Antibiotic use; i.v. catheters; immuno- compromised; diabetes mellitus; extensive burns		Precipitating antibody Agglutinating antibody Antigens PCR	Not helpful (false- positive and false-negative results)
		Endocarditis	Recent cardiac surgery; i.v. catheters; heroin addicts			
<i>Histoplasma</i>	Midwestern and southeastern U.S. ^a Avian feces exposure	Acute pulmonary	Normal	Usually positive in endemic area; can cause false-positive <i>Histoplasma</i> serologic result	Complement fixation	More than 90% positive; some falsely positive
		Chronic cavitory Progressive disseminated	Chronic obstructive pulmonary disease elderly; probably infants	Not useful Not useful	Immunodiffusion M band H band Complement fixation Complement fixation Antigen-EIA	70%–80% positive 10%–20% positive in active infection Majority positive ^b Majority positive Serum 80% positive Urine >90% positive

(Continued)

Table 17.1. (Continued)

Fungus	Epidemiologic Features	Major Clinical Entities	Host/Setting	Skin Test	Immunologic Test	Value of Immunologic Studies
<i>Cryptococcus</i>	Worldwide	Pulmonary	Normal; immuno-compromised	Not useful	Latex agglutination (antigen)	Some positive; false-positive results with rheumatoid factor
<i>Coccidioides</i>	Southwestern U.S.	CNS	Normal; immuno-compromised	95% positive ^e ; can cause false-positive <i>Histoplasma</i> serologic results	Latex agglutination Precipitins	Sensitive and specific
		Acute pneumonitis	Normal		Complement fixation	75% positive; disappears after 4-6 weeks
		Chronic cavity	Normal	Minority positive ^e	Precipitins Complement fixation	>50% positive; develops after 4-12 weeks Usually negative
		Pulmonary nodule	Normal	Not useful ^d	Precipitins Complement fixation	50%-60% positive Usually negative
		Disseminated	Immunocompromised; Filipinos, Mexicans, blacks, pregnant women	Not useful	Precipitins	Minority positive Usually negative
					Complement fixation	80%-95% positive; 75%-95% positive in CSF if meningial infection

<i>Aspergillus</i>	Worldwide	Allergic broncho-pulmonary aspergillosis	Asthma	99% positive; false-positive results occur	Precipitating antibody (precipitins)	70% or more positive; false-positive results occur
		Aspergilloma	Prior pulmonary cavity	Minority positive	Serum IgE	Markedly elevated
		Invasive aspergillosis	Immunocompromised; rare in normal host	Insufficient data	Precipitins	90%–100% positive
<i>Blastomyces</i>	Southeastern and midwestern U.S. soil contact	Acute pneumonitis; chronic (lungs, 75%; skin, bone, genitourinary tract)	Normal	Not available	Precipitins antibody	Not helpful
					Complement fixation	Not helpful
<i>Mucorales</i> (<i>Zygomycetes</i>)	Worldwide	Rhinocerebral; pulmonary	Diabetes in poor control; immunocompromised	Not available	Immunodiffusion	Variable; up to 70%–80% in cases of disseminated disease
		Disseminated	Immunocompromised; extensive burns			
		Gastrointestinal	Young children with malnutrition or colitis			
<i>Sporothrix</i>	Worldwide: soil; sphagnum moss; rose and berry bushes	Cutaneous lymphatic	Normal	Not available	Agglutinating antibody	90% positive
		Pneumonitis	Normal; alcoholics			
		Disseminated	Normal; immunocompromised; alcoholics		Agglutinating antibody	

^a May also occur in many cities in the United States. See text. Cultures necessary for diagnosis.

^b Tissue histopathologic examination or if recent conversion from negative to positive reactivity is shown.

^c Helpful diagnostically.

^d Does not differentiate between active disease and past infection.

i.v., intravenous; PCR, polymerase chain reaction; EIA, enzyme immunoassay; CNS, central nervous system; CSF, cerebrospinal fluid.

and diabetics have a higher incidence of paronychia than does the general population. Therapy with topical agents such as nystatin or miconazole creams are usually very effective for cutaneous infection in the normal host. Onychomycosis and more extensive cutaneous disease in the immunocompromised host requires treatment with an oral azole, such as fluconazole or itraconazole. Itraconazole 200 mg twice daily for 1 week repeated monthly for 3 to 4 months is recommended for onychomycosis [2].

B. Mucosal infections

1. **Oral candidiasis.** Thrush may occasionally occur in normal hosts such as neonates and denture wearers but is **most common in persons with** recent antibiotic treatment, inhaled or systemic steroid use, other immunosuppressive therapy, cancer, and AIDS [3]. The lesions most often appear as raised white plaques on the tongue and other oral mucosal surfaces. Oral candidiasis may also present with an atrophic appearance or as angular cheilitis. The diagnosis may be made by examining scrapings under light microscopy, which reveals masses of yeasts and pseudohyphae.

2. **Esophageal candidiasis.** Esophagitis generally **occurs in immunocompromised patients**, particularly patients with hematologic malignancy or AIDS. **Dysphagia and retrosternal pain with swallowing** are the most common symptoms. Oral candidiasis is often but not always present. Many clinicians initiate empiric therapy for esophageal candidiasis in high-risk patients who have typical symptoms in the presence of thrush [4]. Definitive diagnosis requires endoscopy.

3. **Nonesophageal involvement of the GI tract** by *Candida* is diagnosed most commonly in cancer patients [5]. The stomach is the organ most often involved. *Candida* may cause significant gastritis, invade ulcer beds, and cause superficial ulcerations in the small and large intestine. Disseminated candidiasis frequently is present in these settings.

4. **Vulvovaginal candidiasis** (see Chapter 16).

5. Therapy

a. **Oral candidiasis** may be treated initially with either **nystatin** oral suspension 5 mL four times a day or **clotrimazole** troches four times a day for 7 to 10 days. Oral azoles are also effective; fluconazole 100 mg daily for 7 to 14 days was more effective than topical therapy in some studies. Oropharyngeal candidiasis that does not respond to fluconazole may be treated with itraconazole solution 200 mg/day [4,6].

b. **Esophagitis.** Systemic therapy is required for esophageal candidiasis. Fluconazole 100 to 200 mg/day is highly effective and is a reasonable first choice. Esophageal disease refractory to fluconazole can be treated with itraconazole oral solution 200 mg/day or amphotericin B intravenously (i.v.) [4,6,7].

Recurrence of oral and/or esophageal candidiasis is common in immunosuppressed hosts, particularly patients with HIV infection. Chronic suppressive therapy with fluconazole is effective at preventing recurrences but unfortunately is associated with the emergence of resistance [8,9]. It is therefore recommended that suppressive therapy is used only in the setting of very frequent severe recurrences [4] (see Chapter 18).

C. **Chronic mucocutaneous candidiasis.** This group of disorders is typified by persistent and recurrent *Candida* infections of the skin, nails, and mucous membranes [10]. Chronic mucocutaneous candidiasis may occur in young children or adults and is associated with large disfiguring cutaneous lesions. Disseminated candidiasis usually is not seen, but other infections with bacteria or dermatophytes may occur. Endocrinopathies, such as Addison disease, hypothyroidism, or hypoparathyroidism, are present in some patients. Various immune defects have been documented in patients with chronic mucocutaneous candidiasis, but the most consistent finding is that of abnormal T-lymphocyte function, as shown by anergy to delayed hypersensitivity testing. Treatment of chronic mucocutaneous candidiasis centers around therapy for the individual *Candida* infections. The **oral azoles** are the drugs of choice, and chronic suppressive therapy for many years has proven safe and successful.

D. **Disseminated candidiasis.** Once a rare disease, **disseminated candidiasis has become a very important nosocomial infection** because of the increased

numbers of susceptible hosts. *Candida* species are now the fourth most common cause of bloodstream infections in hospitalized patients in the United States [11]. The clinical spectrum ranges from widespread involvement of multiple organs in a severely ill patient to isolated candidemia in a minimally symptomatic patient. Most cases are caused by *C. albicans*, but disseminated candidiasis caused by non-*albicans* species is becoming more common [12].

1. **Risk factors.** Several risk factors have been identified in patients with disseminated candidiasis: recent **abdominal surgery, neutropenia, broad-spectrum antibiotics, indwelling intravenous catheters, peripheral alimentation, cancer chemotherapy, immunosuppressive therapy in transplant recipients, and colonization with *Candida* species** [12–14]. In addition, recent evidence suggests the acquisition of candidal infection from hospital environmental sources [15,16]. Multiple risk factors are often present simultaneously in an individual patient.
2. **Manifestations.** Dissemination may present as **fever of unclear etiology or as the sepsis syndrome** with chills, spiking fevers, hypotension, and prostration. Multiple organs are usually involved with the formation of diffuse microabscesses. **Dissemination to brain, lungs, liver, and spleen** reflects a major and often preterminal breakdown in host defense. Spread to any organ may occur in this setting, but **infections of the eye and skin** are particularly important, because they may provide important diagnostic clues.
 - a. **Macronodular skin lesions** represent embolic foci but are seen in only some patients. They are 0.5 to 1.0 cm in diameter, pink or red, and single or multiple and generalized. **Punch biopsy** may reveal the fungi on histopathologic study and culture. *Candida* may also produce lesions that resemble ecthyma gangrenosum or purpura fulminans.
 - b. **Endophthalmitis** [17] occurs in approximately 20% to 50% or more of disseminated candidiasis patients and correlates closely with multiple visceral organ involvement. Endophthalmitis may cause blurry vision, scotomas, or ocular pain, but extensive disease may be present without symptoms. Endophthalmitis is a clinical diagnosis made in the proper setting and at times requires **serial funduscopic examinations**, which reveal white, cotton-like, circumscribed exudates with filamentous borders in the chorioretina extending into the vitreous. A **good ophthalmologic examination is an important part of the evaluation** of a patient with risk factors for disseminated disease.
3. **Diagnosis is problematic.** The definitive diagnosis of disseminated candidiasis can be made only by histopathologic demonstration of the organism invading tissue or by the isolation of *Candida* species from normally sterile body sites such as blood. Positive blood cultures are the most common way to make the diagnosis, but unfortunately blood cultures are negative in many patients with disseminated infection, and the rate of premortem diagnosis is only 10% to 40%. Thus, a **presumptive clinical diagnosis based on the presence of typical signs and symptoms in a high-risk patient is often the basis for initiating antifungal therapy**, because time is of the essence if the underlying disease is severe. The most important diagnostic technique in a high-risk patient is a thorough daily physical examination.
 - a. **Serologic tests** to detect *Candida* antibodies or antigens such as arabinolase or enolase as an aide to diagnosis have been reviewed extensively elsewhere [18,19]. Current serologic tests lack sensitivity for the diagnosis of invasive candidiasis and cannot reliably differentiate colonization and invasive disease. As noted by Edwards [1], the decision to initiate antifungal therapy in a patient with suspected disseminated candidiasis should not be made on the basis of serologic test results alone, but in the context of a **comprehensive evaluation of a high-risk patient**. Because of their limitations, serologic tests have not become widely used in clinical practice as of this writing.
 - b. **Colonization often precedes dissemination.** Positive cultures of urine, sputum, or stool are common in patients with disseminated disease. Isolation of *Candida* species from these specimens has some predictive value but

is not diagnostic. Only a small proportion of patients who are colonized by *C. albicans* develop invasive disease due to this organism [20]. The **isolation of *C. tropicalis* from an immunocompromised patient, however, has been shown to be more predictive of disseminated disease** [21].

- c. Polymerase chain reaction** assays using universal fungal primers, multi-copy gene targets, and species specific probes are currently being developed for the early diagnosis of invasive fungal infections, including candidiasis. The sensitivity, specificity, and predictive value of these polymerase chain reaction-based assays need to be established in prospective clinical trials and correlated with clinical outcome [21a].
- 4. Therapy.** Systemic candidal infection must be treated with systemic antifungal chemotherapy. The most effective currently available systemic antifungal agents for the treatment of invasive candidal infections are amphotericin and fluconazole. The choice of therapy is dependent on the clinical status of the patient and knowledge of the particular infecting *Candida* species.
- a. Amphotericin B** (0.5–0.7 mg/kg/day) has broad activity against various *Candida* species and has traditionally been the drug of choice in treating patients with disseminated disease, but recent comparative studies have shown that therapy with **fluconazole** provides comparable efficacy with less toxicity [22–24]. Most experts now recommend **initiating treatment with fluconazole 400 to 800 mg/day** in patients infected with an unknown *Candida* species who are clinically stable and have not recently been treated with azoles [4,25]. Because of concern for the presence of azole-resistant *Candida* species, **amphotericin B is recommended for patients recently treated with fluconazole** [25]. For patients who are clinically unstable (hypotension, rapidly worsening condition, multiorgan failure), high-dose amphotericin B 0.7 to 1.5 mg/kg/day is recommended as initial therapy.
- Disseminated infection with *C. albicans*, *C. parapsilosis*, or *C. tropicalis* may be treated with either fluconazole or amphotericin B at usual doses, because these species are generally broadly susceptible to both azoles and amphotericin in most clinical settings. ***C. krusei* strains are resistant to fluconazole** and should be treated with amphotericin B. Most experts also recommend amphotericin B as treatment for infections due to *C. glabrata*, although high-dose fluconazole (800 mg/day) has been suggested [4]. **Many strains of *C. lusitanae* are resistant to amphotericin B**, and fluconazole 400 to 800 mg daily is recommended as therapy for infections with this species. Infectious disease consultation is advised.
- b. Lipid-based preparations of amphotericin B** may be used in patients who are intolerant or refractory to amphotericin B deoxycholate or are at high risk for nephrotoxicity due to amphotericin B. Three lipid formulations are currently available: amphotericin B lipid complex (ABLc, Abelcet), amphotericin B colloidal dispersion (ABCD, Amphotec), and liposomal amphotericin B (L-AMB, Ambisome). Doses of 3 to 5 mg/kg/day are recommended [26]. For further discussion of amphotericin lipid formulations, see section II under Antifungal Chemotherapy later in this chapter.
- c. Flucytosine.** Flucytosine may be used for selected patients in combination with amphotericin B or fluconazole for its synergistic effect against *Candida* species. Candidates for dual therapy include those patients with endocarditis, meningitis, and endophthalmitis. Patients whose blood cultures remain positive after therapy with amphotericin or fluconazole is started may also be candidates for combination therapy. Bone marrow suppression may be a complication of flucytosine therapy. The recommended flucytosine dose is 25 mg/kg every 6 hours, but this should be adjusted in the presence of renal insufficiency [25].
- d. New therapeutic options are on the horizon** for the treatment of invasive candidiasis.
- (1) **Caspofungin (Cancidas)** is the first commercially available echinocandin. This new class of antifungal agents interferes with fungal cell wall synthesis and, as the case with caspofungin, is fungicidal against *Candida*

species [27,28]. The results of initial clinical trials using caspofungin for the treatment of candidal infections appear to be promising. See section V under Antifungal Chemotherapy later in this chapter.

- (2) **Voriconazole** is a new triazole recently approved. Voriconazole has excellent *in vitro* activity against *Candida* species and has proven efficacious in several animal models of candidal infection [29]. Large-scale clinical trials are currently ongoing to study the effectiveness of voriconazole in the treatment of invasive candidiasis in neutropenic and non-neutropenic patients. See section IV.E. under Antifungal Chemotherapy later in this chapter for further discussion.
 - e. The presence of intravascular catheters is a risk factor for the development of disseminated candidiasis, and data indicate that **all intravenous lines should be changed** as soon as candidemia is detected, if possible [30].
 - f. The recommended duration of therapy is 2 weeks after the last positive blood culture for *Candida* and resolution of signs and symptoms of disseminated infection [4].
 - (1) **Isolated catheter-related candidemia.** Candidemia frequently occurs in patients with indwelling catheters but in whom signs of disseminated disease are minimal or absent. Several reports have documented late complications of disseminated candidiasis in such patients who did not receive antifungal chemotherapy, particularly immunocompromised patients but also normal hosts. Most authorities recommend **removal of the catheter and a course of antifungal chemotherapy** in patients in this setting [25,30]. The principles of therapy are as outlined for disseminated candidiasis (see section D.4).
- E. Empiric therapy for suspected disseminated candidiasis** is considered most commonly in two situations:
1. **Neutropenic patients**, after chemotherapy, with persisting fever despite treatment with antibiotics. The approach to these patients is discussed in section LH under Antifungal Chemotherapy, below.
 2. **Critically ill intensive care unit patients.** In febrile patients who lack an obvious focal infection and have risk factors for disseminated candidiasis (e.g., broad-spectrum antibiotics, hyperalimentation, surgery, *Candida* colonization of multiple sites), empiric antifungal therapy with fluconazole or amphotericin B may be warranted.
- F. Specific deep organ infections**
1. **Hepatosplenic candidiasis** is seen typically in patients with acute leukemia and prolonged leukopenia that has resolved [31]. This condition is characterized by widespread microscopic and macroscopic abscesses in the liver, spleen, kidney, and lungs.
 - a. **Manifestations** include persistent fevers, abdominal pain, hepatosplenomegaly, increased alkaline phosphatase levels, and leukocytosis.
 - b. **Diagnosis.** Computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography reveal multiple hepatosplenic (and occasionally renal) filling defects and/or abscesses. **CT is the most specific diagnostic tool.** The lesions are hypodense, and ring enhancement often is seen. Definitive diagnosis requires biopsy with culture and histopathologic examination or, if possible, aspiration of one or more of these abscesses in an attempt to identify the infecting organism.
 - c. **Treatment requires long-term antifungal therapy.** Fluconazole 400 to 800 mg/day for months is recommended by most experts [4]. Some authorities would initiate therapy with a short course of amphotericin B followed by a prolonged course of fluconazole. Therapy should be continued until radiographic resolution of all lesions has occurred. Infectious disease consultation is advised.
 2. **Candidal endocarditis** is particularly **common in heroin addicts**, in patients with prolonged intravenous catheterization, and after recent cardiac surgery [32]. Most cases are caused by *C. albicans*. Addicts have a predilection for tricuspid involvement (see Chapter 12).

- a. **Manifestations** are similar to those of bacterial endocarditis, except for a propensity toward large valvular vegetations. Many patients suffer **major embolic episodes** with occlusion of medium-size arteries (brain, extremities, lungs, mesentery). Invasion of the myocardium may occur and generally is irreversible.
 - b. **Diagnosis.** Although early diagnosis is crucial in preventing significant morbidity or death, **only 50% of patients have positive blood cultures** (up to 75% are positive in prosthetic valve endocarditis), and fever and leukocytosis may be absent. **Clinical clues strongly suggestive of the diagnosis** include the presence of endophthalmitis, major embolic episodes, or large vegetations demonstrated by echocardiography. Biopsy of skin lesions may be diagnostic.
 - c. **Therapy** combines early surgical intervention with amphotericin B (0.5–0.8 mg/kg/day). Prolonged intravenous therapy and careful follow-up are vital because relapse is common (see also Chapter 12).
 - d. **Prognosis** has been poor, especially in patients treated with medical therapy alone. Successful therapy is being described with increasing frequency, however, due mostly to earlier diagnosis and surgical intervention. With amphotericin B and surgical therapy, 50% of patients may survive.
- 3. Genitourinary infection. Candiduria is common in hospitalized patients, especially in an intensive care setting. Risk factors include diabetes, broad-spectrum antibiotics, indwelling urinary catheters, and immunosuppressive therapy.** The most commonly involved species is *C. albicans*.
- a. **Colonization versus infection.** There are no established criteria that reliably distinguish urinary colonization with *Candida* species from invasive infection, although the absence of pyuria makes invasive infection less likely [33]. Urinary colonization is asymptomatic and usually associated with an indwelling urinary catheter and may not require antifungal therapy. **Invasive disease is more likely in the presence of risk factors** such as neutropenia and immunosuppression and does require antifungal therapy.
 - b. **Manifestations.** Lower tract infection (cystitis) is usually asymptomatic, but symptoms when present include dysuria, hematuria, and frequency. Upper tract infection presents with typical signs and symptoms of bacterial pyelonephritis: fever, elevated white count, and costovertebral angle tenderness. **The presence of granular casts with hyphal elements** on urinalysis indicates involvement of the renal parenchyma. Hematogenous spread is the most common route resulting in renal infection, but urinary obstruction may on occasion lead to upper tract candidiasis via ascending infection.
 - c. **Therapy. Asymptomatic candiduria does not generally require antifungal therapy** [4,25]. Most patients with asymptomatic candiduria do not have invasive disease, and antifungal therapy does not necessarily result in long-term eradication of *Candida* species. **Catheter removal alone** resulted in eradication of candiduria in 41% of patients in a recent study and can be generally recommended if possible [33,34].
- Symptomatic patients and those with risk factors for invasive disease—renal transplant recipients, neutropenic patients, or patients about to undergo a genitourinary tract procedure—should be treated with antifungal therapy. Fluconazole 200 mg/day** is recommended [4,25]. **Amphotericin B** is an alternative and may be given either i.v. or as a bladder irrigation 50 to 200 $\mu\text{g}/\text{mL}$ for 3 to 5 days [4,35]. Catheters and other urinary tract instruments should be removed if possible. **Persistence of candiduria in an immunocompromised host** despite antifungal therapy should prompt abdominal CT or ultrasound to rule out focal renal abscess or fungus ball.
- 4. Central nervous system (CNS) infection** is usually a complication of disseminated disease in critically ill adults or neonates. Most cases have occurred in the setting of immune suppression, trauma, neurosurgery, and, more recently, AIDS [36,37]. The diagnosis is generally made on the basis of isolation of *Candida* species from cerebrospinal fluid (CSF). Therapy with amphotericin B and

flucytosine is recommended [4]. Shunts, if present, should be removed if possible. The role of fluconazole in therapy of CNS infection is unknown. Infectious disease consultation is advised. See related discussion in Chapter 6.

5. **Pulmonary infection** is usually secondary to hematogenous dissemination and results in fever and cough. Although positive sputum cultures are common in hospitalized patients, this usually represents colonization. Definitive diagnosis relies on biopsy, with demonstration of tissue invasion. Primary *Candida* pneumonia is rare except in the compromised host, and even in this setting it is uncommon [38].
6. **Peritonitis** caused by *Candida* species is generally a complication of peritoneal dialysis or GI surgery [39,40]. Dissemination is uncommon in patients undergoing chronic ambulatory peritoneal dialysis but may occur in association with bowel surgery. All patients with candidal peritonitis should be treated with either amphotericin B or fluconazole, and in chronic ambulatory peritoneal dialysis patients the dialysis catheter should be removed [4]. See additional discussion in Chapter 13.
7. **Musculoskeletal infection** with *Candida* species is another complication of disseminated disease. Arthritis may be acute or chronic and presents in a fashion similar to bacterial arthritis [41]. Bone disease usually involves the vertebral spine in adults or the long bones in children [42]. Diagnosis requires aspiration of the infected area. Treatment of osteomyelitis generally requires initial surgical debridement combined with systemic antifungal therapy. Both amphotericin B and fluconazole have been used successfully, and some experts recommend an initial 2 to 3 weeks of amphotericin B followed by a prolonged course of fluconazole [4]. Joint drainage combined with a lengthy course of systemic antifungal therapy is indicated in the management of candidal arthritis.
8. **Ocular infection** due to hematogenous dissemination of *Candida* was discussed in section **D.2.b**. Exogenous infection after trauma or surgery may also occur. Systemic therapy with fluconazole or amphotericin B with or without flucytosine is indicated [4]. The role of vitrectomy is unclear. Infectious disease and ophthalmologic consultation is recommended.
9. **Septic thrombophlebitis** of the peripheral or great vessels may occur in association with intravenous catheters. Fever, signs of sepsis, and persistent candidemia are characteristic of peripheral thrombophlebitis caused by *Candida* species. If suppuration is found with a peripheral phlebitis, the vein should be excised and antifungal therapy initiated. Septic thrombophlebitis of the great vessels has been treated successfully with amphotericin B [43].

HISTOPLASMOSIS

Histoplasma capsulatum is a dimorphous fungus that causes histoplasmosis, the most common systemic fungal infection in the United States. Inhalation of the infectious spores of *H. capsulatum* usually results in asymptomatic infection. Symptomatic pulmonary disease may occur in the normal host, and the organism may occasionally produce chronic progressive pulmonary infection or disseminated disease in some patients. *H. capsulatum* is an important opportunistic pathogen in the immunocompromised host, especially persons infected with HIV [44].

- I. **Growth and identification characteristics.** *H. capsulatum* can be grown on routine fungal culture media, although growth is augmented on enriched agar such as brain-heart infusion. The mycelial phase requires 10 to 21 days to grow at room temperature and can be identified in the laboratory by characteristic large tuberculate spores. Conversion to the yeast phase at 37°C requires another 7 to 14 days. Biopsied tissue specimens should be stained and cultured; Gomori methenamine silver and periodic acid–Schiff preparations may reveal characteristic small intracellular yeasts. The organism may also be detected by Wright stain of sputum or blood.

II. Epidemiologic features

- A. **Endemic areas.** Although histoplasmosis occurs throughout the world, the disease is endemic in the central United States, particularly in the Ohio and

Mississippi River valleys. In areas of Tennessee and Kentucky, more than 90% of the adult population has been infected with *H. capsulatum*, as manifested by positive skin test reactions. As far east as Maryland and Virginia, 85% of those tested have been exposed.

- B. Sources of infection.** *H. capsulatum* is found in nature in the soil. The organism grows particularly well in soil contaminated with excreta of birds (e.g., starlings, chickens, and blackbirds) and bats. Persons involved in cleaning chicken houses or blackbird roosts and in exploring caves are at risk for heavy exposures, and these conditions provide the setting for epidemic outbreaks [45]. Histoplasmosis may also be seen in urban residents. Foci of *H. capsulatum* spores may be present in open fields, parks, or old buildings, and an outbreak of acute pulmonary histoplasmosis may result if these foci are disturbed by construction or demolition [46,47].

III. Pathogenesis

- A. Agent. Infection occurs via inhalation of airborne spores.** The spores are deposited in pulmonary alveoli, where conversion to the yeast form and phagocytosis by macrophages occur. Infected macrophages spread through lymphatic channels to regional lymph nodes, followed by hematogenous spread to organs of the reticuloendothelial system, liver, spleen, and bone marrow.
- B. In the normal host,** cell-mediated immunity develops within 7 to 21 days of primary exposure [44]. T lymphocytes secrete cytokines that activate macrophages to kill intracellular yeasts, eventually resulting in caseating or noncaseating granulomas at infected sites. This response controls the infection. The granulomas become calcified with time, resulting in the characteristic Gohn complex and splenic calcifications commonly seen on roentgenography.
- C. In some persons, effective cellular immunity never develops.** The infection is not contained, and **disseminated histoplasmosis occurs.** Persons at greatest risk for disseminated disease include the elderly and very young children and immunosuppressed patients, such as those with leukemia or lymphoma, transplant recipients, and patients receiving corticosteroids. **Persons with AIDS are at very high risk for developing disseminated histoplasmosis.**

IV. Clinical presentation, diagnosis, and therapy

A. Acute pulmonary histoplasmosis

1. Manifestations

- a. In the normal host, infection after a mild inhalational exposure is usually subclinical and asymptomatic.** Uncommonly, mild exposure results in symptomatic illness, usually in children or infants. Rarely, pulmonary infection may result in disseminated disease.
- b. Infection after a heavy inhalational exposure** to spores may cause symptomatic disease, referred to as **acute pulmonary histoplasmosis** [45–47].
- (1) **Acute illness in those without prior exposure** often presents with an **influenza-like picture** (chills, fever, malaise, headache, myalgias, nonproductive cough, and chest pain) after an incubation period of 10 to 18 days. Erythema nodosum, erythema multiforme, and migrating polyarthritis have been described in this setting. The **chest x-ray** generally reveals bilateral, patchy, nodular infiltrates with hilar or mediastinal adenopathy. Pleural effusion is uncommon. Symptoms in most patients resolve within 2 to 3 weeks.
- (2) **Acute disease in a previously exposed individual** follows a slightly different pattern. Symptoms are similar but milder in degree and occur after a shorter incubation period (3–7 days). The chest roentgenogram may be different in that nodules are fine and miliary and there is no adenopathy, pleural involvement, or late calcification.

2. Diagnosis

- a. Subclinical infections** are diagnosed retrospectively by skin test conversion or by characteristic x-ray patterns of calcification.
- b. Acute symptomatic pulmonary histoplasmosis** can be diagnosed by culture and examination of sputum in no more than 10% of patients. Additional diagnostic aids include the following:

- (1) **The chest x-ray** may be suggestive, as noted previously.
- (2) **Skin tests** generally are not useful to diagnose acute infection because most individuals in endemic areas will react due to prior exposure.
- (3) **Complement fixation tests** detect antibodies to either yeast or mycelial antigens. If either or both tests are performed, more than 90% of patients with acute disease will have titers of 1:8 or greater, and 70% will have titers of at least 1:32 [48]. Titers of 1:8 to 1:16 are suspect because false-positive results in healthy persons often fall into this range, particularly in endemic regions. False-positive results, generally titers of 1:8 or 1:16, are also seen in 20% to 40% of persons with other fungal or granulomatous diseases. A complement fixation titer of at least 1:32, or a fourfold rise in titer, in conjunction with a compatible clinical syndrome is strongly suggestive of acute pulmonary histoplasmosis.

The **immunodiffusion test** for precipitins to the H and M antigens is more specific than complement fixation but is not very sensitive. Antibodies may be undetectable for more than 3 weeks after exposure, and the immunodiffusion and complement fixation tests often are negative if performed early in the course of infection.

- (4) **Antigen test.** The polysaccharide antigen of *H. capsulatum* may be detected in the urine or serum in up to 20% of patients with acute pulmonary infection [49].

3. Therapy. Most normal hosts have benign self-limited infection and require no therapy. Treatment with itraconazole 200 mg daily for 6 to 12 weeks is recommended for patients whose symptoms persist for more than 2 to 4 weeks [50]. Amphotericin B 0.5 to 0.7 mg/kg/day should be used initially in patients who have respiratory failure and require ventilatory support. Infectious disease consultation is advised.

B. Progressive disseminated histoplasmosis [51,52] is uncommon, occurring in approximately 1 of 2,000 to 5,000 acute infections and generally in an immunocompromised host (e.g., AIDS, transplant recipients). On occasion, it has been reported in an otherwise healthy adult. Disseminated disease may occur soon after an acute exposure or years later, after the patient has left an endemic region and subsequently developed immunosuppression. **Infection with HIV should be excluded in patients with disseminated disease** who have no apparent predisposing condition.

1. Clinical manifestations may vary from very severe illness (usually seen in infants and patients with AIDS) to more chronic disease, extending over months to years [52].

- a. Systemic symptoms** of fever, chills, malaise, anorexia, and weight loss are common. Symptoms that follow an acute inhalational exposure and last more than 3 weeks may indicate systemic involvement.
- b. Hepatosplenomegaly** and abnormal liver tests are common and may be striking in infants.
- c. Mucosal ulcerations** occur in 35% to 40% of patients throughout the GI tract, especially the ileum, causing anorexia, nausea, abdominal pain, diarrhea, frank bleeding, or perforation. **Oropharyngeal, nasal, labial, gingival, and laryngeal ulcers** provide excellent biopsy sites for diagnosis.
- d. The adrenal glands** are frequently infected and adrenal insufficiency can occur early or even years after initial infection. The incidence of clinically significant adrenal insufficiency is unclear.
- e. Chest x-rays** may be normal or show interstitial or nodular infiltrates.
- f. Anemia and leukopenia** are common, especially in patients with severe disease.
- g. Uncommon manifestations** include meningitis, skin lesions (papules, nodules, or ulcers), endocarditis, and lytic bone lesions.
- h. Patients with AIDS and disseminated histoplasmosis** frequently have severe disease and may present with shock, adult respiratory distress syndrome, disseminated intravascular coagulopathy, and CNS involvement [51,52].

2. Diagnosis

- a. **Complement fixation tests** are positive in 50% to 70% of patients but should be interpreted with caution, as previously discussed (see section **A.2.b.(3)**).
- b. **Antigen detection.** *H. capsulatum* polysaccharide antigen may be detected in the blood of more than 50% and in the urine of more than 90% of patients with disseminated histoplasmosis [48]. **Serial antigen measurements are helpful in following treatment response** because the antigen disappears with treatment and reappears with relapse.
- c. **Cultures of bone marrow** are positive in more than 75% of patients with disseminated disease, and **blood cultures** are positive in 40% to 70% of cases [51,52]. The lysis-centrifugation technique improves the yield from blood cultures and is particularly useful in AIDS patients. The organism can be isolated from **sputum and urine** cultures in more than half of the patients.
- d. **Special stains.** Demonstration of organisms by methenamine silver stain from specimens such as bone marrow or sputum provides a diagnosis within 24 to 48 hours in many patients. A Wright stain of the peripheral blood may reveal organisms within leukocytes in patients with severe disease. Biopsy specimens may also be obtained from oral lesions, the liver, and lymph nodes.

3. Therapy. Antifungal therapy is clearly indicated in all cases of progressive disseminated histoplasmosis.

- a. **In the immunocompromised HIV-negative patient** with symptoms severe enough to require hospitalization, amphotericin B 0.7 to 1.0 mg/kg/day is recommended [50,52]. A total dose of 30 to 35 mg/kg should be given to adults. Alternatively, amphotericin may be discontinued when symptoms have resolved and antifungal therapy may be completed with itraconazole, 200 to 400 mg daily for 6 months [52,53]. Itraconazole alone may be used at the indicated dose in patients with mild disease not requiring hospitalization.
 - b. **Patients with AIDS** who have CNS involvement or immediately life-threatening disease should receive an **induction course of amphotericin B**. Induction therapy may be completed with itraconazole 200 mg twice daily for 8 to 12 weeks after resolution of symptoms [50,53,54]. AIDS patients with mild to moderate disease may be treated with **itraconazole** 300 mg twice daily for 3 days and then 200 mg twice daily for 8 to 12 weeks as induction therapy [50,53,54]. To prevent relapse, all AIDS patients should be placed on **maintenance** therapy with itraconazole (200–400 mg/day) indefinitely after resolution of the acute illness [55]. Itraconazole prophylaxis (200 mg daily) to prevent disseminated histoplasmosis may be considered for AIDS patients with CD4 counts less than 100/mm³ who live in an area with a high incidence of histoplasmosis [56,57].
 - c. **In immunocompetent HIV-negative patients**, itraconazole, 200 mg/day for 6 months, is well tolerated and very effective [50,53]. Fluconazole 400 to 800 mg daily and ketoconazole 200 to 400 mg daily are alternatives for patients who do not tolerate itraconazole [50,58]. Patients with severe disease or involvement of the CNS should be treated with amphotericin B. Infectious disease consultation is advised.
- ## 4. Prognosis.
- Without treatment, mortality is approximately 90%. In HIV-negative patients, treatment with amphotericin B decreases the mortality rate to 7% to 15%. The prognosis in AIDS patients is related to the severity of the histoplasmosis on presentation. Most relapses occur within 1 year of treatment.
- ## C. Chronic pulmonary histoplasmosis [59] occurs in the setting of preexisting chronic lung disease. It manifests initially as a lingering segmental interstitial pneumonitis. Approximately 10% to 20% of cases progress to chronic cavitary disease.
1. **Early noncavitary pneumonitis**
 - a. **Manifestations.** Malaise, fever, cough, and pleuritic pain are common, but some patients may be asymptomatic. Chest x-ray shows an interstitial infiltrate occurring typically in the apical-posterior area of the lung. The infiltrate disappears in 2 to 3 months, and the infarct-like necrotic areas become larger, leading to contraction and volume loss.

- b. **Diagnosis.** Sputum cultures are positive in about one-third of cases.
- c. **Therapy.** Early pneumonitis episodes usually are self-limited and generally follow a benign course but may result in the destruction of significant amounts of lung tissue, thereby exacerbating any existing respiratory insufficiency. In some patients, large air spaces, or bullae, become infected, and this progresses to chronic cavitory disease. When patients show evidence of clinical progression and/or progressive pulmonary infiltrates, treatment should be initiated as outlined for cavitory histoplasmosis (see section 2.c).

2. Cavitory infection

- a. **Manifestations.** Cough and sputum production are prominent and are usually accompanied by weight loss, low-grade fever, and easy fatigability. Hemoptysis is common, and in general there is an acceleration of the manifestations of the underlying chronic lung disease. **Chest x-ray** reveals cavitation, usually immediately adjacent to a pneumonic lesion and at the extreme apex. If inflammation subsides, cavitory walls often remain thin, but active infection leads to wall thickening. Continuing infection is probable if wall thickness exceeds 2 mm.

b. Diagnosis

- (1) **Definitive bacteriologic diagnosis** by culture or Wright stain of sputum may be achieved in 35% to 60% of patients, but positive cultures do not necessarily indicate active disease or threat of relapse.
- (2) **The chest x-ray** affords a better index of disease activity than do microbiologic data.
- (3) **Complement fixation tests** are positive in 75% of patients but should be interpreted with caution.
- c. **Therapy.** Many cases, especially those with thin-walled lesions (<2 mm), may regress spontaneously. Such cases can therefore be managed with an initial period of observation. Without treatment, 30% to 40% of thin-walled cavities persist and enlarge, and progressive pulmonary insufficiency results. If cavitation progresses and clinical improvement does not occur, antifungal therapy is indicated [50,53]. Oral therapy with itraconazole (200–400 mg/day) or ketoconazole (400 mg/day) for 6 months or more yields response rates of 65% to 80% [50,53], which compare favorably with results seen with amphotericin B. The indications for surgical resection are not well defined, and underlying lung disease often precludes a surgical approach. Infectious disease consultation is advised.

D. Uncommon manifestations of histoplasmosis

- 1. **Histoplasmosis** may form during the healing phase of a primary lung infection. These asymptomatic lesions may appear as solitary pulmonary nodules (1–4 cm in diameter) that have central calcification. **No antifungal therapy is indicated.**
- 2. **Mediastinal fibrosis** is the term used to describe a very thick (> 1 cm) fibrotic capsule in the mediastinal perihilar region, with actual invasion or compression of adjacent structures [60]. The process tends to be slowly but relentlessly progressive, and no therapeutic approach has proven to be reliably effective.
- 3. **Mediastinal granuloma** refers to large caseous lymph nodes that mat together and become encapsulated after primary infection. These may occasionally result in symptoms due to compression of adjacent structures in the mediastinum [60]. Treatment with amphotericin B 0.7 to 1.0 mg/kg/day or itraconazole 200 to 400 mg daily may be beneficial [50].

CRYPTOCOCCOSIS

Cryptococcus neoformans is a saprophytic fungus that may cause disease in normal hosts as well as in the immunosuppressed. Meningitis and pulmonary infection are the most common manifestations, and *C. neoformans* is a common cause of meningoencephalitis in AIDS patients [61].

- I. **Growth and identification characteristics.** Clinical cryptococcal isolates are encapsulated yeast and often are identifiable on India ink and Wright stain. Visualization in

clinical specimens may yield an early presumptive diagnosis. Standard culture techniques are used. Media used for isolation should not contain cycloheximide because it inhibits growth of the organism. Growth generally occurs in 3 to 7 days, with identification in 3 to 4 days. Occasionally growth is slower, however, and incubation should be continued for 4 to 6 weeks before the culture is discarded as negative.

II. Epidemiologic features and host factors. *C. neoformans* is an ubiquitous fungus that is found worldwide in avian feces, particularly pigeon droppings. It has also been found in soil, certain fruits, contaminated milk, and food products [62]. Disease generally occurs after inhalation of the organism. **Many patients have no demonstrable underlying immune defect.** Patients who are immunocompromised, however, especially those with defective cell-mediated immunity, are prone to more serious infections, with rapid progression and dissemination. **Patients at highest risk for severe disease** include those with AIDS and lymphoma or leukemia, transplant recipients, and those receiving corticosteroids [61,63].

III. Pulmonary involvement [64,65]. The respiratory tract is presumed to be the primary portal of entry of *C. neoformans*. Pulmonary cryptococcosis is probably the **most common form of the disease**, although it is diagnosed less often than meningoencephalitis because it is **usually transient and often subclinical.**

A. Clinical presentation. Pulmonary infection usually results in few sequelae, and **many patients are asymptomatic.** If a patient inhales a large inoculum of organisms or if host defenses are compromised systemically or locally (because of a chronic respiratory disorder), the occurrence of symptomatic pulmonary disease is more likely. Clinically significant illness typically manifests as a subacute process with dull chest pain, cough with scant sputum production, and dyspnea. Low-grade fever and weight loss may occur with illness of longer duration.

B. Diagnosis. The manifestations of cryptococcal infection are nonspecific, and diagnosis depends on a high index of suspicion. **Patients who are immunocompromised are especially at risk.** Because of the lack of a vigorous inflammatory response, the routine indices of infection, such as leukocytosis and sedimentation rate elevations, may be absent.

1. Sputum cultures will isolate the organism in only 10% to 30% of patients with invasive disease. Because saprophytic colonization of the respiratory tract may result in a positive sputum culture, definitive diagnosis often requires open lung or bronchoscopic biopsy and **demonstration of tissue invasion.** Characteristic yeasts are readily seen with methenamine silver, periodic acid–Schiff, or Mayer mucicarmine stains.

2. Chest x-ray findings are variable and may range from solitary nodules in asymptomatic individuals to focal or lobar infiltrates with symptomatic infection. Patients may present with diffuse interstitial infiltrates and the adult respiratory distress syndrome. Cavitation and pleural effusion are uncommon.

3. In all patients suspected or proven to have pulmonary cryptococcosis, the spinal fluid and blood should also be cultured for *C. neoformans*, and the cryptococcal antigen test should be performed on CSF and serum to rule out disseminated disease [61].

C. Therapy. Pulmonary cryptococcosis does not need to be treated in every patient.

1. A 2- to 4-month period of observation without therapy is acceptable in a normal host if the following conditions are met: (a) Extrapulmonary lesions are absent; (b) cultures of blood, CSF, and urine are negative; (c) cryptococcal antigen is negative in the CSF and the serum titer is absent, low, stable, or falling; and (d) pulmonary lesions are small, few, stable, or regressing.

2. Antifungal therapy should be instituted if (a) the radiographic picture worsens, (b) increasing ventilatory impairment is evident, (c) dissemination is evident, or (d) the patient is immunocompromised. **Patients who are immunosuppressed need antifungal therapy because the risk of dissemination is high** [63,64]. Fluconazole 200 to 400 mg daily for 3 to 12 months may be used in immunocompetent hosts with mild to moderate symptoms [65,66]. Amphotericin B 0.5 to 0.7 mg/kg/day is recommended for severe disease in the normal host and in the case of fluconazole treatment failure. In immunosuppressed patients with pulmonary disease, initial therapy with amphotericin B 0.7 to 1.0 mg/kg/day for

2 weeks followed by fluconazole 400 to 800 mg daily for 8 to 10 weeks and then fluconazole 200 mg daily for 6 to 12 months has been suggested [66]. Infectious disease consultation is recommended.

IV. Disseminated disease. Blood-borne cryptococcal yeast may disseminate from the lung to any organ but has a **predilection for the CNS**. Skin and bone involvement may also occur. All patients with disseminated disease require antifungal therapy.

A. CNS. Meningoencephalitis is the most common clinical manifestation of infection with *C. neoformans*. Most persons with cryptococcal CNS infection are immunocompromised. **See related discussion in Chapters 6 and 18.**

1. The clinical manifestations of cryptococcal meningitis are highly variable. Patients may present with acute symptoms of only a few days' duration, particularly if they are very immunosuppressed (e.g., HIV-infected persons). Conversely, others may have subtle symptoms for weeks or months before the diagnosis is made. The most common signs and symptoms include headache, fever, nuchal rigidity (often absent), cranial nerve palsies, impaired memory and judgment, lethargy, obtundation, and coma [67].

2. Diagnosis

a. CSF

(1) Standard tests. Of symptomatic patients, 90% demonstrate some abnormality of the CSF—increased opening pressure, elevated protein, decreased glucose, or a lymphocytic pleocytosis—although on occasion the CSF may be normal. Normal or only slightly abnormal CSF parameters are common in AIDS patients, and greater reliance should be placed on more specific tests [67].

(2) India ink stains. Cryptococcal yeast may be demonstrated on India ink stain in at least 50% of non-AIDS patients with CNS involvement and in more than 70% of AIDS patients. False-positive results may occur, however, if yeasts are confused with artifact or lymphocytes. Organisms may also be seen on Gram stain of the CSF.

(3) Definitive diagnosis generally requires isolation of the organism in culture of the CSF. Centrifuged sediments from large volumes of CSF (4–8 mL) should be used.

b. Cryptococcal polysaccharide antigen may be detected by the latex agglutination slide test. **The cryptococcal antigen test is particularly useful for making a presumptive diagnosis of cryptococcal meningitis**, with virtually all patients demonstrating titers of 1:8 or higher in the CSF. The test is more than 90% sensitive and specific for cryptococcal infection when performed properly. Rarely, false-positive results may occur in the presence of rheumatoid factor or the opportunistic fungus *Trichosporon beigeli*. Cryptococcal antigen may also be detected in serum and urine. **The serum antigen test is usually positive in persons with AIDS and cryptococcal meningitis and is therefore a useful screening test in this cohort of patients.**

3. Therapy. Cryptococcal meningoencephalitis is an absolute indication for systemic antifungal chemotherapy.

a. In patients with AIDS and cryptococcal meningitis the primary goal of treatment is to **gain control of the acute illness** and then continue therapy with an easily tolerated agent that will **suppress continuing cryptococcal infection** and allow patients to maintain their functional status. An aggressive **induction course of amphotericin B** (0.7 mg/kg/day) with **flucytosine** (25 mg/kg every 6 hours) for the initial 2 to 3 weeks is recommended by most experts [66,68]. Amphotericin effects more rapid sterilization of the CSF than does fluconazole. If induction therapy is successful, consolidation therapy with fluconazole 400 mg daily for 8 weeks may then be administered. Infectious disease consultation is suggested.

b. Maintenance therapy in AIDS patients is critical to prevent the otherwise inevitable relapse. When consolidation therapy has been completed, patients should receive **fluconazole** 200 mg/day indefinitely. This is both a highly effective and well-tolerated maintenance regimen. Fluconazole is preferred over itraconazole for maintenance [69].

- c. **HIV-negative immunocompetent patients** may be treated successfully with the traditional combination of amphotericin B 0.3 mg/kg/day and flucytosine 25 to 37.5 mg orally every 6 hours for 4 to 6 weeks [70]. However, given the relative toxicity and inconvenience of this regimen, many experts advocate an induction course of amphotericin B 0.5 to 1.0 mg/kg/day with flucytosine 25 mg/kg every 6 hours for 2 weeks followed by fluconazole 400 mg daily for another 8 to 10 weeks [66]. Lumbar puncture should be repeated to document CSF sterilization.
- d. **HIV-negative immunosuppressed patients** (e.g., transplant recipients) require prolonged therapy. Amphotericin B 0.7 to 1.0 mg/kg/day for 2 weeks followed by fluconazole 400 to 800 mg daily for 8 to 10 weeks and then fluconazole 200 mg daily for 6 to 12 weeks has been recommended [71].
- e. **Elevated intracranial pressure** is common in patients with cryptococcal meningitis and is associated with increased morbidity and mortality [72]. Treatment options include lumbar puncture repeated daily or the placement of a lumbar drain or a ventriculoperitoneal shunt [72,73]. Infectious disease consult is recommended.
- f. **See additional discussion in Chapter 6.**

B. Non-CNS extrapulmonary disease

1. **Skin.** Nearly 10% to 15% of patients with disseminated disease have skin involvement, which occurs most frequently on the face and scalp. Although rare reports suggest the occurrence of primary skin cryptococcosis, essentially **all patients with cryptococcal skin lesions should be considered to have disseminated disease.** Cryptococcal skin involvement should be suspected in any immunosuppressed patient with erythematous papules, pustules, warts with a molluscum contagiosum-like appearance, subcutaneous nodules, or ulceration. Mucosal lesions are uncommon. Skin biopsy with fungal stains and cultures may be diagnostic.
2. **Bone.** Approximately 5% of patients with disseminated disease manifest osseous lesions. The prominences of long bones, cranial bones, and vertebrae are involved most commonly. Radiographs reveal round lytic areas without sclerosis. Biopsy with culture is necessary for diagnosis.
3. Spread to most organs has been documented at postmortem examination in patients with disseminated disease. **Detection of cryptococcal organisms in any organ always mandates a search for the presence of cryptococcal infection elsewhere in the body.** Patients infected with HIV may have a syndrome of disseminated cryptococcal infection without specific organ localization. These patients have fever, chills, myalgias, lethargy, and a positive serum cryptococcal antigen.
4. **The therapeutic approach** to patients with non-CNS extrapulmonary cryptococcosis should be similar to that described above for CNS disease [66]. Prolonged treatment may be required.

COCCIDIIDOMYCOSIS

Coccidioides immitis is a highly infectious fungus that frequently causes pulmonary infection in endemic areas of the United States. **Although most disease caused by this organism is benign and self-limited, infection may occasionally result in chronic pulmonary or skin disease, meningitis, or disseminated illness [74,75].**

- I. **Growth and identification characteristics.** Routine culture methods are used, with presumptive identification in 2 to 5 days. The fungus grows readily on most culture media. **All culture plates should be handled with extreme care, because they are highly infectious to laboratory personnel. Direct human-to-human transmission is not known to occur, however.** *C. immitis* spherules may be identified in sputum, drainage material, or infected tissue. It is doubly refractile and thick walled, measures 20 to 80 μm, and is typically seen in several stages of development. Several preparations may be used to identify spherules, including potassium hydroxide, hematoxylin and eosin, methenamine silver, and periodic acid–Schiff stain.

II. Epidemiologic features. Coccidioidomycosis is endemic in the southwestern United States, Mexico, and parts of Central and South America. Cases may be seen outside endemic areas in persons who have traveled through these regions or as reactivation of infection acquired years earlier by a former resident of an endemic area. Because **infection is caused by inhalation of airborne arthrospores**, outbreaks may occur in dry weather in association with fresh diggings, newly plowed ground, and dust storms.

III. Clinical aspects

A. Acute pulmonary coccidioidomycosis. Most persons with primary infection by *C. immitis* **have an acute self-limited infection in the lungs.**

1. Subclinical or asymptomatic illness occurs in approximately 60% of patients. Prior infection in these persons can be detected only by skin testing.

2. Symptomatic illness. Forty percent of patients develop flulike symptoms after an incubation period of 7 to 28 days (average, 10–16 days).

a. Signs and symptoms. Fever, malaise, dry cough, shortness of breath, night sweats, anorexia, and pleuritic chest pain are common. Within the first few days of the onset of symptoms, a fine, generalized, erythematous maculopapular rash, sometimes urticarial in appearance, develops in 10% to 40% of patients. Peripheral eosinophilia may be present. The development of cutaneous hypersensitivity may be manifest as erythema nodosum or erythema multiforme, which occurs in fewer than 25% of infected individuals. This finding often is accompanied by arthralgias and, in association with pneumonitis, constitutes the classic picture of so-called valley fever.

b. Roentgenographic findings. The most common radiologic manifestation of acute coccidioid pneumonia is a segmental pneumonia, seen in approximately 50% of cases. Minimal infiltrates occur in nearly 30%, whereas hilar adenopathy and pleural effusion, sometimes massive, are seen in approximately 20%. In addition, solitary or multiple nodules, thin- or thick-walled cavities, and mediastinal lymphadenopathy may occur. Chest x-ray abnormalities usually resolve in 1 to 3 weeks.

3. Diagnosis

a. Sputum. Approximately 40% to 70% of primary infections will yield positive cultures [76]. A positive sputum culture is virtually diagnostic of pulmonary coccidioidomycosis, because this organism rarely colonizes the oropharynx.

b. Skin tests cannot differentiate between acute and remote infection and often are negative in persons with disseminated disease. They are, therefore, primarily useful only in epidemiologic evaluations.

c. Serologic tests often are diagnostic in primary coccidioidomycosis. **Serum precipitins**, as detected by tube precipitin, immunodiffusion, or latex agglutination testing, are IgM antibodies that are demonstrable in more than 75% of patients within 3 weeks of the onset of symptoms. Precipitins usually cannot be detected after 4 weeks. **Complement fixation detects IgG antibodies**, which appear more slowly but persist longer than IgM precipitins. More than 50% of patients will have a positive complement fixation titer, usually less than 1:32 by 3 months after the occurrence of clinical disease. More than 90% of patients with symptomatic acute pulmonary disease will have detectable antibodies by either precipitin testing or complement fixation [74,75]. Rising or persistently high complement fixation titers are a poor prognostic sign, whereas decreasing titers indicate improvement.

4. Treatment. In many patients with acute coccidioidomycosis, the disease resolves within 6 to 8 weeks without specific therapy. However, systemic antifungal therapy should be considered in the following settings: debilitation, pregnancy, immunosuppression, racial groups predisposed to disseminated disease (see section C), rising or persistently high (>1:16) complement fixation titers, progressive pulmonary disease, and persistent symptoms for more than 2 weeks [74]. For uncomplicated acute pulmonary coccidioidomycosis, most experts recommend itraconazole 200 mg twice daily or fluconazole 400 to 800 mg daily for 3 to 6 months [74,77]. If diffuse infiltrates are present, therapy with amphotericin B is recommended until significant clinical improvement has occurred, followed by oral azole therapy for at least 1 year.

B. Other pulmonary manifestations may occur.

1. **Chronic pulmonary coccidioidomycosis.** In some patients, symptoms of the acute pneumonia may persist for months or years. These patients have low-grade fever, weight loss, and cough. Serum complement fixation titers are positive, and sputum cultures often grow *C. immitis*. Therapy with itraconazole or fluconazole for at least 1 year is recommended [77].
2. **Solitary pulmonary nodules** due to *C. immitis* are common in endemic areas. In the absence of symptoms or immunosuppression no antifungal therapy is indicated.
3. **Cavitory disease** may be seen after acute primary infection and usually resolves spontaneously, but persistent cavitation sometimes occurs. Patients may be asymptomatic or have hemoptysis and low-grade fever. Sputum cultures often are positive. The course of persistent coccidioidal cavities is unpredictable, but most will resolve spontaneously over a period of 1 to 2 years. In a few patients, complications such as hemoptysis or rapid expansion with involvement of the adjacent lung may require some combination ofazole drug therapy and surgery [77].

C. Disseminated coccidioidomycosis. Fewer than 1% of infected individuals will develop disseminated (extrapulmonary) infection. This complication **most often occurs in immunocompromised hosts such as transplant recipients, patients with hematologic malignancies, or those receiving immunosuppressive chemotherapy** [74]. **AIDS patients are at increased risk for disseminated disease**, although focal pulmonary disease may also be seen [78,79]. Dissemination appears to be more common during pregnancy, particularly in the third trimester. In addition, persons of non-white ethnic groups (e.g., Filipino, Hispanic, African American) more commonly have disseminated disease than do whites. Dissemination may occur within a few weeks of the primary infection or years later, after reactivation of quiescent disease.

1. **Osteoarticular disease.** More than one-third of patients with disseminated disease have **involvement of the bones or joints** [74]. The bones most commonly affected are the skull and vertebrae and the bones of the hands and feet. **Lytic lesions** are typical and frequently involve the overlying soft tissue, producing abscesses or draining sinuses. Articular lesions usually are limited to a single joint, generally the knee or ankle.
2. **Cutaneous disease.** The skin is commonly involved in patients with disseminated coccidioidomycosis. The lesions may vary in appearance from pustules or plaques to verrucous wart-like growths. Rarely, skin lesions may result from the direct inoculation of *C. immitis*.
3. **Meningitis.** CNS involvement by *C. immitis* usually is subtle and nonspecific and generally occurs within several months of the primary infection. Headache, fever, and weight loss are common symptoms [80]. Examination of the CSF typically reveals a mononuclear pleocytosis with an elevated protein. Peripheral blood eosinophilia has been noted (see also Chapter 6).
4. **Other less common manifestations** of dissemination include involvement of the genitourinary tract in the form of prostatitis or epididymitis. Coccidioidal peritonitis and lymphadenitis have been described, and, rarely, the eyes may be involved. **Miliary disease**, as manifested by diffuse reticular infiltrates on chest x-ray, is a common presentation **in AIDS patients** [78] (see Chapter 18).
5. **Diagnosis.** Definitive diagnosis requires **histopathologic evidence and/or culture of the organism** from infected tissue or fluid. Positive blood or urine cultures are uncommon. CSF cultures are positive in approximately one-third of patients with meningitis. **Elevated complement fixation titers** are the rule in disseminated coccidioidomycosis. Most patients have serum titers of 1:32 or higher [74,75]. The exception to this generalization is meningitis, in which serum titers tend to be much lower. Complement-fixing antibodies are **detectable in the spinal fluid** in more than 75% of patients with meningitis. Complement fixation titers show considerable variation between laboratories. The reporting laboratory's experience with these assays should thus be borne in mind when assessing the significance of a particular result.

6. Therapy. Systemic antifungal therapy is indicated in all forms of disseminated disease.

- a. **Treatment of nonmeningeal forms of disseminated disease** is usually initiated with an oral azole, generally **itraconazole or fluconazole 400 mg daily**. Duration of treatment should be at least 1 year and for 6 months beyond the point at which the disease has become inactive. **Amphotericin B 0.5 to 0.7 mg/kg/day** may be used as an alternative, especially for severe disease with rapidly progressive lesions [74,75].
- b. **Oral fluconazole 400 to 800 mg daily** is now recommended by most experts as the **preferred treatment for coccidioidal meningitis** [81]. Response rates with fluconazole are comparable with those seen with intrathecal amphotericin B with much less toxicity. Itraconazole 400 to 800 mg daily has also been used successfully. Relapse rates are unfortunately quite high, and an indefinite duration of treatment is indicated [82]. Infectious disease consultation is recommended. **See further discussion in Chapter 6.**

ASPERGILLOSIS

Aspergillus species are common contaminants in the bacteriology laboratory, and the relationship of a positive culture to clinical disease must always be questioned. However, *Aspergillus* may cause a variety of illnesses, from **hypersensitivity pneumonitis to disseminated overwhelming infection in immunosuppressed patients**.

- I. **Growth and identification characteristics.** *Aspergillus* species are easily grown on routine fungal culture media, with identification possible within 48 to 72 hours. The species most frequently associated with human infections are *A. fumigatus* and *A. flavus*. Although a positive culture may suggest a causative relationship in the setting of a typical clinical syndrome, it may also represent benign colonization. **Definitive diagnosis of *Aspergillus* infection depends on demonstration of the organism invading tissue.** Staining with periodic acid–Schiff and methenamine silver permits ready identification of *Aspergillus* organisms in clinical specimens by visualization of their acutely branching septate hyphae.
- II. **Epidemiologic features.** *Aspergillus* species are ubiquitous soil saprophytes that are found in all parts of the world. *Aspergillus* frequently is cultured in hospital wards from unfiltered outside air circulating through open windows. Aspergillosis usually is acquired through the inhalation of airborne conidia by a susceptible host.
- III. **Clinical aspects.** Infection with *Aspergillus* species may result in one of several forms of a broad range of illnesses known as aspergillosis.
 - A. **Tracheobronchial colonization.** *Aspergillus* may colonize ectatic bronchi or cavities in the lungs of patients with chronic pulmonary disease without invasion of the surrounding pulmonary parenchyma, and therefore the organism may be isolated in the absence of associated clinical illness. In these instances, allergic or invasive aspergillosis is not present. In most cases no specific therapy is required. Sometimes, however, slowly progressive pulmonary infiltrates develop in some patients, and treatment is required.
 - B. **Allergic aspergillosis** may involve either the alveoli (extrinsic allergic alveolitis) or the airways (allergic bronchopulmonary aspergillosis [ABPA]).
 1. **Extrinsic allergic alveolitis is a hypersensitivity pneumonitis** that occurs in nonatopic individuals who are repeatedly exposed to conidia of *Aspergillus*, as in farmers who work in close proximity to moldy grain. Cough, dyspnea, fever, chills, and malaise typically develop 4 to 8 hours after exposure. Repeated attacks can lead to granulomatous disease and pulmonary fibrosis.
 2. **ABPA results from a hypersensitivity reaction of the airways to *Aspergillus* fungal antigens present in the bronchial tree** [83]. The pathophysiology of this disorder is complex and only partially understood. The immediate hypersensitivity (type I) reaction is believed to be IgE-mediated, probably accounting for the bronchospastic symptoms that are so characteristic of this disorder. A type III reaction (mediated by immune complexes) is most likely responsible for the roentgenographic features and more destructive changes of the bronchi [84].

- a. Manifestations.** ABPA is characterized by symptoms of bronchospasm, particularly episodic wheezing and dyspnea. Cough that produces mucopurulent sputum, low-grade fever, peripheral eosinophilia, and pulmonary infiltrates are common. Pleuritic chest pain and hemoptysis may also be seen. The illness may be mild and without sequelae, but recurrent episodes frequently result in progression to bronchiectasis and pulmonary fibrosis.
- b. Diagnosis.** ABPA is highly likely in a patient if several diagnostic criteria are present [84].
- (1) Patients will have a history of episodic asthma.
 - (2) Peripheral blood eosinophilia is a nearly universal feature.
 - (3) The skin test with *Aspergillus* antigenic extract usually is positive but is nonspecific, because it may be positive in patients who do not have ABPA.
 - (4) Serum precipitating antibodies to *Aspergillus* antigens are present in 70% to 100% of cases.
 - (5) Total serum IgE levels are markedly elevated. Both total IgE and IgE specific for *Aspergillus* antigens are increased in active ABPA and decrease with remissions.
 - (6) Chest x-rays show a wide variety of abnormalities from small, patchy, fleeting infiltrates (commonly in the upper lobes) to lobar consolidation, atelectasis, or cavitation. Most patients eventually develop central bronchiectasis.
 - (7) Sputum cultures often are positive for *A. fumigatus* and are suggestive but not diagnostic.
- c. Differential diagnosis.** Tuberculosis may be suggested by the upper lobe infiltrates or cavitation. Cystic fibrosis has features in common with ABPA, and this disorder must be excluded before treatment with steroids is begun. Carcinoma of the lung and eosinophilic pneumonia or bronchiectasis of other etiologies are additional considerations [83].
- d. Therapy** is determined by the severity and frequency of attacks. Mild disease may not require specific treatment.
- (1) Corticosteroids are the mainstay of therapy for ABPA. During acute exacerbations, large daily doses of prednisone (0.5–1.0 mg/kg) have been recommended until the chest x-ray has cleared, followed by alternate-day therapy at 0.5 mg/kg. This is continued for 3 to 6 months and then gradually tapered [83]. Aggressive treatment of early episodes may halt or delay progression to the final fibrotic stage.
 - (2) Bronchodilators and physiotherapy with postural drainage may help prevent mucous plugging.
 - (3) Serial chest x-rays and monitoring of IgE levels are helpful in guiding corticosteroid therapy and detecting exacerbations.
 - (4) Preventive aspects. Patients should avoid locations (e.g., compost heaps and grain silos) and activities (e.g., smoking marijuana) in which exposure to *Aspergillus* spores is likely.
 - (5) A recent randomized study demonstrated an additional benefit of itraconazole 200 mg twice daily for 16 weeks to that of steroids in patients with ABPA [85], so itraconazole can now be recommended as a steroid-sparing agent [86].
- C. Aspergillomas** (“fungus balls”) generally represent secondary saprophytic colonization of preexisting pulmonary cavities, most commonly in patients with a history of chronic lung disease such as tuberculosis, sarcoidosis, or emphysema [87,88]. Aspergillomas may occur as a late consequence of invasive aspergillosis and have been described, on occasion, in patients with ABPA. Aspergillomas are masses of tangled hyphal elements, fibrin, and mucus.
1. **Manifestations.** Hemoptysis is the most common symptom associated with aspergilloma, occurring in 55% to 85% of cases. Hemoptysis may vary from blood-streaked sputum to active bleeding that requires urgent surgical resection. Chronic cough is not uncommon. Many patients are asymptomatic.
 2. **Diagnosis** can be established by a typical radiologic picture, sputum culture, and serologic tests.

- a. **Chest x-rays or CTs usually** show the characteristic intracavitary mass partially surrounded by a crescent of air.
 - b. **Sputum cultures** are positive in one-half to two-thirds of patients.
 - c. **Serum precipitins** are present in more than 90% of cases and are suggestive of the diagnosis when accompanied by the characteristic x-ray appearance.
3. **Therapy and prognosis.** The natural history of aspergilloma is variable, and therapy must be individualized based on symptoms and underlying pulmonary status. A conservative approach is prudent, with observation alone indicated for asymptomatic patients and those with mild infrequent hemoptysis. Spontaneous disappearance or lysis of aspergillomas has been reported in 7% to 10% of cases. Surgical resection is indicated for patients with severe hemoptysis [89]. A beneficial role of antifungal therapy has not been demonstrated definitively [86].
- D. **Invasive aspergillosis.** *Aspergillus* is a common opportunistic pathogen in the compromised host and occasionally occurs in those whose immunocompromise is not obvious. Cancer patients with prolonged neutropenia from cytotoxic chemotherapy are particularly prone to infection. Patients receiving high-dose corticosteroids or other immunosuppressive agents or those with chronic granulomatous disease of childhood are also at increased risk [90]. Invasive aspergillosis occurs in AIDS patients, especially those patients who are leukopenic and on multiple antibiotics (azithromycin, trimethoprim-sulfamethoxazole) [91,92].
1. **Manifestations**
- a. **Pulmonary involvement** is by far the most common manifestation of invasive aspergillosis [90]. The lungs typically manifest a necrotizing bronchopneumonia, ranging from small areas of infiltrate to intensive bilateral hemorrhagic infarction. The most common presentation is that of **unrelenting fever and a new pulmonary infiltrate despite broad-spectrum antibiotic therapy in an immunosuppressed patient**. Dyspnea and nonproductive cough are common. Hemoptysis is uncommon. Chest x-ray may reveal patchy bronchopneumonia, nodular densities, consolidation, or cavitation. In immunocompromised patients, invasive pulmonary aspergillosis (IPA) generally is acute and evolves over days to weeks. Less commonly, patients with normal or only mild abnormalities of their immune systems may develop a more chronic slowly progressive form of IPA [93].
 - b. **Extrapulmonary dissemination** is found at autopsy in many patients with IPA [90].
 - (1) **Involvement of the CNS** may occur after either hematogenous dissemination or direct extension of invasive disease in the sinuses and results in infarction or abscess. The CSF may show a pleocytosis and increased protein content, but **cultures of CSF usually are negative**.
 - (2) **Necrotizing skin ulcers**, usually on the extremities, may occur secondary to hematogenous dissemination or after direct inoculation from an environmental source.
 - (3) **Osteomyelitis** due to *Aspergillus* typically involves a rib or the vertebral column and is most common in the immunosuppressed patient.
 - c. **Rapidly invasive infections of the paranasal sinuses** may occur in immunocompromised hosts and may extend into the orbit or cranial vault. A chronic form of invasive *Aspergillus* sinusitis typically occurs in normal hosts [90].
2. **Diagnosis of invasive aspergillosis. Definitive diagnosis requires the demonstration of tissue invasion** seen on a biopsy specimen or a positive culture from tissue obtained by an invasive procedure such as transbronchial biopsy. These patients often are severely ill, however, and invasive procedures may be associated with a high morbidity. **Noninvasive tests in the presence of an appropriate clinical syndrome may suggest the diagnosis.** For example, **pulmonary invasive disease is probable** in patients with chest radiographs that show new nodules or new cavities in the context of neutropenia, cytotoxic chemotherapy, or chronic corticosteroid therapy **and** sputum cultures or bronchoalveolar lavage washings or brush cultures for *Aspergillus* species or

cytologic examination on bronchoalveolar lavage that reveals characteristic septate hyphae.

- a. **Sputum and nasal cultures** are positive in some patients with invasive aspergillosis, and the organisms can sometimes be isolated from these sites in the absence of invasive disease. **In the high-risk patient, isolation of *Aspergillus* from sputum, bronchoalveolar lavage fluid, or bronchial washings is strongly suggestive of invasive aspergillosis [94,95].**
 - b. **Serologic studies.** The standard *Aspergillus* precipitin assay, usually elevated in ABPA, rarely is elevated in patients with invasive disease and in general is not helpful.
 - c. **Blood cultures** usually are negative.
 - d. **Lung biopsy usually is necessary for definitive diagnosis of IPA**, because parenchymal invasion of lung tissue must be demonstrated to confirm the diagnosis. Most investigators recommend open lung biopsy to ensure adequate tissue for histopathologic evaluation. The transbronchial biopsy approach has also been used. Unfortunately, lung biopsy cannot be performed safely in many patients at high risk for invasive aspergillosis. Therefore, **if the suspicion for IPA is very high, based on the clinical syndrome and positive sputum or nasal cultures, empiric antifungal therapy may be indicated.** Infectious disease consultation is advised.
 - e. **Biopsy and culture of extrapulmonary lesions** will provide the diagnosis in patients with invasive disease outside the lungs.
3. **Therapy.** Invasive aspergillosis is often a fulminating illness that results in death. With early therapy, many patients have survived [96]. Prognosis is highly dependent on the course of the underlying disease. Infectious disease consultation is advised.
 - a. **Amphotericin B has traditionally been standard treatment.** Most clinicians prescribe high daily doses (0.8–1.0 mg/kg/day). Doses as high as 1.5 mg/kg/day have been given to patients who respond poorly. The optimal duration of therapy has not been defined and should be individualized based on the severity of illness and the degree of immunosuppression. Lipid preparations of amphotericin may be preferred in patients with renal dysfunction or in those receiving other nephrotoxic agents [86,97].
 - b. Studies of **itraconazole** in the treatment of invasive aspergillosis have demonstrated similar response rates to those of amphotericin B [98,99]. **Therapy with itraconazole 300 mg twice daily for 4 days and then 200 mg twice daily** is an alternative to amphotericin B for selected patients not receiving other agents that may interact with itraconazole [86].
 - c. An initial course of treatment with intravenous itraconazole or amphotericin B until disease stabilization or regression has occurred followed by prolonged oral therapy with itraconazole has been suggested by some clinicians [86].
 - d. **Caspofungin** is the first of the new echinocandin class of antifungal agents and was recently approved by the U.S. Food and Drug Administration (FDA) for the treatment of invasive aspergillosis (70 mg i.v. on day 1, then 50 mg i.v. daily) in patients who have failed or have been intolerant to amphotericin and/or itraconazole. It has not been studied as initial therapy [100].
 - e. **Voriconazole**, is a newly approved triazole that has been used in open-labeled studies of invasive aspergillosis. Complete or partial response rates of 50% or greater have been reported for patients treated with voriconazole who have been intolerant to or failed other therapies for invasive aspergillosis [86]. Other investigational triazoles such as posaconazole also exhibit excellent activity against *Aspergillus* species [101].
 - f. **Combination therapy.** Because of the high mortality rates of invasive aspergillosis treated with single antifungals, a variety of combination therapies using amphotericin B with azoles, flucytosine, or rifampin has been evaluated both *in vitro* and in animal models. A combination of caspofungin and itraconazole has been used successfully in the treatment of invasive aspergillosis in a small number of patients [102]. The combination of caspofungin with newer azoles, such as voriconazole and posaconazole, appears to be promising.

- g. Reduction of corticosteroids or cytotoxic chemotherapy**, if possible, appears to improve prognosis.
- h. Surgical resection** may be useful in selected patients with focal lesions.
4. **Prognosis** is improved with early diagnosis and aggressive therapy, remission of the underlying disease, and reversal of chemotherapy-induced bone marrow suppression. **Resolution of neutropenia is particularly important** if a favorable response to therapy is to be seen.
 5. **Future chemotherapy if the patient survives.** Patients who have survived a prior episode of invasive aspergillosis are at risk for reactivation of invasive disease during subsequent myelosuppression with repeat courses of chemotherapy. Some studies suggest at least a 50% rate of reactivation during chemotherapy in patients who have recovered from prior invasive aspergillosis. **Prophylactic amphotericin B (1 mg/kg/day) beginning at least 48 hours before chemotherapy** and continuing until the time of granulocyte recovery to prevent relapse of invasive disease in patients undergoing repeat chemotherapy has been recommended [103].
- E. Rare manifestations of aspergillosis**
1. **Aspergillus endocarditis** mimics *Candida* endocarditis in that it occurs most commonly on prosthetic heart valves and is associated with large vegetations that embolize to medium-sized vessels. **Diagnosis is difficult because blood cultures are rarely positive.** Early valve replacement is essential if cure is to be achieved.
 2. **Allergic Aspergillus sinusitis** is a recently recognized form of sinusitis that occurs primarily in young atopic persons [104]. Nasal polyps and mucoid material containing eosinophils and fungal hyphae are found commonly. Optimal therapy requires corticosteroids and surgical debridement.

BLASTOMYCOSIS

Blastomyces dermatitidis is a dimorphous fungus that causes the acute and chronic illness blastomycosis. Infection with *B. dermatitidis* occurs via the lungs and then may be followed by hematogenous dissemination. Pulmonary disease is most common, followed by disease of skin, bone, and genitourinary tract. **Widely disseminated disease is most common in immunocompromised hosts, especially those with AIDS.**

- I. **Growth and identification characteristics.** *B. dermatitidis* mycelial colonies are usually visible 1 to 2 weeks after clinical specimens are incubated at 30°C. Conversion to the yeast phase at 37°C is necessary for definitive diagnosis and usually occurs within another 10 days of culture. Microscopic examination of sputum, pus, or drainage from skin lesions is a rapid method for presumptive diagnosis of blastomycosis. When seen in a wet preparation or after digestion with KOH, the **characteristic yeast forms** are as spherical cells with a diameter of 8 to 15 μm , have a highly refractile thick cell wall, are multinucleate, and reproduce by a single broad-based bud. These same characteristics allow identification of the organism in histopathologic specimens with the use of special stains such as periodic acid–Schiff, Gomori methenamine silver, Papanicolaou, and Giemsa stains.
- II. **Epidemiologic and host characteristics.** Infection caused by *B. dermatitidis* has been reported only occasionally outside of North America. Most patients reside in the southeastern and south central states, especially those bordering the Mississippi and Ohio River valleys, and the midwestern states and Canadian provinces that border the Great Lakes [105–107]. Isolates from the environment indicate that ***B. dermatitidis* exists in nature in warm moist soil that is rich in organic material**, usually decaying vegetation [108,109]. When these microfoci are disturbed, either during work or recreational activities, the aerosolized spores (conidia) are inhaled into the lungs. Disease at other body sites is the result of dissemination from this initial pulmonary infection. Primary cutaneous disease, however, has been reported after dog bite and after accidental inoculation injury. A rare case of vaginal infection transmitted sexually from a man with genitourinary blastomycosis has been described [105].

B. dermatitidis is a primary pathogen that causes disease primarily in normal hosts. Virulence is probably mediated to some extent by the rapid conversion of conidia to the yeast form after inhalation into the lung. The yeast form is more resistant to phagocytosis and killing by leukocytes. Additionally, the elegant work of Klein and coworkers [110–114] has clearly documented a 120-kDa protein antigen on the cell wall surface, designated WI-1, which is not only a major immunodominant epitope for humoral and cellular immunity but also is an important virulence factor for *B. dermatitidis*.

III. Clinical manifestations. Blastomycosis is a systemic disease with both pulmonary and extrapulmonary manifestations. Pulmonary disease may be acute or chronic. Extrapulmonary disease occurs most commonly during the chronic form of illness.

A. Acute blastomycosis often is unrecognized and is characterized by **pneumonitis** that occurs after a median incubation time of 30 to 45 days. Analysis of point source outbreaks indicate that only 50% or so of infected individuals become symptomatic [108,109].

1. Symptomatic patients usually have an influenza-like syndrome with fever, chills, arthralgias, myalgias, cough, fatigue, and pleuritic chest pain. The symptoms may be mild or severe. Spontaneous resolution of disease is well recognized, and the duration of illness in these cases is generally less than 4 weeks [115].

2. Chest roentgenograms usually show lobar or segmental consolidation. Small pleural effusions are seen occasionally. Hilar adenopathy usually does not occur [116].

B. Chronic blastomycosis is indolent in onset and follows a widely variable course. Recent clinical experience indicates that extrapulmonary disease occurs in only approximately one-fourth of patients with blastomycosis [117]. Infection has been documented in almost every body organ, but skin, bone, and genitourinary sites of disease are most common [105,106].

1. Pulmonary manifestations. Most patients have signs and symptoms of a **chronic pneumonia that mimics tuberculosis**. The most frequent symptoms are cough, sputum production, hemoptysis, pleuritic chest pain, and weight loss. Fever tends to be low grade. The chest roentgenogram is nonspecific, with a wide variety of findings [116]. Lobar or segmental alveolar infiltrates, especially of the upper lobes are most common. These infiltrates may progress to cavitation. Masslike infiltrates that mimic lung cancer occur nearly as often as alveolar infiltrates. Other radiologic findings include solitary cavities, lung nodules, and fibronodular infiltrates, with or without cavities. Pleural thickening and small pleural effusions occur, whereas large pleural effusions are uncommon. Miliary disease and diffuse pneumonitis, often associated with respiratory failure, are occasionally reported and are associated with a high mortality.

2. Skin lesions are the most common form of extrapulmonary blastomycosis. Skin disease usually occurs in conjunction with pulmonary disease but may occur alone. Skin lesions tend to occur on exposed parts of the body. The characteristic lesion begins as a small papule or pustule that gradually enlarges over a period of weeks or months, becoming elevated, verrucous, and crusted (Color Plate 4.6). Outer borders are well demarcated and indurated. Older lesions commonly exhibit central healing and scarring at the same time that the outer border of the lesion is active and advancing. Removal of the crust reveals a granulomatous base with numerous small abscesses exuding purulent material. Less frequently, the lesion may begin as a small pustule that ulcerates. These ulcerative lesions bleed easily. Subcutaneous abscesses that sometimes drain spontaneously are seen in a minority of patients. **The organism easily is seen and is cultured from pus aspirated from these abscesses.**

3. Bone infection has been reported in 10% to 50% of patients. Lesions are osteolytic and often painless. The long bones, vertebrae, and ribs are most commonly involved. Some patients present with a contiguous soft tissue abscess or draining sinus. Contiguous spread to joints may cause a pyarthrosis. **Diagnosis is made by biopsy** of the involved bone or aspiration of the contiguous soft tissue abscess.

4. Genitourinary disease has been noted in 10% to 30% of patients. The prostate and epididymis are most commonly involved. The kidney usually is spared.

Patients may note a painful swelling of the testis or epididymis, a perineal ache, or symptoms of urinary obstruction. The prostate may be tender and enlarged. Cultures of urine or prostatic secretions obtained after massage frequently are positive.

5. **CNS disease** is reported in fewer than 5% of cases. However, CNS complications of blastomycosis are more common in AIDS patients, noted in 40% of patients with blastomycosis and AIDS in one series [118]. Abscesses are most common and present as mass lesions. Meningitis is usually a late complication and is frequently associated with multiorgan disease.
6. **Other sites** of disease are reported less frequently and include the lymph nodes, spleen, larynx, esophagus, thyroid, pituitary, and heart.

C. Infections in the compromised host. Blastomycosis in the immunocompromised host is more severe and more often disseminated and is associated with greater mortality than in immunocompetent patients [118,119]. As noted in the preceding section, CNS infection is especially common in AIDS patients. Death rates of 30% to 40% are reported despite treatment with amphotericin B.

IV. Diagnosis. Definitive diagnosis is **established by culture**. A presumptive diagnosis can be made by visualizing the distinctive yeast forms in clinical specimens and is often sufficient to initiate antifungal therapy. Serologic studies must be interpreted with caution because of their high false-positive and false-negative rates.

A. Culture. Clinical specimens should be cultured on Sabouraud or more enriched agar. Sputum, pus from soft tissue abscesses, scrapings from skin lesions, and prostatic secretions may all be cultured successfully.

B. Direct examination of clinical specimens

1. **Wet preparation.** Sputum, scrapings from skin lesions, pus, or pleural fluid should be examined microscopically as a fresh wet preparation. The use of 10% KOH to digest cellular debris may facilitate seeing the organism. Occasionally, multiple specimens must be collected before the organism can be seen on smear. Bronchoscopy is helpful in patients who are unable to produce sputum. Visualization of the yeast form on cytology preparations is facilitated by Papanicolaou stain.

2. **Histopathology.** The typical inflammatory response is characterized by pyogranulomas. Yeast forms usually are not seen with hematoxylin and eosin stains but may be demonstrated with special stains, as noted earlier in section I.

C. Skin tests. No skin test reagent is currently available for the diagnosis of blastomycosis in patients with suspected disease.

D. Serologic tests for the diagnosis of blastomycosis are complicated by their **lack of sensitivity and specificity** [120]. Thus, negative tests should never be used to rule out disease. Neither should an isolated positive test prompt antifungal therapy. Rather, **a positive result should stimulate the clinician to search diligently for evidence of disease.**

1. **Complement fixation tests** are neither sensitive nor specific. Fewer than 50% of patients with blastomycosis will develop a positive test, and cross-reactions with *H. capsulatum* and *C. immitis* are common.

2. **Immunodiffusion tests.** The detection of precipitating antibodies is highly specific for blastomycosis, but sensitivity is variable. Positive results have been reported in up to 80% of patients with blastomycosis. However, lower rates of positivity (33%) have been reported in patients with localized disease [120]. Positive results are most frequently noted in patients with symptoms lasting 50 days or longer. Thus, immunodiffusion is **not helpful in acute disease.**

3. **Radioimmunoassays and enzyme immunoassays** that are highly sensitive have been developed [121]. False-positive results, however, are well documented. An enzyme immunoassay is now commercially available and may prove useful for initial screening of specimens. Positive results should be confirmed with the more specific immunodiffusion test.

4. **Recent advances** in the characterization of the yeast antigens of *B. dermatitidis* may facilitate the development of more reliable serologic tests. A novel 120-kDa surface protein, designated as WI-1, has been described by Klein and Jones [110].

Preliminary results using this antigen in a radioimmunoassay appear promising, but currently this test is investigational [121].

- V. Therapy.** Although amphotericin B was previously considered the primary drug for treating all clinical forms of blastomycosis, recent studies have proven that either ketoconazole or itraconazole is an effective alternative for the treatment of immunocompetent patients with mild to moderate disease. Neither azole is indicated for patients with CNS disease.

A. Acute blastomycosis. Some patients may not require therapy. Because the acute form may be a benign self-limited illness, it has been suggested that patients with acute blastomycosis should be followed, without specific chemotherapy but with prolonged observation [115]. However, illness progresses in some patients to chronic infection with significant morbidity. Because there are no known clinical characteristics that predict which patients are susceptible to chronic involvement, some authorities recommend that all patients with acute blastomycosis receive chemotherapy. **The indication for antifungal therapy in this group remains controversial, and infectious disease consultation is advised.**

B. Chronic blastomycosis

- 1. Amphotericin B** is the **drug of choice for patients with life-threatening disease, patients who are immunocompromised, and patients with CNS disease** [122]. A total dose of at least 1.5 g is recommended. For selected patients treated initially with amphotericin B who are immunocompetent and who do not have CNS disease, an azole may be substituted for amphotericin B after clinical improvement is noted. Cure rates of greater than 90% are reported in immunocompetent patients who complete a full treatment course of amphotericin B, and relapse rates are less than 5%. Relapse is more frequently reported in immunocompromised patients, especially those with AIDS. Maintenance therapy with an oral azole has thus been advocated after successful primary therapy of blastomycosis in AIDS patients [118].
- 2. Ketoconazole.** Two clinical trials have documented cure rates of approximately 80% for patients treated with a daily dose of 400 mg ketoconazole [123,124]. For patients who do not respond satisfactorily, the dose may be increased in 200-mg increments to a maximum of 800 mg/day. At least 6 months of treatment is recommended.
- 3. Itraconazole** is highly effective against *B. dermatitidis* both *in vivo* and *in vitro*. At doses of 200 to 400 mg/day, itraconazole was effective in 90% to 95% of patients with blastomycosis [53,122]. Because efficacy rates were similar at both doses, the initial recommended daily dose of itraconazole is 200 mg. For patients who fail this initial therapy, the dose may be increased in 100-mg increments to a maximum daily dose of 400 mg. Itraconazole generally has fewer side effects than ketoconazole and is the preferred agent for the treatment of blastomycosis at the authors' medical center.
- 4. Fluconazole** has been studied in only a limited number of patients. In studies using daily doses of 400 to 800 mg, a successful outcome was noted in 80% of a cohort of 39 patients [125,126]. These results indicate that fluconazole and ketoconazole are essentially equivalent when administered at equivalent doses of more than 400 mg/day. Adverse events are less common with fluconazole. Fluconazole penetrates well into the CNS and therefore may have a role in the treatment of blastomycotic meningitis and cerebral abscesses in patients who are intolerant to amphotericin B.
- 5. Surgery** has a limited role in the treatment of blastomycosis.
- 6. Special patient populations**
 - a. Pediatric blastomycosis.** Blastomycosis is reported less commonly in children. However, the clinical spectrum of disease and therapeutic and treatment considerations are similar to adults. That is, children with life-threatening or CNS disease should be treated with amphotericin B. Children with mild to moderate disease without CNS involvement have been successfully treated with itraconazole daily dose of 5 to 7 mg/kg/day.
 - b. Pregnancy.** Amphotericin B is the drug of choice for the treatment of blastomycosis in pregnant women.

7. **Prognosis.** Most patients ($\geq 90\%$) with chronic blastomycosis are cured with therapy. Mortality is greatest in patients with AIDS and those with respiratory failure or CNS disease.

MUCORMYCOSIS

Mucormycosis (or *zygomycosis*) is the term for infection caused by fungi of the order Mucorales. A number of families of this order are associated with disease, but the Mucoraceae (which include the genera *Absidia*, *Mucor*, *Rhizomucor*, and *Rhizopus*) are the most common [127]. **Mucoraceae may produce severe disease in susceptible individuals, notably patients with diabetes and leukemia.** Mixed infections with other fungi and with bacteria are common.

- I. **Growth and identification characteristics.** The Mucorales are cultured on routine fungal media, and growth is abundant in 24 to 72 hours. A saline preparation will reveal broad nonseptate hyphae with right-angle branching. **The laboratory should be alerted when mucormycosis is a diagnostic possibility.** Microscopic examination of smears and histopathologic evaluation of scrapings and biopsy material often reveal the diagnosis when cultures are negative. The organisms stain readily with periodic acid-Schiff, methenamine silver, and routine hematoxylin and eosin stains.
- II. **Epidemiologic and host characteristics.** The **organisms that cause mucormycosis are ubiquitous** molds commonly found in the soil and on decaying organic debris. They are infrequent contaminants in the laboratory. Occasionally, Mucorales species have been isolated from sputum or sinus specimens in the absence of invasive disease. There is **no evidence for person-to-person transmission.** **Certain conditions predispose** to tissue invasion by these normally saprophytic fungi, including **diabetes mellitus, leukemia, lymphoma, corticosteroid therapy, severe malnutrition, organ transplantation, extensive burns, and uremia.** Several cases of mucormycosis have been reported in dialysis patients who were being treated with the chelating agent **deferoxamine** [128].
- III. **Clinical aspects.** Mucormycosis is usually an acute fulminant infection characterized pathologically by the **invasion of major blood vessels, with resultant ischemia and infarction of adjacent tissue.**
 - A. **Rhinocerebral mucormycosis** most commonly manifests in the setting of **poorly controlled diabetes, especially with ketoacidosis.** The causative organism in most cases is *Rhizopus arrhizus*. The organisms invade through the palate or the mucous membranes of the nose or paranasal sinuses. Subsequently, invasion through the ethmoids may occur, with direct extension into the orbital region and the frontal lobes of the brain. Progression of disease is usually rapid, although it may become indolent if ketoacidosis resolves.
 1. **Clinical manifestations.** Local symptoms of sinusitis and palatal or orbital cellulitis may be present. **The nasal septum may be ulcerated, necrotic, or even perforated, and dark bloody nasal discharge commonly results.** The nasal turbinate bones often are black and necrotic. Soft periorbital or perinasal swelling may progress to induration and discoloration. **Neurologic sequelae** evolve after a few days and usually are rapidly progressive. Ptosis, proptosis, and dilatation or fixation of the pupil may occur. Drainage of **black** pus from the eyes sometimes is seen. Progressive neurologic deficits ensue, with ophthalmoplegia, blindness, cranial nerve involvement, and, finally, contralateral hemiplegia due to thrombosis of the internal carotid artery. Progressive lethargy develops despite control of the diabetes, and coma follows.
 2. **Diagnosis** requires a **high degree of suspicion** to permit early therapy.
 - a. **A tissue biopsy or wet preparation** of the necrotic areas may demonstrate the characteristic nonseptate hyphae. This is the **best rapid diagnostic procedure** because cultures require 1 to 3 days and are often negative.
 - b. **The CSF** usually shows nonspecific findings with a mononuclear pleocytosis and slight elevation of protein. CSF cultures typically are negative.
 - c. **Radiologic examination** may demonstrate sinusitis or findings suggestive of osteomyelitis. CT or MRI may be useful to demonstrate tissue or bone

destruction, cerebritis, or retro-orbital disease. Arteriograms may reveal filling defects, narrowing, occlusions, and infarction.

3. **Therapy. Because of the rapidity with which this disease progresses, prompt and aggressive therapy is essential** [127]. Surgical and infectious disease consultations are advised.
 - a. **Treatment directed toward reversing the underlying condition** (e.g., diabetic ketoacidosis) or decreasing immunosuppressive therapy is necessary.
 - b. **Amphotericin B is the only truly effective agent.** The dosage should be rapidly advanced to 1 to 1.5 mg/kg/day. If there is a favorable clinical response, an alternate-day regimen can be adopted. A total dosage of 2 to 3 g given over 2 to 3 months usually is required, depending on the clinical course and control of the underlying disease. A lipid formulation of amphotericin may be used in the presence of renal dysfunction. Cases have occurred where lipid formulations at doses as high as 16 mg/kg/day have been used and succeeded when amphotericin appeared to be failing.
 - c. **Surgical debridement.** Extensive surgical extirpation or debridement of devitalized tissue and adequate drainage of sinuses and abscesses are essential elements in controlling infection.
 4. **Prognosis.** With aggressive combined chemotherapy and surgery, the mortality is approximately 50%. Survivors often have significant neurologic deficits. Rapid diagnosis and treatment may improve prognosis.
- B. Pulmonary mucormycosis** may occur after inhalation of fungal spores or from hematogenous or lymphatic spread during dissemination. Most patients have hematologic malignancy, severe neutropenia, or are transplant recipients, and most have received steroids.
1. **Manifestations.** Fever is common with **pulmonary infiltration or cavitation that progresses despite antibiotic therapy.** Occasionally, subacute cases occur in diabetics, with progression over weeks to months.
 2. **Diagnosis.** The diagnosis of pulmonary mucormycosis requires **histopathologic evidence of pulmonary invasion.** Cultures of respiratory secretions are usually negative. The chest x-ray is nonspecific.
 3. **Therapy.** Most patients in whom pulmonary mucormycosis is diagnosed have had advanced disease with extensive tissue destruction, and results of treatment have been disappointing. Early diagnosis, reversal of the underlying disease, and high-dose amphotericin B may improve the prognosis. Surgical resection of pulmonary lesions may be beneficial in selected patients.
- C. Gastrointestinal mucormycosis** has been diagnosed primarily in patients with severe malnutrition or in transplant recipients [129]. Any part of the GI tract may be involved, but the stomach and large bowel are the most common sites of infection. Abdominal pain and bloody diarrhea are typical, and signs of peritonitis may ensue if the intestinal wall is perforated. The disease is usually acute and rapidly fatal. **Diagnosis requires biopsy of involved tissue.** A combination of surgical resection and antifungal chemotherapy with amphotericin B is indicated as treatment.
- D. Cutaneous mucormycosis.** Involvement of the skin with the Mucorales may be primary (after direct inoculation of organisms during minor trauma) or secondary (after dissemination from another site) [130]. Extensive involvement of burn wounds may result in disseminated disease. **Diagnosis depends on the demonstration of tissue invasion in biopsy specimens.** For patients with primary localized cutaneous disease, surgical debridement may be adequate for cure. However, in patients with evidence of disease distant to the cutaneous site of infection or invasion of hyphal forms into the subcutaneous tissue, systemic therapy with amphotericin B is required.
- E. Disseminated mucormycosis** usually occurs in debilitated patients with hematologic malignancies [131]. Dissemination is most often from the lungs or GI tract and may involve any part of the body. Multiple areas of infarction and abscess formation are common. Cutaneous lesions that resemble ecthyma gangrenosum have been described. The clinical course is acute and rapidly progressive. Biopsy of involved tissue is required to make the diagnosis. Intensive therapy with amphotericin B is indicated, but the outcome is generally poor.

SPOROTRICHOSIS

Sporothrix schenckii is a saprophytic fungus found widely in nature. Infection due to *S. schenckii* generally is limited to the skin and regional lymphatics, although systemic and disseminated disease occasionally occur.

- I. **Growth and identification characteristics.** *S. schenckii* is a dimorphous fungus. The mycelial phase can be grown and identified on routine culture media in 3 to 5 days. Conversion to the yeast phase is desirable for definitive diagnosis. **Isolation of *S. schenckii* in the laboratory usually indicates infection**, because it is not a normal commensal of humans.
- II. **Epidemiologic features.** *S. schenckii* is found worldwide. The organism is found in the soil and on rose and barberry bushes, sphagnum moss, tree bark, and other vegetation. **Infection usually occurs after inoculation injury after contact with thorny plants** [132].
- III. **Clinical aspects.** Sporotrichosis can be divided into cutaneous and extracutaneous infection.
 - A. **Cutaneous disease** accounts for 75% to 80% of cases of sporotrichosis. Transmission to humans typically occurs through a break in the skin, often after minor or unrecognized injuries. Cutaneous sporotrichosis is therefore an **occupational disease** of gardeners, farmers, horticulturists, nursery workers, and florists.
 1. **Manifestations.** The fungus usually gains entry in the fingers or hands, where a **small papule or raised, erythematous, subcutaneous nodule develops**. The lesion may be evident at any time from 1 week to 6 months after inoculation. Spread to regional lymphatics results in **progression of secondary nodules** up the arm, which often ulcerate and drain but do not produce significant pain or disability. Localized cutaneous infection without lymphatic spread is less common; these lesions may be nodular, crusted, or fungating and may occur anywhere at a site of trauma. Lesions may wax and wane for months or years.
 2. **Diagnosis.** Although the clinical appearance may be very suggestive of sporotrichosis, other infectious diseases may cause identical lesions, including nontuberculous mycobacterial infection, nocardiosis, blastomycosis, and leishmaniasis [132]. **Culture of drainage or aspirated material** should reveal the causative organism and is **diagnostic**. Histopathologic examination of punch biopsy specimens reveals granulomatous lesions with fungal cells confined to the dermis. The fungal cells may be surrounded by an aggregation of material that stains with periodic acid–Schiff, the so-called asteroid body.
 3. **Therapy**
 - a. **Oral potassium iodide** remains an effective inexpensive treatment for cutaneous and lymphatic sporotrichosis. However, it is associated with frequent allergic reactions and GI intolerance.
 - (1) **Mode of administration.** Saturated potassium iodide solution is given orally in doses of 3 to 4 mL (maximum) every 8 hours, beginning with 1 mL per dose and gradually increasing the dose while monitoring for toxicity. Some advise putting the drug in root beer to disguise the taste. Treatment is continued until 1 month after the skin lesions disappear.
 - (2) **Toxicity.** Nausea, vomiting, parotid swelling, iodism (acne) or other skin lesions, coryza, sneezing, eyelid swelling, and depression generally respond to discontinuing the drug for a few days and restarting it at a lower dosage.
 - (3) Application of local heat to the lesions may also be helpful.
 - b. **Treatment with itraconazole** results in response rates of greater than 90% [133,134]. Itraconazole 200 mg daily for 3 to 6 months is well tolerated and more convenient than potassium iodide and can now be recommended as the **treatment of choice** [135].
 - B. **Extracutaneous disease** represents approximately 20% of cases of sporotrichosis. Therapy with potassium iodide is ineffective in all forms of extracutaneous disease. Treatment with itraconazole or amphotericin B is required.
 1. **Pulmonary sporotrichosis is uncommon.** It may be a primary infection after inhalation of *S. schenckii* spores or may occur secondary to dissemination

[136]. Many patients have a history of chronic obstructive pulmonary disease, diabetes, alcohol abuse, or some other chronic medical condition. Symptoms include the insidious onset of cough, sputum production, malaise, weight loss, and fever. **Chest x-rays** generally reveal parenchymal infiltration progressing to cavitation, and hilar adenopathy may be marked. Infection is usually indolent but progressive. **Diagnosis depends on isolation of the fungus from sputum, bronchial washings, or lung tissue. Amphotericin B** is recommended for life-threatening disease. Mild to moderate disease may be treated with **itraconazole 200 mg twice daily** [135,137].

2. **Osteoarticular sporotrichosis** is an extremely indolent infection that primarily involves the joints and bones. Involvement of a single joint is typical. Cutaneous disease usually is absent. Most patients have pain, effusion, and decreased mobility of the affected joint. Cultures of joint fluid are frequently negative, and synovial biopsy may be required for diagnosis. **Itraconazole 200 mg twice daily** is effective and recommended for most patients [135]. Amphotericin B may be used in cases of itraconazole treatment failure.
3. **Disseminated sporotrichosis is rare**, usually occurring in an immunosuppressed host. Involvement of multiple sites, including the skin, lungs, joints, bones, and CNS, has been reported. Risk factors for dissemination include alcoholism, diabetes, chronic obstructive pulmonary disease, and AIDS [138]. Clinical manifestations depend primarily on the organ systems involved. **Skin lesions**, often ulcerative, are found in most patients. Lymphatic spread generally is not seen due to hematogenous dissemination. **Multifocal joint involvement** is common, in contrast to the normally unifocal osteoarticular disease. Nodular pulmonary lesions are present in 10% to 20% of patients. **Meningitis** is a rare manifestation of infection with *S. schenckii*.
 - a. The **diagnosis** may be suspected on the basis of the characteristic skin and joint lesions. **Culture of the fungus** from an infected lesion generally is not difficult, although multiple cultures occasionally are required. Recovery of the organism from blood cultures has been reported. Repeated culture of the CSF often is necessary to isolate the organism in patients with meningitis, and serologic tests of serum and CSF may be useful [139].
 - b. **Amphotericin B** is the preferred therapeutic agent for disseminated sporotrichosis, including meningitis. Itraconazole may have a role as maintenance therapy in patients with AIDS after initial treatment with amphotericin [132]. Infectious disease consultation is advised.

MISCELLANEOUS FUNGAL INFECTIONS

- I. **Paracoccidioidomycosis** is a systemic infection caused by the dimorphous fungus *Paracoccidioides brasiliensis* [140]. The **disease is endemic in Latin America, particularly Brazil**, and is diagnosed only rarely in North America. Pulmonary infection is the most common manifestation, but involvement of the mucous membranes, skin, and lymph nodes after dissemination occurs frequently. **Itraconazole** is the drug of choice for treatment.
- II. **Mycetoma** (Madura foot) is a localized noncontagious infection involving cutaneous tissue, fascia, and bone [141]. The disease is reported most frequently in patients who live in tropical or temperate zones. Mycetoma may be caused by either aerobic actinomycetes or various species of fungi and generally occurs after the traumatic implantation of the organisms into the subcutaneous tissue of a healthy host. Most cases involve the foot or hand and progress very slowly over months to years. Combined surgical–medical treatment is the best therapeutic approach for mycetoma caused by fungi.
- III. **Dematiaceous fungi** are a group of darkly pigmented organisms that cause infections termed *phaeohyphomycoses*. These infections occur most frequently in immunocompromised hosts and manifest clinically as subcutaneous, sinus, or cerebral infection [142]. Surgical resection of localized lesions is crucial for diagnosis and treatment, but the prognosis is usually poor.
- IV. **Penicillium marneffei** is a dimorphic fungus endemic in southeast Asia that causes disseminated infection with papular skin lesions in persons with AIDS [143, 144]. Disseminated penicilliosis may be **treated effectively with amphotericin B**

followed by itraconazole 200 mg twice daily for 10 weeks and then 200 mg daily as maintenance therapy to prevent relapse [145].

- V. Emerging opportunistic fungal infections.** Many fungal species that formerly were considered nonpathogenic or only rarely were associated with invasive disease are now causing increasingly common infections in immunosuppressed hosts. *Trichosporon* and *Malassezia* species are common causes of superficial dermatologic infections but may cause disseminated disease in immunocompromised or debilitated patients [146,147]. *Fusarium* species cause disseminated infection primarily in patients with hematologic malignancies or severe burns [148]. *Pseudallescheria boydii* is an agent of mycetoma and may cause more deep-seated infections such as pneumonia or disseminated disease in the immunocompromised host [149]. There is no standard well-defined antifungal treatment for most of these infections, and infectious disease consultation is suggested.

ANTIFUNGAL CHEMOTHERAPY

The agents currently available for the systemic therapy of mycotic infections are presented in Table 17.2. The decision regarding whether to initiate systemic antifungal chemotherapy must be based in part on consideration of the toxicity of these drugs (Table 17.3). **Infectious disease consultation is recommended** to help determine the indications for therapy and to assist in administration of the drugs. The following general guidelines provide an introduction to systemic antifungal chemotherapy.

- I. Amphotericin B (Fungizone)** has been the most reliable agent against most of the invasive fungal pathogens [150,151].

- A. Mode of action.** Amphotericin binds to ergosterol, the primary sterol in the membrane of susceptible fungi, resulting in the opening of pores in the membrane and leakage of cellular constituents followed by cell death [152].

Table 17.2. Systemic Antifungal Agents

Class	Route	Daily Dose	Action
Polyenes			
Amphotericin B deoxycholate	i.v.	0.5–1.0 mg/kg	Membrane: binds to fungal sterols
Lipid formulations	i.v.	3.0–6.0 mg/kg	
Azoles			
Ketoconazole	p.o.	200–400 mg	Membrane: interferes with ergosterol synthesis
Fluconazole	p.o., i.v.	400–800 mg	
Itraconazole	p.o., i.v.	200–400 mg	
Voriconazole	p.o., i.v.	200–400 mg	
Allylamines			
Terbinafine	p.o.	250 mg	Membrane: interferes with ergosterol synthesis
Echinocandins			
Caspofungin	i.v.	50–70 mg	Cell wall: glucan synthesis inhibitor
Nucleic acid analogues			
5-Fluorocytosine	p.o.	100–150 mg/kg	Nuclear: interferes with DNA and RNA synthesis
Griseofluvin	p.o.	500 mg	Nuclear: interferes with microtubules
Iodides			
SSKI	p.o.	Titrate 5–40 drops t.i.d.	Unknown

SSKI, saturated solution of potassium iodide.

Table 17.3. Principal Adverse Effects of Antifungal Agents

Amphotericin B	Flucytosine	Ketoconazole	Fluconazole	Itraconazole	Voriconazole	Terbinafine	Caspofungin
Fever, chills, nausea, vomiting	Suppression of bone marrow	Gastrointestinal distress	Gastrointestinal distress (less than with ketoconazole)	Gastrointestinal distress (less than with ketoconazole)	Visual disturbances	Gastrointestinal	Nausea, vomiting
Nephrotoxicity	Nausea, vomiting	Rash, pruritus	Rash	Rash	Rashes	Headaches	Fever
Thrombophlebitis	Diarrhea	Transiently increased hepatic enzymes	Headache	Pruritus	Photosensitivity	Dysgeusia	Rash
at site of administration	Increased hepatic enzymes	Severe hepatotoxicity (rare)	Transiently increased hepatic enzymes	Headache	Severe dermatologic reactions (rare)	Pruritus	Histamine reactions with infusion
Anemia	Rash	Alopecia	Severe hepatotoxicity (?)	Drizziness	Infusion-related anaphylactoid reaction	Urticaria	Phlebitis at administration site
Electrolyte imbalance (K ⁺ , Mg ²⁺)	Decreased synthesis of testosterone leading to diminished libido, impotence, and gynecomastia	Decreased synthesis of testosterone leading to diminished libido, impotence, and gynecomastia	Chapped lips	Transiently increased hepatic enzymes	Transiently elevated hepatic enzymes	Severe cutaneous reaction (rare)	
Pulmonary deterioration (rare)	Menstrual irregularities	Decreased synthesis of cortisol	Dry skin	Severe hepatotoxicity (?)	Severe hepato-toxicity (?)	Increased hepatic enzymes	
			Alopecia	Possible impotence and gynecomastia	Severe hepatotoxicity (?)	Severe hepato-toxicity (?)	
				Syndrome of mineralocorticoid excess			
				Congestive heart failure			

Adapted from Patel R. Antifungal agents, Part I. Amphotericin B preparations and flucytosine. *Mayo Clin Proc* 1998;73:1205–1225; and Terrell CL. Antifungal agents. Part II. The azoles. *Mayo Clin Proc* 1999;74:78–100, with permission.

- B. The pharmacokinetics of amphotericin B are poorly understood.** Amphotericin B is poorly absorbed from the GI tract. Systemic infections must be treated intravenously. No metabolism of the drug has been identified, and elimination occurs slowly via the biliary tract.
- C. Distribution.** The highest concentrations of amphotericin B are achieved in the liver, spleen, lung, and kidneys [153]. Distribution into spinal fluid, parotid gland fluid, aqueous humor, urine, and hemodialysis solutions is poor. Plasma levels do not predict treatment success.
- D. Dosage and administration. The method of calculating the dose of amphotericin B remains controversial.** Many experts maintain that duration of therapy is the best predictor of therapeutic success and advocate, for example, low doses daily for 6 to 12 weeks. Other experts advocate administration of high daily doses, if tolerated, until a specific total dose is achieved. **There is no consensus as to the optimal regimen, total dose, or total duration of therapy.** General guidelines are available, however, and depend on the clinical response, site of infection, identity of the fungus, and the patient's tolerance of the drug [150,151].
- 1. Some authorities suggest an initial test dose** of 1 mg i.v. over 30 minutes to 1 hour because rarely patients experience an idiosyncratic reaction of hypotension or an anaphylaxis-like reaction. The necessity of this test dose has been questioned [154] because it delays therapeutic doses. We do not routinely use a test dose.
 - 2. Several dosage regimens** are used. The dose may be gradually increased daily (by increments of 5–10 mg/day), or full-dose intravenous administration (e.g., 0.5 mg/kg/day) may begin immediately. **In seriously ill patients we prefer this latter approach.** The dose may be increased to as much as 0.7 to 1.0 mg/kg/day, although some prefer not to exceed a maximum daily dose of 50 mg.
 - 3. The daily dose is typically infused over 4 to 6 hours;** we prefer 4-hour infusion. Some authors believe a more rapid infusion of 1 to 2 hours may decrease the incidence or intensity of side effects (e.g., fever, chills, nausea, and vomiting). Studies suggest that more rapid infusions in patients with normal renal function are as well tolerated as the traditional 6-hour infusion [155]. Amphotericin B binds to some degree to cholesterol of mammalian cells, causing release of intracellular potassium, potentially resulting in severe hyperkalemia, especially in patients with renal failure. Therefore, **rapid infusion rates should not be used in patients with renal insufficiency** [156]. Arrhythmias have additionally occurred during amphotericin B administration, and rapid infusion rates should thus not be used in patients with cardiovascular disease [156]. In general, **we favor a 4-hour infusion for most patients.**
 - 4. Alternate-day or thrice-weekly regimens** may be used to minimize side effects. Thrice-weekly therapy facilitates outpatient or home administration. The usual maximum individual dose in these regimens is 50 to 80 mg.
 - 5. If serum creatinine rises to exceed 2.5 to 3.0 mg/dL or blood urea nitrogen exceeds 40 mg/mL,** many experts suggest lowering the dose, discontinuing the drug until renal function improves, or switching to alternate-day therapy. However, diminishing renal function does not affect the rate of elimination. Although amphotericin B is nephrotoxic, it does not accumulate in renal failure. Dosage adjustments are made to minimize toxicity, but hemodialysis patients usually receive full doses.
 - 6. Intrathecal or intraventricular amphotericin B** may be indicated for coccidioidal meningitis and in some refractory cases of cryptococcal meningitis [157]. Administration is technically complicated, and neurosurgical and infectious disease consultations are suggested.
- E. Toxicity**
- 1. Fever and rigors** during infusion are common in the first week of therapy and usually diminish thereafter. Fever and chills may be the result of amphotericin B-induced release of interleukin-1 and tumor necrosis factor from mononuclear cells [158,159], which leads to a secondary release of prostaglandin E₂. Because they alter the hypothalamic set point of the brain, prostaglandins have been implicated as a cause of fever and rigors. **Some physicians premedicate**

patients with a standard dose of acetaminophen (e.g., 650 mg orally for adults), diphenhydramine hydrochloride (Benadryl) (e.g., 25–50 mg i.v./orally for adults), and meperidine (e.g., 25–50 mg i.v. in adults) approximately 30 minutes before the infusion of amphotericin B. Because 25% of patients who have not received premedication fail to experience an adverse event with amphotericin B infusion, **we do not advocate the routine pretreatment regimens. However, if adverse reactions occur, use of pretreatment regimens in subsequent infusions of amphotericin B is advised [160]. If the patient has additional chills during the infusion, the dose of meperidine may be repeated at 3-hour intervals.** This routine decreases the incidence of fever and rigors in many patients. **Ibuprofen** (a single dose of 10 mg/kg up to a maximum dose of 600 mg) **is also useful as premedication [159].** Because protracted use of this agent should be associated with nephrotoxicity, ibuprofen may be helpful for the initial 1 to 2 weeks of therapy while tolerance to side effects is developing. Simultaneous administration of hydrocortisone, 25 to 50 mg i.v., may be effective when fever is particularly troublesome. Corticosteroids alone for pretreatment are not advised.

2. **Anorexia, nausea, and vomiting** are common but usually diminish as therapy progresses. Pretreatment with antiemetics may be helpful.
3. **Nephrotoxicity is the major dose limiting factor** in amphotericin administration [160]. Early toxicity is dose dependent, whereas later toxicity is related to the total dose. Renal function returns to nearly normal in most patients several months after therapy is stopped, but irreversible renal failure occurs. Renal function should be monitored at least every other day during the early stages of therapy. In the stable patient who is receiving intravenous amphotericin B at home or in an outpatient setting, serum creatinine (and potassium levels) should be monitored at least 2 to 3 times per week. Other renal abnormalities such as cylindruria and mild renal tubular acidosis are not used as guides to dosage but may be predictors of renal dysfunction.

The incidence of renal failure may be reduced if a saline infusion is given before each dose or if a high salt intake is maintained [161]. In patients who can tolerate the sodium load, we often give 500 mL to 1 L of normal saline over 1 to 2 hours before amphotericin B administration.

4. **Anemia** develops in more than 75% of patients, due to the inhibition of erythropoietin production and direct bone marrow suppression [162]. Leukopenia and thrombocytopenia are rare.
5. **Hypokalemia** from a renal tubular defect develops in 25% of patients and may require potassium supplementation. **Serum potassium levels should be monitored serially. Hypomagnesemia** may also occur.
6. **Infusion-related phlebitis** is common. Limiting the concentration of amphotericin to no more than 0.1 mg/mL reduces the incidence of phlebitis. The simultaneous infusion of heparin may also help to ameliorate phlebitis [160].
7. **Serious pulmonary reactions** with acute dyspnea, hypoxemia, and interstitial infiltrates on chest films have been described in patients receiving combined amphotericin B and leukocyte transfusions [163]. Therefore, it is advised that the interval between the infusion of amphotericin B and the leukocyte infusion is as long as possible.
8. **A preprinted order sheet**, including the saline load and premedications described in section E.1, **and preprinted flow sheet** are used by some institutions to monitor the daily and cumulative doses of amphotericin B, serum creatinine, and other therapies.
- F. **Pregnancy.** Amphotericin B has been used during pregnancy for the treatment of systemic fungal infections, without any adverse effects on fetal development.
- G. **Combination chemotherapy.** Addition of flucytosine may be synergistic, especially for cryptococcal infection in non-AIDS patients. Preliminary studies reporting the enhanced efficacy of amphotericin B in combination with other agents are encouraging but have been only studied in animal models of infection.
- H. **Empiric amphotericin B therapy in the persistently febrile granulocytopenic patient.** The source of fever in neutropenic patients often defies careful

physical and laboratory examination (including multiple cultures), and fever frequently persists despite broad-spectrum antibiotic therapy. Because the early diagnosis of disseminated fungal infection (e.g., candidemia) is very difficult, the empiric addition of a systemic antifungal agent is a consideration. Typically, if fever persists beyond 5 to 7 days despite negative blood cultures and broad-spectrum antibiotic therapy, empiric amphotericin B (commonly 0.5 mg/kg/day) often is started and continued until the leukopenia resolves [164]. Empiric amphotericin B sometimes is initiated even more rapidly (within hours) in the hospitalized leukopenic patient who has been stable for several days on broad-spectrum antibiotics and then becomes febrile and acutely ill. In addition to reculturing and broadening antibiotic therapy if indicated, empiric amphotericin B may be added for a possible disseminated fungal infection. The role of fluconazole as a substitute for amphotericin B in febrile neutropenic patients has been established in large prospective trials [4,22–24]. See discussion under Candidiasis, section III.D.4.a. **Infectious disease consultation is advisable in this setting.**

I. Cost (Table 17.4)

II. Lipid formulations of amphotericin B. With conventional amphotericin B, dosage is often limited by adverse effects. Targeted drug delivery systems using liposome technology has made it possible to give more amphotericin and to attain much higher drug level concentrations in some organs without any increase in systemic toxicity. Three lipid preparations are currently commercially available (26,165,166) (Table 17.4).

A. Mechanisms for improved therapeutic index

1. The mechanisms by which lipid formulations may enhance efficacy with a reduction in toxicity is unknown. However, the following is postulated:
 - a. Lipid-associated amphotericin B may be targeted preferentially to organs rich in macrophages that are commonly the site of fungal infection (i.e., liver, spleen, lungs).
 - b. The rapid uptake in tissue macrophages may spare the kidneys from the higher dose that is seen with the amphotericin B deoxycholate administration.
 - c. There may also be the selective transfer of amphotericin B from the donor lipid to the fungal cell membrane.

Table 17.4. Comparative Cost of Common Antifungal Agents

Agent	Route	Typical Daily Dose	Approximate Daily Cost
Amphotericin B			
Deoxycholate	i.v.	50 mg	\$ 23.28
Lipid preparations			
Abelcet	i.v.	5 mg/kg/day ^a	\$ 920.00
Ambisome	i.v.	3 mg/kg/day	\$ 942.00
		6 mg/kg/day	\$1,413.00
Amphotec	i.v.	4 mg/kg/day	\$ 559.98
Flucytosine	p.o.	100 mg/kg/day	\$ 112.40
Ketoconazole	p.o.	200 mg	\$ 2.78
		400 mg	\$ 5.96
Fluconazole	p.o.	400 mg	\$ 26.49
	i.v.	400 mg	\$ 191.29
Itraconazole	p.o.	200 mg	\$ 15.56
	i.v.	200 mg	\$ 184.97
Voriconazole	i.v.	400 mg	\$ N/A
	p.o.	400 mg	\$ N/A
Terbinafine	p.o.	250 mg	\$ 8.68
Caspofungin	i.v.	50 mg	\$ 360.00

^a All mg/kg doses were calculated for a 70-kg adult with normal renal function.

From 2002 *Drug topics red book*. New Jersey: 2000. Thomson Medical Economics, with permission.

d. *In vitro* data indicate that lipid preparations of amphotericin B do not elicit the release of pyrogenic cytokines to the same degree as amphotericin B deoxycholate. For further discussion on these proposed mechanisms, see the recent review by Slain [26].

B. Pharmacokinetics. Pharmacokinetic studies have been limited with lipid-based amphotericin B products. Further, no single clinical pharmacokinetic study has systematically compared the three commercially available lipid-based products with deoxycholate amphotericin B. Although these lipid formulations alter amphotericin B pharmacokinetics, it is uncertain if and how these changes affect clinical efficacy or toxicity. A compilation of pharmacokinetic studies with the lipid-based amphotericin B formulations is presented in a comprehensive review by Slain [26].

C. Clinical indications and dosage. These preparations are given i.v. once daily.

1. **Amphotericin B lipid complex** (Abelcet, ABLC) is approved for the treatment of invasive fungal infections in patients intolerant or refractory to amphotericin B [167]. The recommended dose is 5 mg/kg.

2. **Liposomal amphotericin** (Ambisome, L-AMB) is approved for the empiric therapy of presumed fungal infections in febrile neutropenic patients [168]. It is also approved for the treatment of patients with serious fungal infections who are refractory to or intolerant to amphotericin B deoxycholate. Recommended daily dose is 3 to 5 mg/kg.

3. **Amphotericin B colloidal dispersion** (Amphotec, ABCD) is approved only for the treatment of invasive aspergillosis in patients who fail treatment with or are intolerant to amphotericin B. The recommended daily dose is 3 to 4 mg/kg [169].

D. Clinical efficacy and toxicity

1. Although there is paucity of large, prospective, randomized trials, the cumulative data indicate that all the lipid formulations of amphotericin B have significantly less renal toxicity than amphotericin B deoxycholate. Infusion-related toxicity is still seen with lipid preparations but appears mildest with Ambisome. Abelcet and Amphotec appear to have a similar infusion-related toxicity and are intermediate between Ambisome and amphotericin deoxycholate.

2. The lipid formulations appear to be equally or more effective compared with treatment with amphotericin B deoxycholate. The ability to give higher dosages with less nephrotoxicity may take advantage of the drug's concentration-dependent pharmacodynamic effects.

3. Because of the high mortality of invasive aspergillosis and mucormycosis in the compromised host, it is our practice to initiate treatment with a liposomal AMB at the highest dose for these patients.

4. Because of their high costs, the lipid-based formulations should be reserved as an alternative therapy for patients who fail treatment with other antifungal agents, cannot tolerate deoxycholate amphotericin B, or are at great risk of developing renal failure if given amphotericin B.

III. Flucytosine (5-fluorocytosine, Ancobon) is an effective antifungal drug, but because drug resistance develops it rarely is used alone. It is active against *C. neoformans*, *Candida* species, and *Torulopsis* species in particular.

A. Mode of action. Flucytosine is converted within susceptible fungal cells to 5-fluorouracil and 5-fluor-2-deoxyureidylic acid, which inhibit the function of **RNA and DNA**, respectively, and result in subsequent cell death [170].

B. Distribution is excellent into all body water spaces, **particularly the CSF, where 60% to 80% of the serum drug level is achieved.**

C. Elimination. Approximately 90% of the drug is excreted unchanged in the urine, and so **reduced renal function will lead to accumulation of the drug.** In contrast, reduced hepatic function does not alter drug excretion. Protein binding is negligible, and flucytosine is removed by hemodialysis and peritoneal dialysis.

D. Mode of administration and dosage. This oral agent is well absorbed (>90%) from the GI tract. Only oral capsules (250 and 500 mg) are available.

1. Patients with normal renal function usually receive 12.5 to 37.5 mg/kg orally every 6 hours (i.e., 50–150 mg/kg/day). Most infectious disease consultants recommended a maximum daily dose of 100 mg/day.

Table 17.5. Recommended Dosages of Flucytosine in Patients with Renal Insufficiency

Creatinine Clearance (mL/min)	Dosage (mg/kg)	Interval (h)	Total Daily Dose (mg/kg)
>40	25	6	100
20–40	25	12	50
<20	25	24	25
<10	^a	^a	^a
Hemodialysis	25	After each hemodialysis	—

^a Avoid or adjust use to maintain peak serum level between 40 and 60 $\mu\text{g/mL}$. See text discussion.

From Patel R. Antifungal agents. Amphotericin B preparations and flucytosine. *Mayo Clin Proc* 1998;73:1205–1225, with permission.

2. **Dosage is reduced in the presence of renal impairment. The dose should be regulated by monitoring serum levels**, which should be maintained at less than 100 $\mu\text{g/mL}$ (preferably 40–60 $\mu\text{g/mL}$). Stamm et al. [171] published a nomogram to guide therapy. Also, see dose reductions in Table 17.5.
- E. Toxicity** is noted most often in patients with blood concentrations exceeding 100 $\mu\text{g/mL}$.
1. **Hepatic abnormalities** (e.g., elevation in transaminases) are seen in approximately 5% to 7% of patients and are generally asymptomatic and reversible. Fatal hepatic necrosis has been reported, and so weekly liver function panels are suggested.
 2. **Leukopenia and thrombocytopenia are potentially lethal complications** [171] and occur more commonly in those with previous bone marrow damage. In initial reports, many **AIDS patients** who receive flucytosine along with amphotericin B for the treatment of cryptococcal meningitis were reported to develop significant bone marrow suppression. Therefore, flucytosine use was advised with caution in AIDS patients; amphotericin B is often used alone in the treatment of HIV-related cryptococcal meningitis. Additional clinical studies, however, have determined that the combination of flucytosine and amphotericin B result in significant improvement in outcome without excess toxicity in the treatment of AIDS-associated cryptococcal meningitis as compared with amphotericin B alone [68]. Flucytosine has also been used successfully in combination with fluconazole to treat cryptococcal meningitis in patients with AIDS [172,173].
 3. **GI intolerance** usually is limited to mild diarrhea, but in severe cases patients have had copious diarrhea, anorexia, nausea, vomiting, and abdominal pain.
 4. **Teratogenic effects.** Flucytosine has been shown to be teratogenic in animals and therefore should be avoided during pregnancy unless the potential benefit is greater than the potential risk to the fetus.
 5. **Nursing mothers.** It is not known whether flucytosine is excreted in breast milk. Mothers should be advised to discontinue nursing if flucytosine is administered.
- F. Combination chemotherapy.** Although many isolates of *Candida* and *Cryptococcus* are sensitive to flucytosine, **the rapid emergence of drug resistance precludes the use of the drug as a single agent in serious infections.** The combination of flucytosine with amphotericin B has an additive or synergistic effect, both *in vitro* and *in vivo*, against *Candida* and *Cryptococcus*. The additive effects may not only offer increased efficacy but may also allow amphotericin B to be given in lower doses, thus decreasing the toxicity of this agent. **Unfortunately, amphotericin B may increase the toxicity of flucytosine by impairing its renal excretion. Therefore, serum concentrations of flucytosine must ideally be monitored in patients who are taking this combination** and the dosage lowered or the drug stopped if flucytosine accumulates. This combination is frequently recommended for cryptococcal meningitis [66,68] and, occasionally, for systemic candidiasis.
- G. Cost** (Table 17.4)

IV. Azoles. The azoles are safe and effective alternatives to amphotericin B for the treatment of many of the systemic mycoses [174]. They are also useful in the management of superficial mycoses recalcitrant to topical therapy. The azoles are chemically classified by the number of nitrogen atoms in their five-membered azole rings as either imidazoles (miconazole and ketoconazole) or triazoles (itraconazole or fluconazole). **All the azoles exert their fungistatic activity by the same mechanism:** inhibition of the biosynthesis of ergosterol, the main sterol in the fungal cell membrane, via interference with the cytochrome P450-dependent fungal enzyme C-14 lanosterol demethylase. This results in altered membrane permeability with inhibition of cell growth and replication. **Unfortunately, the azoles may also interact with mammalian enzymes that are dependent on the cytochrome P450 system, and this interaction may induce major toxicities and drug interactions.** The triazoles, as compared with the imidazoles, have much greater affinity for fungal rather than mammalian cytochrome P450 enzymes and, in general, have less toxicity and fewer drug interactions.

A. Miconazole (Monistat) is an imidazole that is available only in the United States as a topical preparation. See Chapter 16 for its topical uses. Its **usage as a systemic antifungal agent was limited by its toxicity and by the development of more effective and less toxic systemic azoles.**

B. Ketoconazole (Nizoral), an oral imidazole, was the first azole to prove clinically useful as a systemic antifungal drug.

1. **Antifungal activity.** Ketoconazole is active against clinical isolates of *Candida*, *C. immitis*, *H. capsulatum*, *B. dermatitidis*, and *Paracoccidioides brasiliensis*.
2. **Pharmacokinetics.** Only an **oral** preparation is available. Ketoconazole is well absorbed if there is enough gastric acidity. The administration of antacids, proton pump inhibitors, or H₂-blocking agents reduces absorption. Other situations that reduce gastric acid secretion (and that may reduce absorption) include aging, gastric surgery, and AIDS gastropathy. **Because of the uncertainty of absorption in these settings, many clinicians may prefer to use fluconazole** when appropriate. Sucralfate does not affect absorption.

The drug is extensively degraded *in vivo*, and very little active drug is excreted by either the renal or biliary pathway. Therefore, **the dose does not have to be changed in renal failure.** Whether dosage should be adjusted in hepatic failure is unknown. Isoniazid, phenytoin, and rifampin increase the metabolism of ketoconazole, and concurrent use of these drugs may result in treatment failure. Ketoconazole does not penetrate well into the CSF.

3. Clinical uses [175]

- a. **Chronic mucocutaneous candidiasis.** Ketoconazole has been very effective in treating this uncommon disease [10]. Chronic maintenance therapy over many years has been effective and well tolerated.
- b. **Dermatophyte infections.** Ketoconazole is indicated for the treatment of severe or recalcitrant cutaneous dermatophyte infections that have not responded to topical therapy or oral griseofulvin or for patients who are unable to take griseofulvin. It has also been used with success in onychomycosis due to *Trichophyton* species, *Microsporium* species, and *Epidermophyton floccosum*.
- c. **Oral thrush and candidal esophagitis.** These conditions in AIDS patients and others often respond well to ketoconazole. Treatment failure may result from the concomitant use of antacids, proton pump inhibitors, or H₂-receptor antagonists because an acid gastric pH is necessary for adequate absorption. Patients with AIDS frequently have gastric hypochlorhydria, which impairs ketoconazole absorption and may result in clinical failure.
- d. **Systemic fungal infections.** Ketoconazole may be used for the treatment of a variety of systemic fungal infections in immunocompetent patients who do not have life-threatening or CNS disease, including **histoplasmosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis.** (Itraconazole due to enhanced efficacy and less toxicity has supplemented the use of ketoconazole in most clinical situations.) Infectious disease consultation is recommended.

e. Miscellaneous

- (1) **Vaginal candidiasis.** The therapy of vaginal candidiasis is discussed elsewhere (see Chapter 16). Ketoconazole is not indicated in the routine management of this problem.
- (2) **Prophylaxis of fungal infections in neutropenic patients with ketoconazole is not advised.**
- (3) ***Candida balanitis*** often responds well to a 7- to 10-day course of ketoconazole.

4. Dosage. Ketoconazole is available in a scored 200-mg tablet.

- a. Adults.** The usual starting dose for superficial candidal or dermatophyte infections is 200 mg/day. Higher doses (400–800 mg/day) are used in the treatment of histoplasmosis, blastomycosis, and coccidioidomycosis [50,122]. In a patient with candidal esophagitis and AIDS, 400 mg/day may be necessary. **Achlorhydria or concurrent administration of agents that decrease gastric acidity** (e.g., antacids, anticholinergics, proton pump inhibitors, or H₂ blockers) **decreases the absorption of ketoconazole.** Administering ketoconazole with cola or another liquid with an acid pH (e.g., orange juice) may improve its absorption. In such circumstances, however, fluconazole, which does not require an acid pH for absorption, is preferable.
- b. Children.** In small numbers of children older than 2 years, ketoconazole in a single daily dose of 3.3 to 6.6 mg/kg has been used successfully (see the package insert). The potential benefits should outweigh the risks before using ketoconazole in children.
- c. The duration of treatment** must be individualized depending on the presence of associated diseases and response to therapy. Usually only 1 or 2 weeks of treatment are necessary for the management of superficial *Candida* infections. A minimum treatment period of 6 months is recommended for the systemic mycoses [50,122].
- d. In renal failure** dose modification is not necessary. Ketoconazole is not substantially removed by hemodialysis or peritoneal dialysis.
- e. In hepatic insufficiency** no dose adjustment is necessary for mild to moderate hepatic insufficiency. In patients with severe liver failure, ketoconazole should be avoided or the dose reduced and serum levels monitored if no alternative agent is available.
- f. Cost** (Table 17.4)

5. Contraindications or drug interactions

- a. Pregnancy.** Ketoconazole is teratogenic in the rat model and should be avoided in pregnancy.
- b. Nursing mothers** who must receive ketoconazole should not breast-feed for the duration of treatment.
- c. Drug interactions**
 - (1) Ketoconazole increases the blood levels of **cyclosporine, digoxin, and phenytoin.** Serum levels of these drugs should be carefully monitored.
 - (2) **The coadministration of ketoconazole with terfenadine or astemizole is contraindicated.** When ketoconazole is administered with either of these antihistamines, it may prolong the QT interval, sometimes causing life-threatening ventricular arrhythmias [175,176]. A similar interaction has been described in patients receiving **cisapride (Propulsid)** for upper gastrointestinal motility problems.
 - (3) **Isoniazid, rifampin, and phenytoin** increase the metabolism of ketoconazole. These drugs should not be used concomitantly. Monitoring serum ketoconazole levels may be helpful.
 - (4) **The anticoagulant effect of coumadin** may be enhanced by ketoconazole. The patient's prothrombin time should be followed closely.
 - (5) Ketoconazole may potentiate the hypoglycemic effect of some oral **hypoglycemic agents.**

6. Adverse effects. In general, ketoconazole is well tolerated (Table 17.3) [175,177].

- a. **Nausea** is the most common side effect. It can be reduced when ketoconazole is taken with food or at bedtime. Abdominal pain may occur.
 - b. **Pruritus and skin rashes** are not uncommon. **Anaphylaxis** after the first dose has been reported rarely.
 - c. **Hepatotoxicity** due to hepatocellular damage **may occur**, and rare fatalities damage have been reported. Liver damage usually is reversible when the drug is discontinued. **Liver function tests should be obtained before starting therapy and at frequent intervals during drug administration**, especially in patients on prolonged therapy or those receiving other potentially hepatotoxic agents. Transient minor liver function test elevations often occur during ketoconazole therapy. The drug should be discontinued if elevated levels of transaminases persist or are three to five times greater than normal.
 - d. **Miscellaneous.** Gynecomastia in men, rashes, dizziness, constipation, and diarrhea have occurred. Temporary suppression of serum testosterone levels and of adrenal cortisol production in response to adrenocorticotropic hormone has been described. Rarely, adrenal crisis has been reported in the setting of high-dose ketoconazole therapy [178]. Oligospermia may occur at high daily doses, especially if the dosage exceeds 400 mg/day. Loss of libido and loss of potency also have been reported [179].
- C. Fluconazole (Diflucan)** is a bis-triazole antifungal that was released in 1990. Fluconazole is indicated for the treatment of candidal infections and for initial treatment (of selected patients) and prevention of cryptococcal meningitis in AIDS patients. It is available in both an intravenous and an oral preparation.
- 1. Pharmacokinetics**
 - a. **Absorption** from the GI tract is **excellent**, with oral bioavailability exceeding 90% [179–181]. Serum levels are similar after oral and intravenous administration. **Gastric acid is not required for absorption.** Absorption is not reduced by concomitant use of H₂ blockers or antacids.
 - b. There is little metabolism of fluconazole, and renal excretion accounts for approximately 80% of its elimination as unchanged drug. Therefore, **dosage reduction is necessary in patients with renal failure.**
 - c. **Urine concentrations of fluconazole are high.** Thus, it may be an effective agent in urinary tract candidiasis [181].
 - d. Fluconazole has **excellent penetration into the CSF**, with levels reaching 60% to 80% of serum levels.
 - e. Fluconazole diffuses well into sputum, saliva, skin, and the vitreous and aqueous humor of the eye. Pharmacokinetics are similar in healthy young adults and in the elderly [180].
 - 2. Clinical uses**
 - a. Fluconazole has proven useful for **cryptococcal meningitis in AIDS patients** as both initial therapy and maintenance therapy. Amphotericin B, however, is preferred as initial therapy in those patients who are seriously ill or confused or who have other poor prognostic findings. In these patients, fluconazole may be substituted for amphotericin B once the patient has clinically stabilized and the CSF parameters have improved (see Cryptococcosis, above, and Chapters 6 and 18). For maintenance therapy of AIDS patients, oral fluconazole (200–400 mg/day) is the treatment of choice.
 - b. Fluconazole is effective in the treatment of **oropharyngeal and esophageal candidiasis** in immunocompromised hosts [6,179].
 - c. Fluconazole is not recommended for the routine management of **vaginal candidiasis**. However, it may be helpful in selected patients who fail topical therapy or who have frequent recurrences (see Chapter 16).
 - d. The use of fluconazole for patients with **candidemia and systemic candidiasis** has been controversial. However, recent studies indicate that fluconazole has equivalent efficacy to amphotericin B for treating these syndromes in patients with and without neutropenia. See section **III.D** under Candidiasis, above.

- e. Fluconazole has also been used successfully to prevent candidiasis in patients undergoing bone marrow transplantation. Unfortunately, an increased rate of infections due to fluconazole-resistant *C. krusei* was noted in these studies [182,183]. Many AIDS patients receive fluconazole either continuously or intermittently over long periods of time. Concomitant with its widespread use (over 15 million patients since 1988), there have been **increasing reports of fluconazole resistance**. This topic has been reviewed elsewhere [184].
 - f. The role of fluconazole in the treatment of coccidioidomycosis, histoplasmosis, blastomycosis, and sporotrichosis is currently under investigation. Initial studies indicate that fluconazole will be a useful agent in treating coccidioidal meningitis.
 - g. **Hepatosplenic candidiasis** has responded to fluconazole (see section III.F.1 under Candidiasis, above).
- 3. Dosages.** Because fluconazole is well absorbed after oral therapy, **the daily doses for oral and intravenous therapy are the same**. Intravenous administration is preferred when GI motility is impaired or nasogastric suction is used. Tablets are available in 50, 100, or 200 mg. A suspension is also available.
- a. **For oropharyngeal candidiasis**, 200 mg on the first day followed by 100 mg once daily is continued until infection has subsided. Most patients respond in a few days, and treatment for longer than 1 week usually is not necessary. Frequent relapses of disease are noted in AIDS patients, and maintenance therapy has proven helpful in these instances. We found a dose of 100 mg once weekly is effective in preventing relapse in most of our patients [7].
 - b. **For esophageal candidiasis**, 200 mg on the first day followed by 100 mg once daily is routinely suggested. Higher doses (up to 400 mg/day) may be necessary. Patients should be treated for a minimum of 2 weeks.
 - c. **Systemic candidiasis or candidemia**. Two recent randomized trials indicate that non-neutropenic patients treated with fluconazole, 400 mg/day, have similar outcomes to those treated with amphotericin B [22,23]. However, some non-*albicans* species, such as *C. krusei*, are resistant to fluconazole, and amphotericin B should be used in individuals infected with these organisms.
 - d. **For cryptococcal meningitis**
 - (1) **For suppression of relapse** in patients with AIDS, 200 mg once daily is suggested [67–69].
 - (2) **For primary therapy of cryptococcal meningitis** in patients with AIDS, after an initial 400 mg on the first day, 200 to 400 mg once daily may be effective in selected low-risk patients [65]. However, most experts recommend an initial course of amphotericin, followed by fluconazole once the patient has clinically stabilized and the CSF parameters have improved. Infectious disease consultation is advised in this setting. See section IV.A.3 under Cryptococcosis, above.
 - (3) The role of fluconazole in the treatment of cryptococcal meningitis in HIV-negative individuals is yet to be defined.
 - e. **Dosage needs to be reduced in patients with renal failure**. After the initial loading dose, the following dose reductions are suggested: For a creatinine clearance in excess of 50 mL/min, give the normal dose; if the clearance is 21 to 50 mL/min, give 50% of the usual dose; if the clearance is 11 to 20 mL/min, give 25% of the usual dose. In patients on regular hemodialysis, give the usual dose once after each dialysis treatment.
 - f. **Intravenous fluconazole** is used in patients who cannot take the oral, less expensive, route, as in patients who have nausea and vomiting, are taking nothing by mouth, and so on. Otherwise, there is no advantage of the intravenous preparation, which provides serum concentrations similar to the oral preparation. For dosages see section 3.
 - g. **Pregnancy**. The package insert notes that there are no adequate and well-controlled studies in pregnant women; this agent should be used in pregnancy only if the potential benefit justifies the possible risk to the fetus.

- h. Nursing.** The package insert notes that fluconazole is excreted in human milk at concentrations similar to plasma. Therefore, the use of fluconazole in nursing mothers is not recommended.
- 4. Side effects.** Fluconazole has been well tolerated, with reports of toxicity most frequent in AIDS patients (Table 17.2) [179,180].
- Rash** occurs in fewer than 5% of recipients.
 - Nausea and vomiting** occur in 2% to 10% of recipients. Nausea is less frequent with fluconazole than with ketoconazole.
 - Stevens-Johnson syndrome** and **hepatotoxicity** are reported rarely. Transient elevations of liver function tests are relatively common in AIDS patients.
 - Fluconazole affects adrenal steroid synthesis much less than does ketoconazole. Endocrine side effects, including impotence, gynecomastia, and menstrual disturbances, are reported less frequently.
- 5. Drug interactions.** Drug interactions are less frequent and less pronounced as compared with ketoconazole. When another agent is administered with fluconazole, the following drug interactions may occur.
- Rifampin** decreases serum concentrations of fluconazole.
 - The hypoglycemic effects of oral agents, especially **tolbutamide**, may be enhanced.
 - Warfarin, phenytoin, rifabutin, and cyclosporine** levels are variably increased, especially with higher doses of fluconazole [185]. Monitoring the prothrombin time or serum drug levels is important in patients receiving fluconazole.
 - The potential interaction between fluconazole and terfenadine or astemizole has not been adequately studied. Until these data are available, it seems prudent to avoid these combinations.** Fluconazole may interact with **cisapride** (Propulsid), and these two agents should not be used together.
- 6. Cost.** Fluconazole is expensive (Table 17.4).
- D. Itraconazole (Sporanox)** is a triazole that was originally released as an oral agent for the systemic treatment of fungal infections. It has subsequently been formulated with a β -cyclodextrin as an oral suspension and intravenous agent [186–188]. It is approved for primary therapy of histoplasmosis and blastomycosis. Recent approval has been obtained for the treatment of invasive aspergillosis.
- 1. Pharmacokinetics**
- Absorption of the capsules** while fasting is only 30% to 40%. **Bioavailability** is significantly **enhanced by food**, and it is recommended that the drug be taken with meals. Absorption is also enhanced by the presence of gastric acid and is reduced by antacids [187].
 - The oral suspension** is better absorbed on an empty stomach and is less dependent on acid for absorption.
 - Itraconazole is **highly protein bound** (99.8%), and there is little or no CSF penetration.
 - The drug is lipophilic, and **tissue levels exceed serum concentrations**. The drug can be detected in tissue, including the skin and nails, for longer periods of time than in serum after the drug has been discontinued.
 - Extensive hepatic metabolism occurs, but one of the major metabolites has antifungal activity. Less than 1% of active drug is excreted in the urine.
 - Renal failure, hemodialysis, and peritoneal dialysis do not alter serum levels or metabolism of itraconazole when given as capsules or suspensions. Note, however, that the β -cyclodextrin present in the intravenous preparation is excreted by the kidneys [188].
- 2. Clinical uses**
- Itraconazole currently is approved for the treatment of **histoplasmosis** and **blastomycosis** [50,122] and as an alternative agent in aspergillosis [96]. See individual discussions of these topics earlier in this chapter.
 - Itraconazole has a broad range of *in vitro* antifungal activity, including *Candida* species, *C. immitis*, *S. schenckii*, *C. neoformans*, and *Aspergillus* species.

- c. Itraconazole has proven helpful in the management of selected patients with chronic skin and nail infections due to dermatophyte fungi. The role of itraconazole for onychomycosis was recently reviewed; doses of 200 mg once a day, with a meal, for 3 months are suggested [189,190].
3. **Dosage.** Itraconazole is available in 100-mg capsules, which **should be taken with meals**. An oral suspension is also available and has enhanced bioavailability. The availability of an intravenous preparation has proven useful in patients unable to tolerate oral medications. Doses above 200 mg/day should be given in divided doses.
- a. **Histoplasmosis and blastomycosis.** In a recent prospective trial, patients treated with 200 mg/day had a similar outcome to those treated with 400 mg/day. Thus, the initial recommended daily dose of itraconazole is 200 mg. Patients whose disease progresses on therapy should have their dose increased in 100-mg increments to a maximum daily dose of 400 mg. A minimum of 6 months' therapy is recommended, but the successful treatment of histoplasmosis frequently requires treatment for 1 year or longer [50,122].
- b. **Aspergillosis.** Itraconazole was later approved for use in the treatment of pulmonary and extrapulmonary aspergillosis in patients who are intolerant of or refractory to amphotericin B therapy. A loading dose of 200 mg three times day should be given for the first 3 days (in severe infection) and then 200 to 400 mg/day is suggested. Itraconazole has also been used for the treatment of ABPA and mycetomas [85,86].
- c. Although not FDA approved for **sporotrichosis**, initial studies indicate that itraconazole is an effective alternative to potassium iodide in this setting. For cutaneous or lymphocutaneous disease, the usual dose is 200 mg/day for 3 to 6 months. Higher doses (200 mg twice daily) are used for osseous or articular disease and pulmonary disease [133,135]. Therapy for 1 or 2 years may be required in extracutaneous disease. Infectious disease consultation is recommended.
- d. **Pediatric use.** The safety and efficacy of itraconazole in children has not been established.
- e. **Renal failure.** Dosage adjustments of the capsules and suspension are not necessary in renal failure. Neither hemodialysis nor peritoneal dialysis alters serum levels of itraconazole. The β -cyclodextrin contained in the intravenous formulation is cleared by the kidneys. As such, dose should be adjusted in patients with renal insufficiency. It is recommended that intravenous itraconazole should not be used in patients with a creatinine clearance of less than 30 mL per minute.
- f. **Hepatic dysfunction.** Whether dosage adjustment is necessary in patients with hepatic dysfunction is unclear. Plasma concentrations should be monitored in patients with severe hepatic insufficiency.
4. **Toxicity.** Itraconazole is generally well tolerated in the currently recommended doses of 200 to 400 mg/day. Toxicity is reported more frequently at doses of 600 mg or higher.
- a. **Nausea and vomiting** are seen in approximately 10% of patients but usually do not necessitate discontinuation of therapy. Giving the dose with the evening meal or dividing the daily dosage into two equal doses may be helpful.
- b. **Liver function abnormalities** are mild and transient; symptomatic hepatitis is rare.
- c. Less common side effects include **pruritus, skin rash, headache, hypertension, hypokalemia, pedal edema, and congestive heart failure**.
- d. **Impotence**, usually reversible, has been reported despite normal testosterone levels.
- e. At doses of less than 600 mg/day, itraconazole has little or no effect on adrenal cortisol production.
5. **Drug interactions** have been well documented between itraconazole and a variety of other medications. Compared with ketoconazole, it is not as potent an inhibitor of liver microsomal enzymes.

- a. **Antacids, and possibly proton pump inhibitors and H₂-receptor antagonists**, will decrease peak serum levels and so should be avoided if possible.
 - b. **Rifampin and phenytoin** will induce the metabolism of itraconazole and **result in decreased serum levels**. The dosage of itraconazole may need to be increased in patients failing therapy when these agents are used concurrently. Some suggest that concurrent use of rifampin, phenytoin, carbamazepine, and phenobarbital should be avoided in patients receiving itraconazole for life-threatening infection (e.g., invasive aspergillosis) [86].
 - c. **The coadministration of itraconazole and terfenadine, or astemizole, is contraindicated. A prolonged QT interval and life-threatening ventricular arrhythmias have been reported** [191]. A similar potential interaction has been noted for **cisapride** (Propulsid).
 - d. Itraconazole will raise the levels of **cyclosporine, digoxin, and phenytoin** when coadministered with these agents. Levels should be monitored.
 - e. The anticoagulant effect of **warfarin** may be increased by itraconazole.
 - f. The hypoglycemic effect of **oral sulfonylurea drugs**, especially tolbutamide, may be enhanced when coadministered with itraconazole.
- 6. Pregnancy.** Itraconazole is teratogenic in rats and should not be given during pregnancy unless benefits outweigh potential risks. The drug is secreted in breast milk and should not be administered to nursing mothers.
- 7. Cost.** Itraconazole is an expensive agent (Table 17.4).
- E. Voriconazole** is a new triazole antifungal agent recently approved for the treatment of invasive aspergillosis. In addition, it has also been approved for the treatment of serious fungal infections caused by *Scedosporium apiospermum* (the asexual form of *Pseudallescheria boydii*) and *Fusarium* species in patients intolerant or refractory to other therapies. Voriconazole also has good activity *in vitro* against many other pathogenic fungi, including *Candida* species, *Cryptococcus* species, and *Dermatophyte* species [192–194]. Voriconazole can be administered either orally or parenterally and has a favorable adverse events profile. The most commonly reported adverse effects are visual disturbances and elevation in liver function tests.
- 1. Pharmacokinetics** [195,196]. Voriconazole is available for both oral and intravenous administration and has a wide tissue distribution, including the CNS. The drug is hepatically metabolized with the renal excretion of metabolites and exhibits nonlinear pharmacokinetics.
 - a. **The oral tablets contain 50 or 200 mg of voriconazole.** The bioavailability of these tablets is approximately 96% in humans, and peak concentrations occur within 2 hours after an oral dose. Other pharmacokinetic properties of voriconazole are similar after intravenous and oral administration.
 - b. **The intravenous formulation contains a sulfobutyl ether β -cyclodextrin.** This cyclodextrin is not excreted by the kidneys and thus may accumulate in patients with renal failure. Dosage adjustment is necessary for patients with renal failure.
 - c. Approximately 58% of voriconazole in the blood is protein bound.
 - d. The distribution of voriconazole is rapid and extensive; the volume of distribution is 4.6 L/mg. Concentrations have been measured in the CSF between 30% and 68% of simultaneous serum concentrations.
 - e. **Voriconazole is metabolized in the liver** by the cytochrome P450 enzyme system. The pharmacokinetics of voriconazole are nonlinear due to saturation of its metabolism. A dosage adjustment is necessary in patients with hepatic insufficiency.
 - f. Peak plasma concentrations approach steady-state levels in the first 24 hours of dosing if a loading dose is administered.
 - 2. Clinical usage**
 - a. Voriconazole is approved for the treatment of invasive aspergillosis, both as primary or salvage therapy. **As primary therapy for invasive aspergillosis**, a satisfactory response rate of 53% was reported for voriconazole as compared with 32% in amphotericin B-treated patients. In the combined clinical

vinca alkaloids will result in increased activity of these drugs. Although not contraindicated, careful monitoring or dosing adjustment of these drugs is required.

- c. Some drugs when given concurrently will result in significant reduction in voriconazole serum/tissue levels and may adversely effect clinical outcome. These include rifampicin, rifabutin, and phenytoin. Increasing the voriconazole dose in patients receiving these agents is suggested. Avoiding the use of these agents in patients with life-threatening infections seems more prudent.
 - d. Although not well studied, carbamazepine and long-acting barbiturates are also likely to decrease plasma voriconazole concentrations.
 - e. Little or no significant interactions have been noted between voriconazole and cimetidine, ranitidine, digoxin, macrolide antibiotics, or indinavir.
- 6. Voriconazole is Pregnancy Category D and should not be used in pregnant women.**
- 7. Pediatric experience is limited but promising [198], and the safety of voriconazole in children has not been adequately established.**
- V. Echinocandins** are a new class of antifungal drugs that inhibit the synthesis of B-(1,3)-d-glucan, an integral component of the fungal cell wall. Caspofungin acetate (Cancidas) is the first glucan synthesis inhibitor commercially available [100]. Caspofungin acetate is currently indicated only for the treatment of invasive aspergillosis in patients refractory or intolerant to other therapies. Because of its excellent *in vitro* and *in vivo* activity against isolates of *Candida* species (including non-*albicans Candida*), caspofungin will assume a prominent role in the treatment of patients with invasive candidiasis and candidemia. **Caspofungin has little or no activity *in vitro* or *in vivo* against *Cryptococcus neoformans* or *Mucor* species.**
- A. Pharmacokinetics of caspofungin**
1. **Caspofungin acetate** is only available as an intravenous formulation.
 2. **Caspofungin** is extensively bound to albumin (approximately 97%).
 3. **Caspofungin** is slowly metabolized by hydroxylation and *N*-acetylation. Thus, dosing adjustments are necessary in patients with liver failure.
 4. **Dosing in patients with renal failure.** No dosage adjustment is necessary for patients with renal insufficiency. Caspofungin is not dialyzed, and supplemental dosing after hemodialysis is not necessary.
- B. Clinical uses**
1. Caspofungin is currently indicated only for the treatment of invasive aspergillosis in patients refractory or intolerant to other therapies, including amphotericin B, lipid formulations of amphotericin B, or itraconazole. Studies using caspofungin as initial therapy for invasive aspergillosis have not been completed. Although this is the only approved use, observations in disseminated candidiasis and refractory candida esophagitis in AIDS suggest that approval for these uses will occur very soon.
 2. Caspofungin exhibits good *in vitro* activity against *Aspergillus fumigatus*, *Aspergillus flavus*, and *Aspergillus terreus*.
 3. Sixty-nine patients were enrolled in an open-label noncomparative study of caspofungin in patients with invasive aspergillosis intolerant or refractory to other therapies. Sixty-three patients met entry criteria and had outcome data. Overall, 41% (26 of 63) receiving at least one dose of caspofungin had a favorable response. For those patients who received greater than 7 days of therapy, 50% had a favorable response. The favorable response rate for patients intolerant to previous therapy was 70% as compared with 36% of those who failed previous therapy.
 4. **Combination therapy with caspofungin and itraconazole** has been used successfully in the treatment of patients with invasive aspergillosis who have failed monotherapy. We believe that combination therapy may be especially important in patients with prolonged immunosuppression.
- C. Dosage**
1. For the treatment of invasive aspergillosis a single 70-mg intravenous dose is given on day 1 followed by 50 mg/day thereafter. Limited safety data indicate that

a 70-mg daily dose is also well tolerated. Doses above 70 mg/day are currently undergoing evaluation but have not been adequately studied for either safety or efficacy.

2. No dosage adjustments are needed in patients with renal failure.
3. **Dosing in patients with hepatic insufficiency.** No dosage adjustments are needed for patients with mild hepatic insufficiency (Child-Pugh class A). For patients with moderate hepatic insufficiency (Child-Pugh class B) the daily dose (after the initial 70-mg loading dose) should be reduced to 35 mg. There is no clinical experience in treating patients with severe hepatic insufficiency as defined by Child-Pugh class C.

D. Toxicity. Caspofungin is generally well tolerated in the currently recommended doses of 50 to 70 mg/day.

1. **Histamine-mediated symptoms** during infusion have been reported. Symptoms include rash, facial swelling, pruritus, and the sensation of warmth. Anaphylaxis has also been rarely reported.
2. Other reported adverse effects include fever, rash, nausea, vomiting, and phlebitis at the injection site.
3. Elevations in hepatic transaminases have also been reported especially when caspofungin and cyclosporine are given concurrently.

E. Drug interactions. Caspofungin is not an inhibitor of any of the enzymes in the cytochrome P450 system. Additionally, caspofungin does not appear to induce the CYP 3A4 metabolism of other drugs.

1. Although caspofungin is not metabolized by the hepatic cytochrome system, its concurrent use with other drugs that broadly activate hepatic enzyme systems may accelerate the metabolism of caspofungin. This may have an adverse effect on clinical outcome. Thus, increasing the dose of caspofungin is warranted when administered with efavirenz (Sustiva), nelfinavir (Viracept), phenytoin, dexamethasone, rifampin, and carbamazepine.
2. Serum levels of tacrolimus are reduced by approximately 25% when caspofungin is coadministered.

F. Special considerations

1. Caspofungin is **Pregnancy Category C** and should only be used in pregnant women if the potential benefits of therapy justifies the potential risk to the fetus.
2. Safety in pediatric patients has not been adequately established.

VI. Allylamines. The allylamines exert their antifungal activity by inhibition of the fungal squalene epoxidase. Inhibition of this enzyme not only decreases ergosterol synthesis but also results in the accumulation of squalene, which is toxic to the fungus and is responsible for the fungicidal action seen with this class of agents [199]. The first of these compounds available for systemic use is terbinafine (Lamisil). Terbinafine is the most active antifungal agent *in vitro* against the dermatophyte fungi. Hence, its primary use is for treatment of onychomycosis of the toenails or fingernails due to the dermatophytes (tinea unguium).

A. Pharmacokinetics [199]

1. Terbinafine is well absorbed from the GI tract (>70%) with a peak plasma concentration occurring within 2 hours after an oral dose.
2. Terbinafine is greater than 99% bound to plasma proteins.
3. The drug is also lipophilic and keratophilic, which results in a depot effect in the skin and nails. A terminal elimination half-life of 200 to 400 hours has been reported and represents the slow elimination of terbinafine from skin and adipose tissue.
4. Before excretion, terbinafine is extensively metabolized in the liver. Most metabolites (70%–80%) are excreted in the urine.

B. Clinical indications and dosage [199]. Terbinafine tablets are currently indicated only for treatment of onychomycosis of the toenails or fingernails. Antifungal activity has been established *in vitro* against other fungi, including *S. schenkii* and *C. albicans*. Clinical efficacy in treating lymphocutaneous sporotrichosis has also been documented, but this usage is not currently FDA approved.

1. Onychomycosis [190,199,200]

- a. **Fingernails.** A dose of 250 mg/day given over 6 weeks is currently recommended for onychomycosis of the fingernails. Clinical and mycologic cure rates are reported in up to 60% of patients.
- b. **Toenails.** For treatment of toenail infections, the same daily dose is extended for 12 weeks. Clinical and mycologic cure rates of 38% to 59% have been reported.
- c. **Relapse** of infection (especially of toenails) after apparent successful therapy is significant and remains problematic.
- d. **Alternative treatment regimens that take advantage of the high concentrations achieved in the nails and skin (depot effect) have been developed.** In these "pulse therapy" protocols, 500 mg of terbinafine is given daily for 1 week for 4 successive months for toenail infections and 3 months for fingernail infections. Cure rates for patients treated with terbinafine pulse therapy was similar for that reported in patients treated with daily terbinafine or pulse with itraconazole.

2. **Sporotrichosis.** Terbinafine has also shown clinical efficacy in the treatment of lymphocutaneous sporotrichosis. In open-label studies, terbinafine in a daily dose of 250 to 500 mg had a favorable clinical response [135].

C. Toxicity. In general, terbinafine has been well tolerated. The most frequently reported toxicities are as follows [199]:

1. GI symptoms (nausea, abdominal pain, diarrhea) are most common and are dose dependent.
2. Skin reactions, headache, and dysgeusia are also uncommonly reported.
3. Elevated hepatic transaminases are also reported. Rare cases of liver failure, some leading to death or transplantation, have been reported. Thus, liver function studies should be monitored regularly.

D. Drug interactions. Terbinafine is metabolized in the liver by the cytochrome P450 enzyme system. However, it has only moderate affinity for these enzymes and has less drug interaction than noted for the azoles.

1. Terbinafine does not effect the clearance of digoxin, warfarin, or terfenadine.
2. Terbinafine does increase clearance of cyclosporine by approximately 15% and monitoring drug levels is prudent.
3. Rifampin increases the clearance of terbinafine by 100%, and this combination of drugs should be avoided.
4. Cimetidine decreases the clearance of terbinafine by approximately one-third.

E. Special considerations.

1. **Terbinafine is Pregnancy Category B** and should not be initiated during pregnancy.
2. The safety and efficacy of terbinafine has not been established in pediatric patients.

VII. Other agents

A. Potassium iodide has long been an effective agent for the treatment of the cutaneous-lymphatic form of sporotrichosis. See the discussion in section **III** under Sporotrichosis.

B. Griseofulvin is produced by a species of *Penicillium*. It exerts its fungicidal activity by inhibiting fungal mitosis, most likely due to the polymerization of cell microtubules and disruption of the mitotic spindle [201]. Griseofulvin is active against the dermatophytes (*Trichophyton*, *Epidermophyton*, and *Microsporum* species) that cause ringworm of the skin, hair, and nails. It has no clinically significant activity against *Candida* species or any other pathogenic fungi.

1. **Mode of administration.** Griseofulvin is sold in a microsize form in capsules (125 and 250 mg), in an ultramicrosize form in tablets (165 and 330 mg), and as a pediatric suspension (125 mg/5 mL) [201].

- a. The **usual adult dose** is 500 mg/day of the microsize preparation or 330 mg of the ultramicrosize preparation given as a single daily dose. In severe or more recalcitrant cases of disease, these doses may be doubled.
- b. The duration of therapy varies depending on the site of infection and clinical response. For skin infections, treatment courses of 4 to 8 weeks usually

are curative. Nail infections are more difficult to treat and usually require a minimum of 4 months for fingernails and 6 months for toenails.

2. **Toxicity and drug interactions.** Griseofulvin is **generally well tolerated**. Headache is common but usually resolves during the first week of therapy. A variety of skin reactions has been reported and may necessitate stopping the drug. Occasionally nausea, vomiting, a bad taste in the mouth, paresthesias of the hands and feet, insomnia, confusion, or dizziness may occur. Reversible granulocytopenia and hepatotoxicity have been reported. Patients on high-dose or prolonged therapy should have blood count and liver tests followed on a routine basis.

ACTINOMYCOSIS

Actinomyces species are gram-positive **filamentous bacteria** that once were classified as fungi. These organisms cause subacute and chronic granulomatous inflammations that closely resemble true fungal infections.

- I. **Growth and identification characteristics.** Clinical actinomycosis is almost always caused by *Actinomyces israelii* [202]. *Actinomyces* can be grown on routine culture media with augmentation using brain–heart infusion. The **primarily anaerobic character of *Actinomyces* requires rapid transport of abscess material to the laboratory or direct inoculation into an anaerobic container**. Mature colonies may be present after 3 to 7 days of incubation. In some cases, however, growth may take up to 21 days. Prior antibiotic use may dramatically decrease culture yields. We recommend notifying the laboratory to hold all cultures for at least 21 days when the diagnosis of actinomycosis is suspected. *A. israelii* is seen on Gram stains of exudates or tissue sections as pleomorphic, beaded, branching gram-positive rods. Infection with *Actinomyces* may result in the formation of yellow, white, gray, or brown macroscopic particles called **sulfur granules**, which represent conglomerate masses of organisms.
- II. **Epidemiologic features.** *Actinomyces* is worldwide in distribution and is a common saprophyte of the oral cavity, pharynx, and intestines. Therefore, **simple recovery of the organism from culture does not necessarily establish the presence of infection**.
- III. **Pathogenesis.** The normal commensal status of *Actinomyces* is altered when the organism gains entrance to deeper tissues through a break in intact mucous membranes. Once it enters a microaerophilic or anaerobic atmosphere, *Actinomyces* produces a subacute or chronic granulomatous infection with a tendency to cause externally draining sinuses.
- IV. **Clinical syndromes.** Actinomycosis most commonly involves the cervicofacial, thoracic, or abdominal regions and on occasion the CNS.
 - A. **Cervicofacial actinomycosis** commonly occurs one to several weeks after dental extraction or minor trauma to the oral mucous membrane or in association with poor oral hygiene.
 1. **Manifestations.** The patient usually has a bluish swollen lesion at the angle of the mandible or in the neck. The lesion may enlarge slowly and may be painless or may progress rapidly and cause considerable pain. A visible sinus tract or fistula may be present. Sulfur granules may be seen in the exudate. Nonspecific symptoms of fever, weight loss, chills, and trismus may occur. Infection spreads without regard to fascial tissue planes and may involve the salivary and lacrimal glands, mandible, orbit, or paranasal sinuses.
 2. **Diagnosis.** Definitive diagnosis is made by culture of the organism from biopsy specimens or exudate. Pus should be collected by aspiration from closed lesions, transferred to an anaerobic environment quickly, and examined for the presence of sulfur granules. X-rays may reveal bony changes ranging from a minor subperiosteal reaction to overt lytic destruction.
 - B. **Thoracic actinomycosis** may result from oropharyngeal aspiration of the organism, direct extension from the neck into the mediastinum, or spread from the abdominal cavity. Severe periodontal disease is commonly present.
 1. **Manifestations.** Nonproductive cough, low-grade fever, and weight loss are common, gradually progressing to mucopurulent sputum production, occasional

hemoptysis, and pleuritic chest pain. **Local chest wall spread may involve pleura and ribs and may produce externally draining cutaneous sinuses.** Extension of a pulmonary lesion through the thoracic wall may occur. Infection may extend to the pericardium, heart, and thoracic vertebrae or through the diaphragm, producing subphrenic or subhepatic abscesses. Hematogenous dissemination may result in spread to other organs, particularly the skin. Chest x-rays may show mass lesions, dense infiltrates, cavities, or pleural disease. **Draining sinus tracts through the chest wall are particularly suggestive of actinomycosis.**

2. Diagnosis. Because *A. israelii* may colonize the upper respiratory tract, **definitive diagnosis requires isolation of the organism from a resected specimen, growth in culture from an empyema cavity, or recovery from a draining sinus.**

C. Abdominal infection occurs most frequently after appendectomy, appendiceal abscess, or traumatic perforation of the bowel and represents 20% to 50% of all cases of actinomycosis [203].

1. Manifestations. Infection occurs most commonly in the ileocecal area and produces abdominal discomfort, fever, and a palpable mass. The process may localize or spread directly into the peritoneal cavity, abdominal wall, or pelvis. The course is usually subacute to chronic. Sinuses may appear in the abdominal wall. Extension to the urinary tract, pelvic organs, or vertebral bodies may occur. Anorectal involvement may result from secondary extension or may arise primarily through a break in an anal crypt. Pelvic actinomycosis may occur in women in association with an intrauterine device.

2. Diagnosis is by culture of specimens at the time of exploratory laparotomy, unless draining sinuses are present in the abdominal wall. Culture isolation may be frequently lacking, and diagnosis is made on the basis of sulfur granules on histopathology along with the characteristic clinical syndrome.

D. Involvement of the CNS is usually in the form of brain abscess and generally results from hematogenous spread of primary infection from the lung or abdomen [202]. Diagnosis requires culture of the organism from a biopsy specimen.

V. Therapy. Penicillin remains the drug of choice for actinomycosis [203]. Prolonged treatment with large doses is required to ensure adequate penetration into areas of fibrosis. Intravenous aqueous penicillin G (10–20 million units/day) for 4 to 6 weeks, followed by oral penicillin for 6 to 12 months, is suggested. Some recommend probenecid along with oral penicillin. Tetracyclines may be used in the nonpregnant penicillin-allergic patient. Other alternative agents include erythromycin and clindamycin. Surgical drainage of abscesses and excision of sinus tracts are important aspects of treatment. Infectious disease consultation is advised.

NOCARDIOSIS

Nocardiosis is a localized or disseminated disease most commonly caused by *Nocardia asteroides* and less often by *Nocardia brasiliensis* and *Nocardia caviae*. *Nocardia* species are gaining increased recognition as **opportunistic pathogens, although they also cause illness in normal hosts.** Although originally believed to be fungi, *Nocardia* are now classified as higher order **bacteria** and are related to the *Actinomyces*.

I. Growth and identification characteristics. *Nocardia* species are gram-positive, aerobic, **weakly acid-fast bacilli** and are readily isolated on routine bacterial, fungal, and mycobacterial media. Colonies usually appear within 4 days but in some instances may require 2 to 4 weeks of culture. *Nocardia* can be difficult to isolate by culture, particularly because of overgrowth by nonpathogenic colonizers. **If nocardiosis is suspected clinically, the bacteriology laboratory should be informed and cultures should be kept longer than usual.** Gram-stained preparations reveal delicately branching, gram-positive, beaded filaments. With a modified Ziehl-Neelsen or Kinyoun stain, *Nocardia* organisms are weakly acid-fast, a characteristic that helps to distinguish them from *Actinomyces*. **However, the histologic appearance of *Nocardia* is not unique, and culture is necessary for definitive diagnosis.**

II. Epidemiologic and host factors. *Nocardia* species are soil saprophytes with worldwide distribution. *N. brasiliensis* most often causes primary cutaneous disease. Infection with *N. asteroides* most frequently occurs after inhalation of the organism into the lungs of predisposed individuals. The organism is an **opportunistic invader** in the setting of compromised host defenses: patients with leukemia, lymphoma, solid tumors, AIDS, dysgammaglobulinemia, collagen vascular disease, and chronic granulomatous disease and individuals on steroids or immunosuppression for organ transplantation are especially susceptible. In addition, prior pulmonary disease, including chronic obstructive lung disease and pulmonary alveolar proteinosis, are risk factors. Nevertheless, **approximately 15% of patients with nocardiosis have no underlying disorder** [204,205].

III. Clinical aspects. Although a few cases of skin or subcutaneous disease may occur by primary inoculation, clinical infection usually begins in the lungs, with 75% of patients exhibiting a primary pneumonitis. Secondary dissemination occurs by hematogenous spread and is almost always due to *N. asteroides*.

A. Pulmonary and systemic nocardiosis usually follows a subacute to chronic course, spanning weeks to months. Fulminant disease may occur in severely immunosuppressed patients. Pulmonary disease may be much more common than previously reported. Sputum cultures obtained for *Legionella pneumophila* in perplexing pneumonia often yield *Nocardia*.

1. Manifestations. Constitutional symptoms of fever, night sweats, malaise, anorexia, and weight loss are reported in most cases. Leukocytosis is not consistently present.

a. Pulmonary findings. Cough may be dry but usually is productive of thick mucopurulent sputum. Hemoptysis and pleuritic chest pain also are reported. **Chest roentgenograms** are variable and **nonspecific**. Localized infiltrates, often in the upper lobes, are common. Single or multiple nodules, cavities, diffuse infiltrates, consolidation, abscesses, large masses, and pleural effusions have all been reported.

b. CNS involvement has been noted in approximately 25% of patients. This is usually in the form of a **brain abscess**, and the diagnosis may be suspected on the basis of CT or MRI. Meningitis has been reported. Decreased mental status, unsteadiness, headaches, nausea and vomiting, seizures, or focal neurologic deficits may occur. (CSF does not reveal *Nocardia* on smear or culture, and brain biopsy may be necessary.)

c. Skin and subcutaneous abscesses are present in approximately 10% of patients.

d. Pleural and chest wall invasion from a contiguous pneumonic infection occurs in 10% of cases. Patients may complain of pleuritic pain or may manifest sinus tracts. Pleural effusions may become infected, with the development of empyema.

e. Metastatic infection to virtually every organ has been documented.

2. Diagnosis. **Nocardiosis should be considered in any chronic pneumonia that persists despite conventional antimicrobial therapy. The combination of pulmonary and CNS or skin infection in a compromised host is particularly suggestive.**

a. Sputum or pulmonary specimens. Positive sputum cultures are diagnostic, but false-negative results are common. Invasive procedures such as thoracentesis, transtracheal aspiration, lung aspiration, or lung biopsy may be necessary.

b. Blood cultures are rarely positive.

c. Smears and culture material obtained from skin lesions, sinus tracts, and tissue biopsy specimens are important sources. Histologic examination is suggestive but not diagnostic.

d. Skin and serologic tests are not available.

3. Therapy. Sulfonamide-based regimens have proven to be the most effective treatment for nocardiosis. Infectious disease consultation is advised.

a. Trimethoprim-sulfamethoxazole is considered to be the treatment of choice for nocardiosis [205–207]. This rationale is supported by the *in vitro*

synergy, the excellent tissue levels achieved (including the CNS), and their excellent bioavailability when given orally. Sulfa levels in serum should be monitored to achieve concentrations of 12 to 15 mg/dL [207].

- b. **Sulfonamides** as single agents are also very effective against *Nocardia*. For example, sulfadiazine, 8 to 12 g/day, can be used (see Chapter 27). The dosage should be monitored to achieve peak serum concentrations of approximately 15 mg/dL.
 - c. **Other regimens** may be necessary if the organisms are resistant or if patients are intolerant to sulfa drugs. Susceptibility testing is difficult and ideally should be performed at reference laboratories. **Minocycline, doxycycline, and amoxicillin-clavulanate** have been effective. Many *Nocardia* strains are susceptible to **amikacin**, and this drug may be added to a sulfa regimen or an alternative regimen [208]. **Imipenem** may be another alternative agent.
 - d. The duration of therapy is not well defined, but **most authorities recommend a prolonged course of treatment**. For minor infections and in immunocompetent hosts, therapy is given for at least 2 to 3 months. For severe infections or in immunosuppressed individuals, therapy for up to 1 year is recommended. Some experts suggest maintenance therapy to prevent relapse in transplant recipients or in patients continuing on immunosuppressive therapy [205,206].
 - e. **Surgical drainage and excision** should be performed on abscesses, if possible.
4. **Prognosis.** Mortality varies with the site of disease and the severity of the patient's underlying immunosuppression. Survival definitely is improved if therapy is initiated early and before hematogenous seeding occurs. Individuals with CNS infection have the highest mortality, approximately 40%. Mortality in patients with isolated pulmonary disease ranges between 10% and 29%, the higher rate being reported in transplant recipients and other immunocompromised patients [204,205].
- B. *N. asteroides* is a rare laboratory contaminant, and isolation from sputum usually indicates active disease.** However, positive sputum cultures have been found in asymptomatic patients, individuals with mild upper respiratory tract infections, and some persons with bronchitis. In patients with malignancies or immunosuppressive disorders, the isolation of *Nocardia* from clinical specimens should prompt the initiation of therapy. On the other hand, in immunocompetent individuals a positive culture for *Nocardia* should stimulate further investigation but may not mandate therapy if solid evidence of invasive disease cannot be found. Infectious disease consultation is advised.

18. OPPORTUNISTIC INFECTIONS IN HIV DISEASE

Jin S. Suh and Kent A. Sepkowitz

This chapter focuses on current diagnostic and treatment modalities against opportunistic infection, updates of preventive strategies, and the changing spectrum of disease associated with immune reconstitution. The U.S. Public Health Service/Infectious Diseases Society of America (USPHS/IDSA) guidelines for preventing opportunistic infections have been published in *Morbidity and Mortality Weekly Reports* [1] and *Clinical Infectious Diseases* [2]; updated information is available as a “living document” on the AIDS Treatment Information Service (ATIS) website at www.hivatis.org. A comprehensive review of the pathophysiology and treatment of acquired immunodeficiency syndrome (AIDS), and of its complications, is beyond the scope of this chapter. The reader is directed to excellent reference sources that are both practical and useful for keeping up with progress in this disease [3–5]. Antiretroviral therapy is reviewed in Chapter 19.

I. HIV in the HAART era

A. Introduction. Since the recognition of the first cases of AIDS in 1981, there have been an estimated 21.8 million deaths worldwide from the devastating human immunodeficiency virus (HIV) pandemic. UNAIDS and the World Health Organization (WHO) estimated that the number of people living with HIV or AIDS at the end of the year 2001 was 40 million, including 5 million who became infected within the preceding year. The virus has spread to all of the continents of the world. The bulk of the epidemic resides in sub-Saharan Africa, where some epicenters report an adult prevalence rate as high as 33% [6]. HIV continues to be spread by sexual contact, by exposure to infected blood or blood products, and by transmission from mother to child.

There has been much progress toward understanding the pathogenesis, clinical presentation, treatment, and prevention of HIV [7]. **The hallmark of infection is immune suppression, making patients susceptible to opportunistic infections (OIs)** [8]. **The CD4 cell count remains the single most important predictor of risk for OIs.** Although the measurement of HIV viral load has led to a greater understanding of the natural history of HIV as well as therapeutic monitoring, no useful scale of viral load exists to determine when patients are at risk for developing specific OIs. It is clear that prevention and treatment of OIs remain priorities in reducing the morbidity and mortality associated with HIV/AIDS. **The introduction of highly active antiretroviral therapy (HAART) has exerted a profound effect on the epidemiology, natural history, clinical manifestations, and responses to treatment of OIs** [9–11]. HAART is defined as at least three medications with activity against HIV, including either a protease inhibitor or a non-nucleoside reverse transcriptase inhibitor.

B. Effects of HAART on opportunistic infections and mortality. The incidence of nearly all AIDS-defining opportunistic infections decreased significantly in the United States between 1992 and 1998 [12]. Decreases in the most common OIs, including *Pneumocystis carinii* pneumonia (PCP), esophageal candidiasis, and disseminated *Mycobacterium avium* complex (MAC), were most pronounced during this period when HAART was introduced (Fig. 18.1). The incidence of major OIs in eight U.S. cities declined from 21.9/100 person-years in 1994 to 3.7/100 person-years by mid-1997 [13]. Mortality declined from 29.4/100 person-years in 1995 to 8.8/100 person-years in 1997 [14], after remaining constant during 1994 and 1995. Several reports have described reductions in mortality and in the rate of hospitalization of HIV-infected patients [15,16]. There were reductions in mortality regardless of sex, race, age, and risk factors for transmission of HIV [13,14,17]. Overall mortality nationally has declined an estimated 21% or a rate of 4.6 deaths per 100,000 in 1998, the lowest rate since 1987. HIV mortality has declined more than 70% since 1995 (Fig. 18.2).

C. Prophylaxis for OIs. The success of HAART in reducing the incidence of AIDS-related OIs has led to a reassessment of the role of prophylaxis against these

FIG. 18.1 Trends for opportunistic infections in HIV-infected adults and adolescents, Adult and Adolescent Spectrum of Disease Project, 1992–1998. (Reprinted from Kaplan JE, Hanson D, Dworkin MS, et al. Epidemiology of human immunodeficiency virus–associated opportunistic infection in the United States in the era of highly active antiretroviral therapy. *Clin Infect Dis* 2000;30(suppl):2–15, with permission.)

FIG. 18.2 Mortality and frequency of use of combination antiretroviral therapy including a protease inhibitor among HIV-infected patients with fewer than 100 CD4⁺ cells/mm³, according to calendar quarter, from January 1994 through June 1997. (Reprinted from Palella FJ, Delaney KM, Moorman AC, et al. Declining morbidity and mortality among patients with advanced human immunodeficiency virus infection. *N Engl J Med* 1998;338:853–860, with permission.)

infections [18–20]. Previously, prophylaxis was continued based on the lowest, or nadir, CD4 cell count [21]. This was based on a concern that recovery of the immune system was incomplete, and patients who lost specific immunity would not regain it even as the CD4 cell count rose. There are now sufficient data to recommend that for patients who have CD4 T-lymphocyte count responses, primary or secondary prophylaxis for some OIs can be discontinued. Consequently, in 2001 the USPHS/IDSA amended their prophylaxis guidelines to include prophylaxis discontinuation [1].

- D. The declining rates of morbidity and mortality, as well as improvement in quality of life, have been well documented among HIV-infected individuals who have access to diagnostic monitoring and potent combinations of antiretroviral drugs. But despite the encouraging trends in incidence of OIs, **patients are still dying from HIV and associated OIs. This is most notable in yet undiagnosed patients not receiving antiretroviral therapy, patients who cannot adhere to regimens, and those who fail therapy.** These three groups pose an important challenge in management, especially because the best treatment for many OIs may be effective antiretroviral therapy. Thus, the treatment of OIs may depend heavily on the effectiveness and tolerability of future antiretroviral regimens.

II. Immune reconstitution

- A. **Phases of immune reconstitution with HAART.** It is important to keep in mind that antiretroviral medications, in general, have no intrinsic antimicrobial effect; therefore, **the change in rates of opportunistic infections are mostly a consequence of improvements in immune function**, usually accompanied by viral suppression and an elevation in CD4 cell count. Several previously untreatable opportunistic infections have responded to HAART, presumably due to immune system recovery, including progressive multifocal leukoencephalopathy (PML), cytomegalovirus (CMV), and AIDS-associated microsporidiosis and cryptosporidiosis. Immune restoration from HAART can be divided into two distinct phases. The initial increase of CD4 cell count after initiation of HAART, which is observed within the first 8 weeks, is believed to be due to the release of trapped memory cells from lymphoid tissues to the blood. There is a minimal increase in these cells as time progresses. Decreased risk of OIs has been demonstrated in this early period [22]. Later, there is a slower, more modest increase in naive cells that have matured in the thymus and extrathymic sites. During this period, both CD4-naive cells and CD8-naive cells tend to increase while memory CD4 cells stabilize or increase modestly and memory CD8 cells tend to decrease [23]. Naive cells respond to newly encountered antigens, and memory cells are capable of rapid responses to previously encountered antigens. It is not clear whether and for how long immune reconstitution persists after the loss of viral suppression. It is also not known whether immune recovery is more effective with earlier antiretroviral intervention [22]. However, it is abundantly clear that the increase in CD4 cell count is associated with clinical evidence of recovery of the immune system.

- B. **Immune reconstitution syndromes.** Paradoxically, some patients who have virologic and immunologic responses to HAART develop inflammation at sites of preexistent or subclinical infection by opportunistic pathogens. These episodes of unexpected exacerbation of disease while on appropriate therapy have been seen within the first 3 months on HAART as the immune response against the specific pathogens is restored.

1. **MAC lymphadenitis** has been described in patients with localized disease who develop **fever and painful generalized adenopathy**, associated with initiation of HAART. This has been linked to the restoration of mycobacteria-specific cell-mediated immune responses. Patients may appear systemically ill with severe abdominal pain, malaise, and leukocytosis. Mediastinal or mesenteric adenopathy with associated endobronchial lesions, pulmonary infiltrates, and inflammatory skin lesions have been reported [24,25]. Biopsies

of involved lymph nodes may demonstrate granulomatous inflammation. Adenopathy may persist for months despite appropriate therapy. Corticosteroids have been used once other possibilities, including lymphoma, have been ruled out.

2. **Paradoxic reactions with tuberculosis (TB)** have been reported in 36% of patients receiving concomitant therapy for both HIV and TB [26]. Manifestations include fever, intrathoracic and cervical lymphadenopathy, and worsening pulmonary infiltrates. Treatment involves the use of antiinflammatory agents, including corticosteroids or pentoxifylline, along with continuation of antitubercular therapy. Corticosteroid-responsive cerebral tuberculoma and relapsing corticosteroid-dependent focal cerebritis also have been reported [27], giving support to the assumption that these exacerbations are distinct from TB treatment failure due to resistance or noncompliance.
3. **CMV vitritis** has occurred in patients with and without retinitis who begin HAART. This appears related to the restoration of T-cell responses against CMV antigens. Vitreal inflammation may occur even though retinitis, if present, undergoes remission. This is usually associated with macular edema and epiretinal membrane formation; retinal detachment also can occur [28]. One study reported an annual incidence of CMV vitritis at 83 cases per 100 person-years [29]. It is not possible to predict which patients are at risk for a relapse of CMV retinitis or vitritis, although use of markers for anti-CMV T-cell response is under investigation. Antiinflammatory therapy should be considered for patients with evidence of vitreal inflammation.
4. **Hepatitis C virus (HCV)–or hepatitis B virus–related hepatitis** has been reported in patients being treated with HAART [30–32]. It may be asymptomatic or present with nausea, abdominal pain, and jaundice. Abnormalities in liver function test results may resolve with discontinuation of HAART. This syndrome must be distinguished from medication-related hepatotoxicity, although the clinical symptoms are similar.
5. **Other syndromes** of immune reconstitution recently described include **herpes zoster** [33,34], and **inflammatory folliculitis** [35]. According to one study, the incidence of herpes zoster associated with HAART was estimated at 9 episodes per 100 patient-years. Case patients were more likely than controls to manifest an increase in CD8 cell count immediately before clinical disease appeared.
6. **Strategies for the prevention of immune reconstitution syndromes** are poorly defined at present. Withdrawal of effective antiretroviral therapy most often is inappropriate. Options include continuation of HAART with the addition of antimicrobial therapy to suppress the OI, and antiinflammatory agents for symptoms of pain or organ dysfunction. Discontinuation of HAART, even temporarily, should be reserved as a last resort. Prospective studies using measurement of pathogen-specific immune response are needed to distinguish immune reconstitution syndromes from new OIs, treatment failures, or adverse effect of antiretroviral drugs, which currently pose a diagnostic challenge.

III. Prevention of opportunistic infections. Whenever possible, preventing an OI is preferred to treating an active infection. **Guidelines for preventing OIs in persons infected with HIV** were first published in the summer of 1995 following a year-long effort by federal authorities, professional societies, researchers, clinicians, community groups, and HIV-infected persons, with comments invited from the general public [21]. Because important new data concerning the prevention of opportunistic diseases have emerged since 1995, they were revised in 1999 and 2001. **The guidelines are posted on the Internet as a “living document” where the latest update is available [1]. Health-care providers actively involved in the care of HIV-infected patients are encouraged to review this excellent source material.** The guidelines provide background information and recommendations on those behavioral changes, drug regimens, and immunizations

that are most likely to be beneficial, safe, feasible, and cost effective (Tables 18.1–18.13). The most recent version discusses 19 OIs or groups of OIs, including human herpesvirus 8 (HHV-8) and HCV, two pathogens not previously considered, and provide criteria for discontinuing prophylaxis [1].

Recommendations in the tables designated “A” are supported by evidence that is both statistically and clinically persuasive; the measures designated are strongly recommended, should always be offered, and are considered standard of care. Those designated “B” are recommended for consideration; such measures should be generally offered, but their use should involve some discussion of the “pros and cons” between the provider and patient. Those designated “C” are considered optional, those designated “D” generally should not be offered, and those designated “E” are contraindicated [1]. Recommendations are further rated as I (evidence from at least one properly reported controlled trial), II (evidence from at least one well-designed clinical trial without randomization, or case-controlled studies), or III (evidence from opinions of respected authorities based on clinical experience, from descriptive studies, or from expert communities) [1].

A. For prophylaxis for OIs in adults and adolescents, see Tables 18.1 and 18.2.

For prophylaxis for OIs in infants and children, see Tables 18.3 and 18.4.

B. For criteria for discontinuing and restarting prophylaxis for adults and adolescents whose CD4 counts increased because of HAART, see Table 18.5.

C. For suggestions to help patients avoid OIs, see Table 18.6.

D. For important drug interactions, see Tables 18.7 through 18.9.

E. For adverse effects of commonly used drugs to prevent OIs, see Table 18.10.

F. For recommended dosing in renal insufficiency of commonly used drugs to treat or prevent OIs, see Table 18.11.

G. For a summary of the costs of various prophylactic regimens, see Table 18.12.

H. For recommended immunizations in HIV-infected children, see Table 18.13.

IV. *Pneumocystis carinii* pneumonia. In the pre-AIDS era, PCP was seen uncommonly in patients with impaired cellular immunity: premature, debilitated infants; children with primary immunodeficiency states, particularly severe combined immunodeficiency; and patients receiving immunosuppressive drugs for cancer or organ transplantation. During this period, *P. carinii* was misidentified as a protozoan due to its morphology, failure to grow on fungal media, and its response to drugs used to treat protozoan infections. Molecular analysis of its ribosomal RNA and mitochondrial DNA revealed that it is phylogenetically related to the ascomycetes yeast, and thus is now classified as a fungus.

A. Epidemiology. Reports of PCP in previously healthy men heralded the onset of the AIDS epidemic [36,37]. In the following two decades, PCP gained notoriety as the most common opportunistic infection associated with HIV and the most common infection among persons who died with AIDS. **The best predictor of PCP occurrence in HIV-infected patients is the CD4 lymphocyte blood count.** The majority of AIDS patients have CD4 cell counts in the range of 50 to 70/mm³ at the time of their first episode of PCP, and more than 90% of episodes occur when counts are below 200/mm³ [38]. Clinical manifestations including a history of thrush, herpes zoster, unexplained fever, and weight loss are correlated with an increased risk independent of the CD4 cell count.

Even in the HAART era, PCP continues to be the most common complication of HIV infection. According to the Centers for Disease Control and Prevention (CDC) Surveillance Report, from 1992 through 1997, PCP was the most common AIDS-defining OI, accounting for 36% of AIDS index cases, the most common incident AIDS-defining OI (87.9 cases per 1,000 person-years), and the most common OI among persons who had died of AIDS (53%) [17]. Although the incidence of PCP declined from 108 cases per 1,000 person-years in 1992 to 46 cases per 1,000 person-years in 1997, largely attributed to widespread prophylaxis and HAART, the absolute rates of these infections were still high.

(Text continues on p. 663.)

Table 18.1. Prophylaxis to Prevent First Episode of Opportunistic Disease in Adults and Adolescents Infected with Human Immunodeficiency Virus

Pathogen	Preventive Regimens		
	Indication	First Choice	Alternatives
Strongly recommended as standard of care <i>Pneumocystis carinii</i> ^a	CD4 ⁺ count <200/ μ L or oropharyngeal candidiasis	TMP-SMX 1 DS orally daily (AI) TMP-SMX 1 SS orally daily (AI)	Dapsone 50 mg orally b.i.d. or 100 mg orally daily (BI); dapsone 50 mg orally daily plus pyrimethamine 50 mg orally weekly plus leucovorin 25 mg orally weekly (BI); dapsone 200 mg orally plus pyrimethamine 75 mg orally plus leucovorin 25 mg orally weekly (BI); aerosolized pentamidine 300 mg monthly via Respigard II nebulizer (BI); atovaquone 1,500 mg orally daily (BI); TMP-SMX 1 DS orally t.i.w. (BI)
<i>Mycobacterium tuberculosis</i> Isoniazid-sensitive ^b	TST reaction ≥ 5 mm or prior positive TST result without treatment or contact with case of active tuberculosis regardless of TST result (BII)	Isoniazid 300 mg orally plus pyridoxine 50 mg orally daily for 9 mo (AII), or isoniazid 900 mg orally plus pyridoxine 100 mg orally b.i.w. for 9 mo (BII)	Rifampin 600 mg orally daily (BIII) for 4 mo or rifabutin 300 mg orally daily (CII) for 4 mo Pyrazinamide 15–20 mg/kg orally daily for 2 mo plus either rifampin 600 mg orally daily (BI) for 2 mo or rifabutin 300 mg orally daily (CII) for 2 mo Pyrazinamide 15–20 mg/kg orally daily plus either rifampin 600 mg orally (BI) or rifabutin 300 mg orally (CII) daily for 2 mo
Isoniazid-resistant	Same as above; high probability of exposure to isoniazid-resistant tuberculosis	Rifampin 600 mg orally (AIII) or rifabutin 300 mg orally (BIII) daily for 4 mo	

Multidrug (isoniazid and rifampin)-resistant	Same as above; high probability of exposure to multidrug-resistant tuberculosis	Choice of drugs requires consultation with public health authorities. Depends on susceptibility of isolate from source patient.	—
<i>Toxoplasma gondii</i> ^c	IgG antibody to <i>Toxoplasma</i> and CD4 ⁺ count <100/ μ L	TMP-SMX 1 DS orally daily (AII)	TMP-SMX 1 SS orally daily (BIII); dapson 50 mg orally daily plus pyrimethamine 50 mg orally weekly plus leucovorin 25 mg orally weekly (BI); dapson 200 mg orally plus pyrimethamine 75 mg orally plus leucovorin 25 mg orally weekly (BI); atovaquone 1,500 mg orally daily with or without pyrimethamine 25 mg orally daily plus leucovorin 10 mg orally daily (CIII)
<i>Mycobacterium avium</i> complex ^d	CD4 ⁺ count <50/ μ L	Azithromycin, 1,200 mg orally weekly (AI) or clarithromycin ^d 500 mg orally b.i.d. (AI)	Rifabutin 300 mg orally daily (BI); azithromycin 1,200 mg orally weekly plus rifabutin 300 mg orally daily (CI)
Varicella zoster virus (VZV)	Significant exposure to chickenpox or shingles for patients who have no history of either condition or, if available, negative antibody to VZV	Varicella zoster immune globulin 5 vials (1.25 mL each) i.m., administered \leq 96 h after exposure, ideally within 48 h (AIII)	
Generally recommended	CD4 ⁺ count \geq 200/ μ L	23 valent polysaccharide vaccine, 0.5 mL i.m. (BII)	None
<i>Streptococcus pneumoniae</i> ^e	All susceptible (anti-HBc-negative) patients	Hepatitis B vaccine: 3 doses (BII)	None
Hepatitis B virus ^{f/g}			

(Continued)

Table 18.1. (Continued)

Pathogen	Preventive Regimens		
	Indication	First Choice	Alternatives
Influenza virus ^{f,h}	All patients (annually, before influenza season)	Inactivated trivalent influenza virus vaccine: one annual dose (0.5 mL) i.m. (BIII)	Oseltamivir 75 mg orally daily (influenza A or B) (CIII); rimantadine 100 mg orally b.i.d. (CIII), or amantadine 100 mg orally b.i.d. (CIII) (influenza A only)
Hepatitis A virus ^{f,g}	All susceptible (anti-HAV-negative) patients at increased risk for HAV infection (e.g., illicit drug users, men who have sex with men, hemophiliacs) or with chronic liver disease, including chronic hepatitis B or hepatitis C	Hepatitis A vaccine: two doses (BIII)	None
Evidence for efficacy but not routinely indicated			
Bacteria	Neutropenia	Granulocyte colony-stimulating factor 5–10 $\mu\text{g}/\text{kg}$ s.c. daily for 2–4 wk or granulocyte-macrophage colony-stimulating factor 250 $\mu\text{g}/\text{m}^2$ s.c. for 2–4 wk (CII)	None
<i>Cryptococcus neoformans</i>	CD4 ⁺ count <50/ μL	Fluconazole 100–200 mg orally daily (CI)	Itraconazole capsule, 200 mg orally daily (CIII)
<i>Histoplasma capsulatum</i> ⁱ	CD4 ⁺ count <100/ μL , endemic geographic area	Itraconazole capsule 200 mg orally daily (CI)	None
Cytomegalovirus (CMV) ^j	CD4 ⁺ count <50/ μL and CMV antibody positivity	Oral ganciclovir 1g orally t.i.d. (CI)	None

Information included in these guidelines might not represent U.S. Food and Drug Administration (FDA) approval or approved labeling for the particular products or indications in question. Specifically, the terms "safe" and "effective" might not be synonymous with the FDA-defined legal standards for product approval. The Respirgard II nebulizer is manufactured by Marquest, Englewood, Colorado. Letters and roman numerals in parentheses indicate the strength of the recommendation and the quality of evidence supporting it. Anti-HBc, antibody to hepatitis B core antigen; b.i.w., twice a week; DS, double-strength tablet; HAART, highly active antiretroviral therapy; HAV, hepatitis A virus; HIV, human immunodeficiency virus; i.m., intramuscular; i.v., intravenous; SS, single-strength tablet; t.i.w., three times a week; TMP-SMX, trimethoprim-sulfamethoxazole; s.c., subcutaneous; TST, tuberculin skin test.

^aProphylaxis should also be considered for persons with a CD4⁺ percentage of <14%, for persons with a history of an AIDS-defining illness, and possibly for those with CD4⁺ counts >200 but <250 cells/ μ L. TMP-SMX also reduces the frequency of toxoplasmosis and some bacterial infections. Patients receiving dapsone should be tested for glucose-6 phosphate dehydrogenase deficiency. A dosage of 50 mg daily is probably less effective than 100 mg daily. The efficacy of parenteral pentamidine (e.g., 4 mg/kg/mo) is uncertain. Fansidar (sulfadoxine-pyrimethamine) is rarely used because of severe hypersensitivity reactions. Patients who are being administered therapy for toxoplasmosis with sulfadiazine-pyrimethamine are protected against *Pneumocystis carinii* pneumonia (PCP) and do not need additional prophylaxis against PCP.

^bDirectly observed therapy is recommended for isoniazid, e.g., 900 mg b.i.w.; isoniazid regimens should include pyridoxine to prevent peripheral neuropathy. Rifampin or rifabutin are administered concurrently with protease inhibitors or non-nucleoside reverse transcriptase inhibitors, careful consideration should be given to potential pharmacokinetic interactions. There have been reports of fatal and severe liver injury associated with the treatment of latent TB infection in HIV-uninfected persons treated with the 2-month regimen of daily rifampin and pyrazinamide; therefore, it may be prudent to use regimens that do not contain pyrazinamide in HIV-infected persons whose completion of treatment can be assured. (Centers for Disease Control and Prevention. Update: fatal and severe liver injuries associated with rifampin and pyrazinamide for latent tuberculosis infection and revisions in American Thoracic Society/CDC recommendations, United States 2001. *MMWR* 2001;50:733.) Exposure to multidrug-resistant tuberculosis might require prophylaxis with two drugs; consult public health authorities. Possible regimens include pyrazinamide plus either ethambutol or a fluoroquinolone.

^cProtection against toxoplasmosis is provided by TMP-SMX, dapsone plus pyrimethamine, and possibly by atovaquone. Atovaquone may be used with or without pyrimethamine. Pyrimethamine alone probably provides little, if any, protection.

^dDuring pregnancy, azithromycin is preferred over clarithromycin because of demonstrated teratogenicity in animals with clarithromycin.

^eVaccination may be offered to persons who have a CD4⁺ T-lymphocyte count of <200 cells/ μ L, although the efficacy is likely to be diminished. Revaccination 5 years after the first dose or sooner if the initial immunization was given when the CD4⁺ count was <200 cells/ μ L and the CD4⁺ count has increased to >200 cells/ μ L on HAART is considered optional. Some authorities are concerned that immunizations might stimulate the replication of HIV.

^fAlthough data demonstrating clinical benefit of these vaccines in HIV-infected persons are not available, it is logical to assume that those patients who develop antibody responses will derive some protection. Some authorities are concerned that immunizations might stimulate HIV replication, although for influenza vaccination, a large observational study of HIV-infected persons in clinical care showed no adverse effect of this vaccine, including multiple doses, on patient survival (J. Ward, CDC, personal communication). Also, this concern may be less relevant in the setting of HAART. However, because of the theoretical concern that increases in HIV plasma RNA following vaccination during pregnancy might increase the risk of perinatal transmission of HIV, providers may wish to defer vaccination for such patients until after HAART is initiated.

^gHepatitis B vaccine has been recommended for all children and adolescents and for all adults with risk factors for hepatitis B virus. For persons requiring vaccination against both hepatitis A and hepatitis B, a combination vaccine is now available. For additional information regarding vaccination against hepatitis A and B, see CDC. Hepatitis B virus: a comprehensive strategy for eliminating transmission in the United States through universal childhood vaccination. Recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR* 1991;40(RR-13):1.

^hOseltamivir is appropriate during outbreaks of either influenza A or influenza B. Rimantadine or amantadine are appropriate during outbreaks of influenza A (although neither rimantadine nor amantadine is recommended during pregnancy). Dosage reduction for antiviral chemoprophylaxis against influenza might be indicated for decreased renal or hepatic function, and for persons with seizure disorders. Physicians should consult the drug package inserts and the annual CDC influenza guidelines for more specific information about adverse effects and dosage adjustments. For additional information about vaccination, antiviral chemoprophylaxis and therapy against influenza, see CDC. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR* 2001;50(RR-4):1.

ⁱIn a few unusual occupational or other circumstances, prophylaxis should be considered; consult a specialist.

^jAcyclovir is not protective against cytomegalovirus (CMV). Valacyclovir is not recommended because of an unexplained trend toward increased mortality observed in persons with AIDS who were being administered this drug for prevention of CMV disease.

From Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, pages 38–41. Posted November 28, 2001 as a "living document" at www.hivatis.org/trguidhs.htm#Opportunistic.

Table 18.2. Prophylaxis to Prevent Recurrence of Opportunistic Disease in Adults (after Chemotherapy for Acute Disease) in Adults and Adolescents Infected with Human Immunodeficiency Virus

Pathogen	Preventive Regimens		
	Indication	First Choice	Alternatives
Recommended as standard of care <i>Pneumocystis carinii</i>	Prior <i>P. carinii</i> pneumonia	TMP-SMX 1 DS orally daily (AI); TMP-SMX 1 SS orally daily (AI)	Dapsone 50 mg orally b.i.d. or 100 mg orally daily (BI); dapsone 50 mg orally daily plus pyrimethamine 50 mg orally weekly plus leucovorin 25 mg orally weekly (BI); dapsone 200 mg orally plus pyrimethamine 75 mg orally plus leucovorin 25 mg orally weekly (BI); aerosolized pentamidine 300 mg monthly via Respigard II nebulizer (BI); atovaquone 1,500 mg orally daily (BI); TMP-SMX 1 DS orally t.i.w. (CI)
<i>Toxoplasma gondii</i> ^a	Prior toxoplasmic encephalitis	Sulfadiazine 500–1,000 mg orally q.i.d. plus pyrimethamine 25–50 mg orally daily plus leucovorin 10–25 mg orally daily (AI)	Clindamycin 300–450 mg orally every 6–8 h plus pyrimethamine 25–50 mg orally daily plus leucovorin 10–25 mg orally daily (BI); atovaquone 750 mg orally every 6–12 h with or without pyrimethamine 25 mg orally daily plus leucovorin 10 mg orally daily (CIII)
<i>Mycobacterium avium</i> complex ^b	Documented disseminated disease	Clarithromycin ^b 500 mg orally b.i.d. (AI) plus ethambutol 15 mg/kg orally daily (AI); with or without rifabutin 300 mg orally daily (CI)	Azithromycin 500 mg orally daily (AI) plus ethambutol 15 mg/kg orally daily (AI), with or without rifabutin 300 mg orally daily (CI)
Cytomegalovirus	Prior end-organ disease	Ganciclovir 5–6 mg/kg/day i.v. 5–7 days/wk or 1,000 mg orally t.i.d. (AI); or foscarnet 90–120 mg/kg i.v. daily (AI); or (for retinitis) ganciclovir sustained-release implant every 6–9 mo plus ganciclovir 1.0–1.5 g orally t.i.d. (AI)	Cidofovir 5 mg/kg i.v. q.o.w. with probenecid 2 orally 3 h before the dose followed by 1 g orally 2 h after the dose, and 1 g orally 8 h after the dose (total of 4 g) (AI). Fomivirsen 1 vial (330 µg) injected into the vitreous, then repeated every 2–4 wk (AI); valganciclovir 900 mg orally daily (BI)

<i>Cryptococcus neoformans</i>	Documented disease	Fluconazole 200 mg orally daily (AI)	Amphotericin B 0.6–1.0 mg/kg i.v. 1–3 times/wk (AI); itraconazole 200 mg capsule orally daily (BI)
<i>Histoplasma capsulatum</i>	Documented disease	Itraconazole capsule 200 mg orally b.i.d. (AI)	Amphotericin B 1.0 mg/kg i.v. weekly (AD)
<i>Coccidioides immitis</i>	Documented disease	Fluconazole 400 mg orally daily (AII)	Amphotericin B 1.0 mg/kg i.v. weekly (AD); itraconazole 200 mg capsule orally b.i.d. (AII)
<i>Salmonella</i> species, (nontyphi) ^c	Bacteremia	Ciprofloxacin 500 mg orally b.i.d. for several months (BII)	Antibiotic chemoprophylaxis with another active agent (CIII)
Recommended only if subsequent episodes are frequent or severe	Frequent/severe recurrences	Acyclovir 200 mg orally t.i.d. or 400 mg orally b.i.d. (AI)	Valacyclovir 500 mg orally b.i.d. (CIII)
Herpes simplex virus	Frequent/severe recurrences	Famciclovir 250 mg orally b.i.d. (AI)	Itraconazole solution 200 mg orally daily (CI)
<i>Candida</i> (oropharyngeal or vaginal)	Frequent/severe recurrences	Fluconazole 100–200 mg orally daily (BI)	Itraconazole solution 200 mg orally daily (BI)
<i>Candida</i> (esophageal)	Frequent/severe recurrences		

Information included in these guidelines might not represent U.S. Food and Drug Administration (FDA) approval or approved labeling for the particular products or indications in question. Specifically, the terms “safe” and “effective” might not be synonymous with the FDA-defined legal standards for product approval. The Respigard II nebulizer is manufactured by Marquest, Englewood, Colorado. Letters and roman numerals in parentheses after regimens indicate the strength of the recommendation and the quality of evidence supporting it.

b.i.d., twice a day; DS, double-strength tablet; i.v., intravenous; q.o.w., every other week; SS, single-strength tablet; t.i.d., three times a day; t.i.w., three times a week; TMP-SMX, trimethoprim-sulfamethoxazole.

^aPyrimethamine-sulfadiazine confers protection against *Pneumocystis carinii* pneumonia (PCP) as well as toxoplasmosis; clindamycin-pyrimethamine does not offer protection against PCP

^bMany multiple-drug regimens are poorly tolerated. Drug interactions (e.g., those seen with clarithromycin and rifabutin) can be problematic; rifabutin has been associated with uveitis, especially when administered at daily doses of >300 mg or concurrently with fluconazole or clarithromycin. During pregnancy, azithromycin is recommended instead of clarithromycin because clarithromycin is teratogenic in animals.

^cEfficacy for eradication of *Salmonella* has been demonstrated only for ciprofloxacin. From Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, pages 42–43. Posted November 28, 2001 as a “living document” at www.hivatis.org/irtgd/ins.html#Opportunistic.

Table 18.3. Prophylaxis to Prevent First Episode of Opportunistic Disease in Infants and Children Infected with Human Immunodeficiency Virus

Pathogen	Preventive Regimens		
	Indication	First Choice	Alternatives
Strongly recommended as standard of care <i>Pneumocystis carinii</i> ^a	HIV-infected or HIV-indeterminate, infants aged 1–12 mo; HIV-infected children aged 1–5 yr with CD4 ⁺ count <500/ μ L or CD4 ⁺ percentage <15%; HIV-infected children aged 6–12 yr with CD4 ⁺ count <200/ μ L or CD4 ⁺ percentage <15%	TMP-SM, 150/750 mg/m ² /day in 2 divided doses orally t.i.w. on consecutive days (AII) Acceptable alternative dosage schedules (AII): Single dose orally t.i.w. on consecutive days; or 2 divided doses orally daily; or 2 divided doses orally t.i.w. on alternate days	Dapsone (children aged \geq 1 mo) 2 mg/kg (max 100 mg) orally daily or 4 mg/kg (max 200 mg) orally weekly (CII); aerosolized pentamidine (children aged \geq 5 yr) 300 mg monthly via Respigard II nebulizer (CIII); atovaquone (children aged 1–3 mo and >24 mo, 30 mg/kg orally daily; children aged 4–24 mo, 45 mg/kg orally daily) (CII)
<i>Mycobacterium tuberculosis</i> ^b Isoniazid-sensitive	TST reaction \geq 5 mm or prior positive TST result without treatment, or contact with any case of active tuberculosis regardless of TST result Same as above; high probability of exposure to isoniazid-resistant tuberculosis	Isoniazid 10–15 mg/kg (max 300 mg) orally daily for 9 mo (AII) or 20–30 mg/kg (max 900 mg) orally b.i.w. for 9 mo (BII)	Rifampin 10–20 mg/kg (max 600 mg) orally daily for 4–6 mo (BIII)
Isoniazid-resistant	Same as above; high probability of exposure to multidrug-resistant tuberculosis	Rifampin 10–20 mg/kg (max 600 mg) orally daily for 4–6 mo (BIII)	Uncertain
Multidrug (isoniazid and rifampin)-resistant	Same as above; high probability of exposure to multidrug-resistant tuberculosis	Choice of drugs requires consultation with public health authorities and depends on susceptibility of isolate from source patient	
<i>Mycobacterium avium</i> complex ^b	For children aged \geq 6 yr, CD4 ⁺ count <50/ μ L; aged 2–6 yr CD4 ⁺ count <75/ μ L; aged 1–2 yr, CD4 ⁺ count <500/ μ L; aged <1 yr, CD4 ⁺ count <750/ μ L	Clarithromycin 7.5 mg/kg (max 500 mg) orally b.i.d. (AII), or azithromycin 20 mg/kg (max 1,200 mg) orally weekly (AII)	Azithromycin, 5 mg/kg (max 250 mg) orally daily (AII); children aged \geq 6 yr, rifabutin 300 mg orally daily (BI)

Varicella zoster virus ^c	Significant exposure to varicella or shingles with no history of chickenpox or shingles HIV exposure/infection	VZIG 1 vial (1.25 mL)/10 kg (max 5 vials) i.m., administered ≤96 h after exposure, ideally within 48 h (AII) Routine immunizations (see Table 18.13)	None
Vaccine-preventable pathogens ^d			None
Generally recommended <i>Toxoplasma gondii</i> ^e	IgG antibody to <i>Toxoplasma</i> and severe immunosuppression	TMP-SMX 150/750 mg/m ² /day in 2 divided doses orally daily (BIII)	Dapson (children aged ≥ 1 mo), 2 mg/kg or 15 mg/m ² (max 25 mg) orally daily plus pyrimethamine 1 mg/kg orally daily plus leucovorin 5 mg orally every 3 days (BIII) Atovaquone (aged 1–3 mo and > 24 mo, 30 mg/kg orally daily; aged 14–24 mo, 45 mg/kg orally daily) (CIII)
Varicella zoster virus	HIV-infected children who are asymptomatic and not immunosuppressed	Varicella zoster vaccine (see vaccine-preventable pathogens section of this table) (BII)	None
Influenza virus	All patients (annually, before influenza season)	Inactivated split trivalent influenza vaccine (see vaccine-preventable section of this table) (BIII)	None
Not recommended for most children; indicated for use only in unusual circumstances			
Invasive bacterial infections ^f	Hypogammaglobulinemia (i.e., IgG <400 mg/dL)	IVIG (400 mg/kg every 2–4 wk) (AI)	None
<i>Cryptococcus neoformans</i>	Severe immunosuppression	Fluconazole 3–6 mg/kg orally daily (CII)	Itraconazole 2–5 mg/kg orally every 12–24 h (CII)
			Osetamivir (during outbreaks of influenza A or B) for children ≥ 13 years, 75 mg orally daily (CIII); rimantadine or amantadine (during outbreaks of influenza A) aged 1–9 yr, 5 mg/kg in 2 divided doses (max 150 mg/day) orally daily; aged ≥ 10 yr, use adult doses (CIII)

(Continued)

Table 18.3. (Continued)

Pathogen	Indication	First Choice	Preventive Regimens	Alternatives
<i>Histoplasma capsulatum</i>	Severe immunosuppression, endemic geographic area	Itraconazole 2–5 mg/kg orally every 12–24 h (CIII)	None	None
Cytomegalovirus (CMV) [§]	CMV antibody positivity and severe immunosuppression (CII)	Oral ganciclovir 30 mg/kg t.i.d. (CII)	None	None

Information included in these guidelines might not represent U.S. Food and Drug Administration (FDA) approval or approved labeling for the particular products or indications in question. Specifically, the terms “safe” and “effective” might not be synonymous with the FDA-defined legal standards for product approval. The Respigard II nebulizer is manufactured by Marquest, Englewood, Colorado. Letters and roman numerals in parentheses after regimens indicate the strength of the recommendation and the quality of the evidence supporting it. b.i.w., twice a week; i.m., intramuscular; IVIG, intravenous immune globulin; t.i.d., three times a day; TMP-SMX, trimethoprim-sulfamethoxazole; VZIG, varicella zoster immune globulin.

^aDaily TMP-SMX reduces the frequency of some bacterial infections. TMP-SMX, dapsone-pyrimethamine, and possibly atovaquone (with or without pyrimethamine) appear to protect against toxoplasmosis, although data have not been prospectively collected. When compared with weekly dapsone, daily dapsone is associated with lower incidence of *Pneumocystis carinii* pneumonia (PCP) but higher hematologic toxicity and mortality (McIntosh K, Cooper E, Xu J, et al. Toxicity and efficacy of daily vs. weekly dapsone for prevention of *Pneumocystis carinii* pneumonia in children infected with HIV. *Pediatr Infect Dis J* 1999;18:432–439).

The efficacy of parenteral pentamidine (e.g., 4 mg/kg every 2–4 wk) is controversial. Patients receiving therapy for toxoplasmosis with sulfadiazine-pyrimethamine are protected against PCP and do not need TMP-SMX.

^bSignificant drug interactions can occur between rifamycins (rifampin and rifabutin) and protease inhibitors and nonnucleoside reverse transcriptase inhibitors. Consult a specialist.

^cChildren routinely being administered IVIG should receive VZIG if the last dose of IVIG was administered >21 days before exposure.

^dHIV-infected and HIV-exposed children should be immunized according to the childhood immunization schedule in Table 18.13, which has been adapted from the January–December 2001 schedule recommended for immunocompetent children by the Advisory Committee on Immunization Practices, the American Academy of Pediatrics, and the American Academy of Family Physicians. This schedule differs from that for immunocompetent children in that both the conjugate pneumococcal vaccine (PCV-7) and the pneumococcal polysaccharide vaccine (PPV-23) are recommended (BI), and vaccination against influenza (BII) should be offered. MMR should not be administered to severely immunocompromised children (DIII). Vaccination against varicella is indicated only for asymptomatic nonimmunosuppressed children (BII). Once an HIV-exposed child is determined not to be HIV infected, the schedule for immunocompetent children applies.

^eProtection against toxoplasmosis is provided by the preferred antipneumocystis regimens and possibly by atovaquone. Atovaquone may be used with or without pyrimethamine. Pyrimethamine alone probably provides little, if any, protection.

^fRespiratory syncytial virus (RSV) IVIG (750 mg/kg), not monoclonal RSV antibody, may be substituted for IVIG during the RSV season to provide broad antimicrobial protection, if this product is available.

^gOral ganciclovir and perhaps valganciclovir results in reduced CMV shedding in CMV-infected children. Acyclovir is not protective against CMV.

^hFrom Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, pages 55–57. Posted November 28, 2001 as a “living document” at www.hivatis.org/trig/dlms.html#Opportunistic.

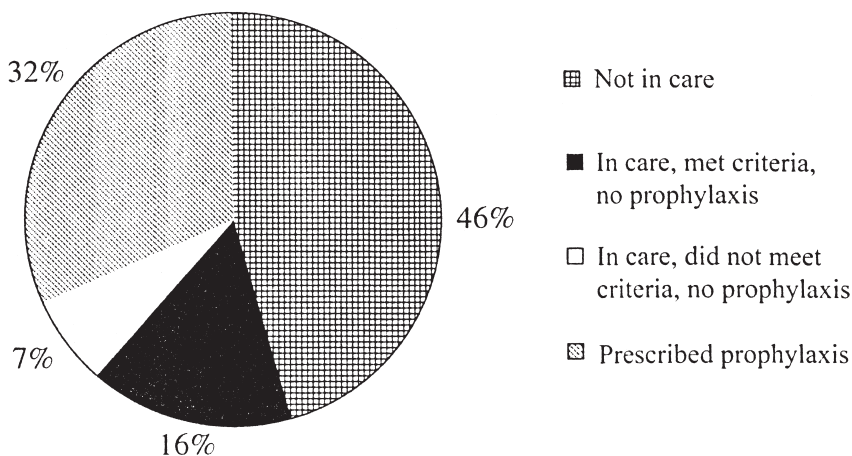

FIG. 18.3 Reasons why persons developed *Pneumocystis carinii* pneumonia, from the Adult and Adolescent Spectrum of Disease Project, 1996–1998 (N = 1,837). (Reprinted from Kaplan JE, Hanson D, Dworkin MS, et al. Epidemiology of human immunodeficiency virus–associated opportunistic infection in the United States in the era of highly active antiretroviral therapy. *Clin Infect Dis* 2000;30(suppl):2–15; with permission.)

PCP still occurs, particularly among individuals who are unaware of their HIV seropositivity or adhere poorly to prophylaxis, or those with poor access to adequate health care (Fig. 18.3). Even with appropriate prophylaxis, PCP is one of the most common serious opportunistic infections among HIV-infected persons, because prophylaxis failure may occur. Thus, PCP continues to be a substantial cause of morbidity and mortality during the HAART era.

B. Clinical manifestations

- Symptoms** are often present for weeks and are accompanied by weight loss and malaise. Slowly worsening exertional dyspnea, nonproductive cough, fever, and hypoxemia are common. Some patients may have pleuritic chest pain, but rigors, chills, and hectic fevers are uncommon. **Results of the lung examination** are usually normal, although fine bibasilar inspiratory rales may occasionally be heard. Tachypnea and tachycardia may be present, depending on the severity of illness. Findings that reflect the degree of CD4 depletion also may be noted, including thrush.
- Laboratory findings** often include an elevated serum lactate dehydrogenase (LDH) level, although this abnormality is neither sensitive nor specific for PCP. Some studies have suggested a strong correlation between the degree of LDH elevation and survival [39,40]. **The best indicator of prognosis is the alveolar-arterial gradient at the time that specific therapy is initiated.**
- Chest radiographs** classically reveal a diffuse bilateral, interstitial, and then alveolointerstitial infiltrate progressing from perihilar to peripheral regions. Pneumatoceles are associated with more prolonged, indolent disease. Apical disease, often confused with TB, has been associated with use of aerosol pentamidine prophylaxis [41]. Pleural effusions and intrathoracic adenopathy are rare, whereas spontaneous pneumothorax is more common, in PCP. Normal chest radiographs have been reported in the range of 0% to 40% [4], particularly early in the process.
- Extrapulmonary disease** is rarely encountered in patients receiving systemic chemoprophylaxis. Reported sites of disseminated *P. carinii* infection include the lymph nodes, liver, spleen, bone marrow, intestine, peritoneum, adrenal gland, pancreas, skin, eye, ear, and meninges [42,43]. Most case

Table 18.4. Prophylaxis to Prevent Recurrence of Opportunistic Disease (after Chemotherapy for Acute Disease) in HIV-infected Infants and Children

Pathogen	Indication	Preventive Regimens	
		First Choice	Alternatives
Recommended for life as standard of care <i>Pneumocystis carinii</i>	Prior <i>P. carinii</i> pneumonia	TMP-SMX 150/750 mg/m ² /day in 2 divided doses orally t.i.w. on consecutive days (AII) Acceptable alternative schedules for same dosage (AII): single dose orally t.i.w. on consecutive days; 2 divided doses orally daily; 2 divided doses orally t.i.w. on alternate days	Dapsone (children aged ≥ 1 mo) 2 mg/kg (max 100 mg) orally daily or 4 mg/kg (max 200 mg) orally weekly (CII); aerosolized pentamidine (children aged ≥ 5 yr) 300 mg monthly via Respirgard II nebulizer (CIII); atovaquone (aged 1–3 mo and >24 mo, 30 mg/kg orally daily; aged 4–24 mo, 45 mg/kg orally daily) (CI)
<i>Toxoplasma gondii</i> ^a	Prior toxoplasmic encephalitis	Sulfadiazine 85–120 mg/kg/day in 2–4 divided doses orally daily plus pyrimethamine 1 mg/kg or 15 mg/m ² (max 25 mg) orally daily plus leucovorin 5 mg orally every 3 days (AI)	Clindamycin 20–30 mg/kg/day in 4 divided doses orally plus pyrimethamine 1 mg/kg orally daily plus leucovorin 5 mg orally every 3 days (BI)
<i>Mycobacterium avium</i> complex ^b	Prior disease	Clarithromycin 7.5 mg/kg (max 500 mg) orally b.i.d. (AII) plus ethambutol 15 mg/kg (max 900 mg) orally daily (AII), with or without rifabutin 5 mg/kg (max 300 mg) orally daily (CII)	Azithromycin 5 mg/kg (max 250 mg) orally daily (AII) plus ethambutol 15 mg/kg (max 900 mg) orally daily (AII), with or without rifabutin 5 mg/kg (max 300 mg) orally daily (CII)
<i>Cryptococcus neoformans</i>	Documented disease	Fluconazole 3–6 mg/kg orally daily (AII)	Amphotericin B 0.5–1.0 mg/kg i.v. 1–3 times/week (AI); itraconazole 2–5 mg/kg orally every 12–24 h (BI)
<i>Histoplasma capsulatum</i>	Documented disease	Itraconazole 2–5 mg/kg orally every 12–48 h (AIII)	Amphotericin B 1.0 mg/kg i.v. weekly (AII)

<i>Coccidioides immitis</i>	Documented disease	Fluconazole 6 mg/kg orally daily (AIII)	Amphotericin B 1.0 mg/kg i.v. weekly (AIII); itraconazole 2–5 mg/kg orally every 12–48 h (AIII)
Cytomegalovirus	Prior end-organ disease	Ganciclovir 5 mg/kg i.v. daily; or foscarnet 90–120 mg/kg i.v. daily (AI)	(For retinitis) ganciclovir sustained-release implant every 6–9 mo plus ganciclovir 30 mg/kg orally t.i.d. (BIII) Antibiotic chemoprophylaxis with another active agent (CIII)
<i>Salmonella</i> species (nontyphi) ^c	Bacteremia	TMP-SMX 150/750 mg/m ² in 2 divided doses orally daily for several months (CIII)	Antibiotic chemoprophylaxis with another active agent (BIII)
Recommended only if subsequent episodes are frequent or severe Invasive bacterial infections ^d	>2 infections in 1-yr period	TMP-SMX 150/750 mg/m ² in 2 divided doses orally daily (BI); or IVIG 400 mg/kg every 2–4 wk (BI)	Antibiotic chemoprophylaxis with another active agent (BIII)
Herpes simplex virus	Frequent/severe recurrences	Acyclovir 80 mg/kg/day in 3–4 divided doses orally (AII)	
<i>Candida</i> (oropharyngeal)	Frequent/severe recurrences	Fluconazole 3–6 mg/kg orally daily (CIII)	
<i>Candida</i> (esophageal)	Frequent/severe recurrences	Fluconazole 3–6 mg/kg orally daily (BIII)	Itraconazole solution 5 mg/kg orally daily (CIII)

Information included in these guidelines might not represent U.S. Food and Drug Administration (FDA) approval or approved labeling for the particular products or indications in question. Specifically, the terms “safe” and “effective” might not be synonymous with the FDA-defined legal standards for product approval. The Respirgard II nebulizer is manufactured by Marquest, Englewood, Colorado. Letters and roman numerals in parentheses after regimens indicate the strength of the recommendation and the quality of evidence supporting it. i.v., intravenous; IVIG, intravenous immune globulin; t.i.d., three times a day; t.i.w., three times a week; TMP-SMX, trimethoprim-sulfamethoxazole.

^aOnly pyrimethamine plus sulfadiazine confers protection against *Pneumocystis carinii* pneumonia as well as toxoplasmosis. Although the clindamycin plus pyrimethamine regimen is recommended in adults, it has not been tested in children. However, these drugs are safe and are used for other infections.

^bSignificant drug interactions might occur between rifabutin and protease inhibitors and non-nucleoside reverse transcriptase inhibitors. Consult an expert.

^cDrug should be determined by susceptibilities of the organism isolated. Alternatives to TMP-SMX include ampicillin, chloramphenicol, or ciprofloxacin. However, ciprofloxacin is not approved for use in persons aged <18 years; therefore, it should be used in children with caution and only if no alternatives exist.

^dAntimicrobial prophylaxis should be chosen based on the microorganism and antibiotic sensitivities. TMP-SMX, if used, should be administered daily. Providers should be cautious about using antibiotics solely for this purpose because of the potential for development of drug-resistant microorganisms. IVIG might not provide additional benefit to children receiving daily TMP-SMX but may be considered for children who have recurrent bacterial infections despite TMP-SMX prophylaxis. Choice of antibiotic prophylaxis vs. IVIG should also involve consideration of adherence, ease of intravenous access, and cost. If IVIG is used, respiratory syncytial virus (RSV) IVIG (750 mg/kg), not monoclonal RSV antibody, may be substituted for IVIG during the RSV season to provide broad antimicrobial protection, if this product is available.

Table 18.5. Criteria for Starting, Discontinuing, and Restarting Opportunistic Infection Prophylaxis for Adults with Human Immunodeficiency Virus Infection

Opportunistic Illness	Criteria for Initiating Primary Prophylaxis	Criteria for Discontinuing Primary Prophylaxis	Criteria for Restarting Primary Prophylaxis	Criteria for Initiating Secondary Prophylaxis	Criteria for Discontinuing Secondary Prophylaxis	Criteria for Restarting Secondary Prophylaxis
<i>Pneumocystis carinii</i> pneumonia	CD4 ⁺ <200 cells/ μ L or oropharyngeal candidiasis (AI)	CD4 ⁺ >200 cells/ μ L for ≥ 3 months (AI)	CD4 ⁺ <200 cells/ μ L (AIII)	Prior <i>Pneumocystis carinii</i> pneumonia (AI)	CD4 ⁺ >200 cells/ μ L for ≥ 3 months (BII)	CD4 ⁺ <200 cells/ μ L (AIII)
Toxoplasmosis	IgG antibody to toxoplasma and CD4 ⁺ <100 cells/ μ L (AI)	CD4 ⁺ >200 cells/ μ L for ≥ 3 months (AI)	CD4 ⁺ <100–200 cells/ μ L (AIII)	Prior toxoplasmic encephalitis (AI)	CD4 ⁺ >200 cells/ μ L sustained (e.g., ≥ 6 mo) and completed initial therapy and asymptomatic for toxoplasmosis (CIII)	CD4 ⁺ <200 cells/ μ L (AIII)
Disseminated <i>Mycobacterium avium</i> complex (MAC)	CD4 ⁺ <50 cells/ μ L (AI)	CD4 ⁺ >100 cells/ μ L for ≥ 3 months (AI)	CD4 ⁺ <50–100 cells/ μ L (AIII)	Documented disseminated disease (AII)	CD4 ⁺ >100 cells/ μ L sustained (e.g., ≥ 6 months) and completed 12 mo of MAC therapy and asymptomatic for MAC (CIII)	CD4 ⁺ <100 cells/ μ L (AIII)

Cryptococcosis	None	Not applicable	Not applicable	Documented disease (AI)	CD4 ⁺ > 100–200 cells/ μ L sustained (e.g., \geq 6 mo) and completed initial therapy and asymptomatic for cryptococcosis (CIII)	CD4 ⁺ < 100–200 cells/ μ L (AIII)
Histoplasmosis	None	Not applicable	Not applicable	Documented disease (AI)	No criteria recommended for stopping	Not applicable
Coccidioidomycosis	None	Not applicable	Not applicable	Documented disease (AI)	No criteria recommended for stopping	Not applicable
Cytomegalovirus retinitis	None	Not applicable	Not applicable	Documented end-organ disease (AI)	CD4 ⁺ > 100–150 cells/ μ L sustained (e.g., \geq 6 mo) and no evidence of active disease and regular ophthalmic examination (BII)	CD4 ⁺ < 100–150 cells/ μ L (AIII)

From Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, page 60. Posted November 28, 2001 as a "living document" at www.hivatis.org/irrigdlns.html#Opportunistic.

Table 18.6. Recommendations to Help Patients Avoid Exposure to or Infection with Opportunistic Pathogens

Sexual exposures

Patients should use a latex condom during every act of sexual intercourse to reduce the risk for acquiring cytomegalovirus, herpes simplex virus, and human papillomavirus, as well as other sexually transmitted pathogens (AII). Condom use also will, theoretically, reduce the risk for acquiring human herpesvirus 8, as well as superinfection with an HIV strain that has become resistant to antiretroviral drugs (BIII) and will prevent transmission of HIV and other sexually transmitted pathogens to others (AII). Data regarding the use and efficacy of female condoms are incomplete, but these devices should be considered as a risk-reduction strategy (BIII).

Patients should avoid sexual practices that might result in oral exposure to feces (e.g., oral-anal contact) to reduce the risk for intestinal infections (e.g., cryptosporidiosis, shigellosis, campylobacteriosis, amebiasis, giardiasis, and hepatitis A) (BIII). Latex condom use alone may not reduce the risk of acquiring these fecal-orally transmitted pathogens, especially those that have low infectious doses. Persons wishing to reduce their risk of exposure might consider using dental dams or similar barrier methods for oral-anal and oral-genital contact, changing condoms after anal intercourse, and wearing latex gloves during digital-anal contact. Frequently washing hands and genitals with warm soapy water during and after activities which may bring these body parts in contact with feces may further reduce risk of illness (CIII).

Hepatitis B immunization is recommended for all susceptible (anti-HBc–negative) HIV-infected patients (BII).

Hepatitis A immunization is recommended for all susceptible men who have sex with men, as well as others at risk for infection with hepatitis A virus (BIII).

Injection drug use exposures

Injection drug use is a complex behavior that puts HIV-infected persons at risk for hepatitis B virus and hepatitis C virus infection, other possibly drug-resistant strains of HIV, and other blood-borne pathogens. Providers should assess the individual's readiness to change this practice and encourage efforts to provide education and support directed at recovery. Patients should be counseled to stop using injection drugs (AIII) and to enter and complete substance-abuse treatment, including relapse prevention programs (AIII).

If they are continuing to inject drugs, patients should be advised (BIII):

- to never reuse or share syringes, needles, water, or drug preparation equipment; if, nonetheless, injection equipment that has been used by other persons is shared, to first clean the equipment with bleach and water (U.S. Public Health Service. HIV prevention bulletin: medical advice for persons who inject illicit drugs. May 8, 1997. Rockville, MD: CDC, 1997)

- to use only sterile syringes obtained from reliable source (e.g., pharmacies or syringe exchange programs)

- to use sterile (e.g., boiled) water to prepare drugs; if not possible, to use clean water from a reliable source (e.g., fresh tap water); to use a new or disinfected container ("cooker") and a new filter ("cotton") to prepare drugs

- to clean the injection site with a new alcohol swab before injection

- to safely dispose of syringes after one use

All susceptible injection drug users should be immunized against hepatitis B (BII) and hepatitis A (BIII).

Environmental and occupational exposures

Certain activities or types of employment might increase the risk for exposure to tuberculosis (BIII). These include volunteer work or employment in health-care facilities, correctional institutions, and shelters for the homeless, as well as other settings identified as high risk by local health authorities. Decisions about whether to continue with such activities should be made in conjunction with the health-care provider and should be based on such factors as the patient's specific duties in the workplace, the prevalence of tuberculosis in the community, and the degree to which precautions designed to prevent the transmission of tuberculosis are taken in the

Table 18.6. (Continued)

workplace (BIII). These decisions will affect the frequency with which the patient should be screened for tuberculosis.
Child-care providers and parents of children in child care are at increased risk for acquiring CMV infection, cryptosporidiosis, and other infections (e.g., hepatitis A and giardiasis) from children. The risk for acquiring infection can be diminished by good hygienic practices, such as hand washing after fecal contact (e.g., during diaper changing) and after contact with urine or saliva (AII). All children in child-care facilities also are at increased risk for acquiring these same infections; parents and other caretakers of HIV-infected children should be advised of this risk (BIII).
Occupations involving contact with animals (e.g., veterinary work and employment in pet stores, farms, or slaughterhouses) might pose a risk for cryptosporidiosis, toxoplasmosis, salmonellosis, campylobacteriosis, or <i>Bartonella</i> infection. However, the available data are insufficient to justify a recommendation against work in such settings.
Contact with young farm animals, especially animals with diarrhea, should be avoided to reduce the risk for cryptosporidiosis (BII).
Hand washing after gardening or other contact with soil might reduce the risk for cryptosporidiosis and toxoplasmosis (BIII).
In areas endemic for histoplasmosis, patients should avoid activities known to be associated with increased risk (e.g., creating dust when working with surface soil; cleaning chicken coops that are heavily contaminated with compost droppings; disturbing soil beneath bird-roosting sites; cleaning, remodeling, or demolishing old buildings; and cave exploring) (CIII).
In areas endemic for coccidioidomycosis, when possible, patients should avoid activities associated with increased risk, including those involving extensive exposure to disturbed native soil (e.g., at building excavation sites or during dust storms) (CIII).
Pet-related exposures
Health-care providers should advise HIV-infected persons of the potential risk posed by pet ownership. However, they should be sensitive to the possible psychologic benefits of pet ownership and should not routinely advise HIV-infected persons to part with their pets (DIII). Specifically, providers should advise HIV-infected persons of the following precautions.
<i>General</i>
Veterinary care should be sought when a pet develops diarrheal illness. If possible, HIV-infected persons should avoid contact with animals that have diarrhea (BIII). A fecal sample should be obtained from animals with diarrhea and examined for <i>Cryptosporidium</i> , <i>Salmonella</i> , and <i>Campylobacter</i> .
When obtaining a new pet, HIV-infected patients should avoid animals aged <6 months (or <1 year for cats; see Cats section, which follows), especially those with diarrhea (BIII). Because the hygienic and sanitary conditions in pet-breeding facilities, pet stores, and animal shelters are highly variable, the patient should be cautious when obtaining a pet from these sources. Stray animals should be avoided. Animals aged <6 months, especially those with diarrhea, should be examined by a veterinarian for <i>Cryptosporidium</i> , <i>Salmonella</i> , and <i>Campylobacter</i> (BIII).
Patients should wash their hands after handling pets (especially before eating) and avoid contact with pets' feces to reduce the risk for cryptosporidiosis, salmonellosis, and campylobacteriosis (BIII). Hand washing for HIV-infected children should be supervised.
<i>Cats</i>
Patients should be aware that cat ownership increases their risk for toxoplasmosis and <i>Bartonella</i> infection, as well as enteric infections (CIII). Those who elect to obtain a cat should adopt or purchase an animal that is aged >1 year and in good health to reduce the risk for cryptosporidiosis, <i>Bartonella</i> infection, salmonellosis, and campylobacteriosis (BII).
Litter boxes should be cleaned daily, preferably by an HIV-negative, nonpregnant person; if the HIV-infected patient performs this task, he or she should wash hands thoroughly afterward to reduce the risk for toxoplasmosis (BIII).

Continued

Table 18.6. (Continued)

To reduce the risk for toxoplasmosis, HIV-infected patients should keep cats indoors, not allow them to hunt, and not feed them raw or undercooked meat (BIII). Although declawing is not generally advised, patients should avoid activities that might result in cat scratches or bites to reduce the risk for *Bartonella* infection (BII). Patients should also wash sites of cat scratches or bites promptly (CIII) and should not allow cats to lick the patients' open cuts or wounds. Care of cats should include flea control to reduce risk for *Bartonella* infection (CIII). Testing cats for toxoplasmosis (EII) or *Bartonella* infection (DII) is not recommended.

Birds
Screening healthy birds for *Cryptococcus neoformans*, *Mycobacterium avium*, or *Histoplasma capsulatum* is not recommended (DIII).

Other
Contact with reptiles (e.g., snakes, lizards, iguana, and turtles) as well as chicks and ducklings should be avoided to reduce the risk for salmonellosis (BIII). Gloves should be used during the cleaning of aquariums to reduce the risk for infection with *Mycobacterium marinum* (BIII). Contact with exotic pets (e.g., nonhuman primates) should be avoided (CIII).

Food- and water-related exposures
Raw or undercooked eggs (including foods that might contain raw eggs [e.g., some preparations of hollandaise sauce, Caesar and certain other salad dressings, some mayonnaises, uncooked cookie and cake batter, eggnog]); raw or undercooked poultry, meat, and seafood (especially raw shellfish); unpasteurized dairy products; unpasteurized fruit juice; and raw seed sprouts (e.g., alfalfa sprouts, mung bean sprouts) should not be eaten. Poultry and meat are safest when adequate cooking is confirmed with a thermometer (internal temperature of 180°F for poultry and 165°F for red meats). If a thermometer is not used, the risk for illness is decreased by consuming poultry and meat that have no trace of pink. Color change of the meat (e.g., absence of pink) does not always correlate with internal temperature. Produce should be washed thoroughly before being eaten (BIII).
Cross-contamination of foods should be avoided. Uncooked meats should not be allowed to come in contact with other foods; hands, cutting boards, counters, knives, and other utensils should be washed thoroughly after contact with uncooked food (BIII).
Although the incidence of listeriosis is low, it is a serious disease that occurs frequently among HIV-infected persons who are severely immunosuppressed. An immunosuppressed HIV-infected person who wishes to reduce the risk of acquiring listeriosis as much as possible may choose to do the following:
Avoid soft cheeses (e.g., feta, Brie, Camembert, blue-veined, and Mexican-style cheese such as queso fresco). Hard cheeses, processed cheeses, cream cheese (including slices and spreads), cottage cheese, or yogurt need not be avoided.
Cook leftover foods or ready-to-eat foods (e.g., hot dogs) until steaming hot before eating.
Avoid foods from delicatessen counters (e.g., prepared salads, meats, cheeses) or heat/reheat these foods until steaming before eating.
Avoid refrigerated pates and other meat spreads, or heat/reheat these foods until steaming if eaten. Canned or shelf-stable pate and meat spreads need not be avoided.
Avoid raw or unpasteurized milk (including goat's milk) or milk products, or foods that contain unpasteurized milk or milk products (CIII).
Patients should not drink water directly from lakes or rivers because of the risk for cryptosporidiosis and giardiasis (AIII). Water-borne infection also might result from swallowing water during recreational activities. Patients should avoid swimming in water that is likely to be contaminated with human or animal waste and should avoid swallowing water during swimming (BII).
During outbreaks or in other situations in which a community "boil water advisory" is issued, boiling water for 1 minute will eliminate the risk for acquiring cryptosporidiosis (AI). Using submicron, personal-use water filters (home/office types) and/or drinking bottled water might also reduce risk (CIII). Current data are inadequate to support a recommendation that all HIV-infected persons boil or otherwise avoid drinking tap

Table 18.6. (Continued)

water in nonoutbreak settings. However, persons who wish to take independent action to reduce their risk from water-borne cryptosporidiosis may choose to take precautions similar to those recommended during outbreaks. Such decisions are best made in conjunction with a health-care provider. Persons who opt for a personal-use filter or bottled water should be aware of the complexities involved in selecting the appropriate products, the lack of enforceable standards for destruction or removal of oocysts, the cost of the products, and the difficulty of using these products consistently. Patients taking precautions to avoid acquiring cryptosporidiosis from drinking water should be advised that ice made from contaminated water also can be a source of infection (BII). Such persons should be aware that fountain beverages served in restaurants, bars, theaters, and other public places might also pose a risk, because these beverages, as well as the ice they might contain, are made from tap water. Nationally distributed brands of bottled or canned carbonated soft drinks are safe to drink.

Commercially packaged noncarbonated soft drinks and fruit juices that do not require refrigeration until after they are opened (i.e., those that can be stored unrefrigerated on grocery shelves) also are safe. Nationally distributed brands of frozen fruit juice concentrate are safe if they are reconstituted by the user with water from a safe source. Fruit juices that must be kept refrigerated from the time they are processed to the time of consumption might be either fresh (unpasteurized) or heat-treated (pasteurized); only juices labeled as pasteurized should be considered free of risk from *Cryptosporidium*. Other pasteurized beverages and beers are also considered safe to drink (BII). No data are available concerning survival of *Cryptosporidium* oocytes in wine.

Travel-related exposures

Travel, particularly to developing countries, might result in significant risks for the exposure of HIV-infected persons to opportunistic pathogens, especially for patients who are severely immunosuppressed. Consultation with health-care providers or with experts in travel medicine will help patients plan itineraries (BIII).

During travel to developing countries, HIV-infected persons are at even higher risk for food-borne and water-borne infections than they are in the United States. Foods and beverages—particularly raw fruits and vegetables, raw or undercooked seafood or meat, tap water, ice made with tap water, unpasteurized milk and dairy products, and items purchased from street vendors—might be contaminated (AII). Items that are generally safe include steaming hot foods, fruits that are peeled by the traveler, bottled (especially carbonated) beverages, hot coffee or tea, beer, wine, and water brought to a rolling boil for 1 minute (AII). Treating water with iodine or chlorine might not be as effective as boiling but can be used, perhaps in conjunction with filtration, when boiling is not practical (BIII).

Water-borne infections might result from swallowing water during recreational activities. To reduce the risk for cryptosporidiosis and giardiasis, patients should avoid swallowing water during swimming and should not swim in water that might be contaminated (e.g., with sewage or animal waste) (BII).

Antimicrobial prophylaxis for traveler's diarrhea is not recommended routinely for HIV-infected persons traveling to developing countries (DIII). Such preventive therapy can have adverse effects and can promote the emergence of drug-resistant organisms. Nonetheless, several studies (none involving an HIV-infected population) have shown that prophylaxis can reduce the risk for diarrhea among travelers (CDC. *Health information for international travel, 1999–2000*. Atlanta, GA: U.S. Department of Health and Human Services, 1999:202). Under selected circumstances (e.g., those in which the risk for infection is very high and the period of travel brief), the provider and patient may weigh the potential risks and benefits and decide that antibiotic prophylaxis is warranted (CIII). For those persons to whom prophylaxis is offered, fluoroquinolones (e.g., ciprofloxacin [500 mg daily]) can be considered (CIII), although fluoroquinolones should not be given to children or pregnant women. Trimethoprim-sulfamethoxazole (TMP-SMX) (one double-strength tablet daily) also has been shown

Continued

Table 18.6. (Continued)

- to be effective, but resistance to this drug is now common in tropical areas. Persons already taking TMP-SMX for prophylaxis against *Pneumocystis carinii* pneumonia (PCP) might gain some protection against traveler's diarrhea. For HIV-infected persons who are not already taking TMP-SMX, health-care providers should be cautious in prescribing this agent for prophylaxis of diarrhea because of the high rates of adverse reactions and the possible need for the agent for other purposes (e.g., PCP prophylaxis) in the future.
- All HIV-infected travelers to developing countries should carry a sufficient supply of an antimicrobial agent to be taken empirically should diarrhea develop (BIII). One appropriate regimen is 500 mg of ciprofloxacin twice a day for 3–7 days. Alternative antibiotics (e.g., TMP-SMX) should be considered as empirical therapy for use by children and pregnant women (CIII). Travelers should consult a physician if their diarrhea is severe and does not respond to empirical therapy, if their stools contain blood, if fever is accompanied by shaking chills, or if dehydration develops. Antiperistaltic agents (e.g., diphenoxylate and loperamide) are used for the treatment of diarrhea; however, they should not be used by patients with high fever or with blood in the stool, and their use should be discontinued if symptoms persist beyond 48 hours (AII). Antiperistaltic agents are not recommended for children (DIII).
- Travelers should be advised about other preventive measures appropriate for anticipated exposures (e.g., chemoprophylaxis for malaria, protection against arthropod vectors, treatment with immune globulin, and vaccination) (AII). They should avoid direct contact of the skin with soil or sand (e.g., by wearing shoes and protective clothing and using towels on beaches) in areas where fecal contamination of soil is likely (BIII).
- In general, live-virus vaccines should be avoided (EII). One exception is measles vaccine, which is recommended for nonimmune persons. However, measles vaccine is not recommended for persons who are severely immunosuppressed (DIII); immune globulin should be considered for measles-susceptible, severely immunosuppressed persons who are anticipating travel to measles-endemic countries (BIII). Another exception is varicella vaccine, which may be administered to asymptomatic nonimmunosuppressed children (BII). Inactivated (killed) poliovirus vaccine should be used instead of oral (live) poliovirus vaccine, which is contraindicated for HIV-infected persons. Persons at risk for exposure to typhoid fever should be administered an inactivated parenteral typhoid vaccine instead of the live attenuated oral preparation. Yellow fever vaccine is a live-virus vaccine with uncertain safety and efficacy in HIV-infected persons. Travelers with asymptomatic HIV infection who cannot avoid potential exposure to yellow fever should be offered the choice of vaccination. If travel to a zone with yellow fever is necessary and vaccination is not administered, patients should be advised of the risk, instructed in methods for avoiding the bites of vector mosquitoes, and provided with a vaccination waiver letter.
- In general, killed and recombinant vaccines (e.g., diphtheria-tetanus, rabies, hepatitis A, hepatitis B, Japanese encephalitis vaccines) should be used for HIV-infected persons just as they would be used for non-HIV-infected persons anticipating travel (BIII). Preparation for travel should include a review and updating of routine vaccinations, including diphtheria-tetanus for adults and all routine immunizations for children. The currently available cholera vaccine is not recommended for persons following a usual tourist itinerary, even if travel includes countries reporting cases of cholera (DII).
- Travelers should be informed about other area-specific risks and instructed in ways to reduce those risks (BIII). Geographically focal infections that pose a high risk to HIV-infected persons include visceral leishmaniasis (a protozoan infection transmitted by the sandfly) and several fungal infections (e.g., *Penicillium marneffe* infection, coccidioidomycosis, and histoplasmosis). Many tropical and developing areas have high rates of tuberculosis.

Table 18.7. Effects of Food on Drugs Used to Prevent Opportunistic Infections

Drug	Food Effect	Recommendation
Atovaquone	Bioavailability increased up to threefold with high-fat meal	Administer with food
GCV (capsules)	High-fat meal results in 22% (GCV) or 30% (VGCV) increase in AUC	High-fat meal may increase toxicity of VGCV
Itraconazole	Grapefruit juice results in 30% decrease in AUC	Avoid concurrent grapefruit juice
Itraconazole (capsules)	Significant increase in bioavailability when taken with a full meal	Administer with food
Itraconazole (solution)	31% increase in AUC when taken under fasting conditions	Take without food if possible

GCV, ganciclovir; VGCV, valganciclovir; AUC, area under the curve.

From Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, page 44. Posted November 28, 2001 as a "living document" at www.hivatis.org/trtgdlns.html#Opportunistic.

reports associate extrapulmonary disease with the use of aerosol pentamidine [44].

C. Diagnosis. Patients who present with an illness suggestive of PCP should undergo chest radiography. If the chest film is supportive, then attempts should be made to confirm the diagnosis by identification of *P. carinii* on microscopic examination with Gomori **methenamine silver stain** or **toluidine blue O**. If the chest film is negative but PCP is still suspected, further studies are indicated to help support the diagnosis prior to treatment.

- 1. Sputum.** Expecterated sputum is rarely suitable for microscopic evaluation. Similarly, purulent sputum, even when induced, may be inadequate for examination due to the presence of cellular debris and artifact. Sensitivity of the induced sputum examination greatly depends on the quality of the sampling and the experience of the laboratory, and has ranged from 30% to 90% [45,46].
- 2. Bronchoscopy with bronchoalveolar lavage (BAL) is the diagnostic procedure of choice for obtaining adequate pulmonary secretions.** A negative BAL for *P. carinii* should strongly suggest an alternative diagnosis. Transbronchial biopsy or open lung biopsy usually are not necessary to diagnose PCP in AIDS patients.
- 3. Other tests.** Gallium citrate scanning is highly sensitive (90%) but nonspecific (50%) for PCP [47,48]; it is seldom used due to the high cost and time delay for results (3 days). Likewise, high-resolution computed tomography (CT) showing ground glass infiltrates and pulmonary function testing are nonspecific and do not provide an etiologic diagnosis. Polymerase chain reaction (PCR) tests to detect *P. carinii* DNA has yielded positive results in patients without pneumonia. Refinements in the methodology may make this sensitive assay appropriate for routine clinical use in the future [49].
- 4. Empiric treatment without attempts to confirm a diagnosis is not generally recommended.** However, this may be appropriate in patients with mild illness who are clinically stable and not hypoxic; have clinical, laboratory, and radiographic support for PCP; and are at low risk for other OIs or conditions that may mimic PCP. It also may be used for individuals who do not have prompt access to diagnostic facilities.

Table 18.8. Effects of Medications on Drugs Used to Prevent Opportunistic Infections

Affected Drug	Interacting Drug(s)	Mechanism/Effect	Recommendation
Atovaquone	Rifampin	Induction of metabolism/ decreased drug levels	Concentrations might not be therapeutic; avoid combination or increase atovaquone dose.
Atovaquone	Lopinavir-ritonavir	Potential for induction of metabolism/ decreased drug levels	Concentrations may not be therapeutic; may require increased atovaquone dose, but data insufficient to make specific recommendation.
Clarithromycin	Efavirenz	Induction of metabolism/decrease in clarithromycin AUC by 39%, increase in AUC of 14-OH clarithromycin by 34%	Clarithromycin efficacy uncertain.
Clarithromycin	Ritonavir	Inhibition of metabolism/increased clarithromycin drug levels by 77%	Dose adjustment of clarithromycin necessary only if renal dysfunction is present. For CrCl <60 mL/min, reduce clarithromycin dose by 50%; for CrCl <30 mL/min, reduce dose by 75%.
Clarithromycin	Lopinavir-ritonavir	Inhibition of metabolism/increased clarithromycin drug levels	Dose adjustment of clarithromycin necessary only if renal dysfunction is present. For CrCl <60 mL/min, reduce clarithromycin dose by 50%; for CrCl <30 mL/min, reduce dose by 75%.
Clarithromycin	Nevirapine	Induction of metabolism/decrease in clarithromycin AUC by 35%, increase in AUC of 14-OH clarithromycin by 27%	Efficacy of MAC prophylaxis may be decreased; monitor closely.
Ketoconazole	Lopinavir-ritonavir	Inhibition of metabolism/increased ketoconazole AUC	Use with caution at ketoconazole doses >200 mg/day

(Continued)

Table 18.8. (Continued)

Affected Drug	Interacting Drug(s)	Mechanism/Effect	Recommendation
Ketoconazole	Antacids, didanosine (but not didanosine EC), buffered products, H ₂ blockers, proton pump inhibitors	Increase in gastric pH that impairs absorption of ketoconazole	Avoid use of ketoconazole with pH-raising agents or use alternative antifungal drug.
Quinolone antibiotics (ciprofloxacin, levofloxacin, gatifloxacin, moxifloxacin)	Didanosine (but not didanosine EC), antacids, iron products, calcium products, sucralfate (cation preparations)	Chelation results in marked decrease in quinolone drug levels	Administer cation preparation at least 2 h after quinolone.
Rifabutin	Fluconazole	Inhibition of metabolism/marked increase in rifabutin drug levels	Monitor for rifabutin toxicities such as uveitis, nausea, neutropenia.
Rifabutin	Efavirenz	Induction of metabolism/significant decrease in rifabutin AUC	Increase rifabutin dose to 450–600 mg daily or 600 mg twice weekly. ^a
Rifabutin	Ritonavir, lopinavir-ritonavir, ritonavir-saquinavir	Inhibition of metabolism/marked increase in rifabutin drug levels	Decrease rifabutin to 150 mg every other day or three times per week.
Rifabutin	Indinavir, nelfinavir, amprenavir	Inhibition of metabolism/marked increase in rifabutin drug levels	Decrease rifabutin to 150 mg daily or 300 mg three times per week.

AUC, area under the curve; MAC, *Mycobacterium avium* complex; H₂, histamine; CrCl, creatinine clearance.

^aAppropriate dose of efavirenz is uncertain if a protease inhibitor is used with efavirenz plus rifabutin. From Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, pages 45–46. Posted November 28, 2001 as a “living document” at www.hivatis.org/trtgdlns.html#Opportunistic.

5. **A firm diagnosis must be established in patients on prophylaxis** who present with a clinical picture that is suggestive of PCP. Patients on oral prophylaxis who develop PCP have the same manifestations as described above. However, systemic PCP prophylaxis is quite effective, and many other conditions (including infections) may yield the same clinical picture.
6. **A diagnosis must be established for the pulmonary process, and other OIs should be sought in hypoxic patients given corticosteroids** (see below). This is because the degree of immunosuppression that predisposes to PCP is also a risk for other OIs that may be the true pulmonary diagnosis, or a mixed infection may be present, and the corticosteroids may exacerbate these other infections.

Table 18.9. Effects of Opportunistic Infection Medications on Antiinfective Drugs Commonly Administered to Persons Infected with Human Immunodeficiency Virus

Affected Drug	Interacting Drug(s)	Mechanism/Effect	Recommendation
Amprenavir, delavirdine, indinavir, lopinavir-ritonavir, nelfinavir, saquinavir	Rifampin	Induction of metabolism/marked decrease in protease inhibitor or delavirdine drug levels	Avoid concomitant use.
Efavirenz, ritonavir, ritonavir-saquinavir, nevirapine	Rifampin	Induction of metabolism/decrease in protease or nevirapine levels	Combinations could possibly be used but limited clinical experience. Consider efavirenz 800 mg daily when used with rifampin.
Delavirdine	Rifabutin	Induction of metabolism/50%–60% decrease in delavirdine levels	Avoid concomitant use.
Indinavir, nelfinavir, amprenavir ^a	Rifabutin	Induction of metabolism/50% decrease in protease inhibitor levels	Consider increase in indinavir dose to 1,000 mg q8h; If indinavir is the sole protease inhibitor, decrease rifabutin dose to 150 mg daily.
Ritonavir, ritonavir-saquinavir, lopinavir-ritonavir	Rifabutin	Induction of metabolism of ritonavir	No dosage change for protease inhibitors. Consider rifabutin 150 mg q.o.d. or three times per week.
Efavirenz	Rifabutin	Potential for decreased efavirenz levels	No dosage change necessary for efavirenz; adjust rifabutin dose to 450–600 mg daily or 600 mg twice weekly.
Saquinavir	Rifabutin	Potential for decreased saquinavir levels	Limited data
Didanosine (ddI)	Ganciclovir (oral)	Increased ddI AUC by approximately 100%	Clinical significance unknown; monitor for ddI-related adverse effects.

q 8h, every 8 hours; q.o.d., every other day; AUC, area under the curve.

^a Little data are available for use of rifamycin drugs with ritonavir-boosting protease inhibitor regimens except for ritonavir-saquinavir and ritonavir-lopinavir. Therefore, concomitant use of rifamycins with these regimens must be approached cautiously.

From Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, page 47. Posted November 28, 2001 as a “living document” at www.hivatis.org/trtgdlns.html#Opportunistic.

Table 18.10. Adverse Effects of Drugs Used in the Prevention of Opportunistic Infections

Bone marrow suppression	Cidofovir, dapsone, ganciclovir, pyrimethamine, rifabutin, sulfadiazine, TMP-SMX
Diarrhea	Atovaquone, clindamycin
Hepatotoxicity	Clarithromycin, fluconazole, isoniazid, itraconazole, ketoconazole, pyrazinamide, rifabutin, rifampin, TMP-SMX
Nephrotoxicity	Amphotericin B, cidofovir, foscarnet, pentamidine, high-dose acyclovir
Ocular effects	Cidofovir, ethambutol, rifabutin
Pancreatitis	Pentamidine, TMP-SMX
Peripheral neuropathy	Isoniazid
Neurotoxicity	Acyclovir (high-dose), quinolones
Skin rash	Atovaquone, dapsone, pyrimethamine, sulfadiazine, TMP-SMX, ribavirin

TMP-SMX, trimethoprim-sulfamethoxazole.

From Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, page 48. Posted November 28, 2001 as a "living document" at www.hivatis.org/trtgdlns.html#Opportunistic.

D. Treatment. Even with proper therapy, **response is gradual**: respiratory rate, dyspnea, and arterial-alveolar gradient improve within 4 to 8 days. Several options are available:

- 1. Trimethoprim** (15–20 mg/kg/day) and **sulfamethoxazole** (75 mg/kg/day) (**cotrimoxazole**) orally or intravenously (i.v.) in three to four divided doses for at least 21 days **is always the drug regimen of choice** unless the patient has a history of life-threatening intolerance. No other agent has demonstrated higher efficacy for PCP. Cotrimoxazole is well absorbed orally and can be used for outpatient therapy for mild disease (room air partial pressure of oxygen [PO₂] of >80 mm Hg) in patients with no major gastrointestinal dysfunction. Side effects include rash, fever, pruritis, digestive disturbances, cytopenias, and hyperkalemia, most of which are easily managed. Life-threatening reactions such as Stevens-Johnson syndrome are rare. Recent reports have documented mutations in the dihydropteroate synthase gene leading to sulfonamide resistance in some human isolates [50,51]. The frequency and clinical significance of these and other mutations are currently being studied, and they could have an obvious negative impact on the efficacy of prophylaxis.
- 2. Trimethoprim** (15 mg/kg/day in three divided doses) **plus dapsone** (100 mg orally once daily) for 21 days has efficacy that is comparable with trimethoprim-sulfamethoxazole and may be somewhat better tolerated but less convenient because they are taken at different times. Side effects include rash, methemoglobinemia, hemolytic anemia, and neutropenia. It is rarely necessary to screen for **G6PD deficiency** prior to dapsone therapy unless there is a strong suspicion of deficiency, as might be the case for those of Mediterranean ancestry. A history of life-threatening trimethoprim-sulfamethoxazole intolerance should preclude the use of dapsone plus trimethoprim.
- 3. Intravenous pentamidine** (4 mg/kg once daily) for 21 days is about as effective as trimethoprim-sulfamethoxazole. Pentamidine was the first drug successfully used in patients who did not have AIDS. Adverse reactions can be life threatening, such as hypotension, hypoglycemia, renal insufficiency, and various cardiac arrhythmias, including torsades de pointes. Other side effects include pancreatitis and diabetes. In addition, patients often feel ill during therapy, with an abnormal taste in their mouth and a loss of appetite. This agent should be restricted to patients with severe disease who cannot tolerate or fail to respond to cotrimoxazole or trimethoprim-dapsone.

(Text continues on p. 681.)

Table 18.11. Dosing of Drugs for Primary Prevention or Maintenance Therapy for Opportunistic Infections in Renal Insufficiency

Drug	Normal Dose	Regimen	CrCl (mL/min/1.73m ²)	Adjusted Dose
Acyclovir	200 mg 5 times/day to 800 mg b.i.d.	200 mg orally t.i.d.	<10	200 mg q12h
		400 mg orally q12h Hemodialysis	<10	200 mg q12h Additional dose after each dialysis
Cidofovir	5 mg/kg i.v. every other week (with probenecid and hydration)	Reduce from 5 mg/kg to 3 mg/kg for an increase in serum creatinine of 0.3–0.4 mg/dL above baseline. Discontinue for an increase in creatinine ≥0.5 mg/dL above baseline or development of 3+ proteinuria. Not recommended for patients with baseline serum creatinine >1.5 mg/dL, CrCl ≤55 mL/min, or ≥2+ proteinuria		
Ciprofloxacin	500 mg orally q12h	CrCl (mL/min/1.73m ²)		Dose
		30–50 mg/dL <30 Hemodialysis		250–500 mg q12h 250–500 mg q18h 250–500 mg after dialysis
Clarithromycin	500 mg b.i.d.	Reduce dose by one-half or double interval if creatinine clearance <30 mL/min		
Famciclovir	250–500 mg q12h	CrCl		Dose
		20–39 (mL/min/1.73μ ²) <20 Hemodialysis		125–250 mg q12h 125–250 mg q24h 125 mg after each dialysis
Fluconazole	50–400 mg/day	CrCl		Dose
		<50 (mL/min/1.73μ ²) (not on dialysis) dialysis		Half dose Full dose after dialysis
Foscarnet	90–120 mg/kg/day	CrCl (mL/min/kg)		Maintenance
		>1.4 1.0–1.4 0.8–1.0 0.6–0.8 0.5–0.6 0.4–0.5 <0.4		High Dose 120 mg q24h 90 mg q24h 65 mg q24h 104 mg q48h 80 mg q48h 65 mg q48h Not recommended

Ganciclovir	Oral: 1 g t.i.d. (capsules) i.v.: 5 or 6 mg/kg/day for 5 days/wk (i.v.)	CrCl (mL/min) 50–69 25–49 10–24 <10	i.v. Dose (mg/kg) 2.5 q24h 1.25 q24h 0.625 q24h 0.625 t.i.w. after dialysis	Capsules 1,500 mg daily or 500 mg t.i.d. 1,000 mg daily or 500 mg b.i.d. 500 mg daily 500 mg t.i.w. after dialysis
Levofloxacin	250–500 mg/day	CrCl (mL/min) 50–80 <50	Dose 500 mg LD, then 250 mg q24h 500 mg LD, then 250 mg q48h	
TMP/SMX	1 DS daily 1 DS t.i.w. 1 SS daily	CrCl (mL/min) 15–30 <15	Dose Half dose Half dose ^a or use alternative agent	
Valacyclovir	500 mg to 1 g q24h	CrCl(mL/min/1.73 m ²) <30	Dose 500 mg every 24–48 h	
Valganciclovir	900 mg/day	CrCl 40–59 25–39 10–24 <10 Dialysis	Dose 450 mg daily 450 mg daily 450 mg twice weekly Not recommended Not recommended	

b.i.d., twice daily; CrCl, creatinine clearance; DS, double-strength tablet; i.v., intravenous; LD, loading dose; q12h, every 12 hours; SS, single-strength tablet; t.i.d., three times daily; t.i.w., three times a week; TMP-SMX, trimethoprim-sulfamethoxazole.

^aFor hemodialysis, give after each dialysis.

From Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, pages 49–50. Table 18.12. Wholesale Acquisition Costs of Agents Recommended for the Prevention of Opportunistic Infections in Adults Infected with Human Immunodeficiency Virus

Opportunistic Pathogen	Drug/Vaccine	Dose	Annual Cost per Patient
<i>Pneumocystis carinii</i>	Trimethoprim sulfamethoxazole	160/800 mg daily	\$135
	Dapsone	100 mg daily	\$72
	Aerosolized pentamidine	300 mg monthly	\$1,185
	Atovaquone	1,500 mg daily	\$11,627
<i>Mycobacterium avium</i> complex	Clarithromycin	500 mg b.i.d.	\$2,843
	Azithromycin	1,200 mg weekly	\$3,862
	Rifabutin	300 mg daily	\$3,352
Cytomegalovirus	Ganciclovir (oral)	1,000 mg t.i.d.	\$17,794
	Ganciclovir implant ^a		\$5,000
	Ganciclovir (i.v.)	5 mg/kg daily	\$13,093
	Foscarnet (i.v.)	90–120 mg/kg daily	\$27,770–37,027
	Cidofovir (i.v.)	375 mg q.o.w.	\$20,904
	Fomivirsen (intravitreal)	1 vial every 4 wk	\$12,000
<i>Mycobacterium tuberculosis</i>	Valganciclovir	900 mg daily	\$21,582
	Isoniazid ^b	300 mg daily	\$23 (9 months)
	Rifampin	600 mg daily	\$294 (2 months)
	Pyrazinamide	1,500 mg daily	\$194 (2 months)
Fungi	Fluconazole	200 mg daily	\$4,603
	Itraconazole capsules	200 mg daily	\$5,340
	Itraconazole solution	200 mg daily	\$5,673
	Ketoconazole	200 mg daily	\$1,230
Herpes simplex virus	Acyclovir	400 mg b.i.d.	\$1,384
	Famciclovir	500 mg b.i.d.	\$5,311
	Valacyclovir	500 mg b.i.d.	\$2,538
<i>Toxoplasma gondii</i>	Pyrimethamine	50 mg weekly	\$49
	Leucovorin	25 mg weekly	\$988
	Sulfadiazine	500 mg q.i.d.	\$1,490
<i>Streptococcus pneumoniae</i>	23-valent pneumococcal vaccine	0.5 mL i.m. once	\$13
Influenza virus	Inactivated trivalent influenza vaccine	0.5 mL i.m. once	\$3
Hepatitis A virus	Hepatitis A vaccine	1.0 mL i.m. twice	\$124
Hepatitis B virus	Recombinant hepatitis B	10–20 µg i.m. three times	\$70
Bacterial infections	G-CSF	300 µg t.i.w.	\$29,406
Varicella zoster virus	VZIG	5 vials (6.25 mL)	\$562

b.i.d., twice daily; G-CSF, granulocyte colony-stimulating factor; i.v., intravenous; i.m., intramuscular; q.o.w., every other week; t.i.d., three times daily; t.i.w., three times a week; VZIG, varicella zoster immune globulin.

^aImplant generally lasts 6–9 months.

^bCost for 9 months of therapy.

Montvale, New Jersey: Medical Economics Inc., 2000; and Masur H, Kaplan JE, Holmes KK, and the USPHS/IDSA Prevention of Opportunistic Infections Working Group. 2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus, page 51. Posted November 28, 2001 as a “living document” at www.hivatis.org/trtgdlns.html#Opportunistic.

4. **Clindamycin** (600 mg i.v. every 8 hours or 300–450 mg orally every 6 hours) **plus primaquine** (30 mg orally daily) for 21 days is an alternative for mild PCP, although efficacy also has been shown in moderate and severe disease. Side effects include rash, methemoglobinemia, hemolysis, elevated serum transaminase, and digestive disturbances. This is an attractive alternative for oral therapy.
 5. **Atovaquone** (750 mg suspension orally twice daily) for 21 days is a second-line alternative for mild to moderate PCP. It should be administered with food to maximize absorption (Table 18.7). A micronized formulation has been developed that might have better oral bioavailability. It is not available in a parenteral form. The primary toxicity is skin rash.
 6. **Trimetrexate** (45 mg/m² i.v. daily) **plus folinic acid** (leucovorin; 20 mg/m² orally or i.v. every 6 hours) is effective when used alone or in combination with a sulfonamide. Leucovorin is needed to rescue the inhibition of dihydrofolate reductase in human cells, thus preventing cytopenia, its major adverse event. Higher relapse rates have been reported when compared to therapy with cotrimoxazole.
 7. **Adjunctive corticosteroids** have been shown to be beneficial for improving oxygenation, reducing the risk of fibrosis, decreasing the need for mechanical ventilation, and reducing the case fatality rate [52]. Tapering doses of corticosteroids are recommended in patients with severe disease (PO₂ <70 mm Hg or A-a gradient >35 mm Hg): prednisone 40 mg orally twice daily on days 1 through 5, followed by prednisone 40 mg/day orally on days 6 through 10, then prednisone 20 mg/day orally on days 11 through 21 for those older than 13 years of age. In patients with preexisting severe immune dysfunction, corticosteroids must be given with extreme caution, because reactivation of other latent coinfections such as mycobacteria and herpes infections may occur.
- E. Prevention** (Tables 18.1–18.5). All patients with a CD4 count of less than 200/mm³, CD4 percentage less than 14%, clinical manifestations from HIV (see section A), or another AIDS-defining condition should receive chemoprophylaxis to prevent a first episode of PCP (primary prophylaxis). All patients should receive prophylaxis following a course of treatment for PCP (secondary prophylaxis). Primary and secondary prophylaxis can be safely discontinued after the CD4 cell count has increased to at least 200/mm³ for more than 3 months in response to HAART [53–58]. Prophylaxis should resume if any indication cited above recurs. Decisions about discontinuing prophylaxis should be individualized in patients whose episode of PCP occurred at a CD4 count or greater than 200/mm³. The following are accepted regimens for prophylaxis in adults (Tables 18.1 and 18.2); see Tables 18.3 and 18.4 for dosing recommendations in children.
1. **Trimethoprim-sulfamethoxazole (cotrimoxazole)** orally (one double-strength [DS] or single-strength [SS] tablet daily) **is the agent of choice**. Alternatively, one DS tablet three times weekly may be used. Daily cotrimoxazole also protects against toxoplasmosis and some bacterial infections.
 2. **Dapsone** 100 mg orally daily is an acceptable alternative; 50 mg daily may be less effective. Dapsone (50 mg daily) plus pyrimethamine (50 mg orally weekly) plus leucovorin (25 mg orally weekly), or dapsone (200 mg weekly) plus pyrimethamine (75 mg weekly) plus leucovorin (25 mg weekly) may be used and also offers protection against toxoplasmosis (dapsone alone does not).
 3. **Atovaquone** 1,500 mg orally daily is as effective as dapsone and probably protects against toxoplasmosis, but is more expensive.
 4. **Aerosolized pentamidine** 300 mg monthly delivered by the Respigard II nebulizer (Marquest, Englewood, CO) does not offer systemic protection, and has been associated with extrapulmonary disease or apical relapses.
- V. Candidiasis** is the most common fungal condition seen in HIV-positive persons. Progression of HIV infection to AIDS is associated with development of oropharyngeal candidiasis [59]. Candidial infections are estimated to occur at some time

Table 18.13. Recommended Immunization Schedule for Human Immunodeficiency Virus–Infected Children

Vaccine	Age											
	Birth	1 mo	2 mos	4 mos	6 mos	12 mos	15 mos	18 mos	24 mos	4–6 yrs	11–12 yrs	14–16 yrs
↓ Recommendations for these vaccines are the same as those for immunocompetent children. ↓												
Hepatitis B ¹	Hep B #1		Hep B #2		Hep B #3							Hep B
Diphtheria and Tetanus toxoids, Pertussis ²		DTaP	DTaP	DTaP	DTaP		DTaP			DTaP		Td
Haemophilus influenzae type b ³		Hib	Hib	Hib	Hib	Hib						
Inactivated Polio ⁴		IPV	IPV	IPV						IPV		
Hepatitis A ⁵										Hep A in selected areas		
↓ Recommendations for these vaccines differ from those for immunocompetent children. ↓												
Pneumococcus ⁶			PCV	PCV	PCV	PCV				PPV23		PPV23 (age 5-7 yrs)
Measles, Mumps, Rubella ⁷	Do not give to severely immunosuppressed (Category 3) children. Give only to asymptomatic non-immunosuppressed (category 1) children. Contraindicated in all other HIV infected children.					MMR				MMR		MMR
Varicella ⁸						Var	Var					Var
Influenza ⁹	A dose is recommended every year											

-  Range of recommended ages for vaccination.
-  Vaccines to be given if previously recommended doses were missed or were given earlier than the recommended minimum age.
-  Recommended in selected states and/or regions.

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines as of November 1, 2000, for children through age 18 years. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturer's package inserts for detailed recommendations.

¹Infants born to hepatitis B surface antigen (HBsAg)-negative mothers should receive the first dose of hepatitis B vaccine (Hep B) at birth and no later than age 2 months. The second dose should be administered at least 1 month after the first dose. The third dose should be administered at least 4 months after the first dose and at least 2 months after the second dose, but not before age 6 months. Infants born to HBsAg-positive mothers should receive Hep B and 0.5 mL hepatitis B immune globulin (HBIG) within 12 hours of birth at separate sites. The second dose is recommended at age 1–2 months and the third dose at age 6 months. Infants born to mothers whose HBsAg status is unknown should receive Hep B within 12 hours of birth. Maternal blood should be drawn at delivery to determine the mother's HBsAg status; if the HBsAg test result is positive, the infant should receive HBIG as soon as possible (no later than age 1 week). All children and adolescents (through age 18 years) who have not been immunized against hepatitis B should begin the series during any visit. Providers should make special efforts to immunize children who were born in or whose parents were born in areas of the world where hepatitis B virus infection is moderately or highly endemic.

in the course of HIV disease in 90% to 95% of patients [60]. *Candida albicans* causes most disease; however, other species, including *C. tropicalis*, *C. krusei*, and *C. dubliniensis*, also have been reported, although much less frequently [60]. *C. glabrata* and *C. parapsilosis* tend to occur in patients with advanced disease and previous exposure to antifungals [61]. Chronic courses of azole therapy (e.g., in prophylaxis) may result in selection of azole-resistant species.

A. Clinical presentation is generally limited to oral, vaginal, or esophageal mucosa. Systemic disease is extremely rare and should not be included in the differential diagnosis of unexplained fever.

1. Symptoms of **oropharyngeal candidiasis** include burning, pain, and altered taste sensation, although many patients are asymptomatic. Pseudomembranous candidiasis or “thrush” appears as removable white plaques on any oral mucosal surface. The erythematous form is seen as smooth red patches and is often missed on routine examination. Candidiasis also can cause angular cheilitis producing erythema, cracks, and fissures at the corner of the mouth.
2. **Vaginal candidiasis** presents as a creamy white vaginal discharge and often is the first evidence of immune dysfunction in women [62]. Recurrent infection is common, and chronic suppressive therapy may be necessary (see Chapter 16).

(Table Footnote Continued.) ²The fourth dose of diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) may be administered as early as age 12 months, provided 6 months have elapsed since the third dose and the child is unlikely to return at age 15–18 months. Tetanus and diphtheria toxoids (Td) are recommended at age 11–12 years if at least 5 years have elapsed since the last dose of diphtheria and tetanus toxoids and pertussis vaccine (DTP), DTaP, or diphtheria and tetanus toxoids (DT). Subsequent routine Td boosters are recommended every 10 years.

³Three *Haemophilus influenzae* type b (Hib) conjugate vaccines are licensed for infant use. If Hib conjugate vaccine (PRP-OMP) (PedvaxHIB or ComVax [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required. Because clinical studies in infants have demonstrated that using some combination products may induce a lower immune response to the Hib vaccine component, DTaP/Hib combination products should not be used for primary immunization in infants at ages 2, 4, or 6 months unless approved by the U.S. Food and Drug Administration for these ages.

⁴An all-inactivated poliovirus vaccine (IPV) schedule is recommended for routine childhood polio vaccination in the United States. All children should receive four doses of IPV at age 2 months, age 4 months, between ages 6 and 18 months, and between ages 4 and 6 years. Oral poliovirus vaccine should not be administered to HIV-infected persons or their household contacts.

⁵Hepatitis A vaccine (Hep A) is recommended for use in selected states or regions, and for certain high-risk groups such as those with hepatitis B or hepatitis C infection. Information is available from local public health authorities.

⁶The heptavalent pneumococcal conjugate vaccine (PCV) is recommended for all children age 2–59 months with HIV. Children 2 years and older should also receive the 23 valent pneumococcal polysaccharide vaccine; a single revaccination with the 23 valent vaccine should be offered to children after 3–5 years. Refer to the Advisory Committee on Immunization Practices recommendations on dosing intervals for children starting the vaccination schedule after 2 months of age. (See Chapter 11)

⁷MMR should not be administered to severely immunocompromised (category 3) children. HIV-infected children without severe immunosuppression would routinely receive their first dose of MMR as soon as possible after reaching their first birthday. Consideration should be given to administering the second dose of MMR as soon as 1 month (i.e., a minimum of 28 days) after the first dose rather than waiting until school entry.

⁸Varicella zoster virus vaccine should be given only to asymptomatic, nonimmunosuppressed children. Eligible children should receive two doses of vaccine with at least a 3-month interval between doses. The first dose may be given as early as 12 months of age.

⁹Inactivated split influenza virus vaccine should be administered to all HIV-infected children ≥ 6 months of age each year. For children aged 6 months to <9 years who are receiving influenza vaccine for the first time, two doses given ≥ 1 month apart are recommended. For specific recommendations, see CDC. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR* 2001;50(RR-4):1.

Posted November 28, 2001 as a “living document” at www.hivatis.org/trtgdlns.html#Opportunistic.

3. Esophageal candidiasis may present with severe dysphagia or odynophagia in patients with or without evidence of oral infection. At endoscopy, exudate, ulcers, and deep erosions are seen lining the esophagus [63].

B. Diagnosis of oral or vaginal disease often is made on clinical appearance alone. In patients who fail to respond to standard therapy, KOH preparation and fungal cultures are indicated. Esophageal disease is diagnosed by endoscopic examination and culture, although response to empiric antifungal therapy is often used.

C. Treatment.

1. Localized oral or vulvovaginal candidiasis responds well to topical therapy.

a. Clotrimazole oral troches 10 mg five times per day, or **nystatin** oral pastilles (200,000 units) or oral suspension (500,000 units/5 mL) five times per day may be used for oral disease.

b. Over-the-counter clotrimazole or miconazole may be used for vaginitis. Fluconazole 150 mg as a single oral dose is also effective.

c. For patients who do not respond to standard therapy or who also have esophageal disease, the oral azole compounds (fluconazole, itraconazole) are effective.

d. Prevention. Chronic suppression may be needed for frequent recurrences, but otherwise prophylaxis is not recommended [1]. Fluconazole is superior to clotrimazole in preventing relapses of thrush (Tables 18.2 and 18.4 for drug choices and dosing recommendations in adults and children, respectively); 200 mg thrice weekly for oral and once weekly for vaginal candidiasis have been used. Azoles should be avoided during pregnancy.

2. Treatment of esophageal candidiasis requires systemic therapy. Drug resistance, particularly azole-resistant candidiasis, is increasingly common [64]. Some patients respond to increased doses of the drug, and some respond to a switch from one azole to another (e.g., fluconazole to itraconazole). However, low-dose therapy with i.v. amphotericin B is required for many. In pregnancy, azoles should be avoided if possible. The role of the new i.v. **echinocandins**, which may be as effective but less toxic than amphotericin B, has yet to be determined [65,66].

a. Fluconazole (100–200 mg/day, oral or i.v., in adults) for 14 to 21 days is preferred; up to 800 mg/day may be successful despite *in vitro* resistance. Maintenance suppressive therapy may be necessary in cases of recurrent esophagitis. Direct comparative trials also have demonstrated superiority versus ketoconazole [67]. Side effects include nausea and skin rash, but generally it is well tolerated.

b. Itraconazole tablets or oral suspension (100 mg twice daily in adults) is equally effective. It requires gastric acid for absorption, and should be taken 1 hour before or 2 hours after antacids; the liquid formulation shows better absorption (serum levels can be followed). Adverse reactions include gastrointestinal upset, rash, and hepatic dysfunction. Concurrent use with cisapride, quinidine, triazolam, and possibly other drugs metabolized by cytochrome P450 3A4 is not recommended. Itraconazole may increase levels of protease inhibitors (e.g., ritonavir, indinavir, saquinavir). Inducers of cytochrome P450 3A4 isoenzymes, such as nevirapine, will decrease itraconazole levels (see Chapters 19 and 27).

c. Ketoconazole 200 mg/day orally is effective, but an increase in gastric pH impairs absorption. Adverse reactions include rash and hepatotoxicity. Ketoconazole suppresses the hepatic cytochrome p450 system; drug interactions are similar to those with itraconazole.

d. Amphotericin B 0.3 mg/kg/day i.v. for 7 days (or 100 mg oral suspension four times daily if available) may be used for disease refractory to other agents. Lipid amphotericins may be better tolerated, but their use is limited by high costs.

e. Prevention. Frequent recurrences require chronic suppression, but primary prophylaxis is not recommended. Fluconazole or itraconazole

solution is effective for most patients (Tables 18.2 and 18.4). Maintenance with oral azoles often can be resumed after i.v. amphotericin B therapy for esophagitis exacerbations, although some patients must be maintained on once- or twice-weekly i.v. amphotericin B.

VI. *Mycobacterium tuberculosis*. TB continues to be a devastating disease worldwide (see also Chapter 11). It is estimated to cause 3 million deaths annually [68]. **HIV infection is by far the most important predisposing factor for the development of TB.** Experts believe that TB accounted for 30% of the 5.0 million AIDS-related deaths in the year 2000 [69]. The risk for a patient with AIDS developing TB is 170 times higher than that for a nonimmunosuppressed person. The risk for death in HIV-infected patients with TB was reported to be twice that in HIV-infected patients without TB, independent of CD4 cell count [70].

A. Epidemiology. In 2000, a total of 16,377 new TB cases were reported in the United States [71], and approximately 25% to 30% were HIV coinfecting. The groups with the greatest increases in rates of TB, specifically black and Hispanic men 25 to 40 years of age, are also the groups with the highest rates of HIV infection, demonstrating how closely intertwined these two epidemics have become [72]. Anonymous HIV testing of serum from TB clinics demonstrated that as many as 40% of all TB patients are HIV infected [73]. This number may be even higher in certain urban areas. In addition, TB is unique among AIDS-related OIs because it is contagious to otherwise healthy persons. This, combined with several nosocomial outbreaks affecting both patients and staff [74], has led to extensive reconsideration of hospital infection control efforts [75]. Finally, resistant TB has been increasing, especially in urban areas [76,77], and is particularly difficult to treat in the HIV-infected patient.

B. Clinical presentation depends largely on the overall immune status of the patient [78]. Patients with high CD4 cell counts ($>200\text{--}300/\text{mm}^3$), generally will have classic TB, with apical cavitary lung disease, respiratory symptoms, fevers, and weight loss. As immunity wanes, presentations become less specific, and diagnosis becomes more difficult as atypical chest radiographic features and extrapulmonary TB are encountered. The most common extrapulmonary manifestations are asymmetric lymphadenopathy, pericarditis, pleurisy, bone disease, and skin lesions. Fever, weight loss, and fatigue may be the only symptoms with disseminated TB, mimicking lymphoma, CMV disease, AIDS wasting syndrome, MAC, and other illnesses [70]. Hilar or mediastinal adenopathy may be the primary chest radiographic abnormality. In addition, pulmonary TB may show lobar and interstitial infiltrates resembling primary TB, and 10% to 20% may have normal radiographs [78]. Thus, HIV-induced immunosuppression may result in unusual presentations and delay the diagnosis.

Concurrent HIV and TB interact in several other ways: (a) HIV-infected persons latently infected with TB develop reactivation TB at a rate of 8% to 10% per year, rather than 5% to 10% per lifetime [73]; (b) HIV-infected persons exposed to an infectious index case develop acute TB at a rate as high as 40% over 6 to 12 months rather than 2% to 5% over 2 years in normal hosts [78]; (c) TB may accelerate the progression of HIV infection by activating expression of HIV from macrophages [70]; and (d) immune reconstitution syndromes may occur (see section II).

C. Diagnosis requires culturing *M. tuberculosis* from appropriate specimens. The sputum smear for acid-fast bacilli is approximately 50% sensitive in HIV-infected persons, a rate similar to that among HIV-negative persons [79]. Cultures using a radiometric system (BACTEC) may speed the diagnosis. Because the initial acid-fast smear cannot distinguish *M. tuberculosis* from MAC, culture with identification and susceptibility tests must be routinely performed. Direct tests of nucleic acid amplification for rapid diagnosis are available. Newer procedures using enzyme immunoassay (EIA) may make serologic testing for *M. tuberculosis* possible in the future (see Chapter 11).

D. Treatment guidelines of the CDC and the American Thoracic Society state that the minimal duration of therapy is 6 months for drug-susceptible TB in patients coinfecting with HIV. If clinical or bacteriologic response is slow, they

recommend extending treatment for a total of 9 months, or for 4 months after cultures become negative [72].

1. **Initial therapy** should consist of standard daily isoniazid (INH) 300 mg orally daily, rifampin 600 mg orally daily, pyrazinamide 20 to 35 mg/kg orally daily, and ethambutol 15 to 25 mg/kg orally daily (see Chapter 11).
2. **Considerations for patients on HAART.** Important **drug interactions** occur between the rifamycins and protease inhibitors and other commonly used agents (Tables 18.8 and 18.9). Rifampin induces the activity of cytochrome P450 CYP3A, which lowers the concentration of protease inhibitors and non-nucleoside reverse transcriptase inhibitors, resulting in incomplete viral suppression [80]. Most experts, however, advise against withholding antiretroviral therapy until completion of TB therapy. **Three principles for treatment of TB in HIV-infected patients have been emphasized:**
 - a. Antiretroviral therapy should be administered when indicated.
 - b. A short-course regimen (6–9 months, depending on the regimen) should be administered as directly observed therapy to enhance compliance.
 - c. Rifabutin at a lower dose (150 mg) is preferred over rifampin because of significant drug interactions of rifampin with protease inhibitors and non-nucleoside reverse transcriptase inhibitors (Tables 18.8 and 18.9).
3. **Patients with CD4 counts of less than 100/mm³** should receive daily therapy for the first 2 months, and no less often than three times weekly during the remainder of treatment. This will minimize the risk of rifampin or rifabutin resistance developing on less frequent intermittent regimens [81].
4. **Sputum cultures and smears** should be checked monthly to document clearing of infection. If they remain positive after 3 months of therapy, resistance, noncompliance, drug interactions, and impaired absorption should be considered.
5. Persistence of fever for more than 2 to 4 weeks in a patient receiving standard four-drug regimen suggests **multidrug-resistant TB** (MDR TB). If susceptibility results are pending, treatment options should be guided by prior drug exposure, history of exposure to a case of MDR TB, and susceptibility patterns in the community [76,82]. Drug fever and a second infection should also be considered.

E. Chemoprophylaxis (Tables 18.1 and 18.3) with INH (300 mg orally daily) for 9 months should be administered to any HIV-infected patient with a tuberculin skin test induration that is at least 5 mm in diameter, once active TB has been ruled out. Chemoprophylaxis also should be initiated regardless of the tuberculin skin test result in patients with a history of positive results who were not adequately treated, a close contact with infectious TB, or a chest radiograph that is consistent with previous untreated TB. Recent studies have shown that the results of anergy testing are not reproducible and that INH prophylaxis does not reduce the incidence of TB in HIV-infected patients with anergy [83]. Therefore, **anergy testing is no longer recommended** in this population (see also Chapter 11).

VII. *Mycobacterium avium* complex disease has been much less common since the widespread use of HAART. Despite declining incidence, the relative frequency of MAC infection compared with other OIs has not changed. MAC disease continues to be the most common systemic bacterial infection in AIDS and is responsible for significant morbidity.

A. Epidemiology. According to the CDC's Adult and Adolescent Spectrum of Disease (ASD) Project, the incidence of MAC declined 39.9% per year between 1996 and 1998, compared with 4.7% per year between 1992 and 1995 [17]. The HIV Outpatient Study reported similar decreases in incidence rates in eight U.S. cities [13]. The prevalence of disseminated MAC for patients with CD4 cell counts of less than 100/mm³ is approximately 10% [83]; at autopsy, prior to HAART and routine use of prophylaxis, the rate was approximately 50% [84].

- B. Clinical presentation** of disseminated MAC includes fever, night sweats, severe weight loss, and, less often, diarrhea. High “spiking” temperatures and a toxic appearance may be seen. Hepatosplenomegaly may be present, but the examination often is quite nonspecific and unrevealing. Common laboratory abnormalities include anemia, neutropenia, and elevated alkaline phosphatase. Immune reactivation lymphadenitis may occur soon after the initiation of HAART (see section II).
- C. Diagnosis** depends on culturing the organism from blood or bone marrow. The utility of cultures from other sites, including lymph node and liver, is less well established. Isolation of organisms from respiratory secretions, stool, or urine does not establish the presence of disseminated infection. Blood cultures using special media (i.e., BACTEC or Dupont Isolator systems) yield the highest results. Whereas a single positive blood culture is diagnostic, a negative culture does not rule out disseminated infection because patients can have low levels of mycobacteremia [85]. Specific DNA probes for MAC can rapidly differentiate MAC from other mycobacteria when there is sufficient growth in culture.
- D. Treatment** of MAC continues to improve. Active drugs include the macrolides (azithromycin and clarithromycin), the rifamycins (rifabutin and rifampin), ciprofloxacin, ethambutol, and amikacin [86–88]. Therapy initially should include a macrolide and ethambutol. A third agent, such as a rifamycin or ciprofloxacin, can either be included in the initial regimen or added if there is a slow response. The addition of amikacin as a fourth agent may be needed in some patients who fail to respond or who relapse [89]. In very ill patients, some experts recommend a multidrug regimen (e.g., clarithromycin, ethambutol, rifamycin, and amikacin) to rapidly diminish the bacteremia. Once the patient clinically responds, at least two oral agents (e.g., ethambutol and clarithromycin) may be substituted to simplify an outpatient regimen. Clofazimine is not recommended due to an association with increased mortality. Susceptibility testing is not routinely performed unless the likelihood of drug resistance is high, as in the case of a patient developing mycobacteremia while receiving macrolide therapy.
- E. Prophylaxis** (Tables 18.1–18.5) for MAC disease is recommended for patients with CD4 cell counts of less than $50/\text{mm}^3$. Patients with a prior history of opportunistic infections, or colonization with MAC in the respiratory or gastrointestinal tract, should also be considered for chemoprophylaxis. It is essential to rule out MAC bacteremia and active TB. Clarithromycin (500 mg orally twice daily) or azithromycin (1,200 mg once per week) is more effective than rifabutin and with fewer potential drug interactions [90–92]. In one comparative trial, clarithromycin was superior to azithromycin in time to clearing MAC bacteremia [86]. Preliminary data suggest that low-dose clarithromycin (500 mg orally daily) may be effective [93]. Azithromycin is preferred in pregnancy because clarithromycin has been teratogenic in animals. Recent studies support the **discontinuation of primary prophylaxis** in patients who respond to HAART with sustained increases in CD4 cell counts to **greater than $100/\text{mm}^3$ for 3 to 6 months** (Table 18.5) [1,94]. There are only limited data to recommend discontinuation of secondary prophylaxis, although this may be considered for adult patients on HAART with CD4 counts of greater than $100/\text{mm}^3$ for at least 6 months (Table 18.5) [1,95]. Children should be given lifelong prophylaxis [1].

VIII. Other mycobacteria

- A. *Mycobacterium kansasii*** is the second most common nontuberculous mycobacterial infection in patients with AIDS [96,97]. Most often disease is localized to the lungs, but the organism also can cause extrapulmonary infection.
- 1. Clinical presentation** resembles that of TB and includes fever, cough, and dyspnea. Chest radiographic appearance includes either upper lobe or diffuse infiltrates.
 - 2. Diagnosis** is made by culture. *M. kansasii* is always considered pathogenic. Of note, *M. kansasii* is not transmitted person to person, so respiratory isolation is not required.

3. **Treatment** recommendations include high-dose INH (600 mg/day), rifampin (600 mg/day), and ethambutol (15–25 mg/kg/day), even though most strains are resistant to INH. Clarithromycin (500 mg orally twice daily) can be substituted for rifampin for patients on protease inhibitors or with rifampin resistance. *M. kansasii* is intrinsically resistant to pyrazinamide. Other antimycobacterial agents, including erythromycin, ciprofloxacin, and streptomycin, have been used with some success [97]. Infectious disease or pulmonary consultation is advised.

B. *Mycobacterium haemophilum* is a rare mycobacterium that causes disease in immunosuppressed patients with and without HIV [98].

1. **Clinical presentation** most often includes involvement of skin, bone, or joints. Lung involvement also has been described and is associated with a high mortality rate [99].

2. **Diagnosis** is made by special culture of specimens plated on chocolate heme-enriched agar and incubated at 30°C.

3. **Treatment** has not been standardized but should include a macrolide, rifampin, or rifabutin, and probably at least one other agent from among ciprofloxacin, ethambutol, and amikacin [99,100]. Duration of therapy is not known, but usually extends 12 to 24 months. Infectious disease consultation is advised.

C. Many other mycobacteria, including *M. xenopi*, *M. simiae*, *M. scrofulaceum*, *M. malmoense*, *M. genavense*, *M. gordonae*, *M. fortuitum*, *M. chelonae*, and *M. marinatum*, also have been recovered [101–103]. In the future, additional mycobacterial strains undoubtedly will be associated with disease in persons with advanced AIDS due both to improvements in mycobacteriology and to prolonged survival. Distinguishing colonization from invasive disease will remain difficult. Treatment regimens for many unusual mycobacterial infections are not standardized, but often include a macrolide, ethambutol, and either a rifamycin or quinolone. More severe infections should be treated with amikacin or streptomycin as well. Infectious disease consultation is advised.

IX. Cytomegalovirus disease has declined with the availability of more potent HIV therapies. Prior to HAART, CMV was diagnosed in up to 40% of AIDS patients [104], and at autopsy more than 90% had documented CMV infection [105]. **Virtually all patients with disease due to CMV have CD4 counts below 100/mm³** [106]. CMV syndromes still occur during the early months of HAART (presumably before immunorestitution), in those who fail or are intolerant of HAART, and in patients with limited medical care. The shedding of CMV as detected by culture does not necessarily indicate invasive disease. Clinical presentation, histopathologic findings, and viral culture all must be considered in the diagnosis. CMV is often cultured in blood and urine specimens, and detected histopathologically at autopsy. However, the positive predictive values of CMV viremia (35%) and viruria (28%) for the development of end-organ disease were poor in one study [107].

A. Chorioretinitis is now seldom the presenting manifestation but occurs when the CD4 count is less than 50/mm³ [108]. It remains the most common intraocular infection in patients with AIDS, accounting for at least 90% of HIV-related infectious retinopathies [109]. Symptoms include decreasing visual acuity, the presence of so-called floaters, and visual field defects. Blindness will result if CMV is left untreated [110].

1. **Diagnosis** is made by **ophthalmologic examination**. Typical findings include creamy or yellow-white granular areas with perivascular exudates and hemorrhages. These lesions are found initially in the periphery of the fundus but can progress to involve the macula and optic disk [110]. Recently, molecular diagnostic testing has been utilized to predict and detect CMV disease. Antigenemia testing and nucleic acid amplification testing have been used to identify at-risk patients and predict CMV end-organ disease, but their value for this purpose has not been established. Following serial antigen results is a means of assessing viral response to treatment [111].

2. **Therapy**. Drugs currently available that act to inhibit viral DNA polymerase are **ganciclovir (and valganciclovir), foscarnet, and cidofovir**.

Induction therapy includes 2 weeks or more of high-dose drug. At times, ganciclovir and foscarnet are given together to control relapsed or rapidly advancing disease (ocular or extraocular). When retinitis is stable, patients are placed on lifelong maintenance therapy until there is evidence of immune recovery (discussed below).

- a. **Ganciclovir** has an initial response rate of 80% to 90%; however, 30% of patients relapse within 1 year [112]. Side effects include myelosuppression, particularly neutropenia. The induction dose is 5 mg/kg i.v. every 12 hours for 14 to 21 days or until there is an adequate clinical response; the maintenance dose is 5 mg/kg/day i.v. or 1.0 g every 8 hours orally. Oral ganciclovir, despite its low bioavailability of 8%, at a dose of 1,000 mg three times a day, is nearly equivalent to i.v. ganciclovir in preventing progression and preserving vision, particularly if the initial CMV retinitis was not sight threatening. Oral ganciclovir alone is not approved for initial treatment.
 - b. **Foscarnet** is only available for i.v. use. A comparison trial with ganciclovir found no difference in the frequency and rate of retinitis progression. Although foscarnet was not as well tolerated as ganciclovir, it offered survival advantage, perhaps secondary to its direct antiretroviral activity [106]. Side effects include renal impairment, periurethral ulceration, paresthesia, seizures, and other central nervous system (CNS) symptoms. The induction dose is 60 mg/kg every 8 hours or 90 mg/kg every 12 hours; the maintenance dose is 90 to 120 mg/kg/day.
 - c. **Cidofovir** plus probenecid (2 g orally 3 hours before each dose, 1 g orally 2 and 8 hours postdose) to limit nephrotoxicity may be effective in patients who fail or are intolerant of ganciclovir or foscarnet [113]. Its long half-life permits administration every 2 weeks during maintenance therapy. No oral form is available. The induction dose is 5 mg/kg i.v. weekly; the maintenance dose is 5 mg/kg i.v. every other week.
 - d. **An intraocular ganciclovir release device** (every 6 months) **plus oral ganciclovir or valganciclovir** is preferred by some clinicians, especially for immediately sight-threatening infection. This is superior to i.v. ganciclovir in time to relapse, but there is increased risk of involvement of the other eye and extraocular disease [114].
 - e. **Valganciclovir**, the first oral drug for CMV induction therapy (900 mg orally twice daily), is a prodrug of ganciclovir that is well absorbed from the gastrointestinal tract conferring greater bioavailability; absorption is increased, and the potential for toxicity enhanced, if taken with high-fat meals (Table 18.7). Efficacy is comparable with i.v. ganciclovir without the risk of catheter-related complications; side effects are similar to those of ganciclovir [115,116]. The maintenance dose is 900 mg daily.
 - f. **Alternative therapy** includes **intraocular injections** of foscarnet 1.2 to 2.4 mg in 0.1 mL or ganciclovir 2,000 μ g in 0.05 to 0.1 mL. Fomivirsen (330 μ g by intravitreal injection at days 1 and 15, then monthly) is a new antisense compound [117]. Any local therapy should be accompanied by systemic anti-CMV therapy such as oral ganciclovir or valganciclovir [118].
3. **Prophylaxis (Tables 18.1–18.5).** Current data suggest that long-term ganciclovir prophylaxis can be safely discontinued in adults after resolution of lesions, if the CD4 cell count has been above 100 to 150/mm³ for at least 6 months, if the lesions are not sight threatening, and if regular follow-up with an ophthalmologist can be assured (Table 18.5) [1,109,119,120]. There are insufficient data about the safety of this approach in children. Discontinuation of secondary prophylaxis for extraocular CMV disease is not supported by the current literature.
- B. **CMV colitis** previously developed in 5% to 10% of AIDS patients but is now uncommon. Symptoms are nonspecific and may include diarrhea, weight loss, abdominal pain and cramping, anorexia, and fever [121].

1. **Diagnosis** is made by endoscopic biopsy. Endoscopy reveals mucosal ulceration and submucosal hemorrhage. Biopsy shows the pathognomonic “owl eye” inclusions in tissue, or demonstrates CMV antigens (e.g., by immunohistochemical staining).
 2. **Therapy** with ganciclovir and foscarnet is variably effective. Some studies have shown improvement of symptoms and the appearance of the colon, as well as decreased incidence of extracolonic CMV infection. However, not all patients respond, and the optimal dose and length of treatment are not well defined. One approach is to treat patients for 2 weeks and follow them clinically off therapy.
- C. CMV pneumonitis** is a major concern in bone marrow transplantation, but seldom is seen in AIDS. CMV is often isolated in respiratory specimens, yet treatment of other pathogens alone usually results in clinical improvement [122]. True CMV pneumonitis is seen in fewer than 10% of patients who undergo evaluation of pulmonary infiltrates of unknown etiology [123]. **Symptoms** include worsening shortness of breath, dyspnea on exertion, and dry cough. Chest radiographs may show diffuse infiltrates similar to those seen in PCP.
1. **Diagnosis** is established by finding pathognomonic intranuclear inclusion bodies (owl eyes) in biopsy samples. The diagnosis is suggested in patients with positive CMV cultures, no other recovered pathogens, and response to appropriate therapy.
 2. **Therapy** is with ganciclovir at routine doses. Unlike bone marrow transplant patients, there is no proven benefit to concurrent i.v. immunoglobulins. Maintenance therapy should be considered for responders.
- D. CMV esophagitis** is less common than that caused by *C. albicans*. Symptoms include odynophagia, dysphagia, or vague dyspepsia [124]. Diagnosis is made by endoscopic biopsy. Ganciclovir is effective for treatment. Maintenance therapy is not used unless symptoms recur.
- E. CMV encephalitis** usually is diagnosed postmortem [125]. Symptoms are varied and include cognitive deficits, personality changes, increased somnolence, and focal neurologic signs [126]. Diagnosis often is confused with progressive AIDS dementia. Antiviral treatment has not been shown to be effective, although combination therapy with ganciclovir and foscarnet is often recommended.
- F. CMV ventriculoencephalitis** is a late infection with acute onset often associated with cranial nerve palsies. Patients may either have no history of CMV disease [127] or are already on therapy for CMV [125]. Spinal fluid analysis shows pleocytosis, usually with lymphocytes but sometimes with polymorphonuclear leukocytes, marked increase in protein, and low glucose [127]. Magnetic resonance imaging (MRI) may reveal a characteristic periventricular ringlike enhancement [125]. Viral culture of the cerebrospinal fluid (CSF) is not always positive; CMV DNA can often be detected in CSF using PCR. Therapy with ganciclovir or foscarnet may ameliorate symptoms if given early, but response is unpredictable and most cases progress [128].
- G. CMV polyradiculitis** may cause radicular pain, progressive Guillain-Barré–like ascending paralysis, and urinary retention [129]. The CSF may have a pleocytosis with a predominance of neutrophils (unusual for viral infection), elevated protein, and low glucose [130]. Diagnosis is made by viral culture of CSF; PCR also may be useful [131]. Therapy with ganciclovir has resulted in improvement of symptoms in some patients [132]. Some experts give ganciclovir concurrently with foscarnet.
- H. CMV involvement of the adrenal glands** is seen at autopsy in up to 50% of patients [133]. However, adrenal insufficiency is less common, and the correlation between adrenal infection and clinical adrenal dysfunction is incomplete. Adrenal insufficiency should be considered in all patients with CMV and symptoms consistent with Addison disease (e.g., electrolyte abnormalities, unexplained hypotension, fever, and fatigue). Diagnosis is confirmed by **cosyntropin stimulation test**. Dramatic improvement may be seen with steroid replacement therapy.

- X. Toxoplasmosis.** *Toxoplasma gondii* is the most common cause of focal encephalitis in AIDS patients [134]. Disease is usually due to recrudescence of latent infection; therefore, all patients with antibodies to *T. gondii* are at risk. Seroprevalence varies among geographic locations. In the United States, 20% to 40% of the general population has evidence of past infection [135]. Approximately 25% to 40% of seropositive patients with AIDS will develop disease unless given prophylaxis [136]. The risk of reactivation infection increases with a decreasing CD4 cell count, especially when the CD4 count falls below 100/mm³. In the United States, toxoplasmic encephalitis (TE) has been reported in 1% to 5% of patients with AIDS. TE in AIDS patients is associated with a mortality rate of 70% by 12 months after diagnosis [137]. Effective prophylaxis and potent combination antiretroviral regimens have resulted in a marked decrease in the incidence of this disease [136,138].
- A. Clinical presentation** ranges from focal neurologic findings to generalized symptoms, including weakness, confusion, seizures, and coma. Constitutional symptoms such as fever and malaise are variable, but meningismus is rare. The CSF may show a mononuclear pleocytosis and elevated protein, or may be normal. **Disseminated toxoplasmosis**, involving heart, lung, colon, skeletal muscles, and other organs, has been described [139]. Septic shock also has been seen, with presentation of prolonged fever, dyspnea, thrombocytopenia, and high lactate dehydrogenase levels [140].
- B. Serologic tests** for antitoxoplasma antibodies are highly reliable but not specific for active disease. Almost all patients with toxoplasmosis have immunoglobulin G (IgG) antibody. From a practical standpoint, a patient with CNS symptoms and a recent negative test result for toxoplasma IgG antibody is unlikely to have TE. Seronegative toxoplasmosis is rare, accounting for only 0% to 3% of cases [135,141]; however, one study reported a seronegative rate of 22% [141]. The level of antibody is not predictive of likelihood of reactivation or severity of disease.
- C. Radiographic evaluation** reveals single or multiple CNS lesions with ring or nodular enhancement. Lesions are most frequently found in the basal ganglia or corticomedullary junction [142]. The MRI scan is the best imaging technique and may detect lesions not seen by CT scanning [143]. The presence of edema, a mass effect, and hemorrhage may help to distinguish TE from CNS lymphoma. Thallium 201 single-photon emission computed tomography (SPECT) scans may distinguish between these two entities because a negative scan is unlikely to represent lymphoma [144], although their value has recently been questioned [145]. Positron emission tomography is useful but is not as widely available [146].
- D. Diagnosis** is definitive when *T. gondii* tachyzoites are seen on brain biopsy; however, this can be difficult because the organism may be difficult to find and histopathologic changes may resemble other infections [147]. Most often, a presumptive diagnosis is made based on positive serology, typical radiographic findings, and response to specific therapy.
- E. Polymerase chain reaction** can detect *T. gondii* DNA in brain tissue, CSF, BAL fluid, sputum, and blood in patients with AIDS [148,149]. The sensitivity of PCR in CSF has been between 11% and 77%, and the specificity is almost 100% [150,151]. PCR is widely available and should be used when the diagnosis is in question.
- F. Differential diagnosis.** The main diagnosis of exclusion is CNS lymphoma. All patients with characteristic lesions on CT or MRI and positive serology for *T. gondii* should be treated empirically for toxoplasmosis. In patients with single lesions, the predictive value for TE is less. CNS lymphoma is four times more likely to present with a single lesion than multiple lesions [143]. Patients with CNS lymphoma often have Epstein-Barr virus (EBV) detected on PCR of CSF. However, toxoplasma antibody-positive patients with a single lesion also should receive empiric treatment for TE. Response to empiric treatment is the most practical means of making the diagnosis. Half of patients with toxoplasmosis will clinically respond by day 3 and 90% by day 14 [134], and radiographically within 2 weeks. For responders, a repeat scan in 1 month is reasonable. For those

who do not respond by day 14 or do not have a positive serology, brain biopsy should be considered. **Corticosteroids** will result in radiologic improvement with either lymphoma or toxoplasmosis and should not be given unless the diagnosis is already secured.

G. Treatment is based on combination chemotherapy, with most agents acting to block folic acid metabolism.

1. **Standard regimens** include **pyrimethamine** (100–200 mg loading dose, then 50–100 mg orally daily) plus **folinic acid** (10 mg orally daily) plus either **sulfadiazine** (1–1.5 g orally every 6 hours) or **clindamycin** 900 mg i.v. every 6 hours or 450 to 600 mg orally every 6 hours for at least 6 weeks.
2. **Alternatives** include pyrimethamine plus folinic acid plus either **azithromycin** (1,200–1,500 mg orally daily) or **clarithromycin** (1 g orally twice daily) or **atovaquone** (750 mg orally with food four times daily). These combinations are clearly inferior and should therefore be reserved for patients with true intolerance to standard regimens.
3. **Corticosteroids (decadron)** 4 mg orally or i.v. every 6 hours are used for significant edema/mass effect.

H. Prevention (Tables 18.1–18.6). Patients seronegative for *T. gondii* antibodies should be educated about appropriate precautions to avoid exposure, for example, while working with soil or in considering cat ownership (Table 18.6).

1. **Primary prophylaxis** (Tables 18.1 and 18.3) is used for patients with positive IgG antibody and a CD4 count of less than 100/mm³. **Trimethoprim-sulfamethoxazole**, 1 DS or SS tablet orally daily is the agent of choice. **Dapsone** 50 mg orally daily plus **pyrimethamine** 50 mg orally weekly plus folinic acid 25 mg orally weekly is an alternative. Both regimens also prevent PCP. See Table 18.3 for pediatric dosing recommendations. Primary prophylaxis may be discontinued in adults if HAART raises the CD4 count to more than 200/mm³ for at least 3 months (Table 18.5).
2. **Secondary prophylaxis** (Tables 18.2 and 18.4), or suppressive therapy, should be given following treatment for toxoplasmosis; 80% relapse after discontinuation of therapy. **Pyrimethamine** 25 to 50 mg orally daily plus **folinic acid** 10 to 25 mg orally daily plus **sulfadiazine** 500 to 1,000 mg orally four times daily is preferred. Alternatives include **clindamycin** 300 to 450 mg orally every 6 hours plus **pyrimethamine** 25 to 50 mg orally daily plus **folinic acid** 10 mg orally daily (which does not protect against PCP), or **atovaquone** 750 mg orally two to four times daily with or without pyrimethamine plus folinic acid. See Table 18.4 for pediatric dosing recommendations. Discontinuation of secondary prophylaxis in adults may be considered if HAART raises the CD4 count to greater than 200/mm³ for at least 6 months (Table 18.5).
3. **Other considerations.** The safety of discontinuing prophylaxis in children has not been evaluated and is not recommended [1]. Pyrimethamine should be used only with caution in pregnancy because of potential teratogenicity.

XI. Cryptococcosis. *Cryptococcus neoformans* most often causes meningitis or disseminated disease. Six percent to 10% of patients with AIDS will develop cryptococcosis. It is the most common systemic fungal infection and third most common CNS disorder (behind toxoplasmosis and lymphoma) in HIV-infected patients. The incidence of cryptococcosis has decreased due to more widespread use of azoles and potent antiretroviral therapy.

A. Presentation. Cryptococcal meningitis is usually an indolent disease (see Chapter 6). Symptoms, including headache, fever, and malaise [152] typically are present for weeks prior to diagnosis. The headache often is worse with sneezing or coughing. Lethargy, mental status changes, and forgetfulness are common. Classic meningismus and focal neurologic signs are uncommon, occurring less than 10% of the time. Pulmonary symptoms with an abnormal chest radiograph may be seen. Prostatitis occurs and the prostate may serve as a nidus for subsequent recurrence [153]. Other sites of involvement include the joints, pericardium, myocardium, mediastinum, skin, and oral cavity. CSF often reveals a poor inflammatory response; protein and glucose levels may be

normal, with little pleocytosis. Poor prognostic factors include impaired mental status at presentation [154], fewer than 20 white blood cells (WBCs) per mm³ in CSF, elevated opening pressure (>200 mm H₂O), and a CSF cryptococcal antigen titer greater than 1:1,024 [155].

- B. Diagnosis.** Isolation of *C. neoformans* from blood, CSF, or other specimens is the standard for diagnosis. However, the latex agglutination test for cryptococcal polysaccharide antigen is highly sensitive and specific. In one large study of patients with culture-proven meningitis, 98% tested positive for a serum antigen and 91% for a CSF antigen, whereas CSF India ink stains tested positive in 74% [156]. In general, a serum titer of greater than 1:4 should be repeated and a full evaluation considered; a titer of greater than 1:32 is considered diagnostic. All patients with a positive serum antigen titer should undergo a spinal tap. Routine screening with the serum cryptococcal antigen test is not recommended.
- C. Therapy** for cryptococcosis in AIDS patients is lifelong (see Chapters 6 and 17). The treatment of choice is **amphotericin B** (0.7–1.0 mg/kg/day i.v.) **with concurrent flucytosine** (25 mg/kg orally every 6 hours) **for 14 days, followed by fluconazole 400 mg daily to complete an 8- to 10-week course. Suppression with fluconazole 200 mg daily is then recommended.** Pregnancy should be avoided during chronic fluconazole therapy because of potential teratogenicity. Weekly amphotericin B produces a higher relapse rate than fluconazole, but amphotericin is an alternative (0.6–1.0 mg/kg one to three times weekly). Itraconazole (200 mg/day) is not as effective as fluconazole for suppressive therapy [157]. Increased intracranial pressure greater than 250 mm H₂O requires urgent CSF drainage. In the absence of obstructive hydrocephalus, serial lumbar punctures are recommended for increased intracranial pressure. In addition, corticosteroids may ameliorate the sequelae of increased intracranial pressure. If cerebral edema occurs, high-dose steroids may offer temporary benefits. Long-term use, however, is discouraged because it may interfere with the effectiveness of antifungal therapy.
- D. Prevention** (Tables 18.1–18.5). Studies to support the use of primary prophylaxis for cryptococcosis are limited. Although cryptococcal meningitis decreased with either fluconazole or itraconazole prophylaxis, no survival benefit was noted. Due to concerns regarding development of antifungal resistance, especially in *Candida* species, the relative infrequency of cryptococcal disease, the possibility of drug interactions, and costs, USPHS/IDSA guidelines do not endorse routine primary prophylaxis [158]. Discontinuation of suppressive therapy (secondary prophylaxis) may be considered if HAART raises the CD4 count to greater than 100 to 200/mm³ for at least 6 months (Table 18.5); this is not recommended in children [1].
- XII. Histoplasmosis** occurs in at least 5% of HIV-infected patients residing within endemic regions (central and south central) of the United States, and it often is their first OI (>70%). Nearly all cases are disseminated at the time of diagnosis. In these regions, histoplasmosis has been the second or third most common opportunistic disease [159]. Dissemination may result either from primary or reactivation *H. capsulatum* infection.
- A. Clinical presentation** includes fever and weight loss in greater than 95% of patients, and at least 50% have pulmonary complaints. Examination is often notable for hepatosplenomegaly, lymphadenopathy, and, rarely, skin lesions [160]. The chest radiograph may show streaky infiltrates but can be normal in 50%. An **elevated LDH** level, often over 1,000 U/L, may be a clue to diagnosis. The median CD4 cell count at the time of diagnosis is 50/mm³. Disseminated disease can cause a sepsis-like syndrome characterized by hypotension, respiratory and liver failure, and disseminated intravascular coagulopathy. On rare occasions, histoplasmosis may cause retinitis, prostatitis, pericarditis, pancreatitis, or colitis [161,162].
- B. Diagnosis** of active disease is made by isolation of *H. capsulatum* from appropriate sites, including blood, bone marrow, lung tissue, or lymph node. Sensitivity is approximately 90% for blood and bone marrow cultures, and slightly less for respiratory specimens. Isolates are confirmed using a DNA probe for specific

ribosomal DNA. **Detection of polysaccharide antigen is the mainstay of rapid diagnosis.** In one series of HIV-positive patients, it had a sensitivity of greater than 90% in urine and approximately 75% in blood [163]. Monitoring antigen levels is much more sensitive than serology for detecting early relapse [164]. The complement fixation test does not distinguish past and active disease, and is less sensitive in HIV-infected patients [164]. Following the LDH level is also a sensitive means of detecting early relapse, and is used with serial urine antigen tests.

C. Therapy with amphotericin B until there is definite clinical improvement (usually 0.7–1.0 mg/kg for 7–14 days; some clinicians suggest giving 10–15 mg/kg total cumulative dose) **is followed by itraconazole** (200 mg orally twice daily) for 12 weeks. **Liquid formulation itraconazole is preferred** due to improved absorption and fewer drug interactions. Interactions of itraconazole preparations with food are listed in Table 18.7. Failures of this approach were seen in patients who were severely ill at diagnosis [160]. Oral itraconazole can be used alone for mild nonmeningeal, nonsepticemic cases (200 mg three times daily for 3 days, then 200 mg twice daily for 12 weeks total). **Lifetime maintenance therapy is required** to prevent relapse (Tables 18.2, 18.4, and 18.5) [160]. Although weekly or biweekly amphotericin B (1 mg/kg) decreases relapse rates from 80% to 10%–15%, itraconazole (200 mg orally once or twice daily in adults) is equally effective, more convenient, and better tolerated [165]. **Fluconazole** has less *in vitro* activity for *H. capsulatum* and is inferior for both initial and maintenance therapy [166,167]. See Table 18.4 for pediatric doses.

D. Prevention. Routine primary prophylaxis is not recommended, although some clinicians argue that patients with low CD4 counts living in endemic areas would benefit. Concern for developing resistant organisms is the major argument against this practice. Further study is necessary before this controversial issue can be resolved. Secondary prophylaxis has been discussed above.

XIII. Coccidioidomycosis is endemic to areas of the southwestern United States (see Chapter 17). Rates and severity of illness are higher in HIV-infected persons [168]. The majority of these patients have CD4 counts of less than 250/mm³. Primary antifungal prophylaxis is not recommended.

A. Presentation depends on the immunologic status of the patient. Patients with relatively normal immune function have either subclinical illness or lower respiratory symptoms [169]. For patients with CD4 cell counts of less than 250/mm³, pneumonia and meningitis are more common. Illness may resemble PCP, with fever, dyspnea, nonproductive cough, and a chest radiograph with diffuse nodular infiltrates [168,169]. Coccidioidal meningitis presents with headache, fever, and lethargy. The CSF may have more than 50 WBCs per mm³ (predominantly lymphocytes) with low glucose and high protein. In addition, the disease may present as a fever of unknown origin with diffuse lymphadenopathy and pancytopenia.

B. Diagnosis. Results of coccidioidal **serologic tests are positive in approximately 90%** of HIV-positive patients. **Titers reflect the activity of infection and therefore can be used to monitor response to therapy.** Antibody detection tests include the tube precipitins method, complement fixation, latex agglutination, immunodiffusion, and EIA. Skin testing for delayed-type hypersensitivity to coccidioidal antigens has a limited diagnostic role because of anergy and a positive test result indicates only prior infection. **Definitive diagnosis is made from clinical specimens by culture of the organism or identification of coccidioidal spherules on histopathologic examination,** using stains such as methenamine silver or Papanicolaou. Although it is difficult to culture the organism from CSF, the presence of complement-fixing antibodies suggests the diagnosis of meningitis. Laboratory personnel need to take appropriate precautions when coccidioidomycosis is suspected.

C. Treatment of disseminated disease is with **amphotericin B** (1 mg/kg/day) for a total dose of as much as 2.5 g. The oral azoles including **itraconazole** (200 mg twice daily) and **fluconazole** (400 mg/day) also have been used with success

as initial therapy [170,171]. Although meningitis has been treated with i.v. and intrathecal amphotericin B, currently oral fluconazole (400–800 mg/day) is often used initially. Lifelong maintenance therapy with oral azoles (400 mg/day in adults) is recommended to prevent relapse (Tables 18.2, 18.4, and 18.5) [172]. Studies are under way to evaluate optimal regimens for both induction and maintenance therapy.

XIV. Blastomycosis is endemic to areas of the midwestern and south central United States. It rarely causes disease in HIV-infected persons even in endemic regions [173]. Most patients have had a prior opportunistic infection and CD4 cell counts of less than 200/mm³.

A. Presentation. Pulmonary or disseminated disease may be seen. Unlike normal hosts, in whom skin, bone, and prostate involvement is common, HIV-positive persons with disseminated disease frequently have infection in the CNS (meningitis or blastomycoma), liver, spleen, and bone marrow [174].

B. Diagnosis by growth in culture may require 2 to 4 weeks. **Microscopic examination** of sputum, BAL fluid, and other tissue specimens should be used to rapidly detect the characteristic organism (see Chapter 17). Serologic tests lack sensitivity and specificity.

C. Treatment. Patients should receive amphotericin B until they are stable (usually 10–20 mg/kg total dose) followed by lifelong maintenance therapy with itraconazole [173,175].

XV. Penicilliosis. *Penicillium marneffei* is a dimorphic fungus endemic in Southeast Asia, especially Vietnam, Thailand, and parts of southern China. Although rare in the United States, it is the third most common opportunistic infection in HIV-infected patients in Northern Thailand. Most reported cases in the United States occur in individuals who have traveled to endemic regions [176]. The actual route of human infection with this organism is unknown. *P. marneffei* infection is serious and potentially fatal without therapy. Travelers to endemic regions should be informed of the risk for acquiring this infection (Table 18.6).

A. Clinical presentation may be similar to that of disseminated histoplasmosis. Fever is the most common symptom, along with anemia and weight loss. Respiratory complaints occur in approximately half of cases. The majority of patients with disseminated disease present with cutaneous involvement characterized by multiple papular lesions. Disseminated infection usually occurs in advanced HIV infection (CD4 cells <50/mm³).

B. Diagnosis is made by direct microscopy or culture of blood, skin lesions, lymph nodes, and bone marrow [176].

C. Treatment. Amphotericin B (0.6 mg/kg/day) for 2 weeks followed by oral itraconazole (200 mg twice daily) for 10 weeks is regarded as standard therapy [177]. As with other endemic mycoses, relapse is common; therefore, chronic suppressive therapy with itraconazole (200 mg/day) is recommended [177]. Although ketoconazole is active *in vitro*, it is less effective than itraconazole both for treatment and prevention [178].

XVI. Herpes simplex virus (HSV) types 1 and 2 commonly cause mucocutaneous disease in HIV-infected persons; 95% of homosexual men with AIDS have antibodies to HSV [179,180], as do up to 77% of the HIV-infected population in general [181]. Reactivation occurs frequently, resulting in chronic lesions in patients with AIDS. Direct contact with oral (HSV-1) or genital (HSV-2) secretions is the primary mode of transmission.

A. Clinical manifestations may vary from typical grouped vesicles with an erythematous base, to chronic, nonhealing ulcers or indistinct erosions; they most frequently involve the orolabial, genital, and anorectal regions. Disseminated disease, which occurs rarely in AIDS patients, may involve the esophagus, lung, liver, and adrenal glands. CNS infection is rare but life threatening (see Chapter 6). Fever and weight loss are common with gastrointestinal involvement [181].

B. Diagnosis is usually suggested by the clinical appearance. Techniques for diagnosis include cytologic preparations for multinucleated giant cells (e.g., Tzanck test), fluorescein-conjugated monoclonal antibody staining of scrapings from lesions, viral culture, and PCR assays for HSV DNA [182].

C. Therapy. Oral **acyclovir** (200 mg five times daily or 400 mg three times daily, up to 800 mg five times daily) for 7 to 10 days **is the treatment of choice for an initial mucocutaneous outbreak**. Bioavailability of oral acyclovir is approximately 10% to 20%. Topical acyclovir is not highly effective in patients with HIV infection and should not be used. **Famciclovir** (250 mg orally three times daily) or **valacyclovir** (1.0 g orally twice daily) given for 7 to 10 days is equally effective. Both have excellent bioavailability after oral administration. **Severe mucocutaneous disease may require i.v. acyclovir** (5 mg/kg every 8 hours). **Esophagitis or other visceral disease also is treated with i.v. acyclovir** (10 mg/kg every 8 hours for up to 21 days). **Recurrent mucocutaneous lesions** are treated with acyclovir (400 mg three times daily), famciclovir (125 mg twice daily), or valacyclovir (500 mg twice daily) orally for 5 days. **Suppressive therapy** (Tables 18.2 and 18.4) is recommended for frequent recurrent infections or relapses [183,184]. Many patients are controlled with acyclovir 400 to 800 mg/day in divided doses, famciclovir 125 to 250 mg orally twice daily, or valacyclovir 500 mg orally twice daily or 1 g orally daily. Dosages should be individualized to the patient's response. Acyclovir is the agent of choice for children (Table 18.4).

Acyclovir-resistant HSV infection is increasingly common, particularly in those with an extensive prior history of acyclovir use. **Foscarnet** (40–60 mg/kg/day i.v.) is the treatment of choice despite its potential toxicity and added costs [185].

XVII. Varicella-zoster virus (VZV) is a common pathogen that causes an array of clinical syndromes, ranging from chickenpox and shingles, to disseminated skin involvement and visceral disease, to postinfectious vasculitis. Because shingles may be the first evidence of HIV infection, many experts recommend HIV testing for any young to middle-aged individual presenting with shingles [186].

A. Clinical features. The typical rash associated with **primary VZV (chickenpox)** appears 10 to 21 days after exposure/infection. Lesions evolve over 1 to 3 days to form vesicles, pustules, and various stages of crusting. Early cases with few vesicles or multidermatomal cases may be more difficult to diagnose clinically. In such cases, confirmatory viral culture is recommended. A Tzanck preparation from scrapings from the base of lesions may reveal multinucleated giant cells but is not specific for VZV. Fluorescein-conjugated monoclonal antibody staining is specific and more rapid than viral culture [187].

The unique unilateral dermatomal distribution of clustered vesicles allows clinical diagnosis of most cases of **shingles (herpes zoster)**. Herpes zoster in the immunocompromised patient is often more severe. HIV-positive patients (regardless of the CD4 cell count) have a higher incidence of dermatomal zoster and are at increased risk for disseminated disease compared with age-matched immunocompetent hosts [186]. **Involvement of the ophthalmic division of the trigeminal nerve (V1), herpes zoster ophthalmicus**, causes anterior uveitis and corneal scarring with visual loss.

B. Other syndromes. Varicella-zoster virus rarely has been recovered from retinal tissue in patients with sudden blindness due to **acute retinal necrosis** [188]. Most cases appear to be postinflammatory in nature. **Varicella encephalitis**, a subacute encephalitis characterized by slowly progressive dementia and confusion that involves the white matter preferentially, also may be seen. Granulomatous vasculitis causing contralateral stroke syndrome is a rare CNS complication of herpes zoster ophthalmicus [189].

C. Treatment of VZV requires higher doses of antivirals than that used for HSV.

1. Dermatomal zoster may be treated orally, although patients with advanced disease or uncertain absorption are best treated intravenously until stable. The standard i.v. acyclovir dose for adults and children under 1 year of age is 10 mg/kg every 8 hours (500 mg/m² every 8 hours in children between 1 and 2 years of age) for 7–10 days. Oral dosages in adults with uncomplicated cases are acyclovir 800 mg five times daily, valacyclovir 1.0 g three times daily, or famciclovir 500 mg three times daily.

2. **Chickenpox, disseminated zoster, multidermatomal zoster, or involvement of V1 should be treated with i.v. acyclovir** until stable.
3. **Acyclovir-resistant VZV infection** has been reported. The vesicles in this syndrome often are atypical, with a more necrotic base and larger, more leathery appearance. Foscarnet is the antiviral agent of choice for infection with acyclovir-resistant VZV [185].
4. The best therapy for **retinal necrosis** is not known. There is no apparent response to either steroids or antiviral therapy, although antiviral therapy is often tried. Ophthalmologic consultation is recommended.
5. **Aspirin should not be given to children** with varicella to reduce the risk for Reye syndrome.

D. Prevention. HIV-infected children and adults known to be susceptible to VZV are candidates for varicella-zoster immune globulin within 96 hours of an exposure. There are no data to support the use of postexposure acyclovir. Asymptomatic children in CDC class I (CD4 counts $\geq 25\%$) may be considered for varicella vaccination (Table 18.13). (See also Chapter 23.)

XVIII. Human herpesvirus 8 and Kaposi sarcoma (KS). KS is the most common neoplasm in AIDS. Early in the AIDS epidemic, a 20,000-fold increased rate of KS was noted among homosexual men [190]. Promiscuity and oral-fecal contact were identified as risk factors, suggesting the presence of an infectious etiology [191,192]. In 1994, HHV-8 was detected in biopsy samples of KS tissues from a patient with AIDS [191,193]. Abundant data now support the assertion that **HHV-8 infection is etiologically related to KS** [191,194]. It also is linked to the development of B-cell body cavity lymphomas and Castleman disease.

A. Epidemiology. HHV-8 infection appears restricted to the human population. About 30% to 40% of homosexual men with HIV are seropositive for HHV-8 [192]. Although all infections result from human-to-human transmission, the exact modes of transmission have not been defined. HHV-8 most often is acquired through sexual contact or body fluids, and is not readily transmitted by blood, although injection drug use is a risk. Moreover, the mechanisms by which HHV-8 infection induce KS remain incompletely understood. A 10- to 30-fold decreased incidence of KS has been reported since the introduction of HAART in 1996 [195,196]. Despite declining frequencies, KS was present in 20.5% of U.S. patients who died from AIDS in 1997 [17].

Before the AIDS epidemic, KS was recognized as a rare, indolent dermal tumor usually found on the lower extremities of elderly white men of Mediterranean or Eastern European origin. KS also was known to occur occasionally in renal transplant patients in whom lesions often regressed when immunosuppressive agents were discontinued.

B. KS in AIDS patients is usually aggressive. It is a multicentric tumor that initially presents as purplish nodules on the skin or mucous membranes. Patients with high CD4 cell counts ($>300\text{--}400/\text{mm}^3$) may develop limited cutaneous lesions. In the early stage, lesions are irregular, reddish blue or purple to violaceous, nonblanching macules. The macules may become papular or nodular, or coalesce to form large patches, plaques, and fusiform or ovoid tumors. Individual lesions are usually asymptomatic, although pain, itching, and burning can be noted [197]. Lesions commonly are less than 1 cm in diameter. KS frequently spreads to lymph nodes and visceral organs and can be seen in any organ. In advanced disease, lymph node involvement may result in edema, particularly of the legs and scrotum. More than half of patients with cutaneous KS have oral involvement. Oral lesions are especially common on the hard palate and gingival margins and often are asymptomatic. Immunosuppression is an important risk factor for KS, although it may occur in persons with CD4 cell counts of greater than $500/\text{mm}^3$. Remission of cutaneous and pulmonary disease has been noted in patients receiving HAART.

C. Diagnosis of KS is confirmed by biopsy, which shows vascular proliferation. Any patient with presumed KS should have a biopsy, because other conditions, such as bacillary angiomatosis, may mimic the disease.

D. Therapy for KS can be local or systemic. Local therapies include surgical excision, cryotherapy, laser, intralesional injections, and radiation therapy. Recombinant interferon- α (IFN- α) therapy has been used for extensive cutaneous lesions [198–200]. In life-threatening situations, where KS lesions may obstruct vital structures such as the bronchus, bowel, or biliary tract, either radiation or chemotherapy may be necessary. Systemic treatments involve various combinations of vinblastine, etoposide, bleomycin, and doxorubicin. Paclitaxel (taxol) is generally well tolerated and is the treatment of choice for refractory KS [201]. **Lesions may regress in response to HAART** [202].

E. Prevention. There is currently no recommended drug regimen for preventing HHV-8 infection. Thus, HIV-infected patients should avoid sexual and injection drug use exposures to HHV-8 (Table 18.6). However, there is evidence that some antiherpesvirus drugs (i.e., ganciclovir, foscarnet, and cidofovir) may inhibit HHV-8 replication. In addition, the incidence of KS has decreased since the advent of potent antiretroviral therapy.

XIX. Progressive multifocal leukoencephalopathy is a demyelinating disease caused by **JC virus**, a polyomavirus that infects the oligodendrocytes. Pre-HAART, approximately 4% of AIDS patients developed PML [203], which typically progressed to death within months from diagnosis.

A. Clinical presentation varies from diffuse encephalopathy to focal deficits such as ataxia, hemiparesis, or speech difficulties. Symptoms tend to progress rapidly over several months, although rare patients have a waxing and waning course extending for years. Unlike global dementia of AIDS, the cognitive deficit of PML often progresses rapidly and can occur with other focal neurologic deficits. The typical finding is progressive dementia concurrent with a stroke syndrome.

B. Definitive diagnosis must be made by brain biopsy, which shows focal myelin loss with bizarre astrocytes and other changes. Suggestive CT findings include multiple nonenhancing lesions scattered throughout the white matter without mass effect. MRI shows lesions as hypodense in T1 images and hyperdense in T2 images [204]. **PCR detection of JC virus** has a diagnostic sensitivity of 70% to 80% and a specificity of virtually 100% [205] and is increasingly used in place of brain biopsy. The value of markers for JC-specific cellular and humoral immune responses, including VP-1, the major capsid protein of JCV, are being studied [206].

C. There is no proven treatment for PML. Prednisone, acyclovir, vidarabine, HLA-matched platelets, amantadine, IFN- α , and cytarabine have not resulted in consistent improvement [207]. One study demonstrated clearance of JC virus DNA in five of six patients treated with HAART for 35 to 365 days [206]. Cytarabine did not affect survival [207,208]. Response to cidofovir has been disappointing; in a recent pilot study, cidofovir did not prolong PML survival beyond what has been reported without treatment [209]. Cidofovir added to HAART, however, has been associated with improved survival due to more effective control of JC virus replication [210]. **Improvement with HAART has been reported** and this is the treatment of choice [211,212].

XX. Cryptosporidiosis was considered a rare and insignificant protozoan infection prior to the AIDS epidemic. *Cryptosporidium parvum*, the parasite that causes human cryptosporidiosis, is now known to be ubiquitous. It is recognized as one of the most common enteric pathogens in humans and domesticated animals worldwide. Transmission is primarily by the fecal-oral route; numerous U.S. waterborne outbreaks in normal hosts have heightened awareness of this parasite's threat to public health [213]. Person-to-person transmission and animal-to-person transmission also have been described. The prevalence of cryptosporidiosis in HIV-infected patients was estimated to be 10% to 15% prior to the advent of HAART [214]. According to the CDC, the incidence of chronic cryptosporidiosis has decreased from 16.4 per 1,000 person-years in 1992 to 3.7 cases per 1,000 person-years in 1997 [17]. This decline is consistent with the decreasing rates of other OIs [215].

A. Clinical presentation varies depending on host immune status. Whereas immunocompetent patients have a transient illness, patients with AIDS have a spectrum of disease ranging from asymptomatic carriage to fulminant,

persistent, cholera-like diarrhea [214]. *Cryptosporidium* causes diarrhea, nausea, vomiting, abdominal pain, and weight loss; fever is uncommon. Biliary tract involvement occurs in at least 15% of AIDS patients and results in severe right upper quadrant pain with protracted nausea and vomiting. Laboratory studies reveal an elevated alkaline phosphatase level, and ultrasonography demonstrates gallbladder wall thickening and dilated bile ducts [216,217]. CMV and microsporidia cause similar signs and symptoms, and often are concomitant pathogens.

- B. Diagnosis** is made by modified acid-fast stain of stool or other tissue specimens. Biopsy of the small intestine may be less sensitive than stool examination owing to focal intestinal involvement and the absence of inflammatory changes to guide the endoscopist. Immunofluorescent antibody assays and enzyme linked immunosorbent assays (ELISAs) are available; ELISA sensitivities range from 66% to 100% and specificities from 93% to 100% [218]. Serologic detection is primarily used as an investigational tool because antibody persistence limits its utility in diagnosis of acute infection. PCR assays have not undergone large clinical trials.
- C. Treatment.** There is no reliable palliative or curative therapy for cryptosporidiosis in immunodeficient hosts. There are numerous reports of limited success with the nonabsorbable aminoglycoside paromomycin, but its unpredictable activity and limitations in preventing extraintestinal spread have dampened enthusiasm. A recent controlled trial showed that 3 to 6 weeks of paromomycin was no more effective than placebo for treatment of symptomatic cryptosporidial enteritis in HIV-infected patients [219]. Lactose-free azithromycin was found to have some promise in a placebo-controlled trial, but further studies are needed. Other tested agents with marginal results include spiramycin, diclazuril, roxithromycin, allicin, and immunomodulatory therapies such as bovine colostrum immunoglobulins and hyperimmune egg yolks [220–222]. Responses are usually transient or incomplete; therefore, symptomatic therapy with loperamide, opioids, and somatostatin analogues may be necessary. Restoration of immune function with HAART appears to be the most effective intervention, resulting in significant clinical, microbiologic, and histologic improvements [223].
- D. Prevention.** Patients with CD4 cell counts of less than 200/mm³ should be educated about measures to reduce the risk for acquiring cryptosporidiosis (Table 18.6). **Chemoprophylaxis is not available**, although patients taking clarithromycin or rifabutin for MAC may have less cryptosporidiosis [1].

XXI. Microsporidiosis. *Microsporidium* species are pathogens of animals, but only since 1985 have they been recognized as an AIDS-associated infection [224,225]. At least 11 species are known to cause human disease, and serious illness is restricted to persons with abnormal immunity. In AIDS patients with chronic diarrhea, the prevalence of microsporidiosis has ranged from 4% to 50% [224] prior to HAART. Similar to cryptosporidiosis, the prevalence of microsporidiosis has dropped off dramatically with the use of HAART [17].

- A. Clinical presentation.** Over 90% of intestinal microsporidiosis is caused by *Enterocytozoon bienersi*. Chronic diarrhea, anorexia, and weight loss are the most common manifestations [224]. *E. bienersi* also has been associated with cholangitis and cholecystitis in AIDS patients. *Encephalitozoon hellem* appears to disseminate to lungs and kidneys and often spares the intestine [225]. *Septata intestinalis* involves the intestine but also causes disseminated disease [226]. *Pleistophora* and *Nosema* are rare in HIV-infected patients.
- B. Diagnosis** is by stool examination using special stains, including modifications of Weber chromotrope-based stains and other chemofluorescent agents. Such tests may be available only at reference laboratories or hospitals with a special interest in this diagnosis. Transmission electron microscopic examination of a small-bowel biopsy specimen is often used to confirm the diagnosis of microsporidiosis and to determine the genus and species. The specificity of serologic tests for antibodies to microsporidia is unknown, and their clinical utility is unclear.

C. Treatment. There is no effective therapy, but anecdotal reports suggest that albendazole (400 mg every 12 hours) for 2 to 4 weeks may be useful for certain microsporidial species. There are case reports of patients treated with azithromycin, metronidazole, atovaquone, furazolidone, and various other antibiotics [227]. Eradication of the parasite was reported with fumagilin, but follow-up found frequent relapses [228]. Although HAART is promising, its potential role in preventing microsporidiosis is unclear [223].

D. Prevention involves the same precautions as for cryptosporidiosis (Table 18.6). There is no effective chemoprophylaxis [1].

XXII. Isosporiasis. *Isospora belli* is an acid-fast coccidian protozoan that causes a clinical syndrome indistinguishable from cryptosporidiosis. Infection follows ingestion of food and water contaminated with human feces. Humans are the only known reservoir. Isosporiasis accounts for less than 1% of AIDS-defining illness in the United States [17], with higher prevalence in developing regions. Thus, precautions during overseas travel are indicated (Table 18.6). Profuse watery diarrhea, anorexia, malaise, and weight loss are common clinical findings. Atypical presentations include acalculous cholecystitis and reactive arthritis [229]. *Isospora* can be eradicated with trimethoprim-sulfamethoxazole therapy (one DS tablet four times daily for 10 days). Alternatively, pyrimethamine (75 mg daily) plus folinic acid (10 mg daily) may be successful. Because of a high relapse rate (up to 50% within 6–8 weeks), chronic suppression with trimethoprim-sulfamethoxazole (1 DS tablet three times per week) or pyrimethamine (25 mg/day) plus folinic acid (5 mg/day) is recommended.

XXIII. Cyclosporiasis. Infection caused by *Cyclospora cayentanensis*, an acid-fast coccidian, occurs worldwide but is relatively rare among AIDS patients in the United States [230,231]. The parasite is transmitted by the fecal-oral route, and likely acquired through contaminated water or food. Direct person-to-person transmission is unlikely because excreted oocytes require time outside the host to sporulate and become infective [232]. Clinical presentation is similar to cryptosporidiosis, microsporidiosis, or isosporiasis. Diagnosis requires identification of oocytes in the stool; *Cyclospora* (8 μm) is about twice the size of *Cryptosporidium* (4 μm). Repeat stool examinations may be necessary because the parasite is excreted intermittently and in low numbers. Tests for *Cyclospora* species, *Isospora* species, *Cryptosporidium* species, and *Microsporidia* should be requested specifically, in addition to routine stool ova and parasites, to ensure that specific methods to detect these organisms are applied. The only treatment is trimethoprim-sulfamethoxazole (1 DS tablet four times daily) for 10 days followed by one DS tablet three times a week indefinitely [231].

XXIV. Syphilis and HIV infection are uniquely associated. Epidemiologic studies have shown that a history of sexually transmitted diseases is associated with increased risk of HIV infection, and genital ulcerations caused by *Treponema pallidum* may facilitate HIV transmission [233–235]. In fact, recent *in vitro* studies have shown induction of HIV-1 gene expression in human monocytes by this spirochete [236]. HIV infection may alter the clinical course of syphilis, especially latent and tertiary disease [237–239]. Annual syphilis screening should be performed in HIV-infected patients due to high rates of coinfection [5,240].

A. Clinical presentation varies depending on the stage of HIV infection. Most HIV-infected patients with early syphilis have clinical manifestations comparable with those of primary and secondary lesions observed in HIV-uninfected persons [241]. A higher incidence of neurosyphilis may be seen, which may develop rapidly. Some case reports indicate that syphilis in HIV-infected patients can present with atypical lesions and in aggressive forms; the frequency of these atypical presentations, however, is unknown [238]. (See Chapters 6 and 16.)

B. Diagnosis. Serologic tests, patient history, clinical examination, and dark-field examination of tissue are all used. Serology remains a cornerstone of diagnosis.

1. Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin test are nontreponemal screening tests. Up to 6% of HIV-infected patients have biologic false-positive test results [242].

False-negative results also occur, but are rare. The fluorescent **treponemal antibody-absorption test** and the **microhemagglutination *T. pallidum*** treponemal test detect antibodies directed against *T. pallidum* antigens. Treponemal tests are used to confirm reactive nontreponemal tests. Therefore, a negative test result does not always rule out current or previous infection. Once positive, treponemal test results usually stay positive for life, although some studies indicate that HIV-positive patients appear more likely to serorevert to negative following therapy [243]. In addition, microhemagglutinating antibody may be lost with progression of HIV disease.

2. **Dark-field examination** with biopsy of lesions may be useful when serologic tests are nonreactive but clinical suspicion remains high. Dark-field examination is the only means of practical, direct diagnosis.
3. **Lumbar puncture** is recommended for all patients with latent syphilis regardless of the apparent duration of infection [240]. CSF evaluation is also indicated for any HIV patient with unexplained behavioral changes or neurologic abnormalities. Diagnosis of **neurosyphilis** is made by a positive CSF serology, high protein level, or pleocytosis; however, there are many false-negative results [244].

C. Treatment with penicillin is recommended by the CDC whenever possible for all stages of syphilis in HIV-infected patients [240]. Furthermore, there are no proven alternatives to penicillin for treatment of congenital syphilis, neurosyphilis, or syphilis in pregnancy. Penicillin desensitization is recommended for these situations.

1. **Benzathine penicillin G** (2.4 million units intramuscularly) is recommended for primary or secondary syphilis in patients who have no evidence of neurosyphilis. A total of 7.2 million units (2.4 million units intramuscularly weekly for 3 weeks) is advised for treatment of non-neurologic latent syphilis regardless of apparent duration of infection.
2. **Follow-up nontreponemal serologies** should be obtained at 3, 6, 9, and 12 months. In HIV-positive patients, a slower decrease in serologic response may be seen, but clinical failures are rare [245,246]; reinfection is more common than relapse. However, even after proper therapy some patients have stable or increasing serologic titers. Therefore, careful long-term follow-up is essential, and repeated courses of penicillin may be needed [244]. Optimal therapy in this setting is not clear, and some experts advocate higher doses of penicillin for primary and secondary syphilis in the HIV-positive patient (see Chapter 16). Infectious disease consultation is suggested for complicated or puzzling cases.
3. **Treatment of neurosyphilis** is with high-dose i.v. penicillin G (3–4 million units every 4 hours) for 10 to 14 days. Penicillin-sensitive patients should be desensitized.

D. Prevention. Patients should be counseled on means to reduce the risk for sexually transmitted diseases (Table 18.6).

XXV. Hepatitis C virus infects approximately 4 million people in the United States, of whom an estimated 10,000 die each year [247,248]. HCV is a major pathogen in HIV-infected patients, reflecting shared epidemiologic risk factors. HCV is transmitted chiefly by percutaneous exposure to blood through injection drug use in the United States. Sexual transmission occurs less commonly. All HIV-infected patients should be screened for HCV because approximately 30% to 50% (about 240,000 persons in the United States) are coinfectd [249,250]. Children born to coinfectd mothers also should be screened for HCV. HIV is an important cofactor for HCV disease progression. Moreover, coinfectd individuals have poorer responses to HAART compared with HIV-positive matched controls [251]. The majority of these patients will develop chronic hepatitis; others may progress to cirrhosis, hepatic decompensation, and hepatocellular carcinoma [252]. Awareness of HCV status is also important so that liver function abnormalities can be properly evaluated during HAART. Hepatotoxicity may be more common in persons with chronic HCV; some clinicians may be reluctant to use certain antiretroviral medications for fear of inducing severe hepatic damage. However, current data do not support

withholding antiretroviral therapy in patients with concomitant HCV infection. Immune reconstitution hepatitis is also possible (see section II.B.4). Overall morbidity and mortality related to HCV among HIV-infected persons are substantial [247] (see also Chapter 14).

A. Clinical presentation. Most patients with chronic HCV are asymptomatic and unaware of their infection. Patients may complain of lethargy, inability to concentrate, or abdominal pain. Jaundice, encephalopathy, ascites, splenomegaly, or gastrointestinal bleeds secondary to portal hypertension indicate decompensated cirrhosis. Laboratory findings may include hypoalbuminemia, thrombocytopenia, coagulopathy, and elevated hepatic transaminases. **Extrahepatic manifestations** include mixed cryoglobulinemia, membranous proliferative glomerulonephritis, and porphyria cutanea tarda. Hepatocellular carcinoma should be suspected in patients with sudden decompensation in previously stable chronic liver disease and elevated α -fetoprotein (see Chapters 13 and 14).

B. Diagnosis is made by detection of antibody to HCV in blood by EIA. EIA-positive patients should undergo confirmation testing with recombinant immunoblot assay or reverse transcriptase PCR for HCV RNA. Acute HCV, however, cannot be reliably diagnosed by antibody tests because of a prolonged window period. If clinical suspicion remains high despite negative HCV antibody test results, HCV RNA is useful. However, unlike HIV viral load, the HCV RNA quantitative level is not closely associated with outcome or overall prognosis. Similarly, the magnitude of alanine aminotransferase elevation or other abnormality in liver biochemistry does not correlate well with disease outcome or histologic changes. Liver biopsy provides information about degree of inflammation and the stage of fibrosis. A recent prospective study revealed that the combination of several basic serum markers (α_2 -macroglobulin, haptoglobin, γ -globulin, apolipoprotein A₁, γ -glutamyltranspeptidase, and total bilirubin) may have predictive value similar to liver biopsy in determining significant fibrosis [253].

C. Treatment. Despite advancements in treatment, the data regarding safety and efficacy in HIV-coinfected persons is limited. The majority of trials with IFN for chronic hepatitis C have excluded patients with HIV coinfection.

- 1. Interferon- α** was the first licensed treatment for HCV, but its mechanisms of action in viral hepatitis remain uncertain. About 15% to 20% of patients achieve a long-term or sustained virologic response with IFN monotherapy. A standard dosing regimen is 3 million units three times weekly for 6 months. Adverse events commonly associated with IFN therapy include self-limited, dose-dependent, flulike illness with mild fever, chills, headache, lethargy, arthralgias, and myalgias. Other important side effects include depression, irritability, anorexia, rash, and alopecia. Patients need to be warned about potential adverse events. Results of therapy in HIV-coinfected patients have been limited and mostly disappointing. In one prospective, controlled trial, a response rate of 38% was noted in coinfecting patients compared with 47% in HIV-negative patients [254]. However, a sustained virologic response was diminished in both groups. Given the low sustained response rate, use of monotherapy has been abandoned in favor of combination therapy with ribavirin.
- 2. Ribavirin** is an oral nucleoside analogue that is active *in vitro* against many RNA and DNA viruses. The precise mechanism of action of ribavirin in chronic hepatitis C is not well understood. The major toxic effect of ribavirin appears to be reversible, dose-dependent hemolytic anemia.
- 3. Combination therapy with IFN- α and ribavirin**, which is approved by the U.S. Food and Drug Administration, is more effective than IFN alone [255]. Used together, sustained response rates increase to approximately 50%. Combination therapy in smaller series with HIV-infected patients is encouraging; larger controlled trials are currently under way.
- 4. Pegylated IFN- α (PEG-IFN)** is approved by the U.S. Food and Drug Administration, and is easier to administer because of a longer half-life [256]. Polyethylene glycol (PEG), an inert polymer, is covalently bonded to

standard IFN, resulting in delayed recognition as a foreign substance by the immune system, thus prolonging the half-life of PEG-IFN to approximately 54 hours compared with 8 hours for routine IFN- α . PEG-IFN administered once weekly with daily ribavirin is now the treatment of choice in HIV-negative patients. Prospective multicenter trials comparing PEG-IFN alone, PEG-IFN plus ribavirin, and IFN plus ribavirin in HIV-infected populations are in progress.

5. Susceptible patients should be **vaccinated against hepatitis A and B** (see Table 18.13 for recommended childhood immunizations).

6. **Alcohol** consumption should be limited.

D. Hepatotoxicity due to antiretroviral medications. Zidovudine may be the most potentially hepatotoxic drug in the nucleoside analogue class. Among protease inhibitors, indinavir and ritonavir are hepatotoxic, and nelfinavir and saquinavir are much less so. Nevirapine and other non-nucleoside reverse transcriptase inhibitors are also potentially hepatotoxic [251] (see Chapter 19).

E. Prevention. Patients should be counseled on how to limit their risk for acquiring hepatitis C [1], and offered referral for substance abuse treatment when appropriate (Table 18.6). Risks from body piercing and tattooing, sharing needles, sharing dental equipment and razors, and sexual practices should be reviewed.

XXVI. Bacillary angiomatosis (BA) is a disease caused by small gram-negative organisms of the genus *Bartonella* (formerly *Rochalimaea*), specifically *B. henselae* and *B. quintana*. These vascular proliferative lesions can form in many different organs, including skin, bone, brain parenchyma, lymph nodes, bone marrow, and the gastrointestinal and respiratory tracts. Most patients with BA are significantly immunocompromised. In one study of 42 patients with BA, the median CD4 count was 21 cells/mm³. Disseminated infection may be more common in immunosuppressed patients with a history of cat contact or homelessness.

A. Clinical presentation depends on the organ system involved.

1. **Cutaneous lesions** are raised erythematous areas that bleed when traumatized. They also can appear as a cellulitic plaque, which often overlies osteolytic lesions. They can occur singly or multiply and can occur in any location. These lesions are indolent and may be present for as long as 1 year before diagnosis is made. Most often they are confused with KS.

2. **Osseous BA**, often seen with cutaneous lesions, causes pain and radiologically lytic lesions. Bones most often affected include the tibia, fibula, and radius.

3. **Hepatic BA (peliosis hepatis)** is characterized histopathologically by cystic spaces of varying size filled with blood [257,258]. Patients present with abdominal pain, fever, and high alkaline phosphatase. CT demonstrates heterogeneity in the liver. Lesions are also seen in the spleen [259].

4. **Other manifestations** without vascular proliferation include necrotizing lymphadenitis, cat-scratch disease-type necrotizing infection, and bacteremias. Endocarditis has been reported in HIV-infected patients in the absence of cutaneous involvement.

B. Diagnosis is made by tissue biopsy and demonstration of the organisms by **Warthin-Starry stain**. Histopathologic evaluation demonstrates vascular proliferation that can be mistaken for KS, angiosarcoma, or pyogenic granuloma. The organism has been cultured from blood, but specimens need to be incubated at 35°C for 3 weeks. Use of the Isolator lysis centrifugation system may increase the yield of blood cultures, which should be incubated at least 14 days. Isolation of *Bartonella* species directly from cutaneous BA lesions is difficult because of the organism's fastidious growth characteristics. Indirect immunofluorescence assay to detect antibodies to *B. henselae* are useful for diagnosis of both acute disease and relapse [260]. PCR detection techniques remain experimental and are not routinely available.

C. Treatment. Clarithromycin (500 mg orally twice daily), azithromycin (250 mg orally daily), and fluoroquinolones are first-line therapy, although cures also have been reported with doxycycline, trimethoprim-sulfamethoxazole, and minocycline [261]. Despite *in vitro* susceptibility, penicillins and first-generation

cephalosporins have no activity against *Bartonella*. Cutaneous lesions are treated for 8 to 12 weeks, and osseous and liver lesions are treated for at least 3 months [259]. However, the optimal duration of therapy is unknown. Rifampin may have a role when added to either erythromycin or doxycycline for severely ill patients. There have been numerous reports of relapse of *Bartonella* infection in immunocompromised patients. If relapse occurs in the HIV-infected patient, lifelong maintenance therapy with erythromycin or doxycycline is recommended.

D. Prevention. Patients should be counseled on the potential risks of cat ownership, and how to limit their exposure to this organism (Table 18.6). There is no known chemoprophylaxis for *Bartonella*, although the widespread use of macrolides for prophylaxis against MAC may decrease the incidence of BA. Secondary prophylaxis is not generally indicated unless there is relapse or reinfection.

XXVII. Salmonellosis, particularly bacteremias, is seen in higher frequency in HIV-infected patients and often presents without intestinal symptoms [262]. Nontyphoid *Salmonella* species, especially *S. enteritidis* and *S. typhimurium*, are isolated most often. Travelers' diarrhea may be a severe illness that is more resistant to therapy in HIV-infected patients [263]. One study found an increased risk of salmonellosis among HIV-positive persons who were residents of the Northeast, had a history of injection drug use, or were African American or Hispanic [264]. The incidence of *Salmonella* bacteremia has declined with the use of trimethoprim-sulfamethoxazole prophylaxis and antiretroviral therapy [265].

A. The clinical course in patients with AIDS is more severe than in normal hosts (see Chapter 13). Rates of bacteremia are increased, fever may persist for 1 to 2 weeks, and relapse rates are higher. Bacteremic relapse may be secondary to hidden foci of infection. Other sites of involvement include the prostate, heart, CNS, joints, parotids, and bones.

B. Diagnosis is made by bacterial culture of blood, stool, or urine. Other localized infections are diagnosed by culture of the appropriate anatomic site.

C. Treatment with ampicillin, quinolones, third-generation cephalosporins, or trimethoprim-sulfamethoxazole is effective. Therapy should extend for at least 7 to 10 days after defervescence. Some experts place all patients with salmonellosis on **chronic suppressive therapy** (Tables 18.2 and 18.4) [1]; others give suppressive therapy only to those with recurrent disease. Oral ciprofloxacin 500 mg twice daily in adults is recommended for susceptible isolates, although amoxicillin and trimethoprim-sulfamethoxazole are equally effective for chronic suppression (Table 18.2). Trimethoprim-sulfamethoxazole is the drug of choice for suppression in children (Table 18.4) [1]. Fluoroquinolones should not be used in children or during pregnancy (see Chapter 27).

D. Prevention. Steps to avoid acquisition of *Salmonella* should be reviewed with patients, including animal exposures, safe food handling, and during travel (Table 18.6). Household contacts with salmonellosis should be checked for chronic carriage of the organism to limit the risk for reinfection [1].

XXVIII. AIDS-associated bacterial pneumonia. Pulmonary infections cause significant morbidity and mortality in HIV-infected patients. Recurrent bacterial pneumonia as an AIDS-defining disease is defined as two or more episodes of bacterial pneumonia within 1 year, regardless of CD4 cell count [266,267]. Although the incidence of bacterial pneumonia has declined with widespread use of PCP and MAC prophylaxis [268], the rate of recurrent pneumonia was still approximately 20.2 cases per 1,000 person-years from 1992 to 1997 [17]. In contrast to PCP, bacterial pneumonia can occur at any CD4 cell level.

A. Etiology. *Streptococcus pneumoniae* is the most commonly identified cause. Pneumococcal bacteremia occurs at an approximately 100-fold greater rate in the HIV population [269,270]. Injection drug use is an independent risk factor for both bacterial pneumonia and pneumococcal bacteremia. Other pathogens causing bacterial pneumonia in HIV-infected patients include *Staphylococcus aureus*, *Haemophilus influenzae*, and gram-negative organisms, most notably *Klebsiella* and *Pseudomonas* [271–273]. Patients with low CD4 cell counts have

higher rates of *Pseudomonas aeruginosa* pneumonia, which is usually indolent, resembling infection in patients with cystic fibrosis, and may be recurrent [274,275]. Risk factors include CD4 cell counts of less than 50/mm³, neutropenia, bronchiectasis, and corticosteroid therapy.

- B. Clinical presentation.** Bacterial pneumonia may be more severe when associated with HIV disease. Symptoms usually occur with abrupt onset and include fever, productive cough, dyspnea, and acute pleuritic chest pain. This is usually distinct from PCP, which typically is indolent and associated with dry cough and infrequent chest pain, but symptom overlap occurs. Thus, diagnosis should not be based only on clinical findings.
- C. Diagnosis** is based on radiographic findings and appropriate laboratory tests, including blood cultures and sputum Gram stains plus culture. A lobar infiltrate generally suggests bacterial pneumonia, but radiographic findings alone will not identify the cause. Blood cultures should be obtained in all patients. HIV patients with pneumonia have higher rates of bacteremia compared with HIV-negative individuals [276]. It is essential to identify the pathogen to appropriately treat the pneumonia and improve outcome. Invasive procedures such as bronchoscopy may be necessary, particularly in patients with poor response to therapy or when PCP is suspected (see Chapter 11).
- D. Empiric treatment** is warranted in order to improve the outcome (see Chapter 11). Selection of agents should be based on local patterns of drug resistance. Once the pathogen has been identified, appropriate adjustments in therapy should be made (see Chapter 11) [277].
- E. Prevention** (Tables 18.1, 18.3, and 18.13). Protection against *Streptococcus pneumoniae* is best achieved with pneumococcal vaccine (see also Chapter 11). However, efficacy is blunted by diminished antibody responses in patients with CD4 cell counts of less than 200/mm³. *H. influenzae* type B vaccine is not generally recommended for adults because most infections involve nontypeable strains. Children should receive these vaccines according to current recommendations (Table 18.13) [1]. Trimethoprim-sulfamethoxazole used for PCP prophylaxis has coverage against several pathogens responsible for bacterial pneumonia (*Streptococcus*, *Haemophilus*, *Staphylococcus*, *Pseudomonas*, and *Klebsiella*). However, indiscriminate use, when not indicated for PCP prophylaxis, may lead to development of resistant organisms. Antibiotic prophylaxis or i.v. gamma globulin is not recommended to prevent bacterial pneumonia except in children with recurrent sinopulmonary or other serious bacterial infections (Tables 18.3 and 18.4) [1]. Annual influenza vaccine (Tables 18.1, 18.3, and 18.13) may help to prevent some bacterial pneumonias.

XXIX. Malignancies associated with AIDS. The association between certain malignancies and HIV infection was recognized early in the AIDS epidemic when **KS** was noted in homosexual men at a 20,000-fold increased rate compared with the pre-AIDS era [190]. Increased incidence of other cancers such as **squamous cell neoplasia**, particularly cervical and anal intraepithelial neoplasia (CIN, AIN), **non-Hodgkin lymphoma**, **Hodgkin disease**, and **primary CNS lymphoma** also has been well documented [278–280]. A correlation with viral coinfections exists with several of these malignancies. HHV-8 or KS herpesvirus promotes the development of KS, although the exact mechanism is not defined (see section XVIII). Moreover, certain types of **human papilloma virus** are associated with more advanced CIN lesions (CIN II and CIN III) and are found in the majority of cases of invasive carcinoma [281]. The presence of EBV has been reported in approximately 40% of systemic HIV-associated lymphomas and in a majority of primary CNS lymphomas [282].

Some AIDS-related malignancies have declined in frequency in the HAART era similar to other opportunistic infections. According to data from the ASD project, reductions were noted for KS and CNS lymphoma as a result of antiretroviral combinations, presumably by slowing the progression of HIV disease and delaying the onset of severe immunosuppression [283]. Lymphomas other than primary CNS lymphoma have not changed dramatically despite the widespread use of HAART. Similarly, available but limited data indicate no significant impact of HAART on

CIN or AIN. Although the presentation of malignancy in patients infected with HIV is often different from that seen in immunocompetent hosts, patients with controlled HIV and moderate CD4 counts generally are capable of tolerating full-dose chemotherapy and radiotherapy.

19. ANTIRETROVIRAL THERAPY: THERAPEUTIC AGENTS, DOSING, PHARMACOKINETICS, AND THEIR USE

Amneris E. Luque, Susan E. Cohn, Geoffrey A. Weinberg, and Peter R. Mariuz

I. Introduction and background. The advent of potent combination antiretroviral therapy (ARVT) in 1996, also referred to as highly active antiretroviral therapy (HAART), has revolutionized the treatment of human immunodeficiency virus (HIV) infection. The time to progression from HIV infection to acquired immunodeficiency syndrome (AIDS) has been delayed. Dramatic decrease in AIDS mortality and morbidity from opportunistic infections and certain malignancies (e.g., Kaposi sarcoma) has occurred [1–3]. The attendant increase in CD4 cell counts and return of pathogen-specific lymphoproliferative responses (immune reconstitution) [4] has permitted the discontinuation of primary prophylaxis for *Pneumocystis carinii* pneumonia (PCP) and for disseminated *Mycobacterium avium* complex infection (MAC). Accumulating evidence suggests that secondary prophylaxis of CMV retinitis [5], PCP [6], MAC [7], toxoplasmosis [8], and cryptococcosis [9] also can be discontinued. However, up to 62% of patients fail HAART therapy [10,11]. Furthermore, none of the current HAART regimens eradicates HIV even after continued use for up to 3 years [12]. In fact, a recent review suggests that eradication would require complete suppression of viral replication for decades [13], and thus is not a realistic goal at the present time. This finding—coupled with concerns about the complexity of drug regimens, drug interactions, the adverse effects of long-term ARVT, and antiretroviral resistance—has recently led to changes in the guidelines on initiation of therapy in asymptomatic HIV infection.

II. The virus

A. Life cycle. Understanding the life cycle (Fig. 19.1) and pathogenesis of HIV helps explain the mechanism of action of antiretroviral agents, the rationale for therapy, antiretroviral resistance, and future therapeutic targets.

B. Virus structure

- 1. HIV, an enveloped RNA virus,** belongs to the lentivirus genus of retroviruses.
- 2. The HIV genome** contains three primary genes: *gag*, *pol*, and *env*. These genes encode for the major structural proteins (*gag*), enzymatic proteins (*pol*), and envelope (*env*). Five other genes (*tat*, *nef*, *rev*, *vpu*, and *vif*) regulate expression of proteins, assembly, and release of virus from infected cells.

3. Steps in synthesis

- a. HIV binds** via surface glycoprotein 120 (gp120) to CD4 receptors (on lymphocytes, macrophages, and dendritic cells). Cells without CD4 receptors are infected by another mechanism.
- b. Fusion** with the host cell plasma occurs by the interaction of the HIV fusion protein (gp41) and a coreceptor on the host cell membrane. This is chemokine receptor 5 (CCR5) on macrophages or CXCR4 on lymphocytes. This is followed by nucleocapsid penetration of the cell membrane followed by release of the viral genome (two single strands of RNA) into the cytoplasm.
- c. Reverse transcription** of HIV RNA to DNA requires viral reverse transcriptase (RT), which is an RNA-dependent DNA polymerase. RT generates a first-strand copy of proviral DNA. After viral ribonuclease H partially degrades the original RNA template, RT controls the synthesis of second-strand DNA.
- d. Mechanism of resistance.** Because of the low fidelity of RT, which lacks the error-correcting mechanisms seen in eukaryotic and prokaryotic polymerases, and the high degree of guanine-to-adenine nucleotide hypermutation in HIV (a characteristic of all lentiviruses) [14], mutations are frequent. A high mutation rate coupled with the extraordinarily large daily production of virions ensures that resistance may occur easily, particularly under pressure of therapy. A single mutation in RT confers resistance to lamivudine (3TC), which occurs by 1 week with 3TC monotherapy [15].
- e. Comparative mechanisms of action of antiretroviral agents.** The nucleoside reverse transcriptase inhibitors (NRTIs) and non-nucleoside reverse

FIG. 19.1 The life cycle of human immunodeficiency virus (HIV). *Immature viral particles bud. (Reprinted from Fauci AS. The human immunodeficiency virus: infectivity and mechanisms of pathogenesis. *Science* 1988;239:619, with permission.)

transcriptase inhibitors (NNRTIs) block the function of RT by different mechanisms. Proviral DNA transported to the host cell nucleus is inserted into the host genome by viral integrase. Subsequent viral replication depends on the coordinated activity of both cellular and viral factors (HIV regulatory proteins *tat*, *rev*, and *nef*) that activate and regulate HIV transcription. Viral DNA is translated to genomic and messenger RNA, and production of virion structural and enzymatic proteins occurs. At the cell membrane HIV RNA is incorporated into capsids that bud from the cell surface, taking up viral envelope glycoproteins. An HIV protease mediates final viral maturation by cleaving first itself, then other viral proteins (RT, integrase, capsid, matrix, and nucleocapsid proteins) from a precursor polyprotein. This maturation step, blocked by protease inhibitors (PIs), is essential for viral release and infectivity. Currently available antiretroviral agents inhibit two essential steps in the HIV life cycle: reverse transcription and protease activity. Other potential targets include inhibition of fusion, integrase, and regulatory proteins (see section VII on investigational drugs), and binding to CD4 receptors. In addition, methods of improving specific anti-HIV immunity are being investigated.

III. Pathogenesis of HIV infection

- A. CD4 cell changes.** With continuous HIV replication in CD4⁺ T cells, their numbers gradually decline (50–75 per year). This eventually leads to AIDS [16]. The mean time from HIV infection to AIDS is 8 to 10 years. Twenty percent of patients develop AIDS in less than 5 years. Less than 5% remain asymptomatic with normal immune function for more than 10 years [17].
- B. Virus changes.** Billions of virions are produced and destroyed every day [18] in a dynamic equilibrium between production in lymphoid tissues and clearance by the immune system. The HIV 1 RNA level in plasma (viral load) [19] predicts disease progression. This can be measured using branched-chain DNA signal amplification (bDNA assay) or reverse transcriptase polymerase chain reaction (RT-PCR). The

assays used should be constant because HIV RNA values by RT-PCR are about twice those of bDNA assay.

- C. Viral load and CD4 cell interaction.** HIV replication and its associated CD4 cell destruction are assessed by measuring HIV viral load. CD4 cell counts independently predict disease progression and give an estimate of HIV-induced immune destruction. Viral load and CD4 cell count measurements are best used together to assess the risk of disease progression. When the CD4 cell count was over 750/mL and the HIV-1 RNA level was less than or equal to 1,500 copies/mL (by RT-PCR), 1.7% developed AIDS within 6 years. When the CD4 cell count was less than or equal to 200/mL and the HIV-1 RNA level was over 60,000 copies/mL, 97.9% develop AIDS in 6 years [20]. Viral load and CD4 cell counts from several studies have been used to generate guidelines for the U.S. Department of Health and Human Services and the International AIDS Society (IAS)-USA [21,22] for when to initiate ARVT (Table 19.1). It is extremely useful to review this information

Table 19.1. Risk of Progression to AIDS-Defining Illness in a Cohort of Homosexual Men Predicted by Baseline CD4⁺ T-Cell Count and Viral Load

Plasma Viral Load (Copies/mL) ^a		% AIDS (AIDS-Defining Complication) ^b			
		n	3 Years	6 Years	9 Years
bDNA	RT-PCR				
CD4 Count ≤ 200					
≤500	≤1,500	0 ^c	—	—	—
501–3,000	1,501–7,000	3 ^c	—	—	—
3,001–10,000	7,001–20,000	7	14.3	28.6	64.3
10,001–30,000	20,001–55,000	20	50.0	75.0	90.0
>30,000	>55,000	70	85.5	97.9	100.0
CD4 Count 201–350 ^d					
≤500	≤1,500	3 ^c	—	—	—
501–3,000	1,501–7,000	27	0	20.0	32.2
3,001–10,000	7,001–20,000	44	6.9	44.4	66.2
10,001–30,000	20,001–55,000	53	36.4	72.2	84.5
>30,000	>55,000	104	64.4	89.3	92.9
CD4 Count >350					
≤500	≤1,500	119	1.7	5.5	12.7
501–3,000	1,501–7,000	227	2.2	16.4	30.0
3,001–10,000	7,001–20,000	342	6.8	30.1	53.5
10,001–30,000	20,001–55,000	323	14.8	51.2	73.5
>30,000	>55,000	262	39.6	71.8	85.0

RT-PCR, reverse transcriptase polymerase chain reaction.

^aMACS numbers reflect plasma HIV RNA values obtained by version 2.0 bDNA testing. RT-PCR values are consistently 2- to 2.5-fold higher than first-generation bDNA values, as indicated. It should be noted that the current generation bDNA assay (3.0) gives similar HIV-1 RNA values as RT-PCR except at the lower end of the linear range (<1,500 copies/mL).

^bIn this study AIDS was defined according to the 1987 CDC definition and does not include asymptomatic individuals with CD4⁺ T-cell counts of <200 mm³.

^cToo few subjects were in the category to provide a reliable estimate of AIDS risk.

^dA recent evaluation of data from the MACS cohort by of 231 individuals with CD4⁺ T-cell counts of >200 and <350 cells/mm³ demonstrated that of 40 (17%) individuals with plasma HIV RNA <10,000 copies/mL, none progressed to AIDS by 3 years (Alvaro Muñoz, personal communication). Of 28 individuals (29%) with plasma viremia of 10,000–20,000 copies/mL, 4% and 11% progressed to AIDS at 2 and 3 years, respectively. Plasma HIV RNA was calculated as RT-PCR values from measured bDNA values.

Data are from the Multi-Center AIDS Cohort Study (MACS) as reported by Alvaro Muñoz, Ph.D. (personal communication.) Reprinted from the Report of the NIH panel to define principles of therapy of HIV infection and guidelines for the use of antiretroviral agents in HIV-infected adults and adolescents. *MMWR* 1998; with permission.

with patients when discussing the rationale and indications for antiretroviral treatment.

- D. Effect of HAART on viral load and CD4 cell count.** HAART is a combination drug regimen that reduces plasma HIV RNA viral load to an undetectable level (<50 copies/mL) in treatment-naïve patients. This leads to biphasic increases in CD4 cell counts [23] with associated clinical benefits, delayed disease progression, and decreased morbidity and mortality from HIV infection. The initial response is an increase in memory CD4⁺ cells that may reflect release of trapped memory cells from lymphoid tissues. The second phase, usually seen after 6 months, is made up of new naïve CD4⁺ cells [23]. Plasma HIV-1 RNA viral load and CD4 cell counts are used to decide when to begin therapy, to monitor the efficacy of therapy, and as end points in clinical trials.
- IV. Historical milestones in ARVT.** In 1987 in placebo-controlled trials, zidovudine (or azidothymidine, or AZT) was shown to improve survival and decrease disease progression to AIDS [24]. In less advanced HIV, AZT decreased disease progression, but there was no survival advantage [25]. In clinical trials of dual NRTI therapy versus AZT alone, combination therapy provided improved and more durable clinical and survival benefits. In 1997, combination therapy with a PI and two NRTIs was shown to be superior to dual NRTI therapy [26]. More recently, two NRTIs with one NNRTI have been compared with regimens containing a PI and two NRTIs [27]. Results from all of these trials indicate that resistance to antiretroviral agents eventually leads to therapeutic failure. The most effective way to avoid the emergence of antiretroviral resistant HIV-1 is to achieve maximum suppression of HIV replication.
- V. Pharmacology of individual antiretroviral agents.** Currently available antiretroviral agents can be grouped according to the site and mode of action as NRTIs, nucleotide reverse transcriptase inhibitors, NNRTIs, and PIs.
- A. Nucleoside reverse transcriptase inhibitors.** The available NRTIs are listed in Table 19.2.
- 1. Description. NRTIs** are synthetic nucleoside analogue prodrugs. AZT and stavudine (d4T), for example, are analogues of thymidine. NRTIs must be phosphorylated to the active 5'-triphosphate form by intracellular enzymes (kinases, nucleotidases). Certain NRTIs (AZT, d4T) are primarily active against proliferating HIV-infected cells [28]. Others, such as didanosine (2',3'-dideoxyinosine, or ddI) and zalcitabine (dideoxycytidine, or ddC), are active even in HIV-infected resting cells. This is dependent on the growth phase during which the cellular kinases that metabolize NRTIs to the 5'-triphosphate form are most active [29].
 - 2. Mechanism of action.** NRTIs competitively bind to HIV-RT in place of the natural nucleotide. They lack the 3'-hydroxyl group on the ribose sugar needed for the 5'-3' linkages essential for DNA synthesis and thus cause chain termination [30]. High intracellular levels of AZT monophosphate may impair HIV-1 RNase H activity [31].
 - 3. NRTI class-related toxicity.** Lactic acidosis/hepatic steatosis is a rare, frequently fatal complication associated with the use of AZT, ddI, d4T as monotherapy and combinations of AZT/ddC or 3TC with other NRTIs [32]. It is seen more commonly in obese women, typically after several months of therapy.

Table 19.2. Nucleoside Reverse Transcriptase Inhibitors

Zidovudine (AZT, ZDV, Retrovir)
Didanosine (ddI, Videx)
Zalcitabine (ddC, HIVID)
Stavudine (d4T, Zerit)
Lamivudine (3TC, Epivir)
Abacavir (ABC, Ziagen)
Combivir (AZT+3TC)
Trizivir (AZT+3TC+Abacavir)

Symptoms include nausea, vomiting, early satiety, abdominal bloating and pain, malaise, fatigue, dyspnea, occasionally fever, and right upper quadrant pain. Laboratory tests show anion gap acidosis, decreased bicarbonate, elevated lactic acid, and mild to moderate elevations of transaminases. Ultrasonography or abdominal computed tomography (CT) shows hepatomegaly and hepatic steatosis. Histopathology shows microvesicular, macrovesicular, or mixed steatosis, and electron microscopy (EM) shows abnormal mitochondria. NRTIs inhibit (to different degrees) mitochondrial DNA polymerase gamma, which is responsible for mitochondrial DNA synthesis [33]. Mitochondrial dysfunction leads to increased lactic acid production and acidosis [34]. Asymptomatic lactic acidemia (or lactemia), an increase in venous lactate levels in the absence of abnormal arterial pH, also has been described [35,36]. Coexistent riboflavin deficiency also may play a role. The incidence of lactemia increases over time in patients treated with NRTIs [37]. Whether this leads to lactic acidosis/hepatic steatosis is not certain. Fatal cases have occurred in pregnant patients taking ddI and d4T. **This combination should therefore be avoided.** Treatment with AZT (or other NRTIs) should be discontinued. There is no known effective therapy. Anecdotal reports suggest riboflavin 50 mg orally daily, or L-carnitine alone or in combinations with complex vitamin B may be effective [38,39] because some patients have riboflavin deficiency. The use of mechanical ventilation, thiamine supplements, and bicarbonate infusions have not been effective. Currently there are no recommendations to screen for this entity (by measuring lactate levels) in NRTI-treated patients. **Lactic acidosis/hepatic steatosis** should be suspected in any patient taking NRTIs with an unexplained decrease in serum bicarbonate level, increased anion gap, or elevated hepatic transaminases, particularly if associated with fatigue, nausea, abdominal pain, or bloating. Dyspnea without other pulmonary findings on physical examination and chest radiography is a late manifestation, consistent with respiratory compensation for metabolic acidosis.

4. Zidovudine

a. Formulations: 300-mg tablets, 100-mg capsules, syrup 10-mg/mL, and intravenous (i.v.) infusion 10 mg/mL.

b. Dosage

- (1) Adults may be given 300 mg orally twice daily or 200 mg three times daily, taken without regard to meals.
- (2) Children over age 12 may be given the adult dosage; or 180 mg/m² of body surface area (BSA) per dose three times daily (which approximates the adult dosage). For children under age 13, 160 mg/m² BSA/dose is given three times daily [40].
- (3) Newborns are given 2 mg/kg/dose orally every 6 hours for 6 weeks as part of a tripartite regimen to prevent vertical transmission of HIV (see section VIII.C.1-3). The suggested dose for premature newborns (28-33 weeks' gestation) is 1.5 mg/kg/dose orally or i.v. every 12 hours for the first 2 weeks of life, then 2 mg/kg/dose orally or i.v. every 8 hours for the next 8 weeks [40,41].

c. *In vitro* activity. AZT is active against HIV-1 and HIV-2. *In vitro*, AZT is active predominantly against HIV-infected proliferating cells [28].

d. Pharmacology [42]

- (1) **Absorption.** Bioavailability is 65% to 70%. Protein binding ranges from 18% to 38%.
- (2) **Half-life** in plasma is 1 hour. Active 5'-triphosphate has an intracellular half-life of 3 to 4 hours, allowing twice-daily dosing. Plasma and intracellular 5'-triphosphate levels do not correlate [43].
- (3) **Tissue distribution.** AZT is widely distributed to most tissues and fluids [42], including breast milk and semen. AZT crosses the placenta.
- (4) **Cerebrospinal fluid (CSF).** AZT crosses into CSF, yielding 60% of serum levels (CSF:plasma ratio = 0.3:1 to 1.35:1) [44].
- (5) **Metabolism and elimination.** Liver conjugates to an inactive glucuronide, which is rapidly excreted in the urine; less than 20% is found

unchanged in the urine. Renal clearance is greater than creatinine clearance, indicating both glomerular filtration and tubular secretion.

- (6) **Dose modifications.** In **hepatic disease**, clearance of AZT is reduced by 70% in patients with cirrhosis [45], resulting in two- to threefold increases in peak plasma levels and half-life. In the setting of severe hepatic dysfunction, a reduced dose of 100 mg orally every 8 hours seems appropriate [42]. In **renal disease**, the half-lives of AZT and its glucuronide increase. Dose adjustments [46] should be instituted as follows: in the setting of glomerular filtration rate (GFR) of more than 10 mL/min, no change; GFR of less than 10 mL/min, 100 mg orally every 8 hours. For patients on hemodialysis, the dose should be the same as that in the setting of GFR of less than 10 mL/min. For patients on continuous ambulatory peritoneal dialysis (CAPD), the dose should be the same as that in the setting of GFR of less than 10 mL/min. Patients with continuous arterial venous diafiltration (CAVH) should be given 100 mg orally every 8 hours.
- (7) **Drug interactions.** Myelosuppressive drugs (e.g., ganciclovir) may increase marrow toxicity, particularly granulocytopenia [47]. Other drugs to be used with caution include trimethoprim-sulfamethoxazole, sulfadiazine, pyrimethamine, dapsone, flucytosine, adriamycin, vinblastine, vincristine, hydroxyurea, interferon, and amphotericin B. Contrary to findings in early studies, acetaminophen has no effect on the metabolism of AZT [42]. These drugs can be given concomitantly. There is antagonism (competition for phosphorylation to the active moiety) between AZT and d4T [48,49]. These drugs should not be used together. Ribavirin inhibits phosphorylation of AZT. AZT plus ddI, ddC, α -interferon, or foscarnet are synergistic against HIV-1. Probenecid increases AZT serum levels and half-life by inhibiting renal secretion and hepatic glucuronidation.

e. Pregnancy category C

f. Adverse effects

- (1) **Subjective adverse effects.** Headache, gastrointestinal (GI) upset, altered taste, insomnia, fatigue, myalgia, and malaise occur early and usually subside with continued therapy. The currently used dosage of 600 mg/day of AZT is better tolerated and less toxic than the initial regimens (1,200–1,500 mg/day).
- (2) **Hematologic toxicity** is related to the dose and duration, degree of marrow reserve, and stage of disease. The mechanism is likely multifactorial and may be related to inhibition of DNA synthesis both in marrow progenitor cells and in mitochondria [29,42]. **Anemia** may occur within 4 weeks, but the greatest risk is in months 3 through 8. Two percent of asymptomatic HIV-infected patients taking 600 mg/day [50] and up to 29% of AIDS patients taking 600 to 1,500 mg/day develop anemia (Retrovir package insert). Anemia usually resolves several weeks after discontinuation of AZT. **Macrocytosis** occurs in over 90% of AZT recipients but does not correlate with development of anemia and is not associated with abnormal vitamin B₁₂ or folate levels. Marrow may be normal or show hypoplasia or aplasia if severe anemia is present [51]. Pure red cell aplasia also has been described [52]. **Neutropenia** occurs in 8% of asymptomatic patients with HIV infection versus 37% of patients with AIDS. **Thrombocytopenia** rarely occurs [51]. AZT is the preferred treatment for HIV-1-associated thrombocytopenia. The effect is dose related; 2.5- and 4.9-fold increases in platelets over baseline with 600 and 1,200 mg/day, respectively [42]. If severe anemia (hemoglobin <8.0 g/dL) or neutropenia develops (<750 cells/mm³), the clinician should switch to another agent rather than using colony-stimulating factors or transfusions.
- (3) **Myopathy** is uncommon. Long-term (>6 months) high-dose (>1,200 mg/day) therapy with AZT has been associated with symptomatic myopathy in 6% to 18% of patients [42,53–55]. Manifestations include myalgia

and diffuse symmetrical weakness of hip or shoulder girdle muscles, resulting in difficulty climbing stairs or arising from a squatting position or a chair. Serum creatinine kinase (CK) is usually elevated. Electromyography shows fibrillation potentials, positive sharp waves, and complex repetitive discharges. Histology shows mitochondrial abnormalities on Gomori trichrome staining (ragged red fibers) and EM, as well as inflammatory infiltrates of the endomysium consisting of CD8⁺ lymphocytes and macrophages [53]. Discontinuation of AZT leads to gradual resolution of weakness over 6 to 8 weeks in 70% to 100% of patients [42]. Myalgia and serum CK improve more quickly. Patients not responding to discontinuation of AZT respond to steroid treatment [53]. AZT myopathy has become rare with the 600 mg/day dosage.

- (4) **Hepatitis.** Reversible liver function abnormalities occasionally occur within 2 to 4 weeks.
 - (5) **Hepatic steatosis/lactic acidosis.** See pharmacology of NRTIs in section V.A.3 above.
 - (6) **Dermatologic.** AZT causes hyperpigmentation of skin and nails. Melanonychia occurs in 40%. The incidence in blacks is 81% versus white, 20%, and Hispanic, 31% [42].
 - (7) **Children.** AZT is generally well tolerated in children, with its major toxicities similar to those in adults: commonly macrocytic anemia and neutropenia, rarely myopathy, and very rarely lactic acidosis. Cardiomyopathy has occurred in children on AZT but it is more likely due to the effects of HIV itself [56–58].
- 5. Didanosine (Videx, Videx EC)** is a purine nucleoside analogue of inosine. It is triphosphorylated by host kinases intracellularly to the active moiety 2',3'-dideoxyadenosine 5'-triphosphate (ddATP). Unlike AZT, ddI is more active in resting cells [59].
- a. Formulations.** Chewable/dispersible tablets containing buffers are available in 25, 50, 100, 150, and 200 mg; buffered powder packets in 100, 167, and 250 mg; pediatric powder for solution (reconstituted with sterile water and antacid buffers) 10 mg/mL; enteric coated capsules (Videx EC, without buffer) in 125, 200, 250, and 400 mg. Advantages compared with buffered tablets are lack of buffer-related side effects and drug interactions, as well as better palatability.
 - b. Dosage**
 - (1) **Adults**
 - (a) For adults weighing at least 60 kg, either 200 mg (buffered tablets) orally twice daily or 250 mg (buffered powder) orally twice daily is preferred. An alternative is 400 mg (buffered tablets) orally daily.
 - (b) For adults weighing no more than 60 kg, either 125 mg (buffered tablets) orally twice daily or 167 mg (buffered powder) orally twice daily is preferred. An alternative is 250 mg (buffered powder) orally daily.
 - (c) Videx EC has the following advantages relative to buffered tablets/powder: lack of buffer-related side effects and drug interactions, and better convenience and palatability. For adults weighing at least 60 kg, 400 mg orally daily is preferred. For adults weighing no more than 60 kg, 250 mg orally daily is preferred.
 - (d) All buffered forms are to be taken half an hour before or 2 hours after a meal.
 - (2) **Children.** Children over 13 years of age may use the adult dose of ddI formulations. Children under 13 years of age should be given 90 mg/m² BSA/dose orally every 12 hours of either the buffered tablets, powder, or pediatric solution (dose range 90–150 mg/m² BSA/dose orally every 12 hours). When using tablets, at least two should be given to ensure adequate buffering (e.g., two 50-mg tablets are preferred to one 100-mg tablet when delivering a 100-mg dose) [40].
 - c. In vitro** activity. ddI inhibits HIV-1 (including AZT-resistant strains) [30]. It is also active against HIV-2.

d. Pharmacology.

- (1) Rapidly **absorbed** bioavailability varies widely depending on formulation of ddI, gastric pH, and presence of food (mean bioavailability 30%); ddI is very acid labile; therefore, oral formulations contain buffering agents (except Videx EC). The chewable tablet is 20% to 25% more bioavailable than powder. Food reduces absorption by 50% or more [60] (presumably by gastric acidity). It should be taken on an empty stomach 1 hour before or 2 hours after a meal.
- (2) **Half-life.** The active triphosphate (ddATP) has an intracellular half-life of 8 to 24 hours [61].
- (3) **Tissue distribution.** Less than 5% protein bound, ddI crosses the placenta and undergoes placental metabolism with only 15% to 50% of the drug reaching the fetal circulation (significantly lower than AZT). ddI penetration into the CNS is also lower than AZT. CSF levels are 20% of serum levels after an i.v. dose [61] (CSF:plasma ratios are 0.16:1 to 0.19:1).
- (4) **Metabolism and elimination.** ddI is metabolized to hypoxanthine (major metabolite) and uric acid. Thirty percent to 50% of an administered dose is excreted unchanged by glomerular filtration and tubular secretion [61]. Approximately 20% of a dose is cleared by 4 to 6 hours of hemodialysis.
- (5) **Dose modification.** In renal disease the half-life increases (Table 19.3).

e. Drug interactions: Concurrent use of ddC and ddI is contraindicated. Drugs that increase risk of pancreatitis (d4T, hydroxyurea, ethyl alcohol [EtOH], pentamidine, azathioprine) or that cause peripheral neuropathy, (isoniazid [INH], ethambutol, ethionamide, chloramphenicol, thalidomide, metronidazole, nitrofurantoin, vincristine, cisplatin, gold, phenytoin [62]), should be used with caution or avoided. Ganciclovir and valganciclovir increase plasma ddI concentrations (57.7% with i.v. ganciclovir). Patients should be monitored for risk of ddI toxicity [63]. If the buffered formulations of ddI are used, drugs requiring gastric acidity for optimal absorption (itraconazole, ketoconazole, dapsone, indinavir [IDV], ritonavir [RTV], delavirdine [DLV]) should be given 1 to 2 hours before or after ddI. The divalent cations in the buffer chelate quinolones and tetracyclines [64].

f. Pregnancy category B**g. Adverse effects**

- (1) **Pancreatitis** can occur 3 to 5 months after starting ddI. The mechanism is unknown. It is sometimes fatal and is dose related (25% of patients receiving 10–12 mg/kg/day [65] vs. <10% with current doses [66]). Perhaps discontinuation of therapy with asymptomatic hyperamylasemia accounts for the low incidence of pancreatitis in some studies [66,67]. Risk is higher with a history of pancreatitis or alcohol abuse, or in the presence of hypertriglyceridemia, AIDS, or obesity, or with the concomitant use of d4T, hydroxyurea, and pentamidine [65,68]. It presents with the typical signs and symptoms. DdI should be discontinued and

Table 19.3. Dose^a (in mg) Adjustments of ddI per GFR, Weight, and Formulation

GFR (mL/min)	>60	>59	>59	30–59	30–59	10–29	10–29	<10	<10
kg	Any	>60	<60	>60	<60	>60	<60	>60	<60
Buffered tablet	Usual dose			200	150	150	100	100*	75
Videx EC		400	250	200	125	125	125	125	^b

GFR, glomerular filtration rate.

^aAn extra dose should be given postdialysis. In the setting of continuous ambulatory peritoneal dialysis or continuous arterial venous diafiltration, the dose given should be the same as when GFR is <10 mL/min. In the setting of hepatic disease, the need for a change in dose is unknown. The patient should be monitored for evidence of ddI toxicity.

^bAn alternative formulation should be used.

pancreatitis usually resolves. Recurrence can occur in patients rechallenged [69]. Routine monitoring of enzymes during therapy is not recommended. Asymptomatic elevations of amylase and lipase (up to two times the upper limit of normal [ULN]) are common in HIV-infected patients [70]. In one study 39% of ddI patients developed asymptomatic increases in pancreatic enzymes, yet none developed pancreatitis during a mean follow-up of 8 months [65].

- (2) **Peripheral neuropathy.** DdI can cause distal symmetric polyneuropathy. The incidence (5%–15%) varies by dose and duration of therapy, by the prevalence of underlying HIV-associated distal symmetric sensory neuropathy, by the presence of AIDS, and according to different criteria used to define neuropathy in various studies [71–73]. With the currently used dose, neuropathy is uncommon, the incidence being similar to that among patients treated with AZT (600 mg/day) [66,73]. It usually occurs after 2 to 7 months of treatment [69], with numbness, tingling, burning, or aching pain over the soles of the feet [69,72]. Over time, lancinating pain of the lower extremities follows, and if ddI is continued, the hands and upper extremities become involved. Initially pain occurs only when ambulating, but eventually becomes continuous. In more advanced cases, pain can interfere with sleep and routine daily activities [69]. Initially, examination and nerve conduction studies are usually unremarkable, but eventually sensory loss appears (vibratory sense, pinprick, and temperature) in a stocking-glove distribution, Achilles reflex is decreased, and nerve conduction studies show an axonal neuropathy. In severe cases mild weakness may be found. Symptoms gradually resolve or substantially improve in most patients 4 to 8 weeks after stopping ddI. In some patients, symptoms worsen for up to 6 weeks (coasting) and then gradually improve. Patients with AIDS or severe neuropathy may not fully recover. Patients with AIDS or HIV neuropathy (or other causes of neuropathy) or those taking ddI with d4T or taking d4T and hydroxyurea are at higher risk of developing ddI-associated neuropathy [74]. It has been suggested, but not proven, that ddI (and d4T and ddC) cause neuropathy by inhibiting mitochondrial DNA synthesis [33,75,76]. Treatment is helped by early recognition, and discontinuation of ddI is most important because this gives a better chance of full recovery. Physicians should make patients aware of the coasting phenomenon [72,77] noted above. Although some patients tolerate rechallenge with a lower dose of ddI, the use of subinhibitory doses of antiretroviral agents cannot be advocated. No specific therapy exists.
 - (3) **Hepatitis.** Asymptomatic elevations of liver function test (LFT) results (more than five times normal) may occur in up to 9% of patients [66]. Fulminant hepatitis occurs rarely [78].
 - (4) **Lactic acidosis/hepatic steatosis.** ddI can cause lactic acidosis/hepatic steatosis (see section **VA.3**).
 - (5) **Miscellaneous effects.** Because GI upset and diarrhea are relatively common with the powdered form, Videx EC is preferred. Hyperuricemia is rare with the current dose [66]. Sodium and magnesium in the powder and buffered tablets may be a concern in patients with decreased renal function or on low-sodium diets.
 - (6) **Children.** Pancreatitis, although reported, is less commonly observed in children than in adults, although it tends to occur in children with other risk factors, including previous pancreatitis or use of other medications such as d4T or pentamidine. Peripheral sensory neuropathy may occur as in adults. Children given ddI develop asymptomatic peripheral retinal depigmentation, which appears to reverse with discontinuation of the agent. It occurs in fewer than 5% of courses [40]. Lactic acidosis occurs rarely as in adults.
6. **Zalcitabine (HIVID)** is a dideoxynucleoside analogue of cytidine. It requires triphosphorylation by cellular kinases to convert to the active 5'-triphosphate.

This takes place most efficiently in resting cells (in contrast to AZT) (DdC package insert).

a. Formulations : 0.375- and 0.75-mg tablets

b. Dosage

- (1) **Adults.** Adults weighing at least 30 kg should receive 0.75 mg orally three times daily; those under 30 kg should receive 0.375 mg orally three times daily.
- (2) **Children.** Children at least 13 years of age may be given the adult dosage; those under 13 should be given 0.01 mg/kg/dose orally every 8 hours [40].

c. *In vitro* activity: HIV-1 (including AZT-resistant strains), HIV-2, hepatitis B [79]

d. Pharmacology [79a]

- (1) **Absorption.** ddC is 70% to 90% bioavailable. Administration with food decreases the rate and extent of absorption. However, the clinical relevance of this is not known.
- (2) **Half-life.** The plasma elimination half-life is 1 to 3 hours [79a].
- (3) **Tissue distribution.** ddC is not highly protein bound. CSF concentration is 20% of plasma i.v. levels (less than that of AZT) (CSF:plasma ratio is 0.14:1 to 0.20:1) [79a]. ddC diffuses across the placenta (50%).
- (4) **Metabolism and elimination.** ddC does not undergo hepatic metabolism. Sixty-two percent of an oral dose is excreted both by filtration and secretion unchanged in urine. Dideoxyuridine is the major metabolite. It is not known whether ddC is dialyzed by any method. Dosage modifications for renal disease are as follows: patients with a GFR of 10 to 40 mL/min should receive 0.75 mg orally every 12 hours; those with a GFR of less than 10 mL/min should receive 0.75 mg orally every 24 hours.
- (5) **Drug interactions.** ddC should not be coadministered with ddI or d4T because of increased risk for neurotoxicity. Other drugs that cause neuropathy (see discussion of ddI, section V.5) should be administered with caution.

e. Pregnancy category C

f. Adverse effects

- (1) **Peripheral neuropathy** occurs in 5% to 18% of patients and is dose related [80–83]. Neuropathy due to ddC is more common than that related to ddI [81,83] (see discussion of ddI, section V.5, for features). Patients with AIDS, diabetes mellitus, EtOH abuse, low baseline vitamin B₁₂ levels, and a history of peripheral neuropathy are at higher risk for developing neurotoxicity [84,85]. ddC should be discontinued when symptoms occur. Although some patients can tolerate rechallenge with a lower dose, the use of subinhibitory doses of ddC cannot be recommended.
- (2) **Oral and esophageal ulcers.** Stomatitis (ulcers of the buccal mucosa, pharynx, tongue, and soft palate) occurs in 2.6% to 8% of patients [82,83]. Esophageal ulcerations also occur [86].
- (3) **Rash.** Transient erythematous maculopapular rash on the extremities and trunk, associated with fever, malaise, and stomatitis, may occur, usually during the first 30 days of therapy [79a]. In a phase I trial, 70% developed rash [79a], although in larger trials, the incidence of rash was not noted [82,83].
- (4) **Pancreatitis** occurred in 0.5% to 3% of patients in large trials [81–83] but less frequently than with ddI and ddC (0.5% vs. 1%–2%) [81,83].
- (5) **Lactic acidosis.** Hepatic steatosis has been described with ddC (see discussion of AZT, section V.4, for details).
- (6) **Hepatitis.** Elevations of LFT results were reported in 6% of patients on ddC monotherapy [82] and in 7.1% of subjects receiving AZT and ddC [83].
- (7) **Children.** Peripheral neuropathy, stomatitis, and lactic acidosis occur as in adults.

7. Stavudine (Zerit) is a nucleoside analogue of thymidine.

a. Formulations: 15-, 20-, 30-, and 40-mg capsules and 1 mg/mL oral solution.

b. Dosage

- (1) **Adults.** Adults weighing at least 60 kg should receive 40 mg orally twice daily; those weighing less than 60 kg should receive 30 mg orally twice daily. It may be taken without regard to meals.
- (2) **Children.** Children at least 13 years of age or weighing over 30 kg may be given the adult weight-based dosage; those under 13 should be given 1 mg/kg/dose orally twice daily [40]. Use of either the oral solution or opening the capsules and sprinkling the medication onto a spoonful of food facilitates administration of medication to children.

c. *In vitro* activity. d4T is active against HIV-1 and HIV-2, especially in proliferating cells [29].

d. Pharmacology [87]

- (1) **Absorption.** Bioavailability is 70%. It is not protein bound.
- (2) **Half-life.** The intracellular half-life of the triphosphate form is 3.5 hours, similar to that of AZT [88]. The 3.5-hour half-life allows twice-daily dosing.
- (3) **Tissue distribution.** CSF levels are 30% to 55% of those found in plasma (similar to those for AZT). d4T crosses the placenta by simple diffusion, with tissue levels lower than those achieved with AZT (approximately 75%). This is consistent with d4T being less lipophilic than AZT [29].
- (4) **Metabolism and elimination.** d4T is excreted by renal and nonrenal routes. Forty percent of a dose is excreted, unchanged in urine by both glomerular filtration and tubular secretion. The remaining portion is metabolized to thymine, which may then be used in pyrimidine-based salvage pathways [89].
- (5) **Dose modifications.** Dose adjustment for renal failure is necessary (Table 19.4).
- (6) **Hemodialysis.** Patients weighing at least 60 kg should receive 20 mg orally every 24 hours; those weighing less than 60 kg should be given 15 mg orally every 24 hours. The dose should be given after dialysis and at the same time on nondialysis days.
- (7) **Drug interactions.** d4T should not be used with AZT [79a,88] (see discussion of AZT, section V.4) or ddC. Drugs that cause peripheral neuropathy should be used with caution or avoided when possible and include vincristine, nitrofurantoin, ethambutol, INH, ethionamide, gold, phenytoin, thalidomide, dapsone, chloramphenicol, cisplatin, ethanol, colchicine, and metronidazole. The risk for peripheral neuropathy is higher when d4T is used in combination with ddI, and with ddI plus hydroxyurea.

Table 19.4. Adjustment of Stavudine (Zerit) in Patients with Varying Degrees of Renal Function

Creatinine Clearance (mL/min)	Recommended Stavudine Dose by Patient Weight	
	>60 kg	<60 kg
>50	40 mg q12h	30 mg q12h
26–50	20 mg q12h	15 mg q12h
10–25	20 mg q24h	15 mg q24h

q12h, every 12 hours.

There are insufficient data to recommend a dose for patients with a creatinine clearance of <10 mL/min or for patients undergoing dialysis.

Reprinted from *Physicians' Desk Reference*, 50th ed. Montvale, NJ: Medical Economics Data, 1996:732; with permission.

Patients should be monitored closely for signs and symptoms of neurotoxicity. Ribavirin *in vitro* interferes with the phosphorylation of d4T [49]. The clinical relevance of this is not known.

e. Pregnancy category C

f. Adverse effects

- (1) **Peripheral neuropathy.** The incidence is similar to that seen with ddI and ddC. The risk is dose related. One-year incidence rates were 6% and 37% for dosages of 0.1 and 2.0 mg/kg/day, respectively [90]. With the currently recommended dosing (1 mg/kg/day), neuropathy develops in 12% of patients [91]. As with ddI and ddC, neurotoxicity occurs more commonly in patients with AIDS (25% 1-year rate vs. 10% among HIV-infected asymptomatic patients) [91]. Upon discontinuation, neuropathy completely resolved within 4 to 57 days (median 17 days) in 63% [91]. The risk is significantly increased when d4T is given in combination with ddI or with ddI plus hydroxyurea [74].
 - (2) **Hepatic steatosis/lactic acidosis** occurs in those receiving d4T (see section V.A.3). Asymptomatic elevations of liver enzymes (greater than five times the ULN) occurred in 12/100 person-years versus 10/100 person-years with AZT [91].
 - (3) **Pancreatitis.** There is no clear association between d4T use and an increased risk for pancreatitis [91].
 - (4) **Children.** d4T is generally well tolerated by children, with similar rates of toxicity as observed in adults. However, peripheral neuropathy is uncommon, and lactic acidosis is rare [40].
- 8. Lamivudine (Epivir)** is a pyrimidine nucleoside analogue of cytosine. It must be triphosphorylated to the active moiety (3TC-triphosphate).
- a. Formulations** include 150-mg tablets and 10 mg/mL oral solution. In combination with AZT it is available as Combivir (150 mg 3TC and 300 mg AZT). In combination with AZT and abacavir (ABC) it is available as Trizivir (150 mg 3TC + 300 mg AZT + 300 mg ABC).
 - b. Dosage**
 - (1) **Adults.** Adults should be given 150 mg every 12 hours. As Combivir, adults should receive one tablet orally twice daily; As Trizivir, they should receive one tablet orally twice daily (administered without regard to food).
 - (2) **Children.** Children at least 13 years of age may be given the adult dosage; those under 13 should be given 4 mg/kg/dose orally twice daily up to a maximum of 150 mg orally twice daily; those under 1 month of age should be given 2 mg/kg/dose orally twice daily. For children and adolescents one may use Combivir or Trizivir tablets or half-tablets to approximate weight-based doses.
 - c. *In vitro* activity.** 3TC is active against HIV-1 (including AZT-resistant strains) and HIV-2 in acutely infected cells [92]. It is also active against hepatitis B virus.
 - d. Pharmacology** [93]
 - (1) **Absorption.** Bioavailability is 82%. It can be taken without regard to meals.
 - (2) **Half-life.** The intracellular half-life of the active moiety is 10.5 to 15.5 hours.
 - (3) **Tissue distribution.** Protein binding varies from 20% to 30%. CSF penetration is 4% to 8% of serum concentration (CSF:plasma ratio of 0.06:1). These levels exceed the 50% inhibitory concentration (IC₅₀) of HIV-1 and are clinically relevant. 3TC diffuses freely across the placenta and is secreted into breast milk [93].
 - (4) **Metabolism and elimination.** Approximately 70% of an oral dose is eliminated via renal mechanisms as unchanged drug. About 5% is metabolized to an inactive trans-sulfoxide metabolite.
 - (5) **Dose modification.** 3TC doses need adjustment in **renal insufficiency** (Table 19.5). Patients undergoing hemodialysis should receive 25 to

Table 19.5. Adjustment of Lamivudine (Epivir) in Patients with Varying Degrees of Renal Function

Creatinine Clearance (mL/min)	Dosage of Lamivudine
≥50	150 mg twice daily
30–49	150 mg/day
15–29	150 mg first dose, then 100 mg/day
5–14	150 mg first dose, then 50 mg/day
<5	50 mg first dose, then 25 mg/day

There are insufficient data to recommend a dosage of lamivudine in patients undergoing hemodialysis.

From Epivir (Lamivudine). Package insert, November 1995.

50 mg orally daily and should receive a supplemental dose after dialysis. For patients on CAPD, the dose should be the same as that in the setting of GFR of 5–14 mL/min. For patients with CAVH, the dose should be the same as that in the setting of GFR of 15–29 mL/min. In the presence of **hepatic dysfunction**, the 3TC dose is unaltered (see Table 19.5).

- (6) **Drug interactions.** Clinically relevant adverse drug interactions have not been reported.

e. Pregnancy category C

f. Adverse effects

- (1) **Adults.** 3TC is well tolerated. No dose-related toxicities occurred in large phase I/II studies [94,95]. The most common complaints were headache, fatigue, GI upset, and insomnia. These were mild and transitory. In a trial of AZT versus 3TC plus AZT there was no additional toxicity versus AZT alone, and the adverse effects in both arms were felt to be secondary to AZT [96,97].
- (2) **Children.** 3TC is very well tolerated. Uncommonly, pancreatitis, peripheral neuropathy, or lactic acidosis occurs. The rare precipitous decrease in hemoglobin following institution of combined AZT/3TC therapy reported in adults [98] has been seen by us in one older adolescent and one newborn of a mother receiving AZT/3TC [99].

9. Abacavir (Ziagen) is a 2'-deoxynucleoside analogue of guanosine that is triphosphorylated by a unique set of enzymes to the active, carboxylic guanosine triphosphate.

a. Formulations include 300-mg tablets and 20 mg/mL oral suspension. In combination with AZT and 3TC it is available as Trizivir (300 mg AZT + 150 mg 3TC + 300 mg ABC).

b. Dosage

- (1) **Adults.** Adults should be given 300 mg orally twice daily. As Trizivir, they should be given one tablet orally twice daily, which may be taken without regard to food.
- (2) **Children.** Children at least 13 years of age may be given the adult dosage; those under 13 should be given 8 mg/kg/dose orally twice daily up to a maximum of 300 mg orally twice daily.

c. In vitro activity. ABC is active against HIV-1 and HIV-2, including AZT-resistant strains.

d. Pharmacology [100,101]

- (1) **Absorption.** Bioavailability is 80%. Approximately 50% is protein bound.
- (2) **Half-life.** The intracellular half-life of the active moiety is 3.3 hours, which allows dosing every 12 hours.
- (3) **Tissue distribution.** CSF penetration data are scant. In three patients, ABC 200 mg every 8 hours yielded a CSF level that was 18% of plasma

level, 1.5 to 2 hours postdose. The mean ABC CSF concentration was twice the established IC_{50} against clinical isolates of HIV [102]. Using different doses of ABC, the average CSF:plasma concentration ratio was 0.42:1 [103]. Animal data suggest that CSF penetration is similar to that for AZT [100]. In an *ex vivo* human placental model, ABC crosses the placenta [104].

(4) **Metabolism and elimination.** ABC is metabolized to inactive 5'-carboxylated and 5'-glucuronide compounds. The major excretion is renal. Less than 2% is found unchanged in urine [105].

(5) **Dose modifications.** None for patients with renal insufficiency.

(6) **Drug interactions.** ETOH can increase ABC levels [105].

e. Pregnancy category C

f. Adverse effects. In placebo-controlled studies the most common adverse effects have been mild and reversible and include nausea, abdominal pain, vomiting, headache, fatigue, and malaise [101,103,106]. There was a trend toward increased frequency of nausea and headache at higher doses [101,106]. At 300 mg twice daily, 45% had nausea, 40% headache, and 40% fatigue over 12 weeks. It was not specified if these adverse effects were solely from ABC [106]. Ten percent of patients on higher doses stopped taking the drug owing to adverse events (nausea, dizziness, photophobia, and palpitations or hypersensitivity syndrome) considered secondary to ABC.

(1) **Hepatic steatosis/lactic acidosis** (see section **V.A.3**). ABC (relative to the other NRTIs) is a weak inhibitor of mitochondrial DNA polymerase gamma [107]. However, hepatic steatosis/lactic acidosis occurs when using ABC in combination with other NRTIs. Asymptomatic elevations of LFT results have not been reported [106].

(2) **Hypersensitivity reaction.** This is a serious and potentially fatal adverse effect reported in 3% of patients [97,106,108]. Onset occurred at a mean of 11 days (range 1–28 days) [108]. **Manifestations initially** include malaise and fever, accompanied by nausea (with or without vomiting) and progression with additional dosing. An urticarial or maculopapular or generalized erythematous rash was present at onset or developed 1 to 3 days after constitutional symptoms began. Rash may be a dominant sign or an incidental finding. Some may have cough. ABC hypersensitivity can be difficult to distinguish from a viral respiratory syndrome [109,110]. Although influenza is less likely to cause GI symptoms, it can be difficult to distinguish these entities on clinical grounds alone [109]. Laboratory value abnormalities may include neutropenia, elevated LFT results, and increased creatinine phosphokinase (CPK). No risk factors have been identified, but there may be a genetic predisposition with certain HLA types [111,112]. The pathogenesis is not known, and there is no specific therapy. Upon discontinuation of ABC, symptoms resolve rapidly (1–2 days). Rechallenge is associated with rapid (within hours) recurrence of more severe symptoms, and deaths have been reported [109,111]. Patients should never be rechallenged with ABC.

(3) **Children.** Toxicities, similar to those occurring in adults include the uncommon (3%–5%) hypersensitivity reaction and the rare lactic acidosis and hepatic steatosis syndromes.

B. Non-nucleoside reverse transcriptase inhibitors are listed in Table 19.6.

1. Mechanism of action [113,114]. NNRTIs are a structurally diverse group of drugs that do not require intracellular processing (phosphorylation, etc.) to

Table 19.6. Non-nucleoside Reverse Transcriptase Inhibitors

Nevirapine (NVP, Viramune)
 Efavirenz (EFV, Sustiva)
 Delavirdine (DLV, Rescriptor)

exert their activity. Thus, unlike NRTIs, they are active in many different cell lines (resting and active, T-lymphocytes and macrophages). They bind to a site on RT distinct from NRTIs, and they are neither DNA chain terminators nor competitive inhibitors of RT. Nucleotide binding is not altered in the presence of NNRTIs. NNRTIs probably slow the rate of the chemical reaction catalyzed by RT [12]. The activity of NNRTIs is highly specific for HIV-1 RT, leaving human DNA polymerase unaffected.

2. Nevirapine (NVP, Viramune), is a dipyrindodiazepinone NNRTI.

a. Formulations include 200-mg tablets and 10 mg/mL syrup.

b. Dosage

(1) **Adults.** Initial dosage is 200 mg orally daily for 14 days then 200 mg orally every 12 hours. This decreases the frequency of rash (see section on adverse effects below) and compensates for autoinduction of hepatic metabolism. If a rash occurs during days 1 to 14, the second daily dose should not be added until the rash has resolved. Some clinicians suggest an even slower dose escalation (100 mg daily for 7 days then increasing by 100 mg/day for the next 7 days and so forth until the 400 mg daily dose is reached) and considering giving prednisone 50 mg every other day for the first 2 weeks. Evaluation in a small group of subjects suggested that this approach is safe [115].

(2) **Children.** Plasma clearance of NVP by children is greater than by adults, especially in children under 9 years of age. Similar to adults, however, are the increase in clearance of NVP by children of all ages after the first 2 weeks of use and the apparent decrease in rash if a stepwise increase in dose is instituted. The majority of pediatric clinical trials used a dose of 120 to 200 mg/m² BSA orally once daily (maximum dose 200 mg) for 14 days, followed by a full dose of 120 to 200 mg/m² BSA orally every 12 hours if no rash had occurred. It should be noted that the U.S. Food and Drug Administration (FDA) recently licensed an alternative pediatric regimen of 7 mg/kg orally every 12 hours for children under 8 years of age and 4 mg/kg for children at least 8 years of age. Again, one begins with once-daily dosing for 14 days and then increases to twice-daily dosing up to a maximum at any age of 200 mg orally twice daily. The alternative regimen is designed by pharmacokinetic modeling to achieve similar plasma concentrations as dosing of 150 mg/m² BSA orally twice daily, but results in an abrupt 43% decrease in dose size after the 8th birthday rather than the more gradual change when BSA-based dosing is used. Some clinicians (including us) prefer to use the BSA-based dosing regimens studied in clinical trials [40]. Neonatal dosing is being studied in clinical trials.

c. In vitro activity. NVP is active only against HIV-1, including NRTI- and PI-resistant strains. NVP-resistant HIV-1 is frequently resistant to all NRTIs.

d. Pharmacology

(1) **Absorption.** Bioavailability is greater than 90% [116] without regard to meals or buffering agents.

(2) **Half-life.** Plasma half-life is 25 to 30 hours at steady state [116]; therefore, studies of once-daily dosing are under way.

(3) **Tissue distribution.** NVP is 60% protein bound, nonionized at physiologic pH, lipophilic, and widely distributed in human tissues. It crosses the placenta completely [117] and is secreted in breast milk [118]. CSF concentrations are 45% of plasma levels [119]. Semen levels are 60% of plasma levels [120].

(4) **Metabolism and elimination.** NVP is extensively metabolized to several hydroxylated inactive metabolites by hepatic cytochrome P-450 (primarily CYP3A). The metabolites are excreted in urine (<3% of an oral dose is excreted unchanged). NVP is an inducer of cytochrome P-450 enzymes that metabolize many other drugs (see following section on drug

interactions). NVP dose must be increased after 14 days because of autoinduction of NVP's own hepatic metabolism (see section on dosing) [116].

- (5) **Dose modifications.** Few data about dosage adjustments for hepatic or renal disease are available. Standard doses should be used with caution.
- (6) **Drug interactions.** NVP induces the CYP3A4 group isoenzymes of hepatic cytochrome P-450, reaching maximum induction 4 weeks after starting therapy. Therefore, certain drugs require dose modification. NVP substantially lowers levels of **methadone and other opiates**. This may precipitate withdrawal beginning on days 4 to 10 of NVP administration [121]. In one study [121], some patients required a mean dose increase of 16%. Used in conjunction with **IDV or lopinavir (LPV) plus RTV**, NVP lowers levels of both IDV and LPV, requiring a dose increase (see respective PI section (6)).
- (7) **Drugs to avoid with NVP.** With ketoconazole, NVP levels are decreased by more than 60%; with oral contraceptives, ethinyl estradiol levels are decreased by 20% (alternative or additional contraceptive methods should be used); and with rifampin, NVP levels are decreased by 37%. St. John's wort (*hypericum perforatum*) also decreases NVP levels. Drug interactions with lipid lowering agents or anticonvulsants are unknown.

e. Pregnancy category C

f. Adverse effects

- (1) **Rash** occurs in up to 22% of patients, sometimes leading to discontinuation [122–124]. Onset is usually within the first 4 to 6 weeks. Risk factors include ETOH use, concomitant hepatitis C infection, and Chinese ancestry [125]. The rash is erythematous maculopapular in nature; occasionally pruritus involves the face, trunk, and extremities. Palms and soles may be spared. It is usually mild and self-limited. Extensive skin involvement associated with fever, constitutional symptoms, and occasionally oral ulcers has been described in 4% to 32% of patients [122]. Stevens-Johnson syndrome with fatalities was reported in less than 1% to 7.6% of patients [123,126,127]. The mechanism of the rash is uncertain.
 - (a) **Treatment.** Mild rash (no systemic symptoms/signs or mucosal lesions) can be treated with antihistamines while patients continue NVP. Severe rash or signs and symptoms suggestive of Stevens-Johnson syndrome (confluent, painful, edematous rash; mucosal membrane and conjunctiva blisters or ulcers; and fever, malaise, and myalgia) require immediate discontinuation of NVP. Patients should not be rechallenged with NVP. Corticosteroids given in conjunction with the lead-in dose (200 mg orally daily) of NVP may decrease the incidence of rash [115], although this is not routine practice.
 - (b) **NNRTI dermatologic cross-reactions.** The molecular structures of the NNRTIs are unrelated; thus, the risk for developing a rash when given another NNRTI would not be expected. However, studies to evaluate this are limited. Two patients with severe hypersensitivity reactions to NVP tolerated efavirenz (EFV) in addition to a tapering dose of prednisone over 11 days [128]. Protection by steroids may have played a role. Other investigators have reported one of six patients with an NVP-associated rash previously also developed a rash when given EFV [129]. However, these investigators concluded that EFV is safe in patients with known hypersensitivity reactions to NVP.
- (2) **Hepatitis.** In phase I/II studies, 10% of subjects had isolated elevation of γ -glutamyl transpeptidase that was five times normal [125,130,131]. However, some of these patients had baseline elevations of the enzyme. Hepatitis occurred in less than 2% of patients in controlled trials [125,130,131], although jaundice and elevated LFT results, with fever,

malaise, anorexia, nausea, and a rash occurring within 2 to 4 weeks of starting NVP, have been reported [125,132]. Clinical manifestations and LFT results resolved within 8 weeks of therapy cessation. Twelve cases of hepatotoxicity (two life threatening) were reported in non-HIV-infected health-care workers given an NVP containing an antiretroviral regimen for postexposure prophylaxis [133,134]. NVP is not recommended for postexposure prophylaxis [134]. Thus far, no serious toxicity has been reported among mother-infant pairs using single-dose NVP for the prevention of perinatal HIV transmission [133,134].

- (3) **Miscellaneous.** In phase I/II studies, mild somnolence, headache, and nausea were occasionally observed that did not require discontinuation of NVP [116].
 - (4) **Children.** The incidence of skin rash, Stevens-Johnson syndrome, hepatotoxicity, and drug interactions is similar in children and adults.
3. **Efavirenz (Sustiva)** is a 1,4-dihydro-2H-3,1-benzoxazin-2-one NNRTI.

a. Formulations include 50-, 100-, and 200-mg capsules and 600-mg tablets.

b. Dosage

- (1) **Adults.** Adults may be given 600 mg orally once daily, usually prior to bedtime to reduce the CNS side effects. Patients should avoid taking it after a high-fat meal, which can cause EFV levels to increase markedly (>50%).
- (2) **Children.** Children at least 13 years of age may be given the adult dosage (600 mg orally daily). Children under 13 should be given EFV based on their body weight (BW) once daily. The dose is as follows: BW 10 to 14 kg, 200 mg; 15 to 19 kg, 250 mg; 20 to 24 kg, 300 mg; 25 to 32 kg, 350 mg; 33 to 40 kg, 400 mg; over 40 kg, 600 mg. Capsule contents may be sprinkled on food. The somewhat bitter taste can be masked with grape jelly or chocolate syrup.

c. *In vitro* activity. EFV is active against HIV-1, including NRTI- and PI-resistant strains. It requires no intracellular metabolism to become activated.

d. Pharmacology [135,136]

- (1) **Absorption.** Bioavailability is 45%, but meals high in fat increase bioavailability by 50% (see section on dose below). EFV is 99.5% to 99.75% protein bound.
- (2) **Half-life** in plasma is more than 24 hours, allowing once-daily dosing.
- (3) **Tissue distribution.** EFV crosses the blood-brain barrier, and CSF ratios are 0.26 to 1.19 of corresponding plasma levels. These levels are over the IC₉₅ for wild-type HIV-1 [135] and were clinically relevant in one small study [137]. EFV crosses the placenta, and malformations have been observed in fetuses of EFV-treated monkeys.
- (4) **Metabolism and elimination.** EFV is metabolized primarily by hepatic cytochrome P-450 and by CYP3A4 and CYP2B6 isoenzymes to inactive hydroxylated metabolites. Fourteen percent to 34% of an oral dose is excreted in the urine as glucuronide metabolites, 16% to 61% in feces as unchanged drug. Less than 1% of a dose is excreted unchanged in urine.
- (5) **Dose modification.** None is required for hepatic or renal disease.
- (6) **Drug interactions.** EFV is both an inducer and inhibitor of CYP3A4 isoenzymes. *In vitro* EFV also inhibits isoenzymes CYP2C9 and CYP2C19, leading to alteration of metabolism of other drugs. Similarly, EFV plasma levels may be lower if drugs that induce CYP3A4 are used in conjunction. **Drugs that should be avoided** include saquinavir (SQV) (but SQV and RTV combination therapy can be used with EFV); clarithromycin (EFV levels decrease by 40%); and astemizole, terfenadine, midazolam, triazolam, and ergot derivatives. **Drugs that require dose adjustments** include IDV (increase dose to 1g every 8 hours), amprenavir (APV; increase dose to 1,200 mg every 8 hours), LPV/RTV (Kaletra; increase dose to 4 teaspoons every 12 hours); and methadone (increase

dose to achieve effect). For phenobarbital, phenytoin, and carbamazepine, the anticonvulsant levels should be monitored and doses adjusted. When used with warfarin, the anticoagulation effect should be monitored closely. EFV decreases rifabutin levels by 35%, so the dose should be increased to 450 to 600 mg/day. Levels of rifampin are not affected, but EFV levels decrease by 25%; the clinical implications are not clear. Estradiol levels increase by 37%. The clinical significance is not known. Because the effect of EFV on other oral contraceptives is not known, a reliable method of barrier contraception is recommended in addition to oral agents.

- e. Pregnancy category C** (similar to other antiretroviral agents). However, EFV should not be used during the first trimester because fetal malformations have been described in monkeys. Women of childbearing age should be informed of this and contraceptive protection should be ensured.

f. Adverse effects

- (1) **Central nervous system** effects occur after the first dose. Manifestations include insomnia, dizziness, abnormal dreaming, impaired concentration, and mood changes in 58% to 73% of patients taking EFV in combination with other antiretroviral agents versus 27% for controls [138,139]. No severe reactions were reported. Median duration of symptoms was 19 to 22 days, but they may persist for several weeks. Less than 2% of patients discontinued EFV because of CNS side effects. **Psychiatric side effects**, including hallucinations, changes in personality, depression, anxiety, and marked cognitive dysfunction, have been described. The cause of CNS effects is not known.
- (2) **Dermatologic.** Rash was reported in 10% to 34% of patients [27], usually occurring in the second week. It is maculopapular in nature, self-limited, and requires no therapy, or a brief course of oral antihistamines. Mean duration of rash is 14 days, and it usually does not lead to discontinuation of EFV [27]. Stevens-Johnson syndrome has rarely been reported [140].
- (3) **Laboratory values.** Occasionally both high-density lipoprotein (HDL) and low-density lipoprotein (LDL) cholesterol are increased [140].
- (4) **Children.** CNS manifestations of EFV are similar to those in adults but less common, whereas skin rash is more common [40]. Drug interactions are similar to those in adults.

4. Delavirdine (Rescriptor). DLV is a bisheteroarylpiperazine NNRTI.

- a. Formulations** include 100- and 200-mg tablets. The 100-mg tablets only may be dispersed in water (see package insert for instructions).

b. Dosage

- (1) **Adults.** Adults should be given 400 mg every 8 hours without regard to meals. Buffering agents (ddI) or antacids should be given at least 1 hour apart from DLV (see section below on drug interactions). Twice-daily dosing (600 mg every 12 hours) is being studied.
- (2) **Children.** Adolescents are given the same dose as adults. Few data are available to guide dosage for children under 13.

- c. In vitro activity.** DLV is active only against HIV-1, including NRTI- and PI-resistant strains. It does not require any intracellular metabolism to become active.

d. Pharmacology [141–143]

- (1) **Absorption.** Bioavailability is 85%, and peak plasma concentrations occur in 1 to 2 hours. DLV is a weak base, with poor solubility at pH above 3.0. Therefore, the rate and extent of absorption is affected by hypochlorhydria of any cause or by drugs that decrease gastric acidity. DLV levels are significantly decreased (by 40%–45%) in patients with hypo- or achlorhydria compared to subjects with normal gastric acidity, even when DLV is given concomitantly with an acidic beverage. DLV is 98% protein bound, primarily to albumin.
- (2) **Half-life** is 2.35 to 4.12 hours, necessitating dosing every 8 hours.

- (3) **Tissue distribution.** Given extensive protein binding, CSF penetration is only 0.4% of plasma concentration; 2% of the serum concentration has been reported in semen. DLV is teratogenic in rats and is excreted in milk. No studies have been done in pregnant women.
- (4) **Metabolism and elimination.** DLV is extensively biotransformed to several inactive metabolites by hepatic CYP3A pathways primarily and to a lesser extent CYP2D6. Five percent appears unchanged in urine, and the metabolites are excreted in the feces (51%) and urine (44%). DLV reversibly inhibits the activity of CYP3A and CYP2C9, common metabolic pathways for other drugs (see drug interactions).
- (5) **Dose modifications.**
 - (a) **Renal disease.** Less than 5% of DLV is excreted intact in urine; no dose adjustment is needed.
 - (b) **Hepatic disease.** The pharmacokinetics of DLV in patients with hepatic impairment have not been studied. Given that DLV undergoes extensive hepatic metabolism, it should be used with caution in patients with liver disease.
- (6) **Drug interactions.** DLV inhibits hepatic CYP3A microsomal enzymes. Elevated levels of drugs metabolized by this pathway may occur and result in serious side effects.

Drugs that should not be coadministered include astemizole, terfenadine, alprazolam, midazolam, triazolam, rifampin, rifabutin, nifedipine, cisapride, sildenafil, quinidine, warfarin, ergot derivatives, clarithromycin, dapson, simvastatin, and lovastatin. Levels of IDV, SQV, RTV, and APV are increased. Doses need to be adjusted (see section (6) on individual PI). **Drugs that induce CYP3A** can result in significant decreases in DLV serum levels and should not be coadministered: rifampin, rifabutin, phenytoin, phenobarbital, and carbamazepine. **Drugs that increase gastric pH** can lower DLV bioavailability; antacids or buffered ddI should be administered at least 1 hour before or after DLV. Chronic histamine receptor antagonists are not recommended. Data are unavailable regarding the use of DLV with methadone or oral contraceptive agents.

e. Pregnancy category C

f. Adverse effects [142]

- (1) **Dermatologic.** An erythematous maculopapular rash, which may be pruritic, becomes confluent and is occasionally associated with fever. It occurs in up to 44% of subjects, typically 7 to 15 days (range 2–18) following the initiation of therapy. It may be dose related and is observed more frequently in patients with CD4 cell counts of less than 200/mL [144]. Over 90% of patients were able to continue therapy despite rash [142,144]. Upon discontinuation of DLV, rash resolved in 3 to 5 days. Severe or life-threatening rash (Stevens-Johnson syndrome) has been reported rarely (1 case among the first 1,000 patients given DLV). Rash resulted in discontinuation of DLV therapy in fewer than 5% of patients [142].
- (2) **Miscellaneous adverse effects.** Headache and nausea occasionally occur.
- (3) **Laboratory values.** No significant LFT or hematologic abnormalities have occurred [142–144].
- (4) **Children.** Rash, headache, nausea, and drug interactions are similar to those observed in adults.

C. Nucleotide reverse transcriptase inhibition

- 1. **Tenofovir (disoproxil fumarate, TDF)** is the first drug of this class approved for treatment of HIV-1 infection. The nucleotide analogues (e.g., tenofovir itself) have poor oral bioavailability and low cellular penetration (because of highly polar phosphate moieties). These disadvantages have been circumvented by the attachment of labile lipophilic groups to mask the polarity of the phosphate moieties. This allows passive diffusion across cellular membranes. Nucleotide

analogues are thus given as prodrugs (e.g., TDF) that require further intracellular processing to become pharmacologically active.

a. Formulation is 300-mg tablets.

b. Dosage

(1) **Adults.** Adults may be given 300 mg once daily.

(2) **Children.** As of spring 2002, there are no published clinical trials providing data for TDF pediatric dosing. Older adolescents could presumably use the adult dose.

c. Mechanism of action [145,146]. TDF is a prodrug of the acyclic adenosine analogue tenofovir. It requires intracellular phosphorylation to become active. In its diphosphorylated form it competes with deoxyadenine triphosphate for uptake by RT (competitive inhibition) and also functions as a chain terminator. It is active in both resting and activated cells [146].

d. *In vitro* activity. TDF is active against HIV-1 (including strains with mutations that confer resistance to most NRTIs), HIV-2, and simian immunodeficiency virus [147].

e. Pharmacology

(1) **Absorption.** Oral bioavailability is estimated to be 25% in the fasting state. Bioavailability is improved when TDF is administered with food (particularly a high-fat meal).

(2) **Half-life** in serum is 12 to 15 hours; intracellular half-life is 10 to 50 hours, allowing once-daily dosing.

(3) **Tissue distribution.** Only 7.2% of TDF is protein bound. No information is available on CSF penetration, or to what degree TDF crosses the placenta.

(4) **Metabolism and elimination.** TDF is not metabolized by cytochrome P-450 enzymes. When multiple (300 mg/day) oral doses are given with food, 22% to 42% is found as unchanged drug in urine. TDF is eliminated by glomerular filtration and active tubular secretion.

(5) **Dose modification**

(a) **Hepatic disease.** TDF is not metabolized by liver enzymes.

(b) **Renal disease** has not been evaluated. The kidneys primarily eliminate TDF. Other drugs may compete with TDF for elimination by this route. TDF should not be given if the rate of creatinine clearance is less than 60 mL/min.

(6) **Drug interactions.** TDF increases (by an unknown mechanism) serum levels of ddI by 44% to 60% in various fasting and fed states [148]. Patients using these drugs concomitantly should be monitored for ddI-related adverse effects [149]. Drugs that compete for active tubular secretion or reduce renal function may increase TDF levels or serum concentrations of other drugs eliminated by the kidneys. Examples include acyclovir, valacyclovir, cidofovir, ganciclovir, and valganciclovir [149].

f. Pregnancy category B

g. Adverse effects. In a phase I/II trial of 49 patients receiving TDF, the only grade III and i.v. adverse events were laboratory value abnormalities: 5 subjects had CK elevations, 2 greater than four times the ULN. All of the CK elevations were associated with recent exercise [146]. Two of five subjects with increased CK had concurrent elevations in aspartate aminotransferase (AST) or alanine aminotransferase (ALT) (greater than five times the ULN), suggestive of a skeletal muscle etiology. In larger placebo-controlled trials of TDF in patients receiving other antiretroviral agents, GI events (nausea 11%, vomiting 5%, abdominal pain 3%) were the most common adverse effects. These were observed with similar frequency in placebo recipients. Discontinuation of TDF because of GI complaints was rare. Laboratory value abnormalities were no more common in TDF than in placebo recipients [150].

(1) **Lactic acidosis/hepatic steatosis.** TDF has much less effect on mitochondrial DNA polymerase gamma than the NRTIs, and no cases have been reported [145,149].

(2) **Children.** As of spring 2002, there are no data available.

Table 19.7. Currently Available Protease Inhibitors

Saquinavir
Ritonavir
Indinavir
Nelfinavir
Amprenavir
Lopinavir

D. Protease inhibitors. The currently available PIs are listed in Table 19.7.

1. **Mechanism of action.** Structural protein components of the viral core and the viral replicative enzymes (RT, integrase, and protease) are synthesized as polyproteins. These must be cleaved, by viral protease, to produce mature infectious virions. PIs mimic the peptide cleavage site of HIV protease. By competitive inhibition, they prevent HIV protease-mediated processing of viral polyproteins. Immature, defective viral particles are produced [151–153], preventing further rounds of infection. PIs do not require any intracellular metabolism to become active and are effective in latently infected cells. The PIs alter the pharmacokinetics of other drugs by inhibiting or inducing hepatic cytochrome P-450. All PIs inhibit cytochrome P-450 enzymes. RTV is the most potent, SQV is the least potent, and IDV and nelfinavir (NFV) are in between [154]. PIs have low affinity for human aspartyl endopeptidases.
2. **PI class-related adverse effects** include lipid abnormalities, insulin resistance and diabetes mellitus, lypodystrophy syndrome, gynecomastia, osteonecrosis, and abnormal bleeding in patients with hemophilia or von Willebrand disease.
3. **Saquinavir** [155] (**Fortovase** [soft-gelatin capsule], **Invirase** [hard-gelatin capsule])
 - a. **Formulations** include 20-mg soft-gelatin capsule (Fortovase; SQV-SGC) and 200-mg hard-gel capsule (Invirase).
 - b. **Dosage**
 - (1) **Adults.** Fortovase is preferred: 1,200 mg every 8 hours, 400 mg every 12 hours if given with RTV 400 mg every 12 hours. Invirase has poor bioavailability and should be used only in combination with RTV and only if Fortovase is unavailable.
 - (2) **Children.** Few data are available on pediatric dosing guidelines for either SQV hard-gelatin or soft-gelatin capsules. Older adolescents could be given the adult dosage of SQV-SGC 1,200 mg orally every 8 hours. No liquid preparation makes SQV impractical for treatment of younger children.
 - c. **In vitro activity.** SQV is active against HIV-1 and HIV-2, including NRTI- and NNRTI-resistant strains.
 - d. **Pharmacology** [155–157]
 - (1) **Absorption.** Invirase is poorly absorbed, and SQV undergoes extensive first-pass hepatic metabolism. Both contribute to the low bioavailability of Invirase (4%). Although the absolute bioavailability of SQV-SGC has not been assessed, it is estimated to be three to four times that of Invirase. Absorption is markedly increased when SQV is taken with meals (particularly fatty foods). This has been attributed (in part) to better solubilization created by increased gastric pH.
 - (2) **Half-life** is 1 to 2 hours, which necessitates dosing every 8 hours.
 - (3) **Tissue distribution.** SQV is highly protein bound (97%) and appears to penetrate poorly into semen (<5%) and CSF (<1% concurrent plasma levels) [155,157–160]. It is not known if SQV is excreted in breast milk. Placental transfer of SQV is expected to be very low (<5% of plasma concentrations) based on the high level of protein binding. An *ex vivo* placental transfer model in animals confirms this [161,162].

- (4) **Metabolism and elimination.** SQV undergoes rapid and extensive first-pass hepatic and intestinal metabolism, primarily (50%) by CYP3A4 isoenzymes. Several inactive mono- and dihydroxylated compounds are the end result. Biliary is the major route of elimination (88% of SQV is excreted in feces); 1% is found in urine as unchanged drug [157].
- (5) **Dose modification.** SQV has not been studied. **Renal disease** should not affect SQV pharmacokinetics. Given the extensive hepatic metabolism, this drug should be used with caution in patients with **hepatic disease**.
- (6) **Drug interactions** [154]. Drugs contraindicated for concurrent use because SQV increases their serum levels include **antihistamines**, terfenadine, astemizole, **GI motility agents** (e.g., cisapride), **sedatives/hypnotics** (e.g., triazolam, midazolam, St. John's wort), **lipid-lowering agents** (e.g., simvastatin, lovastatin), and ergot derivatives. Rifampin and rifabutin are contraindicated for concurrent use because they significantly decrease SQV levels. EFV is contraindicated for concurrent use because SQV decreases its serum levels. Sildenafil requires dose modification when used with SQV (25 mg/48 hours). Drugs that increase SQV levels include RTV, IDV, NFV, DLV, ketoconazole, and clarithromycin. Low-dose RTV with SQV allows twice-daily dosing (see section on dosing). Drugs that may decrease SQV levels and should be avoided if possible include anticonvulsants, phenobarbital, carbamazepine, phenytoin (monitor levels), **corticosteroids** (e.g., dexamethasone), and garlic supplements.

e. Pregnancy category B

f. Adverse effects [154,157]

- (1) **Gastrointestinal.** The most frequent side effects with both formulations are diarrhea, nausea, and abdominal pain (5%–10% and 10%–20% of patients, respectively). Most side effects were described as mild.
- (2) **Laboratory value abnormalities.** CPK (6%), ALT (3%), and AST (4%) elevations have been observed.
- (3) **Children.** Clinical studies, all of which enrolled only small numbers of children given SQV-SGC with NFV, revealed no unexpected adverse effects beyond those seen in adults. Further studies are needed.

4. Ritonavir (Norvir)

a. Formulations include 100-mg soft-gelatin capsules and 80 mg/mL elixir (unpalatable).

b. Dosage

- (1) **Adults.** Adults may be given 600 mg every 12 hours. To improve tolerability (GI upset), the following dose escalation regimen is recommended: 300 mg every 12 hours on day 1, then increased by 100 mg every 12 hours at 2- to 3-day intervals.
- (2) **Children.** Adolescents at least 13 years of age may be given the adult dosage of 600 mg orally twice daily. Administration should begin with 300 mg twice daily and the dose increased stepwise by 100 mg orally twice daily every 1 to 3 days to achieve the full dose by 1 to 2 weeks. **Children under 13** should be given 350 to 400 mg/m² BSA orally twice daily, with a similar stepwise increase in dose starting at 250 mg/m² BSA orally twice daily to achieve full dose by 1 to 2 weeks. Infant and newborn dosing is under study. RTV as a pharmacologic enhancer is given at a dosage of 200 to 400 mg orally twice daily along with another PI used in adolescents and adults.

c. In vitro activity. RTV is active against HIV-1 and HIV-2, including NRTI- and NNRTI-resistant strains.

d. Pharmacology [154,163]

- (1) **Absorption.** Bioavailability is 66% to 75%. Food affects the rate and extent of absorption to a moderate degree depending on dose and formulation of RTV (overall absorption of caplets increases with food but is less pronounced when liquid formulation is used).

- (2) **Half-life** is 3 to 5 hours.
- (3) **Tissue distribution.** RTV is 98% to 99% protein bound; CSF concentrations are only 1% of concomitant plasma levels. RTV is highly protein bound, so placental transfer and secretion in breast milk is likely to be minimal. An *in vitro* model confirms negligible placental transfer [164]. In a small study, levels in semen were less than 5% of plasma concentrations [160].
- (4) **Metabolism and elimination.** RTV is metabolized by hepatic CYP3A microsome enzymes and to a lesser degree by CYP2D6 enzymes. Eighty-five percent of an RTV dose is excreted in stool (34% as unchanged drug), and 11% is excreted in urine, of which 3.5% is unchanged [163].
- (5) **Dose modifications.** No studies have been conducted in patients with renal or hepatic disease. RTV **renal clearance is negligible**, so doses do not have to be adjusted. Given the extensive hepatic metabolism of RTV, **caution** should be exercised when using RTV in patients **with liver disease**.
- (6) **Drug interactions** [166,170]. RTV is a potent inhibitor of CYP3A and CYP2D6. It slows metabolism of drugs by these isoenzymes, leading to potentially life-threatening toxicities. For drugs that should not be coadministered with RTV, see Table 19.8.

RTV increases the levels of several other PIs, such as IDV, SQV, APV, and LPV. Small doses of RTV allow less frequent dosing of the other PIs (boosting) when used in combination (see section IX.C.4.b). RTV can decrease the plasma concentrations of methadone (dose increase may be necessary), ethinyl estradiol (dose should be increased or alternative contraceptive measures used), theophylline (levels should be monitored and dose increased if required), warfarin (international normalized ratio should be monitored), phenytoin, divalproex, lamotrigine (levels should be monitored), and atovaquone. RTV decreases meperidine concentrations, but levels of an active metabolite (norperidine) are increased. Long-term use of meperidine is not recommended. Rifampin, rifabutin, and St. John's wort should not be used with RTV because they significantly decrease RTV levels. Plasma levels of rifabutin or its metabolites may be concomitantly increased, leading to dose alteration of rifabutin to 150 mg daily.

Many other drugs that may have increased plasma concentrations when coadministered with RTV (Table 19.9) should be used with caution. When possible, their levels should be monitored. Patients must be followed closely for adverse effects, and reduced doses may be needed.

e. Pregnancy category B

Table 19.8. Drugs that Should Not Be Coadministered with Ritonavir

Drug Class	Drugs	Possible Effects
Antihistamines	Astemizole, terfenadine	Cardiac arrhythmias
Antiarrhythmics	Amiodarone, quinidine flecainide, encainide, propafenone, bepridil	Cardiac arrhythmias
Sedative/hypnotic	Triazolam, midazolam	Prolonged or increased sedation, respiratory depression
Antimigraine	Dihydroergotamine, ergotamine	Peripheral vasospasm, ischemia of the extremities
GI motility agent	Cisapride	Cardiac arrhythmias
Neuroleptic	Pimozide	Increased or prolonged sedation, respiratory depression
Lipid-lowering agents	Simvastatin, lovastatin, atorvastatin, cerivastatin	?Increased risk of myopathy and rhabdomyolysis

Table 19.9. Drugs for which Ritonavir Increases the Plasma Concentrations

Drug Class	Drugs
Antiarrhythmics	Lidocaine, mexilitine, disopyramide
Calcium channel blockers	Diltiazem, verapamil, nifedipine
β -blockers	Metoprolol, timolol
Anticonvulsants	Carbamazepine, clonazepam, ethosuximide (monitor levels)
Antidepressants	Desipramine (monitor levels), bupropion, SSRIs, tricyclics, nefazodone
Neuroleptics	Perphenazine, risperidone, thioridazine
Sedatives/hypnotics	Diazepam, flurazepam, estazolam, zolpidem, chlorazepate
Antiemetics	Dronabinol
Antiparasitics	Quinine
Stimulants	Methamphetemines
Steroids	Dexamethasone, prednisone
Immunosuppressants	Cyclosporine, tacrolimus (monitor levels)
Analgesics	Propoxyphene, tramadol
Antibiotics	Clarithromycin (dose needs to be adjusted in presence of renal failure)
Antifungals	Ketoconazole (doses >200 mg/day not recommended)
Other	Sildenafil (dose should not exceed 25 mg in 48 hours)

Ritonavir formulations contain alcohol and can produce disulfiram-like reactions when given with metronidazole or disulfiram.

f. Adverse effects. In placebo-controlled studies, GI toxicity, nausea (25%), diarrhea (18%–46%), vomiting (15%), headache (27%), fatigue (15%), and circumoral paresthesia (7%–15%) were common. Seventeen percent of patients withdrew, mostly during the initiation of therapy. Adverse effects are related to RTV concentration. Dose escalation (see section on dosing) may reduce the incidence [165].

(1) **Hepatitis.** Significant asymptomatic increases (>200% of ALT, AST, γ -glutamyl transferase) were seen in 4% to 6% of patients receiving the highest doses of RTV (500–600 mg twice daily) versus placebo [166,167]. In another placebo-controlled study, only elevations of GGT were noted more frequently (24%) in RTV-treated subjects [168]. Hepatitis occurs more frequently with RTV (vs. other PIs), particularly in patients coinfecting with hepatitis C or B [169].

(2) **Lipid abnormalities** include insulin resistance, fat redistribution, osteonecrosis, and increased bleeding with hemophilia (see section on class-related adverse reactions).

5. Indinavir (Crixivan)

a. Formulations include 200- and 400-mg capsules.

b. Dosage

(1) **Adults.** Adults may be given 800 mg every 8 hours on an empty stomach (1 hour before or 2 hours after a meal) or with a light nonfat meal (e.g., cornflakes with skim milk or toast and jelly). To avoid IDV-associated nephrolithiasis (see section below on adverse effects), patients should drink 48 ounces of fluid daily. Twice-daily dosing can be achieved when 800 mg of IDV is boosted with 100 mg of RTV.

(2) **Children.** Adolescents at least 13 years of age may be given an adult dosage of 800 mg orally every 8 hours. In children under 13, limited clinical trial data suggest that 350 to 500 mg/m² BSA orally every 8 hours may be used. No information is available for newborn dosing. No liquid formulation is available for children [40].

c. *In vitro* activity. IDV is active against HIV-1 and HIV-2, including NRTI- and NNRTI-resistant strains.

d. Pharmacology [154,171]

- (1) **Absorption is reduced by food.** Bioavailability is 65% in the fasting state or with a light meal. A full or fatty meal decreases absorption by more than 70%. If IDV is boosted with RTV, food has no effect on absorption.
- (2) **Half-life** is 1.8 hours.
- (3) **Tissue distribution.** IDV is the least protein bound of the PIs (60% vs. 90%–99%). CSF penetration is low (CSF:plasma ratio is 0.004:1 to 2.28:1) but exceeds that of other PIs. CSF levels are generally greater than the IC₉₅ of IDV-sensitive strains [172]. Both CSF and semen concentrations of IDV are greatly enhanced by RTV administered at a dose of 100 mg every 12 hours [173]. Human placental transfer studies are lacking, but IDV crosses the placenta in animals (indinavir sulfate).
- (4) **Metabolism and elimination.** Most IDV is excreted in bile as metabolites (64%) and unchanged drug (19%). IDV is metabolized by hepatic glucuronidation and cytochrome P-450 enzymes, mainly the CYP3A4 isoform. Unchanged drug (9%) and metabolites (10%) are excreted in urine.
- (5) **Dose modifications**
 - (a) **Hepatic disease.** The half-life of IDV is prolonged in cirrhosis and mild to moderate hepatic insufficiency. With liver disease, 600 mg every 8 hours is recommended (indinavir sulfate).
 - (b) **Renal disease.** Limited data are available. Because less than 20% of IDV is excreted in urine, substantial dosage reductions are not necessary [174,175]. However, because IDV is nephrotoxic, another PI should be considered in the presence of renal disease or there must be close monitoring.
- (6) **Drug interactions.** Like other PIs, IDV interacts with drugs that induce or inhibit hepatic cytochrome P-450. **Contraindicated drugs for concomitant use** are listed in Table 19.10.
 - (a) **Drugs that decrease IDV levels** include rifabutin (dose should be decreased to 150 mg/day and IDV increased to 1 g every 8 hours), NVP (IDV should be increased to 1 g every 8 hours), and EFV (IDV should be increased to 1 g every 8 hours). Depending on the specific concentration of flavonoids, grapefruit juice may decrease IDV levels by 25% by inducing intestinal cytochrome P-450 metabolism (coadministration should be avoided). Buffered ddi should be administered either 2 hours before or after IDV, or the Videx EC formulation used. Anticonvulsants (e.g., phenobarbital, phenytoin, carbamazepine) can decrease PI levels (levels of anticonvulsant should be monitored; when possible, alternative anticonvulsants should be used).
 - (b) **Drugs that increase IDV levels.** When using RTV (see section D.4.d.(6)), ketoconazole, or itraconazole, the IDV dose should be decreased to 600 mg every 8 hours. Limited data are available

Table 19.10. Drugs Contraindicated for Concomitant Use with Indinavir

Drug Class	Drugs
Antihistamines	Astemizole, terfenadine
Gastric motility agents	Cisapride
Sedatives/hypnotics	Triazolam, midazolam
Antidepressants	St. John's wort
Migraine therapy	Ergotamines
Lipid-lowering agents	Lovastatin, simvastatin

on using boosted IDV plus NFV in twice-daily dosing. IDV increases serum levels of norethindrone and ethinyl estradiol (no dose changes needed), as well as sildenafil (not to exceed 25 mg/48 hours), trimethoprim, and clarithromycin.

e. Pregnancy category C

f. Adverse effects (see class-related side effects in section VI.A-E).

- (1) **Renal toxicity.** IDV is poorly soluble in water at pH greater than 4. Several consequences have been described, including nephrolithiasis with frank renal colic, flank or back pain without evidence of IDV stones, obstructive uropathy with acute renal failure from stones, sludge, dysuria or urgency (often mistaken for infectious urethritis) associated with crystalluria, crystal-induced tubulointerstitial nephritis (with pyuria and eosinophiluria), and asymptomatic crystalluria or pyuria [176–178]. **Nephrolithiasis** is the most serious side effect of IDV, with an incidence of 3% to 15% [178]. However, in one 3-year follow-up study of 33 patients, the incidence was 39% [179]. Most patients have no prior risk factors for nephrolithiasis. Most cases occur after 5 to 7 months of treatment but have manifested within 1 week of starting IDV [176]. Risk factors for IDV stones include inadequate fluid intake, urinary pH greater than 6, elevated plasma levels of IDV, living in a warmer climate, and possibly hepatitis C coinfection [32]. The clinical presentation is similar to that of standard renal colic. IDV stones are usually radiolucent. Ultrasonography or CT may reveal stones, hydronephrosis, or ureteral obstruction. Light microscopy reveals rectangular plate-like forms with irregular borders, sheafs of densely packed crystals, and rosette or starburst forms [176]. **Crystalluria** occurred in 20% of 142 asymptomatic patients on standard-dose (2,400 mg/day) IDV [32,177]. The clinical presentation is similar to that of nephrolithiasis. Urinalysis shows hematuria, pyuria, proteinuria, and crystalluria. Clinical manifestations similar to nephrolithiasis can be caused by IDV sludge without discrete stone formulation [176]. CT scans reveal bilateral renal parenchymal defects. Hydronephrosis also may be present. Symptomatic crystalluria occurred in 8% of patients taking IDV [177]. Symptoms consisted of dysuria and urgency or symptoms similar to nephrolithiasis without stones. **Treatment** for any of these complications consists of i.v. fluid administration and pain control. Antiretroviral agents should be temporarily discontinued and renal function monitored. Up to 55% of patients respond to conservative therapy. In five patients with biopsy-proven tubulointerstitial disease, elevated serum creatinine and leukocyturia resolved after discontinuation of IDV [174]. In crystalluria and pyuria, drug can be continued and fluids given, but if they do not resolve, IDV should be discontinued.

Most patients can resume IDV therapy, but there may be recurrence. IDV should not be restarted with persistent renal insufficiency or tubulointerstitial disease (increasing blood urea nitrogen or creatinine, or pyuria). IDV stones, asymptomatic crystalluria, and pyuria are **preventable** by increasing daily fluids [177].

- (2) **Gastrointestinal.** Nausea and vomiting occur in 10% to 12% of patients [154,177]. They usually improve or resolve with continued therapy and are rarely a reason to discontinue therapy [180,181]. Asymptomatic hyperbilirubinemia (predominantly indirect bilirubin) occurs in 1% to 15% of patients [154,177]. This is not an indication for discontinuation [177]. Severe cases of hyperbilirubinemia (greater than five times the ULN) occurred in 5.2% of 116 patients taking IDV in the presence of hepatitis C or B coinfection [169]. Overall, this degree of elevation occurs in greater than 10% of patients [154,177]. Clinically significant hepatitis rarely occurs in patients not coinfecting with hepatitis C or B, alcoholic patients, or those using other hepatotoxic medications.

- (3) **Dermatologic** effects include dry skin, dry lips, hair loss (scalp and extremities), paronychia, and cheilitis, secondary to its effect on retinoid metabolism [177]. Hair regrowth occurred (as did regression of other skin changes) when a different PI or an NNRTI was substituted [182].
- (4) **Children.** Nephrolithiasis, crystalluria, and hematuria occur in children as they do in adults in about 10% to 15% of patients. These adverse effects occur slightly more often in children due to the difficulty in assuring adequate fluid intake. Hyperbilirubinemia is seen in 10% of children receiving IDV, similar to the rate in adults. This effect has restricted the use of IDV in newborns, who tolerate hyperbilirubinemia poorly.

6. Nelfinavir (Viracept)

a. Formulations include 250-mg tablets and 50 mg/g oral powder.

b. Dosage

- (1) **Adults.** Adults may be given 750 mg every 8 hours or 1,250 mg every 12 hours, preferably with food.
- (2) **Children.** Adolescents at least 13 years of age may be given the adult dosage, 750 mg orally every 8 hours or 1,250 mg orally every 12 hours. For children 2 to 13, 20 to 30 mg/kg/dose has been approved by the FDA, but this dose is being reassessed in clinical trials. Some clinicians use 30 to 45 mg/kg/dose orally every 8 hours to improve serum concentrations of NFV. Limited data support NFV dosing of children 6 to 13 years of age at 55 mg/kg/dose orally every 12 hours. Although the oral powder was developed for administration to young children in food or liquid, it requires a large amount of powder to deliver the desired dosage and is consequently poorly palatable. Most parents find it far easier to dissolve the tablets in a small volume of liquid; the tablets disperse readily enough that a few children might prefer dissolving them in their mouths. For those who do not like the taste, chocolate syrup or peanut butter disguises NFV very well.

c. In vitro activity. NFV and several of its metabolites are active against HIV-1 and HIV-2, including NRTI- and NNRTI-resistant strains [183,184].

d. Pharmacology

- (1) **Absorption.** NFV has good oral bioavailability, which is markedly improved in the fed state [185]. Bioavailability is 70% to 80%.
- (2) **Half-life** is 3.5 to 5 hours. Coupled with relatively slow absorption, this allows twice-daily dosing.
- (3) **Tissue distribution.** NFV is highly protein bound (>98%) primarily to α_1 -acid glycoprotein. In animal models, organ distribution is extensive, but not into CSF [186].
- (4) **Metabolism and elimination.** NFV is metabolized by the hepatic cytochrome P-450 enzyme system. At least four different cytochrome P-450 enzymes are involved (CYP3A4, CYP2C9, CYP2C19, and CYP2D6). Several metabolites have antiretroviral activity. Eighty-seven percent is eliminated via the biliary tract into stool. Of this, 78% is oxidative metabolites, 22% unchanged NFV; 1% to 2% is excreted mostly as unchanged drug in urine.
- (5) **Dose modifications**
 - (a) **Renal disease.** No dose modification is required [174].
 - (b) **Hepatic disease.** The pharmacokinetics of NFV in this setting have not been studied. Given its extensive hepatic metabolism, NFV should be used with caution in liver disease.
- (6) **Drug interactions.** NFV inhibits cytochrome P-450, primarily CYP3A. **Drugs contraindicated for concurrent use include** astemizole, terfenadine, midazolam, triazolam, cisapride, ergot derivatives, St. John's wort, simvastatin, lovastatin, rifampin, amiodarone, and quinidine.
 - (a) **Drugs that require dose modification.** Ethinyl estradiol serum levels decrease by 47% (an alternative birth control method should be used). Sildenafil levels increase up to 11-fold (dosage should not exceed 25 mg/48 hours). Methadone levels decrease by 30% to 50%, and

should be monitored for signs of opiate withdrawal. Rifabutin levels increase 200%, whereas NFV levels decrease by 30%; 150 mg/day rifabutin should be used. Tacrolimus and cyclosporine levels may be increased (drug levels should be monitored).

- (b) **Others.** Carbamazepine, phenobarbital, and phenytoin may significantly decrease NFV levels. A different anticonvulsant should be considered. DLV levels decrease by 40%, NFV levels increase, and a greater than 20% incidence of neutropenia occurs (this combination should be used with caution).

e. Pregnancy category B

f. Adverse effects (see class-related side effects in section VI.A–E).

(1) **Gastrointestinal.** Mild to moderate diarrhea, greatest at initiation of NFV, is most common (20%–25% of patients), leading to discontinuation in less than 2% [183,187]. The mechanism is unknown. In many patients diarrhea resolves over time with continued NFV use [188]. Treatment of diarrhea [188] has included use of the following agents: oat bran, psyllium, loperamide, calcium, diphenoxylate/atropine, SP-303, and pancreatic enzymes. Nausea or elevated LFT results have been observed in fewer than 10% of patients [154,183,187]. Many of these have coinfection with hepatitis B or C [189].

(2) **Children.** NFV is relatively well tolerated by children, even at high doses. The most common adverse events are diarrhea, flatulence, abdominal pain, and, less commonly, rash.

7. Amprenavir (Agenerase) [190] is the only PI that is a sulfonamide.

a. Formulations include 50- and 150-mg soft-gelatin capsules and 15 mg/mL oral solution. The oral solution and the capsules contain large amounts of propylene glycol (550 mg/mL), which is used to achieve adequate solubility of APV. Because of the potential risk for propylene glycol toxicity, the oral solution is contraindicated in pregnant women, children under 4 years of age, patients with hepatic or renal dysfunction, or those taking metronidazole or disulfiram; APV capsules should be substituted. In addition, both the capsule and the oral form of Agenerase contain a high concentration of vitamin E. There is sufficient concentration that the vitamin E intake exceeds the daily requirement by 50 to 100 times. The consequences of this are unknown, but the patient should avoid taking any additional vitamin E supplement.

b. Dosage

(1) **Adults.** Adults may be given 1,200 mg (eight 150-mg caps) every 12 hours without regard to meals (although high-fat food should be avoided).

(2) **Children.** Adolescents at least 13 years of age (and >50 kg BW) should be given 1,200 mg orally twice daily; children 4 to 12 years of age and greater than 12 but less than 50 kg BW should be given 20 mg/kg/dose orally twice daily up to a maximum of 2,400 mg per day. APV is not recommended for children under 4 years of age because of the propylene glycol content, vitamin E content, and paucity of data concerning dosing. The drug in the liquid preparation is less bioavailable than the capsule. When used, the dose of the liquid should be 14% greater than the capsule dose, or 22.5 mg/kg/dose of liquid orally twice daily up to a maximum of 2,800 mg.

c. In vitro activity. APV is active against HIV-1 and HIV-2, including HIV-1 strains resistant to NRTIs, NNRTIs, and some PIs.

d. Pharmacology [190]

(1) **Absorption.** APV is well absorbed, but the absolute bioavailability has not been established. Absorption is reduced by food. This is significant only with high-fat meals, however.

(2) **Half-life** is 7 to 11 hours, which allows twice-daily dosing.

(3) **Tissue distribution.** APV is 90% protein bound (mostly α_1 -acid glycoprotein). CSF penetration is presumed to be limited by extensive protein binding and P-glycoprotein-mediated efflux. Placental levels and penetration into breast milk has not been studied. HIV-1 RNA levels in semen

decreased significantly in 14 of 19 men on APV monotherapy [190] (APV levels not measured).

- (4) **Metabolism and elimination.** APV is primarily metabolized by hepatic CYP3A4. Most of an administered dose is found as metabolites in stool. There is minimal (<3% unchanged APV) renal excretion.
- (5) **Dose modification.**
 - (a) **Renal disease.** No dose modifications are necessary. The oral solution should not be used.
 - (b) **Hepatic disease.** Only APV capsules should be used, and caution should be exercised in patients with moderate or severe hepatic impairment. With a Child-Pugh score of 5 to 8, the dose should be decreased to 450 mg every 12 hours, and to 300 mg every 12 hours for a Child-Pugh score of 9 to 12 [191].
- (6) **Drug interactions** [190, 192]. **Drugs contraindicated for concomitant use** include astemizole, terfenadine, cisapride, ergot derivatives, St. John's wort, midazolam, triazolam, pimozide, lovastatin, simvastatin, and rifampin. **Drugs that should be used with caution, require dose adjustments, or require monitoring of serum level** include amiodarone, lidocaine, quinidine, amitriptyline, nortriptyline, desipramine, imipramine, and warfarin. For sildenafil, dosage should not exceed 25 mg/48 hours. **Drugs that lower APV levels** include phenobarbital, carbamazepine, and phenytoin, and **concomitant use should be avoided.** The dose of rifabutin should be decreased to 150 mg daily. **Clinically important APV interactions occur with the following antiretroviral agents:** EFV decreases APV levels by 36% (EFV levels increase by 15%), so APV dosing should be increased to three times daily. RTV increases APV levels by more than 300%. Using RTV (100–200 mg twice daily) to boost APV is currently recommended (see section on dosing). APV may lower serum levels of oral contraceptives, so an alternative method of birth control should be used.

e. Pregnancy category C

f. Adverse effects (see class-related side effects in section VI.A–E).

- (1) **Dermatologic.** A maculopapular rash, variably pruritic (mild to moderate severity leading to maximum 3% discontinuation), occurs in 28% of patients, usually during the first few weeks of therapy [179,190]. One percent of patients developed Stevens-Johnson syndrome. The higher incidence of rash compared with other PIs has been attributed to its sulfa moiety. However, patients with known allergy to sulfa drugs may take APV [179]. Therapy can be continued in patients with mild rash not associated with pruritus or systemic symptoms [179]. Antihistamines can be used for pruritus. APV should be discontinued, and rechallenge should not be attempted in patients with rash associated with fever, vomiting, chills, and severe pruritus or mucous membrane involvement.
- (2) **Gastrointestinal.** GI adverse effects (mild to severe) led to discontinuation in 11% of patients and included nausea (38%–73%), vomiting (20%–23%), and diarrhea (33%–56%) [192]. Giving APV immediately after meals ameliorates nausea. Antidiarrheal therapies may be useful.
- (3) **CNS.** Perioral dysesthesias (26%–30%), headache (7%–44%), and depression and mood changes (4%–15%) rarely lead to discontinuation. Headache, usually self-limited, responds to analgesics. No data are available on therapy for APV-related psychiatric adverse effects or dysesthesias.
- (4) **Laboratory value abnormalities** [190]. Grade 3 (more than five times the ULN) elevations in AST (3.1%), ALT (2.8%), and bilirubin (0.6%) are infrequent. Hypertriglyceridemia is also infrequent (3.9%).
- (5) **Children.** Nausea, vomiting, diarrhea, and rash (including Stevens-Johnson syndrome) are the most common side effects and similar to those in adults. As noted above, APV is a sulfonamide that may cause hypersensitivity reactions in the sulfonamide-allergic patient. The recommended

daily allowance for vitamin E in children is 10 IU/day; that for adolescents and adults is 30 IU/day. APV oral solution, at the recommended doses noted above, contains 138 IU/kg/day up to 8,757 IU/day maximum. APV capsules contain up to 1,744 IU/day of vitamin E. Vitamin E toxicity has been associated with necrotizing enterocolitis in infants, and with coagulopathy, creatinuria, and decreased wound healing in adults. Therefore, patients taking APV should be cautioned not to take supplemental vitamin E. Propylene glycol may cause hyperosmolality, lactic acidosis, seizures, and respiratory depression in infants. Children under 4 years of age should not be given APV oral solution.

8. Lopinavir (Kaletra [LPV + RTV]) [193] is the first pharmacologically enhanced PI.

a. Formulations. Each capsule contains 133 mg of LPV and 33 mg of RTV. Oral solution contains 80 mg LPV and 20 mg RTV per milliliter. Oral administration of LPV alone produces only transient, low levels in plasma (2). Coadministration with RTV (which inhibits hepatic metabolism of LPV) increases LPV plasma levels over 100-fold. The combination of LPV/RTV is active against HIV-1 and HIV-2, including NRTI- and NNRTI-resistant strains [194].

b. Dosage

(1) **Adults.** Adults may be given three capsules (400 mg LPV/100 mg RTV) every 12 hours with food.

(2) **Children.** Adolescents at least 13 years of age may be given the adult dose of 400 mg LPV/100 mg RTV (three capsules or 5 mL elixir) orally twice daily. For children 6 months to 12 years of age, LPV dosage is based on weight. Children 7 to 14 kg BW should be given 12 mg/kg/dose orally twice daily; 15 to 40 kg BW, 10 mg/kg/dose orally twice daily. Dosage of LPV must be increased for children receiving concurrent NVP or EFV (see section below on drug interactions). The suggested adolescent dose is 533 mg (four capsules every 12 hours). Children 7 to 14 kg BW should be given 13 mg/kg/dose orally twice daily. Children 15 to 40 kg BW should be given 11 mg/kg/dose orally twice daily. LPV is best absorbed with food.

c. Pharmacology [193]

(1) **Absorption.** The absolute bioavailability of LPV/RTV has not been established in humans. Plasma levels are increased when administered with food and should be given with meals to enhance bioavailability and minimize pharmacokinetic variability.

(2) **Half-life** is 5.8 hours.

(3) **Tissue distribution.** LPV is 98% to 99% protein bound to α_1 -acid glycoproteins and albumin. There are no human data on the levels achieved in CSF or semen, or on placental transfer.

(4) **Metabolism and elimination.** LPV is rapidly metabolized by hepatic CYP3A4. The major metabolites are less active against HIV-1 than LPV [193,195]. Most LPV is excreted in stool as unchanged drug (19%), and metabolites with less than 3% excreted unchanged in urine.

(5) **Dose modification.** No dose adjustments would be expected in **renal failure**. This was confirmed in one patient receiving LPV/RTV while on hemodialysis [196]. With regard to **hepatic disease**, although not specifically studied, LPV is extensively metabolized in the liver, and concentrations may be increased in the presence of liver disease. LPV/RTV should be used with caution.

(6) **Drug interactions.** LPV/RTV use is contraindicated with drugs that are extensively metabolized by CYP3A or CYP2D6 enzymes and for which elevated plasma levels are associated with serious or life-threatening effects (Table 19.11). **Several drugs increase the metabolism of LPV/RTV leading to subtherapeutic levels**, including anticonvulsants (e.g., carbamazepine, phenytoin, phenobarbital), rifampin, and St. John's wort. Concomitant use with rifampin and St. John's wort is contraindicated.

Table 19.11. Drugs Contraindicated for Use with Lopinavir/Ritonavir

Drug Class	Drugs
Antiarrhythmics	Flecainide, propafenone
Antihistamines	Astemizole, terfenadine
Ergot derivatives	Ergotamine, dihydroergotamine, ergonovine, methylergonovine
Gastric motility agents	Cisapride
Neuroleptics	Pimozide
Sedatives/hypnotics	Midazolam, triazolam
Lipid-lowering agents	Lovastatin, simvastatin

When used concomitantly with LPV/RTV, several drugs require dose adjustments, level monitoring, or close clinical monitoring. Levels of the following drugs are increased when used with LPV/RTV: sildenafil (should be used with caution, and the dose reduced [25 mg every 48 hours]), dihydropyridine calcium channel blockers (e.g., nifedipine, felodipine, nicardipine), antiarrhythmics (e.g., amiodarone, lidocaine [systemic use], quinidine, depredil), rifabutin and its metabolites (which are increased, so dose should be reduced to 150 mg three times per week and the patient monitored for uveitis), lipid-lowering agents (e.g., atorvastatin, cerivastatin, of which the lowest possible dose should be used, or an alternative agent considered [pravastatin]), immunosuppressants (e.g., cyclosporine, tacrolimus, rapamycin; levels should be monitored), clarithromycin (dose adjustment is necessary for patients with decreased renal function [among those with creatinine clearance of 30–60 mL/min, and the dose should be reduced by 50%; <30 mL/min, reduced by 75%]), and ketoconazole and itraconazole (doses of >200 mg/day are not recommended).

Levels of the following drugs are decreased when used with LPV/RTV: methadone (patient should be monitored for withdrawal symptoms, and methadone dose may need to be increased), ethinyl estradiol (an additional or alternative contraceptive method is recommended), and atovaquone (clinical significance is not known; dose may need to be increased).

Drugs that significantly lower LPV levels include EFV and NVP. The dose of LPV/RTV should be increased to 4 capsules every 12 hours. **Drugs that increase LPV/RTV levels** include DLV (appropriate dose for either drug is not known when these are coadministered). LPV/RTV can increase the levels of other PIs (appropriate doses for combination therapy with other PIs are unknown). LPV/RTV oral elixir contains alcohol, and when used with disulfiram/metronidazole, disulfiram-like reactions may occur.

d. Pregnancy category C

e. Adverse effects [193,197] (see class-related side effects in section VI.A–E).

- (1) **Gastrointestinal.** In two large prospective double-blind randomized trials involving over 700 therapy-naïve patients, moderate diarrhea (more than three loose stools/day) occurred in 17% to 25% of patients, nausea in 9%, abnormal stools (fewer than three loose stools/day) in 6% to 19%, and vomiting in less than 5%.
- (2) **Others.** Headache and asthenia were reported in 6% to 13% of patients.
- (3) **Laboratory value abnormalities.** LFT elevations (more than five times the ULN) developed in 14% of subjects on the currently recommended dose. Some had coinfection with hepatitis B or C. Hepatitis B surface antigen or hepatitis C virus antibody at baseline was associated

with an eightfold increased relative risk of developing a grade III/IV AST or ALT elevation on LPV/RTV.

- (4) **Children.** The most common adverse effects associated with LPV in children are diarrhea, asthenia, and elevation of triglycerides and cholesterol, similar to that occurring in adults. LPV/RTV elixir is somewhat more palatable than RTV elixir.

VI. Protease inhibitor class–related adverse effects

- A. Glucose intolerance** occurs with all currently available PIs, with the possible exception of APV [198]. The prevalence of abnormal glucose metabolism in PI-treated patients varies widely. Two percent to 25% had hyperglycemia, 16% to 35% had glucose intolerance, and 4% to 9% had frank diabetes mellitus (type II) [32]. Significant elevation in fasting plasma glucose occurs by 4 weeks [198,199]. PIs cause abnormal insulin secretion and peripheral insulin resistance in both HIV-1– and non HIV-1–infected patients [152,200].
- B. Weight.** Patients in whom this occurs are often overweight. Inhibition of the insulin-responsive glucose transporter GLUT-4 [201] is the proposed mechanism. Blood glucose should be monitored at 3-month intervals, especially with a history of impaired glucose tolerance or risk factors for type II diabetes. Insulin doses may require adjustment. Given the similarities between PI-associated hyperglycemia and type II diabetes, dietary modifications, exercise, and weight loss for obese patients should be attempted. No large studies are available to guide the selection of specific oral hypoglycemic agents. Metformin is associated with lactic acidosis (also a complication of NRTI use), particularly in renal insufficiency. Some patients require insulin therapy. Improvement in insulin resistance and normalization of blood sugars occur over months after PIs are discontinued (switched to an NNRTI) [136,202,203].
- C. Hyperlipidemia.** Untreated HIV-1 infection and particularly AIDS are associated with hypertriglyceridemia and decreased LDL and HDL and cholesterol [204]. Triglyceride levels correlate with elevated α -interferon levels (the host response to HIV-1 infection). Both triglyceride and interferon levels decrease with antiretroviral treatment. By contrast, fasting triglycerides, and total and LDL cholesterol increase significantly after a mean of 7 months of PI therapy, whereas HDL levels do not change [199]. These lipid abnormalities may occur in the absence of significant weight gain or lipodystrophy [199]. Patients treated with PIs for 3 to 36 months have a prevalence of hypertriglyceridemia of 50% to 78% and hypercholesterolemia of 26% to 83% [32]. For many patients, the PI-associated increase in LDL is a correction of the prior HIV infection–associated decrease in LDL. However, some patients will have significant elevations of triglycerides and cholesterol that require therapy. Of the HMG CoA reductase inhibitors (statins), only pravastatin is not metabolized by hepatic CYP3A4 enzymes. Levels of the other statins may increase significantly when coadministered with PIs (see section on individual PIs). If dietary restrictions, weight loss, and pharmacotherapy are not effective, changing the PI to another agent (NNRTI) is an option [205].
- D. Lipodystrophy syndrome** (i.e., fat redistribution syndrome) refers to three body habitus changes discernible in some patients: lipoatrophy, lipohypertrophy, or a combination of the two. Changes occur with either stable or increased total body weight (as opposed to HIV-associated wasting syndrome). Lipodystrophy syndrome is usually accompanied by hyperlipidemia and insulin resistance [206,207]. The onset is often insidious. It is not clear if lipodystrophy is dose related, and it has been reported in patients receiving PI therapy for acute HIV-1 infection and for post-exposure prophylaxis [206]. It also has been reported in antiretroviral-naïve patients and some receiving non-PI-containing regimens [32]. NRTI use (particularly Zert) correlates with lipoatrophy [208]. Unfortunately, at present no definition of lipodystrophy syndrome exists. Most studies have not been prospective, nor have standardized methods to measure changes in adipose tissue always been used. Thus, reports on the prevalence of lipodystrophy syndrome vary widely (1.8%–71%). Efforts are under way to develop standardized criteria and methods. Dyslipidemia associated with insulin resistance and central (truncal/abdominal) adiposity has raised concern about associated cardiovascular disease [209]. Case reports of

coronary artery disease in young patients on HAART have been described [206], as has endothelial dysfunction [210]. The etiology of lipodystrophy remains unknown [211]. There is no known effective therapy at the present time [212]. Switching the PI to another agent has not been effective in reversing lipodystrophy (particularly fat wasting) [207]. Possible therapeutic approaches were recently reviewed [212]. Physical signs are first observed 1 to 7 months after starting therapy.

1. **Lipoatrophy** (fat wasting) is usually manifested as loss of subcutaneous fat in the face or limbs and buttocks. Loss of buccal adipose tissue resulting in hollow cheeks, sunken eyeballs and a cachectic appearance occurs. There may be symmetric loss of subcutaneous fat of the upper or lower extremities and buttocks (particularly in women), resulting in thinning of the limbs and development of prominent veins. Muscle mass and strength in wasted areas is not affected.
2. **Lipohypertrophy** (fat accumulation) manifests as fat deposition in the abdomen in both the subcutaneous and visceral areas (manifested as increased abdominal girth), dorsocervical region (buffalo hump), breasts (sometimes accompanied by pain), face, neck, and salivary glands. Increased abdominal girth is occasionally accompanied by GI symptoms (distention, fullness, bloating). Serum prolactin levels, 24-hour urinary free-cortisol concentrations, plasma cortisol levels, testosterone, β -human chorionic gonadotropin, dehydroepiandrosterone, follicle-stimulating hormone, luteinizing hormone, results of thyroid function tests, and response to dexamethasone suppression are normal. Alcoholism does not seem to be a factor. CT, magnetic resonance imaging, and dual-energy x-ray absorptiometry reveal intraabdominal fat accumulation (particularly of visceral abdominal adipose tissue) and loss of adipose tissue in lipoatrophic areas but no organomegaly or ascites. Mammograms are unrevealing. At least some of the body habitus changes (particularly lipoatrophy and increased abdominal girth) may be due to the normal aging process [213].
3. **Abnormal bleeding.** Increased rates of spontaneous bleeding in PI-treated patients with hemophilia or von Willebrand disease occurs [214,215]. Bleeding occurs in both usual and unusual (e.g., finger joint) sites. Hematuria and mucous membrane bleeding is common. It is more resistant to treatment with factor concentrates, although some patients are able to tolerate continued PI therapy without further episodes [214]. The mechanism of the bleeding tendency is unknown.

E. Bone disease. The incidence of avascular necrosis (AVN) may be increasing in HIV [216], but there is no evidence that AVN or decreased bone density is associated with PI use [217].

VII. Investigational drugs for HIV infection

The goal of this summary is not to detail all drugs now under consideration for trials against HIV. However, a few comments may help the reader become aware of some of the new agents or new combinations now undergoing clinical investigation [218].

A. New formulations of existing medications

1. Sustained-release versions (e.g., of AZT and D4T) to allow for less frequent dosing.
2. Higher dose versions of medications or prodrug formulations to reduce total pill burden (e.g., EFV 600 mg, SQV [Invirase] 800 mg for use with RTV, and FOS-APV, a prodrug of APV [219]).

B. Nucleosides

1. **Emtricitabine-FTC.** Emtricitabine (2',3'-dideoxy-5-fluoro-3'-thiacytidine, or FTC) is a fluorinated NRTI that has potent *in vivo* antiretroviral activity. It is remarkably similar to 3TC, but its pharmacokinetic profile allows once-daily dosing. It was compared with 3TC, combined either with d4T or with an NNRTI, in a randomized blinded study in 468 treatment-naive subjects [220]. The activity and toxicities of the two regimens were comparable. Unfortunately, the M184V resistance mutation, occurring in patients failing a 3TC-containing regimen, confers cross-resistance to emtricitabine. Its long-term toxicity profile needs further evaluation.
2. **Diaminopurine dioxolane (DAPD).** DAPD (B-D-2,6-diaminopurine dioxolane) is a purine nucleoside analogue metabolized to dioxolane guanosine

(DXG), which has potent *in vitro* activity against wild-type and AZT-resistant and 3TC-resistant HIV-1 variants, including those containing the multi-NRTI resistance insert at codon 69. It is well tolerated and shows antiretroviral activity in both naive and treatment-experienced patients, although the antiretroviral activity of DAPD is diminished in patients with prior NRTI experience.

3. **ACH-126,443** is an L-nucleoside analogue RTI with 10- to 20-fold greater anti-HIV activity than 3TC, a half-life of longer than 24 hours, and little apparent mitochondrial toxicity. It maintained activity *in vitro* against virus with the known NRTI-resistance mutations, including M41L, M184V, T215Y, Q151M, and 69S [221]. Clinical studies will soon be under way.
4. (–)**dOTC** The thiacytidine derivative dOTC (2'-deoxy-3'-oxa-4'-thiocytidine) is a racemic mixture similar in structure to 3TC, but with *in vitro* activity against AZT- and 3TC-resistant strains. The negative enantiomer (–)dTC, which maintains antiretroviral activity but has little *in vitro* toxicity, has been selected for further development.

C. Non-nucleoside reverse transcriptase inhibitors

1. **TMC120** (R147681) is a diaminopyrimidine that retains *in vitro* activity against virus resistant to current NNRTIs [222]. In a 7-day study in naive patients, TMC120 demonstrated potent dose-dependent activity, the highest dose 100 mg twice daily, achieving a 30-fold reduction in plasma HIV-1 RNA levels [223]. Mild somnolence was the most common side effect. Studies are in development.

D. Protease inhibitors

1. **Tipranavir** is the first nonpeptidomimetic PI, and has potent *in vitro* activity against HIV-1 resistant to current PIs. In a panel of 105 isolates with at least 10-fold resistance to three or more PIs, only 10 had a greater than fourfold increase in the IC₅₀ for tipranavir, compared with wild-type virus, and only two had a greater than 10-fold increase [224]. Development has been delayed by problems in producing a formulation that offers both adequate bioavailability and an acceptable pill burden. However, when combined with RTV, twice-daily dosing is feasible. Studies in PI-experienced patients are needed to determine if *in vitro* promise of tipranavir translates into clinical utility [225].
2. **Atazanavir** (BMS-232632), a novel azapeptide PI, is highly potent *in vitro*, with *in vitro* activity against most HIV-1 strains that are resistant to 1, 2, or 3 currently available PIs, including NFV, SQV, RTV, and APV. If the virus tested is resistant to four current PIs, greater than sixfold decreases in susceptibility to atazanavir is observed. All viruses resistant to all five current PIs were resistant [226]. Mutations emerging during *in vitro* passage are different from those seen with other PIs, suggesting that cross-resistance to current agents may be limited. This observation remains to be confirmed *in vivo* [226]. Pharmacokinetic studies support once-daily dosing without RTV boosting [227]. Of particular interest, atazanavir appears to be less likely to induce the lipid abnormalities and provoke insulin resistance compared with current PIs. It has little effect on triglyceride levels. Increased bilirubin and jaundice have been reported with atazanavir that was not associated with major alterations in liver enzymes and resolves after the drug is discontinued. Also, cardiac arrhythmias may be more frequent during atazanavir therapy. Clinical studies are under way.

E. Inhibitors of HIV-I fusion and entry

1. **T20-pentafuside**. Work is currently under way to develop medications that inhibit the binding of the HIV envelope protein gp120 to the CD4 molecule on the cell surface or the binding of the viral envelope to chemokine coreceptors (e.g., CXCR4 and CCR5). These are still in early development. Some progress has been made with inhibition of fusion between virus and cell, thus preventing HIV entry into the host cell. These would be used in conjunction with the RT and PI inhibitors. T-20 is a 36-amino acid peptide that corresponds to the HR-2 sequence of the viral envelope protein gp41. For successful fusion to occur, the HR-1 and HR-2 regions of gp41 must form a hairpin structure. However, T-20 binds to HR1 near the fusion domain, preventing interactions with the HR-2 region and fusion of the virus and cell membranes. T-20 must be administered parenterally, but has significant short-term antiretroviral activity when given

by means of i.v. infusion or twice-daily subcutaneous injection [228]. T-20 was generally well tolerated, but some patients developed subcutaneous skin nodules that in some cases evolved into subcutaneous abscesses. They were slow to resolve. Because resistance has developed during T-20 monotherapy, this agent should ideally be used in conjunction with several other agents [229].

2. **T-1249.** Development of a second more potent fusion inhibitor is under way. A 39-amino acid peptide, it retains activity against HIV variants that are resistant to T-20 [230] and has significant antiretroviral activity. Adverse events were uncommon. No cases of subcutaneous skin abscesses were seen. T-1249 elimination kinetics allows once-daily dosing.

F. Other experimental drugs

1. **Interleukin-2 (IL-2).** HIV-1 infection is associated with decreased production of IL-2. Replacement of IL-2 has been viewed as a possible form of immunotherapy [231,232]. Recombinant IL-2 therapy is combined with potent ARVT. Although IL-2 is known to upregulate the production of HIV-1 *in vitro* and may increase viral load, the rate of CD4 cell destruction, and theoretically worsen clinical progression, in clinical trials, high-dose intermittent IL-2 has resulted in impressive increases in peripheral CD4 cell counts. The impact of these changes on long-term clinical outcome is unknown. In addition, lower doses of IL-2 are associated with a sustained increase in natural killer (NK) cell function and interferon- γ production, both of which could be beneficial. For now, IL-2 use in HIV should be restricted to experimental protocols.
2. **Mycophenolate mofetil (MMF, CellCept)** is used in solid organ transplantation. After oral adsorption, it is hydrolyzed to mycophenolic acid (MPA), the active metabolite. MPA is a potent inhibitor of inosine monophosphate dehydrogenase (IMPDH), and thus inhibits the *de novo* synthesis of guanosine nucleotide synthesis [233]. *In vitro*, MPA increases the activity of ABC, ddI, and TDF against wild-type and multinucleoside RT inhibitor-resistant HIV. A clinical trial is planned to assess the safety, tolerability, and antiretroviral activity of combining MMF with DAPD to provide a potent salvage antiretroviral regimen.

VIII. HIV in pregnant women

- A. **Transmission of HIV to the baby during pregnancy.** The rate of perinatal HIV transmission in the absence of ARVT is approximately 25%. Transmission can occur during the course of pregnancy, during labor and delivery, or postpartum through breast-feeding. Two-thirds to three-fourths of transmissions occur during or close to the intrapartum period, particularly in non-breast-feeding populations [234,235]. Perinatal transmission is multifactorial, and influenced by viral, immune, and clinical factors in both the mother and infant (Table 19.12) [236,237]. Maternal plasma viral load is the strongest predictor of transmitting HIV perinatally. Although the risk is low with undetectable plasma viral load, transmission has occurred at all maternal plasma viral loads [238]. Perinatal transmission also appears to be more common with advanced HIV disease (CD4 cell counts of <200/mL), with acute maternal seroconversion, and vaginal delivery. Other obstetric factors thought to be associated with increased perinatal HIV-1 transmission include chorioamnionitis, placenta previa, and invasive interventions such as scalp monitoring, chorionic villus sampling, amniocentesis, cord blood sampling, and placental biopsy [239,240].

B. Antiretroviral use in pregnancy

1. **Introduction.** Antiretroviral therapy should be offered to pregnant women with HIV infection. To prevent perinatal transmission, AZT chemoprophylaxis should be incorporated into the antiretroviral regimen when possible [241]. The use of ARVT by pregnant women to treat HIV infection, to reduce perinatal transmission, or for both purposes should be accompanied by a discussion of the known and unknown short- and long-term benefits and risks of such therapy for infected women and their infants [242,242a]. Because information on the use of ARVT in pregnancy is rapidly evolving, we strongly recommend reviewing the U.S. Public Health Service Guidelines, which are updated regularly at hivatis.org/trtgdlns.html, link perinatal.

Table 19.12. Potential Factors Influencing Mother-to-Child Transmission of HIV

Maternal factors
Advanced HIV disease as measured by
Clinical staging
Low CD4 count
Higher viral loads
p24 antigenemia
Primary HIV infection
Viral phenotype: syncytium-inducing
Viral genotype: resistant HIV mutant strains
Coinfection with other sexually transmitted diseases
Vitamin A deficiency
First born twins
Obstetrical events
Vaginal delivery
Invasive procedures/fetal monitoring during labor
Prolonged premature rupture of membranes (>4 h)
Older maternal age
Cigarette smoking and illicit drug use during pregnancy
Breast-feeding
Unprotected sexual intercourse with multiple partners
Lack of antiretroviral use
Fetal/placental factors
Chorioamnionitis
Prematurity
Low birth weight
Labor/birth canal factors
Cervicovaginal viral load
Local HIV-specific immune response
Maternal-fetal transfusion of blood
Immune factors
Humoral
Neutralizing antibody
Antibody-dependent cellular cytotoxicity
gp 120 V3 loop antibody
MCH concordance
Other
Cell-mediated
Cytotoxic T-lymphocytes
CD8 suppression
Mucosal immunity

Data from Bryson YJ. Perinatal HIV-1 transmission: recent advances and therapeutic interventions. *AIDS* 1996;10(suppl 3):33-42; and Mofenson LM. Mother-child HIV-1 transmission: timing and determinants. *Obstet Gynecol Clin North Am* 1997;24:759-784.

2. Nucleoside reverse transcriptase inhibitors

- a. Zidovudine** was the first agent studied. It reduced perinatal transmission by 67.5% [243,244]. Women with more than 200 CD4 cells/mL received 100 mg oral AZT five times a day initiated between 14 and 34 weeks' gestation and continued throughout pregnancy. When labor commenced, a 2 mg/kg loading dose was given over 1 hour, followed by an i.v. infusion of 1 mg/kg/h that was continued until delivery. Newborn infants received AZT syrup, 2 mg/kg every 6 hours, for 6 weeks after delivery. Perinatal transmission was reduced to 8.3% in 205 women who received AZT versus 25.5% in 204 not on ARVT ($p = 0.00006$) [244]. In August 1994, the U.S. Public Health Service task force issued recommendations for the use of AZT for reduction of

perinatal HIV-1 transmission [245]. This was followed in July 1995 by recommendations for universal prenatal HIV-1 counseling and HIV-1 testing with informed consent for all pregnant women in the United States [246]. Rate of transmission is dependent on when AZT prophylaxis was begun. If begun prenatally, the rate was 6.1%; when begun intrapartum, the rate was 10.0%; when begun within 48 hours of life, the rate was 9.3%; and when begun on day 3 of life or later, the rate was 18.4% [247]. Without AZT prophylaxis, the rate of transmission was 26.6% [247]. The AZT regimen was well tolerated, and the only toxicity observed more frequently in the treatment group was a lower hemoglobin concentration in neonates that was not clinically significant. Hemoglobin levels in the AZT infants were equivalent to the untreated group by week 12. Because the long-term effects are unknown, all exposed children, regardless of HIV status, should receive careful long-term follow-up [248]. The mechanism of reduction in transmission is unknown. The effect of AZT on maternal HIV viral load is insufficient to explain fully its efficacy, especially when given to pregnant women with extensive prior AZT experience [249,250]. Whatever the explanation, the use of AZT by HIV-infected pregnant women in the United States and Europe has resulted in marked declines in perinatal transmission rates, typically as low as 3% to 4%. Because of its complexity and cost, this extended prenatal or postnatal AZT regimen unfortunately has not been used in most developing countries.

- b. Other NRTIs.** All of the NRTIs are classified as FDA pregnancy category C, except for ddI, which is classified as category B [241]. Only AZT, 3TC, and ddI pharmacokinetics have been evaluated in clinical trials [251,252]. The pharmacokinetics of 3TC are not altered by pregnancy, so no dose modification is indicated. In the newborn, the dose is decreased because of reduced clearance in infants 1 week of age. The oral pharmacokinetics of ddI antepartum are not different postpartum, nor are they different from the published mean values for pregnant and nonpregnant women. No dose adjustment is necessary for oral ddI [252].

Mitochondrial toxicity of NRTIs may be of particular concern for pregnant women and infants with *in utero* exposure to nucleoside analogue drugs. Pregnancy may mimic some of the early symptoms of lactic acidosis/hepatic steatosis syndrome. It is unclear if pregnancy is a risk factor for lactic acidosis/hepatic steatosis syndrome, which may have a female preponderance and has similarities to the syndrome of acute fatty liver of pregnancy. The triad of hemolysis, elevated LFT results, and a low platelet count (HELLP syndrome), which rarely occurs during the third trimester, is a concern. The frequency of HELLP syndrome in HIV is not known. Pregnant women receiving NRTIs should have hepatic enzymes and electrolytes assessed more frequently during the last trimester (every 4–6 weeks) of pregnancy, and any new suggestive symptoms should be evaluated thoroughly. Additionally, because of several cases of maternal mortality secondary to lactic acidosis from prolonged use of the combination of d4T and ddI, this antiretroviral combination should be used during pregnancy with caution and generally only when other NRTI combinations cannot be used. Thus far, severe or fatal mitochondrial disease in infants exposed to NRTIs is rare [241].

- 3. NNRTIs (pregnancy category C).** The safety and pharmacokinetics of NVP have been evaluated. A single 200-mg dose at labor onset and a single 2 mg/kg dose to the infant 48 to 72 hours after birth were well tolerated, and no adverse effects occurred in women or infants. NVP pharmacokinetics in pregnant women are similar, although somewhat more variable, than in nonpregnant adults. The half-life and elimination were prolonged in the infants. A single 200-mg dose of NVP was sufficient to maintain serum antiviral activity for the first week of life [241]. One needs to be aware that severe, life-threatening, and, in some cases, fatal hepatotoxicity (fulminant, cholestatic hepatitis and hepatic failure), have occurred in HIV-infected patients receiving NVP with other antiretroviral agents. This has occurred in a small number of individuals receiving NVP with other antiviral agents for postexposure prophylaxis of nosocomial or sexual HIV

exposure. **DLV and EFV** have not been studied in pregnant women. DLV at high doses is known to be teratogenic in rodents. Of seven women who inadvertently became pregnant while enrolled in DLV trials, three had ectopic pregnancies, three had healthy infants, and one delivered a premature infant with a muscular ventricular septal defect [241]. EFV studies have been performed on pregnant monkeys that were given human doses. Of 13 monkey infants, one had a cleft palate, one microphthalmia, and another anencephaly and anophthalmia [253]. Long-term and transplacental animal carcinogenicity studies are not available for these three non-nucleosides. Until additional data are available, EFV and DLV should be given to pregnant women only if the benefits outweigh the potential risks.

4. **Protease inhibitors** cause insulin resistance. Pregnancy is a risk factor for hyperglycemia. It is unknown whether PIs increase this risk. Pregnant women should be aware of the risk of hyperglycemia and informed how to recognize the early symptoms and thus seek medical care if such symptoms develop. Blood glucose levels should be monitored. No data are available regarding drug dosage, safety, and tolerance of any of the PIs in pregnant women or in neonates. Phase I studies of IDV, RTV, NFV, and SQV in combination with AZT and 3TC in pregnant HIV-infected women and their infants are currently under way in the United States. APV and LPV/RTV (Kaletra) have not yet been studied. IDV is associated with hyperbilirubinemia, which may be a concern in neonates. Preliminary data suggest that serum levels of IDV, NFV, and SQV in pregnant women may be lower than in nonpregnant women. PIs are highly protein bound, and it is likely that minimal placental transfer occurs. RTV, NFV, and SQV are classified as pregnancy category B, and IDV, APV, and LPV are classified as pregnancy category C.
5. **Other antiretroviral agents.** Hydroxyurea should be avoided because of significant anomalies occurring in multiple animal species exposed to this drug, and because of the uncertain role of hydroxyurea in HIV. TDF, a nucleotide RTI, is classified as pregnancy category B, but no data are available on its use in pregnant women or neonates [242].

C. Management of pregnant HIV-infected women

1. **Evaluation of the pregnant HIV-infected woman.** In evaluating the patient's history, the clinician should assess factors that enhance perinatal transmission: past sexually transmitted diseases, drug and alcohol use, tobacco use, sexual activity, and lack of condom use [254,254a]. Addressing these practices may reduce perinatal transmission risk nonpharmacologically. A pelvic examination may reveal ongoing conditions that warrant therapy. CD4/CD8 subsets and viral load should be done at least every trimester. Some clinicians suggest HIV genotyping to help guide optimal ARVT. Pregnant women should be treated with an antiretroviral regimen that suppresses HIV replication to fewer than 50 copies/mL.
2. **Antiretroviral therapy.** Despite the lack of controlled clinical trials for most antiretroviral agents in pregnancy, current guidelines indicate that ARVT in pregnant women should generally be the same as for nonpregnant adults. Pregnancy is not a reason to defer therapy. However, the physician should assess whether clear fetal or maternal contraindications exist. Further research is needed of combination ARVT in pregnancy before it can be stated to be without risk to the woman or the fetus. Standard combination antiretroviral regimens for treatment of HIV infection should be discussed with and offered to all pregnant women with HIV infection regardless of viral load. However, some women may wish to restrict exposure of their fetus to antiretroviral drugs during pregnancy but still wish to reduce the risk of transmitting HIV to their infant. For those women, antiretroviral prophylaxis provides benefit in preventing perinatal transmission even for RNA levels of less than 1,000 copies/mL. In a meta-analysis of women with fewer than 1,000 copies/mL HIV-1 RNA at or near delivery, the rate of transmission was only 1.0% if the women received antenatal ARVT (primarily AZT alone) compared with 9.8% among those who received no antenatal therapy [238,241]. Furthermore, although the time-limited use of

AZT alone during pregnancy for chemoprophylaxis of perinatal transmission is controversial because of the potential for resistance development, for women with HIV-1 RNA levels of 1,000 copies/mL, induced resistance is unlikely to occur. This is because there is limited viral replication existing in the patient and the exposure is brief. The development of AZT resistance was unusual among the population of antiretroviral-naïve women with CD4 cell counts of greater than 200/mL who participated in Pediatric AIDS Clinical Trials Group Protocol 076 [241,255]. This combination of observations implies that the use of prophylaxis is reasonable for all pregnant women with HIV infection regardless of antenatal HIV RNA level.

3. **Timing of antiretroviral therapy in pregnancy.** After discussion with her health-care provider about the known and unknown benefits and risks of therapy, the pregnant woman should decide whether to use antiretroviral medication in pregnancy. Because the risk of teratogenicity is greatest during the first trimester, many providers advocate waiting until the end of the first trimester before starting new medications. The clinical, immunologic, and virologic status of the mother must be weighed against the potential effect of antiretroviral agents on the fetus. Pregnant women already receiving ARVT may choose either to continue therapy or temporarily discontinue it until 14 weeks' gestational age [241]. If therapy is discontinued, all drugs should be stopped and reintroduced simultaneously to avoid the development of antiretroviral drug resistance. However, discontinuing antiretroviral medications may result in a surge in the viral load that may have an impact on HIV transmission and the subsequent ability to obtain virologic control.
4. **Treatment and prophylaxis of opportunistic infections.** Treatment and prophylaxis of opportunistic infections during pregnancy should follow the guidelines for nonpregnant women [256]. As with antiretroviral medications, the potential benefits must be weighed against their potential risks. Pneumococcal, hepatitis B, and influenza vaccines may be given during pregnancy if indicated. Live vaccines such as rubella, measles, mumps, and varicella are contraindicated during pregnancy and labor, and during the early postpartum period.
5. **Perinatal transmission and mode of delivery.** Recent studies suggest that cesarean section (C-section) performed before the onset of labor and rupture of membranes significantly reduces the risk for perinatal HIV transmission by 55% to 60% [251,257]. These studies were performed in populations not receiving HAART with PIs or NNRTIs. Whether C-section confers protection to patients on HAART or with undetectable plasma viral loads is not known. Furthermore, for HIV-positive women, C-section may be associated with increased risk for postoperative endometritis and other postoperative morbidity, especially in women with advanced HIV disease [258]. Although the morbidity from C-section was low in the prospective randomized trial, postpartum fever was significantly more frequent than in the women who underwent vaginal delivery (6.7% vs. 1.1%, $p = 0.002$) [257]. HIV-infected women should be informed about these study results, and the decision about method of delivery should be individualized. It is possible that C-section plays the most important role in preventing transmission to the newborn in those women with a high viral load that are not receiving prenatal ARVT.
6. **Timing of scheduled cesarean section and intrapartum antiretroviral medications.** Elective C-section delivery should be performed at 38 weeks of gestation. Amniocentesis should be avoided [259]. This contrasts with recommendations for women not infected with HIV. In that setting, unless amniocentesis is performed, one waits until 39 completed weeks, or the onset of labor, to reduce the chance of complications in the neonate. Cesarean delivery at 38 compared with 39 weeks entails a small but definite increased risk of development of infant respiratory distress requiring mechanical ventilation. This increased risk must be balanced against the potential risk for labor or membrane rupture by waiting until 39 weeks. Women should be informed of the risk/benefit ratio to themselves and their infants in choosing the timing and mode of delivery [241].

Table 19.13. Factors that Influence Adherence to Antiretroviral Therapy

Negative Predictors of Adherence	Positive Predictors of Adherence
Active drug or alcohol use	Good understanding of the benefits of antiretroviral therapy
Regimen complexity and side effects	Regimen ease of administration, tolerability
Depression or other psychiatric illness	Good relationship with provider Social support

For a scheduled cesarean delivery, i.v. the patient should begin receiving AZT 3 hours before surgery, using standard dosing [241]. Other antiretroviral medications taken during pregnancy should not be interrupted, regardless of route of delivery. Because maternal infectious morbidity is potentially increased, clinicians may opt to give perioperative antimicrobial prophylaxis. However, there are no controlled data supporting this approach [241].

- 7. Breast-feeding.** The U.S. Public Health Service recommends that all HIV-infected women completely refrain from breast-feeding to avoid postnatal transmission of HIV-1 to their infants, whether or not they are being treated [241]. These guidelines should be ignored only in developing countries without access to clean water and infant formula [260]. Passage of antiretroviral drugs into milk has been evaluated for only a few antiretroviral drugs. NVP, AZT, and 3TC have been detected in breast milk, and ddI, ddC, d4T, ABC, DLV, EFV, TDF, IDV, RTV, SQV, NFV, lopinavir, and APV have been detected in the milk of rats [242]. Whether ARVT prevents postnatal transmission of HIV-1 through breast milk and whether the drug containing milk is toxic to the infant are both unknown.

IX. Therapeutic management in HIV infection. The goals of ARVT are to maximally suppress viral replication (<50 copies/mL) and to preserve or restore immune system function.

- A. Initiating therapy in chronic or established HIV infection** (Tables 19.13 and 19.14). The optimal time to initiate ARVT in asymptomatic HIV-infected patients is unknown. Initiation of ARVT at CD4 cell counts of greater than 350/mm³ has been associated with a higher rate of AIDS-free survival at 2 years. Suppression of HIV RNA is easier to achieve and maintain at higher CD4 cell counts and lower levels

Table 19.14. Initiation of Antiretroviral Therapy

	CD4 ⁺ T-cell Count	Plasma HIV-1 RNA	Recommendation
Symptomatic	Any value	Any value	Treatment
Asymptomatic, AIDS	<200/mm ³	Any value	Treatment
Asymptomatic	>200/mm ³ but <350/mm ³	Any value	Treatment should be offered
Asymptomatic	>350/mm ³	>55,000 (RT-PCR)	Some clinicians recommend therapy because the risk of developing AIDS in 3yr if untreated is >30%
Asymptomatic	>350/mm ³	<55,000 (RT-PCR)	Many clinicians would defer therapy because the risk of developing AIDS in 3yr is <15%

RT-PCR, reverse transcriptase polymerase chain reaction.

Adapted from the U.S. Department of Health and Human Services and Henry J. Kaiser Family Foundation. Guidelines for the use of antiretroviral Agents in HIV-infected adults and adolescents, August 2001.

of plasma viral load [261,262]. However, no clinical outcome data are currently available, and no comparative trials of immediate versus delayed treatment have been conducted in asymptomatic HIV-infected patients with CD4 cell counts of greater than 350/mL to support this approach.

1. Factors that favor early initiation of ARVT in asymptomatic individuals:

May be more effective in immune reconstitution.

May elicit HIV-specific immune responses that contribute to the effectiveness of ARVT.

May suppress viral reservoirs to a greater degree than more advanced HIV disease.

May be important in prevention of HIV transmission.

May tolerate medications less well in more advanced disease stages.

2. Arguments against early initiation of ARVT:

Longer exposure to antiretroviral agents and the inherent risk of short- and long-term side effects.

Higher cost.

ARVT can elicit immune reconstitution even in advanced disease.

Delays exposure to antiretroviral agents and their side effects.

No clear survival benefit from early therapy.

3. Adherence. The decision of when to initiate therapy depends largely on an individual patient's ability to adhere to therapy, which is crucial for long-term therapeutic success. Patients need to be aware that ARVT is life long, that strict adherence is required for success, and that there are inherent costs, inconveniences of side effects, and impact on quality of life. When choosing therapy, the comparative pill burden, dosing frequency, food requirements, convenience, toxicity, and potential for drug interactions between regimens need to be considered. Thus, ARVT can be individualized. The aid of an adherence counselor is valuable in preparing the patient for all of the above.

a. Factors that influence adherence to ARVT

b. Other patient factors. Patient race, gender, disease stage, and history of substance abuse as well as the physician assessment of patient adherence do not predict adherence.

B. Other considerations regarding initiation of therapy

1. Resistance factors. Concern about the long-term complications of ARVT and about the resistance development has dictated a more conservative approach to initiation of treatment.

2. Symptoms or disease. There is unanimous agreement to initiate therapy in all HIV-infected patients who have symptomatic HIV-infection or AIDS.

3. Viral load. Patients with high plasma viral loads (>100,000 copies/mL) are at a higher risk for disease progression and death (see Table 19.1).

4. Lymphocyte markers. In general, patients with CD4 counts of less than 350 cells/ μ L should be offered therapy. The short-term risk of the development of AIDS in 3 to 6 years, at all levels of plasma HIV RNA (see Table 19.1), is substantial for patients with CD4 cell counts of less than 350/mL. Waiting to initiate therapy when CD4 cell counts are below 200/mL has been associated with shorter survival [263].

C. Selecting the initial regimen for the patient naive to ARVT (Table 19.15).

The initial antiretroviral regimen used offers the best chance for therapeutic success [264]. That regimen must be carefully chosen to achieve this goal. Rational sequencing of antiretroviral drugs is also necessary to preserve future therapeutic options.

1. NRTIs, NNRTIs, and PIs. Randomized clinical trials indicate that either two NRTIs in combination with a PI or two NRTIs and an NNRTI are effective.

a. Viral suppression is achieved in various tissue reservoirs, including the genital tract and CSF with either regimen.

b. Sequence treatment. Both regimens spare a class of antiretroviral drugs for future use. However, the PI-based regimen involves a greater pill burden and more potential for drug-drug interactions, and may be more

Table 19.15. Recommended Antiretroviral Agents for Initial Treatment of Established HIV Infection

Column A	Column B
Strongly recommended	
Efavirenz	Didanosine + lamivudine
Indinavir	Stavudine + didanosine
Nelfinavir	Stavudine + lamivudine
Lopinavir/ritonavir	Zidovudine + didanosine
Saquinavir + ritonavir	Zidovudine + lamivudine
Recommended as alternatives	
Abacavir	Zidovudine + zalcitabine
Amprenavir	
Delavirdine	
Nelfinavir + saquinavir sgc	
Nevirapine	
Ritonavir	
Saquinavir sgc	
Not recommended: should not be offered	
Saquinavir hgc	Stavudine + zidovudine
	Zalcitabine + didanosine
	Zalcitabine + lamivudine
	Zalcitabine + stavudine

Adapted from the U.S. Department of Health and Human Services and Henry J. Kaiser Family Foundation. Guidelines for the use of antiretroviral agents in HIV-infected adults and adolescents, August 2001.

demanding for adherence. An NNRTI-based regimen is easier to use and has fewer potential drug-drug interactions. Conversely, resistance to NNRTI confers cross-resistance to the entire class, limiting the future use of another NNRTI, whereas multiple mutations are required for PI resistance.

2. Specific factors to consider

a. Viral load is an essential parameter to consider when initiating ARVT. A greater virologic response was achieved in ARVT-naïve patients on a PI-based regimen when using LPV/RTV than when using NFV [265]. Preliminary data from another trial suggests that a higher proportion of ARVT-naïve patients with baseline viral loads above 100,000 copies/mL achieved better virologic suppression when receiving LPV/RTV and two NRTIs versus NFV plus two NRTIs [266].

b. Resistance. To avoid the development of resistance, all three selected antiretroviral agents must be started simultaneously [267].

c. RTV boost. Although no trial has been conducted to prove the benefit of the inhibitory effect of RTV on the cytochrome P-450 system, it has been used to enhance the pharmacokinetics of other PIs. This boosting results in higher plasma levels and prolonged half-life of the boosted PI, allowing a reduction in the number of pills and daily doses used (see section on PI dosing).

3. Regimens. Two agents from column B and one agent from column A in Table 19.15 are used

a. Nucleoside combinations listed as strongly recommended (column B in Table 19.15) have similar potency and are usually chosen based on their adverse effect profile, ease of administration, and patient preference.

b. Once-daily dosing. At present, among the NRTIs only ddI is recommended. A daily dose of 3TC (300 mg/day) has yielded good results, but trials are lacking.

c. Regimens to avoid or for special attention. The combination of AZT and d4T are antagonistic and should not be used [268]. The combination of either ddC and ddI, ddC and 3TC, or ddC and d4T may have overlapping and additive toxicity and are not recommended.

4. Specific classes

a. Among the PIs, SQV in the hard-gelatin capsule formulation (SQV-HGC) has poor bioavailability and is not recommended unless boosted with RTV. It is associated with inferior virologic and clinical outcome compared with other PIs when used as the only PI [269,270]. Using SQV soft-gelatin capsules (SQV-SGC) has improved bioavailability but requires a high pill burden. The addition of RTV allows a decrease in the number of pills and twice-daily administration. This combination (SQV-SGC/RTV) has been shown to be comparable with IDV or RTV alone [271]. Once a day administration of SQV-SGC (1,600 mg) together with RTV (100 mg) has shown a favorable pharmacologic profile in normal volunteers [272]. Preliminary information in HIV-infected patients appears promising.

b. RTV, although potent, when used at full dose (600 mg twice daily) causes frequent and severe side effects. It interferes with the metabolism of numerous drugs through the cytochrome P-450 system. Currently its use is limited to boosting other PIs.

c. IDV has a short half-life, requiring dosing three times daily and food restriction for better absorption. When administered every 8 hours, in combination with two nucleosides, it is effective [181,273] even in advanced HIV disease with previous exposure to AZT (45% of patients with CD4 cell counts of <50/mL achieved HIV RNA counts of <50 copies/mL at 24 weeks) [274]. The addition of RTV (100 mg twice daily) inhibits IDV metabolism, resulting in an increased area under the curve (AUC) and trough levels [275,276]. When IDV is used (800 mg twice daily), it is boosted with RTV (100 mg twice daily). This combination eliminates the food restriction requirement, but the risk for nephrolithiasis may be higher [277]. The daily fluid intake requirements (see section D.5.b) cannot be waived.

d. NFV can be dosed twice daily, and resistance to this PI does not necessarily confer cross-resistance to other PIs. This makes salvage therapy possible with another PI-containing regimen. However as noted in section 2.a above, NFV may be inferior to LPV/RTV in viral suppression.

e. APV (1,200 mg daily or 600 mg twice daily) boosted with RTV (100 mg daily or 100 mg twice daily) yields an increase in the AUC and trough levels that are similar to those achieved with the current recommended dose of 1,200 mg orally twice daily [278]. The use of APV boosted with RTV allows the use of fewer APV capsules, although the pill burden remains significant.

f. Summary of PIs. Only a few comparative trials have been done to compare PIs. One large multicenter trial did not find any differences in the percentage of patients with an HIV-1 RNA level of less than 20 copies/mL at 72 weeks between RTV, IDV, or SQV/RTV combination therapy. Only half of the patients achieved viral loads of fewer than 20 copies/mL [271]. Comparative trials among PI-based regimens that include the newer PIs are lacking, except for preliminary information as noted in section 2.a above.

5. Combinations of NRTIs and NNRTIs. Two NRTIs and an NNRTI (either NVP or EFV) have shown good efficacy with durable viral suppression achievable even in subjects with high (>100,000 copies/mL) viral loads. EFV and NVP have a convenient dosing schedule with few pills and therefore have gained wide acceptance as first-line regimens. Care should be exercised to prevent failure with these regimens because resistance to one NNRTI usually confers complete cross-resistance to the entire class. DLV requires dosing three times daily and is seldom used in ARVT-naive patients. However, DLV increases the levels of PIs and may have a role in PI boosting in salvage regimens where both an NNRTI and PI are used (see section B.3.d.(6)).

6. **Comparisons between regimens.** Prospective and retrospective studies comparing PI-based regimens (RTV/SQV or IDV every 8 hours) to NNRTI (EFV)-based regimens have shown that the latter are associated with better virologic response rates regardless of baseline viral load [27,279].
7. **Alternative regimens.** Three NRTIs with ABC as one of the agents for ARVT-naïve patients has generated great interest given its ease of administration. AZT, 3TC, and ABC are marketed in combination in one pill (Trizivir) given twice daily. This regimen had similar virologic response rates when compared with IDV plus two NRTIs, particularly in patients with baseline HIV RNA levels of less than 100,000 copies/mL. For patients with HIV RNA levels of greater than 100,000 copies/mL, a three-NRTI combination may not be as potent as the standard PI- or NNRTI-based regimens [280,281] and is not currently recommended for routine use in these patients.

D. Monitoring ARVT

1. **Monitoring response to therapy.** Reviewing the details of the ARVT regimen after instituting therapy should be routine practice. This is always useful in disclosing any misunderstandings regarding dosing or food requirements that could lead to failure. Prompt corrective actions may reestablish the regimen's success early on.
2. **Plasma HIV-1 RNA analysis** should be performed 4 to 8 weeks after starting therapy. A decline of at least 1 log is a satisfactory response. The ultimate goal of therapy (HIV RNA <50 copies/mL) is usually achieved within 6 months. HIV-1 RNA should then be repeated every 3 months to monitor efficacy. Significant declines in HIV-1 RNA at 8 weeks predict the achievement (at 6 months) of HIV-1 RNA levels of less than 50 copies/mL [282]. Once the HIV-1 RNA level has been less than 50 copies/mL, episodic levels of greater than 50 copies/mL but less than 200 copies/mL, or "blips," may occur. In a retrospective analysis of 241 patients receiving triple-combination therapy for 4.5 years who achieved viral suppression, blips occurred in 40%. There was no association between these blips and virologic failure [283]. These blips do not warrant changes in therapy.
3. **Lymphocyte markers** should be measured every 3 months or when clinically indicated in all patients receiving ARVT. A significant increase in CD4 cell counts (>160/mL) at week 48 after initiation of HAART is seen in most patients [284]. There is considerable variation in the degree and timing of the response. The absence of an increase in CD4 cell count does not indicate ARVT failure if the viral load has declined appropriately. Greater median maximum CD4 cell count changes are seen with PI-based regimens, younger patients, and higher baseline CD4 cell counts [285,286].
4. **Other laboratory and clinical parameters** are monitored depending on the side effect profile of the different antiretroviral agents, potential for drug interactions, and the patient's specific comorbid conditions (e.g., hepatitis C, seizure disorders, renal insufficiency).
5. **Poor response.** Failure of ARVT is defined as the inability to achieve an undetectable plasma HIV RNA level within 4 to 6 months of starting therapy, or a less than 0.5 to 0.75 log₁₀ reduction in plasma HIV RNA by 4 weeks after starting therapy or less than 1 log₁₀ reduction by 8 weeks. If an adequate virologic response is not obtained or is suboptimal, adherence and possible drug-drug interactions needs to be assessed.
6. **Resistance development.** Reappearance of virus after initial suppression to undetectable levels or a reproducible significant increase (threefold or greater) from the plasma HIV RNA nadir that is not attributable to intercurrent infection, vaccination, or problems inherent to the test suggests the development of resistance.
7. **Causes of ARVT failure:**
 - Development of resistance (most common cause)
 - Drug-drug interactions
 - Use of a suboptimal regimen
 - Poor absorption leading to inadequate ARV levels

- E. Salvage therapy.** The choice of ARVT after use of an initial regimen (salvage therapy) should be based on a careful review of past antiretroviral treatment, adherence to the current regimen and the use of resistance testing. Currently there are two types of tests available to assess HIV resistance.
- 1. Genotype testing** detects drug resistance mutations by either sequencing relevant genes (RT and protease) or by using probes to detect selected mutations. Assessment of viral genotype involves comparison of the relevant genetic region of the test sample with a consensus wild-type sequence. The results report any amino acid substitutions at the codons tested. The interpretation of genotypic tests remains complex. Assays may vary in their performance at different codons, and their reliability may vary between laboratories. ARVT selection based on genotype results in concert with expert advice has been linked to a better outcome [287–289]. Because wild-type virus usually outgrows resistant virus, resistance testing should be performed while the patient is on antiretroviral medications or within 2 weeks of their discontinuation [290]. Some laboratories report the results of genotype testing accompanied by a virtual phenotype report. Phenotype testing is performed with viral strains of similar genotype resistance pattern to the patient's viral strain. The influence of this interpretation on clinical outcome has not been definitively established but is commonly used in practice. Viruses resistant to newer antiretroviral medications have not been studied long enough to establish genotype resistance patterns, and the patient's genotypic pattern may be difficult to match with the existing ones in the database. In addition, some mutations can increase drug susceptibility.
 - 2. Phenotype testing** uses cells infected with a fixed amount of the patient's virus. This is intuitively an excellent approach to the study of clinical resistance. Unfortunately the only study conducted to compare both genotype and phenotype testing to standard of care failed to show an effect on the clinical outcome and warrants further study [291].
- F. Therapeutic drug monitoring (TDM).** Factors other than poor adherence to ARVT or viral resistance may be responsible for suboptimal response or failure. These include inadequate drug levels caused by differing levels of phosphorylation to the active moiety (NRTIs), membrane efflux pumps (described for PIs and NNRTIs) that extrude ARVs from cells, differing ability to absorb and metabolize drugs, as well as drug-drug interactions. These factors may help explain inter- and intra-subject drug level variability. A significant correlation between *in vivo* antiviral activity and plasma drug concentrations has been demonstrated for PIs [292]. The PI plasma levels are inversely correlated with plasma HIV RNA levels [293]. PIs seem to be the best candidate for TDM because their AUC and trough levels appear to predict their efficacy. TDM may become, along with resistance testing, instrumental in optimizing ARVT. The use of the inhibitory quotient (IQ = the trough concentration of a drug in plasma divided by the *in vitro* IC₅₀) is being studied in clinical trials to assess its role in clinical management.
- G. Laboratory monitoring of potential side effects of antiretroviral medications**
- 1. Bone marrow suppression** is caused by AZT, a widely used agent. A baseline complete blood count and differential are repeated at least every 3 months or when clinically indicated. A different NRTI can be substituted if anemia occurs. Erythropoietin for patients with inappropriately low erythropoietin levels is an option for patients with fewer ARV alternatives, but requires parenteral administration and constitutes an additional expense. Neutropenia is managed by changing AZT to another NRTI, or by administering parenteral granulocyte colony-stimulating factor. Substitution of the ARV is the preferred choice.
 - 2. Hepatitis.** Retrospective data were compiled from 10,611 HIV-infected patients with baseline LFT results showing less than grade 1 toxicity enrolled in 21 AIDS Clinical Trials Group (ACTG) studies including all drug classes between 1991 and 2000. An overall rate of hepatotoxicity of 9% was noted [294]. The development of grade 3 to 4 toxicity led to permanent discontinuation of ARVT in 23%. Most of these patients developed toxicity after 24 weeks, but in some it occurred quite early. PIs, particularly RTV, were associated with the highest

rate of hepatotoxicity, but those on NRTI regimens were more likely to die or to discontinue therapy. Among NNRTIs, DLV was associated with the lowest rate and NVP had the highest rate of hepatotoxicity and permanent discontinuation of therapy and the only hepatic-related death in this class. Overall, 2.5% of deaths were related to hepatotoxicity. Elevated LFT results are seen more frequently in patients coinfecting with hepatitis B or C receiving ARVT. It is difficult to know the exact etiology of the liver damage.

3. **LFTs should be conducted** at baseline and every 3 months in stable patients. They should also be repeated when ARVT changes occur and whenever clinically indicated. More frequent monitoring of LFT results (every 4–6 weeks) is indicated in patients with underlying liver disease. Given the potential for fatal hepatotoxicity with NVP, transaminases should be monitored during the first 12 weeks of therapy. NVP should be discontinued if moderate to severe abnormalities (greater than three times the ULN) develop (NVP package insert [125]).
4. **Hyperglycemia** (see section VI.A). Blood glucose levels should be monitored every 3 months or when clinically indicated. The management of diabetes in HIV-infected patients is the same as in non-HIV-infected patients.
5. **Development of dyslipidemias** (see section VI.C–D). A baseline fasting serum lipid profile should be obtained before initiating ARVT that includes a PI or an NNRTI. The lipid profile should be repeated in 3 to 6 months [295]. Baseline screening for cardiovascular risks and factors that exacerbate dyslipidemia is indicated and should be repeated at least yearly thereafter unless abnormalities are detected or other risk factors for dyslipidemia are present.
6. **Management of dyslipidemias.** Clinical studies to determine the most appropriate treatment for dyslipidemia are ongoing. Meanwhile, initiating treatment according to the NECP guidelines appears reasonable (see section on PI drug-drug interactions with lipid-lowering agents). Preliminary data suggest that switching the PI to NVP (in patients naive to NNRTI) or to ABC may be useful in controlling dyslipidemia, but switching to EFV has yielded inconsistent results.
7. **Lactic acidosis** (see section V.A.3). Currently there are no specific recommendations for laboratory monitoring for lactic acidosis in patients without symptoms (see section on NRTI class-related adverse effects). Risk factors for lactic acidosis include treatment with NRTI, African-American ethnicity, obesity, hepatitis C, and female gender.
8. **Pancreatitis** (see section V.A.5.g.(1)). Unless symptoms of pancreatitis develop, monitoring amylase and lipase levels is not routinely recommended. Risk factors include a history of pancreatitis, use of ddI, d4T, or ddC, CD4 cell count below 50/mL, alcohol use, obesity, hypertriglyceridemia, gallstones, or use of medications that can cause pancreatitis. When pancreatitis occurs, all medications should be held until resolution is complete. A different antiretroviral agent should be substituted for the agent felt to be the cause of the pancreatitis. Hyperamylasemia of nonpancreatic origin may occur in HIV-infected patients. A serum lipase should be obtained in this setting. Patients with asymptomatic elevations of serum amylase and lipase levels (up to three times the ULN) should be monitored clinically without a change in therapy.
9. **Neuropathy** (see section V.A.5.g.(2)). Glucose level, vitamin B₁₂ level, and thyroid function tests should be obtained in HIV-infected patients presenting with signs and symptoms of neuropathy. Electrophysiologic studies may not be necessary for the diagnosis of typical distal symmetric polyneuropathy but may be useful in diagnosing other neuropathies. Analgesics should be offered in a stepwise fashion. Supplementation with antidepressants or antiseizure medications might be useful. If alternative non-neurotoxic antiretroviral agents are available, they should be substituted.
10. **Myopathy** (see section V.A.4.f.(3)). When myopathy is suspected, muscle enzymes should be measured and muscle biopsy performed. Antiretroviral

agents should be discontinued until symptoms and laboratory value abnormalities resolve.

11. **Bone disorders** (see section VI.E). Osteopenia and avascular necrosis usually involving weight-bearing joints occur in HIV-infected patients receiving ARVT. No definitive association with a particular class of antiretroviral agent has been confirmed. Currently there are no specific recommendations for monitoring of these disorders.
12. **Fat redistribution syndrome** (see section on PI class-related toxicities). A definition of fat redistribution syndrome has yet to be established. This term describes a variety of changes in subcutaneous and visceral fat, most commonly loss of subcutaneous fat on the face and legs, and dorsocervical fat deposition (buffalo hump) and increase in visceral fat. Fat redistribution does not require a specific intervention unless cosmetically disturbing to the patient. Changing ARVT has not proven successful, but large trials have not been conducted; growth hormone has yielded unimpressive results. Glitazone did not demonstrate a significant effect on fat redistribution in a small placebo-controlled trial. Fat redistribution syndrome may coincide with dyslipidemia and hyperglycemia. There are no recommended laboratory tests to monitor for fat redistribution syndrome.

H. Changing therapy. Antiretroviral therapy may need to be changed for several reasons: toxicity, treatment failure, convenience, or drug interactions.

1. **Toxicity** (see section on individual agent adverse effects). If a side effect can be attributed to a particular antiretroviral agent with certainty (e.g., anemia from AZT or nephrolithiasis with IDV), and maximal viral suppression has been achieved, the antiretroviral agent may be substituted (see Table 19.15). If the adverse effect requires holding the antiretroviral agent (e.g., pancreatitis), all antiretroviral medications should be held. A new regimen with a different side effect profile should be used once the adverse event has resolved.
2. **Treatment failure** is the inability to obtain a significant decrease in viral load or development of an increase in viral load above 200 copies/mL after achieving viral suppression (<50 copies/mL). In general, agents to which the patient has not been exposed offer the best opportunity for further suppression. Cross-resistance among antiretroviral medications may make it difficult to achieve this goal. A better outcome can be expected when past history of ARVT use is obtained, resistance testing is employed, and expert opinion is used in concert to guide the selection of ARVT for salvage therapy. At least two clinical trials have demonstrated the short-term benefit of genotypic and phenotypic resistance testing to guide the selection of salvage therapy. There are scant data supporting the longer term benefit of resistance testing. Some recent yet unpublished trials have failed to show the benefit of resistance testing [291]. The contrasting results of these trials may be due to many factors, including poorly defined thresholds for resistance, difference in the number of new drugs given, or different past histories of antiretroviral agents used. Nonetheless, many clinicians consider resistance testing the standard of care in this setting at the present time.
3. **Cross-resistance** among the NRTIs has emerged as one of the most important issues related to sequencing therapy. Mutations at RT codons 41, 67, 70, 210, and 215 (referred to as thymidine analogue mutations [TAMs] or nucleoside analogue mutations [NAMs]) cause cross-resistance among the NRTIs. 3TC, when used in regimens that are not suppressive, produces rapid development of resistance conferred by a single point mutation at codon 184 that confers complete 3TC resistance but increases susceptibility to AZT and the nucleotide analogue TDF. The accumulation of increasing numbers of TAMs is associated with increased phenotypic resistance to all of the NRTIs. Resistance mutations with the use of NNRTI often confer cross-resistance to all NNRTIs. Consistently, the K103 mutation of RT that can be selected by EFV, NVP, or DLV confers resistance to all three NNRTIs. The RT mutation Y 181C, selected by NVP, does not exclude the subsequent use of EFV.
4. **Resistance to the PIs** usually requires the development of three or more specific mutations on the protease-encoding gene. SQV's primary mutations include

G48V and L90M. The latter is a secondary mutation for all the other PIs and may confer cross-resistance to all PIs except APV. IDV's primary mutations include M46I/L and V82A/F/T. The latter mutation confers cross-resistance to RTV. NFV has a unique resistance pattern, with D30N selected in two-thirds of patients. This mutation does not compromise the activity of other PIs. Some clinicians therefore prefer to use NFV as the initial PI. However, approximately one-third of individuals who fail NFV develop L90 M, which as noted causes broad PI cross-resistance. APV also has a unique resistance pattern, with I50V as the primary mutation. Thus far this has not been identified as conferring cross-resistance to other PIs. Early failures on APV can be managed successfully by switching to other PI-containing regimens. LPV appears to have a high genetic barrier to the development of resistance compared with other PIs. Perhaps a larger number of mutations must accumulate for resistance to be detected.

5. **Convenience.** European and North American trials support making changes to simplify therapy (fewer pills, less frequent dosing). This should be done only when maximal viral suppression has been achieved. Switching a patient from a less convenient PI inhibitor–based regimen to an NNRTI-based regimen is safely done as long as adherence continues.
- I. **Therapy for acute or primary HIV-1 infection.** Treatment of acute or primary HIV infection can dramatically suppress HIV-1 RNA and preserve HIV-1–specific immune responses. Several uncontrolled studies have documented normalization of CD4⁺ and CD8⁺ lymphocyte subsets as well as virologic suppression. Furthermore, preservation of HIV specific CD4 cell lymphoproliferative responses and stabilization of the T-cell receptor repertoire have been observed (see following section on structured treatment interruptions). Combination ARVT is recommended for acute HIV infection.
- J. **Virus characteristics.** The virus is relatively uniform genetically and typically of a non–syncytium-inducing phenotype. Moreover, infection may not be fully established in all tissues until some time after exposure [296]. These features may render the infection easier to control. Clinical trials with potent antiretroviral medications are under way to determine the feasibility of intense time-limited treatment for acute HIV infection.
- K. **Structured or supervised treatment interruptions (STIs).** With effective HAART, HIV-specific cell-mediated immunity may actually be decreased because the immune system is not exposed to HIV antigens. In theory, during STI when HAART is stopped, HIV antigen is once again provided by the rebound in viral replication. This may stimulate HIV-specific T-helper and cytotoxic T-lymphocyte responses.
 1. **Acute HIV infection.** STI may be useful in acute, primary HIV infection. Small pilot studies of individuals with HIV infection of less than 180 days, who had achieved good virologic control with HAART, showed increases in median cytotoxic T-lymphocyte responses after STI. A similar response was achieved in other subjects after a second round of STI. Sixty percent achieved viral suppression after STI in the absence of further HAART. Larger studies are obviously needed to clarify the role of STI in acute or recent HIV infection.
 2. **Chronic HIV infection.** Several small nonrandomized, uncontrolled studies of STI, using different durations of drug cessation, have yielded conflicting results. However, in all of these studies treatment interruption was followed in the majority of patients by an increase in viremia. The time to viral rebound after discontinuation of HAART varied from as early as 2 to 3 days to as late as 3 weeks. In one study, rebound viremia exceeded pretreatment levels by 27-fold [297]. Upon reinitiation of HAART, although viral suppression was observed, reduction in viral load was delayed by up to 2 months compared with the initial virologic response. Other features of concern include the inconsistent increase in CD4 cell count, the inconsistent HIV-1–specific T-cell helper response to p24 antigen (recovery in only 2 of 12 patients in one study), and inconsistent lymphocyte proliferative response to HIV-1 p24 antigen in only 4 of 22 patients [298]. Fortunately, no mutations associated with resistance developed.

3. **Modified STI.** A small preliminary study using shorter cycles of therapy (7 days) [299] showed no rebound in viremia.
4. **STI summary.** It is not clear which patients with chronic HIV infection are most likely to benefit. Whether STI leads to lasting enhancement of the immunologic response to HIV remains to be firmly established, and further data are needed before its use is adopted. Treatment interruptions, especially in chronic HIV infection, can be potentially dangerous, leading to dramatic increases in HIV viral load and precipitous declines in CD4 cell counts.

X. Use of antiretroviral agents in children

A. Introduction. The pathogenesis of HIV infection and the general principles of ARVT in infants, children, and adolescents are similar to those in adults but there are unique considerations. In addition, the dramatic decline in rates of maternal-infant transmission of HIV when ARVT is given to pregnant women (see section VIII) has resulted in far fewer HIV-infected infants in the United States. This has limited the available number of ARVT-naïve subjects for performance of clinical trials. Thus, health-care providers for HIV-infected infants, children, and adolescents should seek consultation with, or refer such patients to, a pediatric HIV specialist. Ideally, these children should be treated in a center with access to pediatric clinical trials [40,235]. Pediatric guidelines for ARVT use are available at www.hivatis.org, and information on pediatric clinical trials is available at www.hivactis.org.

B. Differences between adult and pediatric HIV infection that may impact use of ARVT

1. **Paucity of pediatric clinical trials data.** Decisions about use of ARVT in children are complex and may rely on assumptions based on adult data only. This is because infants and children make up only 1% to 2% of the HIV-infected population in the United States, and traditional pharmaceutical research practices use testing of compounds in adults before children.
2. **Pediatric acquisition of HIV.** Nearly all infants and children in the United States, and in much of the world, have acquired HIV vertically from their mothers. Thus, infection occurs during the development of the immune system, at a time when the thymus is active and CD4⁺ lymphocytes circulate in the blood in great numbers. Clinical and immunologic manifestations of pediatric HIV, therefore, differ from those of adults [235]. For example, immunologic compromise in children is associated with CD4⁺ lymphocyte counts that would be in the normal range in adults. Thus, starting points for ARVT differ in children [40,235].
3. **Virologic parameters.** Children tend to have a greater “set point” of plasma RNA copy numbers. This may be because of the establishment of infection in the developmentally immature immune system at a time when high numbers of CD4⁺ lymphocytes are circulating in the blood. Thus, a 2 log reduction of 500,000 copies/mL yields a posttherapy viral load of 5,000 copies/mL. Five thousand copies would be considered a failure in adults, but may be tolerated in such children.
4. **Pharmacokinetic parameters.** Plasma clearance of many drugs is increased in children relative to adults. Clearance also may change during puberty. Current guidelines suggest that adolescents in early puberty (Tanner stages I–II) be given pediatric dosage of antiretroviral agents, whereas those in late puberty (Tanner V) should be dosed using adult schedules [40]. Clinical trials are assessing proper dosing, especially for PIs, in midpuberty.
5. **Pediatric formulations.** Not all antiretroviral agents have been licensed for use in children, nor do all have palatable liquids available for use in children who may not be able to swallow large pills.
6. **Adherence issues in children and adolescents.** Because essentially all children and many adolescents require supervision of ARVT administration, there is a necessarily different dynamic of working with a family unit rather than a single patient. Issues affecting adherence include willingness of a child to take a drug. There are also feelings of guilt in mothers who transmitted the virus. This may affect the interaction between caregiver and receiver. There is the complexity of the need to administer the drug in the fasting or fed state when

the infected infant is fed so often. There is the unwillingness to disclose the fact of HIV infection status to young children, their school officials, or other family members, creating a situation where doses are missed frequently. Adolescents may have additional issues revolving around denial and fear of HIV infection, distrust of the medical establishment, unstructured and chaotic lifestyle, and lack of familial and social support [40].

C. ARVT regimens for HIV-infected children. Despite the difficulties posed by the lack of clinical trial data, and differences between adult and pediatric HIV infection mentioned previously, all antiretroviral agents approved for use in adults may be used in children when indicated, irrespective of labeling notations. Continually updated pediatric guidelines are published electronically along with adult guidelines by U.S. Public Health Service task forces. These are available at www.hivatis.org. In general, the most strongly recommended ARV regimen for children is two NRTIs plus one PI. Generally the PI is NFV or RTV. For older children who can swallow capsules, two NRTIs plus EFV is an increasingly used alternative initial therapy. Other combinations include NVP plus two NRTIs or even ABC/AZT/3TC. The consultation of a pediatric HIV specialist should be sought because the field is rapidly changing.

20. INFECTIONS IN TRANSPLANTATION

Sally H. Houston and John T. Sinnott

Transplantation patients have dramatically increased in numbers over the past 40 years. In 2000, approximately 45,000 bone marrow transplants were performed worldwide, and in the United States, 4,954 liver, 2,198 cardiac, 13,372 kidney, 956 lung, 48 heart-lung, and 435 pancreas transplants were performed. As of November 2001, there were 78,802 individuals awaiting organs. One-third of patients waiting for a heart or liver die before an organ becomes available.

The immunosuppressive regimens yield continual risk for infection. This chapter and references to other chapters will orient the reader to the fundamental causes of infection.

BASIC PRINCIPLES

I. Donor selection is the responsibility of a trained procurement team. Because cadavers are a major source of tissue for all but bone marrow recipients, infection with human immunodeficiency virus (HIV) must be ruled out [1]. In general, hearts and kidneys are harvested from donors under 50 years of age, and livers are harvested from donors 2 months to 65 years of age [2], with exceptions made on a case-by-case basis. For solid organs, organ size and ABO compatibility but not human lymphocyte antigen (HLA) compatibility are considered. For bone marrow transplantation (BMT), HLA typing is very important [1].

A. General contraindications for organ donation include systemic malignancy or active infections [1]. Covert bacteremia should be excluded by history and blood cultures.

B. Infectious disease considerations are paramount in this setting. The donor should be screened for syphilis, hepatitis B (HBV) and C viruses (HCV), HIV-1, HIV-2, human T-lymphotropic virus type I (HTLV-I), Epstein-Barr virus (EBV), *Toxoplasma gondii*, and cytomegalovirus (CMV) antibody [3]. These tests guide transfusion and prophylactic strategies after transplantation [4].

II. Recipient selection. Every indication that the recipient will be compliant is crucial. Findings of the presence of varicella-zoster virus (VZV), HIV-1, and HIV-2, HTLV-I, syphilis, toxoplasma, HBV, HCV, EBV, herpes simplex virus (HSV), and CMV antibody guide management. A purified protein derivative (PPD) test (see Chapter 11) should be performed. Patients from developing countries and those from the rural southern United States should have three stool specimens screened for *Strongyloides* cysts. Carriers should be treated with thiabendazole or ivermectin [5]. Transplantation in HIV-positive recipients has been reviewed [6]. Recommendations are to restrict renal transplantation to those with a CD₄ count of greater than 200, and to restrict hepatic grafts to those with a CD₄ count of greater than 100 and an undetectable viral load for at least 3 months on a stable antiretroviral regimen.

Contraindications include recent hemorrhage, active infection, or malignancy [1]. Pretransplantation bacteremia or pneumonia is associated with a poor outcome.

A. Kidney recipients should have disease in which recurrence in the allograft is unlikely. Contraindications include comorbid disease that limits life expectancy to less than 2 years.

B. Heart recipients usually have irreversible vascular, valvular, or idiopathic cardiomyopathy. Contraindications include irreversible pulmonary hypertension, recent pulmonary infarction, and severe peripheral vascular disease [1].

C. Liver recipients must have end-stage cirrhosis, Budd-Chiari syndrome, or primary hepatocellular carcinoma. Children receive transplants for congenital cirrhosis, primary biliary atresia, and metabolic defects such as α_1 -antitrypsin deficiency, tyrosinemia, and glycogen storage disease types I and IV. Contraindications include the extrahepatic complications of cholangiocarcinoma or advanced cardiopulmonary disease. Relative contraindications include patient age over 55 years, portal vein thrombosis, hepatitis B e antigen (HBeAg) seropositivity, active alcohol abuse, or prior hepatobiliary or portocaval surgery [7].

D. Bone marrow recipients. See later in this chapter, under Bone Marrow Transplantation.

III. Immunosuppressive therapy. The ultimate goal of immunosuppression is, after engraftment, to induce tolerance [1]. Most regimens use a combination of agents. Customarily, a daily maintenance regimen is established. Pulse therapy (corticosteroids or antilymphocyte globulin [ALG]) is used for episodes of rejection. Infection and neoplasia [8] occur as a consequence of immune suppression. In cardiac transplantations, about 30% of infections occur after therapy for rejection [9].

A. Cyclosporine, a cyclic polypeptide, inhibits interleukin-2 (IL-2) production, thereby suppressing CD4 proliferation and activation of cytotoxic T cells. Because IL-3 is not inhibited by cyclosporine, the suppressor T-cell population increases, and the ratio of suppressor to cytotoxic cells is increased. Cyclosporine does not lyse effector cells, so it **is more useful for prophylaxis**. Infectious complications are reduced because lower dosages of steroids can be used. Cyclosporine is metabolized in the liver, and its effects are dose dependent [8]. Optimum trough levels vary depending on the type of organ transplanted, time interval since transplantation, and level of rejection.

1. Side effects include nephrotoxicity, hepatotoxicity, hypertension, hirsutism, tremor, gingival hyperplasia, and tumorigenesis. Nephrotoxicity may be potentiated by high-dose trimethoprim-sulfamethoxazole (TMP-SMX) aminoglycosides, vancomycin, erythromycin, amphotericin B, acyclovir (ACV), and ganciclovir (GCV) [10]. Although most patients tolerate prolonged therapy, with long-term cyclosporine use, the kidney is subject to renal vasoconstriction and possible hypertension or nephrotoxicity [11].

2. Monitoring levels is important. **Ketoconazole and erythromycin increase cyclosporine levels** and side effects, whereas rifampin, isoniazid (INH), and TMP-SMX lower levels, increasing the risk for rejection [10]. Drugs stimulating cytochrome P450 activity will result in more rapid metabolism and lower levels of cyclosporine. Idiosyncratic interactions such as renal failure after single doses of aminoglycosides, amphotericin B, or fluoroquinolones may occur. St. John's wort decreases cyclosporine levels [12].

B. Tacrolimus (Prograf; **previously called FK506**) was approved in 1994 for primary prevention of rejection in patients receiving liver transplants. The drug also has been used as rescue therapy for graft rejection unresponsive to other immunosuppressive drugs. Tacrolimus is a bacteria-derived macrolide unrelated to cyclosporine but with similar activity [13]. It interferes with cytotoxic T-cell proliferation and production of IL-1 and -2, interferon- γ (IFN- γ), and IL-2 receptors. It is approximately 10 times more active than cyclosporine, and reduces the incidence of acute rejection and steroid-resistant rejection. Adverse effects and drug interactions are similar to those seen with cyclosporine, although there is an increased risk for glucose intolerance associated with tacrolimus [14].

C. Corticosteroids interfere with production of IL-1 through IL-5, IFN- γ , and immunoglobulin secretion. Acute inflammatory responses are blunted. They predispose to side effects, especially infection. Leukocytosis occurs, but rarely with a white blood cell count of greater than 20,000/mm³ without an underlying infection. Osteoporosis, aseptic hip necrosis, glucose intolerance, cataracts, and hypercholesterolemia often complicate long-term therapy [8,10]. **Modern immunosuppression involves attempting to use a dose that balances rejection and side effects.**

D. Azathioprine, a purine analogue, interrupts DNA synthesis, thereby suppressing T-cell proliferation. It is used in rejection prophylaxis. Dose-related side effects include leukopenia, thrombocytopenia, macrocytic anemia, pancreatitis, hepatotoxicity, tumorigenesis, and infection [10]. Azathioprine does not interact with antibiotics but enhances hematologic toxicity [8]. Used with allopurinol, doses should be reduced.

E. Mycophenolate mofetil (MMF; Cellcept was approved in 1995 for oral use and is superior to azathioprine in preventing organ rejection in renal transplants) [15]. Similar to azathioprine, MMF blocks T- and B-cell proliferation by stopping production of guanine nucleotides needed for DNA synthesis. Proliferation of fibroblasts, endothelial cells, arterial smooth muscle cells, and B-cell production of antibodies is diminished. Side effects include leukopenia and gastrointestinal problems.

- F. Sirolimus**, also a macrolide, is 27 times more potent than tacrolimus and is used in combination with calcineurin inhibitors to prevent rejection. It inhibits T- and B-cell proliferation by interfering with cytokine signals after cytokine attachment to the cell receptor [16]. Doses of calcineurin inhibitors and steroids can be reduced when sirolimus is part of the regimen. Drug interactions are similar to those seen with calcineurin inhibitors. Side effects include elevated cholesterol and triglyceride levels, hypertension, thrombocytopenia, anemia, and leukopenia. The effects of hypercholesterolemia and hypertriglyceridemia seem to be offset by reduction of graft vasculopathy [17].
- G. Antilymphocyte globulins, antithymocyte globulins (ATGs), and OKT3 murine monoclonal antibody** are biologic preparations that lyse host immunocytes. They are effective for both prophylaxis and treatment of rejection. Potential side effects include fever, serum sickness, aseptic meningitis, pulmonary edema, and diarrhea, which may be confused with symptoms of infection or rejection. Concurrent administration of corticosteroids, acetaminophen, and diphenhydramine palliates the side effects of fever and rigors [8]. Rabbit ATG is better tolerated than others and is more effective than horse-derived ATG. All reactivate CMV; however, rabbit ATG is less likely to cause disease [18].
- H. Interleukin-2 inhibitors.** Monoclonal antibodies block T-cell receptors for IL-2, thus inhibiting the signal for T-cell proliferation. They decrease rejection and permit withdrawal of steroids. The incidence of infusion side effects or infection is low [19,20].
- I. Radiation therapy** is used routinely for BMT preparation. Total lymphoid irradiation has been used to treat chronic stubborn rejection in heart recipients [21].
- IV. Problems resembling infection in solid organ transplantation**
- A. Although the patient may feel well, with signs of rejection seen only on biopsy, rejection mimics infection.** Fever, myalgias or arthralgias, and leukocytosis occur. **In any febrile episodes, rejection is considered, but after cultures antibiotics should be initiated.**
- B. Medications** can cause fever. Azathioprine or cyclosporine hepatotoxicity should be considered in posttransplantation hepatitis. Usually fever due to OKT3 occurs early in therapy.
- V. Clinical signs of infection on immunosuppressive therapy may be obscure.** The impaired inflammatory response results in a paucity of signs. The insidious onset and possible rapid progression of infection warrant a prompt and thorough evaluation. This includes a complete history and physical examination, with attention to the skin and oropharynx. A complete blood count (CBC), chest radiography, urinalysis, and blood cultures are indicated. Initiation of empiric broad-spectrum antibiotics is reasonable pending the outcome of studies.
- VI. CMV** is the most important cause of transplant-associated infection. Three clinical syndromes occur between 1 and 6 months posttransplantation. **Primary infection**, the most serious, develops in seronegative recipients of grafts or blood products from a CMV-seropositive donor. **Reactivation** of latent virus occurs. **Reinfection** develops because donor or blood product virus is transmitted into the “immune” recipient [22].
- A. Illness** The proportion of a syndrome group that becomes ill is highest in primary infection. In all groups illness presents as fever and malaise. Some, especially with primary disease, progress to pneumonitis, encephalitis, hepatitis, and other organ involvement. **Graft dysfunction may ensue** [23–26].
- B. Laboratory studies usually show a leukopenia and mild increase in liver enzymes.**
- C. Viral studies.** Antigenemia assays or polymerase chain reaction (PCR) of peripheral blood are early indicators of CMV active infection that predicts disease [27–29].
- D. CMV exerts effects in addition to clinical infectious syndromes** [23,30,31].
- 1.** CMV enhances net immunosuppression by causing leukopenia and depressing cell-mediated immunity and alveolar macrophage function. This may result in opportunistic infections with *Pneumocystis*, *Nocardia*, and *Listeria* species [23,30].

2. CMV mediates allograft injury (and possibly rejection), accelerates atherosclerosis in hearts, and increases the incidence of bronchiolitis obliterans in lung transplants [22,23,28,29].
3. Malignancy may be induced [23].

VII. Strategy to prevent infection in solid organ transplantation and BMT

A. Surgical prophylaxis pretransplantation [6,32]

1. In renal transplantation, cefazolin with or without aminoglycoside is used. The use of prophylactic **TMP-SMX daily for 6 months after renal transplantation has been shown to reduce urinary tract infections (UTIs)** in patients free of anatomic abnormalities [33,34].
2. Heart transplantation. Cefuroxime or cefepime may be given for 24 to 48 hours.
3. Liver transplantation. Selective bowel decontamination for gram-negative organisms and fungi must be undertaken at least 7 days pretransplantation [34], and concurrent fungal prophylaxis with clotrimazole or nystatin should be administered. Cefepime and/or piperacillin/tazobactam is started pretransplantation and continued for 5 days postoperatively. Fluconazole is used in patients with prolonged intubation or operative time, in those undergoing surgical reexploration, in those who require multiple blood products, and in those on perioperative antibiotics or dialysis [35].
4. Lung and heart-lung recipients should receive prophylaxis with activity against *Pseudomonas aeruginosa*. Regimens are then adjusted based on results of donor sputum/endotracheal cultures and recipient sputum/lavage cultures [32,34,36].
5. BMT patients often receive oral ciprofloxacin at the onset of neutropenia and oral acyclovir 400 to 600 mg/day for 6 months for HSV prophylaxis [37,38]. Decreased levels of immunoglobulin reported posttransplantation have been associated with a greater incidence of infections. Data to recommend administration of intravenous immunoglobulin (IVIG) posttransplantation is lacking [39].

B. CMV prevention. Oral GCV or valganciclovir given for 90 days after kidney transplantation prevents CMV disease [40,41]. CMV-negative recipients of CMV-negative grafts must receive CMV-negative blood products or, if not available, leukocyte poor blood products (equivalent to CMV-negative products) [42]. Cases of serious and refractory hypotension during transfusion of blood products through in-line filters have been reported [43]. **Cytomegalovirus immunoglobulin (CMVIG)** has high titers of antibody against CMV and is more effective than IVIG for prevention of CMV disease in renal [44], liver [45], and lung grafts that are CMV mismatches [46]. CMVIG has the additional benefit of decreasing the risk for other opportunistic infections [45].

C. Opportunistic infection prophylaxis

1. **Isoniazid** is used in patients with positive PPD test results, but side effects may outweigh benefits. It is indicated for patients with a history of active tuberculosis (TB), a positive PPD test result and nonwhite background, malnourishment, an abnormal chest radiograph, or with other immune-compromising conditions (i.e., diabetes mellitus, achlorhydria) [33].
2. **TMP/SMX** protects against *Pneumocystis*, *Listeria*, and *Nocardia* infections [33,47]. **Other infection prevention measures pretransplantation** also should be considered.
3. **Dental and other procedures [47].** Heart transplant recipients should receive prophylaxis when undergoing dental, gastrointestinal, or genital urinary procedures [37]. Liver transplant patients should receive antibiotic prophylaxis prior to liver biopsy or cholangiography. See Chapter 27B.
4. **Infection control.** Health care workers must adhere to strict hand washing practices. Recipients must not be exposed to other patients or to visitors with upper respiratory infection, chicken pox, or tuberculosis.
5. **Hot water decontamination** and filtering air may be necessary if *Legionella* or *Aspergillus* outbreaks occur.
6. **Environmental pathogens.** Avoid contact with zoonotic vectors such as birds (chlamydia), cats (toxoplasmosis), and fresh flowers. For the first six months posttransplantation, the patient should wear a mask when going into public. Airplane travel should be avoided, especially to areas where sanitation is

inadequate. Infectious diseases consultation should be sought for travel after that time.

7. **Pretransplant vaccination** against pneumococci [48] once and influenza seasonally is recommended. If not current, inactivated vaccination against tetanus, *Haemophilus influenzae type B (HiB)*, and poliovirus, as well as the live mumps, measles, and rubella (MMR) vaccination should be given. Seronegative recipients to the respective viruses should receive hepatitis A, hepatitis B and varicella vaccines. Meningococcal vaccine should be provided to college-age recipients. In BMT, vaccination of the donor may be helpful.
8. **Posttransplant vaccination.** In BMT, inactivated vaccines: that for influenza starting at 6 months, and those for diphtheria-tetanus-acellular pertussis (DTaP), *Pneumococcus* diphtheria-tetanus (DT), tetanus-diphtheria (Td), HiB, hepatitis B, and inactivated polio vaccine after 12 months. The live MMR vaccine should be given 24 months later [49].
9. **In the transplant unit,** fresh fruits and vegetables should be washed and all meats must be thoroughly cooked [34]. Intravenous lines and Foley catheters should be meticulously maintained and discontinued promptly. Patients should be mobilized as soon as possible. Masks are indicated for patients transported through construction areas [34] and for health-care workers with respiratory infections.
10. **Varicella prophylaxis.** Patients who are seronegative to varicella and exposed to chicken pox or to zoster, require varicella-zoster immune globulin (VZIG). See related discussion in Chapter 26.

INFECTIONS IN RENAL TRANSPLANTATION

During the first month after transplantation, the patient is most likely to experience a nosocomial infection, whereas the second interval (at 1–6 months) is marked by a predominance of opportunistic infections. After 6 months, if immunosuppression is reduced, the major risk is community-acquired infections. (Fig. 20.1). Infectious disease problems of the diabetic transplant recipient have recently been reviewed [50].

The clinical presentation of infection or rejection is similar and sometimes can be resolved only by biopsy of the transplanted kidney. Renal transplant patients differ from other transplant recipients in that in the face of overwhelming infection, immunosuppression may be discontinued and dialysis used as an alternative therapy.

- I. **Immediate posttransplantation period (first month).** Nosocomial infections with or without fever occur particularly during the immediate posttransplantation period. Because the net immunosuppression is still low, opportunistic infections occur only rarely in this interval, and their presence should prompt consideration of environmental exposure [33].
 - A. **Nosocomial infections,** including intravenous (i.v.) catheters, lung, wound, and urinary tract sites. These infections are frequent sources of fever. [33]. Other hospital-acquired infections include sinusitis, prostatitis, and disseminated *Candida* infections.
 1. **Specific syndromes of the early posttransplantation period**
 - a. **Intravenous line infections** are common at both central and peripheral sites. If blood cultures are positive, i.v. lines discontinued in a febrile transplant patient should be quantitatively cultured. See Chapter 2 for a discussion of catheter-related sepsis.
 - b. **Pneumonia may be difficult to distinguish from postoperative atelectasis, adult respiratory distress syndrome, hemorrhage, congestive heart failure, or emboli.** Pneumonia in this period is a complex nosocomial process, and the reader is referred to Chapter 11 for further discussion. Empiric therapy should be based on the clinical setting, sputum Gram stain results, and local susceptibility patterns. If Gram stain does not suggest *Staphylococcus* or yeast, use piperacillin-tazobactam or a third- or fourth-generation cephalosporin as initial therapy. Nephrotoxic antibiotics and

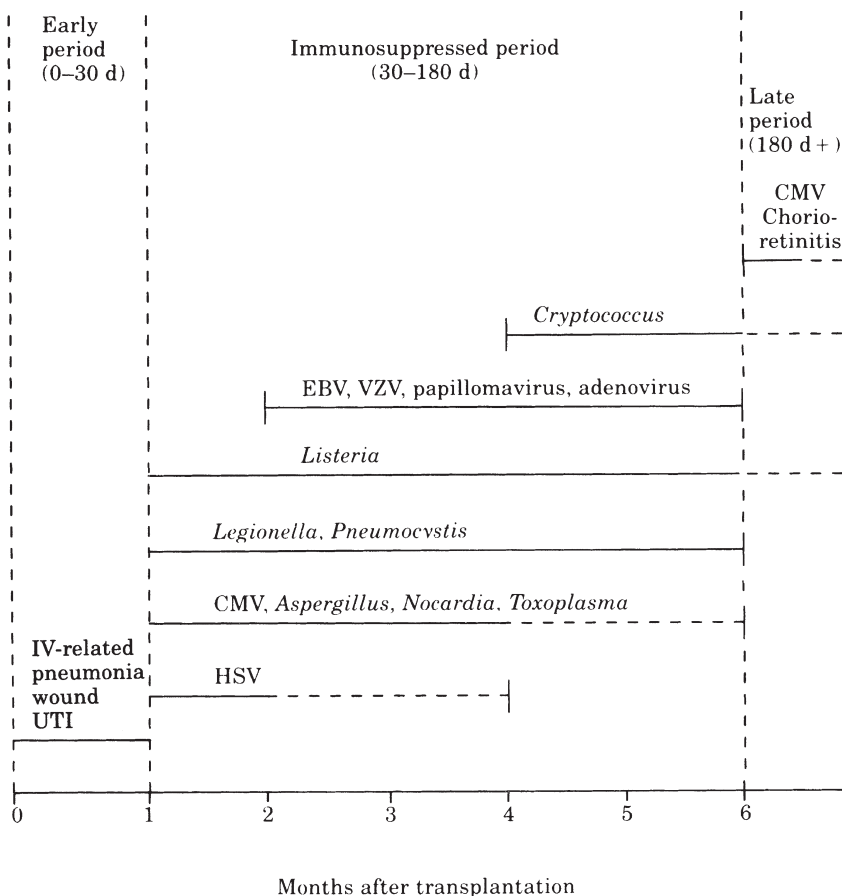

FIG. 20.1 Infection timetable. CMV, cytomegalovirus; EBV, Epstein-Barr virus; VZV, varicella-zoster virus; HSV, herpes simplex virus; UTI, urinary tract infection. (Modified from Rubin RH, et al. Infection in the renal transplant recipient. *Am J Med* 1981;70:405; with permission.)

antibiotics that interact with immunosuppressive agents should be avoided (see section III.A.1).

- c. Wound infection** caused by staphylococci or gram-negative organisms is linked to technical complications that result in urine leaks from anastomoses, wound hematomas, or lymphoceles [51]. The use of systemic antibiotics and improved surgical techniques has decreased the incidence to 1% [51]. **However**, incisional pain, erythema, and fever are either mild or absent. **A high index of suspicion is necessary for early diagnosis.**

- (1) A Gram stain and culture should be performed on any wound drainage, and blood cultures should be obtained. A CBC and a urinalysis with culture are indicated.
- (2) Computed tomography (CT) of the transplanted kidney will show changes of infection. Aspiration of perirenal fluid for Gram stain and culture should be performed. Management may require surgical drainage and antibiotics. Empiric *Pseudomonas* coverage until Gram stain

or culture results are available is indicated. In early studies, 75% of deep infections required a nephrectomy to prevent anatomic disruption and for cure [51].

- d. Urinary tract infections.** Due to surgical handling, for the first 90 days the urinary tract is a prime site of infection [51]. An infected allograft is a source of upper tract infection or sepsis. Infection due to hospital-acquired gram-negative rods or *Candida* species usually originates with an indwelling catheter. Graft loss due to *Candida* pyelonephritis has been reported [52]. Another cause of graft failure is BK virus, a polyomavirus. Hemorrhagic cystitis or interstitial nephritis with possible graft failure occur. Cidofovir may be helpful [53]. A mild febrile episode may be the only finding.

- (1) **Diagnosis.** With bacteria, urinalysis reveals white blood cells and casts.

Gram stain results of urine **will often guide therapy. In BK virus infection**, decoy cells present on urine cytology or PCR is diagnostic.

- (2) **Therapy. Intravenous therapy is used** for these early (4–6 months posttransplantation) intrarenal processes then therapy is completed with TMP-SMX or a quinolone for 4 to 6 weeks [54]. Candiduria, whether symptomatic or not, should be treated for 10 days with oral antifungals followed by repeat urinalysis and culture [54]. Significant interactions with cyclosporine are not seen. Search for surgically drainable foci or fungus balls should be undertaken. Treatment of asymptomatic bacteriuria is controversial [54,55].

- (3) **Prophylaxis** with TMP-SMX yields significantly fewer bacterial UTIs [56]. Those at high risk for recurrence (diabetics, patients on cyclophosphamide or high-dose steroids, or those with recurrent UTIs) should have prophylaxis indefinitely [56]. Antifungal prophylaxis is not indicated [57].

2. Nosocomial infections less commonly seen

- a. Sinusitis. Coronal head CT scans are the best methods to diagnose sinusitis related to nasogastric or nasotracheal tubes.** Oxymetazoline 0.5% and removal of the tube on the affected side may be sufficient therapy. Optimal management may require antral puncture or surgery. Febrile sinusitis should be treated with antibiotics such as piperacillin-tazobactam to cover gram-negative organisms and anaerobes.

- b. Prostatitis** from the Foley catheter may manifest as pus around the indwelling catheter. Rectal examination reveals a boggy, tender prostate. Culture of expressed prostatic secretions may identify the pathogens. TMP-SMX is a reasonable empiric choice. Quinolones are an alternative in the sulfa-sensitive patient. Patients receiving quinolones and cyclosporine should be monitored for nephrotoxicity.

- c. Disseminated fungal infections** occur from line sepsis, especially in association with prolonged antibiotic use [33]. New lipid formulations of amphotericin B are less nephrotoxic than standard amphotericin B. The latter may cause increased serum creatinine levels in 50% to 100% of patients [58,59]. At doses ranging from 1 to 4 mg/kg/day, liposomal amphotericin B concentrations are greater than the inhibitory concentrations of most fungal organisms [60]. Among the three formulations, liposomal amphotericin B has the best toxicity profile (61) and a clinical response in invasive aspergillosis of 61% [61a]. Caspofungin (Cancidas) shows promise for treatment of *Candida* or *Aspergillus* infections. Elevation of liver function tests (LFTs) occur if cyclosporine but not tacrolimus is used. Approval by the U.S. Food and Drug Administration of voriconazole, which is active against filamentous and dimorphic fungi and *Candida* species, is expected early in 2002. It does interfere with cytochrome P450.

B. Reactivation of latent infection

- 1. CMV** often reactivates and may produce a self-limited febrile illness with malaise and neutropenia. See section VI under Basic Principles.
- 2. Preexisting tuberculous** disease can disseminate, resulting in miliary disease.
- 3. *Strongyloides stercoralis*** infestation may evolve into a hyperinfection syndrome with pulmonary infiltrates and polymicrobial bacteremia. Mortality

approaches 70% [6]. Treatment employs thiabendazole or ivermectin [6]. Screening of stool (five samples), sputum, and duodenal aspirate will identify larvae in 91% of these patients.

C. Allograft-derived infections. Pyelonephritis, occasionally developing immediately after transplantation, results from the graft having been seeded prior to being harvested [62]. Donors who have been in the intensive care unit for more than 1 week pose the greatest risk. Graft contamination during preservation may be more common than donor infection. Culture of perfusate identifies this potential source of infection. Kidney recipients with a culture-positive perfusate should receive 7 to 14 days of i.v. antibiotics. CMV, EBV, TB, hepatitis, syphilis, *Strongyloides*, *Candida*, and HIV have all been transmitted by renal allografts [63].

II. Immunosuppressive period (1–6 months). This is the interval of maximum immunosuppression. Both primary and reactivated CMV infection add to the immunosuppression. The combination of these factors predisposes both to infection and to tumorigenesis [29,30]. **Infections may present in an unusual fashion and may be caused by exotic and unexpected pathogens.**

A. Pulmonary infections mandate a rapid diagnostic approach. Diagnosis within 5 days yields 80% versus 35% survival if diagnosis is delayed [64].

1. Clinical approach to pulmonary infections

a. A history and physical examination should be performed, with particular attention to mode of onset; travel; serostatus of the donor and recipient with respect to CMV, EBV, HSV, and VZV; animal contacts; exposure to ill persons; compliance with prophylactic regimens; vaccination history; and receipt of blood products. The immunosuppression regimen should be reviewed, including pulse immunotherapy for rejection. Recall that CMV predisposes to other complications [23,29,30].

b. Expectorated or induced sputum (using inhalation of 10% glycerin plus 10% NaCl for 10 minutes) is obtained for Gram and regular and modified acid-fast stains, as well as routine, acid-fast, and *Legionella* culture. Because atypical pneumonia and opportunistic processes present with a dry cough, sputum induction improves identification of mycobacteria and fungi as well as *Pneumocystis* species. Cultures should be held for 2 weeks to detect *Nocardia* or *Legionella*. A Papanicolaou smear should be performed to search for *Strongyloides*.

c. Blood cultures, arterial blood gases, and serial chest radiography are appropriate. **Samples for serum analysis of cryptococcal antigen should be obtained, and urinalysis should be performed to look for *Legionella* urinary antigen.**

d. Imaging studies must be carefully interpreted. Chest x-ray patterns do not correlate with a specific etiology. Radiographs are abnormal in only 56% of cases of pneumonia; CT scans are often helpful when the chest radiograph is nondiagnostic.

e. Bronchoscopy should be performed if diagnosis is uncertain within **24 to 48 hours**, or earlier if the clinical course mandates. Quantitative cultures obtained by protected brush, bronchoalveolar lavage, and biopsy are helpful. With a protected brush, 10^3 bacteria/mL suggests infection [65]. If these studies are unrevealing, open lung biopsy is indicated [66].

f. Transthoracic needle aspiration of discrete peripheral lesions or infiltrates can be attempted, especially if the lesions are cavitory. Limited tissue is a drawback when attempting to diagnose a process that may be multietiologic (see Chapter 11).

g. Initial empiric therapy should be initiated immediately after bronchoscopy (or immediately after specimen collection if bronchoscopy is not performed initially) and should be based on clinical setting and results of Gram staining. Coverage for resistant gram-negative organisms with a third- or fourth-generation cephalosporin and a second-generation quinolone is reasonable. For dosing, see Chapter 27F and G. Macrolides including azithromycin should be avoided in patients on calcineurin inhibitors.

Table 20.1. Immunocompromised Protocol: Studies Done on Biopsy Samples of Lung Tissue or Bronchoalveolar Lavage Washings

Gram stain and bacterial culture
Fungal culture
Acid-fast bacilli smear and culture
<i>Nocardia</i> smear and culture
<i>Legionella</i> smear and culture
Respiratory viral culture
Cytomegalovirus smear and culture
Smears for herpes simplex virus and adenovirus and, in the proper season, influenza virus, respiratory syncytial virus, and parainfluenza virus
Cytology
Gomori methenamine silver stain for <i>Pneumocystis carinii</i> pneumonia

Empiric therapeutic doses of TMP-SMX can be initiated if the patient has not received prophylaxis for *Pneumocystis* (see Chapter 18). Cyclosporine levels should be followed closely when TMP-SMX is used. Sputum for acid-fast bacilli (AFB) smear and culture postbronchoscopy have an increased yield of mycobacteria after the procedure [67].

2. The laboratory approach is complex (see also Chapters 11 and 25). Bronchoscopy and open-lung biopsy specimens must be handled meticulously (Table 20.1).

a. The protected brush technique is used to differentiate upper airway colonization from lower infection. A quantity of greater than 10^3 organisms suggests that the organism is the cause of the infection [68].

b. Bronchoalveolar lavage fluid should be stained for *Pneumocystis* species, fungi, and AFB. Direct fluorescent antibody testing of smears is useful for detecting *Legionella* species and viruses such as CMV, herpes simplex adenovirus, and, in the appropriate season influenza, parainfluenza, or respiratory syncytial virus (RSV). Bronchoalveolar lavage can be used to detect organisms in 69% of cases [65].

c. Biopsy tissue is stained with hematoxylin and eosin and examined for viral inclusions and granulomas. Tissue should be cultured for viruses and *Mycobacterium tuberculosis* and stained by the immunoperoxidase technique for toxoplasma (see Chapter 25).

d. Open lung biopsy is relatively safe and should not be delayed in the critically ill patient. It is especially useful in diffuse infiltrates. Lung tissue should be studied as in section c.

B. Dermal infections present a diagnostic challenge. **Biopsy of the lesion is usually necessary for accurate diagnosis.** Lesions should be evaluated promptly. They may be a *forme fruste* of disseminated infection, and early systemic therapy can be successful [69].

1. Skin infections may be similar to those seen in immunocompetent individuals.

a. Cellulitis due to staphylococci or streptococci is commonly observed because of skin fragility from chronic corticosteroids. Ampicillin-sulbactam, an antistaphylococcal penicillin, or clindamycin for penicillin-allergic individuals, should be used. A portal of entry such as dermatophyte infection should be sought.

b. Cellulitis caused by unusual pathogens. Gram-negative bacteria, cryptococci, or *Candida*, may be clinically indistinguishable from pyogenic cellulitis. **Biopsy with culture is indicated when response to standard therapy is lacking** [33].

2. Skin infections producing localized or mild infections.

a. Herpes simplex viruses. The severity of HSV infection is governed by the type and intensity of immunosuppressive therapy. Lympholytic preparations (OKT3, ALG) are major promoters of HSV infection. Approximately one-half

of kidney recipients experience reactivation of cutaneous lesions within 30 to 60 days after transplantation [33]. With lympholytic therapy, these infections may develop earlier.

- (1) **Herpes labialis** usually is caused by HSV type 1 and is exacerbated by the presence of endotracheal and nasogastric tubes. It may progress to involve the oral and esophageal mucosa and may mimic *Candida* esophagitis radiographically. The lesions often become superinfected with *Candida* [69]. Acyclovir is effective [47].
- (2) **Anogenital lesions due to HSV type 2 are less common.** Lesions after transplantation may be typical vesicles or less characteristic ulcers. A Tzanck preparation is helpful diagnostically, as are viral cultures. There is a potential for secondary infection with gastrointestinal flora and subsequent bacteremia. Oral acyclovir is effective.
- (3) **Cutaneous dissemination of HSV**, (Kaposi varicelliform eruption), presents with crops of vesicles arising in separate sites. This is due to autoinoculation. It usually involves areas of prior trauma (e.g., burns). Treatment is i.v. acyclovir.

b. Varicella-zoster virus.

- (1) **Reactivation of latent VZV** occurs in a dermatomal distribution in 10% of renal transplant recipients; dissemination is a rare event. Immunosuppression need not be changed. Acyclovir enhances healing and decreases acute pain. With normal renal function, 10 mg/kg every 8 hours is indicated. Patients should be isolated until lesions crust [47].
- (2) **Primary VZV infection** (chickenpox) is uncommon because of immunity. When it occurs, hepatitis, pneumonitis, central nervous system (CNS) infection, and disseminated intravascular coagulation can result. **Prophylaxis with VZIG is imperative for seronegative patients exposed to VZV.** VZIG will prolong the incubation period (see Chapter 26). If lesions occur, acyclovir 10 mg/kg i.v. every 8 hours, should be initiated promptly (assuming normal renal function) [33].

c. **Papillomavirus**, the cause of warts, affects 40% of renal transplant patients and occasionally develops into extensive or disfiguring lesions [33]. Furthermore, malignant transformation of warts can occur. Initial therapy is reduction of immunosuppression followed by cryosurgery. Dermatologic consultation is suggested.

3. Primary skin infections caused by opportunistic organisms usually are diagnosed by biopsy with histologic examination and routine, fungal, and mycobacterial cultures.

a. **Localized infections** with atypical mycobacteria, fungi, and algae occur.

b. **Systemic spread** can follow cutaneous infection with *Candida* and the zygomycetes. The lung and gastrointestinal tract are the usual portals of entry for *Aspergillus* and *Candida* organisms, respectively. The zygomycetes have been introduced by trauma from dressings or i.v. line placement.

4. **Disseminated skin infection may originate from a noncutaneous source**, heralding a systemic infection that requires systemic therapy. *Nocardia*, *Cryptococcus*, and *Candida* are noted for this. In 25% of patients with cryptococcosis, dermal lesions appear weeks to months prior to CNS disease. Disseminated candidal infections present with skin lesions in 15% of patients [33]. *Nocardia* is noted for the concurrence of dermal and lung lesions.

C. Central nervous system infections

1. **Meningoencephalitis and brain abscess** are the most frequent CNS infections and present in a subacute fashion. Causative organisms include *Aspergillus*, *Toxoplasma*, *Nocardia*, and viruses. **See related discussions in Chapter 6.**

a. ***Aspergillus* infection** is common in the first 1 to 2 months posttransplantation [69a]. It usually originates from a pulmonary focus (83%–90%). Mental status changes vary between those that rapidly progress to obtundation and death or focal neurologic findings occur. **The diagnosis should be suspected if sinus or pulmonary aspergillosis is present. Magnetic resonance imaging (MRI) is more sensitive than CT.** Lesions are multifocal at the gray and

white junction [69a,70]. Lipid complex amphotericin B is the drug of choice. Fatality rates approach 100% [71].

- b. *Toxoplasma gondii* is uncommon. The initial presentation is altered mental status in 45% and seizures in 35%; MRI demonstrates single- or multiple-ring-enhancing lesions in periventricular areas [71]. A stereotactic biopsy is useful for diagnosis. Sulfisoxazole and pyrimethamine are the agents of choice [72]. Clindamycin may be substituted for the sulfonamide in the sulfa-allergic patient (see Chapter 18).
- c. **Nocardiosis.** See section II.A.2 under Infections in Heart Transplantation.
2. **Meningitis** is another common presentation of CNS infection during this period. Patients may complain of headache, lethargy, or fever, or may demonstrate meningismus. The organism responsible for **acute meningitis usually is *Listeria*, whereas *Cryptococcus* and *Coccidioides* present in a subacute fashion.** Meningitis often occurs after treatment for rejection, regardless of the time that has elapsed since transplantation [70].
 - a. ***Cryptococcus*** causes a basilar meningitis with increased intracranial pressure and the risk for deafness and blindness. CT findings are often normal. Infection usually occurs more than 3 months posttransplantation and presents with headache (80%) and fever (60%). Cerebrospinal fluid (CSF) cryptococcal antigen is obtained, which is positive in 100% of cases; whereas culture is positive in only 90%. Opening pressure should be measured. Fluconazole or lipid complex amphotericin B and flucytosine are the drugs of choice [73,74] for the transplant recipient in whom interactions with cyclosporine are a primary concern. Repeated lumbar puncture to lower pressure is indicated if initial pressure is elevated.
 - b. ***Listeria*** occurs late after transplantation. It presents as brain stem encephalitis with cranial nerve palsies or pontomedullary signs [75]. CSF Gram stain is always negative. Treatment is ampicillin plus an aminoglycoside. TMP-SMX is used in penicillin-allergic patients.
 - c. ***Coccidioides immitis*.** Fluconazole or itraconazole are effective, but amphotericin B—systemically or, in refractory cases, intrathecally—remains the standard of care [76–78]. If possible, immunosuppression should be decreased.
 - d. **Rhinocerebral phycomycoses** due to *Mucor* and *Rhizopus* are encountered only rarely in renal transplant recipients, even during the height of immunosuppression. Physical examination reveals periorbital swelling, cranial nerve palsies, and necrosis of the nasal turbinates. Biopsy with histologic examination demonstrating hyphal elements is diagnostic. Lipid complex amphotericin B is adjunctive to extensive surgical resection.
- D. **Urinary tract infections** in this period parallel those seen in the immediate post-transplantation period (see section I.A.1.d).
- E. **Gastrointestinal complaints in the renal transplant recipient warrant aggressive diagnostic evaluation, because the severity of illness can be masked by immunosuppression.** See related discussions in Chapter 13.
 1. **Viral infections are common.**
 - a. Stomatitis or esophagitis usually is caused by concurrent HSV and *Candida* infections. In stomatitis, the diagnosis is made clinically, but esophagitis requires endoscopy with biopsy and culture. Acyclovir is effective for HSV esophagitis. Oral or i.v. fluconazole is used for candidal esophagitis [77].
 - b. **Gastrointestinal ulceration** and bleeding may be caused by CMV. Diagnosis requires endoscopy with biopsy and viral culture. GCV is the drug of choice [79]. *Helicobacter pylori* and rarely invasive fungal disease may be etiologic.
 2. **Bacterial infections are seen less often.**
 - a. **Acute gastroenteritis** is caused by pathogens that occur in immunocompetent patients.
 - b. **Hemorrhagic diarrhea** can be seen with *M. tuberculosis* infection, CMV, pseudomembranous colitis, posttransplantation lymphoproliferative disorder, diverticulitis, or *Campylobacter* or *Salmonella* infection (see section III.E).
 - c. **Intraabdominal abscess.** Chronic steroid therapy leads to perforation at any

weak area in the bowel. Perforation is followed by abscess formation. Diagnosis can be made via ultrasonography or CT.

3. **Diverticulitis** caused by chronic constipation is seen in patients given long-term phosphate-binding antacids. It should be suspected with abdominal pain or change in bowel habits. Diverticulosis before transplantation predisposes a patient to diverticulitis. Classic signs of peritonitis frequently are absent in the immunosuppressed patient. Surgical evaluation, CT scanning, or a water-soluble contrast enema may be helpful (see Chapter 13).
 4. **Cholecystitis** may be calculous or acalculous. In the latter, dehydration is a contributing factor. **Corticosteroids can mask the manifestations of cholecystitis** [69].
- F. Fever of uncertain origin.** A search for hepatic, neurologic, and gastrointestinal disease is indicated, and a low threshold for biopsy of the involved organ with routine AFB smear, viral culture, and histology is necessary. Human parvovirus B19 infections following transplantation may cause fever of unknown origin, myalgias, and refractory anemia [80]. IVIG may be helpful. **However, in this period fever often is caused by CMV** (see section VI under Basic Principles). Neutropenia accompanying CMV infection may necessitate decreasing the dose of MMF or azathioprine. In our experience, CMV infection contributes profoundly to the net immunosuppressive effect. A CMV-infected patient should be observed for the development of other opportunistic infections or malignancies.

III. The late period (>6 months posttransplantation) is characterized by community-acquired infections in patients who are successfully grafted. Patients chronically infected with CMV and hepatitis viruses and those with ongoing rejection remain at risk for opportunistic disease.

A. Late pulmonary infections

1. ***M. tuberculosis* and atypical mycobacterial infections** may exhibit unusual presentations. A history of exposure or a reactive PPD test result may be difficult to obtain. Accordingly, a **high index of suspicion** must be maintained when late pulmonary infiltrates develop. Acid-fast stains of sputum may be negative, and bronchoscopy may be necessary to obtain adequate specimens. Optimal treatment for highly susceptible *M. tuberculosis* and atypical mycobacteriosis is controversial. Although 9 months of INH and rifampin may be sufficient, the immunocompromised patient may require an additional 9 months of therapy [47,67] (see Chapter 11).

Greater controversy surrounds the treatment of multiply resistant TB. Consideration of this possibility must be made when evaluating individuals exposed to TB. Resistant and atypical mycobacterial infections require individualized therapy based on the results of susceptibility testing. Infectious disease consultation is suggested (see Chapter 11). Lung resection is an alternative in patients with localized pulmonary involvement caused by atypical mycobacteria [47].

2. **Fungal infection** with *Histoplasma*, *Coccidioides*, and *Cryptococcus* species can present without obvious pulmonary involvement. Histoplasmosis and coccidioidomycosis generally are encountered in endemic areas, whereas cryptococcosis occurs throughout the United States. The clinician should alert the laboratory when sputum is submitted. Positive culture should be assumed to represent invasive disease. For treatment of cryptococcosis, fluconazole is used. Histoplasmosis and blastomycosis respond to itraconazole, which exhibits 90% efficacy [78] (see Chapter 17). The clinician should be alert to interactions with the calcineurin inhibitors.
 3. **Pneumococcal and *H. influenzae*** pretransplantation vaccination is important. See section VII.C.6–7 under Basic Principles. Influenza vaccine should be administered annually posttransplantation. Renal transplant recipients have a reduced antibody response to vaccine, but vaccine does not compromise graft function [81].
- B. Dermal infections.** See section II.B.
- C. Central nervous system infection** is more likely if the patient has continued rejection or persistent viral infection. See section II.C. In the patient requiring low-dose immunosuppression, routine bacterial pathogens and cryptococci should be suspected.

D. Urinary tract infections. During this period, these usually are benign, and the incidence of such infections is decreased by prophylactic use of TMP-SMX. **Low-dose quinolones** are effective and relatively safe in the transplant patient. Bacteremic pyelonephritis suggests anatomic abnormality and warrants urologic evaluation [33].

E. Gastrointestinal infections

1. Chronic hepatitis caused by HBV, with or without hepatitis delta virus (HDV) and HCV infection, is a leading cause of morbidity and mortality in patients with functioning renal allografts who survive 10 years [82]. Donor and recipient serologies for HBV must be analyzed carefully prior to transplantation. Hepatitis surface antigen (HBsAg)-positive or anti-hepatitis core antibody (HBcAb) IgM-positive donors pose a high risk for transmission of HBV. Anti-HBcAb IgG-positive or HBsAb-positive grafts are unlikely to transmit HBV to kidney recipients. Pretransplantation immunization and posttransplantation prophylaxis may allow use of seropositive grafts [83]. Hepatocellular injury is cytopathic in HBV and primarily immune mediated in HCV. IFN is a difficult drug to use in transplant recipients because it has an immunostimulatory effect [84]. A recent study by Pereira et al. showed that liver disease was increased in recipients of HCV-positive organs but the rate of graft loss or mortality during a 3.5-year follow-up period [85] was similar. In a more recent study, HCV-positive recipients of renal allografts had an increased incidence of membranoproliferative glomerulonephritis compared with HCV-negative recipients, and HCV positivity was a predictor of graft loss [86]. Interestingly, HCV exerts an immunomodulating effect during the first year. Allograft survival is significantly greater in these patients. The infection rate is also greater in the first year. Boletis et al. established that liver biopsy, not simply transaminase level, is required to determine the severity of disease, prognosis, and response to treatment [87]. Cirrhosis may ensue.

2. Salmonella infections may result in metastatic infection or bowel perforation. **Any patient with *Salmonella* gastroenteritis should always be treated** (see Chapter 13).

F. Eye infection. Visual field defects are a common manifestation of CMV retinitis. However, this occurs rarely in transplant recipients. The patient may be asymptomatic and the clinical course evolves over weeks. GCV 5 mg/kg every 12 hours for 2 weeks will halt disease progression, but patients may relapse (see Chapter 18). Toxoplasmosis presents similarly but is very uncommon. Ophthalmologic consultation is imperative (see Chapter 27).

G. Epstein-Barr virus is associated with a spectrum of B-cell lymphoproliferative diseases that infrequently develop following kidney transplantation. These have recently been reviewed [88].

INFECTIONS IN HEART TRANSPLANTATION

Problems in cardiac transplantation parallel those in renal transplantation. However, prevention of rejection is the top priority in heart transplant recipients, because retransplantation is risky and expensive. The 1-year survival rate for repeat cardiac transplantation is approximately 55% [89]. Therefore, aggressive immunosuppression must be enforced, but this increases the incidence and severity of infection. Patients who receive transplants for ischemic disease tend to experience more infections than those who receive transplants for other reasons, but this may be related to their greater mean age [90]. Infection in heart transplant recipients has been reviewed [91].

I. Immediate posttransplantation period (first month). The infectious complications encountered during this period are the same as those in renal transplant recipients, with the exception of surgical wound infections.

A. Nosocomial infections are a common cause of fever in this time period.

1. Intravenous catheter infections should be managed as for renal transplant recipients. The avoidance of bacteremia is paramount because of the vascular anastomoses (see Chapter 2). Lines should be removed as soon as feasible, and pacer wires should be removed promptly.

2. Refer to section **I.A** under Infections in Renal Transplantation and Chapter 11 for the presentation, diagnosis, and treatment of **pneumonia**. A recent review of pneumonia found rates of 21.1 per 100 heart recipients—75% occurred in the first 3 months. Sixty percent were caused by opportunistic organisms, 25% were nosocomial pathogens, and 15% were community-acquired pathogens. Bronchoscopy was 95% sensitive for diagnosis [92]. Influenza vaccination is safe after heart transplantation and induces adequate antibody responses in most patients [93]. *Pneumocystis carinii* pneumonia (PCP) prophylaxis should be given for 1 year posttransplantation and reinstated following treatment of rejection [32].
 3. **Surgical wound** infections are uncommon, but potential progression into the mediastinum makes this a grave complication. Needle aspirate or bone biopsy is important [94]. Diagnosis is made by results of Gram staining and culture. Responsible organisms include coagulase-positive and -negative staphylococci, as well as by *Enterobacter*, *Serratia*, and *Pseudomonas* species. Sternotomy infections require debridement and systemic antibiotics.
 4. **Urinary tract** infections are less common than in renal transplant recipients and are managed as would be any nosocomial UTI. Prophylaxis with TMP-SMX for PCP also reduces the incidence of UTIs (see Chapter 15).
 5. **Pleural effusions** might occur postoperatively. In an asymptomatic patient, these may be observed, but if infection is suspected, a diagnostic thoracentesis is indicated.
- B. Reactivation of prior infection can occur.** Refer to section **I.B** under Infections in Renal Transplantation. With respect to HBV, some investigators suggest that transplantation of HBV-positive carriers is safe given that lamivudine controls viral replication posttransplantation [95]. Despite the finding that survival posttransplantation was not impacted by HBV status pretransplantation, others caution against transplantation in this setting. Liver biopsy pretransplantation may be helpful. Fagioli's group found that HBV and HCV behaved more aggressively after cardiac transplantation [96].
- C. Various infections may be transmitted by allograft.**
1. **Transplantation of a *Toxoplasma***-seropositive heart into a seronegative patient poses a 25% to 50% risk for disseminated toxoplasmosis, with a high risk for mortality [97]. A 6-month course of TMP-SMX or pyrimethamine and folinic acid prophylaxis should be initiated [34,97,98].
 2. The risk for **CMV** disease is higher in heart than in kidney recipients. Prophylaxis involves short-term i.v. GCV, then 3 months oral GCV [32,99]. Prophylaxis including immunoglobulin seems to be more effective than use of either agent alone [100]. Alternatively, preemptive approaches have become popular. Various regimens have been identified. One is to start i.v. GCV when ATG/ALG is given for rejection. Addition of oral GCV for 3 months after rejection therapy nullifies the risk for CMV disease [101]. Many centers use quantitative PCR or pp65 antigenemia assays to determine when to give preemptive i.v. GCV [102–107]. Advantages of preemptive approaches include avoidance of drug toxicity and reduction in CMV resistance because fewer patients receive GCV [107]. Furthermore, prophylactic GCV prevents induction of CMV-specific T-cell responses, allowing for late-onset CMV disease after prophylaxis is stopped [103], whereas preemptive therapy allows this T-cell response to occur. Hibberd showed a 52% reduction of CMV disease if GCV was used with ALG [108].
 3. **HCV**-positive donors are a possibility for critically ill heart patients. However, the risk for HCV transmission approaches 80%. Consequences of HCV remain to be seen [109].
 4. **HBV**. Some programs use hearts from donors positive for HBsAg or HBeAb if the recipient has natural immunity to HBV or has been successfully immunized [110].
- II. Immunosuppressive period (1–6 months).** As in renal transplantation, this is the time of maximum immunosuppression. Opportunistic infections surpass nosocomial infections as the most common causes of fever. Infections are similar but often more severe than in renal transplants. *Legionella* and *Nocardia* are more common in heart transplant recipients. With TMP-SMX prophylaxis, the incidence of *Nocardia* has diminished.

- A. Pulmonary infections** constitute the most commonly encountered infectious process [111] and are similar to those encountered in renal transplant patients (see section **II.A** under Infections in Renal Transplantation) [112].
- 1. Legionellosis** is more common in some centers. (See related discussion in Chapter 11.)
 - a. Legionellosis usually presents as a patchy, interstitial pneumonia** that progresses to an alveolar infiltrate. Any appearance is possible; cavitation has been described [33].
 - b. Legionella is difficult to isolate from sputum.** Bronchoscopy with culture may be necessary [113]. An indirect fluorescent antibody study is available, but an increase in titer may be delayed. A single titer of 1:256 or greater is presumptive evidence, whereas paired sera reflecting a fourfold increase are diagnostic. Eighty percent of cases of *Legionella* are caused by serogroup 1. Urinary antigen detection tests, which detect only serogroup 1, have good sensitivity and specificity. Histologic examination usually reveals a bronchopneumonia.
 - c. Treatment.** A second-generation quinolone should be started empirically because of the difficulty in confirming the diagnosis and given for 21 days. Late relapse can occur. Rifampin 600 mg orally twice daily may be added in severe or refractory cases [113]. Azithromycin is generally avoided when patients are on tacrolimus or cyclosporine. Clarithromycin has significant interactions with calcineurin inhibitors.
 - 2. Nocardiosis is seen in heart transplant recipients [114].**
 - a. Nocardia infections** have decreased with use of TMP-SMX prophylaxis for PCP. Most patients have symptomatic lung disease. Although radiographic findings are variable, **the concurrence of skin lesions and a pulmonary infiltrate strongly suggests nocardiosis or cryptococcosis.** See related discussion in Chapter 17.
 - b. Sputum cultures** have a yield of only 30%. **Diagnosis often requires invasive procedures** to obtain tissue for culture and histologic examination. As in renal transplants, about 30% of open-lung biopsy specimens yield a previously unexpected diagnosis [66]. In sputum or lung tissue, acid-fast, gram-positive, filamentous bacteria suggest nocardiosis. All patients with nocardiosis should undergo brain MRI to exclude intracranial disease.
 - c. The drug of choice** is a sulfonamide (e.g., sulfadiazine 2 g orally every 6 hours or TMP-SMX 2 double-strength tablets orally three times daily) for 3 to 6 months (see Chapters 17 and 27L). Serum levels ideally should be monitored, with peak levels adjusted to 12 to 15 mg/dL. Sulfadiazine may crystallize in the renal tubules, resulting in acute renal failure. To prevent this outcome, sodium bicarbonate (or sodium citrate and citric acid [Bicitra]) should be used to maintain the urine pH at greater than 7. In patients allergic to sulfonamides, various combinations of amikacin, minocycline, ceftriaxone, and imipenem have been used with success. Duration of therapy has not been well defined. Infectious disease consultation is advised.
- B. Dermal infections.** See section **II.B** under Infections in Renal Transplantation.
- C. Central nervous system infections.** See section **II.C** as above.
- D. Urinary tract infections.** See section **II.D** under Infections in Renal Transplantation.
- E. Gastrointestinal infections.** See section **II.E** under Infections in Renal Transplantation.
- F. Posttransplantation lymphoproliferative disorders (PTLDs).**
- 1. Etiology and pathogenesis.** Most PTLDs are of B-lymphocyte origin and are often the result of primary EBV infection [115]. **Early diagnosis is essential, because the syndrome may be reversible in the early stages, but** progresses to malignancy if diagnosis is delayed. Those at risk for developing PTLD include a seronegative recipient (10% of the population [116]) of a seropositive graft; patients receiving ALG therapy [116], cyclosporine, or tacrolimus; recipients of nonrenal grafts; and patients with other infections, particularly CMV [117]. Clinical presentation may mimic CMV, with fever, malaise, leukopenia, adenopathy, or splenomegaly. Involvement of the GI tract, lungs, CNS, or the graft itself is

typical [116,118]. A spectrum may occur after transplantation. EBV-associated disease occurs early posttransplantation (≤ 1 year). Several histopathologic patterns have been described. Posttransplantation infectious mononucleosis and plasma cell hyperplasias are distinct forms of PTLD. EBV-associated polymorphic lymphomas, polymorphic B-cell hyperplasia, and lymphomatous PTLD characterize true PTLDs [115]. Adults are more likely to have EBV-negative non-Hodgkin lymphomas after transplantation and are most often EBV-seropositive men over 45 years of age. Retransplantation is another risk factor for EBV-negative non-Hodgkin lymphomas [119]. Lesions are monomorphic and respond poorly to conventional antineoplastic therapies [120].

2. **Diagnosis.** Semiquantitative PCR has been developed to monitor for PTLD. It appears that this assay is better for ruling out PTLD than confirming the diagnosis [121].
3. **Treatment** is relatively ineffective. Initially it involves minimizing immunosuppression. Because high EBV viral loads may be immunosuppressive, the risk for rejection with this reduction is minimal. Because CMV may serve as a cofactor, treatment with GCV and CMVIG may be helpful [115]. Localized symptomatic lesions may be removed surgically; radiation and chemotherapy are reserved for systemic involvement and failure to respond to initial treatment. Monoclonal anti-CD 20, 21, and 24 B-cell antibodies are efficacious against PTLD lesions that contain the targeted cell marker [122].

G. Fever of uncertain origin. See section **II.F** under Infections in Renal Transplantation.

III. Late period (>6 months). The infectious problems encountered in this period are similar to those described in section **III** under Infections in Renal Transplantation.

INFECTIONS IN LIVER TRANSPLANTATION

Infection, the most important determinant of morbidity and mortality in orthotopic liver transplantation (OLT) [123–126], is difficult to **diagnose because of the similarities between infection and rejection**. Bacterial infections tend to occur during treatment of rejection episodes, and devitalized liver tissue is a haven for bacteria. Infections or their treatment may contribute to hepatic dysfunction. Furthermore, liver histology may be altered by infection. The differentiation between rejection and infection is difficult [127].

I. Infection or not infection—that is the question.

A. Rejection may be acute or chronic.

1. **Acute rejection** crisis is the most common cause of graft dysfunction and typically occurs on approximately the fifth day after transplantation.
 - a. **Symptoms and signs** of malaise, anorexia, abdominal discomfort, fever, increased organ size, or clear bile are present in rejection [128].
 - b. **Laboratory studies** should assess for rapidly rising hepatic values, especially bilirubin and prothrombin time. **Liver biopsy is the best diagnostic tool** for evaluating rejection but is dangerous because of preexisting coagulopathy or neovascularization of the implanted liver [128].
 - c. **Radionuclide scans** (dimethyl iminodiacetic acid [HIDA]) shows decreased uptake and excretion not only in rejection but also in ischemic, obstructive, viral, drug, and septic complications. Ultrasonography undertaken with HIDA scan can be used to distinguish between tumor, biloma, abscess, and hepatic infarction.
 - d. **Treatment** of acute rejection requires pulse immunosuppression, which can potentiate infectious complications. **The prognosis** of rejection is guarded; children fare better than adults. Acute rejection leads to 20% of all posttransplantation deaths in OLT [128].
2. **Chronic rejection** targeting the intrahepatic ducts is an ongoing process and may eventuate in a “vanishing bile duct syndrome” at any time [128].
 - a. **Jaundice**, which reflects the obliteration of bile ducts during the rejection process, is the hallmark of chronic rejection, whereas increasing aspartate aminotransferase (AST) and alanine aminotransferase (ALT) values are less specific.

b. Treatment of vanishing bile duct syndrome has been disappointing. In approximately 20% of such recipients, retransplantation is required; survival averages 50% [129].

B. Hepatic dysfunction can occur with viral or bacterial infection. CMV that is established by liver biopsy, or by other diagnostic approaches is most common [130]. Less commonly, bacteremia, an intraabdominal abscess, or pneumonia can produce hyperbilirubinemia, usually in association with an elevated alkaline phosphatase and minimally elevated transaminases [128]. This is referred to as cholestatic jaundice. Hepatotoxic drugs and technical problems such as biliary leak or stricture, bleeding, or hepatic artery thrombosis may simulate infection or rejection.

II. Infection complicates liver transplantation in 80% of recipients. Many will have polymicrobial infection or multiple episodes of infection. Mortality varies between 20% and 30%. Risk factors include length of surgery, multiple blood products, Roux-en-Y anastomosis, CMV infection, and prior abdominal surgery [123–126]. In OLT, the timing of specific infections is less predictable because the graft is an “immunologic” organ. **All patients with fever of unclear origin should undergo CT or ultrasonography to rule out abscess or ductal dilatation. Additionally, because the biliary tree is colonized, antibiotic prophylaxis is essential before biopsy or cholangiogram and should be continued for 48 hours** [32].

A. Immediate posttransplant period (first month). Rejection and infection, the latter involving the peribiliary liver tissue, and the biliary and vascular anastomoses, mark this period. The greater infection rates in liver transplantation can be directly attributed to the technical complexity of the surgery. **Procedure-related infections** increase with the duration of surgery and the number of prior operations [125]. They occur at vascular or enterobiliary anastomoses. Thrombocytopenia is a marker of risk for early infections and increased mortality [131]. **Organisms** are similar to those in renal transplants, although in some centers vancomycin-resistant *Enterococcus faecium* is a significant problem. Selective bowel decontamination seems to lower the incidence of infections [132, 133].

1. Hepatic artery anastomoses can become infected or undergo thrombosis, especially in children, during the first posttransplantation week. This results in peribiliary duct necrosis with secondary abscess formation. Bacteremias have arisen from hepatic or portal vein thrombosis as well. The clinical onset often is heralded by an isolated episode of fever. Alternatively patients may present with ascites or an increase in liver function tests [128].

2. Biliary anastomoses may leak, become obstructed, or become infected by the adjacent gastrointestinal flora. The normal flora will not cause clinical infection unless leaks or an obstruction is present. The manifestations are variable and may include cholangitis, liver abscess, or bacteremia [128]. Postoperative ileus may lead to increased pressure on biliary anastomoses, with subsequent biliary leak and infection.

3. Invasive candidiasis arising from the upper small bowel can occur in up to 44% of patients [134]. Risk factors include hemodialysis, perioperative antibiotics, multiple blood products, prolonged mechanical ventilation, and need for surgical reexploration. These patients should receive prophylactic fluconazole. Use of amphotericin B should be entertained for patients who are intubated for long periods of time. Clotrimazole (10-mg troche) or nystatin suspension (10 mL orally four times daily) often is given to reduce colonization [35].

B. Infection after 30 days more typically mirrors the processes seen in patients receiving heart or kidney transplants. Mortality is lower than in patients who develop infectious complications during the immediate posttransplantation period [33]. However, the infections are more diverse and reflect prolonged immunosuppression.

1. Nosocomial infections can occur in any hospitalized transplant patient. See section **I.A** under Infections in Renal Transplantation.

2. Opportunistic infections are seen in this period and decrease only when immunosuppression is decreased. See section **II.A–F**.

a. CMV infection causes mild persistent hepatic dysfunction and can be distinguished from rejection only by biopsy with **histology and viral culture**.

CMV prophylaxis after liver transplantation consists of two approaches. A short course of i.v. GCV (until bowel function returns) followed by 90 days of oral VGCV lowers the risk for CMV disease even in donor-positive/recipient-negative patients [29]. Oral GCV has proved effective in recipients of antilymphocyte therapy [135]. Preemptive therapy (based on quantitative pp65 antigenemia or PCR assays) consisting of 14 to 21 days of i.v. GCV has established efficacy for prevention of CMV disease [29]. A cost-effectiveness study by Das found that universal prophylaxis consisting of 100 days of oral GCV was the most cost-effective strategy [136]. See section VI under Basic Principles and section II under Infections in Renal Transplantation.

- b. Human herpesvirus 6 (HHV-6)** is a member of the herpesvirus family. Most studies have examined liver transplant recipients. Seroprevalence rates in adults are greater than 90% [137]. Although this is a controversial area, infections have been reported in 30% to 50% of solid organ recipients [137a]. Based on positive CSF PCR results, HHV-6 has been linked with mental status changes and fever (as high as 40°C). However 50% of normal children have a positive CSF PCR result. There is general agreement that HHV-6 causes fever and a rash and possibly thrombocytopenia, leukopenia, and anemia. Infections have peak incidence at 4 weeks. Like other herpesviruses, it is postulated that HHV-6 diminishes cell-mediated function, perhaps elevating the risk for CMV, invasive fungal disease, and mortality [137b]. Calcineurin inhibitors have been associated with an immunosuppression-induced leukoencephalopathy, which may mimic those allegedly related to HHV-6 [138]. MRI demonstrates subcortical white matter lesions in posterior cortical hemispheres. Because both the development and the time of onset of immunosuppression-induced seizures is similar, the exact role of HHV-6 is uncertain.
- c. Hepatitis B** can significantly affect graft survival. There is a high rate of recurrence (83%–100%) of HBV following OLT [139], with progression to chronic active hepatitis by 9 to 12 months, and cirrhosis 2 to 3 years posttransplantation. HBV leads to increased levels of IFN- γ and tumor necrosis factor- α (TNF- α), along with upregulation of TNF- α receptor expression by hepatocytes with subsequent graft injury. Prophylaxis against HBV infections is useful. Regimens of i.v. or intramuscular HBIG reduce recurrence of HBV to less than or equal to 20% [140]. Lamivudine or famciclovir have been given posttransplantation [141], but lamivudine has better activity than famciclovir. Both are more effective in the setting of HBeAg-positive patients, higher ALT levels pretreatment, and HDV coinfection. About 5% of patients have breakthrough elevated HBV DNA levels after initial viral suppression [141]. Despite the emergence of resistance, ongoing lamivudine results in a less aggressive disease course. HBV-positive liver recipients have more infectious complications and probably a greater risk for hepatic neoplasm if HBV recurs [128].
- d. Hepatitis C.** The implications of HCV infection in liver transplantation are unclear. The rate of recurrence of HCV after transplantation is 42% to 88%. Approximately 10% of patients will die or have graft failure due to recurrent HCV. However, 5-year graft survival rates in HCV-positive liver transplant recipients are similar to those for HCV-negative recipients [142]. HCV genotype 1B, high cumulative doses of corticosteroids, and steroid-resistant rejection result in elevated HCV viral loads [142]. Pegylated IFN with or without ribavirin should be considered, before the serum bilirubin exceeds 3 mg/dL, in those who demonstrate histologic recurrence of HCV. Rejection risk is not increased [143]. If IFN three times weekly is not tolerated, benefit may accrue from low-dose daily IFN.
- C. In the late period (>6 months),** opportunistic infections diminish in frequency. The transition from opportunistic infection to community-acquired infection is less clear in the liver transplant recipient. TB presents a particularly difficult problem because of hepatotoxicity from standard antituberculous drugs. Meyers et al. reported on regimens of 2 months of induction followed by continued treatment with ethambutol and ofloxacin for 9 months in patients who developed TB

posttransplantation. Six of seven patients treated with this protocol were alive and free of TB at the end of follow-up [144].

INFECTIONS IN LUNG TRANSPLANTATION (A UNIQUE AND FREQUENTLY ENCOUNTERED SET OF PROBLEMS)

- I. **Outcome.** Survival rates after lung transplantation are 74% the first year, 65% the second year, and 47% at 5 years. Infectious complications account for 50% of deaths, and two thirds involve the respiratory tract [145]. The cumulative incidence of bacterial pneumonia during the first year after lung transplantation is 70%.
- II. **Pathophysiology.** Sinus surgery to decrease colonization pretransplantation is controversial. As a result of the procedure, the graft is denervated, resulting in a diminished cough reflex and disrupted mucociliary clearance. Environmental exposure further escalates the risk for pneumonia. [145]. The bronchial anastomosis is subject to ischemic/infection that may lead to dehiscence or stenosis.
- III. **Etiology**
 - A. Common pathogens include *Pseudomonas* species, other gram-negative organisms, *Staphylococcus aureus*, and *Enterococcus* species. Colonizing organisms found pretransplantation, especially in cystic fibrosis (CF) patients, produce postoperative infections. CF patients benefit from double lung transplantation to lower the risk for graft pneumonia. Colonization by *Aspergillus* species leads to invasive disease in 13% to 26% and is consistently fatal [146]. Risk for invasive aspergillosis peaks in the first 6 months posttransplantation, but 30% occur more than 6 months out.
 - B. CMV incidence is increased after lung transplantation. Risks include size of the organ and amount of lymphoid tissue in the graft. CMV disease occurs in 90% to 100% of donor-positive/recipient-negative patients and in 60% of donor-positive/recipient-positive patients [147]. CMV has been linked to obliterative bronchiolitis, which leads to progressive deterioration in lung function [145,147].
 - C. PTLD occurs more frequently after lung transplantation than for other solid organs. The risk approaches 30% [148] and most often affects the graft. Bronchoscopic lung biopsy (BLB) is an important diagnostic technique and is also useful for diagnosis of infectious complications. BLB specimens are less reliable for detecting graft rejection. Blood loss in excess of 100 mL is the leading complication.
- IV. **Prevention and treatment.** Special considerations after lung transplantation address prevention of invasive fungal infections, multiply resistant bacteria, CMV, viral respiratory pathogens, HSV, and EBV-associated PTLD. For fungus, some centers use a combination of antifungal agents, including lipid complex amphotericin B or itraconazole and inhaled amphotericin B to achieve higher local tissue levels [149]. Lifelong PCP prophylaxis is recommended by some clinicians; at a minimum it should be reinstated with antirejection treatment. TB may occur either due to reactivation, to posttransplantation exposure, or to transmission from the donor. INH prophylaxis is safe and effective [144]. Prophylaxis against HSV with acyclovir or valacyclovir for 3 months posttransplantation is given because HSV pneumonia may be severe. For CMV there may be a benefit to adding CMVIG to GCV.

Infections in pancreatic transplantation will not be reviewed here.

BONE MARROW TRANSPLANTATION

Bone marrow transplantation differs significantly from solid organ transplantation. In BMT patients, HLA typing is closely observed; the immunosuppression is profound; and graft-versus-host disease (GVHD) occurs frequently. Most marrow recipients have undergone therapy for leukemia and have received at least one round, and often several rounds, of antibiotics. Other differences are the absence of a surgical wound and the presence of an initial period of complete immunosuppression lasting approximately 30 days. Absolute leukopenia and the absence of cell-mediated immunity make predictions of infectious agents difficult.

- I. **Basic principles.** Allogeneic transplantation is distinctly different from reinfusion of autologous marrow/stem cells. Immunosuppression posttransplanta-

tion is not done, and GVHD does not occur in the latter group, only the pre-transplantation conditioning.

A. Donor and recipient selection and preparation before BMT

1. **The marrow donor** is ideally an HLA-identical sibling. Twenty-five percent of siblings are HLA identical. Use of partially matched family member marrow and matched, unrelated donor marrow is increasing. It is preferable that the donor and recipient be matched at the HLA-A, -B, and -DR locus, and their mixed lymphocyte cultures must have mutual nonreactivity. Donors should be screened for syphilis, CMV, HSV, HIV, HCV, VZV, EBV, and HBV. Cardiac and pulmonary status should be evaluated if anesthesia will be used for marrow harvest.
2. **Recipient selection.** BMT is used to treat leukemia, lymphoma, multiple myeloma, severe combined immunodeficiency, aplastic anemia, sickle cell disease, and enzyme deficiencies. Common to these disorders is an immunologic deficiency that predisposes to infection even prior to marrow irradiation and immunosuppression therapy. Research into BMT for solid organ tumors is ongoing.
3. **Immunosuppressive therapy.** Before BMT, patients receive a regimen that ablates existing disease and allows donor marrow engraftment, combining chemotherapy with total body irradiation for those with malignancy. Potential regimens include methotrexate (MTX), cyclosporine, ATG, and corticosteroids. Donor marrow is pretreated with monoclonal antibody or lectins to remove T cells in an attempt to prevent GVHD [150].

B. Measures to prevent infection

1. **Protective environment.** Patient hygiene and fastidious handwashing by staff and visitors is essential. Allogeneic recipients should be housed in rooms that have at least 12 air exchanges per hour. Use of portable high-efficiency particulate air filters is recommended [151]. If available, laminar air flow rooms are useful, but patients find them uncomfortable for prolonged periods of time [49].
2. **Antimicrobial prophylaxis.** In the early posttransplantation period, before fever develops, many centers use ciprofloxacin prophylaxis. Later, one TMP-SMX double-strength tablet daily is useful for chronic GVHD because of the high incidence of bacterial infections. This also decreases the frequency of PCP [151], toxoplasmosis, and nocardiosis. IVIG may be indicated in patients who are hypogammaglobulinemic to prevent upper and lower respiratory tract infections [151]. Prophylactic fluconazole 400 mg/day orally reduces the incidence of superficial and systemic fungal infections in allogeneic and high-risk autologous BMT patients if they are likely to have prolonged neutropenia [152]; itraconazole prophylaxis has been effective as well [153].
3. **CMV prophylaxis** with CMVIG is considered for seropositive marrow into a seronegative recipient. However, the risk for CMV disease is greatest in the seropositive recipient. Options for CMV prevention include i.v. GCV from engraftment to day 100 posttransplantation or preemptive i.v. GCV triggered by a positive CMV antigenemia or PCR assay result. If the CMV pairing is donor positive/recipient negative, preemptive therapy coupled with leukocyte-poor blood products is preferred for BMT recipients because the risk for CMV disease is low [49].

II. Infections in BMT have been recently reviewed [154].

A. The early period (0–21 days) is characterized by an **absolute neutrophil count (ANC) of less than 100, lymphopenia,** and mucositis. Fever, which usually is the only sign of infection, is the hallmark and almost invariably complicates the early neutropenic period. Noninfectious fever—from transfusion, embolism, deep hemorrhage, or drugs—may occur. Central venous and Foley catheters contribute to the breakdown of normal anatomic barriers. Both increase the chance for bacteremia [49]. HSV infection occurs at this time [155].

1. **Blood cultures must be obtained. In the febrile patient, bacteremia** occurs in 20% to 30% of patients. Patients appear septic. Organisms include Enterobacteriaceae, coagulase-negative staphylococci, and viridans streptococci [156]. Empiric β -lactam antibiotic (e.g., piperacillin, cefepime, or imipenem) with or without an aminoglycoside is administered (see Chapter 2). With the increasing incidence of gram-positive infections, two options exist. Many authorities hold vancomycin until gram-positive organisms are isolated [156a]. Others initiate therapy with

vancomycin and stop it if blood cultures are negative. Antibiotics are continued until the ANC increases to $500/\text{mm}^3$, unless infection is proven, then duration should follow standard practice. Treatment may be abbreviated in the febrile clinically stable patient after 1 week, when the ANC is greater than $200/\text{mm}^3$ and cultures remain negative. For indwelling catheter infections, see Chapter 2.

2. **Candida infections** are considered if fever persists or recurs while the patient is on antibiotic treatment. The incidence is related to the duration of neutropenia [152]. Febrile patients should undergo urine, blood, and sputum cultures, biopsy of skin lesions, and retinal examination for lesions. A course of antifungal therapy is warranted even with negative cultures [35,157]. As noted above, these individuals are on prophylactic oral fluconazole. Therefore, for allogeneic transplant patients on nephrotoxic immunosuppressive agents, lipid complex amphotericin B is the agent used [35]. In auto-BMT recipients with a serum creatinine level of at least 2.0 mg/dL, 50% will require hemodialysis; if amphotericin is initiated and creatinine increases, early switch to lipid complex amphotericin B is reasonable. **Molds such as *Aspergillus*** that are resistant to fluconazole present as sinusitis and lung nodules or abscess and are difficult to treat. Although initially they may look very well, the rate of mortality is high in patients with *Aspergillus*. Radiographic imaging of the chest and sinuses may demonstrate otherwise occult fungal infections. The treatment regimen for *Aspergillus* is not settled. Some clinicians administer liposomal amphotericin up to 15 mg/kg.
3. **Orolabial HSV reactivation** occurs in 75% of seropositive patients and progresses to esophagitis or pneumonia [151,158]. Oral acyclovir is used for prophylaxis and in i.v. preparation for treatment.

B. The middle period (21–100 days) often is characterized by continued granulocytopenia from graft failure or rejection. Bacterial and fungal infection remain important. With successful engraftment and the gradual return of immune function, **the main obstacle is acute GVHD**. This presents with rash, diarrhea, and hepatic dysfunction, and is believed to result from proliferation of donor T-lymphocytes reacting to host tissue antigens. In parallel, viruses and protozoa become important causes of infection.

1. **Interstitial pneumonia. The second major risk to the patient during this period is interstitial pneumonia** [159], which is seen in 40% to 60% of patients. The mortality rate exceeds 50% [159]. Fever, increased respiratory rate, and nonproductive cough occurring approximately 45 days after BMT are characteristic. CMV is found in one-half of the cases. Pretransplantation lung function is a predictor of interstitial pneumonia due to CMV. HHV-6 infections may cause interstitial pneumonia in BMT recipients (137a). The incidence of PCP is declining with the use of prophylactic TMP-SMX. Uncommonly, *Aspergillus*, adenovirus, HSV, parainfluenza, adenovirus, RSV, and *Chlamydia* are causative agents. RSV is associated with a high mortality rate [160]. Thirty percent to 45% of cases are idiopathic [159]. **Idiopathic interstitial pneumonia** [161–163] has a similar presentation, but no infectious etiology can be demonstrated. Pulmonary fibrosis may be immune mediated. Risk factors include preconditioning irradiation and chemotherapy, MTX to control GVHD, age greater than 20 years, and a low pretransplantation Karnovsky score [161]. Treatment is supportive. Superinfection is a frequent complication. The mortality rate approaches 60% [161].
 - a. **Diagnosis.** Hypoxemia and infiltrates characterize interstitial pneumonia. If bronchoscopy with lavage and biopsy is nondiagnostic and the patient has not improved after 24 to 48 hours of appropriate antibiotics, open lung biopsy should be performed.
 - b. **Treatment. Until biopsy results are known, a broad-spectrum β -lactam with an aminoglycoside is recommended** [151]. GCV in combination with CMV immunoglobulin is used for CMV pneumonitis [162].
2. **Dermal infections** are associated with acute GVHD or with indwelling catheters.
 - a. **Acute GVHD** with its generalized maculopapular skin rash can evolve into bullae, ulcers, and epidermolysis. The rash mimics maculopapular drug eruption. Histologic confirmation is necessary. Corticosteroids, MTX, ATG, and

cyclosporine have been used for treatment. HHV-6 infections and GVHD are interrelated. Both cause increase in cytokines with subsequent reactivation of HHV-6 or induction of GVHD.

- b. **Skin infections are often associated with an indwelling catheter** (see Chapter 4).
3. **Central nervous system infections can** present as meningitis or as subtle changes in mental status (see Chapter 6).
4. **Urinary tract infections** (see Chapter 15).
5. **Gastrointestinal tract infections.** Nausea, vomiting, and anorexia during the first 2 weeks after BMT are usually side effects of chemoradiotherapy or of drugs. Between days 15 and 60, acute GVHD, HSV infections, and drug toxicity are possibilities.
 - a. **Diarrhea** is common in this period. Chemoradiotherapy sequelae are diagnosed by biopsy and treated supportively. Drug toxicity is excluded by discontinuation or substitution of medications. Chemotherapeutic agents and antimicrobials may cause *Clostridium difficile* colitis (see Chapter 13). Patients developing acute GVHD present with nausea and vomiting and have hemocult-positive, watery stools with a high protein content. CT scans or sonograms showing edematous intestine, or mucosal biopsies of duodenum or colon may aid in the diagnosis. Enteroviruses, rotavirus, and especially adenovirus may mimic or be associated with GVHD. The same may be said for fungi, parasites, and bacteria. Stool should be cultured for viruses and enteric pathogens and examined for ova and parasites. Endoscopic biopsy with viral culture is indicated if CMV or HSV is suspected or if the diagnosis remains unclear.
 - b. **Mucositis or acute GVHD often causes gastrointestinal bleeding**, but other causes include CMV, EBV-induced PTLT, peptic ulcer, and Mallory-Weiss tears.
 - c. **Esophagitis** caused by chemoradiotherapy occurs early in the posttransplantation period and usually is self-limited. Because viruses, fungi, or bacteria may cause disease singly or in combination [164], diagnosis requires biopsy. Stricture formation may be a late sequela.
 - d. **Abdominal pain. Early-onset abdominal pain** may be caused by **chemoradiotherapy or venoocclusive disease**. Right upper quadrant pain, ascites, and fluid retention can be seen with the latter. Such disease involves the terminal hepatic venules and sublobular veins, with necrosis of hepatocytes leading to fibrosis and obstruction of sinusoidal blood flow. No intervention has altered the disease course, which carries a mortality rate of 30% [164].

Later, acute GVHD and infectious enteritis are common causes of abdominal pain and may occur together. Bacterial invasion and inflammation of the bowel wall characterize typhlitis or neutropenic enterocolitis that presents with right lower quadrant pain, vomiting, fever, and diarrhea. *Clostridium septicum* may be cultured from blood, although other anaerobes, gram-negative organisms, or yeast may be involved. Sepsis syndrome and edema of the colonic mucosa on CT scanning further suggest this diagnosis. Supportive therapy with appropriate antibiotic treatment is indicated; surgical resection is a consideration while waiting for the neutropenia to resolve [164].
6. **Disseminated CMV infection.** GVHD predisposes to symptomatic disease. Approximately 50% of cases are caused by reactivation, but other CMV infections are acquired from the donor or from CMV-seropositive blood products. The nonspecific presentation may include fever, neutropenia, or organ dysfunction. Many patients are asymptomatic [49]. One-fifth or so of CMV infections culminate in pneumonia, with a mortality rate of 50% to 60% [153,165]. Diagnosis requires biopsy of the involved organ and CMV cultures of blood and urine. Alternatively, PCR or pp65 antigenemia assays may be helpful. Avoidance of seropositive marrow donors, use of filtered blood products, and early preemptive therapy based on quantitative PCR or pp65 antigen can prevent most disease [35]. Treatment of visceral disease comprises GCV with CMVIG [162].
7. **Line-related bacteremias.** The patient's immunosuppressed state, the presence of GVHD, and indwelling venous catheters all contribute to the development

of *Candida*, *Staphylococcus epidermidis*, or *Corynebacterium* species sepsis (see Chapter 2).

- C. The late period (>100 days)** is associated with fewer infections because most i.v. lines have been removed, fewer immunosuppressive agents are used, and the immune system has progressively recovered. **Chronic GVHD** occurs in 30% to 50% of patients. It may follow acute GVHD or arise *de novo* [164]. It may be focal and mild, or it may be generalized, resembling autoimmune disease with scleroderma-like skin lesions, hepatitis, malabsorption, and sicca syndrome. Chronic GVHD leads to an increased risk for infection owing to interruption of skin and mucosal barriers, delayed recovery of cell-mediated and humoral immunity, and functional asplenia.
- 1. Pulmonary infections.** The entire respiratory tract is susceptible to infection because chronic GVHD leads to IgA deficiency and sicca syndrome. *Streptococcus pneumoniae* predominates, whereas fungi, CMV, and PCP are less common. TMP-SMX is used for bacterial and PCP prophylaxis.
 - 2. Dermal infections.** VZV occurs in 30% of all patients and 45% of patients with chronic GVHD. Both primary and reactivation disease are encountered. Bacterial superinfection, scarring, postherpetic neuralgia, and trigeminal zoster occur. Visceral involvement is life threatening, affecting pelvic and abdominal organs, the lungs, the oral and genital mucous membranes, and the CNS. Patients with cutaneous or visceral VZV should be isolated and treated with i.v. acyclovir. VZIG is indicated for primary exposure to prevent or ameliorate illness. See discussions in Chapters 4 and 26.
 - 3. Disseminated infections.** Pneumococcal sepsis is seen, as are bacteremias with *H. influenzae*, *Neisseria meningitidis*, *S. aureus*, and gram-negative aerobes. A β -lactam and aminoglycoside should be used empirically when these bacteremic syndromes are suspected. TMP-SMX prophylaxis is effective in decreasing the incidence of bacteremia.

21. ZONOOSES (INCLUDING LYME DISEASE)

Candace L. Mitchell and J. Thomas Cross, Jr.

ZONOOSES

Although Virchow coined the phrase “zoonosis,” zoonoses have been identified for over 4,000 years. The Eshunni Code of Mesopotamia (before 2300 B.C.) stated that the owner of a vicious dog who had bitten a man causing his death should be fined. This was likely the first description of rabies. In 1959, the World Health Organization convened a committee of experts and **defined zoonosis as “Those diseases and infections naturally transmitted between animals and man.”** Today we know that over 200 different zoonoses are transmitted from animals to humans. A single chapter is inadequate to provide the depth necessary to explore each of the many zoonoses encountered in the United States and their widely varying geographic and vector-dependent features. We have selected a few zoonoses and the animals associated with them for a brief review. Lyme disease, which is the most common vector-borne infection in the United States today, is discussed in greater detail.

I. Factors influencing acquisition of zoonoses. The probability of zoonotic disease transmission from animals to humans is influenced by many factors: length of time the animal is infective, length of the incubation period in animals, stability of the organism in the environment, available modes of transmission, virulence of the organism for humans, density of infected animals in a community, and community control of wild rodents and insects.

A. Human contacts with animals. Domesticated animals are an important part of almost all cultures, including in the United States (Table 21.1). However, many opportunities exist for contact with other animals and disease vectors. **Thus, a thorough exposure and travel history is essential in evaluating patients for a suspected zoonosis.** This identifies the likely animals and vectors encountered, which in turn suggests the most likely possible infections (Tables 21.2 to 21.12).

1. Pets. In the United States, it is estimated that 55% of households have a dog or cat. Additionally, 15% to 20% have pet birds. Common pets in the United States are listed in Table 21.1. Their presence in the household should always be sought in the history.

2. Farm animals are also frequent in rural households, including those that are not working farms.

3. Outdoor exposure. Many people venture into the wilderness for recreation or build houses in undeveloped settings. Others spend their time gardening or similar outdoor activity nearer to the home. This increases the likelihood of exposure to specific animals or vectors for zoonoses. For example, a person camping in Connecticut in the summer is much more likely to be exposed to Lyme disease than is a person camping in southern Louisiana. International travel adds the possibility of more exotic diseases.

B. Animal and vector contact with humans. Climate and habitat changes may increase animal and vector populations, permitting their encroachment into residential areas and increasing the chances for disease transmission.

C. Combinations of human and animal/vector factors are usually present to influence the transmission of animal-borne infections to humans. For example, the return of forests in the northeast enabled population expansion of the white-tailed deer and white-footed mouse, important hosts in the life cycle of *Ixodes* ticks. Suburban living near forested areas and outdoors activities brought more susceptible people into contact with the tick and contributed to the risk for Lyme disease. Other influences on these complex interactions include natural cycles of food sources for animal reservoirs (such as acorns) and choice of landscaping [1,2].

D. Routes of transmission. Zoonoses can be transmitted by any of the following routes:

1. Direct or indirect contact with animals (e.g., their feces, urine, saliva, blood, milk, and bedding).

2. Biting insects.

Table 21.1. Common Household Pets in the United States

Snakes
Iguanas
Turtles
Fish
Monkeys
Miniature pigs, goats
Ferrets
Rabbits

3. **Inhalation** of airborne contaminated secretions.

4. **Ingestion** of contaminated foods or drinks.

5. **Xenotransplantation** refers to the transfer of animal tissue into humans. This new and developing field is regulated in the United States because of the theoretical risks for transferring animal viruses or other agents into human recipients. Resulting infections have been called “xenoses” or “xenozoonoses” [3]. The risks of cross-species infection have been underscored by the recent demonstration of replication-competent baboon cytomegalovirus in blood from a patient who had received a baboon liver 4 weeks earlier [4] and the propensity of retroviruses to infect varying species [3]. As xenotransplantation becomes more common, surveillance must be maintained for the emergence of new infectious diseases.

6. Interestingly, humans can also transmit infection to animals (e.g., *C. jejuni* spread from owner to dog).

II. Infections acquired from cats (Table 21.2)

A. Cat bites [5]

1. Microbiology

a. *Pasteurella multocida* is a small, nonmotile, polymorphic, gram-negative bacillus. It inhabits the oral cavity and upper respiratory tract of many

Toxoplasmosis
Tularemia

animals besides cats (rabbits, rodents, dogs, mice, and birds). Cats and dogs are frequently healthy carriers. This organism has been cultured from 75% of cat bites.

- b. **Other aerobes commonly involved** include *Streptococci*, *Staphylococci*, *Moraxella*, and *Neisseria*. **Common anaerobes** include *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella*. *Erysipelothrix rhusiopathiae* has been isolated from cat bites on occasion [3].
2. **Clinical manifestations.** Most bites and scratches lead to local inflammation around the site and can be complicated by abscess formation and/or systemic symptoms. Patients usually present with a wound infection from bites and scratches (Color Plate 4.11). Occasionally, cat bites can lead to meningitis, endocarditis, septic arthritis, and septic shock [6].
 3. **Treatment.** Cat bites in general require treatment at the time of the bite because 80% will become infected. **Amoxicillin/clavulanate or doxycycline** is recommended for treatment [7]. It should be noted that *P. multocida* is resistant to dicloxacillin, cephalixin, and clindamycin.

B. Cat scratches

1. **Cat scratch disease** was described more than 50 years ago [8]. The causative organism has been identified as *Bartonella henselae* (formerly *Rochalimaea*) [9,10]. More than 40,000 cases are diagnosed in the United States annually, with more than 2,000 hospitalizations [10,11]. Most reported cases occur in males under the age of 20 with a peak incidence in the fall and winter [12]. More than 90% of patients have a history of some type of contact with cats, and 57% to 83% have a history of a cat scratch. Highest risk seems to occur with kittens younger than 12 months of age and being exposed to a kitten with fleas.
 - a. **The cardinal clinical manifestation is tender regional lymphadenopathy.** Because adenopathy usually appears 1 to 2 weeks after a cat scratch or bite, the **primary inoculation papule or pustule** proximal to the nodes may have subsided or be overlooked. Malaise and other systemic symptoms are common, but significant fever is infrequent. Long-standing nodes may suppurate, but these are the minority. Adenopathy is self-limited, slowly subsiding over several months. Parinaud oculoglandular syndrome occurs with infection of the conjunctiva and ipsilateral preauricular nodes. Other less common manifestations include encephalitis, meningitis, myelitis, hepatic or splenic infection, and osteomyelitis.
 - b. **Diagnosis** can be made on clinical grounds for patients with a typical presentation and history of recent cat scratch. Testing for serum antibodies to *B. henselae* is helpful. Biopsy of involved nodes reveals a characteristic granulomatous reaction that is not diagnostic. Organisms can be visualized by Warthin-Starry stain or similar silver impregnation methods. Polymerase chain reaction (PCR) on tissue is sensitive and specific but not readily available. Skin testing is not useful.
 - c. **Treatment** of cat scratch disease with most antimicrobials has been ineffective. However, azithromycin in a small (29 patients) prospective, randomized, double-blind, placebo-controlled trial showed 80% reduction in node size in 7 of 14 azithromycin-treated patients during the first 30 days of infection [13]. After 30 days, there was no difference between placebo and azithromycin.
2. **Other syndromes caused by *B. henselae*** include fever of unknown origin and encephalitis in children [10,14]. In patients with acquired immunodeficiency syndrome (AIDS), *B. henselae* from cats has been shown to produce bacillary angiomatosis and hepatic and splenic peliosis; it also frequently causes fever of unknown origin in human immunodeficiency virus-infected patients (see Chapter 18).
3. Occasionally other agents are associated with cat scratches and fleas (Table 21.2). These include tularemia, plague [15], *Capnocytophaga canimorsus* septicemia [16], and the newly recognized gram-negative organism Centers for Disease Control and Prevention (CDC) group NO-1 [17].

C. Toxoplasmosis (*Toxoplasma gondii*)

1. Cats are the definitive host for the protozoan parasite *T. gondii*. Toxoplasmosis is of particular concern in immunocompromised patients and in pregnant women.

a. Congenital toxoplasmosis is the “T” in TORCH infections. *T. gondii* may infect the unborn child by transplacental passage during initial maternal infection. If a mother seroconverts during pregnancy there is a 50% probability that the infant will be infected at the time of delivery; however, only about 10% have clinical manifestations of disease. Clinical presentation in newborns can include chorioretinitis, meningitis, microcephaly, and cerebral calcifications. Additionally, petechiae, hepatosplenomegaly, jaundice, various rashes, and pneumonitis are commonly seen. Diagnosis can be difficult and relies on serologic assays (see Chapter 3).

b. Toxoplasmosis in immunocompetent hosts is usually asymptomatic. When clinically apparent the most common manifestation is cervical adenopathy, although other nodes may also be involved. Many patients also have systemic symptoms, and the illness may mimic mononucleosis (see Chapter 9).

Ocular toxoplasmosis may cause symptomatic progressive chorioretinitis. Most cases represent congenitally acquired infection, and both eyes may be affected. Acquired toxoplasmosis may also result in retinal involvement; this may occur during acute infection or from later progression. Thus, ocular toxoplasmosis may present at any age (see Chapter 7).

c. Toxoplasmosis in immunocompromised hosts is a potentially life-threatening illness. This may result from newly acquired infection or from reactivation of latent infection. Patients with AIDS and others with impaired cell-mediated immunity (e.g., bone marrow or solid organ transplantation) are at greatest risk. Although encephalitis is the most commonly recognized syndrome, other sites of involvement may result in pneumonia, retinitis, myocarditis, and hepatitis. Seronegative immunocompromised patients should take precautions to avoid acquiring toxoplasmosis (see Chapters 6 and 18).

D. Cat organisms not infectious to humans include tapeworms, feline giardia, feline immunodeficiency virus, feline infectious peritonitis, and feline leukemia virus.

III. Infections associated with dogs (Table 21.3). Dogs may transmit the same organisms as cats. In fact, a case of meningitis due to *Pasteurella* occurred in a woman who kissed her dog frequently.

Table 21.3. Diseases Associated with Dogs

Anthrax

Rocky Mountain spotted fever
Salmonellosis
Strongyloidiasis
Tularemia
Yersiniosis

- A. Rabies** is the most deadly of the diseases that can be transmitted from animals to humans. In the United States the largest concern for this organism occurs in areas where humans infringe on the habitat of infected wild animals, especially raccoons.
1. **The virus** that causes rabies belongs in the genus *Lyssavirus* of the family Rhabdoviridae [18] and causes an acute almost invariably fatal disease. In the United States, wildlife rabies most frequently involves skunks, raccoons, and bats. Only about 5% to 10% of cases occur in domesticated animals each year. Transmission occurs in virus-laden saliva by bite, scratch, or abrasion. Rabid dogs can shed virus for 5 to 7 days before symptoms occur. Aerosol transmission has occurred in laboratory workers, as well as in caves where bats roost.
 2. **Animal rabies.** The clinical course in dogs can be divided into three phases: the prodromal, the excitative, and the paralytic. In any animal, the first sign is a change in behavior, which can be indistinguishable from an injury, foreign body in the mouth, poisoning, or an early infectious disease. Temperature change is usually not significant. Animals usually stop eating and drinking and may seek solitude. After the prodromal period of 1 to 3 days, animals either show signs of paralysis or become vicious. The disease progresses rapidly after paralysis develops and death occurs within 10 days of the first signs of infection. Bats flying in daytime are probably rabid.
 3. **Human rabies.** Cases in the United States rarely have a history of an animal bite, although this is much more common in other parts of the world. Pain appears at the site of the bite, followed by paresthesias. The skin is sensitive to changes of temperature, especially wind or air-conditioning currents. Attempts at drinking cause extremely painful laryngeal spasm, so that the patient refuses to drink (hydrophobia). Large amounts of thick tenacious saliva are present. The patient is restless and behaves in an unusual manner. Muscle spasm, laryngospasm, and extreme excitability are present. Seizures are common.
 4. **Diagnosis** in animals can be established by viral isolation from body fluid or tissue or fluorescent antibody staining of tissues, including cornea, frozen skin, and brain. Human diagnosis premortem is usually made by PCR or staining for viral antigen in saliva, skin, brain, or cornea. Nuchal skin biopsy and saliva offer better yields than do corneal specimens.
 5. **Treatment** is usually supportive and the disease is invariably fatal in humans.
 6. **Prevention [19].** Prophylaxis is essential because there is no treatment for clinical rabies. Nonetheless, each year in the United States many more persons than necessary receive postexposure rabies prophylaxis.
 - a. **Preexposure prophylaxis** with vaccine is indicated for veterinarians, animal handlers, and persons with potential exposure to rabies (e.g., spelunkers). Booster doses are indicated when antibody levels fall.
 - b. **Postexposure prophylaxis** is given after a careful consideration of the animal and the exposure. In the United States rabies is almost never transmitted by adequately vaccinated dogs or cats, squirrels, lagomorphs, and small rodents, including gerbils and hamsters. If a biting dog, cat, or ferret is healthy and available, prophylaxis may be withheld while the animal is observed for 10 days. Prophylaxis should be started at the first sign of a rabies-compatible illness, and the animal should be killed for testing. **Animals such as skunks, foxes, raccoons, coyotes, and bats should be regarded as rabid** unless captured and proven otherwise. Local authorities should be consulted to review the current epidemiology of rabies in the animal species under scrutiny, including dogs and cats that are unavailable for observation or testing.

The circumstances of the incident should be thoroughly elucidated.

 Unprovoked attacks are an indication of increased risk. The details of the exposure must be ascertained, including whether a bite occurred and if there was saliva exposure to cuts, broken skin, or mucous membranes (see also Chapters 4 and 23).
- (1) **The wound should be cleaned** with soap and water or a virucidal preparation (e.g., povidone-iodine).
 - (2) **Rabies immune globulin, 20 IU/kg**, should be infiltrated around the wound to the fullest possible extent. Any remaining rabies immune

globulin should be given intramuscularly at a site distant from vaccine. Previously vaccinated individuals do not need rabies immune globulin.

- (3) **Rabies vaccine** (any of the available preparations) should be given. It is administered intramuscularly in the deltoid on days 0, 3, 7, 14, and 28; previously vaccinated individuals only need injections on days 0 and 3. Small children may be given vaccine in the thigh (see Chapter 23).

B. Leptospirosis

1. **Animal sources.** Dogs, rats, mice, guinea pigs, gerbils, rabbits, hamsters, and reptiles can transmit *Leptospira* to humans. It has been noted that 40% of stray dogs may be seropositive for this organism. Rodents are the only major animal species that can shed leptospires throughout their lifespan without clinical evidence of disease. Active shedding by lab animals can go unnoticed until personnel handling the animals become ill.
2. **Transmission.** The organism is most often transmitted to humans by the urine of the reservoir host and may survive in water for prolonged periods. Handling affected animals, contaminating hands or abrasions with urine, or aerosol exposure during cage cleaning are among the most common routes of acquisition. Many infections are reported in those after bathing or swimming in infected waters or with infected pets. The organism may also enter through minor skin abrasions and the conjunctiva. Outdoor activities, including athletic events, are important risk factors [20].
3. **Animal disease.** In cattle, fever and anorexia occur with rapid decline in milk yield and atypical mastitis. Pregnant cows abort with retention of placenta. In dogs and cats, gastroenteritis, jaundice, and nephritis may occur.
4. **Human disease.** This ranges from inapparent infection (most) to severe illness and death. Although leptospirosis is classically a biphasic illness, signs and symptoms are frequently continuous and not biphasic. Initially, weakness, headache, myalgias, chills, and fever occur. This is accompanied by leukocytosis, painful orchitis, conjunctival suffusion, and nonspecific rash. Improvement generally occurs within a week, but fever and myalgias may recur if the patient has a biphasic illness. It is during this phase that aseptic meningitis may be present (see Chapter 6). Icteric leptospirosis (Weil syndrome) is the most severe form of the disease, characterized by impaired renal and hepatic function, abnormal mental status, pulmonary infiltrates, hypotension, and a 5% to 10% mortality rate.
5. **Diagnosis.** The organism may be identified by darkfield examination of the patient's blood or urine, but this requires expert interpretation. Culture of blood, urine, and cerebrospinal fluid (CSF) should be attempted but is difficult and requires several weeks. Cultures are usually only positive in the blood and central nervous system (CNS) in the first week of infection and in the urine later in disease. Antibody testing may provide a retrospective diagnosis. PCR testing is not widely available.
6. **Treatment.** The value of treatment in mild cases is controversial, but antibiotics should be given to patients with more severe illness. Penicillin G (1.5 million units qid) or ampicillin can be used intravenously for moderate or severe disease, and amoxicillin or doxycycline may be used orally for mild disease.
7. **Prevention** involves several steps. Vaccination in cattle, swine, and dogs is important to eliminate domestic reservoirs. Risky activities should be avoided, particularly swimming in or drinking from potentially contaminated water. Animal workers should wear boots and gloves. Rodent control is also important. Weekly doxycycline has been used for those who cannot avoid prolonged potential exposures [20].

IV. Diseases associated with other animals (Tables 21.4 to 21.12)

- A. **Salmonellosis.** For many years, infections with *Salmonella* species have been a problem in the United States. Animals commonly associated with this infection included chickens and turtles, but the recent popularity of iguanas has resulted in these animals as a commonly reported source. This has been especially important in pediatric cases (see Chapter 13).
- B. **Plague** is an acute febrile illness caused by the gram-negative bacillus *Yersinia pestis*. Human infection results from the bites of infected rodent fleas. The incubation

Salmonellosis
<i>Vibrio</i> infection

period is usually 2 to 8 days. The clinical course can be rapidly fatal without prompt therapy. In the United States, plague is generally confined to the southwestern United States with ground squirrels, prairie dogs, and wood rats being the common reservoirs. Classic bubonic plague occurs with sudden onset of fever, chills, and headache followed quickly by a localized lymphadenitis known as a bubo. See Chapters 4 and 11 for a further discussion of plague.

C. Brucellosis (undulant fever)

1. Epidemiology. Most cases in the United States are due to occupational exposure to *Brucella abortus* from cattle; veterinarians, farmers, and abattoir workers are at greatest risk. Those affected are mainly men, and occasionally laboratory and technical personnel are infected. However, in Texas and Florida the ingestion of unpasteurized dairy products infected with *Brucella melitensis* (from goats, sheep, and camels) occurs in adults and children of both sexes. *B. melitensis* produces a more severe clinical pattern and can produce a chronic form. *B. suis* is found in swine, and *B. canis* is found in dogs.

2. Clinical manifestations. Acute infection presents with high fever, malaise, headache, sweats, and arthralgias. In many cases, constipation, back pain, and weight loss are found. Weight loss of 20 pounds in 2 months is not uncommon. Localization of infection may occur at any time in the illness and is heralded by symptoms and signs in that organ system. Hepatic enlargement may indicate granulomatous hepatitis or abscess, and splenomegaly may be seen. Hematologic manifestations include various forms of cytopenias. Articular complaints are seen with reactive arthritis and septic arthritis. Vertebral osteomyelitis may also occur. CNS findings may indicate neurobrucellosis. Renal and cardiac involvement are possible.

A subacute form occurs more commonly in endemic areas of the world (known as Malta fever). The chronic form occurs after a year of illness and usually requires bone marrow biopsy to diagnose.

3. Diagnosis is usually made by routine agglutination assays to detect antibodies to *Brucella*. However, *B. canis* does not react in the standard assay, and must be requested from the CDC. Blood or bone marrow cultures are helpful but must be incubated for at least 2 weeks. The laboratory should be notified when brucellosis is suspected to correctly process cultures.

4. Treatment is difficult because of the intracellular nature of the infection. In adults oral doxycycline 100 mg twice daily for 45 days plus streptomycin 1 g intramuscularly daily for 2 weeks or doxycycline 100 mg twice daily plus oral rifampin 600 mg daily for 45 days are recommended. In children under the age of 8, a combination of oral rifampin 15 to 20 mg/kg once daily for 4 weeks plus gentamicin for 5 to 10 days is effective.

5. Prevention is by control of animal infections and proper food safety measures.

Table 21.12. Diseases Acquired from Exotic Animals

Armadillos
Leprosy
Bears
Trichinosis
Camels
Brucellosis
<i>Campylobacter</i> infection
Plague
Salmonellosis
Elephants
Anthrax
<i>Mycobacterium tuberculosis</i> infection

Weasels, otters, badgers, skunks
Bovine tuberculosis
Rabies
Whales, dolphins, porpoises
<i>Mycobacterium marinum</i> infection

D. Psittacosis. *Chlamydia psittaci* has a wide range of host species, including birds, humans, and lower mammals. The systemic illness associated with *C. psittaci* has been termed “psittacosis” because of its association with parrots and other psittacine birds. The term “ornithosis” is likely more appropriate because of the wide range of birds that harbor this organism.

- 1. Epidemiology.** Those at greatest risk include workers in aviaries, poultry abattoirs, zoos, pet shops, and veterinary offices. Poultry breeders are at significant risk and account for most outbreaks. It must be noted that birds can be healthy appearing yet transmit the disease.
- 2. Clinical manifestations.** *C. psittaci* is inhaled in aerosol form and travels to the alveoli. It disseminates to regional lymph nodes and the reticuloendothelial system. Classically it presents as an atypical pneumonia (see Chapter 11), although it may also manifest as fever of unknown origin (see Chapter 1). Endocarditis, rash, panniculitis, and a pseudotypoid presentation can occur. Incubation periods range from 5 to 21 days. In about 20% of cases no exposure to birds is found. Most patients present with fever, sweats, and minimally productive cough. Headache may be prominent and can be helpful in the setting of pneumonitis. Diarrhea and myalgias are also common. Splenomegaly and hepatomegaly may be found. Chest radiography usually shows a lobar infiltrate, but any pattern is possible.
- 3. Diagnosis** is based on serologic confirmation. A fourfold rise in complement fixation antibody titer, or a random titer greater than 1:32, supports the diagnosis in a patient with a compatible illness. Because the complement fixation test detects cross-reacting antibodies with other *Chlamydia*, the serum microimmunofluorescence assay may be used to detect specific antibodies.
- 4. Therapy.** The antibiotic of choice is usually a tetracycline, and patients usually improve within the first few days. Most use doxycycline 100 mg twice daily for 14 to 21 days. In endocarditis, courses up to 6 weeks of a tetracycline are recommended and valve replacement is almost invariably necessary. The newer agent azithromycin has been shown to be effective at a dose of 10 mg/kg of body weight for 7 days.

E. Tularemia

- 1. Epidemiology.** *Francisella tularensis* is a gram-negative coccobacillus that causes the disease tularemia. Sources of the organism include over 100 species of wild animals (most commonly rabbits, hares, squirrels, and deer), some domestic animals (rabbits, cats, dogs, and cattle), and arthropods (particularly ticks, deerflies, and mosquitoes). In the United States, rabbits and ticks are the major sources for infection. People at risk are those with occupational or recreational exposure to infected animals or their habitat. The incubation period is usually 1 to 21 days, with most cases occurring 3 to 5 days after exposure.
- 2. Clinical manifestations.** Tularemia can occur in six distinct forms. The most common is the ulceroglandular syndrome characterized by a primary painful maculopapular skin lesion at the site of entry (see Chapter 4). Illness usually begins acutely or subacutely with nonspecific symptoms that include fevers, myalgias, and malaise. There is subsequent ulceration and slow healing of the skin lesion (Color Plates 4.10 and 4.25), with associated painful and acutely inflamed lymph nodes that may drain spontaneously.

The other forms of tularemia are glandular (where no skin or mucous membrane lesion is present), oculoglandular (severe conjunctivitis and preauricular lymph node involvement), oropharyngeal (severe exudative pharyngitis), typhoidal (high fever, hepatosplenomegaly), and pneumonic (see Chapter 11).

- 3. Diagnosis** is most often established by serologic assays (see Chapter 11). A fourfold rise in tube agglutinin titer frequently is found after the second week of illness. An isolated titer of 1:160 or greater, or a microagglutination titer of 1:128 or greater, is consistent with recent or past infection.
- 4. The treatment** of choice has been streptomycin. However, with recent shortages of the drug, gentamicin has become the recommended agent. Duration of therapy is usually 6 to 10 days. Tetracyclines may be used but have a higher relapse rate and are usually reserved for less severe infections.

F. Ehrlichiosis

- 1. Epidemiology** [21]. There are two distinct forms of ehrlichiosis infection in the United States. The human monocytic form (HME) occurs in persons from the southeastern and south central United States. HME is caused by *Ehrlichia chaffeensis* and is transmitted by the Lone Star tick (*Amblyomma americanum*). Most cases of human granulocytic ehrlichiosis (HGE) have been reported from Wisconsin, Minnesota, Connecticut, and New York, but cases have been reported in many states, particularly those on the west coast. Most cases of HGE are due to *Ehrlichia phagocytophila* [22]. HGE is transmitted by the *Ixodes scapularis* tick, which also is the vector of *Borrelia burgdorferi* (the agent of Lyme disease). The principal reservoirs for the agents of human ehrlichiosis remain to be identified, although white-tailed deer and white-footed mice may be infected naturally with *E. chaffeensis* and *E. phagocytophila*. Patients with *Ehrlichia* are characteristically older than those with Rocky Mountain spotted fever, and age-specific incidences are highest in persons older than 40 years of age. Most infections occur between April and September; peak occurrence is in May through July. Coinfections with other tick-borne diseases, including babesiosis and Lyme disease, are reported [23]. The incubation period typically is 7 to 14 days after a tick bite. The canine species *E. ewingii* may occasionally cause human infections, including in patients with AIDS [24].
- 2. Clinical manifestations.** The two disease forms have different causes but similar presentations [25,26]. Both are acute, systemic, febrile illnesses that are similar to Rocky Mountain spotted fever except more frequently have leukopenia, anemia, and hepatitis. Ehrlichiosis presents with rash less frequently than Rocky Mountain spotted fever. The febrile illness often is accompanied by headache, chills, malaise, myalgias, arthralgias, nausea, and vomiting. If rash does occur, it typically develops 1 week after onset of illness and occurs in only 50% of reported cases of HME and fewer than 10% of those with HGE. Diarrhea, abdominal pain, and change in mental status occur on occasion. Reported complications of both forms include pulmonary infiltrates, bone marrow hypoplasia, respiratory failure, encephalopathy, meningitis, disseminated intravascular coagulation, and renal failure; although both may cause severe infections, mortality has been higher with HME. Anemia, hyponatremia, leukopenia, thrombocytopenia, elevated liver enzyme concentrations, and CSF abnormalities are common. Both diseases typically last 1 to 2 weeks, and recovery generally proceeds without sequelae. However, neurologic complications have been reported in some children. Additionally, fatal and asymptomatic infections are reported.
- 3. Diagnosis.** The CDC defines a confirmed case of ehrlichiosis as one with a four-fold or greater rise in indirect immunofluorescent assay antibody titer between acute and convalescent samples (ideally collected 3–6 weeks apart), or PCR amplification of ehrlichial DNA from a clinical sample, or detection of intraleukocyttoplasmic *Ehrlichia* microcolonies (morulae) and a single immunofluorescent assay titer of more than 64. A probable case is defined as a single immunofluorescent assay titer of more than 64 or the presence of morulae within infected leukocytes. Tests for HME and HGE must be requested separately because they are designed to detect the different specific causative agents.
- 4. Treatment.** Doxycycline is the drug of choice for treatment. The recommended dosage of doxycycline is 100 mg intravenously or orally twice daily for adults and 3 to 4 mg/kg/day in two divided doses for children (to a maximum of the adult dose). For children younger than 8 years of age, the recommendations are to use doxycycline as the risk of serious disease is much greater than the risk of teeth or bone abnormalities for the short course of therapy. Treatment is continued for 3 days after defervescence and a minimum total course of 5 to 7 days. Severe or complicated disease may require longer treatment courses. It is prudent to start presumptive therapy with doxycycline for patients with clinical evidence of disease and no other identified cause.
- 5. Prevention.** Specific measures should focus on limiting exposure to ticks. No data exist on the use of prophylactic antibiotics after tick bite for this infection.

G. Babesiosis [27]

1. **Epidemiology** [28]. The primary reservoir for *Babesia microti* is the white-footed mouse (*Peromyscus leucopus*), and the primary vector is the tick *Ixodes scapularis*. This tick can also transmit Lyme disease and human granulocytic ehrlichiosis. Humans acquire infection from the bites of infected ticks, although recently lice and fleas have also been implicated as vectors. The white-tailed deer (*Odocoileus virginianus*) is the important host for the tick but is not a reservoir for *B. microti*. An increase in the deer population in the last few decades is thought to be a major factor in the spread of *I. scapularis* and the infections they transmit. Rare cases have been reported from blood transfusions. Transplacental and perinatal transmission of babesiosis have also been reported. Most cases have been reported in the northeast, midwest, and west coast of the United States. Most cases occur in the summer or fall. In endemic areas, asymptomatic infections are common. The incubation period ranges from 1 to 9 weeks.
2. **Clinical manifestations** [29]. Many clinical features are similar to those of malaria. Patients with babesiosis present with gradual onset of malaise, anorexia, and fatigue. This is followed by fever, with temperatures as high as 40°C, and one or more of the following symptoms: chills, sweats, myalgias, arthralgias, nausea, and vomiting. Less common findings are emotional lability and depression, hyperesthesia, headache, sore throat, abdominal pain, conjunctival injection, photophobia, weight loss, and nonproductive cough. Physical examination usually has minimal findings often consisting only of fever, but mild splenomegaly and hepatomegaly have been reported. The illness can last for a few weeks to several months with a prolonged recovery taking up to 18 months. Severe illness is most likely in people older than 40 years of age, those with asplenia, and in the immunocompromised (including human immunodeficiency virus infection). Splenectomized persons are particularly at risk for death and severe infection.
3. **Diagnosis**. Microscopic identification of the organism on Giemsa- or Wright-stained thick and thin blood smears establishes the diagnosis. Multiple thick and thin smears may be required. Serologic tests are available from the CDC but require 2 to 4 weeks to become positive; thus, examination of blood smears should always be done.
4. **Therapy** is generally reserved for those with moderate or severe disease. Most with a mild clinical course are undiagnosed and recover without specific therapy. The combination of clindamycin (adult dose of 1.2 g twice daily intravenously or 600 mg three times daily orally) and oral quinine (adult dose of 650 mg three times a day) for 7 days or atovaquone (adult dose of 750 mg orally every 12 hours) and azithromycin (adult dose of 500 mg orally on day 1 and then 250 mg/day) for 7 days are the current regimens of choice [30]. Exchange transfusions have been successful in asplenic patients with life-threatening disease and should be considered in severely ill patients with a high parasitemia.
5. **Prevention**. Specific recommendations concern prevention of tick bites.

H. *Baylisascaris procyonis* infection is an under-appreciated emerging infection [31]. It also has the potential to be used as an agent of bioterrorism because it is quite hardy, the infectious inoculum is small, illness is severe, and there is no vaccine or effective therapy [31].

1. **Epidemiology**. The infectious roundworm of raccoons, *B. procyonis*, is an increasingly recognized human pathogen. The host raccoon, *Procyon lotor*, is widespread in its distribution, with human infections being documented in California, Massachusetts, New York, Michigan, Illinois, Pennsylvania, and Germany. Greater than 90% of juvenile raccoons are parasitized and can excrete up to 45,000,000 eggs per day in stool. Latrines where raccoons communally defecate have been found in close proximity to playgrounds and neighborhoods, raising concern over potential infection of children at play. Pica is an important risk factor for infection, with infants being especially at risk due to their propensity for oral exploration of their surroundings.
2. **Clinical manifestations**. Humans are dead-end hosts, and disease represents worm migration through tissues. The complete clinical spectrum of disease and the frequency of asymptomatic infections currently are not known. **Eosinophilic**

meningoencephalitis has been the most commonly recognized presentation, but retinitis and eosinophilic cardiac pseudotumor have also been described [31]. Severe neurologic and/or ocular sequelae occur early after larval invasion.

3. **Diagnosis.** This infection should be considered when meningoencephalitis, diffuse unilateral subacute neuroretinitis, or cardiac pseudotumor occurs in patients with a history of pica and raccoon exposure, especially in the setting of **blood and CNS eosinophilia**. Imaging studies reveal diffuse white matter disease. Definitive diagnosis requires observation of larval forms in the tissues. However, biopsy may not contain larvae or they may be misidentified due to the rarity of the infection. Several reported cases of diffuse unilateral subacute neuroretinitis have been associated with tissue larval parasites. Serologic testing is performed in research settings, but no serologic test is commercially available.
4. **Treatment** consists of supportive care only. Several antihelminthic agents have been tried in human infections without efficacy. All reported human cases either died or sustained severe neurologic and/or ocular sequelae [31].
5. **Prevention.** Infants and developmentally challenged adults must be observed closely for pica behaviors. Ownership of raccoons as pets should be discouraged unless the animals are routinely evaluated for the presence of intestinal parasites. A public awareness program informing communities about the risks of interaction with raccoon feces is important (discouraging feeding wild raccoons and explaining the hazards of not securing pet food), especially in neighborhoods where large numbers of raccoons share human habitat. Routine screening of children or adults is not recommended.

LYME DISEASE

The manifestations of Lyme disease have been well described since early in the 1900's. Various worldwide clinical presentations have been recognized as "erythema chronicum migrans," "Bannwarth syndrome," and "acrodermatitis chronica atrophicans" [32]. In 1975, children in Lyme, Connecticut experienced an outbreak of oligoarticular arthritis resulting in increased investigations for an etiology [33]. Yale researchers were able to link the neurologic sequelae with the erythema migrans (EM) rash and an antecedent tick bite as a syndrome named for the town in which it appeared. In 1982, a spirochete isolated from the midgut of the *Ixodes* tick was implicated as the causative agent of Lyme disease [33–35]. This spirochete, *Borrelia burgdorferi*, is now established as the definitive etiologic agent and occurs in at least three groups (together referred to as *B. burgdorferi sensu lato*). Although present in many parts of the world, the focus of this discussion is on Lyme disease in the United States, which is caused by *B. burgdorferi sensu stricto*.

- I. **Epidemiology.** Lyme disease is the most common vector-borne illness in the United States with more than 15,000 cases each year. Most cases occur in children and in middle-aged adults, although all ages can be affected and there is no sex predilection.
 - A. **Endemic regions.** The most important historical information to obtain when considering Lyme disease is whether a patient lives in or has visited an endemic area. In the absence of a classic presentation, if no endemic exposure history is elicited the diagnosis of Lyme disease is significantly more difficult [36]. **In the United States there are three endemic areas:** the Northeast (New York, New Jersey, Massachusetts, Rhode Island, Connecticut, Pennsylvania, Virginia), the Midwest (Wisconsin, Minnesota), and the Pacific Coast (Oregon, California) [37].
 - B. **Vectors.** Four species of *Ixodes* ticks serve as *B. burgdorferi* vectors, including *I. scapularis* (Northeast and Midwest), *Ixodes pacificus* (Pacific Coast), *Ixodes ricinus* (Europe), and *Ixodes persulcatus* (Asia) [38,39]. Human risk is predicated on the regional density of ticks and the percentage of their parasitism by spirochetes [40,41]. The ticks begin as larvae and enter adulthood after evolution through a nymphal stage, which is the period of their life cycle when most infections are transmitted. The animal reservoirs available to nymphal ticks are determinants of overall tick parasitism and thus are indirectly responsible for the prevalence of human disease. In the Northeast and Midwest, nymphal ticks feed on white-footed mice, a thriving reservoir for *B. burgdorferi*. In contrast, in the Pacific region, *I. pacificus*

ticks feed on lizards, a poor spirochete reservoir, and to a much lesser extent the dusky-footed woodrat. Only those *Ixodes* ticks in the Pacific region that feed on the woodrat carry enough spirochetes to cause human infection; hence, the prevalence of Lyme disease in California and Oregon is less than that observed in the Northeast and Midwest [42–44]. Nymphal ticks reside on tips of tall grasses in the summer months, which helps account for the abundance of clinical cases in the summer and early fall [36]. White-tailed deer are hosts to adult ticks and are critical to completing the tick life cycle.

II. Pathogenesis

A. Transmission and incubation period. *B. burgdorferi* adapts to the midgut of its tick host, traverses to the tick salivary glands, and is transmitted during the blood meal. Dissemination occurs to the skin and hematogenously to many other sites including the joints, heart, and CNS. The small *Ixodes* ticks must be attached for longer than 24 hours before sufficient transfer of spirochetes occurs to cause disease. The incubation period for cutaneous lesions is generally between 7 and 14 days and ranges from 3 to 32 days after the initial bite [45]. However, in many patients there is no history of a specific tick bite in the region of the skin lesion because ticks that are noticed are removed before they can efficiently transmit the organism.

B. Outer surface proteins of *B. burgdorferi* are its major virulence factor, and they promote attachment to mammalian cells [37]. Organism binding to cellular and extracellular matrix components contributes to its tissue tropism. Spirochete tissue spread is accomplished in part through binding of host plasminogen and urokinase-type plasminogen activator to its surface. Plasmin is then activated and acts as a protease, which facilitates tissue invasion [46]. The spirochetes secrete no toxins and require the host to provide all elements of nutritional support [47]. They are capable of remaining viable in host tissues for prolonged periods of time in the absence of treatment.

C. The host immune response is slow to develop and results in a broad range of specific antibodies. In murine models there is a genetic determination of susceptibility and the host immune response in controlling early spirochete dissemination. *B. burgdorferi* is a potent stimulus for pro-inflammatory mediator production, and histology of lesions is marked by mononuclear cell infiltrates with some degree of vascular damage. In cases of chronic arthritis, joint destruction is ascribed to an ongoing inflammatory response that may continue despite antibiotic sterilization of the joint.

III. Clinical manifestations. The uninterrupted disease evolves through three phases: early localized disease; early disseminated disease to the skin, nervous system, heart, and joints; and late disease [37,48]. **It is most important to understand that not all phases may be clinically recognized and that overlap can exist among these phases.** Thus, late manifestations may occur without any preceding signs or symptoms of infection, and patients with late neurologic disease may have EM lesions or chronic arthritis.

A. Early localized disease begins when the tick regurgitates or salivates sufficient spirochetes into the bite, with subsequent local inflammation occurring at the site. As the spirochetes move centrifugally within the skin away from the bite, they create the classic rash of **EM** (Color Plate 4.4) [36,49]. EM lesions are flat with partial central clearing and usually have a bright red outer border and a target center; variations exist with some lesions being homogenous and losing the target center, and others having vesicular centers [37]. In fact, these “atypical” EM lesions may be more common than the classic target appearance [50].

The bite of the Lone Star tick (*A. americanum*) has been associated with an EM-like illness in the southeastern United States, called southern tick-associated rash illness or STARI [51,52]. Such patients have had no evidence by culture or serology of *B. burgdorferi* infection. *Borrelia lonestari*, an uncultured spirochete found in *A. americanum* ticks, is a likely cause for this syndrome [52].

B. Early disseminated disease occurs within weeks or months of infection and is marked by systemic illness with **fever, headaches, myalgias, arthralgias, and/or lymphadenopathy**. It also may involve the **skin, CNS, or heart**.

1. During this phase 50% of patients experience **new EM lesions**, which are often multiple and in new sites [36].
 2. **Acute neuroborreliosis** develops in 15% of untreated patients and results from spirochetes invading the CNS during early dissemination; it usually presents weeks or months after infection. Lymphocytic meningitis (see Chapter 6), encephalitis, cranial nerve involvement, radiculopathies, mononeuritis multiplex, cerebellar ataxia, and myelitis may occur [37,53,54]. **Bell palsy** may be an isolated manifestation of early disseminated disease, or it may occur with other neurologic findings in late disease [55]. It is a common manifestation, occurring in 50% of those with meningitis, and may be bilateral. However, because isolated cranial nerve VII palsy is caused more commonly by herpes infection in nonendemic areas, it is not considered a *sine qua non* of Lyme disease [56]. Case reports detail *B. burgdorferi*-infected children who developed optic nerve damage secondary to nerve inflammation or increased intracranial pressure resulting in blindness. Pseudotumor cerebri is another rare CNS phenomenon observed in children secondary to Lyme disease [57].
 3. **Lyme carditis** develops in 5% of untreated patients [37]. The median time to presentation of cardiac involvement is 5 weeks after acute infection. Common symptoms include dyspnea, syncope, dizziness, and palpitations [58]. **The most common abnormality is atrioventricular block**, and a PR interval longer than 300 ms predicts an increased risk of complete heart block [59]. Myocarditis occurs less frequently, and valvular disease has not been reported [36].
- C. Late disease**
1. **Arthritis** occurs in 60% of untreated patients months after the initial infection and is the most common form of late disease. It manifests **primarily in the large joints (especially the knees)**, causing recurrent asymmetric monoarticular or oligoarticular arthritis [58]. Joints have significant swelling and warmth but minimal erythema, and joint erosions can occur, leading to significant disability. Baker cysts are seen frequently and result in further debilitation secondary to swelling and pain [60]. Joint fluid contains various numbers of leukocytes that are mostly neutrophils. Synovial biopsy reveals hypertrophy, vascular proliferation, and a mononuclear cell infiltrate. Untreated patients often have recurrent attacks and are considered to have chronic Lyme arthritis if these continue for 1 year or longer. Ten percent of cases develop chronic arthritis despite adequate antimicrobial therapy, especially in those patients with HLA-DRB1*0401 or related alleles [61], suggesting an autoimmune pathogenesis. Fatigue may be prominent in many patients with chronic arthritis and is episodic with periods of wellness between attacks [60,62,63].
 2. **Chronic neurologic syndromes** develop in as many as 5% of untreated patients and may become apparent many years after the original infection [37]. “Lyme encephalopathy” is characterized by subtle cognitive deficits in adults [64,65], and children may experience mood swings, decreased concentration, and declining school performance. Focal CNS lesions may occur characterized by a chronic axonal polyneuropathy, spinal radicular pain, or distal paresthesias [54,66]. In the European species of *Borrelia*, vestibular and optic neuritis have been observed in combination with cognitive impairment [54].
 3. Violaceous skin lesions that become sclerotic or atrophic over time are acrodermatitis chronica atrophicans and are found in Europe and Asia as a result of *Borrelia afzelii* infection [37].
- D. Lyme disease during pregnancy.** The clinical manifestations of Lyme disease in pregnant women are the same as in nonpregnant patients. Despite a few case reports of fetal transmission of *B. burgdorferi*, prospective studies have failed to identify documented cases of congenital infection or an adverse effect on pregnancy outcome [48,67].
- E.** “Chronic Lyme disease” and “post-Lyme disease syndrome” are terms that have been applied to heterogeneous groups of patients with myalgias, arthralgias, neurocognitive impairment, or fatigue that persists after adequate antibiotic treatment [37,68,69]. Recently the validity of these terms has been questioned because there is little evidence to support them as specific diagnoses [68,69]. **Fatigue alone,**

without any other convincing evidence of Lyme disease, should not be considered Lyme disease.

IV. Diagnosis. To reduce over-diagnosis and unnecessary treatment, the CDC developed a case definition for Lyme disease that requires the classic EM rash or another characteristic clinical manifestation with positive laboratory evidence of *B. burgdorferi* infection [70]. When evaluating patients for possible Lyme disease, routine laboratory studies (liver function tests, erythrocyte sedimentation rate, etc.) generally are not helpful.

- A. Culture** of *B. burgdorferi* from blood, synovial aspirate, or CSF is difficult [58]. Spirochetes can be grown from the leading edge of the lesions in 50% of EM cases when cultured on Barbour-Stoenner-Kelly medium [71]. A positive culture is diagnostic of Lyme disease.
- B. PCR** evaluation of blood, CSF, and urine for evidence of the organism has been unhelpful in reliably establishing the diagnosis because of low sensitivities. Although rarely positive on culture, 85% of synovial fluid or synovial biopsy specimens are PCR positive for *B. burgdorferi* DNA. However, joints with chronic erosive arthritis that persists after adequate treatment usually are PCR negative. Thus, PCR on joint specimens may be used for initial diagnosis of Lyme arthritis [72] and also to determine whether retreatment with antibiotics may be helpful for chronic arthritis [72–75].
- C. Lumbar puncture** in early localized disease is unremarkable, but in early dissemination and late disease it often reveals a CSF mononuclear cell pleocytosis associated with an elevated protein and normal glucose [76]. Patients with acute neuroborreliosis often have an elevated CSF-to-serum *B. burgdorferi* antibody ratio (> 1) using an antibody-capture immunoassay, but this test is reliable only at specialized institutions [77]. Previously, single photon emission computed tomography was used to assist in evaluation of CNS Lyme disease, but its reliability has been questioned. With peripheral nerve involvement nerve conduction velocities are often abnormal [37].
- D. Electrocardiograms** in patients with Lyme carditis reveal varying degrees of atrioventricular block. As mentioned above, PR intervals greater than 300 msec predict progression to complete heart block.
- E. Current serologic testing for Lyme disease is neither sensitive nor specific**, with frequent false-positive and false-negative results in the detection of both IgM and IgG antibodies [78]. They also remain positive for prolonged periods, so they do not necessarily represent active infection. Because other studies are not usually diagnostic or readily available, diagnosis often rests on these difficult to interpret serologies. As a result, the American College of Physicians and the CDC recommend carefully applying a two-step approach to serodiagnosis [70,79–81]. Patients with a pretest probability of Lyme disease between 20% and 80% should initially undergo enzyme-linked immunosorbent assay (ELISA) testing of acute and convalescent sera. Intermediate ELISA test results require Western blot confirmation. To reduce the variability that exists among laboratories, the Western blot results should be interpreted according to the criteria established by the CDC [70]. Patients with *Treponema pallidum* infections can have false-positive ELISA results, as can patients with infectious mononucleosis or polyclonal B-cell activation from other causes [82].
 - 1. In early localized disease when EM lesions are seen, serology is not indicated** for diagnosis because many patients will not have made antiborrelial antibodies yet, and the pretest probability is above 80% [67,80,81].
 - 2. Often the most challenging patients are those who complain of arthralgias, myalgias, headache, palpitation, or fatigue and who have an endemic exposure history. These symptoms alone are not enough to warrant Lyme disease serologic testing** because such patients have a low pretest probability of having Lyme disease [80,81]. Persons with these symptoms from nonendemic regions have an even lower probability of having Lyme disease. **Patients appropriate for Lyme disease serologic testing should have objective joint, cardiac, and/or neurologic findings** either on the physical exam, electrocardiogram, synovial fluid aspirate or biopsy, nerve conduction studies, CSF analysis, or neuropsychological testing.
 - 3. Serologic tests should not be used for screening** of otherwise healthy individuals with a history of tick exposure.

Table 21.13. Treatment of Lyme Disease

Stage of Disease	Antibiotic Choices ^a
Early infection (local or disseminated)	
Adults	Doxycycline, 100 mg orally twice daily for 14–21 days Amoxicillin, 500 mg orally three times daily for 14–21 days
Doxycycline or amoxicillin allergy	Cefuroxime axetil, 500 mg orally twice daily for 14–21 days Erythromycin, 250 mg orally 4 times a day for 14–21 days
Children	Amoxicillin, 250 mg orally 3 times per day or 50 mg/kg of body weight/day in 3 divided doses for 14–21 days
Penicillin allergy	Cefuroxime axetil, 125 mg orally twice daily or 30 mg/kg per day in 2 divided doses for 14–21 days Erythromycin, 250 mg orally 3 times per day or 30 mg/kg/day in 3 divided doses for 14–21 days
Neurologic abnormalities (early or late)	
Adults	Ceftriaxone, 2 g i.v. once daily for 14–28 days Cefotaxime, 2 g i.v. every 8 hours for 14–28 days Penicillin G, 3.3 million units i.v. every 4 hours (20 million units/day) for 14–28 days
Ceftriaxone or penicillin allergy	Doxycycline, 100 mg orally 3 times per day for 30 days
Facial palsy alone	Oral regimens may be adequate
Children	Ceftriaxone, 75–100 mg/kg/day (maximum, 2 g) i.v. once daily for 14–28 days Cefotaxime 150 mg/kg/day in 3 or 4 divided doses (maximum, 6 g) i.v. once daily for 14–28 days Penicillin G, 200,000–400,000 units/kg/day in 6 divided doses for 14–28 days
Arthritis (intermittent or chronic)	Oral regimens listed above for 30–60 days or i.v. regimens listed above for 14–28 days
Cardiac abnormalities	
First-degree atrioventricular block	Oral regimens listed above for 14–21 days
High-grade atrioventricular block (PR > 0.3 s)	i.v. regimens listed above and cardiac monitoring (treatment may be finished orally after the patient has been stabilized)
Pregnant women	Standard therapy for manifestation of illness; avoid doxycycline

^aAlternatives are in order of acceptability, with the drug of choice listed first in each category. Modified from Steere AC. Lyme disease. *N Engl J Med* 2001;345:122, with permission.

F. There are no useful tests to detect *B. burgdorferi* antigens at present. In particular, a marketed urine Lyme antigen detection test is unreliable and is not recommended [83].

V. Evidence-based treatment recommendations from the Infectious Diseases Society of America [37,69] are presented in Table 21.13. It is important to recognize and accurately diagnose Lyme disease because the manifestations are reversible with appropriate treatment most of the time. The fear of a missed diagnosis coupled with pressure from the media and patients often results in significant over-diagnosis and

treatment. This can be avoided by incorporating an endemic exposure history and an understanding of the clinical manifestations of Lyme disease, with the appropriate use of laboratory diagnostic tests (see section **IV**). This benefits patients and physicians alike by decreasing unnecessary medical expenditures and reducing the anxiety fostered by abnormal test results.

A. Early localized and early disseminated disease. Oral therapy is appropriate for EM, isolated cranial nerve palsy, and cardiac involvement limited to first- or second-degree heart block. Doxycycline is the drug of choice for patients older than 8 years of age because it also is effective against HGE, a common coinfecting agent (see section **IV.F** under Zoonoses). Alternatives are listed in Table 21.13. Macrolides should be reserved for those who cannot tolerate doxycycline, amoxicillin, or cefuroxime. More than 90% of patients with early localized disease have satisfactory outcomes after the recommended treatment regimens [37].

1. **Acute neuroborreliosis** resolves over several weeks with treatment [37]. Intravenous therapy for meningitis and radiculopathy remains the standard of care in the United States (Table 21.13).
2. In Lyme **carditis**, patients with prolonged PR intervals should be monitored for complete heart block, with placement of a temporary pacer when appropriate. Patients with third-degree block should be hospitalized and treated with intravenous ceftriaxone (Table 21.13). Patients with PR intervals great than 300 ms are also best managed initially with hospital monitoring and intravenous treatment [37]. Permanent pacing is rarely required.

B. Late disease

1. **Arthritis** may be treated orally or intravenously (Table 21.13) and usually resolves over several months. Oral therapy is preferred for patients without CNS disease because it is easier, less costly, and has fewer adverse effects [69]. Patients with arthritis and concomitant CNS disease should be treated intravenously. Recurrent arthritis after an initial course of appropriate therapy should be retreated with either another oral 4-week course or with 2 to 4 weeks of intravenous ceftriaxone [69]. Unfortunately, some patients will have persistent synovitis even after such therapy. It is in this select population where *Borrelia*-specific PCR synovial aspirate testing is helpful in distinguishing active infection with spirochetes versus persistent immune destruction of the joint [37]. Patients with negative PCR tests are treated symptomatically with nonsteroidals, and some eventually may require arthroscopic synovectomy.
2. **Chronic neuroborreliosis** improves slowly over months after therapy, and the response may be incomplete. Repeat treatment should not be undertaken without objective evidence of relapse, which is uncommon after 28 days of intravenous ceftriaxone [37,69].

C. Pregnant women should be diagnosed and treated conventionally according to the recommendations in Table 21.13. However, because maternal-to-fetal transmission of *Borrelia* is rare, the risk of doxycycline to the fetus obligates use of an alternative treatment [69].

D. Failure to respond to recommended treatment. There are several possibilities to explain the persistence of symptoms after appropriate treatment for Lyme disease.

1. Patients with early disease who remain symptomatic should be evaluated for possible coinfections with HGE and babesiosis (see sections **IV.F** and **IV.G** under Zoonoses) [23]. Inadequate dosing and incomplete adherence, particularly to oral therapy, also should be considered. As discussed above, late disease responds slowly to treatment, whereas early disease responds more quickly. Patients with late disease should be observed for further improvement or objective evidence of relapse before retreatment. In addition, symptoms may not be due to Lyme disease or concomitant infection but another illness such as fibromyalgia or chronic fatigue syndrome.
2. Prolonged antibiotic therapy for persistent nonspecific symptoms (musculoskeletal, cognitive, or neuropathic) is of no benefit and should not be used [84].

VI. Prevention

A. Avoiding exposure to ticks, using protective clothing and tick repellants, and regularly checking for and quickly removing attached ticks are the best methods to avoid Lyme disease transmission. When traveling to endemic areas, care should be taken to avoid tick-infested environments. If possible, light-colored clothing (so ticks are easily recognizable), long pants, and long-sleeved shirts should be worn. Patients should be instructed to remain on paths away from brush and to consider the use of tick repellants. Unfortunately, spraying city lawns for ticks has not been shown to be effective in reducing infections.

B. Prophylaxis after tick bites

1. A single 200-mg dose of doxycycline within 72 hours of an *I. scapularis* tick bite is effective in preventing Lyme disease [85]. However, if the tick has been removed promptly, no prophylaxis is necessary nor is it recommended in nonendemic areas. Even in endemic areas, the frequency of Lyme disease after tick bite with no prophylaxis is only about 1% [85]. Furthermore, many patients experience repeated tick bites, and doxycycline should not be used in children younger than 8 years of age. Thus, this approach may be best suited for those older children and adults in endemic areas with only an occasional tick bite.
2. Anyone in an endemic area who removes an attached tick should seek medical care for febrile illnesses and skin lesions that occur within the next 30 days [69].
3. Persons treated for EM are considered susceptible to reinfection, but those who develop Lyme arthritis are usually resistant to reinfection [37].

C. Vaccination. The previously available recombinant OspA Lyme vaccine was withdrawn from the market by its manufacturer in February 2002. Although there was unsubstantiated controversy about its safety [86], particularly with the need for regular booster doses, the manufacturer cited economic concerns for this decision because there was waning use of the vaccine.

22. HEALTH ADVICE FOR INTERNATIONAL TRAVEL

David R. Hill and Richard D. Pearson

International travel, including visits to the developing world for business, vacation, study, or missionary and service activities, is a major pursuit of Americans. These travelers are often exposed to bacterial, viral, and parasitic diseases that range from traveler's diarrhea to life-threatening infection with *Plasmodium falciparum*. Complex itineraries and changing patterns of disease and international health requirements make the providing of advice on prevention and immunizations for the traveler a challenging task [1]. Whenever possible, pretravel care should be provided by an expert in the field. Many hospitals and schools of medicine in the United States have specialized travel clinics or units of tropical medicine that can render expert travel advice [2].

Travel medicine should provide preventive advice, immunizations, and medications for disease prevention or self-treatment based on an individual's itinerary and health status. To do this, an assessment of the potential health risks confronting the traveler must be developed by determining their itinerary (including whether rural sites will be visited), planned activities, duration of stay, and medical and immunization histories. This information, as well as the plan of care, should be recorded in a **permanent medical record**. There are multiple sources of information, both printed and on-line, to aid the provider of travel care in decision making (see Appendix).

VACCINATIONS

I. General considerations

A. Types of vaccinations for the traveler. Vaccinations can be divided into those that are routinely recommended for children and adults, whether or not they are traveling; those that are required by countries for entry; and those that are recommended because of potential exposure in the country of destination (Table 22.1).

- 1. Routine vaccinations. The pretravel visit is an excellent time to update routinely recommended vaccines.** Immunizations are discussed in the *Guide for Adult Immunization* [3], in *Health Information for International Travel* [4], in the pediatric *Red Book* [5], in section **II** of Chapter 23, and in recent reviews [6,7].
- 2. Required vaccinations—the International Certificate of Vaccination.** The only vaccine currently required under World Health Organization (WHO) regulations for travel between countries is yellow fever vaccine. Nevertheless, some countries may still ask for evidence of cholera vaccination. This is discussed in more detail in section **III**. A list of the vaccine requirements by country is published by the Centers for Disease Control and Prevention (CDC) in *Health Information for International Travel* [4]. **According to international health regulations, yellow fever vaccination must be recorded in the document “International Certificate of Vaccination” [8] and validated by a stamp issued by state health departments. No vaccinations are required for returning U.S. residents entering the United States. Smallpox vaccination is not required by any country (see section III) [9].**
- 3. Recommended vaccinations.** Travelers and physicians frequently confuse the distinction between **required** and **recommended** vaccines. In reality, only yellow fever may be required. Some vaccines are recommended because infection could be acquired in the country of destination. Examples include epidemic meningococcal disease, which is limited to certain areas of the world, and typhoid fever, which is present throughout developing regions but is a risk to travelers only if they encounter poor food and water sanitation. In addition to vaccination, many diseases transmitted by fecal contamination of the food and water supply can be prevented by care in selecting foods and liquids. Vaccination should never be considered a substitute for practicing preventive measures. **Exposure to foods and liquids in areas of poor sanitation (as may occur in rural areas and small villages) for more than 2 to 3 weeks may be a reasonable criterion for administering vaccines for protection against enteric pathogens (e.g., typhoid)** (see section **IV**). Unfortunately, data are not always available on the

Table 22.1. Vaccinations to Consider for Travel to the Developing World

Vaccine	Type, Route, and Dose ^a	Schedule ^e	Indications ^d	Precautions and Contraindications ^b	Side Effects ^b
Toxoids					
Tetanus-diphtheria (Td)	Adsorbed toxoids i.m. (0.5 mL)	Primary: 3 doses; first 2, 4–8 wk apart; 3rd dose after 6–12 mo Booster: every 10 yr; single dose after age 50	All adults	First trimester of pregnancy Hypersensitivity or neurologic reaction to previous doses Severe local reaction	Local reactions; occasional fever and systemic symptoms Arthus-like reactions in persons with multiple previous boosters Rare—systemic allergy
Inactivated bacteria vaccines					
<i>Streptococcus pneumoniae</i>	Polysaccharide–23 serotypes s.c. or i.m. (0.5 mL) See text for conjugate pneumococcal vaccine	Primary: single dose Booster: high-risk patients after 5 yr	Persons ≥5 yr at increased risk of pneumococcal disease and its complications Healthy adults ≥65 yr	Safety in pregnancy is unknown Previous pneumococcal vaccination (relative)	Approximately 50% of patients have mild erythema and pain at injection site Systemic reaction in <1% of patients Arthus-like reaction with booster doses Infrequent, mild local reactions
<i>Neisseria meningitidis</i>	Polysaccharide containing four serotypes (A, C, Y, W–135) s.c. (0.5 mL)	Primary: single dose Booster: not officially recommended; may be given after 3 to 5 yr in adults and after 2 to 3 yr in children vaccinated at 2 to 4 yr of age Primary: single dose for age ≥2 years Booster: every 2 yr	Travelers to areas with epidemic meningococcal disease (see text) Asplenia or certain complement-deficiency states	Safety in pregnancy is unknown	Arthus-like reaction with booster doses Infrequent, mild local reactions
Typhoid	Polysaccharide Vi antigen i.m. (0.5 mL)	Primary: single dose for age ≥2 years Booster: every 2 yr	Risk of exposure to typhoid fever (see text)	Safety in pregnancy is unknown Hypersensitivity to vaccine components	Local pain and induration—10–20% Systemic reaction in <5%
Attenuated live bacterial vaccine					
Typhoid	Attenuated Ty21a mutant of <i>Salmonella typhi</i> Oral	Primary: 1 capsule every other day for 4 doses Booster: every 5 yr	Risk of exposure to typhoid fever in persons ≥6 yr (see text)	Safety in pregnancy is unknown Immunocompromised host ^c Persons with acute febrile or gastrointestinal illness Persons taking antibiotics If taking mefloquine, separate doses by 24 h Refrigerate capsules	Infrequent gastrointestinal upset or rash

Attenuated live virus vaccines

Measles	Attenuated live virus (available in monovalent form or combined with rubella [MR] ± mumps [MMR]) s.c. (0.5 mL)	Primary: 2 doses; 1st at 12–15 mo, 2nd at 4–6 yr For adults, 2 doses separated by at least 1 mo Booster: none	Persons born after 1956 who have not had documented measles or received 2 doses of live vaccine	Pregnancy Immunocompromised host ^c (asymptomatic HIV-infected persons can be considered for vaccination; see text) History of anaphylaxis to eggs or neomycin Administration of immune globulin within 5 mo	Temperature of >39.4 °C, 5–21 days after vaccination in 5–15% Transient rash in 5% Of persons previously immunized with killed vaccine (1963–1967), 4–55% have a local reaction
Mumps	Attenuated live virus s.c. (0.5 mL)	Primary: 1 dose (usually given as part of MMR vaccine) Booster: none	Persons born after 1956 who have not had documented mumps or mumps vaccine	Pregnancy Immunocompromised host ^c History of anaphylaxis to eggs or neomycin Administration of immune globulin within 5 mo	Mild allergic reactions uncommon Rare parotitis
Rubella	Attenuated live virus s.c. (0.5 mL)	Primary: 1 dose (often given as part of MR or MMR) Booster: none	All persons, particularly women of childbearing age, without documented illness or live vaccine on or after first birthday	Pregnancy Immunocompromised host ^c History of anaphylaxis to neomycin Administration of immune globulin within 5 mo	Up to 40% of postpubertal women have joint pains, transient arthralgias, beginning 3–25 days after vaccination, persisting 1–11 days Frank arthritis in <2%
Varicella vaccine	Attenuated live virus s.c. (0.5 mL)	Primary: 1 dose, children 12 mo to 12 yr; > 12 yr, 2 doses at a 4–8 wk interval	Persons ≥ 12 mo who have not had varicella	Pregnancy Immunocompromised host ^c Potential for rare transmission of vaccine virus to susceptible hosts Administration of immune globulin within 5 mo	Local pain and induration ≈20% Fever ≈15% Localized or systemic varicella rash ≈6%
Yellow fever	Attenuated live virus s.c. (0.5 mL)	Primary: single dose 10 days to 10 yr before travel Booster: every 10 yr	As required by individual countries	Avoid in pregnant women, unless high-risk travel Infants <9 mo (see text) Immunocompromised host ^c Hypersensitivity to eggs	Mild headache, myalgia, fever 5–10 days after vaccination in 2–5% Rare immediate hypersensitivity Rare severe multiorgan system failure (see text)

(Continued)

Table 22.1. (Continued)

Vaccine	Type, Route, and Dose ^a	Schedule ^a	Indications ^a	Precautions and Contraindications ^b	Side Effects ^b
Inactivated virus vaccines					
Hepatitis A (Havrix and Vaqta)	Inactivated virus i.m. (adult and pediatric formulations)	Primary: 2 doses, 2nd dose after 6 to 18 mo provides long-term (perhaps 10–20 yr) protection Booster: not currently recommended	Travel to developing countries Children residing in endemic regions of the United States [44] Some persons may benefit from prevaccine hepatitis A serology (see text)	Safety in pregnancy is unknown	Local reactions with pain and tenderness <20% Occasional fever, <5%
Hepatitis B (Recombivax and Engerix)	Recombinant-hepatitis B surface antigen i.m. (adult and pediatric formulations)	Primary: 3 doses at 0, 1 and 6 mo; can accelerate vaccina- tion (see text) Booster: not routinely recommended	Health-care workers in contact with blood Persons residing in areas of intermediate to high endemicity for hepatitis B Others at risk for contact with blood, body fluids, or blood-contaminated medical or dental instruments	Pregnancy is not a contraindication in high-risk persons Hypersensitivity to vaccine components	Mild local reaction in 10–20% Occasional systemic symptoms of fever, and headache, fatigue, and nausea
Hepatitis A and B antigens combined	Inactivated virus (A) plus recombinant hepatitis B surface antigen i.m. (1.0 mL)	Primary: 3 doses at 0, 1 and 6 mo	Travelers ≥ 18 yr at risk for both hepatitis A and B (see text) Give at least 2 doses of vaccine prior to departure to provide protection against hepatitis A	Safety in pregnancy is unknown Hypersensitivity to vaccine components	Local reactions in ≈35% Systemic symptoms of headache and fatigue, similar to single antigen preparations
Poliomyelitis	Killed poliomyelitis virus, trivalent s.c. or i.m. (0.5 mL)	Primary: 3 doses, first 2 at a 4- to 8-wk interval; 3rd dose 6–12 mo after 2nd Booster: one adult, lifetime dose with travel to endemic regions	Only formulation of polio vaccine used in U.S. Travel to polio-endemic countries: complete primary series or receive one booster in adult lifetime	Safety in pregnancy is unknown Anaphylactic reactions to streptomycin or neomycin	Mild local reactions

Influenza	Inactivated whole and split influenza A and B virus i.m. (0.5 mL)	Annual vaccination with current vaccine	Persons ≥ 6 mo with high-risk conditions (see text) Healthy persons >50 yr Medical care personnel, others Travelers at risk (see text)	First trimester of pregnancy is a relative contraindication Anaphylaxis to eggs	Mild local reactions in < 1 -third Occasional systemic reaction of malaise, myalgia, beginning 6–12 h after vaccination and lasting 1–2 days Rare allergic reaction Local mild reactions lasting 1–3 days (20%) Systemic reactions of fever, myalgia, headache, or gastrointestinal upset (10%) Allergic reactions of urticaria, rash angioedema, or respiratory distress (0.1–10/1,000) Rare sudden death or encephalomyelitis $\approx 30\%$ have local reactions $\approx 20\%$ have mild systemic reactions: headache, nausea, aches, dizziness Occasional (6%) immune reactions with booster doses of HDCV occurring 2–21 days after vaccination
Japanese B encephalitis	Inactivated virus s.c. (1.0 mL)	Primary: 3 doses at days 0, 7, and 30 Booster: 1 dose at 3 yr interval; however, duration of protection is not known	Travelers to area of risk with rural exposure or prolonged residence (see text)	Pregnancy Allergy to mice or rodents History of anaphylaxis or urticaria	
Rabies (Imovax and RabAvert)	Inactivated virus grown in human diploid cells (HDCV) or purified chick embryo cells (PCEC) i.m. (1.0 mL)	Preexposure: 3 doses at days 0, 7, and 21 or 28 Booster: depends on risk category and is based on serologic testing (see text)	Itineraries and activities which place the traveler at risk for rabies; dogs are primary threat in developing regions	Allergy to previous doses May be given in pregnancy if indicated	
Passive prophylaxis Immunoglobulin	Fractionated immunoglobulins (primarily IgG) i.m.	Travel of <3 mo duration: 0.02 mL/kg Travel >3 mo: 0.06 mL/kg every 4–6 mo	For prevention of hepatitis A Some travelers may benefit from pretravel hepatitis A antibody testing (see text)	Should not be given <3 wk after or 5 mo before measles mumps, rubella, or varicella vaccines	Local discomfort Rare systemic allergy

^aManufacturer's full prescribing information should be consulted, because vaccines, doses, and schedules may differ between countries. Doses given are generally for adults; pediatric doses may vary.
^bOnly major precautions, contraindications, and side effects listed.
^cPersons immunocompromised because of immunodeficiency diseases, leukemia, lymphoma, generalized malignancy, or HIV/AIDS, or who are immunosuppressed from therapy with corticosteroids, alkylating agents, antimetabolites, or radiation.

precise risk of most infectious diseases by geographic area, and the benefit-to-risk ratio of specific immunizations must be estimated by the physician [4,10].

B. Vaccine administration pointers

1. **Simultaneous administration of vaccines** is reviewed in detail in Chapter 23. Although most viral and bacterial vaccines, whether attenuated, live, or killed, can be administered simultaneously at different sites, cumulative side effects may preclude this, and the traveler should return for a subsequent visit if there is time before departure. **Attenuated live viral vaccines, which are not given simultaneously, should be separated by 1 month.**
2. **Live viral vaccines generally should not be given to pregnant women**, to patients who are immunocompromised, or to persons with a febrile illness (for exceptions, see discussion of individual vaccines).
3. **Immunoglobulin should not be given less than 5 months before or less than 2 weeks after measles, mumps, or rubella vaccine and not less than 3 weeks after varicella vaccine** because the passive transfer of antibodies may interfere with the immune response (see Chapter 23). These restrictions do not apply to yellow fever vaccine or inactivated viral vaccines.
4. **An individual's risk factors for infection with human immunodeficiency virus (HIV) should be determined before administering vaccines.** Although immunization of otherwise healthy HIV-infected persons is considered safe for most vaccines, progressive infection with live attenuated viruses or bacteria is a possibility [11]. The safety, immunogenicity, and efficacy of any vaccine should be matched with the risk of disease acquisition by the HIV-positive traveler. There is improved immunogenicity if CD4 counts are more than 200 cells/mm³; and this CD4 count, plus clinical status and viral load, may be a reasonable yardstick for safely administering live viral vaccines [12,13].
5. **Documentation.** Before the administration of any vaccine, the full prescribing information provided by the manufacturer should be consulted. The date, dose, site, manufacturer, and lot number of each vaccine should be recorded in permanent records. Adverse reactions in the United States should be reported to the Vaccine Adverse Event Reporting System (800-822-7967) and in Canada to the Division of Immunization in Canada (613-957-1340). Vaccine Adverse Event Reporting System reporting forms can be down-loaded from www.fda.gov/cber/vaers/vaers.htm for the United States and from www.hc-sc.gc.ca/lhpb/lcdc/bid/di/vaae_e.html for Canada (see Chapter 23).

II. Routine vaccinations for travelers.

A summary is provided in this section. More detailed discussion may be found in Chapter 23.

- A. **Tetanus-diphtheria toxoids.** Many adults in the United States are not adequately protected against tetanus and diphtheria. This is particularly true for persons older than 50 years in whom most cases of tetanus occur [14]; these persons may also lack protective antibodies against diphtheria [15]. Outbreaks of diphtheria have occurred in areas where vaccine coverage is lacking or protection has waned, and travelers to these regions (e.g., some countries in Africa, Asia, and Eastern Europe) should ensure immunity to diphtheria [16]. Each traveler should have completed the primary series of vaccination against tetanus-diphtheria and should have received boosters with the combined toxoids at 10-year intervals. **For routine immunization, persons 50 years of age and older should receive only one booster. Some travelers may benefit from a booster at a 5-year interval**, because a tetanus-prone wound requires neither tetanus immunoglobulin (given only to persons who have not received the primary series) nor a tetanus booster if a person has been boosted within 5 years [17]. It is usually easier and safer to be immunized before travel than to try to obtain a booster in a developing area where sterility of needles and storage conditions are less certain (see Chapter 4).
- B. **Pneumococcal vaccine.** There are two pneumococcal polysaccharide vaccines available: a seven-valent conjugate vaccine (PCV7) for routine immunization of all children 2 to 23 months of age [18] and a 23-valent polysaccharide vaccine (PPV23) for use in children 5 years and older and adults [19]. The conjugate vaccine can also be considered for high risk and other children 24 to 59 months of age according to CDC guidelines: children 2 to 4 years of age (who would receive PCV7) and those

5 years of age and older (who would receive PPV23) who are at increased risk of severe pneumococcal disease, including persons with impairment of the cardiorespiratory, hepatic, or renal systems; diabetes mellitus; anatomic or functional asplenia; sickle cell disease; chronic alcoholism; HIV infection; and healthy persons 65 years of age and older [18,19]. In adults, the vaccine is given as a one-time dose, but high-risk individuals may be revaccinated after 5 or more years. See further discussion in Chapters 11 and 23.

- C. Measles.** Travelers may have substantial exposure to measles overseas, particularly if they visit countries in the African and eastern Mediterranean regions [20]. Currently, almost 70% of measles cases in the United States are imported or linked to imported cases [21]. To achieve immunity to measles, all children should receive two doses of measles vaccine, the first at 12 to 15 months of age and the second upon entry to elementary school (ages 4 to 6 years) [22]. Persons born before 1957 are usually immune secondary to natural infection. Those born in 1957 or later who have never had measles infection or received vaccine should receive two doses of a measles-containing vaccine separated by an interval of at least 1 month. Travelers born in 1957 or later who have not had two doses of a live attenuated measles vaccine, with the second dose after 1980, should also be given one or two doses of vaccine depending on their vaccination status. Serologic testing can be helpful in assessing immunity against measles and rubella.

Children traveling to high-risk areas where they are likely to be exposed at a young age can be vaccinated between 6 and 12 months with single-antigen (monovalent) measles vaccine. They should be reimmunized at 15 months with the measles-mumps-rubella vaccine. Vaccination of children younger than 2 years is reviewed elsewhere (see Chapter 23).

Measles vaccine may be carefully considered for HIV-infected individuals if they are asymptomatic with low or undetectable HIV levels and a CD4 in the normal range [22]. For further discussion of measles vaccinations, see Chapter 23.

- D. Rubella and mumps.** Women of childbearing age who are not immune to rubella should be considered for immunization. Most adults probably were infected naturally with mumps virus and are immune; however, if an adult is susceptible to mumps vaccination may be considered. If immunity to more than one virus is lacking, combined measles-mumps-rubella vaccine can be given. There are no increased side effects if a person receives a vaccine virus to which he or she is immune (see Chapter 23).
- E. Influenza.** The composition of influenza vaccine is determined annually and includes the viral subtypes projected to cause disease in the United States during the winter influenza season [23]. Vaccination is recommended for adults with chronic disorders of the cardiovascular or pulmonary system (including asthma); persons with other chronic medical conditions (e.g., diabetes mellitus, renal disease, hemoglobinopathies, and immunosuppression); nursing home and long-term-care residents; children aged 6 months to 18 years who are on chronic aspirin therapy; pregnant women in their second and third trimesters; healthy persons 50 years of age and older; and persons who provide health care in hospitals, custodial facilities, or in the home. Vaccination may also be considered for healthy persons traveling during influenza season. Influenza viruses active in the developing world may or may not be included in the vaccine in the United States.

Influenza vaccine should be given to travelers leaving the United States at any time of the year when destined for the tropics or between April and September when destined for the southern hemisphere. Outbreaks can occur in summer months in northern climates when travelers congregate from throughout the world [24]. High-risk travelers who are unable to receive vaccine may want to carry amantadine or rimantadine for self-treatment of influenza A or one of the new neuraminidase inhibitors, zanamivir or oseltamivir, for treatment of either influenza A or B [24]. Because of potential side effects and medication contraindications, self-treatment should be carefully reviewed with the traveler (see Chapter 10).

- F. *Haemophilus influenzae* type b.** Implementation of childhood vaccination with conjugate *Haemophilus b* vaccines has resulted in a greater than 95% decrement of illness with this organism [25]. All children beginning at age 2 months should be vaccinated [26] (see Chapters 6 and 23).

III. Required vaccinations

A. Yellow fever. Countries that require yellow fever vaccine are listed in *Health Information for International Travel* [4]. Because of its requirement for cold storage and its viability for only 60 minutes after reconstitution, **the vaccine is given only in approved yellow fever vaccination centers**, which may be identified by calling state or local health departments. Persons who are traveling or living in areas **infected** with yellow fever and persons who visit rural areas in countries in the **endemic** zone for yellow fever should receive vaccine. Vaccine should be administered and recorded at least 10 days before travel. Worldwide, yellow fever cases have increased. Infection has spread to urban areas in South America [27,28], and fatal cases of yellow fever have occurred in short-term visitors to infected areas [29].

Infected areas are those where yellow fever cases are occurring; these lie primarily in equatorial South America and approximately 15 degrees on either side of the equator in Africa. They are listed in the *Summary of Health Information for International Travel*, which is published every 2 weeks by the CDC [30] and may be found on-line at the CDC travel website (www.cdc.gov/travel/bluesheet.htm). Zones **endemic** for yellow fever are areas in Africa and South America where yellow fever could occur. Some countries, particularly those in Asia, that are not in the endemic zones require immunization of persons who enter their country from an area in which yellow fever is occurring. Requirements for each country are clearly stated in *Health Information for International Travel* [4].

Recently, several cases of multiple organ system failure, some of them fatal, have occurred in persons receiving yellow fever vaccine [31]. A CDC analysis of U.S. persons with serious reactions to this vaccine indicated an increased risk for the elderly (particularly those 75 years of age and older) [32]. The CDC and Immunization Practices Advisory Committee have made no changes to the recommendations for yellow fever vaccine. However, before administering vaccine, the travel health professional should be sure that it is indicated for the traveler.

It is best not to vaccinate HIV-infected travelers with yellow fever vaccine unless they are asymptomatic, have undetectable viral loads and high CD4 counts, and are traveling to yellow fever-infected areas. Otherwise, they should avoid travel to infected areas. If they have to travel and yellow fever vaccine is required, they should carry with them a letter of medical exemption to vaccination, and they should adhere meticulously to mosquito avoidance measures. Whole-cell inactivated cholera vaccine (no longer available in the United States) given within 3 weeks of yellow fever vaccination may reduce antibody responses to both vaccines. Yellow fever vaccine may be given simultaneously with immunoglobulin.

B. Cholera. Production of the whole-cell inactivated cholera vaccine (the only cholera vaccine that was available in the United States) ceased in 2000. Discontinuation may have been prompted by the vaccine's limited efficacy (around 50%) for only a short duration (3–6 months) and uncomfortable side effects [33]. More importantly, use of this vaccine was extremely limited because of the negligible risk of cholera for international travelers [34,35]. This low level of risk prevails despite increased cholera infection in Latin America and a new serotype of cholera, *Vibrio cholerae* O139, which is circulating in Asian countries [36].

Two oral vaccines are marketed in countries other than the United States [37]. One is live-attenuated and uses a recombinant toxin-deleted strain of *V. cholerae*, CVD HgR 103 (Mutachol, Berna). The second is inactivated, combining whole *V. cholerae* O1 cells with recombinant B subunit of cholera toxin (Dukoral, SBL Vaccine AB). Although these vaccines are generally well tolerated and more effective (60%–80% protective efficacy) than the parenteral vaccine, they are still not recommended because of low risk [38].

Cholera immunization is no longer required for international travel, which further decreases the need for vaccination. Although no country requires vaccination for entry, some local authorities may still request documentation. In these circumstances, the traveler can try to obtain vaccine outside of the United States or may carry a letter of contraindication to vaccine. To avoid infection, travelers should exercise care in food and water consumption.

C. Smallpox. The requirement for smallpox vaccination for international travel was discontinued in 1982 after the worldwide eradication of smallpox [9]. Stocks of the vaccinia virus vaccine have been maintained by several countries and used for vaccination of laboratory workers. With the threat of bioterrorist attacks using smallpox virus [39], there has been renewed interest in protecting a larger segment of the population and having vaccine available for use in control of an outbreak [40]. There are no recommendations for vaccine use for travel, but this is an area that should be closely monitored.

IV. Recommended vaccinations for travelers because of risk

A. Hepatitis prophylaxis

1. Hepatitis A. Hepatitis A virus (HAV), endemic throughout much of the developing world, is the most common vaccine-preventable illness in travelers and causes the most time lost from work in returned travelers [41]. The risk for HAV in unprotected travelers varies from 1 to 10 per 1,000 travelers for a 2- to 3-week stay and includes persons on first-class tours [41–43]. Therefore, most travelers should receive protection [44]. See related discussion in Chapters 14 and 23.

a. Hepatitis A vaccine. There are two inactivated vaccines available in the United States (Havrix, GlaxoSmithKline, and Vaqta, Merck) that are highly immunogenic, protective, and cost effective [44,45]. After a single intramuscular dose in either adults or children, protective antibodies develop in 14 to 28 days and protection should last for at least a year. A dose at 6 to 18 months will likely provide protection for as long as 10 to 20 years, and perhaps for a lifetime. The manufacturers recommend administering vaccine 2 to 4 weeks before travel to allow development of a protective immune response. Indirect information, however, indicates that vaccination may be protective immediately before exposure or within the first several days after exposure [46,47]. If necessary, either Vaqta or Havrix may be administered to boost a primary dose with the other vaccine [48]. When inactivated vaccines were first released, use was often restricted to long-term (≥ 6 months) or frequent (three or more trips) travelers; however, these vaccines are becoming the products of choice.

b. Immunoglobulin, a sterile preparation of antibodies (primarily IgG) with high titers against HAV, is available for **immediate passive protection against infection.** It may be used for children under 2 years of age in whom inactivated vaccines are not approved by the U.S. Food and Drug Administration (FDA). Immunoglobulin provides protection for 2 to 6 months, depending on the dose administered (Table 23.1) [49]. Problems with production of immunoglobulin for intramuscular use have led to intermittent shortages of the product.

c. Pretravel hepatitis A antibody testing may be considered for frequent visitors to the developing world or those with a higher likelihood of having had infection in the past, such as persons older than 50 (30%–75% will be seropositive, depending on the population studied [44,50]), those born in or with prolonged residence in developing regions, and those with a history of hepatitis [51]. The cost effectiveness of this testing depends on the prevalence of hepatitis A antibody, the cost of screening, and the cost of vaccine [52]. Anti-HAV (IgG)-positive travelers do not need either immunoglobulin or inactivated vaccine.

2. Hepatitis B. Vaccination against hepatitis B virus (HBV) is routine for children and adolescents in the United States [26]. Travelers at risk are those who will be in contact with blood or body fluid secretions (e.g., physicians, nurses, other health-care workers, and laboratory technicians) and those likely to have sexual exposure [4]. Travelers who will live in countries with intermediate (2%–7%) or high prevalence ($> 8\%$) of hepatitis B surface antigenemia (such as parts of southeast Asia, Sub-Saharan Africa, and the interior Amazon basin) should also consider vaccination (Fig. 22.1).

HBV vaccine (Engerix, GlaxoSmithKline, and Recombivax, Merck) is administered at 0, 1, and 6 months. Dosage varies between the two licensed products. Adolescents 11 to 15 years of age require only two doses of either vaccine (10 μg

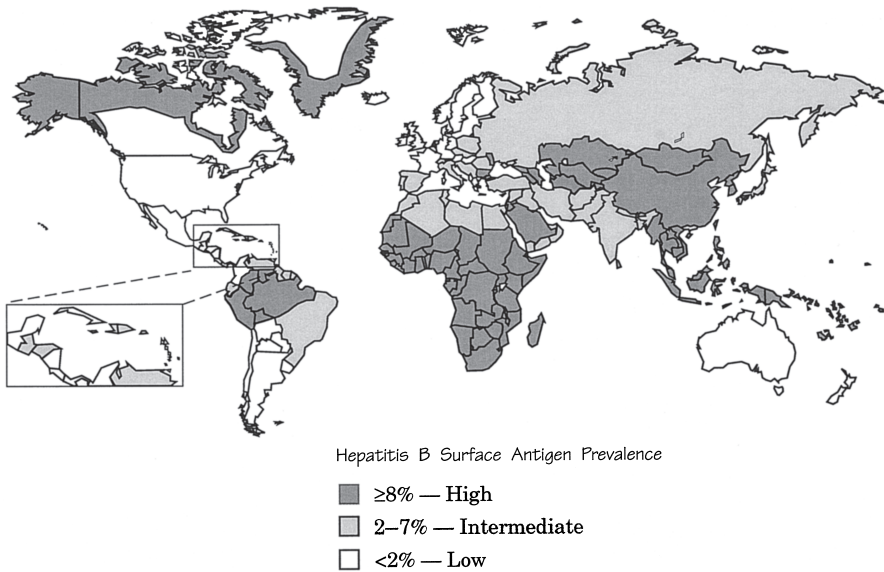

FIG. 22.1 World prevalence of hepatitis B surface antigen. (From Centers for Disease Control and Prevention. *Health information for international travel, 2001–2002*. Atlanta, GA: U.S. Department of Health and Human Services, 2001, with permission.)

dose) at 0 and 6 months. To achieve more rapid immunity for travelers, the dosing intervals of Engerix (20 μg) may be shortened to 0, 1, and 2 months with a 6- to 12-month booster [53]. Further acceleration may be achieved by giving Engerix at 0, 7, and 21 days, which will produce seroprotective titers in 65% of recipients at 28 days [54]; this regimen is not FDA approved.

Intramuscular injections of hepatitis vaccine should be given in the deltoid. **Persons immunized against hepatitis B will also be protected against delta hepatitis** because this incomplete virus requires actively replicating hepatitis B for survival (see Chapters 14 and 23).

3. **Combination vaccination against HAV and HBV.** Twinrix (GlaxoSmith-Kline, released in 2001) combines both HAV and HBV antigens and is approved for persons 18 years of age and older [55]. Indications for use are the same as those for HAV and HBV. Because the vaccine has a lower dose of HAV antigen (720 ELISA Units) compared with either of the two single-antigen HAV vaccines, seroconversion to HAV may be delayed; **two doses of vaccine should be administered before travel to ensure protection.**
4. **Hepatitis C.** There is no vaccine against hepatitis C. Persons may decrease their risk of infection by avoiding exposure to blood products, blood-contaminated needles or dental instruments, and unprotected sexual contact.
5. **Hepatitis E** is recognized throughout much of the developing world [56]. An analysis of clinically apparent cases of hepatitis E in travelers indicated that most cases occurred after travel to the Indian subcontinent and in persons who were traveling for longer than 1 month [57]. Subclinical seroconversion may occur [58]. Water that has been fecally contaminated, often after heavy rains in areas with inadequate sewage disposal, is the most likely source of infection in endemic cases [59]. The overall risk for travelers appears to be less than that for hepatitis A. Pregnant women are at a relatively high risk of mortality. There is no evidence that immunoglobulin will prevent hepatitis E [60] and so proper preparation of food and purification of water needs should be emphasized (see Chapter 14).

B. Typhoid. Typhoid immunization is indicated before traveling to areas endemic for typhoid fever where fecally contaminated food and water are likely to be ingested. Importation accounted for 72% of the 2,445 cases of typhoid in the United States from 1985 to 1994 [61]. Although most cases of typhoid originated in Mexico, travel to the Indian subcontinent presented the highest risk: 1.1 to 4.1 cases of typhoid fever occurred per 10,000 travelers, which was 18 times higher than travel to other destinations. Another reason to consider vaccination is that *Salmonella typhi* acquired internationally is frequently multidrug resistant [62].

1. Live oral vaccine (Vivotif Berna, Swiss Serum and Vaccine Institute). This attenuated live vaccine uses the Ty21a mutant of *S. typhi*. In a meta-analysis of typhoid vaccines, three doses of this vaccine provided a 3-year protective efficacy of 51% (95% confidence interval, 35%–63%) [63]. In the United States, four doses of vaccine are administered, which could lead to improved efficacy. The traveler takes one enteric-coated capsule with a cool to warm drink (<37°C) 1 hour before a meal every other day for a total of four capsules, beginning at least 2 weeks before departure. Although capsules should be refrigerated, they usually retain potency if left at room temperature (20–25°C) for a few days. The availability of this vaccine has been limited in the United States in recent years.

The safety of this vaccine in HIV-infected persons is not known. It should not be given to persons taking antimicrobials, nor should mefloquine be given simultaneously because of the potential of killing the attenuated bacteria. Administration of mefloquine and vaccine should be separated by at least 24 hours; antibiotics can be commenced 48 hours after completing the vaccine series.

2. Typhoid Vi polysaccharide vaccine, which consists of purified Vi capsular polysaccharide of *S. typhi*, is given in a single intramuscular dose and should provide approximately 50% to 70% protection for 2 to 3 years [64,65]. It can be administered to persons 2 years of age or older and should be given at least 2 weeks before travel. The vaccine may be the product of choice when compliance with oral dosing and refrigeration of the Ty21a vaccine are concerns and for children aged 2 to 6 years of age. An experimental conjugate Vi antigen vaccine has demonstrated superior protective efficacy in children 2 to 6 years of age [66].

3. Parenteral whole-cell vaccine. Although this vaccine was as effective as the oral and Vi polysaccharide typhoid vaccines, it was often poorly tolerated, and production in the United States was discontinued in 2000. It could be given to persons 6 months of age and older. Because children under 2 years of age can no longer be vaccinated against typhoid, their parents or guardians must ensure that they ingest only safe foods and liquids during travel.

C. Meningococcal disease. Most international travelers are at low risk for acquiring meningococcal bacteremia or meningitis. Several areas of the world, however, have epidemic or endemic meningococcal disease, and because the consequences of meningococcal infection are severe, vaccination may be warranted [67] (Fig. 22.2).

It is required that religious pilgrims traveling to Saudi Arabia to attend the annual hajj receive vaccine. Long-term visitors to the meningitis belt in Sub-Saharan Africa should be vaccinated. Short-term visitors to this region who travel from December through June and who will have contact with local people should also consider vaccine [4]. Although the serotype A is usually associated with epidemic disease, in the years 2000 and 2001 serotype W-135 affected hundreds of pilgrims to Saudi Arabia, who sometimes carried this serotype back to their country of origin [68]. The meningococcal polysaccharide vaccine in the United States is polyvalent for groups A, C, Y, and W-135. Because of variable efficacy of the current vaccine in children under the age of 5 years, conjugate vaccines against *Neisseria meningitidis* group C have been developed and used in England and Canada [69].

The risk of meningococcal disease is slightly greater among freshman college students who live in dormitories [70]. Therefore, the Advisory Committee on Immunization Practices has recommended that this group of students is informed of the risk and that protection (against serotypes A, C, Y, and W-135) is available by vaccination

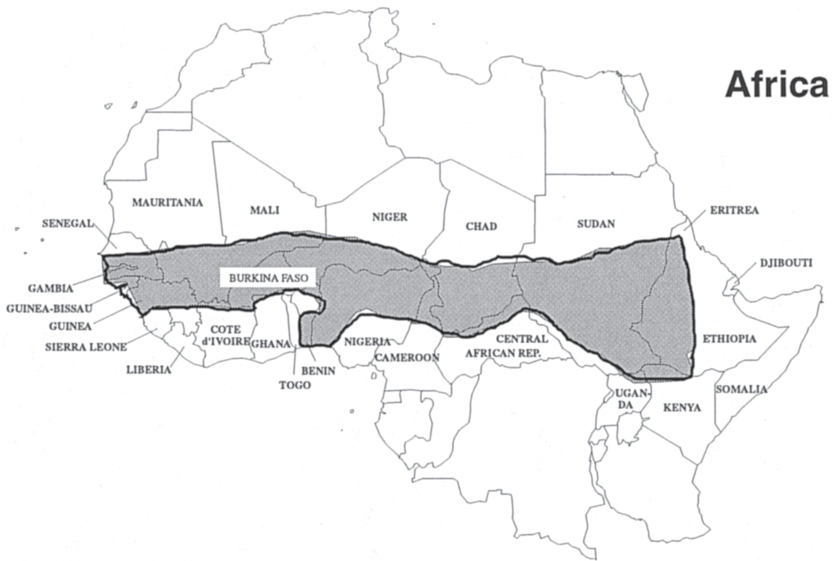

FIG. 22.2 Areas in Sub-Saharan Africa with epidemic meningococcal disease. (From Centers for Disease Control and Prevention. *Health information for international travel, 2001–2002*. Atlanta, GA: U.S. Department of Health and Human Services, 2001, with permission.)

[71]. Other students may also consider vaccination to reduce this small risk of disease. See Chapters 6 and 23 for further discussion.

- D. Poliomyelitis.** Worldwide, much progress has been made in the elimination of poliomyelitis [72]. The Western Hemisphere was declared polio free in September 1994 and the Western Pacific in October 2000 [73]. Most of the world's polio cases occur in Africa (central and western) and in countries with conflict, and in the Indian subcontinent [72]. Despite the progress in control of polio, it remains important to maintain high vaccine coverage. This was illustrated recently in Haiti, the Dominican Republic, and the Philippines where cases of vaccine-strain paralytic disease occurred in unvaccinated or incompletely vaccinated persons [74].

The risk to the international traveler is extremely low [75]. In a study of paralytic poliomyelitis in the United States from 1980 through 1998, there were only six cases imported and only one after 1986 [76,77]. Nevertheless, travelers to endemic areas who are exposed to poor food and water sanitation should be immunized.

In January 2000 the CDC and the American Academy of Pediatrics initiated a change from oral poliovirus vaccine (Sabin; live attenuated, trivalent vaccine [OPV]) to inactivated polio vaccine (IPV) for routine childhood immunization [77]. This was undertaken because of the rare risk of paralytic disease in recipients and contacts of recipients of OPV; all cases of indigenous paralytic poliomyelitis in the United States since 1980 have been associated with the OPV vaccine.

- 1. Primary vaccination of persons of all ages should be accomplished with inactivated poliomyelitis vaccine.** At least two doses of IPV should be given before travel; however, if time is lacking (<4 weeks before departure), a single dose of IPV can be given.
- 2. It is recommended that persons who have completed a primary series receive one adult (generally those age 18 and older) lifetime booster if traveling to an area of risk.**
- 3. See Chapter 23 for further discussion.**

- E. Japanese B encephalitis.** Japanese B encephalitis is a mosquito-borne encephalitis prevalent in many areas of the Indian subcontinent and Asia (Fig. 22.3). It has an

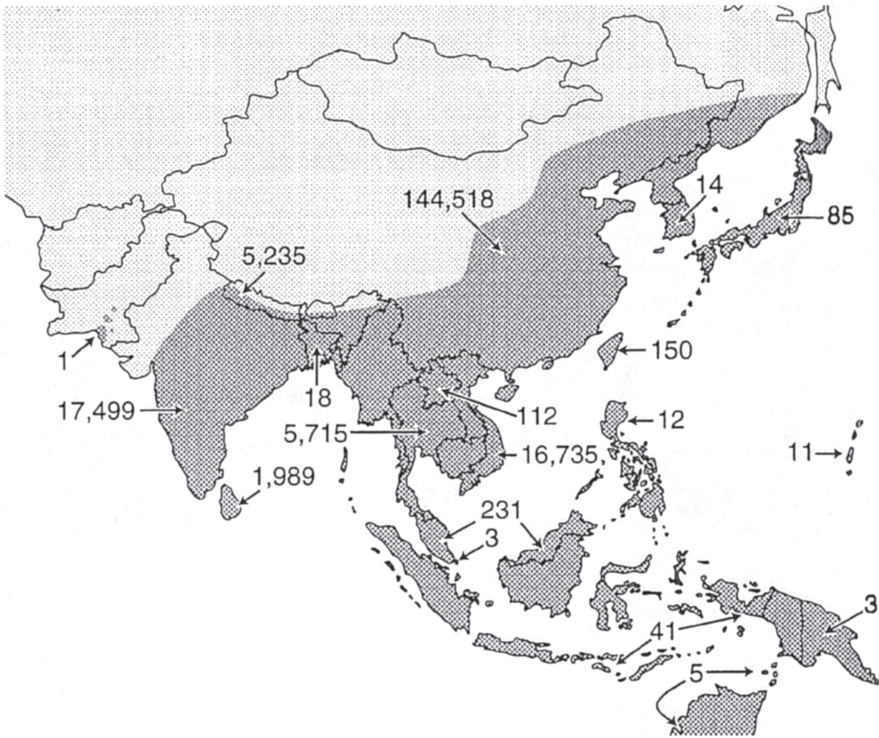

FIG. 22.3 Reported Japanese encephalitis cases by endemic countries and regions of South-east Asia where viral transmission is proven or suspected, 1986–1996. (From Tsai TF, Chang G-JJ, Yu YX. Japanese encephalitis vaccines. In: Plotkin SA, Orenstein WA, eds. *Vaccines*. Philadelphia: W.B. Saunders, 1999:672–710, with permission.)

inapparent-to-apparent case ratio of 50 to 500:1. Among patients with symptomatic disease; however, the fatality rate is approximately 20%, and there is high morbidity in survivors [78]. Disease occurs primarily in young children and adults older than 65 years of age. Seasons and areas of risk are delineated in *Health Information for International Travel* [4], and this guide should be consulted in determining the risk to travelers. Based on the number of cases in expatriate travelers and military personnel, the risk appears to be fewer than one case per 1 million travelers [79]. If risk is based on endemic populations, however, it could be as high as one case per 5,000 to 20,000.

Vaccination against Japanese B encephalitis should be considered for travelers with prolonged residence in endemic areas during transmission seasons or short-term travelers who will engage in high-risk activities such as fieldwork, camping, or bicycling. Transmission is most likely to occur in rural areas where there is rice farming (a breeding site for the *Culex* mosquito vector) in proximity to pig farming (the principal amplifying host for the virus). Most travelers to endemic countries will not need vaccination because their travel is short term and they typically visit only urban and major tourist destinations. All travelers should practice personal protection against the *Culex* mosquito, particularly during the dusk to dawn hours.

Japanese B encephalitis vaccine in the United States is an inactivated mouse brain-derived vaccine (Biken) distributed by Aventis Pasteur. **This vaccine may**

be associated with severe systemic allergic reactions that occur with an approximate frequency of 0.1 to 5 per 1,000 administrations [79–83]. Severe reactions have included urticaria, anaphylaxis, and cardiovascular collapse and can occur within minutes of vaccine administration to several days after vaccination. An allergic history may be associated with an increased risk of adverse reactions and should be a relative contraindication to receiving vaccine [82]. Mild local and systemic reactions occur with a frequency of 10% to 20%. Vaccine recipients should be monitored for 60 minutes after immunization, and the final dose should preferably be completed not sooner than 10 days before departure so that untoward effects may be monitored.

- F. Rabies.** The risk of acquiring rabies during travel is very low; there were only 10 cases in travelers from 1975 to 1984 [84]. Potential exposures (e.g., dog bites), however, may not be uncommon. Most cases in travelers and most transmission of rabies overseas is secondary to the bite of a rabid dog [85]; canine rabies is highly endemic throughout many areas of the world. Other animal species, including bats, are also capable of transmitting the rabies virus. Countries that have reported no cases of rabies are listed in *Health Information for International Travel* [4].

Travelers should be warned about the risk of rabies and if they are exposed how to treat a bite wound and how to access safe and effective postexposure rabies treatment. They should inform their health-care providers about the exposure as soon as possible. All animal bites should be thoroughly cleaned with copious amounts of water and soap. Tetanus prophylaxis may be needed if the traveler has not received a booster within 5 years, and antibiotics should be given to treat a potential bite wound infection. Then travelers should seek **postexposure** rabies treatment. If they have had no preexposure prophylaxis, postexposure treatment will consist of rabies vaccine **plus** rabies immune globulin [86]. If they have received preexposure prophylaxis, only a booster dose of rabies vaccine is necessary. See Chapters 4 and 23 for further discussion of bite wound management and rabies prophylaxis.

Preexposure prophylaxis is recommended based on the individual's itinerary, planned activities, duration of travel, and access to safe postexposure biologics. There are two rabies vaccines available in the United States: the purified chick embryo cell vaccine (RabAvert, Chiron) and the human diploid cell vaccine (Imovax, Aventis Pasteur). These are both administered intramuscularly in the deltoid of adults or the quadriceps of small children; the intradermal formulation of human diploid cell vaccine has been discontinued. Preexposure immunization consists of three doses of vaccine given over 21 or 28 days (Table 22.1). Routine serologic testing after preexposure immunization is not necessary unless the recipient is believed to be at risk for a diminished immune response. Intramuscular administration of vaccine overcomes the interference of immunogenicity that occurred when chloroquine (and possibly mefloquine) was administered with intradermal human diploid cell vaccine.

Preexposure prophylaxis has the advantage of providing protection when there is an inapparent exposure to rabies (such as may occur with small children who do not report a bite) and when postexposure therapy is delayed. It also eliminates the need for rabies immune globulin in the event of an exposure. This product is difficult to obtain in many countries [87] and may be manufactured from nonhuman sources that have variable purity. Equine rabies immune globulin has been used safely in many countries. Preexposure prophylaxis does not eliminate the need for additional doses of rabies vaccine [86]. Travelers who receive postexposure treatment overseas should be evaluated by health-care providers on return and serologic testing should be done to ensure that they developed immunity from their treatment.

- G. Plague.** The plague vaccine is not required by any country. Because of uncertain efficacy and very low risk of disease, production of the vaccine was terminated in 1999. Approximately 2,500 cases of plague are reported annually from 10 to 15 countries (including the United States) [88]. Nearly 80% of the world's plague comes from Africa. Travelers who will reside in plague endemic areas should avoid rodents and use precautions against fleas. For unavoidable exposure, adults can be given tetracycline (500 mg four times a day) or doxycycline (100 mg twice daily) chemoprophylaxis

and children can be given sulfonamides [89]. The efficacy of this measure, however, has not been established.

- H. Tuberculosis prevention.** Tuberculosis exposure in the developing world usually occurs as a result of prolonged contact with respiratory droplets from infected persons in a closed setting. The risk during travel was recently defined in Dutch travelers visiting tuberculosis endemic regions for at least 3 months [90]. Travelers were bacille balié de Calmette-Guerin naive and were screened by pre- and post-travel tuberculin skin testing. The incidence of infection (based on 656 travelers) was 3.5 cases per 1,000 person-months, the incidence of disease was 0.6 cases per 1,000 person-months, and the incidence of infection in health-care workers was 7.9 cases per 1,000 person-months. These risks approach that for the most common vaccine-preventable diseases. For travelers with exposure, particularly long-term travelers and health-care workers, pretravel and posttravel (2 months after return) tuberculin skin testing is indicated. This approach is preferable to administration of the bacille balié de Calmette-Guerin vaccine [91]. For children who will have unavoidable exposure to tuberculosis and for whom other preventive measures such as prophylactic isoniazid cannot be used, bacille balié de Calmette-Guerin vaccine may be considered.

ADVICE ON DISEASE PREVENTION OTHER THAN BY VACCINATION

I. Traveler's diarrhea

- A. Clinical findings. Traveler's diarrhea affects 20% to 50% of visitors to developing regions** in Latin America, Africa, and portions of Asia [92–95]. The risk is intermediate in some of the Caribbean islands and in Eastern Europe. Disease is transmitted through fecally contaminated food or liquids.

1. Etiology. The causative agent is identified in fewer than three-fourths of cases. Enterotoxigenic *Escherichia coli* is most common, accounting for approximately 50% of cases in which the etiology is determined [94,96]. *Shigella*, *Salmonella* species, *Campylobacter*, and enteroaggregative *E. coli* are seen in 10% to 30% of cases [97]. *Vibrio* species, *Aeromonas*, and *Plesiomonas* species are less frequent. Norwalk-like agents and rotavirus are implicated in approximately 20% of cases. *Giardia lamblia* is the most common parasite that causes diarrhea in travelers (approximately 5% of cases) [98]. Symptoms may appear after the traveler has returned to the United States and often persist for more than 2 weeks. *Cryptosporidium parvum* and *Cyclospora cayetanensis* are also seen, with *Entamoeba histolytica* and *Isospora belli* reported infrequently [99]. Most cases of parasitic diarrhea occur in long-term travelers [99,100].

2. Clinical manifestations. Traveler's diarrhea usually occurs during the first week of travel. Diarrhea and abdominal cramps are associated with nausea and malaise. Temperature exceeding 38°C occurs in only 10% to 20% of patients and vomiting in fewer than 15%. Bloody dysenteric stools are unusual (2%–10%). The duration of traveler's diarrhea, even in persons who are not treated, is 3 to 4 days, with 60% of patients recovering within 48 hours.

B. Prevention

1. Routine precautions. The best precaution against traveler's diarrhea is careful choice of food and drink. It is particularly important to exercise this precaution when traveling with infants or small children because the consequences of diarrhea at this age may be considerable. Travelers should ingest only commercially bottled or carbonated beverages (bottled carbonated water, soda, and beer), wine, heated drinks (coffee, tea, boiled water), thoroughly cooked foods and meats served piping hot (particularly seafood and shellfish), and fruits that the traveler can peel. Unpasteurized dairy products, tap water, ice cubes, food from street vendors, salads, and fresh ground-grown leafy greens and vegetables should be avoided. Even persons who exercise these precautions may not always avoid diarrhea.

The most reliable way to purify drinking water is to bring it to a boil; boiling for an additional few minutes may be necessary at high altitude [101]. If used properly, halogens (iodine or chlorine preparations) will kill viruses and bacteria.

Chlorine preparations are more affected by water temperature, pH, and turbidity. Protozoa cysts, particularly *Cryptosporidium* and *Cyclospora*, will not be killed by halogenation [102]. Small-volume water filters of an “absolute” size no more than 1 μm remove bacteria and protozoa cysts.

2. **Antiperistaltic agents.** These should not be used for preventing traveler’s diarrhea.
3. **Prophylactic bismuth subsalicylate.** The prophylactic use of bismuth subsalicylate liquid (Pepto-Bismol, 2 oz four times a day) or tablets (two tablets four times a day) can reduce by approximately 60% the incidence of diarrhea in travelers [103]. Persons taking salicylate-containing compounds may develop salicylate toxicity if bismuth subsalicylate is taken concurrently. **Patients who are allergic to salicylates or who are taking anticoagulants should not take Pepto-Bismol.**
4. **Prophylactic antibiotics.** Several antibacterials (trimethoprim, 160 mg, and sulfamethoxazole, 800 mg, 1 tablet daily; trimethoprim, 200 mg/day; doxycycline, 100 mg/day; norfloxacin, 400 mg/day; ciprofloxacin, 500 mg/day) can decrease the incidence of diarrhea to 5% to 15% for the short-term (<3 weeks) traveler [93]. However, **prophylactic antibiotics may cause serious allergic reactions in a small number of persons** (e.g., Stevens-Johnson syndrome with sulfonamides) or adverse effects in others (e.g., photosensitivity and vaginal yeast infections with doxycycline and antibiotic-associated colitis with any antibiotic) and may contribute to the development of resistance to enteric flora. **Therefore, prophylactic antibiotics to prevent this usually mild illness are not recommended for most healthy travelers** [104]. For the short-term traveler who is on a very important trip or who has a medical condition that would be adversely affected by diarrhea, antimicrobial prophylaxis may be considered after potential risks are weighed.

C. Treatment

1. **Fluid replacement and diet. The most important management principle is to replace fluids and electrolytes lost in diarrheal stools** (Table 22.2) [4,105,106]. This may be the only treatment necessary for many adults and children because the diarrheal illness is often self-limited and of short duration. Oral rehydration must include glucose, sodium, potassium, chloride, and free water. Except in extreme cases, this may be accomplished in adults and older children by ingesting fruit juices, caffeine-free soft drinks, broth, and bouillon. These may be supplemented with salted crackers, rice, or toast. **Dairy products should be avoided initially** because lactose intolerance may be present.

Breast-fed infants should continue nursing. Bottle-fed children should also continue with lactose-free formulas. For oral rehydration, packets that contain glucose and salts at the appropriate concentrations after addition of purified water are available in most developing countries and in the United States (Table 22.2). Some formulas are rice based. Those who travel with infants and small children should consider carrying these packets. Children who experience persistent vomiting, bloody diarrhea, or high fever should receive immediate medical attention.

2. **Antimotility agents.** Drugs such as loperamide (Imodium) or diphenoxylate hydrochloride with atropine sulfate (Lomotil) relieve cramping and help to control diarrhea, allowing patients to participate in planned activities [107]. Loperamide is available over the counter and appears to be better tolerated than diphenoxylate-atropine, particularly in the elderly. It is favored by most physicians who advise travelers.

Antimotility agents may predispose to complications in patients with invasive or inflammatory enterocolitis. Therefore, **they should not be used when temperature exceeds 38.5°C or when blood appears in the stool** [93]. **They should not be taken by children younger than 2 years of age.** Liquid bismuth subsalicylate has proven effective for treatment for mild diarrhea [108]. Experience with this agent in children is limited [109], and it could potentially lead to salicylate toxicity if not used properly [110]. **If symptoms persist beyond 48 hours after any of these agents are initiated, administration should be discontinued and medical attention sought.**

Table 22.2. Treatment of Traveler's Diarrhea^a

Agent	Dose
Oral hydration ^b	
Homemade solution	
Potable water	1 L
Table salt	1/2 teaspoon
Baking soda	1/2 teaspoon
Table sugar (sucrose) ^c	2–3 tablespoons
World Health Organization composition ^d	
Sodium chloride	3.5 g/L
Glucose	20.0 g/L
Sodium citrate	2.9 g/L
Potassium chloride	1.5 g/L
Bismuth subsalicylate	1 oz q 1/2 h × 8 doses, or 2 tabs q 1/2 h × 8 doses
Loperamide (2 mg) ^e	2 capsules with 1st diarrheal stool, then 1 with each subsequent loose stool, not to exceed 8 capsules/day
Antibiotics	
Quinolones ^f	
Ciprofloxacin, 500 mg	Single dose—750 mg; 3-day therapy—500 mg b.i.d.
Norfloxacin, 400 mg	Single dose—800 mg; 3-day therapy—400 mg b.i.d.
Ofloxacin	Single dose—400 mg; 3-day therapy—300 mg b.i.d.
Levofloxacin, 500 mg	Single dose—500 mg; 3-day therapy—500 mg b.i.d.
Azithromycin ^g	
Trimethoprim, 160 mg, and sulfamethoxazole, 800 mg ^h	1 tablet b.i.d.
Doxycycline, 100 mg ^h	1 tablet b.i.d.

^aTravelers who have a temperature of more than 38.5°C, severe cramping, and blood or mucus in their stools should seek prompt medical attention if symptoms do not promptly resolve.

^bRice-based products may also be used. Commercial preparations may be purchased from: Jianas Brothers Packaging Company, Kansas City, MO (816 421-2880); or Cera Products, Inc., 1041 Waterfowl Terrace, Columbia, MD 21044 (301 490-4941).

^cHoney or karo syrup (2 tbs) may be substituted for sugar.

^dThe WHO composition is sodium (90 mEq/L), potassium (20 mEq/L), chloride (80 mEq/L), citrate (30 mEq/L), glucose (20 g/L).

Sucrose (table sugar), 40 g/L, may be substituted for glucose.

Sodium bicarbonate, 2.5 g/L, may be substituted for sodium citrate.

^eAvoid taking loperamide if there is fever >38°C and blood or mucus in the stools.

^fTreatment of enteric infections is not an approved indication for norfloxacin. Quinolones are contraindicated in pregnancy and for children under the age of 18 years. May be safe for short-term use in the pediatric age group.

^gNot FDA approved for treatment of travelers' diarrhea.

^hThere may be resistance to trimethoprim-sulfamethoxazole and doxycycline by enteric organisms.

3. Antibiotic therapy. Patients with mild to moderate traveler's diarrhea can be treated with a single dose or a short course (3 days) of one of several antibiotics [111]. Trimethoprim, trimethoprim-sulfamethoxazole [112], and doxycycline were studied initially; however, widespread resistance of enteric organisms has made these choices less effective [113]. Most experts recommend that travelers carry a quinolone antibiotic: norfloxacin, ciprofloxacin, ofloxacin, or levofloxacin (Table 22.2) [111]. *Campylobacter* species is becoming resistant to quinolones, especially in Asia; in these cases, azithromycin may be effective [114]. New agents that have not yet been approved for use in the United States may prove valuable [115].

Single-dose therapy for traveler's diarrhea has not been extensively studied but is likely to be effective [116]. A single dose may be initiated; if diarrhea does

not resolve after this, treatment may be continued for up to 3 days. Although combining an antibiotic with loperamide for mild to moderate diarrhea has also been shown to effect prompt improvement of symptoms [117,118], this approach has not been found consistently effective in all regions of the world and in all etiologies of diarrhea [95,119]. It is a reasonable approach as long as the traveler is not experiencing severe cramping, fever at least 38.5°C, or bloody stools.

Patients with high fever or bloody diarrhea should seek medical evaluation. If medical attention is not available, empiric antibiotic therapy can be initiated.

II. Malaria. Malaria is a febrile flu-like illness caused by one of four species of malaria parasites: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, or *P. malariae*. From 1993 through 1998, 85% of malaria cases imported to the United States were caused by *P. falciparum* or *P. vivax* [120]. *P. falciparum* is the species that causes the most severe illness and nearly all cases of fatal malaria [4,121]. It is widely resistant to chloroquine phosphate, and in rural and forested border areas of Thailand it is resistant to other antimalarials (Fig. 22.4). From 1995 through 1998, 83% of imported cases of falciparum malaria cases originated in Sub-Saharan Africa [120].

Exposure to malaria depends on the itinerary and duration of a trip, time of year, and prevalence of *Plasmodium* species. The overall risk of acquiring malaria ranges from 0.8 cases to 24 cases per thousand travelers [122,123] and varies greatly between and within countries, the type of travel, and whether or not chemoprophylaxis was taken (Fig. 22.4). Country-specific prevention guidelines are published by the CDC in *Health Information for International Travel* [4] and by the WHO [124]. The United Kingdom and Canada also publish their own guidelines [125,126].

Prevention of malaria requires a multifaceted approach that emphasizes protection against mosquitoes, safe and effective chemoprophylaxis, and plans for medical care if

FIG. 22.4 Distribution of malaria and chloroquine-resistant *Plasmodium falciparum*. For use only as a visual aid. Refer to up-to-date resources for actual distribution. (From Committee to Advise on Tropical Medicine and Travel (CATMAT). Canadian recommendations for the prevention and treatment of malaria among international travelers. *Can Commun Dis Rep* 2000;26[Suppl 2]:1-42, with permission.)

malaria occurs [127]. **All travelers should be informed that no prophylactic regimen is 100% effective and that malaria can develop several months or longer after returning to the United States.** Travelers must be advised to seek prompt medical attention for any acute febrile illness that might be malaria and to inform their physician of their exposure. **Patient compliance with medication and physician prescribing of correct antimalarials** are key. In the United States from 1992 to 2001 75% of United States civilians with malaria had taken either no prophylaxis or inappropriate chemoprophylaxis [128]; in Canada, similar findings have been reported [129].

A. Mosquito avoidance. The first step in malaria prevention is avoidance of the female *Anopheles* mosquito, which typically feeds from dusk until dawn. Travelers should wear long-sleeved, light-weight, loose-fitting, protective clothing; avoid the use of perfumes; use mosquito repellents; and sleep under netting or in well-screened rooms.

Mosquito repellents that contain diethyltoluamide (DEET) in a concentration of 15% to 35% offer best protection [127,130]. With new extended-duration formulations of DEET that may provide protection for 4 to 12 hours, there is no need for highly concentrated preparations. DEET is safe to use on children, but guidelines should be followed carefully to avoid any of the exceedingly rare neurologic complications [130]. **DEET-containing products should be applied sparingly only on exposed skin or clothing.** They should not be inhaled, ingested, or applied to mucous membranes, the eyes, or irritated skin; they should be washed off after coming indoors [4]. If a suspected reaction to a repellent occurs, treated skin should be washed and medical attention promptly sought.

Mosquito coils, sprays, and vaporizing mats may be used in enclosed areas to decrease the mosquito population. **Clothing and netting may be sprayed or dipped in the insecticide permethrin.** Permethrin remains adherent to fabric through several washings and provides weeks of protection against mosquitoes [131].

B. Prophylactic drugs. Current recommendations for antimalarial drugs and their dosing should always be consulted because chemoprophylactic regimens are reviewed on an ongoing basis as to efficacy and safety [4,124]. Table 22.3 lists antimalarial drugs and their recommended adult and pediatric doses.

1. For travel to areas with chloroquine-sensitive malaria. Currently, only the Dominican Republic, Haiti, Central America west and north of the Panama Canal, Mexico, Argentina, Egypt, most countries in the Middle East, and some areas of China have *P. falciparum* strains that are still sensitive to chloroquine. For travel to these areas, chloroquine phosphate remains the drug of choice. It can prevent clinical illness due to the erythrocytic stages of sensitive strains of *P. falciparum* and all other *Plasmodium* species. No agent, including chloroquine, will prevent mosquito bites or kill sporozoites. Occasional cases of chloroquine-resistant *P. vivax* have been reported from Indonesia and Papua [132].

Chloroquine is taken weekly as a single oral dose, beginning 1 to 2 weeks before travel and each week thereafter in the malarious zone and for 4 weeks after leaving the endemic area. Taking the drug after meals can help to reduce any minor gastrointestinal distress. Chloroquine has been reported to exacerbate psoriasis. High doses of chloroquine [133] or hydroxychloroquine [134] taken on a daily basis for treatment of inflammatory conditions have rarely been associated with retinopathy (three cases per 1,500 users). Persons who take chloroquine at a daily dose of less than 250 mg or less than 3.0 mg/kg should have ophthalmologic screening at 6-month intervals [135]. Chloroquine should be stored in child-proof containers to prevent a risk of life-threatening toxicity with accidental ingestion or overdose of the drug in children.

2. Travel to areas where chloroquine resistance occurs. There are three choices for prevention of chloroquine-resistant *P. falciparum*: mefloquine (Lariam, Roche), atovaquone-proguanil (Malarone, GlaxoSmithKline), and doxycycline.

a. Mefloquine is highly effective against both chloroquine-resistant and sulfadoxine-pyrimethamine-resistant *P. falciparum* infections [136–138].

Table 22.3. Drugs Used in the Prophylaxis of Malaria

Drug	Adult Dose	Pediatric Dose
Chloroquine phosphate (Aralen)	300 mg base (500 mg salt) orally, once per wk, beginning 1 wk before travel and continuing for 4 wk after travel	5 mg/kg base (8.3 mg/kg salt), orally, once per week (not to exceed adult dose of 300 mg base)
Mefloquine (Lariam)	250 mg (salt) orally, once per wk, beginning 1 wk before travel and continuing for 4 wk after travel	<15 kg: 5 mg salt/kg/wk 15–19 kg: 1/4 tab/wk 20–30 kg: 1/2 tab/wk 31–45 kg: 3/4 tab/wk >45 kg: 1 tab/wk
Atovaquone/proguanil (A/P) (Malarone)	250 mg A/100 mg P 1 tablet daily, beginning 2 days before travel and continuing for 7 days after travel	62.5 mg A/25 mg P 11–20 kg: 1 tablet daily 21–30 kg: 2 tablets daily 31–40 kg: 3 tablets daily >40 kg: adult dosing
Doxycycline	100 mg orally, 1 tablet daily, beginning 2 days before travel and continuing for 7 days after travel	>8 yr old: 2 mg/kg orally, once per day (not to exceed adult dose of 100 mg)
Hydroxychloroquine sulfate (Plaquenil)	310 mg base (400 mg salt) orally once per wk	5 mg/kg base (6.5 mg/kg salt) orally, once per wk (not to exceed adult dose of 310 mg base)
Proguanil	200 mg/d orally, in combination with weekly chloroquine	<2 yr old: 50 mg/d 2–6 yrs old: 100 mg/d 7–10 yrs old: 150 mg/d >10 yrs old: 200 mg/d
Primaquine	15 mg base (26.3 mg salt) orally, once per day, for 14 days	0.3 mg/kg base (0.5 mg/kg salt) orally, once per day

Adapted from Centers for Disease Control and Prevention. *Health information for international travel, 2001–2002*. 2001, Atlanta, GA: U.S. Department of Health and Human Services.

P. falciparum resistance to mefloquine (and to chloroquine) occurs in rural forested areas of Thailand that border Cambodia and Myanmar (formerly Burma) [139].

(1) **Dosage.** Mefloquine is taken weekly as a single dose, beginning 1 to 2 weeks before travel and continuing weekly during exposure and for 4 weeks after leaving endemic areas. Some authorities recommend a loading dose (250 mg daily for 3 days) of mefloquine to rapidly achieve protective levels and to assess the potential for side effects [126,129]; however, this measure is not recommended by the CDC or WHO.

(2) **Side effects.** Although mefloquine is well tolerated by most persons, concern about potential neuropsychiatric side effects has adversely affected patient acceptance of the drug and physician willingness to prescribe it.

Several studies have reviewed adverse events [138,140,141]. With prophylactic doses, minor side effects of gastrointestinal disturbance and mild neuropsychiatric events occur in 5% to 30% of users. Neuropsychiatric events include sleep disturbance, vivid dreams, dizziness, mood changes, and concentration defects. Approximately 40% of these adverse reactions

occur after the first dose and 78% after the third dose [142,143]. Rarely, a serious adverse event such as psychosis or convulsions will occur during prophylaxis (about one case per 13,000 users) [144,145]. Neuropsychiatric events occur more frequently with treatment doses.

(3) Contraindications to the use of mefloquine.

- (a) Travelers with known hypersensitivity to mefloquine.
- (b) Travelers with history of seizures or psychiatric disorder.
- (c) Travelers with underlying cardiac conduction abnormalities, but not those on beta-blockers (e.g., for hypertension) if they have normal rhythms.
- (d) Although not approved during pregnancy, mefloquine given during the last two trimesters has not been associated with adverse fetal outcomes [146–148]. Limited information also suggests safety during the first trimester. **Therefore, if exposure to chloroquine-resistant falciparum malaria is unavoidable, mefloquine may be considered** [4].

b. Atovaquone/Proguanil (Malarone) is a fixed combination agent approved in the United States in 2000 for the prevention and treatment of *P. falciparum* malaria in both children and adults [149–151]. It has demonstrated excellent efficacy in treatment of both chloroquine-resistant and multidrug-resistant falciparum malaria in semi-immune hosts living in endemic regions of Asia, Africa, and South America [152,153]. It has also been highly effective in prophylaxis of falciparum malaria in semi-immune hosts [154].

Two recent studies have demonstrated safety and efficacy in preventing falciparum malaria in nonimmune travelers [155,156]. It has the advantage of causal prophylaxis (kills developing exoerythrocytic phase organisms) that allows discontinuation of the drug soon after leaving the malarious area [157]. This characteristic makes it a good choice for travelers with a short period of exposure to malaria. Although there are only limited data as to its efficacy in prevention and killing of nonfalciparum malaria parasites, it is presumed to be effective against these species. It does not kill the hypnozoites of *P. vivax* or *P. ovale*.

- (1) **Dosage.** Malarone is taken daily, beginning 1 to 2 days before exposure, continued daily during exposure, and continued for 7 days after leaving the malarious area (Table 22.3).
- (2) **Side effects.** Malarone is well tolerated; some may experience gastrointestinal upset, headache, or rash. Absorption is enhanced by ingestion with fatty foods. Its safety during pregnancy is not known, and it should not be used in these circumstances, unless other options are not available.

c. Doxycycline is effective against chloroquine-resistant and multidrug-resistant falciparum malaria [158,159]. It is taken daily, beginning 1 to 2 days before departure and continued daily during travel in the endemic areas and for 4 weeks after the traveler leaves the malarious area (Table 22.3). Doxycycline is contraindicated in pregnancy and in children younger than 8 years of age. Potential problems with doxycycline include difficulty in complying with a medication taken daily for 4 weeks after return, gastrointestinal upset, photosensitivity dermatitis, vaginal candidiasis, antibiotic-associated colitis, and esophageal ulceration if the pill is not completely swallowed [160]. Use of a sunscreen may decrease the risk of photosensitivity.

d. Other medications. Proguanil, a dihydrofolate reductase inhibitor, has been combined with chloroquine (200 mg daily) to provide coverage for chloroquine-resistant *P. falciparum* in areas of low prevalence (e.g., in India and South America) [124,125]. This approach is not endorsed by CDC, however, because of its inferior efficacy and deaths due to malaria in persons on this regimen and the difficulty in acquiring and adhering to proguanil because it is not available in the United States [128].

Primaquine has been studied for prevention of malaria [150,161]. It has causal prophylaxis against all species of malaria and, like Malarone, may be

discontinued soon after departing the malarious area. There is limited experience with this drug for prevention, and it is not FDA approved for this use; it may also cause hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient individuals. **The G6PD status of anyone receiving primaquine should be checked.**

3. **Self-treatment for malaria.** Travelers who choose not to take chemoprophylaxis or who desire to carry medication in the event of acquiring malaria despite chemoprophylaxis may carry self-treatment medications. Although malaria self-diagnosis kits are available in some countries outside of the United States, they are often not used reliably by the traveler [162]. Thus, if the traveler develops a febrile illness that could be malaria, the first step is to seek medical care. If medical care cannot be obtained within 24 hours, then self-treatment can be considered. **Two options are Fansidar (sulfadoxine/pyrimethamine) or Malarone, the latter is probably best.** Fansidar may not be effective in areas of sulfonamide resistance (southeast Asia, the Amazon River basin, and parts of East Africa) and has been associated with life-threatening severe cutaneous reactions in persons allergic to sulfonamides. Even if self-treatment is taken, travelers should still seek medical evaluation. Halofantrine should not be used for self-treatment because of the risk of sudden cardiac death in persons with cardiac conduction abnormalities [163]. Mefloquine used for self-treatment may also be associated with serious adverse events, including seizures and hallucinations.
4. **Prolonged exposure to malaria in areas intensely endemic for *P. vivax* or *P. ovale* may warrant terminal malaria prophylaxis with primaquine phosphate** to eradicate persistent hepatic forms of these species. Missionaries, Peace Corps volunteers, or refugee camp workers with prolonged exposure and returning travelers who were treated for malaria while abroad are at greatest risk for infection with these parasites. A G6PD level should be checked before prescribing this drug. Primaquine is **contraindicated during pregnancy** because the G6PD status of the fetus cannot be easily ascertained. Primaquine is not necessary for most travelers.
5. **Malaria information.** Detailed recommendations for the prevention of malaria may be obtained 24 hours a day by calling the CDC travel information system (888-232-3228) or by accessing the CDC Travel Health webpage (www.cdc.gov/travel).

III. Other diseases

- A. **Dengue fever.** Dengue fever is a mosquito-borne arboviral illness characterized by the sudden onset of fever, headaches, severe myalgias and arthralgias (break bone fever), abdominal discomfort, rash, and mild liver enzyme abnormalities. The rash appears 3 to 5 days after onset of fever and may spread from the torso to the extremities and face. Dengue fever has been a long-standing problem in the Far East, and during the last 10 years it has also spread throughout the Caribbean and Latin America [164,165]. Outbreaks tend to be focal and urban. Although dengue can progress to a fatal hemorrhagic shock syndrome (more likely in persons with prior dengue infection of a different serotype), most cases in travelers are self-limited. In recent years, 20 to 50 cases of confirmed dengue have occurred in U.S. travelers [165]. **Travelers should avoid the mosquito vectors (*Aedes* species), which tend to bite during the day, by using the personal protection measures discussed for malaria. No vaccine is available.**
- B. **Schistosomiasis.** Acute schistosomiasis (Katayama fever), sometimes associated with severe neurologic sequelae, may occur in travelers [166,167]. **Travelers may be exposed to the parasite in fresh water of endemic areas of the Caribbean, South America, Africa, or Asia. Travelers should avoid swimming, wading, or bathing in fresh water unless it is chlorinated.** In some areas, the local opinion may be that the body of fresh water is free of risk (such as Lake Malawi), but cases of schistosomiasis have occurred in those situations [168]. Swimming in salt water or bathing in fresh water that has been heated to 50°C for 5 minutes or that has stood more than 48 hours is safe. Praziquantel is effective treatment for schistosomiasis caused by all *Schistosoma* species
- C. **Sexually transmitted diseases.** Removed from societal restraints, some travelers are more likely to engage in casual sexual activity and place themselves at risk

for HIV and other sexually transmitted diseases [169]. It has been estimated that 5% or more of short-term travelers have casual sexual encounters and use condoms in fewer than half of them [170]. Among long-term male expatriates living in Sub-Saharan Africa, high-risk sexual activity approached 30% [171]. Drug-resistant isolates of *Neisseria gonorrhoeae* are prevalent in many areas, especially southeast Asia and Africa, and hepatitis B, syphilis, herpes simplex, and venereal diseases uncommon in the United States (chancroid, lymphogranuloma venereum, and granuloma inguinale) occur (see Chapter 16). Of these only hepatitis B is preventable by immunization.

The rapid spread of HIV infection throughout the world poses a major risk for transmission via the sexual route. Seroprevalence of HIV in urban female sex workers varies but has been reported to be as high as 80% in some areas of Africa [172]. **Although the risk of transmission of HIV can be decreased by the use of condoms, diaphragms, and spermicides, the safest course for the traveler is abstinence.** Additionally, condoms manufactured outside the United States may not be reliably protective. The presence of other sexually transmitted diseases and genital lesions can enhance the risk of transmission of HIV and should be an absolute indication for abstinence.

OTHER CONSIDERATIONS FOR THE TRAVELER

- I. **Jet lag.** Travel across multiple time zones is associated with disruption of the normal circadian rhythm. For many travelers this results in adverse subjective and physiologic responses during the first days after arrival. A number of approaches to restore the circadian rhythm have been suggested. Exposure to bright light after arrival facilitates adaptation. Although dietary measures have been proposed, they have not been rigorously evaluated. Short- to intermediate-acting benzodiazepines and the nonbenzodiazepine pyrazolopyrimidines can help to maintain sleep after arrival in the new time zone. These agents should be started at the lowest effective dose, and their duration of action should be matched with the time available for sleep. They should not be used during air travel because they can lead to confusion and disorientation. The hormone melatonin is naturally produced during sleep. Exogenous administration of melatonin has been proposed as a means to reestablish the circadian rhythm, but recent studies have failed to demonstrate a significant effect in travelers [173,174].
- II. **Deep venous thrombosis.** Long-distance travel, particularly by air, has been associated with an increased risk of deep venous thrombosis [175]. This syndrome has been called "economy class syndrome" and may occur in as many as 5% of long-haul (10–15 hours) travelers who have increased cardiovascular risk factors [176]. A smaller percent will experience pulmonary embolism (approximately 1–2 cases per million flights longer than 5,000 km) [177]. Maintaining hydration, exercise, and wearing below the knee support stockings may help to decrease risk [176].
- III. **Motion sickness.** There are several agents for motion sickness. For short-term use, over-the-counter preparations of diphenhydramine (Benadryl) (especially for children) or meclizine may be effective. Travelers should be aware of the potential sedating effects of these agents. For longer trips, such as cruises, a sustained-release transdermal preparation of scopolamine (Transderm-Scop) may be preferred. The package insert instructions should be carefully followed and, after the disk is applied, the hands should be thoroughly washed to remove any scopolamine. For severe nausea, Phenergan pills (25 mg for adults) or suppositories may be used.
- IV. **Sun protection.** Travelers should avoid excessive exposure to the sun to prevent heat exhaustion and sunburn. Sunburn is caused by the effects of both ultraviolet B and ultraviolet A radiation [178]. Most sunscreens offer protection against both types of radiation. Sunscreens should be applied in sufficient quantities to cover skin and may need repeat application if there is prolonged exposure or if they are washed off during swimming. Sunscreens with a sun protection factor of at least 15 should be used. Products that are water insoluble may be longer lasting.
- V. **Skin care.** Skin problems are a major health issue for the traveler [179,180]. Insect bites, sunburn, dermatophyte infections, and cellulitis all can occur. Many dermatophytoses are made worse by warm and humid tropical conditions. Therefore, skin

should be kept as clean and dry as possible, especially in skinfold areas. A topical antifungal preparation should be carried. Arthropod infections such as scabies and lice can be avoided by carefully washing hands and clothes. Persons should refrain from scratching insect bites to avoid pyoderma and cellulitis. Shoes or sandals should be worn at all times to prevent penetration by various nematodes.

- VI. High-altitude illness.** Acute mountain sickness, characterized by headache, nausea, vomiting, insomnia, and lassitude, affects up to 25% of persons who rapidly ascend to altitudes of 2,500 m and an even higher percent of those who exceed altitudes of 3,000 m [181]. Acute mountain sickness occasionally progresses to the potentially fatal syndromes of high-altitude pulmonary edema or cerebral edema. Acclimatization is the best method to prevent acute mountain sickness [181]. Acclimatization can be achieved by spending a few days at an intermediate altitude (1,500–2,200 m) and then gradually ascending to higher altitudes each day, with a return to sleeping at an elevation no more than 300 to 500 m higher than the night before.

Acetazolamide (Diamox) is a carbonic anhydrase inhibitor that may help travelers who ascend rapidly from low elevations. It hastens acclimatization but does not necessarily prevent acute mountain sickness. Acetazolamide is usually taken 24 to 48 hours before and for the first several days during the ascent. Various doses have been used ranging from 125 mg to 250 mg twice daily [181]. Acetazolamide is a diuretic and can cause circumoral and peripheral paresthesias; it is contraindicated in the sulfonamide-allergic patient. Descent and supplementary oxygen are the treatments of choice for mountain sickness. A descent of as little as 500 to 1,000 m can result in resolution of symptoms. Some large expeditions carry portable hyperbaric chambers to simulate descent until affected persons can be moved to lower elevations. When descent is not possible, dexamethasone or acetazolamide can be used for the treatment of acute mountain sickness [181]. Dexamethasone is not recommended for prophylaxis [182], because it only suppresses symptoms but does not enhance acclimatization. Travelers planning trips to altitudes above 3,500 m should seek expert advice.

- VII. Personal safety.** Although many travelers consider only the risk of exotic tropical diseases, more deaths in North Americans overseas are in fact attributable to accidents, injuries, and homicides than to infectious diseases [183,184]. Travelers should try to use safe public and private transport to avoid accidents and injuries and avoid swimming and diving in unfamiliar waters. Travelers may decrease the risk of personal assault by dressing conservatively and avoiding sites and activities that might be targeted by terrorist groups. Travelers should refuse to carry a package from one country to another, even if someone they have befriended (e.g., a personal guide) asks them to carry it; bombs, illicit drugs, or other illegal items may be hidden in the package. The U.S. State Department (888-407-4747 or travel.state.gov/) provides callers with updated travel advisory or visa information, along with safety tips and the names, addresses, and telephone numbers of Foreign Service locations.

- VIII. The HIV-infected traveler. Travelers infected with HIV face special challenges** [12,185]. Preventive measures [186], issues of vaccine safety and efficacy, prevalence of infectious agents overseas, health-care access, and the requirement by some countries for HIV testing prior to obtaining an entry visa (requirements may be accessed at travel.state.gov/HIVtestingreqs.html) all must be considered. Depending on the degree of immunosuppression, vaccines may be ineffective or unsafe. In general, live vaccines should be avoided. In addition, travel to developing countries may carry with it the risk of exposure to opportunistic pathogens such as *Salmonella* species, *Cryptosporidium parvum*, *Isospora belli*, *Cyclospora* species, *Mycobacterium tuberculosis*, and *Leishmania* species.

- IX. Travelers who have chronic lung or cardiovascular diseases, are pregnant, or are traveling with infants and young children.** Some travelers travel with medical conditions or chronic illnesses [187]. Cardiovascular disease is the most common cause of death among older travelers abroad [184]. Patients with severe chronic lung disease should undergo pulmonary function testing with arterial blood gases to determine whether they need supplemental oxygen during air flight [187,188]. Travelers requiring oxygen should contact their carriers 48 to 72 hours before travel and have a prescription from their physician that indicates diagnosis and liter flow rate.

Insulin-dependent diabetics should discuss with their physician the proper adjustment of insulin and diet schedules for time zone changes. Pregnant travelers should consider the potential health risks to self and fetus by air flight, exposure to malaria, and receipt of vaccinations and prophylactic medicines [189]. All travelers with pre-existent medical conditions need to be cautioned about the effects of changes in diet, jet lag, altitude, and climate. They should carry on their persons each medication in a labeled bottle as well as copies of their prescriptions. Special considerations also pertain to those traveling with infants and children [190].

- X. Avoidance of blood-borne pathogens (HIV, hepatitis C, etc.).** The safety and screening of the blood supply may be questionable. Previously used needles or intravenous administration sets, dental equipment, and tattooing and other skin-piercing instruments should be avoided to decrease the risk of HIV, hepatitis B, and hepatitis C. Hepatitis B is preventable by immunization. Travelers who visit areas without access to safe medical care may be supplied with kits containing gloves, alcohol swabs, needles, and syringes. Some have also considered obtaining blood donations if needed from fellow travelers or members of the expatriate community who have tested negative for HIV and hepatitis and who have no risk factors to suggest the likelihood of these pathogens.
- XI. Plans for emergency medical help.** Emergency medical care may be needed during travel. There are several travel health insurance companies that will help the traveler access emergency care, pay for that care, and arrange for air evacuation if medically indicated (travel.state.gov/medical.html). These companies may also provide baggage and trip cancellation protection. The availability of medical care in remote areas may be ascertained by inquiring at U.S. consulates or embassies or by visiting mission hospitals, which often are staffed by expatriates.

THE RETURNED TRAVELER

Fortunately, for most travelers serious illness is unusual, but some return with symptoms or develop them later. The experience of a group of nearly 800 returned U.S. travelers indicated the most common conditions were **diarrhea (13%), upper respiratory tract infections (10%), skin rash (3%), and fever (2%)** [180]. **Febrile illness warrants immediate attention because it may be due to malaria or another potentially life-threatening pathogen.**

When formulating a differential diagnosis, the health-care provider should consider the geographic location(s) visited, the traveler's activities, the frequency of specific diseases in the region(s), the incubation periods of potential pathogens, and the vaccines and other prophylactic measures that were used [191]. Many common bacterial and viral infections have short incubation periods and will develop abroad or within the first week or two of return. Diseases with longer incubation periods, such as giardiasis and amebiasis, viral hepatitis, malaria, and tuberculosis, may present weeks to months after a traveler's return. Travelers should be informed that an illness presenting after their return could be related to travel and requires medical evaluation. Persons who were ill during their trip or who lived for a prolonged period in a developing region should be evaluated after return [192,193].

The following presents an overview of common conditions in returned travelers. More detailed discussions and information about pathogens endemic to specific geographic regions should be consulted.

- I. Traveler's diarrhea.** Traveler's diarrhea is the most common illness among travelers and can begin abroad or after return [194]. Patients should be examined and stools tested for blood, fecal leukocytes, and fecal lactoferrin. Stool culture for enteropathogens is indicated if these screening tests are positive or if the patient presents with tenesmus, fever, or gross blood in the stool. Examination of stool for ova and parasites is typically reserved for those with persistent diarrhea lasting for 10 days to 2 weeks or longer or for those who have resided for a prolonged period in regions of poor sanitation. See related discussion earlier in this chapter, Table 22.2, and Chapter 13.
- A. Noninflammatory diarrhea.** The most frequently identified cause of traveler's diarrhea is enterotoxigenic *E. coli*. Enterotoxigenic *E. coli* has recently been shown

to be important pathogen. Fecal leukocytes and blood are absent with both, and the temperature is normal or only mildly elevated. Oral hydration with a mixture of water, glucose, buffer, and electrolytes is the most appropriate therapy and is often all that is necessary. Antibiotics and antimotility agents can shorten the duration of symptoms. Although uncommon among North American travelers, *V. cholerae* may present as rapidly dehydrating diarrhea that requires fluid and electrolyte replacement.

B. Bacterial dysentery. The presence of fever higher than 38°C, bloody stools, or tenesmus suggests inflammatory enterocolitis caused by bacterial pathogens such as *Shigella* species, *Campylobacter jejuni*, *Salmonella* species, *Yersinia enterocolitica*, or enteroinvasive *E. coli*. **Fecal leukocytes or lactoferrin are usually present in the stool.** Hydration is important, and treatment with an antibiotic, such as one of the fluoroquinolones in adults, frequently is administered pending the results of stool culture. Azithromycin can be used in children. It has also been used for travelers to areas in which *C. jejuni* is prevalent and possibly resistant to fluoroquinolones, such as Asia. Loperamide and other antimotility agents should not be used in travelers with inflammatory enterocolitis. (See related discussions in Chapter 13.) Enterohemorrhagic *E. coli*, such as O157:H7, are generally not seen among travelers, but the development of bloody diarrhea without fever raises this possibility. Neither antibiotics nor antimotility agents should be used in that setting, particularly in children [195].

C. Amebic colitis. Although not common among travelers, amebic colitis is a consideration in those presenting with dysentery. Gross or occult blood is typically found in the stool, but fecal leukocytes may be pyknotic or absent. Cysts or trophozoites of *E. histolytica* may be identified on stool examination: they are morphologically indistinguishable from those of *Entamoeba dispar*, a nonpathogen. The diagnosis of invasive amebiasis can be confirmed by identifying *E. histolytica* antigen in the stool, but not all commercial kits can differentiate between *E. histolytica* and *E. dispar* [196]. Metronidazole eradicates tissue trophozoites but should be followed with a luminal agent, such as paromomycin or iodoquinol, to eradicate cysts. Loperamide and other antimotility agents are contraindicated.

D. Prolonged diarrhea. Noninflammatory diarrhea lasting more than 10 days to 2 weeks raises the possibility of giardiasis, cryptosporidiosis, and other protozoan infections in addition to amebiasis. Stools should be examined for ova and parasites and stained for acid-fast organisms. Three stools, properly examined, will usually yield the diagnosis. Antigen testing for *Giardia* and *Cryptosporidium* is more sensitive than ova and parasite examination. Occasionally, empiric therapy for giardiasis is warranted after other etiologies have been excluded. Metronidazole is currently the drug of choice for giardiasis [197]. Trimethoprim-sulfamethoxazole is effective for cyclosporiasis [198]. There is currently no curative therapy for cryptosporidiosis, and illness in the immunocompetent host is self-limited (see Chapter 13).

II. Upper respiratory tract infections. Upper respiratory tract infections are the second most common illness among travelers. Although not carefully studied, **most are presumed to be viral in etiology.** They are managed symptomatically. Influenza should be considered in returned travelers with fever, myalgia, headache, coryza, and cough. Penicillin-resistant *S. pneumoniae* may be a problem and should be considered in those presenting with pneumonia. *Legionella* pneumonia has been acquired by travelers staying at resort hotels and taking journeys on cruise ships. It is related to water systems and whirlpool spas (see Chapters 8 and 11) [199].

III. Dermatitis. Travelers may suffer sun-related skin injuries, insect bites, drug reactions, or cutaneous infections due to bacteria *Staphylococcus aureus* and *Streptococcus pyogenes*, fungi, parasites, or other pathogens [179]. Cutaneous larva migrans follows skin contact with sand or soil contaminated with animal feces containing dog or cat hookworms (*Ancylostoma braziliensis*) or other nematodes. Furuncular myiasis may be confused with a staphylococcal furuncle. A small round breathing hole in the center of the lesion above the maggot is helpful in the diagnosis. Tungiasis is found on the feet and toenails. Cutaneous leishmaniasis presents as a chronic, nodular, or ulcerative skin lesion(s) that is not usually painful [200].

Systemic diseases can also present with cutaneous manifestations. The combination of rash and fever may indicate a potentially life-threatening disease and warrants immediate evaluation as discussed below. The differential diagnosis of rash in the returned traveler is extensive and is reviewed in detail elsewhere [179,201]. The risk of insect bites and vector-borne diseases can be reduced by the application of repellents to skin and clothing, the presence of window screens, and use of insecticide-impregnated bed nets.

IV. Fever. Fever in the returning traveler may be due to a life-threatening infection and is an indication for immediate evaluation. The differential diagnosis is broad and includes the following considerations [202].

A. Malaria. Malaria is the first consideration in a traveler returning from Africa or other malaria-endemic areas who develops fever.

The mortality of *P. falciparum* malaria among nonimmune Americans is 2% or less; death usually occurs in persons who have not taken any prophylaxis or have taken incorrect chemoprophylaxis and have experienced a delayed or missed diagnosis [120,121]. Symptoms of malaria can begin as early as a week after infection, but they may be delayed for months and occasionally years. Eighty-nine percent of *P. falciparum* cases occur in the first month after return, but 29% of *P. vivax* cases occur after more than 6 months [120]. Compliance with antimalarial chemoprophylaxis does not exclude the diagnosis.

1. The symptoms of malaria often are often systemic and nonspecific: fever, malaise, myalgia, and anorexia. They may be focal: headache, confusion, obtundation, seizures, chest pain, abdominal pain, diarrhea, or respiratory distress. Although a tertian (every 48 hours) or quartan (every 72 hours) pattern of fever points to the diagnosis of malaria, most nonimmune travelers have **hectic fever patterns** when evaluated. Splenomegaly may be present, but there are **no pathognomonic physical findings**.

2. The diagnosis of malaria is confirmed by identifying parasites in thick or thin blood smears; however, parasites may sometimes be sparse and therefore missed. **If no other diagnosis is apparent in a toxic-appearing febrile traveler, empiric treatment for malaria should be initiated.**

3. Therapy (Table 22.4) for chloroquine-resistant *P. falciparum* in persons who can safely be given **oral therapy** is quinine sulfate plus doxycycline, or if the presentation is uncomplicated, atovaquone/proguanil (Malarone) may be given [151,203,204]. Mefloquine can also be used but is frequently associated with side effects. Persons returning from areas with chloroquine-sensitive *P. falciparum* can be treated with chloroquine phosphate. In the United States, **parenteral quinine gluconate should be given to patients with severe *P. falciparum* infection (and severe infection with other species)** who cannot take medications orally [203,205]. Quinidine may not always be readily available for use, and hospitals should consider maintaining a supply or having a protocol for access of the drug [206].

P. vivax or *P. ovale* infections are treated orally with chloroquine. Quinine or mefloquine is used in areas where chloroquine-resistant *P. vivax* is prevalent (such as Indonesia and Papua). Treatment of *P. vivax* and *P. ovale* includes a terminal course of primaquine to eradicate hypnozoites in the liver. G6PD levels should be determined before using primaquine. Primaquine is contraindicated in pregnant women. Infectious disease consultation is advised for returning travelers with malaria. Other supportive measures are also required [205].

B. Typhoid fever. *S. typhi* is endemic throughout developing areas. In the United States 72% of cases of typhoid are international importations; highest risk destinations are the Indian subcontinent, Central and South America, the Philippines, Haiti, and Africa [61]. A progressive increase in fever over a period of days, malaise, headache, abdominal symptoms, a pulse-temperature deficit, Rose spots, and eventually hypotension suggest the diagnosis. Many *S. typhi* isolates are tetracycline, ampicillin, and sulfonamide resistant, so therapy with a quinolone or advanced spectrum cephalosporin is advisable (see Chapter 13).

C. Other bacterial infections. In addition to pneumonia, skin infections, and typhoid fever, a number of other bacteria can produce febrile syndromes in travelers.

Table 22.4. Treatment of Malaria^a

Drug	Adult Dose	Pediatric Dose
<i>P. vivax</i>, <i>P. ovale</i>, <i>P. malariae</i>, and chloroquine-susceptible <i>P. falciparum</i> Chloroquine	600 mg base (1,000 mg chloroquine phosphate) p.o. initially, followed by an additional 300 mg base (500 mg salt) 6 h later, and again at 24 and 48 h	10 mg base/kg p.o. initially (not to exceed 600 mg base) followed by an additional 5 mg base/kg 6 h later and at 24 and 48 h (total dose of 25 mg base/kg over 3 days)
Chloroquine-resistant <i>P. falciparum</i> Oral regimens		
Quinine sulfate plus Doxycycline ^b	650 mg q8h × 3–7 days 100 mg b.i.d. × 7 days	25 mg/kg/day in 3 divided doses × 3–7 days 2 mg/kg/day (max. 100 mg) × 7 days
<i>or</i> Quinine sulfate plus pyrimethamine-sulfadoxine (Fansidar)	Single dose of 3 tabs on the last day of quinine treatment	1–3 yr: 0.5 tablet 4–8 yr: 1 tablet 9–14 yr: 2 tablets
<i>or</i> Quinine sulfate plus clindamycin ^b	900 mg t.i.d. × 3–5 days	20–40 mg/kg/day in 3 divided doses × 3–5 days
<i>or</i> Atovaquone/proguanil (Malarone)	4 adult tabs (each 250 mg/100 mg) daily for 3 days	11–20 kg: 1 adult tablet (each 250 mg/100 mg) daily × 3 days 21–30 kg: 2 adult tabs daily for 3 days 31–40 kg: 3 adult tabs daily for 3 days >40 kg: 4 adult tabs daily for 3 days
<i>or</i> Mefloquine ^c	1,250 mg p.o. as a single dose	25 mg/kg p.o. as a single dose

Parenteral regimens (i.v.) (all species)

Quinidine gluconate^d

Same as adult dose

10 mg (salt)/kg loading dose (max 600 mg) in normal saline infused slowly over 1–2 h, followed by continuous infusion of 0.02 mg/kg/min until patient is able to begin oral treatment

Quinine dihydrochloride^{d,e}

Same as adult dose

20 mg (salt)/kg loading dose in 5% dextrose over 4 hr, followed by 10 mg/kg over 2–4 h q8h (max 1,800 mg/day) until patient is able to begin oral treatment

Prevention of relapse due to *P. vivax* or

P. ovale

Primaquine phosphate^f

15 mg base (26.3 mg phosphate salt) per day p.o. × 14 days

or

45 mg base (79 mg salt) per wk × 8 wk

^aFor help in managing patients with malaria, the CDC may be contacted at (770) 488-7788 (M–F, 8 a.m.–4:30 p.m. eastern standard time) or after hours at (404) 639-2888. ^bDoxycycline and clindamycin are typically begun after 2–3 days of treatment with quinine to ensure that side effects from quinine are not confused with those of doxycycline or clindamycin. Doxycycline should not be given to children <8 yr or pregnant women.

^cAt this dosage, severe side effects such as nausea, vomiting, diarrhea, dizziness, psychosis, and seizures may occur. Medical Letter suggests giving adult single dose as 750 mg followed 12 h later by 500 mg (see ref. below).

^dContinuous cardiac (EKG), blood pressure, and glucose monitoring is recommended. Parenteral quinidine may not be readily available and hospitals may need to contact their distributor; or Eli Lilly Company (800) 821-0538 for the drug.

^eQuinine dihydrochloride is not available in the United States.

^fG-6-PD testing should be done prior to prescribing primaquine phosphate.

Note: For a related reference see Medical Letter: Drugs for parasitic infections. *Med Lett Drug Ther* 2000;1–12.

http://www.medletter.com/html_files/publicreading.htm#Parasitic

Modified from Pearson RD, Weller PF, Thielman, et al. Chemotherapy of tropical infectious diseases. In: Guerrant RL, Walker DH, Weller PF, eds. *Essentials of tropical infectious diseases*. New York: Churchill Livingstone, 2001:613–637.

Leptospirosis is a risk for travelers with rural exposure to water in swamps and rivers. Brucellosis, tularemia, plague, and anthrax are rare in travelers but are potentially life-threatening [202].

D. Rickettsial diseases. Typhus, tick-typhus, and other rickettsial diseases may be acquired during travel [207]. Most are associated with a rash and, in some cases, an eschar at the site of inoculation, but the rash may develop relatively late in the course of infection. If a rickettsial disease is suspected, empiric therapy with doxycycline should be initiated.

E. Viral infections

1. Arthropod-borne viruses. Dengue, yellow fever, and other arthropod-borne viruses are endemic in tropical areas. **Yellow fever** poses a risk in equatorial Latin America and Sub-Saharan Africa. Fortunately, cases of yellow fever are rare among travelers due to the high degree of efficacy of the vaccine [29]. **Dengue**, in contrast, remains a risk, and there is no effective form of immunoprophylaxis [164,165]. The incubation period is short (maximum of 7–9 days), so a disease that begins more than a week after a traveler leaves the tropics is not likely to be dengue (see section III.A under Advice on Disease Prevention other than by Vaccination, above).

2. Hepatitis A, B, C, D, and E. Fever, nausea, vomiting, fatigue, malaise, and jaundice suggest the possibility of viral hepatitis. If the liver enzymes are elevated, serologic studies are indicated to make a specific diagnosis (see Chapter 14).

3. Measles, rubella, and varicella. The common childhood viral exanthemas must be considered in travelers with fever and rash. Measles has been acquired by young adult U.S. travelers who failed to develop immunity after a single childhood immunization. Rubella, mumps, and chickenpox may also be acquired abroad.

4. Viral hemorrhagic fevers. Fortunately, viral hemorrhagic fevers, such as Ebola or Marburg hemorrhagic fever, Lassa fever, Argentine or Bolivian hemorrhagic fever, Rift Valley fever, and Crimean-Congo hemorrhagic fever are rare in travelers. They must be considered in those with unexplained fever, prostration, multiorgan system involvement, and evidence of coagulopathy [208]. Barrier nursing techniques are essential in preventing the spread of these viruses to health-care workers. If a returning traveler has a syndrome suggestive of viral hemorrhagic fever, expert help should be sought, including consultation with the CDC [209].

5. Other viral diseases. Many other viruses can produce febrile diseases in returned travelers. Clinicians should consider infections endemic to the United States, such as Epstein-Barr virus and HIV, as well as viral infections that may be unique to areas visited.

F. Parasitic disease other than malaria. A number of parasitic diseases such as visceral leishmaniasis, Katayama fever (acute schistosomiasis), and Chagas disease must be considered in the differential diagnosis of fever in travelers who have had potential exposure in endemic area, but they are rare [202].

G. Noninfectious diseases. Drug fever should be considered in travelers who are taking antibiotics or other medications. Deep venous thrombosis with or without pulmonary emboli can occur in persons who have been seated for long periods of time.

V. Eosinophilia. The finding of eosinophilia (>500 total eosinophils) in a returned traveler suggests the possibility of a helminthic infection [210,211]. However, many persons will have increased eosinophil counts secondary to drug allergy or atopic conditions, so these conditions should be ruled out before extensive investigations are performed for parasites. **Worms that have an extensive tissue phase are the most common helminths that cause eosinophilia.** These include *Strongyloides stercoralis*, recent infestation with hookworms, *Schistosoma* species, visceral larva migrans (*Toxocara* species), *Trichinella spiralis*, and filaria. Appropriate studies can include three stools for ova and parasites, blood smears for filaria, serology, and skin or tissue biopsies. It may be necessary to repeat testing after 3 to 6 months because of the prolonged prepatent period of many helminths (such as hookworm) before production of ova or worms become clinically manifest. Eosinophilia is not observed in malaria and most other protozoan diseases.

APPENDIX

Suggested Readings, Resources, and Websites for Health-Care Providers

Who Advise Travelers

- I. **Centers for Disease Control and Prevention.** *Health information for international travel, 2001–2002.* Atlanta, GA: U.S. Department of Health and Human Services, 2001.
This publication is for sale by the Public Health Foundation (877-252-1200, or online ordering at bookstore.phf.org). It may be downloaded as a pdf file at the CDC travel website (www.cdc.gov/travel/reference.htm). It lists countries that require yellow fever vaccine, provides the epidemiology of malaria in endemic countries and recommends chemoprophylactic regimens, and discusses diseases (including detailed recommendations on vaccine-preventable disease) that present risks to travelers. **This is an essential reference for advising travelers.**
- II. **Centers for Disease Control and Prevention website:** www.cdc.gov/travel/
This website provides the information found in *Health Information for International Travel, 2001–2002*, including health recommendations based on destination and reports of recent infectious disease outbreaks around the world. **It is revised frequently. This is an essential source to access when advising travelers.**
- III. **Centers for Disease Control and Prevention. Summary of health information for international travel.** Atlanta: U.S. Department of Health and Human Services, Public Health Service. www.cdc.gov/travel/blusheet.htm
Known as the **blue sheet**, this biweekly publication lists countries and areas within those countries (for yellow fever) that are reporting yellow fever, cholera, and plague. This publication is used in conjunction with *Health Information for International Travel* to determine whether yellow fever vaccine should be given.
- IV. **International Certificate of Vaccination** (PHS-731). Superintendent of Documents, U.S. Public Health Service. Washington, DC: U.S. Government Printing Office.
This booklet is used to record required immunizations (currently only yellow fever), other immunizations, and personal medical history. Yellow fever vaccine must be validated by a stamp issued by state health departments.
- V. **Morbidity and Mortality Weekly Report (MMWR)** www.cdc.gov/mmwr/
This CDC publication periodically reports official changes in vaccination requirements and disease outbreaks and is another source of information. Individual subscriptions are available by writing Massachusetts Medical Society, P.O. Box 9120, Waltham, MA 02454-9120.
- VI. **World Health Organization. International Travel and Health. Vaccination Requirements and Health Advice.** Geneva: World Health Organization, 2001. www.who.org
The World Health Organization's version of *Health Information for International Travel*. Available from WHO Distribution and Sales, Geneva. (41 22) 791-2476, e-mail: publications@who.ch.
- VII. **Other resources.** A number of excellent textbooks and reviews of travel and tropical medicine exist [10,212–214]. The *Journal of Travel Medicine* is devoted to issues pertinent to travelers (Decker Periodicals, 800-568-7281, www.istm.org/jtm.html). Several Internet and computer-based resources are available for travel medicine practitioners that provide ready access to information on outbreaks of travel-related disease and information on the likelihood of acquiring diseases in specific locations. These are reviewed by Keystone et al. [215].

23. IMMUNIZATIONS

Paul J. Edelson

Prophylactic immunization is an essential part of primary care at all ages [1,2]. Although childhood immunization remains the primary control strategy for most preventable diseases, major programs for adult immunization have been developed and vaccination recommendations have now been formulated to address the needs of specialized subgroups. New vaccines, adoption of the National Childhood Vaccine Injury Act [3], and changing epidemiologic patterns of disease have affected our practice responsibilities for immunization of both child and adult patients. New approaches have already led to significant improvement in the seroprevalence levels for varicella and hepatitis B in preschoolers [4]. Immunization levels for adults, however, are still inadequate [5]. Recommendations for modern approaches to immunization programs have been published [6–8]. There are a number of reliable sources for current immunization recommendations: reports of the U.S. Advisory Committee on Immunization Practices (ACIP) of the U.S. Public Health Service are published in *Morbidity and Mortality Weekly Reports*, issued by the Centers for Disease Control and Prevention (CDC). This valuable publication, available via the CDC Internet site, is regularly extracted in the *Journal of the American Medical Association*. Specific ACIP recommendations are also available from the CDC National Immunization Program Office and many state health departments. A convenient source of current ACIP recommendations, as well as other immunization resources, is the Immunization Action Coalition's website (www.immunize.org/adultrules). Similar recommendations of the Canadian expert group are published in the *Canadian Medical Association Journal*. Recommendations of other expert panels are collected in the *Report of the Committee on Infectious Diseases* (the so-called Red Book) [9] for infants and children and in the *Guide to Adult Immunization* (the so-called Green Book) [10] for adults. Excellent summaries of current recommendations for immunization of the adult patient in general have been published [11,12]. Recommendations for specific groups of adults are provided below (see section VI). Recent authoritative surveys of the entire field are also available [13–16]. These recommendations are appropriate for use only in the United States because epidemiologic circumstances and vaccines may differ in other countries. Advice regarding immunization for travel abroad can be found in Chapter 22.

I. General principles [16]

A. Immunobiologics. This term refers to all biological materials involved in the artificial production of a specific immune state, including the following.

- 1. Vaccine.** A suspension of live (usually attenuated) or killed microbial organisms, or portions of them, that can be used to induce immunity and prevent infectious disease when injected, inhaled, or ingested. Vaccines may have differing levels of purity. A list of currently licensed vaccines for general use is provided in Table 23.1.
- 2. Toxoid.** A modified microbial toxin that still retains its antigenic specificity and can be used to stimulate immunity to the relevant toxin.
- 3. Immune globulin (IG)** is prepared from large plasma pools by ethanol fractionation (the Cohn method) and was previously designated *immune serum globulin* or *gamma globulin*. It **contains specified amounts of antibody against measles, diphtheria, and poliovirus type 1**. In addition, IG contains **variable amounts of antibody against hepatitis A and B viruses, varicella virus, respiratory syncytial viruses**, and possibly some non-A, non-B hepatitis viruses. IG is not specifically designated as safe for intravenous use and **should be used only intramuscularly**. IG has never been associated with the transmission of human immunodeficiency virus (HIV), although some lots prepared before 1985 have passively transferred transient HIV seropositivity. Although the Cohn procedure has been shown to inactivate HIV, since 1985 all IG used in the United States must be prepared from HIV-seronegative blood.
- 4. Intravenous immune globulin (IVIG).** A fraction of blood plasma is prepared from a large donor pool, similar to that used for IG, but treated for **intravenous**

Table 23.1. Major Types of Vaccines

Live attenuated virus
Measles
Mumps
Parainfluenza virus ^a
Poliovirus (oral)
Respiratory syncytial virus ^a
Rubella
Varicella
Yellow fever
Live attenuated bacteria
Bacillus Calmette-Guérin (BCG)
Tularemia
Typhoid (oral)
Inactivated virus
Hepatitis A
Hepatitis B
Human papillomavirus ^a
Influenza
Poliovirus (subcutaneous)
Rabies
Inactivated bacteria
Anthrax
Cholera
Diphtheria (toxoid)
Gonococcus ^a
<i>Haemophilus influenzae</i> type b (polysaccharide-protein conjugate)
Lyme disease
Meningococcus (polysaccharide)
Pertussis (acellular)
Pertussis (inactivated whole bacteria)
Plague
Pneumococcus (polysaccharide)
Pneumococcus (polysaccharide-protein conjugate)
Tetanus (toxoid)
Typhoid (subcutaneous)
Inactivated rickettsiae
Q fever (<i>Coxiella burnetii</i>)

^aUnder development.

administration. Its use is generally similar to that of IG, but larger amounts can be administered than via the intramuscular route.

- 5. Specific IG.** Special preparations of IGs containing high-titered antibody to specific infectious agents. They are prepared from plasma pools obtained from immunized donors or from individuals recovering from recent disease or by laboratory techniques that produce monoclonal antibodies of animal or human type, including so-called humanized animal antibodies. Human IGs are much less likely to provoke serious hypersensitivity reactions than are IGs derived from animals, which they have generally replaced. Like IG, these preparations are for **intramuscular** injection only unless specifically labeled for intravenous use. Specific IGs currently available for clinical use include hepatitis B IG, varicella-zoster IG, rabies IG, tetanus IG, and vaccinia IG. Recommendations for the use of both specific and pooled IGs have been published [17]. Adverse effects of the administration of IGs have also been reviewed [18].

- 6. Antitoxin.** Antibody prepared in animals that provide passive immunity to specific microbial toxins, such as diphtheria or botulinum antitoxin.
- B. Active immunization** involves the use of immunogens, such as live attenuated virus, inactivated virus, isolated viral proteins, bacterial components, or inactivated toxins (toxoids), to stimulate a protective antibody or cell-mediated immune response, or both (Table 23.1).
- 1. Live attenuated virus vaccines** generally stimulate greater and more durable immunity than do inactivated virus vaccines. The live attenuated vaccines, however, have greater inherent risks and are not appropriate for use in all individuals.
 - a. Live attenuated preparations include measles, mumps, rubella, oral poliovirus, varicella, and yellow fever vaccines.**
 - b. Limitations.** Except under special circumstances, **live attenuated vaccines should not be administered to patients with** congenital or acquired immunodeficiency; leukemia, lymphoma, or generalized malignancy; or to patients receiving immunosuppressive therapy or, in certain cases, to members of their households, because these attenuated agents may cause disease in the impaired host or may be spread after administration in immunocompromised individuals to susceptible hosts. In addition, because these agents present a theoretic risk to the developing fetus, live attenuated virus vaccines are not generally recommended for use in pregnant women or those likely to become pregnant within 3 months after immunization. For special recommendations concerning the use of live attenuated measles or trivalent measles-mumps-rubella (MMR) vaccine in children with HIV infection see section III.A.4.h.
 - 2. Inactivated virus or purified viral components** are used to produce **influenza** and **hepatitis B** vaccines. Because an inactivated virus is used, the limitations in section 1.b may not apply to these vaccines. For example, if poliomyelitis immunization is indicated for immunosuppressed patients, their household contacts, or other close contacts, the (enhanced) inactivated poliovirus vaccine (e-IPV) can safely replace the live attenuated vaccine, as discussed in section III.D.3.
 - 3. Inactivated bacterial vaccines** include the currently available **pertussis**, **typhoid** (parenteral), and **cholera** vaccines. Bacterial-component immunogens may not produce lifelong immunity and may therefore require booster doses at appropriate intervals to ensure adequate and long-lasting protection.
 - 4. Toxoids. Diphtheria** and **tetanus** vaccines are inactivated toxins, referred to as toxoids.
- C. Passive immunization** is produced by the administration of **IG, IVIG, or specific IG**. All these preparations contain specific protective antibodies derived from human plasma.
- 1.** This form of immunization **provides immediate protection** but is of very limited duration and is most useful for time-limited prophylaxis. It may be given up to 3 weeks before or up to 72 hours after specific disease exposure. For the clinical use of specific human IGs, refer to the following:
 - a. Varicella-zoster virus:** see Chapter 4 under Mucocutaneous Vesicles
 - b. Tetanus:** see Chapter 4 under Tetanus
 - c. Rabies:** see Chapter 4 under Bite Wounds and Rabies Prevention
 - d. Hepatitis B:** see section IV.A
 - 2. Animal-derived IGs. Except for treatment of snake and spider bites or in the treatment of diphtheria, animal sera are no longer recommended for human use.** In the past, tetanus and rabies antisera were derived from immunized animals. These were far more likely than human products to cause serum sickness or anaphylaxis.
- D. Passive and active immunizations** are sometimes combined to provide both immediate protection (with preformed antibody) and sustained protection (antigenic stimulation of host immune response). As a rule, each agent is injected at a separate site.

1. For postexposure **rabies** prophylaxis, for example, human rabies IG (passive) is combined with human diploid cell rabies vaccine (active).
 2. For postexposure **tetanus** prophylaxis in the previously nonimmunized individual, human tetanus IG (passive) is combined with tetanus toxoid (active). Note, however, that in this situation **only the alum-precipitated or adsorbed toxoid, and not the fluid toxoid, should be used** (see section **V.E**).
 3. Similar active-passive immunization is used in the prophylaxis of neonates born to mothers who are hepatitis B carriers (see section **IV.A**).
 4. **Immunoglobulin should never be administered to modify the normal and expected reaction to a live attenuated virus vaccine**, as was previously done with the Edmonston-strain measles vaccine.
- E. Simultaneous administration of vaccines.** Studies have shown that it is safe and, in most instances, effective to administer multiple vaccines simultaneously [16]. This is often more convenient for individuals who require a number of different immunizations. When several vaccines are being administered at the same time, the vaccines should not be combined in the same syringe or administered at the same site. **Only prepackaged combination vaccines should be administered at a single site.** However, the antibody **response of both cholera and yellow fever vaccines may be decreased if given simultaneously** or within a short time of each other. If possible, cholera and yellow fever vaccinations should be separated by at least 3 weeks (see Chapter 22).
1. **Live attenuated virus vaccines** were previously administered 1 month apart, but studies have shown that simultaneous administration of some live virus vaccines (e.g., MMR) is just as effective as single injections and does not result in higher rates of adverse reactions.
 2. **Inactivated vaccines** can be administered simultaneously at separate sites. When vaccines commonly associated with local or systemic side effects (e.g., cholera, parenteral typhoid, or plague) are given simultaneously, side effects could be accentuated. For patients with a history of a reaction to one or more vaccines, it is prudent to administer each on a separate occasion.
 3. **An inactivated and a live attenuated vaccine** can be given simultaneously.
 4. **Inactivated bacterial and viral vaccines** can be given simultaneously. An example is the simultaneous administration of influenza and pneumococcal vaccines.
- F. Contraindications and adverse reactions** [19]. The manufacturer's guidelines and recommendations, as contained in the U.S. Food and Drug Administration approved package insert, should be followed carefully.
1. **Hypersensitivity reactions**
 - a. **Some vaccine antigens, particularly measles, mumps, influenza, and yellow fever, are derived from embryonated chicken eggs or embryonic chick cells.** In general, **if patients can eat a whole egg, these vaccines can be safely administered.** Protocols have been developed for immunization of the highly egg-allergic patient [20].
 - b. **Anaphylactic antibiotic reactions.** Some vaccines contain trace amounts of antibiotics. In patients with a history of anaphylactic reactions to specific antibiotics, the current package insert should be carefully reviewed to ascertain whether the antibiotic of concern is in the vaccine. If the vaccine does contain the antibiotic, the vaccine should be avoided. No current vaccines contain penicillin or penicillin derivatives. The history of a minor local contact dermatitis from prior neomycin use is not a contraindication to any vaccine containing neomycin.
 2. **Altered immunity.** Live attenuated virus vaccines may cause serious disease in some immunocompromised individuals. In general, these vaccines should not be used in such patients. Measles vaccine, however, has been recommended for use in certain individuals infected with HIV (see section **III.A.4.h**). **Live attenuated poliovirus vaccines should not be administered to any household member of an immunocompromised person** (see section **VI.F**).
 3. **Severe febrile illness.** Minor illness, such as a mild upper respiratory infection, should not preclude immunization. Vaccination of patients with severe

febrile illnesses should be deferred so that side effects of the vaccine do not complicate the existing illness and so that symptoms of the illness are not incorrectly ascribed to the vaccine.

4. **Pregnancy.** Because **live attenuated virus vaccines pose a theoretic risk to the developing fetus**, these vaccines generally should not be given to a pregnant woman or to a woman likely to become pregnant within 3 months of immunization. Concerns and risks of immunization during pregnancy are further addressed in section **VI.B**.
5. **Recent administration of IG.** Passively acquired antibody (e.g., IG) **may interfere with the response to live attenuated virus vaccines. Administration of such vaccines should be individualized based on specific recommendations** [16].
 - a. **Oral polio vaccine (OPV), yellow fever, and oral typhoid vaccine (Ty21a)** vaccines may be administered without regard to the administration of immune or specific globulins.
 - b. Although it has previously been stated that MMR or any of its component vaccines may be administered as early as 6 weeks to 3 months after a dose of IG, high-titer IGs or IGs administered in large doses may interfere with measles immunization even beyond 3 months and can also inhibit the response to rubella vaccine. Effects on mumps or varicella response are unknown, but standard preparations do contain antibody to each of these agents. Blood products, except *washed* packed red cells, also contain significant amounts of antibody; precautions regarding immunization should apply to recipients of blood products. In general, live antigen vaccines, other than those in section **a**, should be delayed proportionately to the dose of antibody previously administered. When possible, IG should be delayed at least 2 weeks after the administration of live antigen vaccines.
 - c. Most bacterial or inactivated viral vaccines may be administered with IG for specific postexposure prophylaxis (see section **I.D**).

II. Immunization schedules

- A. **Pediatric immunization schedules.** The details of these schedules are published in the serial editions of the **Red Book** [10] and **updated reports** of the Committee on Infectious Diseases in Pediatrics, and in recommendations made by the ACIP as published in *Morbidity and Mortality Weekly Reports*. Schedules are typically updated and issued twice yearly.

A working group of federal and state experts, medical specialty organizations, and vaccine manufacturers has promulgated a **single scientifically valid immunization program, summarized in Table 23.2**. This was intended in part to help resolve variations in prior recommendations. Important recommendations of the working group include the following:

1. The third dose of OPV should be administered routinely at 6 months of age; vaccination at as late as 18 months remains an acceptable alternative.
 2. The first dose of MMR vaccine is suggested at 12 to 15 months of age. The second dose of MMR can be administered at either 4 to 6 or 11 to 12 years of age.
 3. Universal hepatitis B vaccination of infants was recommended in 1991.
 - a. For infants whose mothers are hepatitis B surface antigen (HBsAg) negative, routine hepatitis B vaccination series should begin at birth, with the second dose administered at 2 months of age (see acceptable ranges in Table 23.2). The third dose should be administered at 6 to 18 months.
 - b. For infants of HBsAg-positive mothers, the infant should receive the first dose of vaccine at birth (along with hepatitis B immune globulin [HBIG]), the second dose at 1 month of age, and the third dose at 6 months (see related discussion in Chapter 3).
 4. The schedule for diphtheria-tetanus-pertussis (DTP) vaccination in force for several years is still recommended (Table 23.2).
- B. **Adult immunizations.** The indications for adult immunizations are reviewed in the discussions of individual vaccines below (see sections **III-V**) and in Table 23.3 and in related discussion in Chapter 22. False contraindications sometimes applied to various vaccines have been reviewed by the CDC [19]. Regarding a hypothesized

Table 23.2. Recommended Childhood Immunization Schedule^a—United States

Vaccine	Age										
	Birth	1 mo	2 mo	4 mo	6 mo	12 mo	15 mo	18 mo	4–6 yr	11–12 yr	14–16 yr
Hepatitis B ^b	Hep B-1				Hep B-3					Hep B ^c	
Diphtheria and tetanus toxoids and pertussis vaccine ^d			DTP	DTP	DTP	DTP (DTaP at ≥15 mo)			DTP or DTaP		
<i>Haemophilus influenzae</i> type b ^e			Hib	Hib	Hib	Hib					
Poliovirus ^f			OPV	OPV	OPV				OPV		
Measles-mumps-rubella ^g						MMR			MMR or	MMR	
Varicella zoster virus ^h							Var			Var ⁱ	

Note: Boxed information indicates range of acceptable ages for vaccination.

^aVaccines are listed under the routinely recommended ages. Recommendations of the ACIP are generally updated every 6 months.

^b**Infants born to hepatitis B surface antigen (HBsAg)-negative mothers** should receive 2.5 µg of Recombivax HB (Merck) or 10 µg of Engerix-B (SmithKline Beecham). The second dose should be administered ≥1 month after the first dose. **Infants born to HBsAg-positive mothers** should receive 0.5 mL hepatitis B immune globulin (HBIG) within 12 h of birth and either 5 µg of Recombivax HB or 10 µg of Engerix-B at a separate site. The second dose is recommended at age 1–2 months and the third dose at age 6 months. **Infants born to mothers whose HBsAg status is unknown** should receive either 5 µg of Recombivax HB or 10 µg of Engerix-B within 12 hours of birth. The second dose of vaccine is recommended at age 1 month and the third dose at age 6 months.

^cAdolescents who have not received three doses of hepatitis B vaccine should initiate or complete the series at ages 11–12 years. The second dose should be administered at least 1 month after the first dose, and the third dose should be administered at least 4 months after the first dose and at least 2 months after the second dose.

^dThe fourth dose of diphtheria and tetanus toxoids and pertussis vaccine (DTP) may be administered at age 12 months, if at least 6 months have elapsed since the third dose of DTP. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) is licensed for the fourth and/or fifth dose(s) for children aged ≥15 months and may be preferred for these doses in this age group. Tetanus and diphtheria toxoids, adsorbed, for adult use (Td) is recommended at ages 11–12 years if at least 5 years have elapsed since the last dose of DTP DTaP, or diphtheria and tetanus toxoids, adsorbed, for pediatric use (DT).

^eThree *Haemophilus influenzae* type b (Hib) conjugate vaccines are licensed for infant use. If PedvaxHIB (Merck) *Haemophilus b* conjugate vaccine (meningococcal protein conjugate) (PRP-OMP) is administered at ages 2 and 4 months, a dose at 6 months is not required. After completing the primary series, any Hib conjugate vaccine may be used as a booster.

^fOral poliovirus vaccine (OPV) is recommended for routine infant vaccination. Inactivated poliovirus vaccine (IPV) is recommended for persons or household contacts of persons—with a congenital or acquired immune deficiency disease or an altered immune status resulting from disease or immunosuppressive therapy, and is an acceptable alternative for other persons. The primary three-dose series for IPV should be given with a minimum interval of 4 weeks between the first and second doses and 6 months between the second and third doses.

^gThe second dose of measles-mumps-rubella vaccine (MMR) is routinely recommended at age 4–6 years or at age 11–12 years but may be administered at any visit provided at least 1 month has elapsed since receipt of the first dose.

^hVaricella-zoster virus vaccine (Var) can be administered to susceptible children any time after age 12 months.

ⁱ“Catch-up” vaccination (see also footnote c). Unvaccinated children who lack a reliable history of chickenpox should be vaccinated at age 11–12 years.

Modified from Advisory Committee on Immunization Practices, American Academy of Pediatrics, and American Academy of Family Physicians. *MMWR Morb Mortal Wkly Rev* 1996; 44:942–943.

Table 23.3. Vaccines to Be Considered for Adult Patient Groups^a

Patient Group	Major Vaccines ^b	Other Considerations ^c
Healthy adults		
Adolescents and young adults	Td, MMR up to date, hepatitis B, meningococcal vaccine, completion of childhood immunizations	Varicella (see text)
25–64 yr	Td, rubella (women only), polio	Varicella (see text)
65 yr and older	Td, influenza, pneumococcal	
Pregnant women	MMR is contraindicated; test for rubella antibody and hepatitis B surface antigen	
Those in environmental situations		
Nursing home residents	Influenza, pneumococcal	Tuberculin test
Institutionalized mentally retarded	Hepatitis B	Hepatitis A
Prison inmates	Hepatitis B, rubella	Hepatitis A
Homeless persons	Review all vaccines; consider pneumococcal vaccine	Tuberculin test
Occupational groups		
College students	MMR; consider hepatitis B, polio, influenza	
Health-care workers	Hepatitis B, influenza, MMR	Varicella
Essential community services	Influenza	
Daycare center personnel	MMR, polio, influenza	Hepatitis A, hepatitis B
Laboratory personnel	Hepatitis B	Consider individually
Veterinarians, animal handlers, rural workers, and other field personnel	Rabies	Plague, anthrax
Immigrants and refugees	Review all vaccines, test for hepatitis B surface antigen	Tuberculin test
Those with life-style risks		
Homosexual and bisexual men	Hepatitis B, hepatitis A	
Intravenous drug abusers	Hepatitis B, Td, hepatitis A	
Prostitutes, persons with multiple sexual partners or sexually transmitted diseases	Hepatitis B	Hepatitis A (see Chapter 14)
Accident victims		
Wounds	Td	TIG
Animal bites	Td	Rabies vaccine, RIG
Snake and spider bites	Td	Specific antivenins
Immunocompromised		
HIV infection and AIDS	Pneumococcal conjugate, hepatitis B	IG (measles), VZIG, measles, varicella
Splenic disorders	Pneumococcal conjugate, influenza	<i>Haemophilus influenzae</i> type b, meningococcal
Diabetes	Pneumococcal, influenza	
Renal failure and dialysis	Pneumococcal, influenza, hepatitis B	

(Continued)

Table 23.3. (Continued)

Patient Group	Major Vaccines ^b	Other Considerations ^c
Alcoholism, cirrhosis	Pneumococcal, influenza	Hepatitis B vaccine
Organ transplant recipients, immunosuppressive therapy	Pneumococcal, influenza	<i>Haemophilus influenzae</i> type b, meningococcal
Those with malignant diseases	Consider individually	
International travel groups	Review Td, MMR, polio; consider influenza, pneumococcal, hepatitis B	Yellow fever, IG or hepatitis A, meningococcal, typhoid, cholera, rabies, Japanese encephalitis, antimalarial prophylaxis (see Chapter 22)

^aSee text for specific details on indications, administration, adverse reactions, precautions, contraindications, and special considerations for each vaccine, toxoid, and immunoglobulin preparation. Also see reference 10.

^bMajor vaccines include combined tetanus and diphtheria (Td) toxoids; measles-mumps-rubella (MMR) vaccine; oral polio vaccine and enhanced-potency inactivated polio vaccine; influenza vaccine; pneumococcal vaccine; and hepatitis B vaccine.

^cOther considerations include immunoglobulin (IG), tetanus immunoglobulin (TIG), rabies immunoglobulin (RIG), varicella-zoster immunoglobulin (VZIG), and intravenous immunoglobulin (IVIG).

Modified from ACP Task Force on Adult Immunization and Infectious Diseases Society of America. *Guide to adult immunization*, 3rd ed. Philadelphia: American College of Physicians, 1994. See also Gardner P, et al. Adult immunizations. *Ann Intern Med* 1996;124:35-40.

association between vaccines and **multiple sclerosis**, two recent studies have concluded that routine immunizations, including influenza vaccine, have no effect on the risk of short-term relapse [21] and offer no support for a relationship between hepatitis B immunization and the disease [22].

C. Requirements of the National Childhood Vaccine Injury Act of 1988. This act, which provides for certain indemnifications for vaccine-related injuries, imposes specific record-keeping and reporting obligations on individuals who administer vaccines. Requirements of most relevance to adult vaccinees apply to the administration of tetanus and diphtheria toxoids, tetanus toxoid, and both OPV and IPV. As of March 21, 1988, **physicians and others providing these vaccines are required to maintain immunization records specifying for each recipient** the date of administration; manufacturer and lot number of the vaccine; and the name, address, and title of the person administering the vaccine. In addition, the law specifies a list of reportable events occurring within specified times after vaccine administration and the names of authorities to whom reports must be made. (Additional details are presented in Appendices 9 and 10 of the Green Book [11].)

III. Live attenuated virus vaccines

A. Measles (rubeola) [22] can be a severe disease, with pulmonary, gastrointestinal, and neurologic complications. Encephalitis occurs in approximately 1 of every 1,000 reported cases, and survivors may suffer permanent neurologic impairment or mental retardation. Death occurs in 1 to 2 of every 1,000 cases. Measles during pregnancy increases the risks of spontaneous abortion, premature labor, and low birth weight. Birth defects have been reported in infants exposed to measles virus in their first trimester, but the defects comprise no definable pattern of malformation and measles has not been confirmed as the cause of any of these malformations. Because maternal fever in the first trimester may itself be embryopathic, it is possible that the abnormalities are not the result of a specific malformation syndrome

but rather represent a nonspecific result of maternal fever. Subacute sclerosing panencephalitis is also considered to be a rare but devastating complication of natural infection with measles virus. In countries where there is a significant degree of infantile and early childhood malnutrition or in the setting of large numbers of displaced persons or forced population migrations, measles is a significant cause of childhood deaths. Before measles vaccine became available in 1963, more than 400,000 measles cases were reported annually in the United States, and it is estimated that only 10% of cases were reported. Since then, reported cases (including imported cases representing overseas exposures) have fallen by 100- to 1,000-fold, and a national goal of measles eradication has been set by the U.S. Public Health Service. There has also been a striking decline in the incidence of subacute sclerosing panencephalitis.

The currently available measles vaccine, the measles eradication program, and recommendations for measles outbreak control have been reviewed by the CDC [23].

- 1. Measles elimination efforts in the United States.** The adoption in 1993 of a national program to eliminate measles from the United States, involving the use of a two-dose regimen of immunizations, has markedly improved immunization rates, particularly in preschoolers, adolescents, and young adults. The transmission of indigenous measles appears to have been interrupted for the first time in this country. Further progress in eliminating measles will depend on the continuing effort to immunize all children between 12 and 15 months of age and to ensure that all children receive a second dose of vaccine before they enter school, as well as cooperating with other national governments to eliminate measles abroad.

a. Preschoolers

- (1) **Continued compliance** with recommended measles vaccination programs for young children is essential.
- (2) **Two-dose measles vaccine schedule.** To reduce the number of primary vaccine failure-related cases of measles, the ACIP recommends a routine two-dose measles vaccine schedule. The initial dose is administered at 12 to 15 months of age, whereas the second dose is recommended at school entry (4–6 years of age). The second dose may be administered at any visit after the first birthday, until age 12, provided at least 1 month has elapsed since receipt of the first dose. Children can be vaccinated initially as early as 6 to 9 months of age in an actual outbreak of measles and then reimmunized at 12 months and boosted before beginning school (Table 23.2). MMR is recommended for both doses.

- b. Young adults** (high school and college age). Many educational institutions have already adopted requirements intended to prevent measles outbreaks among individuals who may have been immunized before their first birthdays or received vaccine before 1980 or who for other reasons were among the 2% of persons estimated to be primary vaccine failures. In such people, a second dose of vaccine is generally successful. State-mandated prematriculation immunization guidelines for measles has been effective in reducing the incidence of measles outbreaks in colleges [24,25].

- (1) Evidence of measles immunity (i.e., prior diagnosis by a physician or laboratory evidence) must be provided by matriculating students born in or after 1957.
- (2) Documentation of two doses of live measles vaccine, with the second dose after 1980, must be provided. If this has not been done already, a dose of measles vaccine should be given before school begins to ensure adequate immunity.
- (3) In an outbreak of measles, all persons at risk (e.g., students attending schools where measles has occurred who have not been adequately vaccinated) should be vaccinated (see sections 1 and 2).
- (4) **Although MMR has been considered appropriate for revaccinating college-age students, because of the increased incidence of**

Table 23.4. Current Recommendations for Measles Vaccination

Routine Childhood Schedule, United States	
Primary immunization	Two doses ^{a,b} First dose at 12–15 mo Second dose at 4–6 yr (entry to kindergarten or first grade) ^d
Colleges and other educational institutions after high school	Documentation of receipt of two doses of measles vaccine after the first birthday ^b or other evidence of measles immunity ^c
Medical personnel beginning employment	Documentation of receipt of two doses of measles vaccine after the first birthday ^b or other evidence of measles immunity

^aBoth doses should preferably be given as combined measles-mumps-rubella vaccine (MMR).

^bNo less than 1 month apart. If there is no documentation of any dose of vaccine, vaccine should be given at the time of school entry or employment and no less than 1 month later.

^cA county with more than five cases among preschool-aged children during each of the last 5 years, a county with a recent outbreak among unvaccinated preschool-aged children, or a county with a large inner-city urban population. These recommendations may be applied to an entire county or to identified risk areas within a county.

^dSome areas may elect to administer the second dose at an older age or to multiple age groups.

arthritic reactions seen in young adults after revaccination with rubella vaccine, **it may be prudent to revaccinate with measles vaccine alone if rubella immune status is not a concern** (see section 5 and Table 23.4). Arthritis and arthralgias are known adverse effects of rubella vaccine in nonimmune vaccinees. They occur in approximately 12% to 20% of adults and 0% to 3% of children and have an intermediate incidence in adolescents. Neither MMR nor measles vaccine is recommended in pregnancy.

2. **Vaccine.** The current live attenuated measles vaccine, prepared in chick embryo cell cultures, is less reactogenic than its predecessor, the Edmonston B strain. In addition, stabilizers added in 1980 seem to have improved the storage characteristics of the vaccine. The current vaccine produces a mild or inapparent noncommunicable infection, with antibody developing in over 95% of susceptible recipients vaccinated at 15 months of age or older. Both monovalent (measles only) and combination (i.e., measles and rubella and MMR) forms of the vaccine are available.
3. **Persons can be considered immune to measles if one of the following conditions is met:**
 - a. **Born before 1957.** These individuals are likely to have been infected naturally and are considered immune.
 - b. **Documentation of physician-diagnosed measles.** A clinical case definition includes a generalized maculopapular rash of 3 days' duration or longer (often appearing first at the hairline, forehead, and behind the ears and upper neck, then spreading downward to involve the face and neck and then the trunk and upper extremities); fever of at least 101°F orally; **and** cough, coryza, or conjunctivitis. A *confirmed* case has seropositivity or meets the preceding definition and is epidemiologically linked to a known case or outbreak of measles. A *suspected* case meets the preceding definition (but rash can be of less than 3 days' duration) but has no serologic confirmation or epidemiologic link. Serologic confirmation involves either a positive IgM test or a fourfold rise from acute to convalescent specimens in complement fixation testing without a history of recent vaccination.
 - c. **Documented laboratory evidence of measles immunity.** The enzyme immunoassay and enzyme-linked immunosorbent assay (ELISA) currently used for measles immunity are more sensitive than the hemagglutination

inhibition test, which was the former standard. Demonstration of antibody by any of these tests is sufficient to document immunity. All new cases suspected of being measles should be confirmed by laboratory testing. Routine serologic screening to determine measles immunity is not recommended, except possibly for health-care workers. (See section 10 and Chapter 26 on employee health.)

- d. **Adequate immunization with live measles vaccine at or after 15 months of age.** The maximal rate of seroconversion after measles vaccine occurs at 15 months of age or later. An adequate two-dose measles vaccination schedule in children or a booster dose in young adults is advised (see section 2).
 - e. **During an outbreak,** proof of immunity is documentation of receipt of two doses of measles vaccine or MMR, both administered after the individual's first birthday and after 1980 and not administered with IG unless the Edmonston strain is known to have been used.
4. **Persons needing measles vaccine** (Table 23.4)
 - a. **Susceptible children older than 15 months, adolescents, and adults** should be vaccinated if there are no contraindications. Also, persons who did not receive two doses of the measles vaccine after their first birthday should be vaccinated (see section 2).
 - b. **Those vaccinated with live measles virus before 12 months of age** should be identified and revaccinated.
 - c. **Those immunized with the inactivated (killed) measles vaccine in use from 1963 to 1967** (or to 1969 in Canada) are at risk for developing **atypical measles** when exposed to natural infection. This disease may have significant morbidity in adults and has been reviewed in detail elsewhere [26]. Patients may have conjunctivitis and a characteristic erythematous maculopapular rash progressing to vesicular, petechial, or purpuric lesions. The rash initially involves the palms and soles, with subsequent spread to the proximal extremities and trunk, sparing the face. Pulmonary involvement with significant hypoxemia is common. Although recipients of the killed vaccine may have an increased risk of adverse reaction when revaccinated with the live vaccine, these risks are minor compared with the severity of atypical measles developing after infection with wild-type virus.
 - d. **Young adults** (secondary school or college age) **who have not had measles vaccine since 1980** require revaccination (see section 2).
 - e. **Persons who received IG at the time of measles vaccination** should be revaccinated. Although immunization with the Edmonston B strain vaccine probably was effective even when administered with IG, the use of IG with other vaccines, including the current one, could render the dose ineffective. All individuals in whom IG was used in combination with a vaccine other than the Edmonston B strain or in whom the vaccine type is not known should be reimmunized.
 - f. **Susceptible persons exposed to measles** may benefit from vaccination if the vaccine is given within 72 hours of measles exposure.
 - g. **Travelers to high-risk areas** may require vaccination. Measles continues to be endemic throughout many parts of Asia, Africa, and Central and South America. Nonimmune visitors run the risk of acquiring measles and of exposing others on their return. **Travelers born after 1956 who are planning trips to these areas should have their measles immune status reviewed** (see section 2). Although serologic screening is not routinely recommended, it may be useful in evaluating prospective travelers. If the traveler has prior immunity, there is no evidence of enhanced risk from receiving the live attenuated measles vaccine. For infants traveling to measles-endemic areas, vaccination is recommended as early as 6 months of age, with a second measles immunization at age 15 months and a third dose at school entry. For further discussion see Chapter 22.
 - h. **Persons with HIV infection** may be at special risk for measles complications. Because of several reports of severe or fatal cases of measles in

children with HIV infection [27], it has been recommended that measles vaccine is administered to all such children, regardless of the stage of their HIV disease. However, newer draft recommendations of the CDC advise that MMR not be given to severely immunosuppressed (category 3) children [27].

- 5. The dosage** is the same for children and adults: a subcutaneous dose of properly stored vaccine in the 0.5-ml volume recommended by the manufacturer. The trivalent MMR form is the vaccine of choice for routine childhood immunization. **IG should not be administered with the measles vaccine or, ideally, sooner than 3 months before measles vaccine or 2 weeks after** (see Chapter 22).

6. Precautions and contraindications

- a. Pregnancy.** Live measles vaccine should not be administered to women who are pregnant. Also, women should avoid becoming pregnant for 3 months after vaccination. Although there is no clinical experience of harm to the developing fetus, there is a theoretic risk of such harm. Pregnant women exposed to natural measles infection may wish to consider the use of IG within 6 days of the exposure.
- b. Allergies.** Because the live attenuated virus vaccine is prepared in chick embryo cells, patients with a history of **egg allergy** associated with anaphylactic reaction should be vaccinated only with extreme caution. Herman et al. [20] devised a protocol for immunizing such individuals. There is no evidence that persons with other allergies to chicken or to feathers are at increased risk of reaction to the vaccine.

The vaccine contains trace amounts of **neomycin**. Therefore, persons who have experienced anaphylactic reactions to topical or systemic neomycin also should not receive this vaccine. See related discussion in section **I. F.**

- c. Febrile illness, recent use of IG, and states of altered immunity** are discussed in section **I. F.**

- 7. Side effects.** The currently available measles vaccine is a further attenuated preparation of the Enders-Edmonston virus. It causes fewer adverse reactions than the Edmonston B or other vaccine strains and has an excellent safety record. Side effects include **fever** (beginning approximately the sixth day after inoculation and lasting up to 5 days) in 5% to 15% of recipients, **transient rashes** in approximately 5% of recipients, and **encephalitis** occurring approximately once in every million doses administered. It is estimated that severe illness or death is more than 1,000 times more likely to occur in a person who acquires the disease naturally than in one who becomes ill as a result of vaccination. **There is no association of autism with the receipt of MMR vaccine** [28].

- 8. Revaccination.** Two doses of vaccine are recommended for full immunity. No additional doses are recommended for persons already immune. There is, however, no evidence that revaccination of an immune individual carries an enhanced risk.

- 9. IG is effective in preventing or modifying measles in a susceptible normal host exposed within the preceding 6 days.** The dose used is 0.25 ml/kg intramuscularly, with a maximum dose of 15 ml. **The common intramuscular IG preparation should never be administered intravenously.** IG may be particularly indicated for susceptible household contacts of measles patients, especially contacts younger than 1 year, or for susceptible pregnant women. If not contraindicated, live attenuated virus vaccine should be administered again after the child's first birthday. Whether IG is protective in patients with impaired immunity is unclear. A report from CDC details experience using IG in exposed patients with HIV infection [27].

- 10. Nosocomial measles** can occur, and inadequately vaccinated medical personnel are sometimes the vectors [29].

- B. Mumps** is principally a disease of school-aged children, but approximately 15% of cases occur in adolescents or adults. It is usually self-limited without long-term

sequelae, but deafness, which may be profound, is a rare complication. Although orchitis may occur in up to 20% of cases in postpubertal male patients, sterility is very rare. Naturally acquired mumps infection, including the estimated 30% of cases that occur subclinically, confers durable immunity [30]. There is no evidence that mumps during pregnancy causes congenital malformations. In recent years, there has been an increased occurrence of mumps in susceptible adolescents and young adults, with several outbreaks in high schools, colleges, and occupational settings. This is due to the relative underimmunization of children born between 1967 and 1977, when the mumps vaccine was not used routinely.

1. Mumps live virus vaccine, introduced in 1967, produces a subclinical noncommunicable infection with very few side effects. The live attenuated vaccine is prepared from chick embryo cell cultures and induces antibodies in more than 95% of recipients. Studies over the 35 years since the vaccine was introduced have shown that vaccine-stimulated immunity is long lasting, but its precise duration is unclear. Mumps vaccine is available in both a monovalent form (mumps only) and in combination (e.g., measles, mumps, and rubella). The MMR vaccine is the vaccine of choice for routine administration and should be used in all situations where there are no contraindications and recipients are also likely to be susceptible to measles or rubella [23]. There is no evidence that persons who have previously had mumps or received mumps vaccine are at any increased risk of local or systemic reactions to live mumps vaccine.
2. **Persons can be considered immune to mumps** if one of the following conditions is met:
 - a. **Born before 1957.** Those born before 1957 are likely to have been infected naturally.
 - b. **Documentation of physician-diagnosed mumps.**
 - c. **Documented laboratory evidence of mumps immunity.** Reliable serologic studies (neutralization, complement fixation, ELISA, or radial hemolysis antibody tests) are not readily available. The mumps skin test does not predict immunity reliably. Routine susceptibility testing before vaccination is unnecessary. Persons who are immune from prior infection or immunization are not at an increased risk for reaction if they receive live mumps virus vaccine.
 - d. **Documentation of adequate immunization** with live mumps virus vaccine when 12 months old or older.
3. **Vaccination is indicated for any susceptible person older than 12 months.** Susceptible children, adolescents, and adults should be vaccinated against mumps unless vaccination is contraindicated. Mumps vaccine is of particular value for children approaching puberty, especially adolescent and young adult men who have not had mumps and have not previously been immunized. It should be recognized, however, that the most serious consequence of mumps infection—deafness—may occur in either gender and at any age.
4. **Dosage.** Two doses of vaccine in the volume specified by the manufacturer should be administered subcutaneously. It should not be administered to infants younger than 12 months because persisting maternal antibodies may interfere with seroconversion.
5. **Side effects.** The mumps vaccine is very well tolerated. Rarely, parotitis and allergic reactions (transient rashes and pruritus) have been reported. Very infrequently, febrile seizures or encephalitis occurring within 30 days of immunization have been reported, but an etiologic relationship between these events and prior vaccination has not been established.
6. **Precautions and contraindications**
 - a. **Pregnancy.** The precautions in pregnancy are the same as for measles (see section III.A.6.a).
 - b. **Allergies.** The vaccine is produced in chick embryo culture (see discussion in section I.F). Because vaccines contain traces of **neomycin**, the vaccine should be avoided if the patient has a history of anaphylaxis to neomycin. A history of contact dermatitis to neomycin is not a contraindication to receiving mumps vaccine.

- c. **Prior IG administration and immunodeficiency** (see section **I.F**). An exception to these general recommendations relates to children infected with HIV. All HIV-infected children who are not severely immunosuppressed (those in class 3) should receive MMR at 15 months of age (see section **III.A.4.h**). For other groups see section **4.h** above.
- d. **Febrile illness** (see section **I.F.3**).
- 7. **International travel** (see Chapter 22).
- 8. **Mumps control** measures are reviewed elsewhere [30].
- 9. **Nosocomial mumps** can occur rarely and is, at least in part, preventable [30].
- C. **Rubella** is a common childhood disease with nonspecific signs and symptoms, including postauricular and suboccipital adenopathy, low-grade fever, and a transient erythematous rash [31]. **Because of the nonspecific nature of this infection, a history of rubella illness is not a reliable indicator of immunity. Assessment of immune status is based on the presence of demonstrable antibody.**
 - 1. **Background.** The goal of rubella immunization is unique: the prevention of the congenital rubella syndrome rather than prevention of rubella infections per se. The most important consequences of rubella are fetal anomalies resulting from rubella infection early in pregnancy, particularly early in the first trimester (see Chapter 3). School and infant vaccination programs have reduced the overall incidence of rubella in the United States more than 1,000-fold, but cases continue to occur among nonimmunized adolescents and young adults. **Outbreaks have been reported from schools, colleges, the military, office buildings, prisons, hospitals,** and other institutions in which large numbers of young adults live or work. Therefore, a combined approach to vaccinating both infants and susceptible adolescents and young adults has been recommended.
 - 2. **Live rubella vaccine** is prepared in human diploid cell culture. Since 1979, the available vaccine has been based on the RA 27/3 virus strain. With a single dose, approximately 95% of recipients develop antibody that provides lifelong protection.
 - 3. **Susceptibility status** is determined by serologic studies. Hemagglutination inhibition antibody usually is used to screen for rubella immunity. Other screening tests include passive hemagglutination, hemolysis in gel, and ELISA tests. **Any detectable titer,** whether from natural infection or immunization and no matter how low, **protects against subsequent viremic infection** (i.e., the type of infection that may affect the fetus). The ACIP suggests that revaccination of persons with low levels of rubella hemagglutination inhibition antibody is unnecessary. Rather, attention should be directed toward vaccinating the truly susceptible population.
Routinely performing serologic tests in all women of childbearing age to determine susceptibility is expensive and has been ineffective in some areas. Therefore, the ACIP recommends that rubella vaccination should be given, without prior serologic testing, to all women who are not pregnant, who have been counseled to avoid pregnancy for the subsequent 3 months, and who have no history of vaccination [31].
 - 4. **Indications for vaccination**
 - a. **All children older than 12 months.** These individuals should be vaccinated to protect against rubella and to prevent spread of the virus to susceptible women.
 - b. **Susceptible** prepubertal, adolescent, and adult **women of childbearing age.**
 - c. **Susceptible hospital employees. Both male and female employees should be vaccinated because any infected employee may transmit rubella to pregnant patients.**
 - d. **All susceptible military recruits, applicants to educational and training institutions, and prisoners.**
 - 5. **Risks to the pregnant patient.** Because of the theoretic risk of this live virus vaccine to the fetus, women of childbearing age should receive this vaccine only

if they are not pregnant and are counseled to avoid pregnancy for 3 months after vaccination. However, all available data indicate that teratogenicity from live rubella vaccines has not occurred. The CDC has followed more than 200 known rubella-susceptible pregnant women who were vaccinated within 3 months before or 3 months after conception [32]. None of the babies had malformations consistent with congenital rubella infection. Therefore, the ACIP states that inadvertent rubella vaccination just before or in early pregnancy should not be a reason to recommend routine interruption of pregnancy. Vaccinating susceptible children whose mother or other household member is pregnant poses no risk to the pregnant woman.

6. **Side effects** include occasional rash and lymphadenopathy in children. Arthralgia of the small joints may occur in up to 40% of those vaccinated, but frank arthritis occurs in fewer than 1%. These symptoms are more common in adults and usually occur 7 to 21 days after immunization and persist for 1 to 3 days. The risk of these reactions is no greater if persons already immune are vaccinated.

7. Contraindications

- a. **Pregnancy** (see section 5). As of April 1989, the CDC discontinued accepting new enrollees into the Vaccine in Pregnancy registry. However, any suspected case of congenital rubella syndrome, whether presumed to be due to wild-type or vaccine virus infection, should continue to be reported through state and local health departments.
- b. **Immunocompromised hosts.** Because live attenuated vaccine strains may cause disease in immunocompromised patients, such patients **should not receive this live virus vaccine** (see section I.F.2).
- c. **Severe allergy to neomycin.** This vaccine contains trace amounts of neomycin; persons who have experienced anaphylactic reactions to neomycin should not receive rubella vaccine.

- D. **Poliomyelitis** has been nearly eliminated in the United States since the introduction of poliovirus vaccines in 1955 because of the widespread use of live attenuated OPV first developed by Sabin. However, with the licensure of an e-IPV, the ACIP now recommends the use of inactivated vaccine, either alone or followed by subsequent oral doses [33], as the principal primary immunization strategy. **The routine immunization of persons over the age of 18 years is not recommended, even if they have never been fully immunized.** When polio immunization is appropriate in the adult, e-IPV is recommended. In addition to a greater reliance on IPV, the number of doses necessary for primary immunization has also been modified (see section 2).

1. **Indications for vaccination.** Routine primary immunization of adults (generally those 18 years old or older) in the United States is not necessary. Most adults are immune because of prior immunization or prior wild-type poliovirus infection. In addition, the cessation of circulation of wild-type virus in the 1960s and the small number of cases of poliomyelitis that currently occur in this country make the risk of exposure to wild-type virus very small. **Major emphasis on primary poliovirus vaccinations in the United States is aimed at children.** Certain adults at special risk are also candidates for primary or booster vaccination (see section 4).
2. The IPV has been used extensively since 1955 and is given subcutaneously. The original inactivated vaccine has been superseded by a new enhanced-potency vaccine released in March 1988 [34,35]. Primary vaccination of children with three doses of the e-IPV resulted in immunity to all three poliovirus types in more than 99% of recipients, and early results of long-term follow-up studies suggest that the durability of immunity following e-IPV will be excellent [36].
 - a. **Indications.** In the United States, e-IPV has been used routinely to **vaccinate immunodeficient patients and their household contacts and adults requiring primary immunization.** This vaccine can also be used as a booster dose in adults planning international travel to developing countries (see Chapter 22). In addition, **e-IPV is now the recommended vaccine for the routine primary immunization of healthy infants and children.**

- b. **Risks and side effects.** No paralytic reactions to IPV have occurred with recent preparations. In 1955, a cluster of poliomyelitis cases occurred after use of an IPV preparation containing live poliovirus that had escaped inactivation.
 - c. **Allergic history.** This preparation contains trace amounts of streptomycin and neomycin; **individuals with a history of anaphylactic reactions to systemic or topical streptomycin or neomycin should not receive this vaccine.**
 - d. **Administration.** Primary vaccination consists of three doses given subcutaneously in the volume recommended by the manufacturer. The first two doses are given at a 4- to 8-week interval, and the third dose should follow the second in 6 to 12 months. Most commonly, the first dose is administered at 2 months of age, the second at 4 months, and the third at 12 to 18 months. All children who received all three primary doses of vaccine before 4 years of age should receive a fourth dose before or at school entry. A fourth dose is not necessary if the third dose is received after the fourth birthday.
- 3. **OPV.** Available since 1963, this **live attenuated (Sabin) vaccine**, containing all three poliovirus strains, provides long-lasting immunity in over 95% of recipients after a three-dose primary immunization sequence.
 - a. **Indications. For primary immunization of normal infants and young children,** e-IPV is now the preferred vaccine for routine immunization in the United States. Full immunization may be accomplished with e-IPV or, as an interim strategy, with two doses of e-IPV followed by two doses of OPV. Although it carries the highest risk for vaccine-associated cases of paralytic polio, immunization can also be accomplished solely with OPV. Because OPV interferes with the subsequent infection of the pharynx and gastrointestinal tract by wild-type virus, it may be the vaccine of choice for vaccination campaigns undertaken to control an ongoing polio epidemic.
 - b. **Risks and contraindications of live attenuated poliovirus vaccines.** OPV has rarely been associated with the development of paralytic poliomyelitis in a vaccine recipient or close contact (1 in approximately 3.2 million doses distributed). This risk is increased in immunocompromised individuals (e.g., those with a primary immunodeficiency [see section I.F] or who are receiving immunosuppressive agents) and in adults.
 - (1) **Only e-IPV should be used in immunocompromised hosts or for household contacts of such patients.** If OPV is inadvertently administered to a household contact of an immunodeficient individual, close contact between the two should be avoided for approximately 1 month after vaccination. The family member and the immunosuppressed individual in particular must be carefully counseled to avoid exposure to fecal-oral contamination, essentially by practicing good personal hygiene (i.e., enteric precautions).
 - (2) **Healthy adults requiring primary vaccination may also be at increased risk of vaccine-associated paralysis after OPV. Thus, for primary immunization at all ages and for all health statuses, the inactivated form of the poliovirus vaccine (e-IPV) should be used.**
 - (3) **Pregnancy.** Because there is a theoretic risk to the fetus, vaccination of pregnant women should be avoided. In special circumstances, however, if the risk of exposure to natural infection is substantial and immediate protection is needed (e.g., for the young pregnant woman traveling to a country with endemic poliomyelitis), the risk of poliovirus exposure outweighs the theoretic risk of the vaccine. Either OPV or IPV may be used, although IPV might be preferred on theoretical grounds.
 - (4) Although the risk of vaccine-associated paralysis is extremely rare with OPV (an estimated one case in 5.5 million doses of vaccine in healthy adults), recipients should be informed of this risk.

4. Vaccination of adults. Routine vaccination of those older than 18 years of age is not indicated (see section 1).

a. These adults are at special risk and warrant vaccination:

- (1) **Travelers** to areas of countries where poliomyelitis is endemic or epidemic (see Chapter 22);
- (2) **Laboratory workers** handling specimens that may contain poliovirus;
- (3) **Medical workers** in close contact with patients who may be excreting poliovirus, including those who administer live virus vaccine;
- (4) **Members of communities or specific population groups** with a high prevalence of natural disease, such as Amish and Hutterite communities.

b. Regimens. A full series of IPV is generally recommended for adults without prior primary vaccination. For details of vaccination schedules, see section 2.d. For adults who have completed primary immunization with OPV, a booster OPV dose (or e-IPV) may be given. If adults have completed the primary series with IPV, either e-IPV or OPV may be used for the booster dose. In general, e-IPV is preferred for all uses in adults.

E. Varicella. Live attenuated varicella vaccine (Varivax, Merck, West Point, PA) has been used routinely in the United States since 1995, but experience in this country predates that in studies of children who are immunocompromised [36] and in healthy children [37] and adults [38]. The vaccine has been generally well tolerated in all groups, although mild chickenpox developed in 7% of healthy children and up to one-third of children who had received chemotherapy [39]. In the latter group, children with rash may transmit the virus. In immunocompromised children, a significant number of vaccinees subsequently developed natural infection, although no severe cases were reported. The risk of varicella-zoster infection after vaccine appears to be comparable with that reported by Lawrence et al. [40] or lower than that after natural infection.

In addition to its routine use in infants 12 months of age or older who have not had varicella [41], the vaccine has also been recommended for use in susceptible adolescents and young adults [42] to prevent the serious complications of adult varicella [43] and varicella during pregnancy [44]. Adult immunization may also be useful in controlling disease in hospitals [45].

Before introduction of the vaccine, nearly 100% of persons brought up in the continental United States were varicella immune. Although serious or life-threatening complications occurred at a very low rate, given the large numbers of infected individuals the incidence of serious varicella infections was striking. It is estimated that varicella accounted for about 9,300 hospital admissions annually, and in 1973 through 1979 there were 106 deaths due to varicella [46]. Complications are generally more severe in people 15 years of age or older; pregnant women are particularly susceptible to severe complications themselves and to the occurrence of the congenital varicella syndrome in their fetuses. Two other syndromes have been particularly associated with clinical varicella in childhood: **Reye syndrome** and **severe invasive group A streptococcal disease**.

1. Recommendations for vaccine use have been reviewed in detail elsewhere [47].

- a. Ages 12 to 18 months.** One subcutaneous dose is recommended for universal immunization for all healthy children who lack a reliable history of varicella.
- b. Ages 18 months to 13 years.** One dose is recommended for children who have not been immunized previously and who lack a reliable history of varicella infection.
- c. Healthy adolescents and young adults.** Healthy adolescents older than 13 years who have not been immunized previously and have no history of varicella infection should be immunized by administration of two doses of vaccine 4 to 8 weeks apart. **A two-dose regimen is necessary for adults because of their diminished responsiveness to the vaccine** [38]. One recent report suggests that higher serum titers of antibody are

achieved when the second dose is given at an 8-week rather than a 4-week interval.

- d. Adults.** In healthy individuals older than 18 years who have no history of varicella, **performing serologic tests** before vaccination **is optional** but can be cost effective in that 71% to 93% of adults born in the continental United States who have no history of varicella nevertheless are immune to infection. Persons who grew up in tropical regions, such as the Caribbean, and who have no history of clinical disease appear less likely to be varicella immune. **For adults with negative serology** for varicella, vaccine should be considered in the following:
- (1) Health-care workers.
 - (2) Susceptible family and/or close contacts of immunocompromised hosts.
 - (3) Those adults whose occupations place them at risk for exposure (e.g., teachers and day-care workers).
 - (4) Persons living in conditions where spread of varicella infection is likely, including college students, military personnel, and inmates of correctional facilities.
 - (5) Nonpregnant women of childbearing age who anticipate future pregnancies.
 - (6) Persons planning routine international travel (e.g., non-health-care providers), particularly if they anticipate close personal contact with local populations.
 - (7) The use of varicella vaccine has been proposed in older Americans to improve their levels of specific cell-mediated immunity and in this way to control their increased risk for zoster attacks. No recommendations currently exist for using the vaccine in this way, but a recent review by Raeder and Hayney [48] examined this issue and relevant studies.
 - (8) Other persons may also consider immunization following discussion with their personal physicians.
- e.** Use of the varicella vaccine for **postexposure prophylaxis** is not currently recommended because no data using the currently licensed vaccine in this situation are available. However, in two controlled studies using an earlier vaccine formulation, protective efficacy of more than 90% was demonstrated when immunization was accomplished within 72 hours of exposure.

2. Contraindications and cautions [47]

- a.** Varicella vaccine **should not be given to immunodeficient patients** or to patients who have received **high doses of systemic corticosteroids** (>2 mg/kg/day of prednisone or equivalent) for at least the 2 preceding weeks. Testing for antibody should be done at 6 weeks postvaccination; children who have not seroconverted should be reimmunized. Children receiving higher doses of steroids can be vaccinated if they have not received steroids for 3 months, as is recommended for all live virus vaccines, but 1 month is probably sufficient. Some experts recommend withholding steroids for 2 to 3 weeks after immunization. The vaccine is probably safe for children using only inhaled steroids (see section **e**).

Vaccine is not generally recommended for persons with HIV infection, but a draft of more recent CDC recommendations for persons with HIV infections does recommend varicella vaccine for asymptomatic nonimmunosuppressed children (**category 1**) [47].

- b.** Varicella should not be administered to **pregnant women** because the possible effects on fetal development are unknown. When postpubertal females are immunized, pregnancy should be avoided for 1 month after immunization.
- c.** Varicella vaccine should not be administered to individuals who have had an **anaphylactic reaction to neomycin** because trace amounts of neomycin are in the vaccine. A contact dermatitis history to neomycin is not a contraindication.

- d. The vaccine manufacturer recommends that **salicylates are not administered for 6 weeks** after the varicella vaccine has been given because of the association between Reye syndrome, natural varicella, and salicylates.
 - e. Under special circumstances, vaccine may be appropriate under a special protocol in patients with acute lymphocytic leukemia in remission at least 1 year (see reference 47 for details).
 - f. **Households with potential immunocompromised contacts.** ACIP advises that there is no need to withhold varicella vaccine from persons living in the same household with immunocompromised individuals. Transmission of vaccine type varicella-zoster virus from healthy individuals has been infrequently (if at all) documented. Thus, even in families with immunocompromised individuals, including those with HIV infection, no special precautions are recommended after vaccination of healthy children (and presumably adults) who do not develop a rash. Vaccinees who develop a rash (up to 7%–8% of recipients) should avoid contact with immunocompromised susceptible hosts for the duration of the rash. If contact inadvertently occurs, the use of varicella-zoster immunoglobulin is not currently recommended. Transmission is rare, and if disease develops, it is mild and presumably treatable with acyclovir.
3. Doses are given subcutaneously. The **cost** of the varicella vaccine to physicians is \$39 per dose; the cost of serum antibody testing to varicella is about \$70 but will vary depending on the laboratory used.

F. Rabies. See Chapter 4 under Bite Wounds and Rabies Prevention, and Chapter 22, section IV under Vaccinations.

G. Yellow fever (see Chapter 22)

IV. Inactivated virus vaccines

A. Hepatitis B

1. **Hepatitis B vaccine** [49]. All hepatitis B virus (HBV) vaccines currently available in the United States are recombinant DNA derived. Heptavax, a human plasma-derived vaccine, is no longer produced in the United States.
 - a. **Vaccines** currently available are as follows:
 - (1) Recombivax HB (Merck) is produced by common baker's yeast into which a plasmid containing the gene for HBsAg has been inserted. Heptavax B and Recombivax are equally effective, and approximately 90% of healthy adults will develop protective antibody.
 - (2) Engerix-B (SmithKline Beecham) is a recombinant DNA derived vaccine. Studies show it is as effective as the Recombivax HB vaccine.
 - (3) Twinrix is a combination hepatitis A and B vaccine [50]. Seroresponses are excellent after at least two doses; after a single dose, protection against hepatitis B may be limited. The vaccine is approved for use in children.
 - b. **Dosages of vaccines.** Hepatitis B vaccines are packaged to contain 10 to 40 μg HBsAg protein/ml. The currently recommended dosage schedules are shown in Table 23.5. Primary vaccination consists of three intramuscular doses, with the second and third doses given at 1 and 6 months after the first, respectively. For more rapid protection, an accelerated regimen has been effective [51] for certain high-risk groups (e.g., those with needlestick exposures, certain travelers, infants born of infected mothers) with standard doses of Engerix-B given at 0, 1, 2, and 12 months. Other accelerated regimens have undergone preliminary investigation and may be useful in some international travelers [52]. If routine dose schedules are interrupted, alternative dose regimens are available [49].
 - c. **Antibody response.** Antibody response is higher when the HBV vaccine is given in the arm (deltoid muscle) than in the buttock (gluteal muscle). Therefore, the arm should be used as the site of injection in adults (unless it may jeopardize shunt access in the hemodialysis patient). For infants born to mothers who are HBV carriers, the preferred site for vaccination remains the anterolateral thigh.

Table 23.5. Recommended Doses and Schedules of Currently Licensed Hepatitis B Vaccines

Group	Recombivax HB ^a Dose		Engerix-B ^{a,b} Dose	
	μg	mL	μg	mL
Infants of HBV-carrier mothers	5	0.5	10	0.5
Other infants and children <11 yr	2.5	0.25	10	0.5
Children and adolescents 11–19 yr	5	0.5	20	1.0
Adults >19 yr	10	1.0	20	1.0
Dialysis patients and other immunocompromised persons	40	1.0 ^c	40	2.0 ^{d,e}

^aUsual schedule: three doses at 0, 1, and 6 months.

^bAlternative schedule: four doses at 0, 1, 2, and 12 months.

^cSpecial formulation for dialysis patients.

^dTwo 1.0 mL doses given at different sites.

^eFour-dose schedule recommended at 0, 1, 2, and 6 months.

Centers for Disease Control. Hepatitis B virus. Recommendations of the Immunization Practices Advisory Committee. *MMWR Morb Mortal Wkly Rep* 1991;40(RR-13):5.

2. Preexposure HBV immunization is now recommended for routine use in all newborn infants in the United States [53]. The total hospital cost of the three adult doses of vaccine in the United States is approximately \$55 to \$65. Currently, 90.3% of children from 19 to 36 months of age have received a full series of three injections [4]. Preexposure HBV vaccine **also is recommended** for the following groups:

- a. Persons with occupational risk.** Hepatitis B is a major infectious risk for health-care workers and public-safety workers. Any workers who may be exposed to percutaneous or permucosal contacts with blood or blood products should be immunized. Other workers may also need immunization, based on their occupational responsibilities. Because health-care workers may be exposed to significant risks while still in training, immunization is recommended while workers are still students.
- b. Clients and staff of institutions for the developmentally disabled.** The risks for hepatitis B transmission include not only blood exposures but also bites and contact with skin lesions or other infective secretions. **Susceptible clients and staff** who work directly with clients who are hepatitis B carriers in residential settings should be immunized. **Clients discharged to community programs** should be tested for HBsAg to allow for planning to prevent transmission to others. **Staff of nonresidential day-care facilities** working with persons who are hepatitis B carriers have a risk of infection comparable with that of health-care workers and therefore should also be immunized. **Clients in such programs** have a lower risk of infection, but immunization may be considered for them as well. Immunization of **classroom contacts of HBV carriers** is strongly encouraged if the carrier displays aggressive behavior or has other medical problems that increase risk of exposure to blood or serous secretions.
- c. Hemodialysis patients.** Hepatitis B vaccination is recommended for all susceptible hemodialysis patients, even though seroconversion rates are lower than for healthy persons. Immunization early in the course of renal disease may be more effective than waiting until renal function has deteriorated to require dialysis.
- d. Sexually active homosexual men.** Sexually active homosexual men should be immunized regardless of age or duration of homosexual activity. Persons who are HIV positive should be tested for an anti-HBs response and counseled accordingly.

- e. **Users of nonmedical injectable drugs.** All susceptible persons who engage in drug injection should be immunized as early in their use of drugs as possible.
 - f. **Recipients of certain blood products.** Persons with clotting disorders who require transfusion of clotting factor concentrates should be immunized at the time their disorder is first identified. Those who have already received multiple transfusions of these products should be screened for antibody before immunization.
 - g. **Household and sexual contacts of HBV carriers.** Household contacts are at high risk; sexual contacts are at the greatest risk for infection. When HBV carriers are identified through routine screening programs, they should be notified of their status. All household and sexual contacts should be tested and susceptibles should be immunized.
 - h. **Adoptees from countries where HBV is highly endemic.** Orphans or unaccompanied minors from countries of high or intermediate endemicity for HBV should be screened for HBsAg. Those who are seronegative should be immunized, and those who are seropositive should be presumed carriers; members of their adopting households should be immunized.
 - i. **Populations in which HBV is highly endemic.** Certain U.S. populations, including Alaskan Natives and Pacific Islanders, are highly likely to be or to have been infected during childhood. They should have universal HBV immunization in childhood. "Catch up" immunization schedules should be considered if resources permit.
 - j. **Refugees and immigrants** from areas of high HBV endemicity, particularly Africa, East Asia, and the Pacific Islands, should be screened for HBsAg at the time of resettlement in the United States. Even if no HBV carriers are identified, consideration should be given to immunization of susceptibles below age 7 because of the high rates of interfamilial spread of HBV infection in this group. All infants born to women who are from areas of high endemicity should be immunized as part of the program of universal newborn HBV immunization.
 - k. **Inmates of long-term correctional institutions.** Prison environments may be favorable settings for HBV transmission because of injection drug use or male homosexual behavior. In addition, this setting represents an opportunity to immunize injection drug users. The ACIP recommends that prison officials consider screening and immunization programs for inmates with histories of high-risk behavior.
 - l. **Sexually active heterosexuals.** Risk for HBV increases with the number of sexual partners. Persons recently diagnosed with a sexually transmitted disease other than HBV, sex workers, and persons who have a history of sexual activity with multiple partners in the preceding 6 months should be immunized.
 - m. **Other contacts of HBV carriers.** Persons in casual contact with known or possible HBV carriers in settings such as schools or offices are at minimal risk of infection and do not require immunization on these grounds alone. Transmission of HBV in child-care centers has been documented only rarely. Unless special behavioral (aggressive behavior) or medical (such as dermatologic conditions) are present, contacts of carriers do not require immunization.
 - n. **International travelers.** Recommendations for HBV prophylaxis for international travelers can be found in Chapter 22.
- 3. Responses to hepatitis B vaccine**
- a. **Booster doses** of vaccine are not routinely recommended nor is routine serologic testing to assess antibody levels. However, previously vaccinated persons who experience percutaneous or needle exposure to HBsAg-positive blood should be tested for antibody level. If the antibody level is lower than 10 mIU/ml, two booster doses at 1-month intervals may be useful. Hemodialysis patients should be tested semiannually and may require booster doses. At least one expert group has recommended that all immunocompromised

patients should be regularly tested for anti-HBs antibodies and that they be revaccinated when the titer falls below 10 mIU/ml [54].

b. Nonresponders. Why some adults do not respond to the conventional hepatitis B immunization series is only partially understood. Older age, smoking, and obesity seem to be related to decreased responsiveness to hepatitis B vaccine. Determination of whether real differences exist between antibody response to the two currently available vaccines awaits further prospective studies. The optimal approach to the nonresponder is unclear [55]. Giving two booster doses at 1-month intervals appears to result in an adequate response in only a minority of recipients (see section **b**). Other innovative protocols have been suggested for nonresponders [56].

4. Postexposure prophylaxis of HBV infection should be exercised in the following situations: accidental percutaneous or permucosal exposure to HBsAg-positive blood, sexual exposure to an HBsAg-positive person, or perinatal exposure of an infant born to an HBsAg-positive mother (see Chapter 3 for details). Recent recommendations include the use of both HBIG (single dose) and the HBV vaccine in persons known or suspected to be negative for anti-HBs. This affords an immediate passive immunity combined with long-lasting active immunization. The cost of combined therapy is lower compared with that of previous recommendations, which called for two HBIG immunizations at a total hospital cost of approximately \$300 to \$350 for an average-sized adult. In addition, HBIG alone is only approximately 75% effective.

For details of postexposure prophylaxis, see Table 23.6 and the ACIP recommendations. If HBIG is not immediately available, IG should be used. The latter contains low-level anti-HBs and, although not as efficacious as HBIG, is probably better than no therapy.

5. Prevacination serologic screening for susceptibility. Carriers of HBV and persons having antibody from previous infection do not need to be vaccinated. Serologic screening to detect such individuals before vaccination may or may not be cost effective in a given setting. An approach to the variables involved in screening are discussed elsewhere [57]. The vaccine is well tolerated in carriers or those with protective antibody so that these patients are not at excess risk of side effects if they receive the vaccine in the absence of screening.

B. IPV is discussed in section **III.D**.

C. Influenza (see Chapter 10)

D. Rabies. See Chapter 4 under Bite Wounds and Rabies Prevention and Chapter 22, section **IV** under Vaccinations.

V. Bacterial vaccines. Certain of these vaccines are discussed elsewhere. Only recent developments in vaccines and vaccine regimens are discussed here.

A. Pneumococcal vaccine (see Chapter 11). In case-control studies the pneumococcal vaccine has shown efficacies from 56% to 81%. CDC surveillance studies have reinforced this conclusion, with a 57% overall protective efficacy against invasive disease due to serotypes included in the vaccine in persons aged 6 years and over. Specialized studies of high-risk populations, including diabetics and persons with coronary vascular disease, congestive heart failure, chronic pulmonary disease, or anatomic asplenia, have shown similar efficacy [58]. Efficacy of 75% has been shown for persons 65 years or older. Despite these data and the evidence of risk provided by outbreaks of nosocomial pneumococcal disease among unimmunized residents of nursing homes [59], the principal limit on the effectiveness of the polyvalent pneumococcal polysaccharide vaccine currently available in the United States continues to be the limited use of the vaccine in high-risk individuals, with only 10% of older Americans having been immunized.

Recently, a protein conjugated pneumococcal polysaccharide vaccine has been approved for use in children under age 2 [60]. Such a vaccine might also be useful for groups of adults who have a poorer than optimal response to the unconjugated vaccine, for example, persons with sickle cell anemia or those receiving immunosuppressive chemotherapy. Because the conjugate vaccine includes only eight serotypes, use of the 23-valent pneumococcal polysaccharide vaccine is preferable in those older children and adults in whom it can be used.

Table 23.6. Recommendations for Postexposure Prophylaxis for Hepatitis B Virus

Agent Exposure	HBIG		Vaccine
	Dose	Recommended Timing	
Perinatal ^a	0.5 mL i.m.	Within 12 h of birth	Within 12 h of birth
Percutaneous	0.06 mL/kg i.m.	Single dose within 12 h ^{or c}	Start vaccination series as soon as possible after exposure ^b
Sexual	0.06 mL/kg i.m.	Within 24 h; repeat at 1 mo	Vaccine is recommended for sexually active homosexual men and for regular sexual contacts of chronic hepatitis virus carriers
Household contact	0.06 mL/kg i.m.	Single dose within 14 days of sexual contact	
Chronic carrier	—	—	Start vaccination series as soon as possible ^b
Acute case	None, unless known exposure	None, unless known exposure	None unless known exposure Vaccine is recommended if household case becomes chronic carrier
Known exposure	0.06 mL/kg i.m.	Single dose within 14 days of exposure	
In primary caregiver—infant <12 mo	0.5 mL i.m.	As soon as possible	Start vaccination series as soon as possible ^b

^aFor further discussion, see Chapter 3.

^bFor vaccine doses and time intervals, see Table 23.5. The first dose can be given the same time as the HBIG dose but at a separate site.

^cFor those who choose not to receive hepatitis B vaccine.

HBIG, hepatitis B immunoglobulin.

Adapted from Centers for Disease Control. Hepatitis B virus. Recommendations of the Immunization Practices Advisory Committee. *MMWR Morb Mortal Wkly Rep* 1991; 40(RR-13):6.

- B. Meningococcal vaccine** (see Chapter 6 under Prophylaxis of Meningitis and Chapter 22). This polysaccharide vaccine [61] is protective against serogroups A, C, W135, and Y after a single dose. The need for booster doses is unknown. It does not protect against serogroup B infections. Travelers to areas with epidemic or endemic meningococcal disease should be vaccinated (see Chapter 22). Adolescents in group living conditions, including college residents, armed forces recruits, and inmates of institutions for the developmentally disabled and correctional institutions, should be considered for meningococcal immunization. Like *Haemophilus influenzae* polysaccharide vaccine, children less than 2 years of age respond poorly to the meningococcal vaccine. Protein conjugate vaccines are under development.
- C. Typhoid** (see Chapter 22)
- D. Plague** (see section VII.D and Chapter 22)
- E. Diphtheria, tetanus, and pertussis.** Universal childhood immunization has reduced the prevalence of tetanus and diphtheria to extremely low levels. Pertussis persists, although at a much reduced level, because of adult carriage with transmission to infants not yet fully immunized. In this section, we discuss only those aspects of these diseases relevant to the care of adult patients. The recommendations for DTP immunization in the United States have been comprehensively reviewed [62,63].
1. Diphtheria remains a potentially serious, although rare, disease in the United States, with fatalities in approximately 5% to 10% of respiratory cases. Most cases, in both adults and children, occur in nonimmunized or inadequately immunized individuals. However, waning immunity many years after primary vaccination may also contribute to some adult outbreaks [64]. Although adequate immunization is believed to protect for at least 10 years, recent serosurveys in the United States suggest that many adults may not have protective levels of antibodies [5]. Cutaneous diphtheria has occurred principally among certain groups of Native Americans and indigent adults. Localized epidemics have been reported in the latter group.
 2. **Tetanus** incidence in the United States has declined dramatically with the routine use of tetanus toxoid in childhood. Though vaccine-induced immunity may not be lifelong, it is extremely durable. Currently, the fewer than 100 annual cases of tetanus that do occur in this country involve elderly people who never received primary immunization [65]. Tetanus control, therefore, depends most on universal primary vaccination; however, waning immunity is thought to explain the very low seroprevalence seen in persons over 65. Thus, the control strategy also includes reimmunizations every 10 years and appropriate use of toxoid and human hyperimmune anti-tetanus globulin in accident and emergency rooms. A significant number of emergency room patients are overtreated or, worse, undertreated for tetanus-prone injuries [66]. See related discussion in Chapter 4 under Tetanus.
 3. **Pertussis** is caused by toxigenic strains of the gram-positive rod *Bordetella pertussis*. Its precise incidence is unclear. The disease is highly communicable, with attack rates of more than 90% reported in susceptible household contacts. Most reported illness occurs in children younger than 1 year, with classic lower respiratory symptoms. In adults, who actually represent most symptomatic cases in this country [67], the disease may manifest merely as a modest upper respiratory or catarrhal illness, but such persons can serve as unrecognized reservoirs and disseminators of infection [67,68]. This circumstance may increase the difficulty of providing effective secondary prophylaxis for susceptible contacts.
- 4. Vaccines**
- a. **Diphtheria toxoid** is prepared by formaldehyde treatment of purified diphtheria toxin. The concentration of diphtheria toxoid in preparations for adult use (designated d) is lower than that in pediatric formulations (designated D) to reduce the incidence of adverse reactions, which are considered to be related to both dose and age.
 - b. **Tetanus toxoid** is likewise prepared by formaldehyde inactivation of purified tetanus toxin. It is available in fluid and aluminum salt-adsorbed forms.

The adsorbed toxoid induces more persistent antitoxin titers and is strongly recommended for routine use.

- c. **Pertussis vaccine** has been comprehensively reviewed [62], as have the newer acellular vaccines [69,70]. Until recently, all pertussis vaccine used in the United States was a suspension of inactivated *B. pertussis* bacteria. The use of whole killed organisms in this vaccine probably accounted for its higher rate of adverse side effects. Three combination vaccines, containing an acellular pertussis vaccine (DTaP), are now approved for use in the United States for routine primary immunization in children under 6 years of age [69]. Although the acellular vaccine may appear especially attractive for immunization or boosting of adults [70,71], at the time of this report there is no official recommendation for its use in adults. The combined DTaP would have to be reformulated with a lower dose of diphtheria toxoid for use in adults.
- 5. Preparations and dosages.** Simultaneous immunization against diphtheria, pertussis, and tetanus during infancy and childhood has been routine in the United States since the late 1940's.
- a. For infants and children younger than 7 years, diphtheria toxoid, tetanus toxoid, and the acellular pertussis vaccine adsorbed (DTaP) and diphtheria and tetanus toxoids adsorbed (DT) are most commonly used. Dose schedules are reviewed elsewhere [69].
 - b. For persons 7 years old or older, tetanus and diphtheria toxoids adsorbed (Td) is recommended. This product contains a smaller amount of diphtheria antigen (as indicated by the lowercase "d") for use in older children and adults. Tetanus toxoid should be given with adult-dose diphtheria toxoid every 10 years as part of routine primary medical care. If a dose is given sooner as part of wound management, the next booster is not needed for 10 years thereafter. The use of tetanus toxoid in wound management is discussed in Chapter 4. Some travelers may benefit from a booster at 5-year intervals because a tetanus-prone wound does not require tetanus IG or a booster if a person has been boosted within 5 years (see Chapter 22).
 - c. Single-antigen products are available (i.e., acellular pertussis vaccine adsorbed [aP], tetanus toxoid adsorbed [T], and diphtheria toxoid adsorbed [D]) when combined preparations are not appropriate. For example, pertussis vaccine has been used in hospital personnel to help control a pertussis outbreak [68].
- 6. Side effects and adverse reactions**
- a. DTP administration is commonly associated with **local reactions** such as erythema, induration, and tenderness. These usually are self-limited and require no therapy. Fever beginning several hours after administration is also common and may persist for up to 2 days. Mild somnolence, vomiting, irritability, or malaise can occur, especially with pertussis containing vaccines. Rarely, severe **systemic reactions** such as generalized urticaria, anaphylaxis, or neurologic complications may occur after administration of DTP or, to a lesser extent, after DTaP (see section c).
 - b. **Arthus-type hypersensitivity** reactions, characterized by severe local reactions 2 to 8 hours after an injection, may be seen in persons receiving a number of booster injections at too-frequent intervals, as may happen with tetanus.
 - c. **Pertussis.** Severe reactions occasionally occur after pertussis vaccine injection in infants [19]. However, large studies indicated no evidence of a causal relationship between pertussis vaccine and permanent neurologic illness [72]. The incidence of major adverse reactions is low (below 1 in 1,000 for any symptom and 100–1,000 times less frequent for the most serious reactions). In many cases, the occurrence of major reactions may be merely coincidental with the recent immunization rather than attributable to it. Sudden infant death syndrome is not more likely to occur after a DTP immunization [73,74]. The incidence of all adverse reactions seems decreased when acellular pertussis vaccine is used.

- d. Use of multiple reduced-dose regimens. Some physicians have suggested using reduced doses of pertussis or other vaccines in a multidose regimen to reduce the risk of an adverse reaction. There is no rationale for doing this, because vaccine reactions do not appear to be dose related. In addition, the efficacy of such idiosyncratic dosing schedules is unknown, and children receiving such vaccines would be considered nonimmune for the purpose of school entrance requirements.

7. Precautions and contraindications

- a. If any of the severe reactions that may be seen with DTaP has occurred, the immunizations should be completed with DT. If a serious anaphylactic reaction has occurred, further doses of DTaP should be deferred until it is clear whether the reaction was due to the tetanus toxoid component. If it was, desensitization by an allergist may be appropriate to allow completion of the immunization series with tetanus toxoid alone. Although the presence of an evolving neurologic disorder contraindicates the use of pertussis vaccine until neurologic status stabilizes, a personal or family history of seizures is not an indication to withhold pertussis vaccine. A CDC statement on contraindications to the use of pertussis vaccine has been distributed [71].
 - b. The main contraindication to the use of tetanus or diphtheria toxoids is a history of neurologic or systemic hypersensitivity reaction after a previous dose. Local side effects alone do not preclude further use. When an Arthus-like local reaction occurs after frequent tetanus toxoid doses (e.g., with frequent immunizations such as every 2 or 3 years), further routine or emergency booster doses of Td should not be given more frequently than every 10 years.
 - c. Immunosuppressive therapies may reduce the efficacy of these vaccines. When possible, routine vaccination should be deferred while patients are receiving such therapy or for 3 months thereafter (see also section VI.F).
- F. *H. influenzae* b polysaccharide conjugate vaccine [75].** Four conjugate vaccines have been licensed for use in the United States: a PRP-diphtheria toxoid conjugate (PRP-D), a meningococcal protein conjugate (PRP-OMP), a mutant diphtheria protein conjugate (HbOC), and a tetanus toxoid conjugate (PRP-T). Combination vaccines composed of Hib conjugate vaccine and DtaP (TriHIBit) or OTP (Tetramane) have also been developed. Hepatitis B (Recombivax, 5 µg) and Hib (PRP-OMP) have also been combined (Comvax, Merck), and this vaccine is licensed for use at 2, 4, and 12 to 15 months.

Excellent antibody responses in infants less than 2 years old have been achieved with multidose regimens of all the conjugate vaccines except PRP-D, which is used only at 15 months of age or older. Routine immunization of all children beginning at 2 months of age is recommended. (See Table 23.2 for recommended childhood immunization schedule.) Older children with increased rates of serious Hib disease (e.g., asplenic patients, sickle cell patients, or immunosuppressed individuals) should also be considered for immunization. Rates of both meningitic and nonmeningitic childhood Hib disease have decreased by 90% since the approval of the conjugate vaccine for routine immunization of infants [76]. (See Chapter 6 for further discussion on Hib vaccine for the prevention of meningitis.)

Hib vaccines do not affect infection rates with nonencapsulated (nontypeable) strains. These organisms commonly colonize the respiratory tract and cause pneumonia in persons with chronic pulmonary disease or older Americans but rarely cause bacteremic disease. Encapsulated *H. influenzae* infections are rare in adults, and as such there appears to be little indication for the use of Hib as an adult vaccine.

VI. Immunization considerations for special risk groups. Specific immunization recommendations have been formulated for certain groups with recognized special risks.

- A. Older Americans.** Immunization recommendations for the elderly are well addressed elsewhere [77,78]. Recommendations for pneumococcal and influenza vaccine are discussed above (see section V.A and Chapter 10, respectively). Only approximately 22% of the elderly receive influenza vaccine each year, and only 10%

have received pneumococcal vaccine [79]. A survey of the attitudes and practices of the elderly concerning pneumococcal and influenza vaccines emphasizes that the most important factor in determining immunization status of the elderly is the recommendation of the individual's physician.

- B. Pregnant women.** Immunization of the pregnant woman has been reviewed [80]. In general, immunization during pregnancy should be avoided. Although there is little evidence that currently available live virus vaccines can harm the developing fetus, the theoretic risk exists, making it prudent to avoid such exposures. Inactivated vaccines do not carry this same risk, but it has been suggested that maternal fever may be a risk factor for certain congenital abnormalities, so these vaccines should also be avoided. When necessary, it is possible to administer OPV to pregnant women (see section **III.D.3.b**). Influenza vaccination during pregnancy is discussed in Chapter 10.
- C. College students.** These young adults are at special risk for epidemic illness spread by the respiratory route; outbreaks of measles, rubella, and influenza have repeatedly been reported on college campuses [81]. Since May 1983, the American College Health Association has encouraged institutions to adopt a recommended preadmission immunization policy [82], but serious gaps in immunization among college students persist. Special recommendations for measles and hepatitis B vaccine have also been published for this population.
- D. Prison populations.** As noted above (see section **IV.A.2.k**), HBV infection is a significant risk for persons in long-term incarceration, and HBV vaccine may play an important role in reducing the risks of transmission. Rubella outbreaks in prisons in several different parts of the country [83] have emphasized the need for immunization programs for young adults in prison [84]. Such outbreaks also represent occupational risks for prison staff.
- E. Homeless persons.** The fragmentary, episodic, and disorganized medical care that many of the homeless receive leaves a large group of individuals susceptible to a variety of vaccine-preventable diseases for which new immunization strategies may be required [85]. Homeless adults have been the targets of a diphtheria epidemic [86] and a cluster outbreak of pneumococcal pneumonia [87]. Homeless adolescents may be at high risk for HBV infection [88].
- F. Immunosuppressed individuals.** Immunization of the immunocompromised individual has been reviewed [89–91]. Immunization in this population is problematic for two reasons. Live virus vaccines generally are contraindicated because of their potential for causing disease, whereas many inactivated or component vaccines may not be as effective in this population. However, certain exceptions to these general rules should be noted. Because of reports of severe and even fatal measles occurring in children who were HIV infected, it has been recommended that both symptomatic and asymptomatic HIV-infected children be immunized with the measles vaccine [27]. Children who are HIV infected and who have a measles exposure, regardless of their immunization status, should also receive IG prophylaxis. Pneumococcal vaccination appears to be cost effective in adults with HIV, although routine influenza immunization may be more problematic [92].

The use of bacterial polysaccharide vaccines has been an important issue in Hodgkin disease patients who have previously undergone staging splenectomy. In these individuals, the risk of pneumococcal or *Haemophilus* sepsis is appreciably elevated. Studies of the responses of such individuals show that, although vaccine immunogenicity and durability of the antibody response may be poorer in such persons, protective levels can be achieved in some [93]. Immunization efficacy is not influenced by the scheduling of splenectomy, but better responses are achieved when chemotherapy can be delayed 3 weeks after vaccine administration [93].

- G. Additional special vaccine categories.** Special studies and recommendations have been made for alcoholics [94], persons with rheumatologic disease [95], persons receiving hemodialysis [96], postsplenectomy patients [97], patients who have undergone bone marrow transplantation [98], and persons infected with HIV [99,100]. Recommendations have also been reviewed for health-care workers [101,102] (see Chapter 26).

VII. Vaccines for use in the military and special occupational groups

A. Anthrax, the disease caused by *Bacillus anthracis*, has historically been a disease of persons whose occupations brought them into frequent and close contact with animal hides and hair of hooved animals. Laboratory-derived cases in personnel working with the organism have also been reported. Three clinical forms of disease are recognized: cutaneous, gastrointestinal, and inhalation, the latter being the most lethal (i.e., mortality rates in excess of 80% are reported in untreated cases). *B. anthracis* has the ability to form spores that are highly resistant to most environmental conditions and hence may survive for decades. When inhaled into the lungs of humans, the spores may then germinate and result in inhalation anthrax. These properties have resulted in *B. anthracis* becoming the prototypical organism for development as a biological warfare agent. It is identified by the CDC as a high priority category A, agent for bioterrorism [103]. Since the tragic events of September 11, 2001, the role of *B. anthracis* as a weapon for domestic and international terrorism has been highlighted [104]. The most up-to-date information related to anthrax and other biological weapons may be obtained on the Internet from the CDC (www.bt.cdc.gov) and Johns Hopkins University (www.hopkins-biodefense.org/mdex.html).

A vaccine against anthrax was previously available from the state-owned Michigan Biologics Products Institute. This company was bought by Bioport and remains the only manufacturer of anthrax vaccine, almost exclusively for the Department of Defense. Despite production problems, over 700,000 military personnel have received anthrax vaccine since 1998.

The anthrax vaccine is a noninfectious culture filtrate of an attenuated strain of *B. anthracis* that is adsorbed to an aluminum hydroxide adjuvant. Protective antigen that is present in the filtrate vaccine is thought to generate antibodies that prevent the disease. The schedule for administration is 0, 2, and 4 weeks and again at 6, 12, and 18 months. Annual booster doses are necessary to maintain immunity. Efficacy of this new vaccine has only been demonstrated in animal challenge studies. Despite controversy, the frequency and severity of adverse events related to anthrax vaccine do not exceed those of other routinely used vaccines. Most people experience local injection site reactions (e.g., redness, swelling, soreness, itching). In addition to primary prevention, the anthrax vaccine has also been proposed for use in combination with antibiotics for postexposure prophylaxis [104,105].

B. Lyme disease vaccine (LYMERix, GlaxoSmithKline) is a recombinant outer surface lipoprotein (OspA) of *Borrelia burgdorferi* that is combined with an adjuvant [107]. Vaccination involves three intramuscular injections (30 μ g) given on day 0 and at 1 month and 12 months. Although efficacious, Lyme vaccine is recommended only for individuals who work, live, or travel to areas of unusually high incidence of Lyme disease (i.e., hyperendemic areas). Local injection site pain is the most frequent adverse event, although other serious vaccine reactions have been reported by the manufacturer, including musculoskeletal, neurologic, and hypersensitivity reactions.

C. Q fever. An investigational inactivated vaccine is available for use in animal handlers working with sheep and in laboratory workers exposed to *Coxiella burnetii*. It is available through the U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, Maryland.

D. Tularemia. A live attenuated vaccine is available from the CDC for use in individuals whose work regularly brings them into contact with wild mammals or vectors in tularemia-endemic areas.

E. Plague. Plague vaccine is used rarely except in laboratory or field personnel who are working with *Yersinia pestis* or in certain workers (e.g., Peace Corps volunteers and agricultural advisers) who reside in rural areas where enzootic or epidemic plague exists and where avoidance of rodents and fleas is impossible. Detailed indications and recommendations for the use of this vaccine have been reviewed [106].

F. Rabies vaccine. See Chapter 4 under Bite Wounds and Rabies Prevention.

VIII. Vaccines are currently in *de novo* development for gonorrhea, malaria, and respiratory syncytial virus, and improved vaccines also are being developed for cholera and typhoid. An adenovirus vaccine is approved for use in the military.

IX. Vaccine use in developing countries. This topic is beyond the scope of this chapter. However, it has been reviewed in an international symposium [108] and updated [109].

ACKNOWLEDGMENT

24. ALLERGY TO β -LACTAMS AND OTHER SELECTED ANTIBIOTICS

Stephen F. Kemp and Richard D. deShazo

GENERAL PRINCIPLES OF ADVERSE DRUG REACTIONS

I. Epidemiology. Adverse drug reactions (ADRs) are frequent consequences of medical treatment. Estimates of fatalities in the United States due to ADRs range from 75,000 to 106,000 fatalities per year [1]. Statistics vary, however, depending on the reporting mechanism. One study found a marked disparity between national public-use databases of U.S. death certificates and the U.S. Food and Drug Administration's (FDA's) postmarketing surveillance system (MEDWatch) [2]. A critique of reports and their interpretation has been published elsewhere [3]. Clinical trials may not detect many of the serious ADRs prior to approval of a given drug [4,5]. For proper management, allergic reactions must be distinguished from other reactions.

Allergic and other immunologic drug reactions probably cause 6% to 10% of ADRs [6]. Reports suggest that the risk of an allergic reaction for most drugs is 1% to 3% [7]. Antibiotics, especially β -lactam antibiotics, are the most common cause of allergic drug reactions. Antibiotics are also the most common class of drug associated with prescribing errors. A study over 9 years in a teaching hospital determined that antibiotics were associated with 34% of prescribing errors, at least twice the incidence of any other drug class [8]. Overdose accounted for 33.5% as compared with underdose in 26.3% of instances. Allergic drug reactions accounted for 22.3%.

II. Immunopathogenic mechanisms

A. Gell and Coombs first classified four types of hypersensitivity (immunopathologic) reactions [9]:

1. Type I. Immediate hypersensitivity reactions are immunoglobulin E (IgE) dependent. Clinical examples include urticarial and anaphylaxis.
2. Type II. Cytotoxic reactions are IgG or IgM dependent. Clinical examples include Coombs-positive hemolytic anemia.
3. Type III. Immune complex disease is mediated by antigen-antibody complexes (IgM or IgG). Serum sickness is an example of this type of drug reaction.
4. Type IV. Delayed or cell-mediated hypersensitivity reactions are T-lymphocyte dependent. Contact dermatitis is a clinical example of this type of drug reaction.

B. Sell has proposed an alternate classification system based on seven immunopathologic mechanisms with both protective and destructive functions [10]:

1. Type 1 mechanisms are immune-mediated inactivation/activation reactions of biologically active molecules.
2. Type 2 are antibody-mediated cytotoxic or cytolytic reactions.
3. Type 3 are immune complex reactions.
4. Type 4 are allergic reactions.
5. Type 5 are T-lymphocyte-mediated cytotoxicity reactions.
6. Type 6 are delayed hypersensitivity reactions.
7. Type 7 are granulomatous reactions.

In this classification, one or more mechanisms may be active in an immunopathologic reaction (e.g., ADR) for a given individual.

III. Classification. Some clinicians consider the terminology used in discussions of ADR to be a "tower of Babel" [3]. A useful classification separates ADRs into two categories: types A and B [11]. **Type A reactions** are common and predictable reactions that may occur in any patient. **Type B reactions** are uncommon and unpredictable reactions that occur only in particularly susceptible patients (Table 24.1). At least 80% of ADRs are type A reactions, which are often dose dependent and reflect known pharmacologic actions of the drug.

A. Allergic or hypersensitivity reactions are type B reactions, which occur in small numbers of patients and require previous exposure to the same or a chemically related drug. They develop rapidly after reexposure and produce clinical syndromes commonly associated with immunologic reactions. Higher molecular weight drugs

Table 24.1. Classification of Adverse Drug Reactions

Type A

- Overdosage or toxicity: an exaggerated but characteristic effect from an excessive dose
- Side effects: excessive expressions of known pharmacologic effects that can occur at recommended dosages of a drug
- Drug interactions: can occur when a patient takes two or more medications
- Teratogens: capable of producing developmental defects in a fetus whose mother takes these drugs

Type B

- Intolerance: an undesirable pharmacologic outcome that occurs at a subtherapeutic dosage
- Idiosyncratic reaction: an uncharacteristic response to the administration of a drug that is usually due to a hereditary enzyme deficiency
- Allergic or hypersensitivity reactions: occur in small numbers of patients, require previous exposure to the same or a chemically related drug, develop rapidly after reexposure, and produce clinical syndromes commonly associated with immunologic reactions

Adapted from Rawlins MD, Thompson W. Mechanisms of adverse drug reactions. In: Davies DM, ed. *Textbook of adverse drug reactions*. New York: Oxford University Press, 1991:18–45, with permission.

(e.g., antisera) are more likely to produce immunologic reactions directly, whereas lower molecular weight drugs (e.g., penicillin) are haptens that must combine with carrier proteins before they can elicit reactions [12].

IV. Risk factors. Both drug and patient factors may increase the risk of ADRs.

- A. Drug factors include the class of drug, variations in drug metabolism, and drug exposure (dose, frequency, duration, and route of administration). Patient factors include age, gender, genetic and constitutional factors, prior exposure to medications, and concurrent illnesses and medications or other biologic agents. These risk factors are reviewed in greater detail elsewhere [13].
- B. Some risk factors assume particular significance for antibiotic administration. The route, dose, duration, and frequency of drug administration can influence the risk of drug allergy.
 1. Sensitization may occur by any route of drug administration, but the oral route generally presents the least risk.
 2. Parenterally administered medications, including β -lactam antibiotics, are more likely to cause anaphylaxis than those administered orally [14].
 3. Single prophylactic doses of any antibiotic are less likely to sensitize than is high-dose, prolonged parenteral therapy.
 4. Frequent courses of antibiotic therapy are more likely to result in allergic reactions than courses of therapy separated by several years, which may explain why patients with cystic fibrosis appear particularly susceptible to drug reactions [15].
 5. Children of parents who are allergic to an antibiotic have been reported to be 15 times more likely to develop allergic reactions to antibiotics [16].
 6. Hospitalized patients with a history of drug allergy are nine times more likely to report a history of drug allergy among their first-degree relatives [17].
 7. Although atopy (the hereditary predisposition to develop allergic rhinitis, allergic asthma, or allergic dermatitis) does not affect the incidence of ADRs, it may predispose to more severe reactions [18].
- C. Some patients appear to be at risk for allergic reactions to multiple drugs. The multiple drug allergy syndrome, reported to occur primarily with antimicrobial agents, may reflect a general tendency to respond immunologically to haptens rather than to react to specific classes of drugs [19,20]. Some investigators have challenged its existence [21].

- D.** Concurrent disease and therapy also may influence the risk for ADRs.
1. Viral infections may increase the frequency of cutaneous drug reactions (see section **I.C** under Common Clinical Patterns of adverse Reactions to Antibiotics below).
 2. Patients with systemic lupus erythematosus may have an increased incidence of allergic drug reactions, but it is unclear whether this is related to the underlying immunologic abnormality or to more frequent exposure to drugs [22,23].

COMMON CLINICAL PATTERNS OF ADVERSE REACTIONS TO ANTIBIOTICS

I. Cutaneous reactions

- A. Acute urticaria and angioedema** are common manifestations of antibiotic allergy [24]. The lesions usually appear shortly after beginning drug therapy and resolve rapidly when the drug is discontinued.
1. Acute urticaria should be considered a manifestation of anaphylaxis. Anaphylaxis is an acute, life-threatening immunologic reaction that consists of diffuse erythema, pruritus, urticaria, angioedema, bronchospasm, laryngeal edema, hyperperistalsis, hypotension, or cardiac arrhythmias, alone or in combination. Anaphylaxis usually develops rapidly, often within 5 to 30 minutes after drug administration [25].
 2. Acute urticaria after an antibiotic should be treated as an anaphylactic reaction with epinephrine lest the reaction progress to full-blown anaphylaxis.
- B. Chronic urticaria** (hives persisting for 6 weeks or longer) occasionally occurs despite discontinuation of treatment with a drug to which a patient is allergic.
- C. Maculopapular or morbilliform eruptions**, overall, are the most common drug-induced cutaneous reactions.
1. These eruptions are symmetric, often confluent erythematous macules and papules that typically spare the palms and soles. They originate on the extremities of ambulatory patients or overlie pressure areas of bedridden patients.
 2. Beta-lactam antibiotics and sulfonamides are common causes of antibiotic-associated maculopapular eruptions. These eruptions occur more frequently with ampicillin (approximately 10%) than with other penicillins (approximately 2%) and develop in 50% to 80% of patients with Epstein-Barr virus (including infectious mononucleosis) or cytomegalovirus infections, chronic lymphocytic leukemia, or hyperuricemia, and in patients taking allopurinol concomitantly [7].
 3. Maculopapular eruptions are also common in patients with viral infections, especially those with human immunodeficiency virus (HIV) infection who receive trimethoprim-sulfamethoxazole (TMP-SMX), ampicillin, or other drugs.
 4. These eruptions usually develop within 1 week of initiating the offending drug and follow a variable course. The eruptions may subside spontaneously with continued use of the responsible drug and do not always recur on repeat exposure. However, the reactions may occasionally progress to generalized erythroderma or exfoliative dermatitis. Therefore, a prudent approach to morbilliform drug reactions is to discontinue treatment with the culprit drug and to avoid subsequent administration if possible.
- D. Erythema multiforme/Stevens-Johnson syndrome.** Erythema multiforme is an erythematous, polymorphic eruption that may be caused by drugs in 10% to 20% of cases. Antibiotics, especially sulfonamides, are frequently implicated. Skin manifestations include target lesions, maculopapular rashes, urticaria, and vesicles. Lesions are typically symmetric and have a predilection for the extremities [26].
1. In the most severe form of erythema multiforme, Stevens-Johnson syndrome, 90% of patients have mucosal lesions and 85% have conjunctival lesions; epidermal loss involves 10% or less of body surface area. Approximately 50% of cases of Stevens-Johnson syndrome are associated with drugs, and readministration of a responsible drug produces recurrence.
 2. Sulfonamides, anticonvulsants, nonsteroidal antiinflammatory drugs, and allopurinol account for two-thirds of these reactions.

3. Fever and influenza-like symptoms often precede the mucocutaneous lesions by 1 to 3 days.
4. Visceral involvement is associated with a poor prognosis, but the mortality rate is generally less than 5% [24].
5. Although treatment is supportive, some investigators recommend the early use of systemic corticosteroids [27]. Corticosteroids may prevent visceral involvement and decrease both the duration and severity of clinical findings [28–30]. However, corticosteroid use in Stevens-Johnson syndrome remains controversial.
6. **Readministration of any medication clearly implicated in Stevens-Johnson syndrome is contraindicated.**

E. Toxic epidermal necrolysis (TEN). TEN is an acute illness characterized by fever, epidermal loss exceeding 30% of body surface area, and visceral involvement with an associated mortality rate of 30% to 40% [31]. More than 80% of TEN cases are induced by the same medications that produce Stevens-Johnson syndrome [24].

1. As with Stevens-Johnson syndrome, readministration of the offending drug produces recurrence.
2. It is often difficult clinically to distinguish TEN from Stevens-Johnson syndrome without skin biopsy. For instance, both conditions produce conjunctival lesions in 85% of patients [24].
3. Treatment is supportive and corticosteroids are not advocated.
4. Intravenous immune globulin may be helpful for some patients [32].

F. Histopathology of cutaneous antibiotic reactions

1. T cells are the predominant cells that comprise the inflammatory infiltrate of skin in antibiotic-induced bullous and morbilliform reactions [33,34]. Cells isolated from biopsy samples of these reactions are capable of *in vitro* proliferation after stimulation with the culprit drug [33,35–37]. Several investigators have concluded that these reactions reflect lymphocyte-mediated delayed hypersensitivity because they are often associated with positive results obtained with the patch test or leukocyte transformation test (LTT), or delayed positive results (i.e., >6 hours postadministration) with the intracutaneous test [38–41].

II. Serum sickness-like reactions

A. Serum sickness-like reactions to antibiotics are indistinguishable from the serum sickness due to heterologous serum.

1. The serum sickness-like reaction is a syndrome characterized by fever, malaise, and an urticarial or morbilliform rash, which is often preceded by pruritus and erythema. Arthralgias or arthritis (mainly large joints), lymphadenopathy, abdominal pain (possibly with emesis or melena), nephritis, neuropathy, or vasculitis (cutaneous or systemic) may occur in some cases.
2. Serum sickness-like reactions result from immune complex (IgG) tissue deposition and may develop 6 to 21 days after drug administration, but they can occur within 12 to 48 hours in individuals who have previously been sensitized to the medication or serum.
3. Cutaneous vasculitis, also known as hypersensitivity vasculitis, is usually manifested by palpable purpura, and is most evident on the lower extremities of ambulatory individuals or on the buttocks or sacral region of bedridden patients. Purpuric lesions reflect the leakage of erythrocytes into the skin from inflamed postcapillary venules.
4. Serum sickness-like reactions associated with β -lactam antibiotics appear to be more common with cefaclor. The incidence with cefaclor is low, ranging from 0.024% in controlled clinical trials to 0.5% in published reports [42].
5. Cefaclor-induced serum sickness-like reactions are more common in children taking the oral suspension and have a predilection for the winter months [42,43].
6. No circulating immune complexes have been identified. Kearns et al. have suggested that unique hepatic biotransformation of the parent drug to reactive intermediates capable of lymphocyte activation may cause serum sickness-like reactions attributed to cefaclor [44].

III. Drug fever. Drug fever may occur with any drug, including antibiotics, and its mechanism is unknown. Eosinophilia, leukocytosis, elevated erythrocyte sedimentation rate, and rash may occur in patients with drug fever. Because drug fever almost always

resolves within 48 to 72 hours of discontinuing treatment with the culprit drug, the most useful diagnostic test is the discontinuation of the suspect drug [45].

IV. Other organ system patterns of ADRs

A. Hepatitis. Drug-induced allergic hepatitis may be accompanied by fever, rash, lymphadenopathy, hemolysis, and eosinophilia.

1. Hepatitis begins after several weeks of drug treatment and recurs rapidly on re-exposure. Histologic patterns of liver injury may include hepatocellular necrosis, cholestasis, or both.
2. More than 150 drugs have been reported to cause allergic hepatitis, including semisynthetic penicillins, ceftriaxone, erythromycin, nitrofurantoin, and sulfonamides. Many of these also induce antibodies directed against liver organelles (mitochondria, microsomes), smooth muscle, or nuclear components [46].
3. An immunologic mechanism is suspected for drug-induced allergic hepatitis because these reactions are not dose dependent, are accelerated on rechallenge, and are associated with eosinophilia in peripheral blood samples and on biopsy specimens. Antinuclear antibodies to single-stranded DNA also may be present [47].

B. Hematologic reactions include eosinophilia, thrombocytopenia, and hemolytic anemia. These have been noted with ampicillin, vancomycin, sulfonamides, and streptomycin antibiotics. Eosinophilia in the context of an ADR usually occurs with other commonly associated features of allergic drug reactions, such as dermatitis or hepatitis [7]. Eosinophils may be present in the urine of patients with methicillin-induced interstitial nephritis. Eosinophilia may be the only manifestation of drug hypersensitivity in some instances, such as that associated with intramuscular injections of gold thiomalate sodium.

C. Other adverse reactions. Less commonly, antibiotics, including β -lactams (especially methicillin), rifampin, and ciprofloxacin, can cause renal disease, with nephrosis or acute interstitial nephritis. Pulmonary infiltrates with peripheral eosinophilia have been associated with penicillin, sulfonamides, and nitrofurantoin.

GUIDELINES FOR DIAGNOSIS AND MANAGEMENT OF ADRs

I. General principles. Published protocols are available for the diagnosis and management of a number of adverse reactions to drugs and biologic agents [7,13,48–53]. We have suggested a standardized approach to the management of patients with a previous adverse reaction who require treatment for the same indication (Fig. 24.1). A similar protocol is also available for patients who develop drug reactions while taking multiple drugs [13]. Table 24.2 lists antibiotics and concentrations useful in skin testing to detect the presence of drug-specific IgE.

A. Many patients with purported drug allergy have actually experienced type A reactions for which dose modification or drug substitution may be adequate intervention. Supervised administration of a small test dose for reassurance may be appropriate if a serious reaction after readministration appears unlikely and if therapeutic alternatives are unavailable. These challenges should be administered only in a setting where drug reactions can be treated promptly and adequately.

ALLERGIC REACTIONS TO SPECIFIC ANTIBIOTICS

I. Penicillin and other β -lactam antibiotics are responsible for most allergic drug reactions and drug-induced anaphylaxis.

A. Classified. Allergic reactions to penicillin are classified according to the time of onset after initiation of therapy as immediate (within 1–45 minutes), accelerated (1–72 hours), or late/delayed (>72 hours and up to weeks afterward).

1. Immediate reactions result from the IgE-dependent mast cell and basophil release of histamine and other chemical mediators. These are the most dangerous antibiotic reactions and may be associated with urticaria, angioedema, laryngeal edema, bronchospasm, and anaphylaxis.
2. Accelerated reactions are IgE dependent but also are influenced by IgG. They share clinical features with immediate reactions but, in the absence of laryngeal edema, are generally not life threatening.

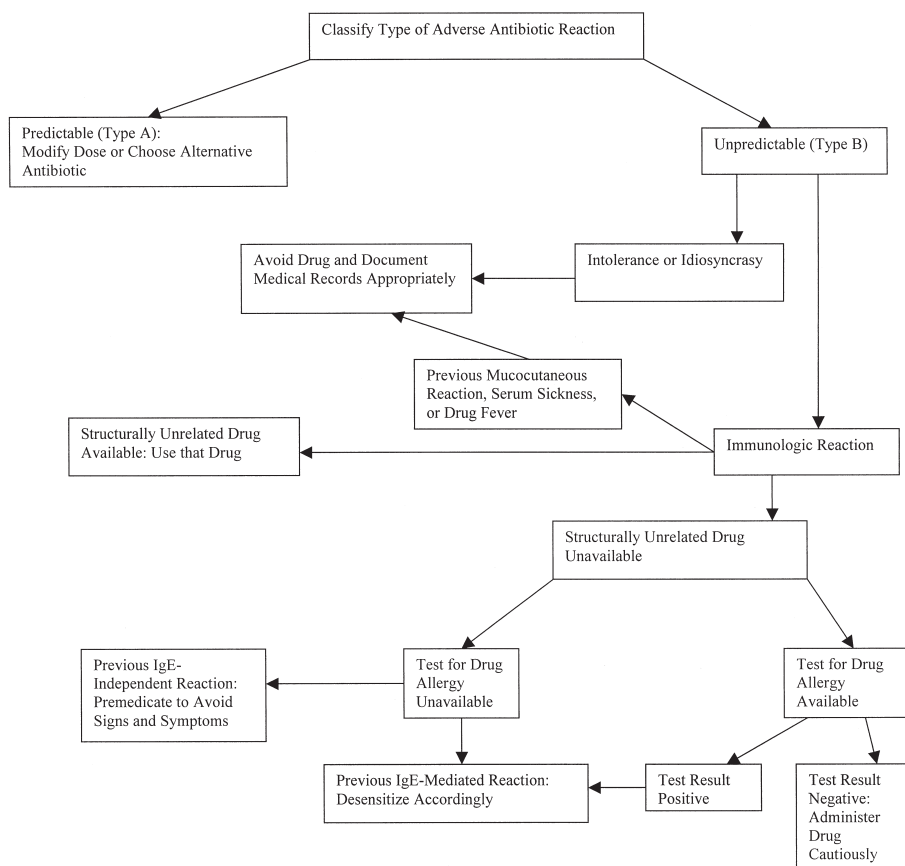

FIG. 24.1 Systematic approach for evaluating the patient who reports a previous adverse antibiotic reaction and requires treatment for the same clinical indication. (Modified from deShazo RD, Kemp SF. Allergic reactions to drugs and biologic agents. *JAMA* 1997;278:1895–1906, with permission.)

3. Late/delayed reactions may account for 39% of all allergic reactions to penicillins and are mediated by T-lymphocytes. Morbilliform or maculopapular eruptions are the most common clinical features [38].
- B. Prevalence and incidence.** The estimated prevalence of penicillin allergy is 2%, but the reported incidence varies widely (1%–10%), depending on a number of factors, including the history of exposure, the route of administration, the duration of treatment, the elapsed time between the reaction and diagnostic testing or exposure, and the nature of the initial reaction [13,54].
1. **Anaphylactic reactions.** Because there is no system for tracking the incidence of ADRs accurately, the true incidence of antibiotic-induced anaphylactic reactions is unknown. In 1968, Idsoe et al. reported the international incidence of penicillin-induced anaphylaxis to be 0.015% to 0.04% (1.5–4/10,000) of treated patients [55].
 2. In another study of 1,740 patients who received monthly prophylaxis with intramuscular penicillin G for an average of 3.4 years, allergic reactions occurred in 3.2%, with an anaphylaxis incidence of 1.23/10,000 injections. The risk of a

Table 24.2. Nonirritating Skin Test Concentrations of Selected Intravenous Antibiotics

Antibiotic	Full-strength Concentration (mg/mL)	Nonirritating Concentration (dilution from full-strength)
Cefotaxime	95	10-fold
Cefuroxime	90	10-fold
Cefazolin	330	10-fold
Ceftazidime	250	10-fold
Ceftriaxone	250	10-fold
Tobramycin	40	10-fold
Ticarcillin	200	10-fold
Clindamycin	150	10-fold
Trimethoprim-sulfamethoxazole	80 (sulfa component)	100-fold
Gentamycin	40	100-fold
Aztreonam	50	1,000-fold
Levofloxacin	25	1,000-fold
Erythromycin	50	1,000-fold
Nafcillin	250	10,000-fold
Vancomycin	50	10,000-fold
Ciprofloxacin	10	10,000,000-fold

Reprinted from Solensky R, Mendelson LM. Systemic reactions to antibiotics. *Immunol Allergy Clin North Am* 2001;21:679–697, with permission.

fatality was 1/32,000 injections [56]. Similarly, two of 9,203 healthy military recruits developed anaphylaxis after prophylactic treatment with a single dose of intramuscular benzathine penicillin, for an incidence rate of 2.17/10,000 [57].

3. Anaphylactic reactions to penicillin occur most commonly in adults between the ages of 20 and 49 years [18].

C. The clinical history is important in identifying patients with a history of penicillin allergy.

1. The more remote the initial reaction from subsequent penicillin administration, the lower the risk of anaphylaxis following readministration. For example, only 20% of subjects with prior anaphylactic sensitivity to penicillin have persistent penicillin-specific IgE antibodies after 10 years of penicillin avoidance [54,58].
2. Selectively amoxicillin-allergic patients tend to lose sensitivity more quickly than those allergic to penicillin, suggesting at least two types of IgE response [59].
3. Because about one-third of penicillin-allergic patients have vague histories of penicillin allergy, it is prudent to assume penicillin allergy exists in a history-positive patient unless testing proves otherwise [60].

D. Immunochemical etiology of penicillin allergy

1. Ninety-five percent of penicillin is metabolized to the penicilloyl hapten, which is called the major determinant (see Fig. 24.2). The penicilloyl hapten is conjugated to polylysine (benzyl penicilloyl polylysine; [BPO-PLL or PPL]) as the commercially available skin testing Pre-Pen (Hollister-Stier, Spokane, WA).
2. The minor determinant mixtures (MDMs) comprise the remaining 5% of penicillin metabolites and include penicilloate, penicilloyl-amine, benzylpenicilloyl-*n*-propylamine, and penilloate. No commercial preparations of MDMs are available for diagnostic testing in the United States.
3. Immunochemical studies using human IgE antibodies have defined no predominance of a given penicillin determinant [61].
4. In addition, side chain-specific antibodies to amoxicillin, penicillin V, and antigenic determinants generated by penicillins demonstrate that additional epitopes exist [61,62].
5. Individuals experiencing anaphylaxis and most with serum sickness have circulating penicillin-specific IgE antibodies.

FIG. 24.2 Structure and metabolism of β -lactam antibiotics. R represents the C-6 or C-7 side chain, R' is a second side chain, A is the β -lactam ring, and B is a fused ring. *All β -lactam antibiotics (penicillins, cephalosporins, monobactams, carbapenems, oxacephems, and clavams) possess a characteristic four-member β -lactam ring that, except for monobactams, is fused to a second five- or six-member ring. All except the clavams have a side chain attached to the β -lactam ring, and some cephalosporins, carbapenems, and oxacephems possess a side chain that is attached to the second ring. Aztreonam, clavulanic acid, imipenem/meropenem, and moxolactam are monobactams, clavams, carbapenems, and oxacephems, respectively. (Reprinted from Blanca M, Vega JM, Garcia J, et al. New aspects of allergic reactions to beta-lactams: cross-reactions and unique specificities. *Clin Exp Allergy* 1994;24:407–415, with permission.)

6. IgG and IgM antipenicillin antibodies are detected with penicillin-associated hemolytic anemia and serum sickness.

E. Diagnostic testing for penicillin allergy

1. Skin test methods

- a. The probability that immediate or accelerated reactions will occur following readministration of penicillin in patients with histories suggestive of previous reactions can be determined by immediate hypersensitivity skin testing with a major determinant, MDMs (available in many research centers), and penicillin G. Table 24.3 lists reagents and concentrations used in skin testing for β -lactam allergy.
- b. Personnel skilled in the placement and interpretation of these tests should perform them in a setting where anaphylactic reactions can be treated promptly and correctly should they occur.
- c. Testing should be performed in the absence of antihistamines or medication with antihistamine properties. Percutaneous (prick) testing should always precede intracutaneous tests, and appropriate positive and negative controls should be used.

Table 24.3. Reagents Used in Penicillin Skin Testing

Reagent	Concentration
Penicilloyl-polylysine (Pre-Pen)	$6 \times 10^{-5} M$
Penicillin G	10,000 units/mL
Penicilloate/penilloate (MDM) ^a	0.01 M
Ampicillin/amoxicillin	12.5 mg/mL

^aMethod of preparation discussed in Macy E, Richter PK, Falkoff R, et al. Skin testing with penicilloate and penilloate prepared by an improved method: amoxicillin oral challenge in patients with negative skin test responses to penicillin reagents. *J Allergy Clin Immunol* 1997;100:586–591. Reprinted from Solensky R, Mendelson LM. Systemic reactions to antibiotics. *Immunol Allergy Clin North Am* 2001;21:679–697, with permission.

- d. Both percutaneous and intracutaneous skin test results are considered positive if the wheal diameter is at least 3 mm greater than the negative control. Results of these tests may not preclude the necessity for desensitization, especially in patients with histories of severe penicillin allergy (see section I.C).
2. Skin test interpretation (Table 24.4)
 - a. Urticaria to penicillin is primarily associated with a positive skin test result to the major determinant.
 - b. Positive skin test results to the MDMs are strongly associated with a risk for anaphylaxis, although anaphylaxis may sometimes occur in the presence of a positive skin test result or positive radioallergosorbent test (RAST) result to the major determinant alone [63].
 - c. Delayed reactions to penicillins account for most allergic reactions. Although assessment of intradermal reactivity after 6 hours has been proposed as a method to diagnose these reactions (see section I.A.3), it has not been carefully evaluated.
 - d. The major factor limiting widespread use of penicillin skin testing in the United States has been the lack of commercial MDM preparations. Liquid solutions are unstable and generally are available only in research centers where they may be synthesized and lyophilized for storage [64].
- F. Utility of penicillin skin tests
 1. Routine penicillin skin testing can facilitate the safe use of penicillin without adverse reactions in 90% of individuals with a previous history of penicillin allergy [65].
 - a. Studies have reported the predictive value of a negative penicillin skin test result to be 97% to 99% for immediate hypersensitivity reactions [18,58,66].
 - b. To the contrary, the positive predictive value of skin testing to assess the risk for allergic reactions to penicillin is unclear because of the risk associated with penicillin challenge in a patient with a positive penicillin skin test result.

Table 24.4. Percutaneous and Intracutaneous Penicillin Skin Test Responses

PPL	Penicillin-G	MDM	Allergic Reaction Expected
+	+	±	Immediate
0	+	0	Immediate
0	0	+	Immediate
+	0	0	Accelerated
0	0	0	None; risk of adverse reaction <3%

PPL, penicilloyl-polylysine (Pre-Pen); MDM, minor determinant mixture.

- c. Studies have reported allergic reaction rates ranging from 40% to 100% in history-positive patients with positive penicillin skin test results [49,67].
 - d. Antibody to a minor determinant causes at least 7% of positive skin test results in penicillin-allergic patients [68].
 - e. Penicillin-induced anaphylaxis has not been reported in subjects with negative skin test results when both major and minor determinant skin tests were performed [67]. Approximately 1% of history-positive, skin test–negative patients experience acute urticaria, and approximately 3% have other mild cutaneous reactions when penicillin is administered [69].
2. “Aged” penicillin is not useful in skin testing because spontaneous degradation of penicillin does not occur and amounts of minor determinant detectable by liquid chromatography or nuclear magnetic resonance are negligible [67]. Published practice parameters recommend skin testing with penicillin G diluted to 10,000 units/mL if MDM is unavailable, followed by an oral test using about 1/100 the desired therapeutic dose if the skin test results are negative [49]. The patient may safely receive the full dose after 60 minutes in most cases in which no drug reaction occurs [49].
 3. Penicillin skin testing is a safe procedure. Combining data from five skin test trials, systemic reactions defined as urticaria beyond the skin test site or worse symptoms occurred in only 10 of 9,249 patients (0.11%) [18,66,70–72]. The prevalence of penicillin allergy is presumed to be about 10%, and approximately 10% of patients who have positive penicillin skin test results react only to MDM. This means that only about 1% (i.e., 10% of 10%) of penicillin-allergic patients will fail to be detected by skin testing that excludes MDM (i.e., using only penicillin 10,000 units and PPL) [69].

G. Other information from penicillin skin tests

1. A negative skin test outcome in the absence of a systemic reaction defines a dose of the test drug that can be tolerated. This permits selection of a drug dosage to be used for desensitization. The dose can then be increased incrementally based on the dose of the drug contained in the skin test. For example, duplicate 0.02-mL intradermal skin tests of a 1 mg/mL concentration of a test drug introduce approximately 40 μ g into a patient [73].
2. Elective skin testing has been proposed as a method by which to correct erroneous labeling of patients as allergic to penicillin. Such testing may eliminate the use of more expensive or toxic drugs. A combination skin test and challenge procedure may be performed in an outpatient setting if the patient is well and has no immediate need for antibiotic therapy.
3. After negative skin tests, the first therapeutic dose can be administered in the office with a brief observation period, and followed by instructions to complete a subsequent 10-day therapeutic course of the medication [67].
4. Skin testing may be repeated several weeks later to exclude the possibility that the elective administration of penicillin has uncovered latent penicillin hypersensitivity (see section I.H below).

H. Activation of latent hypersensitivity by penicillin skin testing

1. Investigators have analyzed whether penicillin history–positive, skin test–negative patients who have tolerated a therapeutic course of penicillin may require skin testing prior to subsequent administration of a β -lactam antibiotic.
2. Reactivation of penicillin allergy in patients with previous penicillin allergy, termed resensitization, has an incidence ranging from approximately 1% to 14% in children [67,72] and 0% to 5% in adults following oral administration [67,74]. Less is known about the risk of penicillin resensitization following intravenous or intramuscular administration of the antibiotic.
3. Skin test conversion rates of 5% and 16% have been reported in adults following a single parenteral injection. To our knowledge, there are no published pediatric data on skin test conversion rates following penicillin treatment [67].
4. The sum of these data appear to support repeat skin testing to exclude resensitization in patients previously noted to be penicillin allergic and who receive a parenteral course of β -lactam antibiotic after negative penicillin skin tests.

I. *In vitro* testing versus skin testing

1. Most investigators consider skin tests for penicillin allergy to be more sensitive than RAST or ELISA [49,68].
2. RASTs with various determinants are of variable quality, and available data on penicillin RASTs are confusing. For instance, although *in vitro* determinations of specific IgE antibodies to the major determinant correspond to skin testing with the major determinant [75], Blanca et al. observed that some penicillin-allergic subjects with negative skin test results to the major determinant (BPO-PLL) and positive skin test results to the MDM had RAST positivity to the major determinant [76]. They also reported amoxicillin-allergic subjects with penicillin test-negative, selective IgE responses to amoxicillin who had negative skin test results to amoxicillin-PLL conjugates, positive skin test results to amoxicillin MDM, and positive RAST results to amoxicillin-PLL [75].
3. **These data suggest that the RAST, despite its limitations, may have a diagnostic role in patients for whom a high degree of clinical suspicion of allergy persists after negative β -lactam skin tests.** Further investigation on the role of RAST testing for β -lactam allergy is needed.

J. Delayed (nonimmediate) allergic reactions to β -lactam antibiotics

1. **Intracutaneous test versus patch testing or the LTT.** Several investigators have evaluated patch tests and the LTT in patients with nonimmediate reactions to β -lactams (i.e., those reactions that occur more than 1 hour after drug administration).
 - a. The LTT reveals sensitization of T cells by an enhanced proliferative response of peripheral blood mononuclear cells to a specific drug. In one study, the specificity of the LTT was 92.8%, and its sensitivity (57.9%) exceeded that of skin testing (36.8%) for the nonimmediate group. However, results of the LTT in patients who received penicillin without allergic reactions were not included as controls. Skin testing sensitivity remained superior for immediate reactions, 77.4% versus 62% [77].
 - b. A similar study reported a sensitivity of 78% and specificity of 85% for the LTT in patients with delayed reactions to β -lactams [78].
 - c. Present data do not suggest the routine use of LTT in the evaluation of allergy to β -lactam antibiotics [49].

K. Penicillin desensitization. Because skin tests are not always available and are not 100% reliable, we recommend desensitization of all patients with histories of life-threatening reactions to penicillin who require the drug, regardless of skin test results.

1. Representative protocols of oral and intravenous penicillin desensitization are presented in Tables 24.5 and 24.6.
2. Oral penicillin desensitization is less likely than parenteral desensitization to induce anaphylaxis [14].
3. The underlying mechanism of desensitization is unclear. An attractive hypothesis is that IgE receptor aggregation may generate counterregulatory forces that actually extinguish activating signals rather than causing mast cell activation [79]. Thus, it is possible that slow rates of IgE receptor aggregation caused by the gradual increase in drug concentration, along with suppression of cellular activation signals, lead to antigen-specific desensitization and clinical tolerance.
4. Complications of oral β -lactam desensitization include mild pruritus and pruritic rashes in approximately 5% of patients during desensitization and approximately 25% during subsequent full-dose therapy.
5. Acute reactions during desensitization may require suppressive medication and adjustments in dosage and dose intervals. Approximately 5% of patients experience drug-induced serum sickness, hemolytic anemia, or nephritis late in the course of full-dose therapy, possibly as a result of increases in penicillin-specific IgG that occur during the desensitization process [80].
6. Premedication with antihistamines or corticosteroids is discouraged because they may mask early manifestations of systemic reactions, and there is no evidence

Table 24.5. Penicillin Oral Desensitization Protocol

Step ^a	Penicillin (mg/mL)	Amount (mL)	Dose Given (mg)	Cumulative Dose (mg)
1	0.5	0.1	0.05	0.05
2	0.5	0.2	0.1	0.15
3	0.5	0.4	0.2	0.35
4	0.5	0.8	0.4	0.75
5	0.5	1.6	0.8	1.55
6	0.5	3.2	1.6	3.15
7	0.5	6.4	3.2	6.35
8	5	1.2	6	12.35
9	5	2.4	12	24.35
10	5	5	25	49.35
11	50	1	50	100
12	50	2	100	200
13	50	4	200	400
14	50	8	400	800

The clinician should observe the patient for 30 minutes, then give full therapeutic dose by the desired route.

^aInterval between doses is 15 minutes.

17	10	25	62.5	123
18	10	50	125	250
19	10	100	250	500
20	10	200	500	1,000

The clinician should observe the patient for 30 minutes, then give full therapeutic dose by the desired route.

^aInterval between doses is 15 minutes.

Adapted from an oral presentation by Timothy Sullivan, MD, and from Solensky R, Mendelson LM. Systemic reactions to antibiotics. *Immunol Allergy Clin North Am* 2001;21:679–697, with permission.

that they prevent severe IgE-dependent reactions. Risk factors for complications during desensitization include poorly controlled chronic respiratory disease and concurrent treatment with β -adrenergic antagonists.

7. **Desensitization is transient and requires that ongoing drug exposure be maintained.** Otherwise, both skin test reactivity and clinical sensitivity may return within 48 hours after interruption of drug therapy. Long-term twice-daily oral penicillin therapy sustains desensitization between courses of parenteral therapy in individuals with cystic fibrosis or other conditions for which intermittent therapy with β -lactam antibiotics is required [14].

L. Cross-reactivity of penicillin with other β -lactams

1. Patients allergic to semisynthetic penicillins are often also allergic to penicillin because of the shared β -lactam ring. Thus, penicillin desensitization allows administration of other β -lactam antibiotics in most circumstances.
2. However, some patients may develop sensitivity to cephalosporins or semisynthetic penicillins without a concomitant allergy to penicillin. This unique sensitivity is presumably due to IgE antibodies specific for the side-chain antigenic determinants that distinguish these antibiotics from penicillin [81].
 - a. The side chains of cephalothin, cephaloridine, and cefamandole are similar to the penicillin side chain [82].
 - b. Cefadroxil has a side chain identical to amoxicillin, and cephalexin has the same side chain as ampicillin [83].
3. Penicillin skin testing may not identify patients with such unique sensitivities. Therefore, some investigators routinely use amoxicillin and ampicillin testing in all studies of penicillin-allergic patients for this reason. However, skin testing and desensitization with nonpenicillin β -lactams remain experimental since their haptenic determinants are unknown [83].
4. Rarely, selective immunologic reactions to clavulanic acid have also been reported [85]. This diagnosis should be considered when a patient has negative skin test results for both penicillin and amoxicillin after experiencing an immediate hypersensitivity drug reaction attributed to amoxicillin-clavulanic acid.
5. Clinical immunologic cross-reactivity is high between penicillin and the carbapenems (e.g., imipenem), less to cephalosporins, and least to monobactams (e.g., aztreonam).
 - a. Aztreonam cross-reacts minimally with most other β -lactam antibiotics, but its clinical spectrum is limited to the treatment of aerobic gram-negative bacilli.
 - b. Ceftazidime has the same side chain as aztreonam, but it is not known whether this structural similarity results in greater cross-reactivity between the two antibiotics [83].
6. Although, the data are contradictory, several studies suggest that patients with histories of penicillin allergy, regardless of skin test results, should be given other β -lactam antibiotics with caution, preferably under medical supervision by personnel prepared to treat anaphylaxis. For example:
 - a. Early cephalosporin antibiotic preparations contained trace amounts of penicillin, possibly leading early studies to overestimate the degree of cross-reactivity between cephalosporins and penicillin [86].
 - b. Current estimates of immunologic cross-reactivity between penicillin and cephalosporins range from 10% for first-generation cephalosporins to 1% to 3% for third-generation cephalosporins [87]. In one study, none of 120 history-positive patients with negative penicillin skin test results reacted to semisynthetic penicillinase-resistant agents, and about 2% of patients with positive penicillin skin test results had allergic reactions when treated with a cephalosporin [86]. Similarly, when 41 patients with penicillin allergy confirmed by skin test and/or provocation test were challenged with cefazolin, cefuroxime, and ceftriaxone, all agents without the penicillin side chain, and none reacted [84]. Eight (38%) of 21 subjects with selective response to amoxicillin had positive responses to cefadroxil, a cephalosporin with the same side chain as amoxicillin [88].
 - c. Conversely, 26 (87%) of 30 subjects with immediate allergic reactions to injectable cephalosporins displayed skin test and RAST reactivity to penicillin

Table 24.7. Intravenous Desensitization for Ceftriaxime

Step ^a	Ceftriaxime (mg/L)	Flow Rate (mL/h)	Dose Given (mg)	Cumulative Dose (mg)
Day 1				
1	100	1	0.025	0.025
2	100	2	0.05	0.075
3	100	3	0.1	0.175
4	100	6	0.2	0.375
5	100	12	0.4	0.775
6	100	25	0.83	1.63
7	100	50	1.66	3.3
8	100	100	2.5	5.8
9	1,000	25	6	11.8
10	1,000	50	12	23.8
11	1,000	100	25	48.8
12	1,000	200	50	98.8
13	1,000	400	100	198.8
14	1,000	600 ^b	307	505.8
Day 2				
1	2,000	1	0.5	0.5
2	2,000	2	1	1.5
3	2,000	3	2	3.5
4	2,000	6	4	7.5
5	2,000	12	8	15.5
6	2,000	25	16.5	32
7	2,000	50	32.3	64
8	2,000	100	50	114
9	2,000	200	100	214
10	2,000	400	200	414
11	2,000	600 ^b	586	1,000

^aInterval between doses is 15 minutes.

^bUntil infusion has completed.

Adapted from Ghosal S, Taylor CJ. Intravenous desensitization to ceftriaxime in cystic fibrosis patients. *J Antimicrob Chemother* 1997;39:556–557, with permission.

determinants and skin test positivity to cephalosporins. Fifteen (58%) reacted to the culprit cephalosporin alone [89].

d. These data must be interpreted with the recognition that skin tests with native cephalosporin have little predictive value [83].

7. Desensitization with cephalosporins remains experimental because their haptenic determinants are unknown. An intravenous desensitization protocol for ceftriaxime is shown in Table 24.7 [90].

II. Sulfonamides

A. Sulfonamide antibiotics possess *p*-aminobenzoic acid rings that are structurally similar to thiazide diuretics, furosemide, sulfonylurea oral hypoglycemic agents, chlorthalidone, and diazoxide. However, case reports of clinical cross-reactivity are rare [91].

1. Sulfonamides are metabolized primarily by hepatic *N*-acetylation and secondarily by cytochrome P-450-catalyzed *N*-oxidation.

2. Slow acetylators are more prone to generate metabolites with reactive oxygen species from sulfonamides. If glutathione reductase does not detoxify these metabolites, they also react efficiently with tissue proteins to produce hapten-carrier complexes [92].

3. The resulting clinical reactions are diverse. For instance, sulfamethoxazole alone may cause more than 20 types of reactions (Table 24.8) [93].

Table 24.8. Adverse Reactions to Sulfonamides

Anaphylaxis	Hypersensitivity vasculitis
Aphthous stomatitis	Lichenoid eruption
Bullous eruption	Photodermatitis
Drug-associated lupus erythematosus	Pruritus
Erythema multiforme/Stevens-Johnson syndrome	Psoriasis
Erythema nodosum	Pustular eruption
Erythroderma	Serum sickness–like reaction
Exanthem	Sweet syndrome
Exfoliative dermatitis	Toxic epidermal necrolysis
Fixed drug eruption	Urticaria/angioedema
Generalized erythema	

Modified from Gruchalla RS. Diagnosis of allergic reactions to sulfonamides. *Allergy* 1999;54(suppl 58): 28–32, with permission.

4. Rarely, immunologic reactivity to the TMP component of TMP-SMX causes clinical reactions. Three different epitopes have been identified on the TMP molecule: the entire TMP molecule, the 3,4-dimethoxybenzyl group, and the 2,4-diamino-5-(3,4-dimethoxybenzyl) pyrimidine group [94].
5. **Reactions in HIV-infected patients.** Adverse reactions to sulfonamides, dapsone, rifampin, and other drugs metabolized by hepatic *N*-acetylation occur 10 to 50 times more frequently in HIV-infected patients than in the general population [51,95].
 - a. The most commonly observed reaction is a maculopapular rash that occurs in more than 3% of all sulfonamide recipients and in more than 50% of HIV-infected individuals. This reaction is more likely to occur in HIV-infected patients during high-dose induction therapy for *Pneumocystis carinii* pneumonia infection. Many patients, however, will tolerate a lower prophylactic dose of TMP-SMX after a short drug holiday. This suggests that the adverse reaction is due to a toxic metabolite and not true allergy.
 - b. For unknown reasons, HIV-infected patients have decreased levels of glutathione reductase. More than 90% of HIV-infected patients treated with sulfonamides generate IgE or IgG antibodies to the N₄-sulfonamidoyl determinant; this may explain the frequently observed clinical features of both immunologic and toxic reactions.
6. **Approach to the patient who is sensitive to TMP-SMX**
 - a. The combination of TMP and SMX is the preferred antibiotic regimen for both prophylaxis and treatment of *Pneumocystis carinii* infections in immunocompromised individuals. Because no reliable skin test or *in vitro* test is available, oral provocative dose challenge-desensitization protocols have been suggested, particularly where the nature of the previous reaction is uncertain. **Previous blistering reactions and aplastic anemia after administration of sulfa compounds are contraindications for these protocols.**
 - b. A recommended test dose challenge and desensitization protocol begins with the administration of 1% of the full dose on day 1, 10% on day 2, 30% on day 3, and a full therapeutic dose on day 4 [48].
 - c. More rapid oral or intravenous dosing may be attempted when the need for drug administration is urgent. TMP-SMX has been given intravenously at 20-minute intervals in doses of 0.8, 7.2, 40, 80, 400, and 680 mg of the SMX component [96]. An 8-hour protocol for TMP-SMX desensitization has been used successfully in seven of nine patients [97].
 - d. A slower 10-day protocol may be used for less urgent circumstances or for any desensitization failures encountered while using the accelerated protocol (Table 24.9) [98].

Table 24.9. Ten-Day Challenge/Desensitization for Trimethoprim-Sulfamethoxazole (TMP-SMX)

Day	Dose Administered	TMP-SMX Concentration (mg)
1	1 mL of 1:20 vol/vol pediatric suspension	0.4 mg/2 mg
2	2 mL of 1:20 vol/vol pediatric suspension	0.8 mg/4 mg
3	4 mL of 1:20 vol/vol pediatric suspension	1.6 mg/8 mg
4	8 mL of 1:20 vol/vol pediatric suspension	3.2 mg/16 mg
5	1 mL of undiluted pediatric suspension	8 mg/40 mg
6	2 mL of undiluted pediatric suspension	16 mg/80 mg
7	4 mL of undiluted pediatric suspension	32 mg/160 mg
8	8 mL of undiluted pediatric suspension	64 mg/320 mg
9	1 single-strength tablet	80 mg/400 mg
10	1 double-strength tablet	160 mg/800 mg

Thereafter, TMP-SMX two double-strength tablets daily for isopsoriasis therapy or one tablet every Monday, Wednesday, and Friday for *Pneumocystis carinii* prophylaxis.

Modified from Absar N, Daneshvar H, Beall G. Desensitization to trimethoprim/sulfamethoxazole in HIV-infected patients. *J Allergy Clin Immunol* 1994;93:1001–1004, with permission.

- e. Administration of corticosteroids and antihistamines may permit a patient to complete the recommended doses if febrile or a nonblistering cutaneous reaction develops during the desensitization process.
- f. Desensitization is not risk free. Potential dangers include the development of Stevens-Johnson syndrome, exfoliative dermatitis, status asthmaticus, profound neutropenia, drug-induced hepatitis, or anaphylaxis [99,100].

III. Vancomycin

- A. Vancomycin (Vancocin) may cause “red man syndrome,” a dose-dependent reaction to vancomycin that is characterized by generalized erythema, pruritus, and a diffuse burning sensation. Vancomycin directly stimulates cutaneous mast cells to release histamine and other mediators. Decreasing the rate of the vancomycin infusion will reduce or prevent symptoms for most affected patients.
- B. Desensitization protocols are available for the rare IgE-mediated, anaphylactic reactions [101–106].

IV. Quinolones

- A. Approximately 50% of systemic reactions to ciprofloxacin are manifested after the first dose, and fatalities may occur [107].
 - 1. A similar risk pertains to other quinolones, such as levofloxacin (package insert, Levaquin [levofloxacin] tablets/injection, Ortho-McNeil Pharmaceutical, Raritan, NJ; revised November 2000).
 - 2. Ciprofloxacin, like vancomycin, directly degranulates mast cells to release histamine and other mediators.
 - 3. Successful desensitization for IgE-dependent reactions to ciprofloxacin and levofloxacin has been reported [108–110].
 - 4. The limited data available suggest that patients with allergic reactions to one quinolone are at high risk for reactions to other drugs of the same class.

EDUCATION AND REPORTING OF ADRs

- I. **Education is essential to risk reduction** in patients who have experienced ADRs. Patients with a history of life-threatening reactions should wear a medical warning bracelet or neck chain and carry epinephrine syringes for self-administration if they are at high risk for inadvertent exposure, as might occur in agriculture or industry. Since one study has reported that many subjects receive improper or no instructions on how to self-administer epinephrine, demonstration of proper technique with a placebo trainer is recommended.

II. Surveillance. The FDA maintains a surveillance system for ADRs. Physicians who observe an ADR should contact either the pharmaceutical manufacturer or the Office of Epidemiology and Biostatistics (HFN-700), Center for Drug Evaluation and Research, FDA, Parklawn Building, Rockville, MD 20857. The FDA MEDWatch may be contacted at 1-800-FDA-1088 (www.fda.gov/medwatch/index.html). The United States Pharmacopeia has also developed MedMARx, an anonymous, Internet-accessible, nationwide service for hospitals to report preventable adverse drug events and reactions [111].

25. MICROBIOLOGY LABORATORY TESTS

Paul S. Graman and Marilyn A. Menegus

DIAGNOSTIC LABORATORY TESTS

Smear and Stain Techniques

The most direct, rapid, and technically least restricted tests are the microscopic examination of stained and unstained smears of material from the site of infection. Direct microscopic evaluation can provide immediate data in such life-threatening illnesses as pneumonia and meningitis. Isolation of the potential etiologic agent may otherwise take hours to days (bacteria) or weeks (mycobacteria and fungi). Sometimes, as in malaria and other parasitic diseases, culture cannot be done [1].

I. Gram stain

A. Differential staining is based on cell wall lipid content and the cell wall's decreased permeability to organic solvents. Gram-positive organisms stain purple from the retained crystal violet-iodine complex, whereas gram-negative organisms do not retain this complex and stain red owing to a counterstain.

B. Uses

1. **Diagnostic aid.** Gram stains can help one make a clinical diagnosis by providing clues to the etiologic agent involved in an infection, which in turn will help one choose the appropriate antibiotic while awaiting culture results. (See Chapter 27A.)
2. **Adequacy of specimens** of culture material can be determined. When large numbers of epithelial cells (>10 /low magnification field, $\times 10$ objective) are present, it is likely that the sputum sample has been collected improperly and that cultures may contain colonizing species. Many laboratories will not culture these sputum samples.
3. **Purulence of a specimen.** Although many polymorphonuclear cells are more likely to be seen in infected, versus colonized, sputum specimens (see Chapter 11), their absence does not exclude an acute bacterial infection (e.g., in leukopenic patients).
4. **Quantitation of bacteria.** When one or more organisms per oil immersion field are seen on a Gram stain of a drop of fresh, unspun bodily fluid such as urine, the culture usually grows more than 10^5 organisms per milliliter. This amount is required to cause disease.

C. Technique of preparation

1. The clinician should make a **thin smear** of the clinical specimen on a clean glass slide.
 - a. **Body fluids.** Cerebrospinal fluid (CSF), joint fluid, pleural fluid, and so forth can be applied directly to the slide or centrifuged (or cytocentrifuged) to concentrate the organisms. For CSF, greater sensitivity can be achieved by placing successive loops on the same spot, allowing the spot to dry between additions.
 - b. **Sputum.** The clinician should use purulent-appearing samples and spread the sample on the slide.
2. **The clinician should air-dry and gently heat-fix** the smear by passing the slide through a flame one or two times. *Making the slide too hot to touch causes artifacts.* Grossly bloody smears can be cleared by flooding with distilled water for 5 minutes after heat fixation.
 - a. **After cooling**, the slide may be flooded with **crystal or gentian violet** for 10 seconds and then rinsed.
 - b. **The clinician should flood the slide with Gram iodine** for 10 seconds and then rinse again. The duration of staining in the first two steps is not particularly critical.
 - c. **The clinician should decolorize** with 95% ethanol or an acetone-ethanol mixture (95% ethyl alcohol, 100 mL; acetone, 100 mL) and repeat the rinse. **Decolorization is the critical step.** Decolorization of the smear is complete when the blue stain is no longer visible and when the solvent is colorless as it runs from the slide.

Thick or purulent exudates resist decolorization. Attempts to clear all portions will result in excessive decolorization of the interpretable areas. Therefore, the clinician should decolorize only until the thin parts of the smear are colorless. Acetone-containing solvents act more rapidly than 95% ethanol. Decolorization should be performed for only 1 or 2 seconds.

d. The clinician should counterstain with safranin for 10 seconds, rinse, and air or blot dry.

D. Factors affecting smear interpretation

1. Incomplete decolorization results in excessive gram-positive staining, and gram-negative organisms could be read as gram positive. If the stain is inadequately decolorized, a new smear should be prepared. If the clinical sample is not available, the immersion oil should be removed with xylene and the decolorization and counterstaining steps repeated.

2. Overdecolorization can cause gram-positive organisms to appear gram-negative. Only gram-negative cells and bacteria are seen. The technique can be evaluated by parallel staining of a known gram-positive sample (e.g., oral secretions). A repeat smear should be made or the immersion oil should be removed with xylene and the entire staining process repeated if further specimens are unavailable.

3. Precipitates of crystal violet are irregular in shape and more refractile but may be misinterpreted as gram-positive cocci or fungi. They occur in the thick areas.

4. Variations of morphologic features on Gram staining. Gram-positive organisms may look gram negative or gram positive/gram negative (gram variable) when the organisms are old or exposed to antibiotics. Some organisms (e.g., *Acinetobacter* species and some *Bacillus* species) are naturally gram variable.

5. Background interference. The clinician should look carefully for small, pleomorphic, gram-negative organisms, such as *Haemophilus* species, which can easily be missed.

6. Almost any **gram-positive cocci** can appear in pairs or short chains, so a specific etiologic diagnosis is not possible. Staphylococci may appear as a single coccus.

II. Acid-fast stains. Organisms that stain well with carbol-fuchsin or auramine and resist decolorization with acid-alcohol are acid-fast bacilli (AFB). These include mycobacteria (which stain poorly or not at all with Gram stain) and *Nocardia* species. The initial diagnostic step for tuberculosis is to examine for AFB. Two types of acid-fast stains are available.

A. The basic fuchsin stain (**Kinyoun** or **Ziehl-Neelsen**) combined with light microscopy.

B. Fluorochrome stains offer the advantages of speed, greater sensitivity, and ease of observation because large areas can be examined. The most well established technique, Truant stain, uses auramine-rhodamine fluorescent dyes. Smears are examined under low power using a fluorescence microscope [2,3]. See Chapter 11 under Tuberculosis: Basic Concepts, including gastric and urine AFB smears.

C. Application and interpretation

1. The sensitivity of microscopy for the diagnosis of mycobacterial infection is relatively low, requiring approximately 5×10^3 bacilli per milliliter for detection. Therefore, all specimens examined by smear also should be cultured. **Whenever possible, sputum specimens should be concentrated.** Mycobacteria are recovered optimally from clinical specimens when methods that release them from cells (digestion) and reduce competing organisms (decontamination) are used. The N-acetyl-L-cysteine-sodium hydroxide method is used, and the N-acetyl-L-cysteine, a mucolytic agent, is added to digest tenacious sputum. Addition of sodium hydroxide is used for decontamination [2]. The sample can then be centrifuged and the sediment stained and cultured, with an improved yield of organisms compared with a direct stain of the patient's sputum.

2. Visible tubercle bacilli implies risk of transmission.

3. One cannot differentiate *Mycobacterium tuberculosis* from the atypical mycobacteria. However, in more than 90% of smear-positive cases, *M. tuberculosis* can be promptly identified in sputum concentrates by nucleic acid amplification (NAA)

assays. Culture followed by biochemical or probe assays takes days to weeks to complete.

4. *Nocardia* species are AFB but they retain acid-fast stains less tenaciously, so modified acid-fast stains with milder decolorization must be used to detect *Nocardia* reliably.

III. Wet-mount preparations of a variety of specimens can be examined microscopically for fungal, bacterial, parasitic, and other pathogens. A drop or small portion of specimen (feces, exudate, CSF, urine sediment, sputum, or scrapings) is mixed in a drop of physiologic saline on the surface of a glass slide. Coverslips prevent evaporation. A dim substage light with a $\times 10$ or $\times 45$ objective or dark field, depending on the organism sought, is used.

A. Wet mounts with physiologic saline are useful for trichomonads of the genital tract and intestinal parasites. They should be examined as soon as possible to avoid drying. Cold environments should be avoided because organisms become immobile. *Trichomonas vaginalis* appear as clear, actively motile forms, approximately the size of neutrophils in vaginal secretions, urethral discharges, or urine sediment. Cultures for *T. vaginalis* (not widely available), are more sensitive (20%–30%) than wet mounts [4]. (See Chapter 16 under Vulvovaginitis.)

B. Potassium hydroxide (KOH) is used primarily for identification of fungal forms.

1. **Specimens.** Cervical discharge, skin scrapings (taken with a no. 11 blade), sputum, and tissue scrapings can be examined using this technique.

2. **Method.** A drop of 10% to 20% KOH solution is mixed with the clinical specimen and allowed to stand for 10 to 15 minutes or the slide back can be gently heated. KOH lyses debris and background material, so fungal forms can be seen more easily.

C. India ink preparations are used to visualize the capsule of *Cryptococcus neoformans*.

1. **Technique.** Centrifuged cerebrospinal fluid or urine or exudates are mixed with a drop of India ink on a slide. A coverslip is applied and the specimen is examined when wet.

2. **Interpretation.** The mucoid capsule appears as a clear halo that surrounds the yeast cell. Mononuclear cells (especially lymphocytes) may be mistaken for *C. neoformans*. Budding forms must be seen to interpret as positive. **The latex test for polysaccharide antigen is now the preferred test because it is more sensitive** [5].

D. Dark-field microscopy is particularly useful in diagnosing primary syphilis. (See Chapter 16.)

IV. Other useful staining methods. A number of different stains are available.

A. Giemsa and Wright stains are available in every hematology laboratory.

1. **Malaria and babesiosis smears.** Thin smears of the patient's peripheral blood or a special malarial smear preparation (e.g., smear of platelet-depleted red blood cells [RBCs]) are suitable for screening for these intracellular parasites and eliminate many artifacts of thick smears. Platelets overlying RBCs can mimic intracellular parasites.

2. **Herpes simplex and varicella-zoster viral skin lesions** can be diagnosed by a Giemsa or Wright stain of a scraping of the periphery of the base of an unroofed vesicle. Herpetic lesions show the characteristic multinucleate giant cells and, rarely, intranuclear inclusions. Methylene blue (**Tzanck preparation**) and Papanicolaou smears are better suited to visualize nuclear detail.

3. *Pneumocystis carinii*, *Toxoplasma gondii*, *Histoplasma capsulatum*, yeast, and bacteria can be detected in **Giemsa stains of touch preparations of tissue**.

B. Silver stains (Gomori's methenamine silver, Warthin-Starry, and Dieterle) are difficult to perform properly and should be used only by skilled individuals. They are most useful for the detection of *Treponema pallidum*, fungi, *P. carinii*, *Legionella* species, rickettsiae, and *Bartonella henselae*, the organism associated with cat-scratch disease.

C. Periodic acid-Schiff (PAS) and calcofluor white stains are used to demonstrate fungi. PAS and Gomori methenamine silver stains often reveal fungi not

well visualized by more conventional techniques (e.g., hematoxylin-eosin and Gram stain).

- D. Calcofluor white** is a nonspecific fluorochrome that binds to cellulose and chitin. The stain is useful for demonstrating fungi, *Pneumocystis*, and some parasites using a fluorescence microscope. Stained organisms fluoresce brightly against a dim background.
- E. Acridine orange**, a fluorochrome DNA stain, detects a variety of microorganisms (e.g., bacteria, fungi, and trichomonads) better than Gram stain for bacteria because organisms are seen under low power, and antibiotic-damaged organisms can still be detected [1].
- F. Methylene blue smears for fecal leukocytes** are discussed in Chapter 13.
- G. Fluorescent antibody and immunocytochemical stains** are discussed later in this chapter.

General Principles for Specimen Collection and Handling

This topic has recently been reviewed in detail [6].

- I. The clinician should obtain specimens before initiating or changing antibiotic therapy.**
- II. Specimens should be collected in a manner that minimizes contamination by resident bacterial flora.**
 - A.** Many potential pathogens can be transient colonizers. Their isolation does not necessarily establish clinical significance. On the other hand, recovery of certain organisms such as *Neisseria gonorrhoeae* or *M. tuberculosis* is significant in any clinical specimen.
 - B.** Suprapubic bladder aspiration, transtracheal or percutaneous lung aspiration, and percutaneous aspiration of vesicles, bullae, or abscesses all avoid contamination.
- III. Specimens should be collected** in clean, sterile containers free of residual detergents or disinfectants. Antibacterial preservatives should be avoided (e.g., tissue aspirates). Lidocaine also has antibacterial activities that affect recovery of organisms from bronchoscopy samples. **Cotton swab collection generally is less satisfactory than syringe or catheter aspiration, which** provides sufficient material for both culture and Gram stain. Anaerobes are sensitive to atmospheric oxygen and desiccation, so special care is needed. Specimens aspirated into a syringe and air expelled can be transported or inoculated into a special oxygen-free system.
- IV. Transportation to the laboratory**
 - A. Rapid transport to the laboratory is preferable over transport media.** Except in acute settings, specimens should be collected when prompt inoculation and handling is possible. Aerobes such as *Streptococcus pneumoniae* and *Neisseria* species are fastidious and may not survive temperature extremes or drying. Long delays before inoculation can result in the growth of clinically insignificant bacterial contaminants in the specimen.
 - B. All specimens should be labeled** to avoid errors in later identification.
 - C. Clinicians should provide the laboratory with diagnostic questions** and note the source of specimen. The inoculation of highly selective media increases the probability of recovering certain organisms such as species of *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*.
- V. Blood culture collection technique.** Strict attention to aseptic technique of skin preparation avoids contaminating blood cultures with resident skin flora (e.g., coagulase-negative staphylococci, diphtheroids, and *Propionibacterium acnes*) and decreases diagnostic confusion. Some organisms that are usually skin contaminants can be true blood-borne pathogens (e.g., catheter-related sepsis, prosthetic valve endocarditis).
 - A.** Technicians should wear gloves when drawing blood to reduce the risk of infection with blood-borne agents (e.g., hepatitis B, hepatitis C [HCV], and human immunodeficiency virus [HIV]).
 - B.** The equipment should be obtained and set up, including appropriate media, 2% tincture of iodine or povidone, alcohol swabs, tourniquet, syringe, and needles.

- C. The caps should be removed from the culture bottles and the stopper swabbed twice with alcohol.
- D. The venipuncture site (usually antecubital) should be selected. Starting at the puncture site, a circular area is scrubbed (radius approximately 2 inches) with povidone-iodine, using a circular motion with overlapping strokes and working toward the periphery. This is repeated once and allowed to dry. (With allergy to povidone-iodine, 70% isopropyl alcohol may be used for 1–2 minutes.)
- E. For better visualization of the actual puncture site, povidone-iodine should be cleaned off the vein site with one or two alcohol swabs, using the same “clean-to-dirty” circular motion.
- F. Venipuncture is carefully performed using the 10- to 20-mL syringe (for adults), taking care not to touch the needle or prepared skin site (a sterile glove may be used to palpate the site).
- G. The needle is removed from the vein (not touching the needle to skin). For adults, **5 to 10 mL is transferred, using the maximum amount suggested by the manufacturer**, into each broth bottle, or the appropriate volume is transferred into the recommended blood culture tube.
- H. The requisition is labeled with the **date and exact time of the culture. Blood drawn through intravascular catheters should be specifically identified.** This information is important in interpreting culture results.

Culture Techniques

- I. **Blood cultures** are indicated whenever there is suspected bacteremia or fungemia. In severely ill patients, blood cultures might be the only source demonstrating the causative agent.
 - A. **Blood culture methods.** Blood is placed into a broth medium or into an isolator tube in which the RBCs are lysed and the lysate is inoculated onto solid media [7].
 - 1. **Broth culture bottles** are electronically monitored on a nearly continuous basis and the information gathered is analyzed using sophisticated computer algorithms to determine when growth has occurred. The majority of positive results are detected within 48 hours, but most laboratories monitor cultures for 5 days before discarding [7].
 - a. **Types of bacteremia.** Continuous bacteremia occurs in endocarditis and other intravascular infections. Intermittent bacteremia is the most common form and occurs in many different infections. Transient bacteremia is self-limited and often follows the manipulation of nonsterile mucosal surfaces or infected tissues [8–10].
 - b. **Volume of sample.** The ideal volume for broth culture is unknown. Because of the low density of most bacteremias, 10- to 20-mL samples (e.g., 5–10 mL per bottle, depending on the manufacturer’s recommendation) for adults and 1- to 5-mL samples for children are recommended. A 1:5 to 1:10 dilution (or even higher [8–10]) of the blood appears to be best to reduce intrinsic serum antibacterial activity and to reduce the concentration of antimicrobials to subinhibitory levels.
 - c. **Timing and number of blood cultures.** Blood should be collected as soon as possible after the onset of fever or chills. **Two to three blood cultures, drawn at intervals of at least 20 minutes before antibiotics are initiated, are recommended both** because of the intermittent nature of most bacteremias and to establish continuous bacteremia [8–10]. (See discussions in Chapters 2 and 27A.)
 - d. **Media.** Many comparable broth media are available. Hypertonic media (usually prepared by the addition of 10% to 15% sucrose to a conventional broth media) appear to improve both the speed and overall recovery of certain organisms, especially organisms from patients being treated with antibiotics. In addition, resin devices and resin-containing media improve the recovery of organisms (staphylococci, in particular) from treated patients, but the usefulness is debated [7].

- 2. Blood lysis tubes.** Two forms—one designed for centrifugation and concentration of organisms and the other, a smaller pediatric tube, from which the contents can be plated directly onto solid media—permit quantitation of organisms in blood. This may be useful to distinguish intravascular catheter-related sepsis from sepsis originating at another site (see Chapter 20). It also results in increased recovery and decreased detection time for certain microorganisms, among them dimorphic fungi, mycobacteria, and *Bartonella species* [7]. Major disadvantages include a high contamination rate, poor recovery of anaerobic organisms, and greater cost.
- B. Fastidious organisms.** Blood cultures for brucellosis, tularemia, leptospirosis, systemic fungal infections, *Bartonella henselae* (formerly *Rochalimaea henselae*), the organism believed to be responsible for cat-scratch disease [see Chapter 21]), and *Mycobacterium avium* require special media and incubation for optimal isolation. The Isolator lysis-centrifugation system (Wampole Laboratories, Cranbury, NJ) has detected *B. henselae* and *M. avium* complex. Laboratories should be alerted to these possibilities for specific recommendations regarding collection and processing of the specimens [7–10].
- II. Special methods for bacterial culture**
- A. Tissue specimens** can be cultured quantitatively or qualitatively. The former may be helpful for burns. Criteria based on the number of organisms per gram of tissue have been established for the diagnosis of burn wound sepsis. **Touch preparations** and subsequent staining for appropriate microorganisms may be helpful (e.g., rapid diagnosis of *P. carinii* pneumonia by staining of touch preparations of lung biopsy specimens).
- B. Foley catheter tips should not be submitted** because they are invariably contaminated.
- C. Intravenous catheters** are cultured qualitatively or semiquantitatively, depending on the laboratory. One technique involves rolling the catheter on a **blood** agar plate and reporting the total number of colonies of organisms grown. To interpret these results, blood cultures must be positive. Using this approach, 15 colonies or more correlate with bacteremia caused by catheter infection, whereas fewer represent extraneous contamination [11]. The optimal laboratory diagnostic method to define catheter-related sepsis has not been established. See related discussion in Chapter 20.
- D. Genital tract cultures** are more likely to yield *N. gonorrhoeae* if transported within 6 hours or if inoculated directly onto a selective medium. Special devices containing a layer of agar in a dish to which a CO₂-generating tablet (Jembec) is added are available.
- III. Anaerobic cultures.** Most anaerobic bacteria of clinical importance are oxygen tolerant. Nevertheless, special anaerobic containers often are recommended for specimen transport. Rapid processing is important to avoid overgrowth by facultative anaerobes [12,13].
- A. Whenever possible, specimens should be aspirated** and transported to the laboratory in the syringe used for collection or via an oxygen-free transport system.
- B. Swabs are less desirable** because of inadequate sample size, air exposure, and sample desiccation. If swabs must be used, they should be placed in an oxygen-free transport system.
- C. Sites for anaerobic culture.** Because many body sites are colonized by anaerobic organisms, only certain sites are appropriate for culture (Table 25.1).
- D. A Gram-stained smear should be performed on all specimens submitted for anaerobic culture.** Because anaerobic cultures take considerable time for processing and identification, the Gram stain can provide useful clues regarding the infecting organisms. **Anaerobes should be considered when organisms are seen on smear but do not grow on routine aerobic cultures.** The unique morphologic features of anaerobes is a clue to the experienced observer. Pale, unevenly stained, pleomorphic gram-negative rods with rounded ends and bipolar staining suggest *Bacteroides fragilis*. Broad gram-positive rods, generally without visible spores, suggest *Clostridium perfringens*. Other *Clostridium* species may be thin and gram variable, with or without spores.

Table 25.1. Sites of Culture for Anaerobic Specimens

Appropriate Sites	Inappropriate Sites
Normally sterile bodily fluids; blood; bile; pleural, peritoneal, joint, and spinal fluid; surgical specimens from normally sterile sites	Specimens contaminated by indigenous anaerobic flora; sputum, throat swabs, fecal specimens, rectal and vaginal swabs
Abscess contents, deep-wound aspirates, surgical biopsy specimens	Superficial wound swabs, sites obviously contaminated by intestinal contents
Transtracheal or percutaneous lung aspirates	Sputum, bronchoscopy washings, nasopharyngeal or throat swabs
Suprapubic bladder aspirates	Voided or catheterized urine specimens
Culdocentesis fluid	Cervical or vaginal swabs

IV. Viral cultures. Clinical differentiation of the specific infecting virus may be difficult, if not impossible (see Chapter 8). The etiology of a viral syndrome can often be established by viral culture, serologic tests, or both. Table 25.2 outlines the appropriate specimens. Rapid diagnostic tests are discussed later under Direct Detection of Microbial Antigens in Clinical Specimens.

A. General guidelines

- Specimens should be obtained from patients early in the course of illness**, when virus shedding is greatest, preferably within 3 days after the onset of symptoms.
- Samples must be placed in viral transport media and transported promptly. Many specimens can be held at 4°C for up to 48 hours (even on wet ice) without decrease in virus recovery. For prolonged storage, specimens should be frozen at -70°C.
- Samples collected on swabs (conjunctival, pharyngeal, nasopharyngeal, rectal) should be placed quickly in a liquid viral transport medium provided by the laboratory.
- The type of specimen and clinical syndrome should be noted because different processing steps prior to attempted isolation are necessary for different types of samples.

B. Specimen collection and transport guidelines

- Blood.** Whole blood (anticoagulated with ethylenediaminetetraacetic acid [EDTA]) is used to obtain leukocytes for cytomegalovirus (CMV). Enteroviruses can be isolated from both serum and leukocytes. However, viremia usually is detected by molecular methods (e.g., HIV-1, hepatitis B and C viruses, CMV, Epstein-Barr virus, and enterovirus) [14,15].
- Nasal secretions.** A cotton swab on a fine wire is introduced through the anterior nares into the nasopharynx, or a cotton swab is inserted into each anterior naris and placed in a viral transport medium. **Nasal washings** (e.g., for respiratory syncytial virus [RSV]) are collected by instilling 4 to 5 mL of saline into each nostril while the patient extends his or her neck slightly and closes the posterior pharynx (by pushing against the *K* sound). The head is tilted forward, and a sample is collected in a clean container held beneath the nose.
- Pharynx.** A swabbing of the posterior pharynx should be accomplished by vigorously rubbing the swab over both tonsillar areas and the posterior pharyngeal wall.
- Vesicular fluid.** Without decontamination of overlying skin, lesion is aspirated with a small-gauge needle attached to a tuberculin syringe, or the vesicle is opened and fluids and cellular elements collected from the base onto a swab. If a crust is present, the crust should be lifted off; the fluid beneath the crust can then be swabbed.
- Cerebrospinal fluid.** The clinician should collect 1 to 3 mL into a sterile container.

Table 25.2. Viruses Associated with Specific Syndromes and Recommended Specimens for Viral Examination

Syndrome	Common Agents	Less Common Agents	Source of Specimen for Viral Examination
Upper respiratory tract infection	Influenza A, B Rhinovirus Parainfluenza 1, 3 Respiratory syncytial virus Adenovirus	Parainfluenza 2 Coxsackievirus A, B Echovirus Coronavirus	Nasal wash or aspirate Nose or throat swab
Lower respiratory tract infection			
Child	Respiratory syncytial virus Parainfluenza 3, 1, 2	Adenovirus Influenza B	Nasal wash or aspirate Nose or throat swab
Adult	Influenza A, B	Adenovirus	Sputum
Pleurodynia	Coxsackievirus A, B		Throat swab Stool
Central nervous system infection			
Meningitis	Coxsackievirus A, B Echovirus	HIV type 1 Lymphocytic choriomeningitis Mumps Arboviruses	Cerebrospinal fluid Throat swab Stool Cerebrospinal fluid
Encephalitis and encephalopathy	Herpes simplex virus type 1 HIV type 1 CMV	Mumps	Blood, brain biopsy
Myocarditis and pericarditis	Coxsackievirus B	Coxsackievirus A Influenza	Throat swab Stool
Gastroenteritis	Rotavirus Norwalk-like viruses	Adenovirus Calicivirus Astrovirus Coronavirus	Stool
Hepatitis	Hepatitis A, B, C		Blood
Urinary tract infection: acute hemorrhagic cystitis	Adenovirus 11 BK virus		Urine
Parotitis	Mumps		Throat swab
Exanthemas (nonspecific, with fever)	Coxsackievirus A9, A16 Echovirus 9, 16, 11	Echovirus 1-6, 14, 18, 19 Coxsackievirus A (2, 4, 23) Coxsackievirus B (1-5) Adenovirus Echovirus 9, 17	Skin vesicle fluid Throat swab Stool
Herpangina	Coxsackievirus A (1-6, 8, 10, 16, 22)	Coxsackievirus B	Skin vesicle fluid Throat swab Stool
Hand-foot-and-mouth disease	Coxsackievirus A Enterovirus 71		Skin vesicle fluid Throat swab Stool
Nonspecific febrile illness	HIV type 1 CMV EBV Enteroviruses Influenza A, B	Adenovirus	Urine (for CMV) Nose and throat swab Stool Blood

HIV, human immunodeficiency virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus. Adapted from Menegus MA, Douglas RG Jr. Viruses, Rickettsiae, Chlamydiae, and mycoplasmas. In Mandell GL, Douglas RG Jr, Bennett Jr, eds. *Principles and practice of infectious diseases*, 3rd ed. New York: Churchill Livingstone, 1990; with permission.

6. **Urine.** The patient provides 5 to 10 mL of a clean-catch, midstream urine into a sterile container, which is processed immediately or stored refrigerated. **Urine should never be frozen.**
 7. **Feces.** A 2- to 5-g sample is placed into a clean specimen container without transport medium. A cotton-tipped rectal swab (less satisfactory) is insert 5 cm into the rectum and gently rotated. In contrast to rectal cultures for the recovery of gonococci, some fecal material **should** be obtained when doing swabs for viral studies.
- C. **Viruses use living cells to support their replication.** Cell cultures, rather than eggs or laboratory animals for virus isolation, are used. Specimens are inoculated and incubated at 33° to 36°C for 2 to 14 days. Periodically, the cultures are examined microscopically for evidence of viral growth. Most viruses are detected within 7 days [14,15].
- V. **Mycobacterial cultures.** The major obstacle for recovering mycobacteria is the presence of large numbers of contaminating organisms. Prompt processing of individual fresh specimens is preferable to pooled samples, in which overgrowth of other microorganisms can occur.
- A. **Appropriate specimens are obtained** (Table 25.3).
 - B. If delays are anticipated, specimens should be refrigerated at 4°C. **If gastric specimens cannot be processed promptly, they should be adjusted to pH 7** with sodium bicarbonate so that the gastric acidity will not affect the viability of the organisms.
 - C. Because mycobacteria may be present in low numbers, multiple large-volume specimens should be cultured when possible (sputum, fluid [CSF and pleural fluid in particular]).
 - D. Sterile, wide-mouth containers with fitted caps should be used. Mycobacteria sometimes adhere to wax-coated surfaces; therefore, **waxed containers should be avoided.**
 - E. During collection and handling, care should be taken to avoid the production of infectious aerosols. **Specimens should be labeled clearly to indicate a possible biologic hazard.**
 - F. *M. tuberculosis* usually grows on conventional solid media (e.g., Lowenstein-Jensen) in 2 to 4 weeks, but cultures routinely are observed for 6 to 10 weeks before being reported as negative. A radiometric system for mycobacteria has significantly shortened the time required for the recovery of *M. tuberculosis* as well as other *Mycobacterium* species [2,3].
 - G. Most laboratories differentiate between *M. tuberculosis* or mycobacteria other than tuberculosis (MOTT) using molecular methods or a few simple biochemical tests. This usually is accomplished within days to 1 or 2 weeks of isolation. Complete speciation of MOTT usually is done in some larger laboratories; whereas others send such isolates to reference laboratories for speciation [2,3,14]. See related discussion in Chapter 11.
 - H. **Nucleic acid probes.** In some laboratories, *M. tuberculosis* and *M. avium* are identified specifically through the use of commercially available nucleic acid probes [2,3]. See section II under Nucleic Acid Methods for the Characterization and Direct Detection of Microbial Pathogens in Clinical Specimens later in this chapter.
 - I. **Susceptibility tests.** Owing to the recent emergence of multidrug-resistant *M. tuberculosis*, the past practice of not performing susceptibility tests has changed. The **Centers for Disease Control and Prevention (Atlanta) now recommends that initial isolates from all patients be tested for susceptibility to first-line antituberculous drugs** [2,3] (see Antimicrobial Susceptibility Testing, under Laboratory Guidance in Therapy).
- VI. **Chlamydiae.** Chlamydia trachomatis is an important cause of conjunctivitis, pneumonia in infancy, urethritis, cervicitis, and pelvic inflammatory disease. Chlamydiae, like viruses, are obligate intracellular parasites. Cultivation in living cells or by direct detection in clinical specimens using antigen, direct probe, or NAA assays assists in diagnosis [16,17].
- A. **Diagnostic methods.** Specimens for culture (e.g., sputum, cervical scrapings, urethral discharge) are placed in special transport media and delivered promptly.

Table 25.3. Specimens for Culture of Mycobacteria

Source	Recommended Number	Volume	Comments
Respiratory tract sputum	3	5–10 mL	Saliva inappropriate
Bronchoscopy washing (e.g., bronchoalveolar lavage)	1		See Chapter 9
Gastric washing	2–3	30–50 mL	Useful if respiratory secretions are not available; early morning specimens required before eating or activity; small volume of sterile water can be used in the tube placement (20–30 mL); requires rapid delivery (within 30–60 min) to microbiology laboratory to prevent inactivation of organism; stains may at times be helpful (saprophytes may cause false positive smears) (see Chapter 9)
Urine	2–3	Maximum volume of single specimen	Use first-voided midstream collections; avoid 24-h collection (too much bacterial overgrowth); stains may at times be helpful (saprophytes may cause false positive smears) (see Chapter 9)
Cerebrospinal fluid		Maximum volume available	
Other: joint, pleural, and peritoneal fluid		Maximum volume available	
Blood	1–2	10 mL	Useful for the recovery of <i>Mycobacterium avium</i> from patients with AIDS (see Chapter 19)

Chlamydia is demonstrated by staining with iodine, Giemsa, or fluorescent antibody 2 to 3 days after cell inoculation. NAA methods are now thought to be more sensitive than culture.

B. Direct detection of *C. trachomatis* in clinical specimens using antigen, direct nucleic acid probe, and NAA assays is now more widely available than cell culture.

1. Antigen assays are available in enzyme immunoassay (EIA) formats for laboratory use and in single test devices for office use. In addition, the elementary body of *C. trachomatis* can be detected in clinical specimens by direct immunofluorescence. In general, antigen assays are less sensitive than all other methods available for *Chlamydia* detection.

2. Direct probe assays are intermediate in sensitivity between antigen detection and NAA assays. The Gen-Probe Pace 2 is the most widely used. It offers the advantage of detecting both *N. gonorrhoeae* and *C. trachomatis* in the specimen.
3. A number of NAA assays are available, including the Roche PCR, Becton Dickinson strand displacement assay (SDA), Abbott ligase chain reaction (LCR), and Gen-Probe transcription-mediated amplification assay (TMA). The NAA assays are more sensitive than all other methods for *C. trachomatis* detection. However, problems with specificity have been reported [16]. NAA assays can be used to detect both *N. gonorrhoeae* and *C. trachomatis* in a single specimen as well as to detect the organisms in urine, which provides a convenient approach for screening patients for sexually transmitted diseases.

VII. Mycoplasma. Despite the clinical importance of *Mycoplasma pneumoniae* in respiratory infections, techniques to culture *M. pneumoniae* from clinical specimens are not widely available. This organism is slow growing, and positive culture results often are not available for 7 to 14 days. Therefore, serologic studies (cold-agglutinin titers or complement-fixing antibodies) are still most commonly used for diagnosis (see Chapter 11).

VIII. Tests for bacterial exotoxins

- A. **Exotoxins** are the major virulence determinant for a number of organisms. Well-known exotoxin-induced disease processes include tetanus, diphtheria, toxic shock syndrome, botulism, cholera, and diarrhea caused by *Clostridium difficile* or enterotoxigenic *Escherichia coli*. Most tests for bacterial toxins are complex and technically difficult. **With the exception of *C. difficile*, tests for bacterial toxin generally are performed only in reference laboratories** and only under special circumstances.
- B. *C. difficile* appears to cause up to 25% of antibiotic-associated diarrhea and plays an important role in the development of pseudomembranous colitis. A variety of assays are available, but tests based on demonstration of cytotoxic activity in cell culture that are sensitive and correlate with the presence of disease [18] are viewed as the gold standard.

Interpretation of Culture Results

I. Isolation of organisms. Microorganisms in culture do not necessarily represent infection.

- A. **Contamination** refers to the introduction of extraneous organisms into the culture during specimen collection or processing. They may originate from the skin of the patient, the clinician, or the technician, or from laboratory materials and the inanimate environment.
- B. **Colonization** of a body site is the **presence of organisms**, including potential pathogens, that are **not causing infection** (no evidence of illness, tissue invasion, or inflammation). Colonizing bacteria inhabit the oropharynx, skin, colon, vagina, and wound surfaces.
- C. **To determine the clinical significance of culture data, the clinician must interpret all culture results in the context of (a) the clinical condition of the patient, (b) the site cultured, (c) the method of specimen collection, and (d) the identity and quantity of organisms recovered.** See chapters on specific infections for further discussion; for example, wound infections in Chapter 4, and pneumonia in Chapter 11.

II. Failure to culture or detect a suspected pathogen can be caused by a number of factors; many are related to improper collection and transport.

- A. **Incorrect diagnosis** can occur. Infection may not be present or may be caused by organisms that are not cultured routinely (e.g., viruses, rickettsiae, or mycoplasmas).
- B. **Misinterpretations of Gram stain results** occur. Artifacts might be interpreted as organisms.
- C. **Specimens** that do not represent material at the infection site may be examined.
- D. **Improper technique or delayed transport of specimens** may cause overgrowth by indigenous flora or loss of anaerobes or fastidious organisms.
- E. **Antimicrobial therapy** prior to specimen collection may inhibit the growth of organisms.

F. Improper culture methods may be used. Special isolation techniques are necessary for anaerobes, mycobacteria, viruses, and certain fungi and bacteria. The physician must communicate with the laboratory so that appropriate cultures can be performed.

III. Preliminary identification of bacteria, although not definitive, may assist the clinician in early diagnosis and choice of empiric antibiotic therapy. Clinical microbiology personnel can provide guidance in the interpretation of preliminary results. In addition to the Gram stain, results of several tests often are available before an organism is finally identified [19,20].

A. Gram-positive cocci

1. **Blood agar hemolysis.** Streptococci produce various patterns of hemolysis.
 - a. **Beta hemolysis** is a clear, colorless zone surrounding colonies of group A (*S. pyogenes*), group B (*S. agalactiae*), and other less common streptococci.
 - b. **Alpha hemolysis**, or partial hemolysis, refers to a greenish zone surrounding colonies of *S. pneumoniae* and many species of viridans streptococci.
 - c. **Gamma hemolysis** actually denotes **nonhemolysis** and is observed typically with group D streptococci, including enterococcal and nonenterococcal species.
 - d. Note that the **Lancefield serogrouping** of streptococci (groups A, B, C, D, etc.), based on antigenic differences in cell wall carbohydrates, is an independent classification system that **should not be confused with the hemolytic patterns.**
2. **Catalase test.** The Gram stain often distinguishes between streptococci (chains or pairs) and staphylococci (clusters). If uncertain, a simple catalase test can be helpful. Hydrogen peroxide bubbles on exposure to catalase-positive organisms. Streptococci are catalase negative, and **staphylococci are catalase positive.**
3. **Coagulase test.** Coagulase-positive staphylococci produce an enzyme that coagulates rabbit plasma. A coagulase **slide test** can be performed in minutes but is less sensitive than an overnight coagulase **tube test.** Negative results of a coagulase slide test should be confirmed with a coagulase tube test. ***S. aureus* is coagulase positive;** *S. epidermidis*, *S. saprophyticus*, and other staphylococcal species test negative. Many laboratories have adopted latex agglutination tests in place of the traditional coagulase test for differentiation between *S. aureus* and other staphylococcal species.
4. **Nomenclature of gram-positive cocci** is a frequent source of confusion.
 - a. **Group A** β -hemolytic streptococci are *S. pyogenes*.
 - b. **Group B** β -hemolytic streptococci are *S. agalactiae*.
 - c. **Group D** streptococci include the following:
 - (1) Enterococcal species. The majority of clinical isolates of enterococci will be *Enterococcus faecalis* (80%–90%) and *E. faecium* (5%–10%). Infrequently, *E. avium*, *E. raffinosus*, and *E. gallinarum* are found.
 - (2) Nonenterococcal species (*S. bovis*). See Chapter 2, under Blood Cultures.
 - d. **Viridans group streptococci**, often referred to as strep viridans, encompass not just one but many species, including the *S. milleri* group (*S. anginosus*, *S. constellatus*, *S. intermedius*), *S. mitis*, *S. mutans*, *S. salivarius*, and *S. sanguis* [21].

B. Gram-negative bacilli

1. **Lactose fermentation.** MacConkey agar plates promote selective growth of gram-negative bacilli. Colonies of **lactose fermenters** (*E. coli*, *Klebsiella*, *Enterobacter*, and *Citrobacter*) appear red on MacConkey plates within 24 hours. **Nonlactose fermenters** (*Proteus*, *Serratia*, *Salmonella*, *Shigella*, *Pseudomonas*, and others) appear colorless or white. **Caution:** Although certain species are typically lactose fermenters (e.g., *E. coli*), some strains are nonlactose fermenters.
 2. **Oxidase test.** Oxidase reagent turns certain colonies purple. *Pseudomonas* species are oxidase positive and Enterobacteriaceae are oxidase-negative.
- C. Gram-positive bacilli** often are contaminants. At times, they may be true pathogens. These organisms can be spore forming or non-spore forming. The most commonly isolated non-spore-forming bacilli are diphtheroids—corynebacteria that normally inhabit the skin. However, when repeatedly isolated from normally sterile fluids or sites, they may be pathogenic (e.g., prosthetic device infection) [19]. When

isolated from blood or CSF, it is important to distinguish corynebacteria from another non-spore-forming bacillus, *Listeria monocytogenes*, which is motile at room temperature and may cause meningitis in newborn infants, immunocompromised hosts [19], and the elderly. The clinical significance of gram-positive bacilli and *Bacillus* species is reviewed in detail elsewhere [22]. (**Note:** Anaerobic gram-positive bacilli may be clostridial species.)

Direct Detection of Microbial Antigens in Clinical Specimens

Immunodiagnostic tests can detect microbial antigens in clinical specimens. The basis for all such tests is the reaction of an antibody with the target antigen in the clinical specimen.

- I. **Antigen detection methods** have successfully been applied to the diagnosis of virtually all classes of microorganisms: bacteria, fungi, parasites, and viruses (Table 25.4) [4,5,23,24].
- II. **There are advantages and disadvantages specific to each method.**
 - A. **Latex agglutination** tests generally are rapid (10–15 minutes) and can be performed by individuals with minimal training. However, in some cases, interpretation of the agglutination reactions may pose a problem for the unskilled reader.
 - B. **Immunofluorescent (IF) and immunocytochemical stains** (e.g., peroxidase, antiperoxidase) are especially useful for detecting and localizing virus-infected cells in infected organs and tissues. IF stains also are widely used to detect virus-infected cells in specimens from the respiratory tract, *C. trachomatis* elementary bodies in cervical and urethral discharge, and a variety of bacteria (e.g., *T. pallidum*, *Bordetella pertussis*, *Legionella* species) in clinical specimens.
 - C. **ELISAs (enzyme-linked immunosorbent assays)** have largely replaced their predecessors, the **radioimmunoassays**, as tools for antigen detection in clinical laboratories. Although some ELISAs remain complex and must be performed in the laboratory setting, a number of simple tests are now available in cassette or strip form that can be performed in the office with reasonable accuracy. Simple kits for group A β -hemolytic streptococci, rotavirus, RSV, and influenza viruses are commercially available and are as reliable as their more complex laboratory counterparts.
- III. **Monoclonal and polyclonal antibodies** are used as both capture and detector antibodies in antigen detection tests. Although monoclonal antibodies are not suitable for all tests, they are preferred because they represent a consistent and reliable antibody source.
- IV. The **sensitivity and specificity of antigen detection tests** varies depending both on the test and the target organism. **In general, they are not as sensitive or specific as culture**, but they often do produce results more rapidly and are a less expensive alternative than culture.
- V. **Clinical applications**
 - A. The sensitivity of immunodetection tests in patients with **meningitis** on initial evaluation of CSF ranges from 82% to 95% for *H. influenzae*, from 40% to 80% for *N. meningitidis*, and from 70% to 80% for *S. pneumoniae*. Unfortunately, they are less sensitive in gram-negative cases. Few laboratories now offer such testing (see Chapter 6) [23].
 - B. The rapid diagnosis of infections with *Legionella pneumophila* is important because cultures may take as long as 3 to 5 days to become positive. Unfortunately, the sensitivity of IF is low (25%–50%), and although its specificity is high, the generally low prevalence of disease compromises the predictive value of positive results [23] (see Chapter 11). The **Legionella urinary antigen test** was discussed in Chapter 11, section VI.F, under Specific Considerations and Specific Therapy, and has been reviewed recently [25]. The test, a commercially available EIA kit (Binax, Portland, ME) detects *L. pneumophila* serogroup 1 antigen in the urine. In a recent report, it proved useful for the diagnosis of legionella pulmonary infection [23,25,26]. Although the urinary assay detects only *L. pneumophila* serogroup 1, this serogroup causes about 80% of cases of Legionnaires disease [25,26]. Because antigen may persist for days to weeks after initiation of antibiotic therapy, the assay results may be positive when other diagnostic test results are negative; the test results could also be positive from a prior and no longer active infection.

Table 25.4. Microorganisms Commonly Detected in Clinical Specimens by Nucleic Acid Amplification Methods for the Diagnosis of Laboratory Infectious Diseases

Agent	Specimens	Uses	Comments
<i>Bordetella pertussis</i>	Nasopharyngeal	Diagnosis of pertussis	Significantly more sensitive than culture and FA
<i>Chlamydia trachomatis</i>	Genital tract specimens	Diagnosis	10%–30% more sensitive than culture Several FDA-cleared assays available
CMV	CSF, blood, ocular fluid, amniotic fluid	CNS infection, systemic infection, retinitis, congenital infection, preemptive therapy	Approximately twice as sensitive as culture for systemic infection Quantitative assays used to distinguish between disease and asymptomatic infection
EBV	CSF, blood	AIDS-associated primary CNS lymphoma, PTLD	Quantitative measures used to monitor for PTLD post-transplantation
Enteroviruses (coxsackie, ECHO, and poliovirus)	CSF, blood	Encephalitis, meningitis	30%–50% more sensitive than culture
Hepatitis B virus		Monitor therapeutic efficacy	
Hepatitis C virus	Blood	Diagnose active infection and monitor therapeutic efficacy	FDA-cleared qualitative assay available
HIV (RNA/DNA)	Blood (EDTA or ACD tube)	RNA: prognosis and monitoring therapeutic efficacy DNA: diagnosis of infected infants	Several FDA-cleared quantitative RNA assays in widespread use No FDA-cleared tests for diagnosis
HSV	CSF, ocular fluid, blood	Encephalitis, meningitis, acute retinal necrosis	Method of choice for CNS disease and acute retinal necrosis
JC virus	CSF	Progressive multifocal leukoencephalopathy	No other detection methods available
<i>Mycobacterium tuberculosis</i>	Sputum	Diagnosis in conjunction with culture	Same day diagnosis in >90% of smear-positive specimens Approximately 50% sensitive for smear-negative specimens FDA cleared for smear-positive sputum specimens
<i>Neisseria gonorrhoeae</i>	Genital tract specimens	Diagnosis	Specificity problems in CAP surveys
Parvovirus B19	Serum, amniotic fluid	Chronic infection in immunocompromised patients, aplastic crisis in patients with hemoglobinopathies, congenital infection	No culture methods available and serology insensitive in certain settings NAA additive diagnostically
<i>Toxoplasma gondii</i>	CSF, amniotic fluid, ocular fluid, tissue, blood, BAL	Toxoplasma encephalitis, retinitis, systemic infection, congenital infection	Culture insensitive and generally unavailable
VZV	CSF, ocular fluid, dermal lesions	Encephalitis, myelitis, congenital infection	Significantly more sensitive than culture in all settings

FA, fluorescent antibody; FDA, U.S. Food and Drug Administration; CMV, cytomegalovirus; CSF, cerebrospinal fluid; CNS, central nervous system; EBV, Epstein-Barr virus; AIDS, acquired immunodeficiency syndrome; PTLD, posttransplant lymphoproliferative disorder; HIV, human immunodeficiency virus; EDTA, ethylenediaminetetraacetic acid; ACD, citric acid; HSV, herpes simplex virus; CAP, community acquired pneumonia; NAA, nucleic acid amplification; BAL, bronchoalveolar lavage; VZV, varicella-zoster virus.

- C. The U.S. Food and Drug Administration (FDA) recently cleared a simple immunoassay that detects **pneumococcal antigen** in urine to aid in the diagnosis of pneumonia and meningitis. The test is similar to the antigen assay for *Legionella*, and its sensitivity in blood culture-positive cases is approximately 90%. The test is potentially useful because conventional methods for the diagnosis of pneumococcal disease are notoriously imperfect [23].
- D. More than 20 different commercial immunodiagnostic kits are available for the detection of **group A β -hemolytic streptococci** in pharyngeal specimens. When compared with culture, the sensitivity of such tests ranges from 60% to 90% or more, and the specificity generally is found to be in excess of 95%. Many clinicians recommend culture for all antigen-negative specimens because of the reports of low sensitivity [23] (see Chapter 8).
- E. ***Helicobacter pylori*** antibody assays are widely used as a screen in the management of patients with gastritis, but they do not distinguish between active and past infection. Detecting *Helicobacter pylori* antigens or DNA in feces (the latter via polymerase chain reaction) as alternatives to the ^{14}C breath test and biopsy/urease test is now being explored [23].
- F. Tests for **group B streptococcal antigen** are used to screen pregnant women to aid in the diagnosis of sepsis in the newborn. However, in 1997 the FDA issued a safety alert describing risks with such testing. The FDA warned of both false-positive and false-negative clinical test results. This warning prompted a substantial decline in their use [23].
- G. The most sensitive and specific test for *C. difficile* infection is the detection of the cytotoxin B in cell culture. However, the test takes 1 to 3 days to complete and requires cell culture facilities. Several ELISAs that detect toxin A or B in stool are also available. These assays have a sensitivity of 71% to 94% and a specificity of 92% to 98%. Because of the rapidity of testing and ease of performance, ELISAs for toxins A and B are now widely used by laboratories for diagnosis of *C. difficile* infection [23].
- H. **Influenza direct antigen tests** were briefly discussed in Chapter 10, section **V.B**, under Influenza. At least five assays in cassette format are available for the diagnosis of influenza, and two are Clinical Laboratory Improvement Act (CLIA) waived for office use [24]. Newer tests detect both influenza A and B. Nasopharyngeal washes or aspirates are preferred because they have more viral particles than do nasal or pharyngeal swabs. In patients in whom wash or aspirate techniques are contraindicated, swabs can be used. When positive, such rapid tests (which generally take less than 1 hour to perform) are very useful. The manufacturers generally report sensitivities of more than 80% and specificities of 95%. However, lower values have been reported in independent studies. Therefore, antigen-negative specimens should be cultured to provide greater sensitivity. By using a direct antigen test as an adjunct to culture isolation in nursing homes or the acute care setting, influenza often can be identified rapidly so that antiviral therapy and isolation measures can be initiated [24].
- I. Immunodiagnostic tests (IF and ELISA) for **RSV** now are used widely. Most have very good performance characteristics, with sensitivities and specificities in excess of 90% and 95%, respectively. In large measure, the good performance of such tests is due to gold standard deficiencies (cell culture growth) against which they are measured [24].
- J. The **CMV antigenemia assay** is used to measure CMV-infected leukocytes in blood. The assay is performed by first lysing RBCs and then depositing the leukocytes on a slide by cytocentrifugation. Leukocytes are stained with a CMV-specific monoclonal antibody. Results are expressed as the number of infected cells per total examined. The antigenemia assay is more sensitive than culture and slightly less sensitive than PCR [24].
- K. Antigen detection assays for ***Giardia* and *Cryptosporidium parvum*** alone and in combination are available in various immunoassay formats. The sensitivity of such assays is equivalent to traditional ova and parasite examinations. Many laboratories now use immunoassays in lieu of traditional methods for detecting these parasites because the latter are more labor intensive and require greater technical skill [4].

- L. The polysaccharide antigen of *C. neoformans* is readily detected in both the CSF and the serum in active infection. Properly controlled, the **sensitivity of the cryptococcal latex agglutination test approximates that of culture** [5] (see Chapters 6 and 18).

Nucleic Acid Methods for the Characterization and Direct Detection of Microbial Pathogens in Clinical Specimens

In recent years, nucleic acid techniques have been used to address a variety of problems in clinical microbiology. **Although many methods remain research tools, a number are already in use in clinical laboratories.**

- I. **Molecular epidemiology.** A variety of typing methods are used to determine if multiple organisms represent a single strain or unrelated strains. **Phenotypic typing schemes** use characteristics expressed by the organism, include biotyping, antimicrobial susceptibility testing, serotyping, phage typing, and multilocus enzyme electrophoresis. Strain relatedness also can be established with **genotypic methods** based on direct analysis of chromosomal and extrachromosomal DNA [27–29].
 - A. Genotyping services for outbreak investigation methods are now readily available through reference and public health laboratories but not routinely in clinical laboratories.
- II. **Nucleic acid probe assays** are based on the combination of labeled, single-stranded DNA or RNA molecules (probes) with single-stranded target nucleic acid. Several techniques, including filter, liquid, Southern blot, Northern blot, and *in situ* hybridization, are in common use. Probes are generally short nucleotide sequences, unique to a given organism or species that serve as a molecular fingerprint for identification [28].
 - A. **Nucleic acid probes can be used to directly detect a wide variety of microorganisms in clinical specimens.** The sensitivity and specificity of nucleic acid probe assays and antigen detection assays are generally similar. The most successful commercial probe systems are those for the direct detection of *N. gonorrhoeae* and *C. trachomatis* (Gen-Probe) [28] (see Chapter 16) and papillomavirus (Digene).
 - B. Nucleic acid probe–based tests are also used to identify organisms grown *in vitro*, to detect virulence determinants (e.g., toxins), and to localize antibiotic resistance determinants.
 - 1. *Mycobacterium* species probes for the rapid identification of mycobacteria are now widely used to identify acid-fast organisms grown on solid media or in liquid media. Probes are available for *M. tuberculosis*, *M. avium* complex (MAC), *M. kansasii*, and *M. goodii*. *M. tuberculosis* frequently can be identified in less than 2 weeks from the time of specimen collection. Mixed infections (e.g., *M. tuberculosis* and MAC) can likewise be identified [28] (see Chapter 11).
 - 2. Probes also have simplified the identification of the dimorphic fungi, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*.
 - C. The VERSANT HCV RNA 3.0 assay is a sandwich nucleic acid hybridization assay for the direct quantitation of RNA in human serum and plasma.
- III. **Nucleic acid amplification assays.** In the mid-1980's, **PCR** was introduced. The usefulness of PCR as a tool for detecting microorganisms was immediately obvious, and because commercialization of PCR was restricted by patent, alternative strategies for NAA and nucleic acid detection were developed. The FDA-cleared NAA products now available are described below. In addition, many laboratories offer “home brew” PCR assays for infectious diseases. Such assays are devised and validated by the laboratory performing the assay. Significant variation in laboratory performance in proficiency test panels has been observed in blinded, interlaboratory comparisons. When the results of NAA testing are used clinically, the limitations of NAA assays, particularly home brew assays, should always be considered.
 - A. Using the **PCR**, more than 1 billion copies of DNA can be made from a single target segment of DNA or RNA (**reverse transcriptase (rt) PCR**). The amplified product can then be detected by any one of a number of methods. The specific advantage of the PCR is its enormous sensitivity. However, the sensitivity of PCR is also its Achilles heel. Contamination resulting in false-positive results should always be considered.

1. The **Roche Amplicor PCR** is the most widely used NAA technology. FDA-cleared kits are available to qualitatively detect *C. trachomatis*, *N. gonorrhoeae*, *M. tuberculosis*, and HCV in clinical specimens.
 2. **Amplicor monitor** assays are designed to quantify virus in plasma. Amplicor monitor assays are now widely used to evaluate therapeutic efficacy in patients infected with HIV and HCV.
 3. Several fully automated versions of Amplicor assays, **COBAS Amplicor** assays, are available. Their performance is similar to their semiautomated counterparts.
 4. **Real-time PCR** measures the product of the PCR reaction as it is formed. A number of larger clinical laboratories now use the **Light Cycler** instrument, a capillary PCR device, to perform both quantitative and qualitative PCR assays.
- B. The Gen-Probe transcription mediated amplification assay (TMA)** isothermal nucleic amplification process, like PCR, can be used to detect both DNA and RNA. The current FDA-cleared menu includes direct tests for *M. tuberculosis* and *C. trachomatis*.
- C.** The second-generation **thermophilic strand displacement amplification (tSDA)** assay was designed by Becton Dickinson. Originally limited to the detection of DNA, the assay has recently been modified and can now be used to detect both DNA and RNA. The tSDA tests, known as **Probe Tec assays**, presently cleared by the FDA include only direct tests for *N. gonorrhoeae* and *C. trachomatis*.
- D.** The **LCR** is the DNA amplification technology developed by Abbott Laboratories. Currently it is the only FDA-cleared LCR assay for the direct detection of *N. gonorrhoeae* and *C. trachomatis*.
- E. Nucleic acid sequence-based amplification (NASBA)** is used to amplify RNA targets and mRNA expression targets. NucliSens assays, NASBA-based amplification assays, formerly marketed by Organon Teknika, are now marketed by bioMérieux. The NucliSens HIV-1 QT assay was recently cleared by the FDA for viral load monitoring.

SERODIAGNOSTIC AND IMMUNE STATUS TESTS

When attempts to recover an infectious agent are unsuccessful or impractical, or when culture techniques or facilities are not available, **serologic studies** frequently are used to provide a specific diagnosis. Unfortunately, serologic diagnoses often are retrospective, and therapeutic decisions must frequently be made before the serology results are available. Examples of infectious diseases that commonly are diagnosed by serologic methods are syphilis, rubella, *M. pneumoniae*, leptospirosis, toxoplasmosis, Lyme disease, and infectious mononucleosis.

- I. General principles. Interpretation** depends on determination of antibody titers in blood.
 - A. Many different assay techniques exist** for demonstrating antibody titers in various infections. Whether antibody is measured by agglutination, complement fixation, neutralization, ELISA, or other techniques depends on the nature of the antigen, the availability of the assay and, most important, the ability of a given serologic technique to detect antibody. For certain infections such as rubella, the titers obtained with different antibody tests can be used to help assess the likelihood of recent infection.
 - B. Clotted blood specimens** are acceptable for most serologic tests. Blood should be collected in tubes without anticoagulant and can be refrigerated for 2 or 3 days prior to testing. If longer delays are anticipated, the serum should be frozen at -20°C .
- II. Clinical applications are for** diagnosis of acute infection and immune status determination.
 - A. Diagnosis of acute infection** usually is accomplished by comparing acute and convalescent sera pairs. Occasionally, a single acute-phase serum or a single convalescent-phase serum also can be used to diagnose acute infection.
 1. **Paired sera.** Using acute and convalescent sera, a conversion from seronegative to seropositive or a fourfold or greater increase in antibody titer is considered indicative of recent infection. A single blood specimen containing antibody to a

specific antigen may indicate that the patient has had prior exposure to that antigen or to a cross-reacting one. **In most cases, single titers are difficult to interpret.**

- a. **Acute-phase serum** should be obtained as early in the course of the illness as possible. In any patient hospitalized with an undiagnosed febrile illness, a 5-mL serum specimen should be frozen for potential use as an acute-phase serum in future serologic studies. It can be discarded if not needed. Blood should be collected aseptically and, to avoid lipemia, preferably during fasting.
 - b. **Convalescent-phase serum** should be collected at least 10 days, but preferably 2 to 4 weeks, after the onset of the illness. **For testing to be valid, both the acute and convalescent sera should be analyzed simultaneously.**
2. **A single acute-phase serum may be helpful diagnostically in some cases.** Immunoglobulin M (IgM) antibody typically develops early during primary infection, persists for several weeks, and then becomes undetectable. Therefore, commercial kits are now available for detecting IgM to hepatitis A virus and to rubella virus.
 3. **Use of a single convalescent-phase serum.** For example, a presumptive diagnosis of *Legionella* is made on the basis of a single elevated indirect fluorescent antibody titer (1:256 or greater), because high titers persist only transiently after infection.

B. Immune status testing of an individual may be important in certain situations. For example, rubella vaccine is recommended for seronegative women of childbearing age as a means of preventing congenital rubella syndrome. Because of the complexity and variety of serologic tests now available, communication with the microbiology laboratory or infectious diseases unit prior to ordering a test is often essential to ensure that the maximum amount of useful information is obtained from the test. **Chapters on individual infectious diseases should be consulted for specific serologic testing.**

LABORATORY GUIDANCE IN THERAPY

The two general types of laboratory tests used as aids in therapy are *in vitro* tests that assess the susceptibility of the infecting organism to various antimicrobial agents and the measurement of antimicrobial concentration or activity in serum or other bodily fluids [18,19,31,32].

Antimicrobial Susceptibility Testing

I. Disk diffusion test (Kirby-Bauer). Worldwide, the most widely used method for testing the activity of antimicrobials against bacteria is the disk diffusion test (also called the **agar diffusion test**). Although dilution tests are believed to be more exact, the Kirby-Bauer disk diffusion test is the initial susceptibility test used in most laboratories. It has ease of performance, reproducibility, and proven value as a guide to antimicrobial therapy.

A. Method. Paper disks impregnated with a standardized quantity of antimicrobial agent are applied to the surface of an agar plate that has been inoculated with a suspension of the organism to be tested. The antimicrobial agent diffuses through the agar in a continuously decreasing gradient. After 16 to 20 hours of incubation, a concentric zone of growth inhibition around the paper disk is measured. In general, large zones are associated with susceptibility to the antibiotic, and small or absent zones with resistance. Standards for interpretation of the zone sizes have been based on susceptibility or resistance by broth or agar dilution tests. The disk diffusion test is applicable only to rapidly growing organisms such as the Enterobacteriaceae and *Staphylococcus* and *Pseudomonas* species. Its reproducibility depends on strictly standardized methods.

B. Clinical application. Disk diffusion susceptibility testing is indicated for clinically significant isolates that have unpredictable sensitivity patterns, such as the Enterobacteriaceae and *Staphylococcus* and *Pseudomonas* species. Susceptibility testing also is indicated for any isolate from normally sterile bodily fluids such as blood and CSF. Disk diffusion testing need not be performed routinely for organisms

that are uniformly sensitive or resistant to a particular antibiotic; for example, group A streptococci and *N. meningitidis* are uniformly sensitive to penicillin G.

C. Interpretation. A three-category system of reporting results often is used.

1. **Susceptible (sensitive)** implies that an infection due to the tested strain should respond to an appropriate dose of the antibiotic recommended for that type of infection.
2. **Resistant** indicates that the strain is not completely inhibited by antimicrobial concentrations within the therapeutic range, and it strongly predicts antibiotic failure.
3. **Intermediate** indicates that a clinical response may occur if unusually high concentrations of relatively nontoxic antibiotics can be achieved at the site of the infection. **For most situations, however, a strain classified as intermediate should be considered resistant until proven otherwise.** If clinical circumstances favor the use of that particular antimicrobial, dilution susceptibility testing may be performed to determine the actual sensitivity or resistance of the organism to the drug. **Some laboratories will routinely report all intermediate zones of inhibition as resistant.**

D. Limitations

1. **For some organisms, the disk diffusion method is not applicable.**

- a. Organisms that are fastidious, slow growing, or have special growth requirements (e.g., anaerobes) cannot be tested. See section IV.
 - b. Mycobacterial and fungal susceptibility testing requires specialized techniques that are usually available only in reference laboratories.
 - c. Normal flora of nonsterile body sites are not routinely tested.
2. Special techniques may be required to detect penicillin-resistant *S. pneumoniae*, oxacillin-resistant (or methicillin-resistant) *S. aureus*, and aminoglycoside resistant or penicillin-resistant enterococci. See Chapter 27 and the E test in section III.B.
 3. Disk diffusion testing may indicate *in vitro* susceptibility, despite lack of therapeutic efficacy in actual practice. Examples are *Salmonella typhi* susceptibility to aminoglycosides and enterococcus susceptibility to cephalosporins.
 4. **Standards for interpreting zones of growth inhibition are based on achievable serum levels of antimicrobials. Disk diffusion testing, therefore, is not always applicable to urinary tract isolates, because the achievable levels of certain antibiotics in urine are much higher than in serum [33].** For example, an enterococcal isolate resistant to ampicillin by disk diffusion testing may nevertheless be successfully treated with ampicillin if the infection is limited to the urinary tract.
 5. Certain antibiotics cannot be accurately tested (e.g., methenamine mandelate and the polymyxins).
 6. Bactericidal activity cannot be tested because the disk diffusion method yields bacteriostatic data only.
 7. **Simple matching of antibiotic to infecting organism susceptibility pattern is a superficial approach to therapy.** The disk diffusion test is only one aid to assessing potential response of the infection. Host defense mechanisms; site of infection; underlying illnesses; route, dose, and penetration of the antibiotic into the infected site; and duration of antibiotic therapy must always be considered (see Chapter 27A).

II. Dilution susceptibility tests are used to determine the **minimum inhibitory concentration (MIC)** and the **minimum bactericidal concentration (MBC)** of an antibiotic for an infecting organism. The **MIC is defined as the lowest concentration of drug that prevents visible growth of the test organism** under a standardized set of conditions (Fig. 25.1). The **MBC of the drug is the lowest concentration that results in 99.9% killing** of the initial inoculum under standardized conditions. The MIC and MBC are usually expressed in micrograms of antibiotic per milliliter. This testing can be done by a broth dilution or agar dilution method.

A. Methods

1. **Broth dilution tests.** Serial, twofold dilutions of an antimicrobial are incorporated into broth-containing tubes, which are then inoculated with a standard

FIG. 25.1 Dilution susceptibility testing for minimum inhibitory concentration and minimum bactericidal concentration determination.

number of organisms, usually 10⁵ to 10⁶ colony-forming units (CFU) per milliliter. After the culture has been incubated at 35°C for 16 to 20 hours, the tubes are inspected for visible growth. Rapid techniques are also available (see section E.) to determine the MIC. If the tubes with no visible growth are subcultured quantitatively to a drug-free medium, the MBC of the antimicrobial can be determined, as indicated in Figure 25.1. **Microdilution susceptibility** testing employs the same principles but uses wells on a microtiter tray rather than dilution tubes, permitting automation.

2. **The Agar dilution test** is similar to the broth technique except that the antibiotic dilutions are incorporated into a solid medium and the inoculum, usually 10⁴ CFU/mL, is applied as a spot to a small portion of the agar plate. The MIC is the lowest antibiotic concentration that prevents visible growth. The MBC cannot be determined.

B. Clinical application. Several commercially manufactured **semiautomated systems are now available that permit routine MIC determinations for all clinically significant bacterial isolates. If not routinely performed, dilution susceptibility testing (MIC and MBC determinations) should be considered in the following situations.**

1. Disk diffusion has yielded intermediate susceptibility to an antibiotic (e.g., an aminoglycoside) chosen to treat a serious infection.
2. Complicated or life-threatening infections exist owing to organisms with an unpredictable susceptibility pattern.
3. Serious infections are caused by organisms susceptible only to relatively toxic agents.
4. Determination of a bactericidal end point is desirable, as in endocarditis.

5. Disk diffusion results are unreliable, as with fastidious or slow-growing organisms.
 6. An infection has failed to respond to an antibiotic, despite disk susceptibility.
- C. Interpretations.** The MIC of an organism may be useful in selecting an antibiotic that will be active against that organism at the site of the infection. Generally, if an antibiotic tissue level exceeds its MIC for the responsible organism, the infection should respond. A blood level that exceeds the MIC twofold to eightfold is a commonly accepted guideline. See time-dependent and concentration-dependent bactericidal activity in Chapter 27.
- D. Limitations**
1. Dilution tests for MIC and MBC often are more expensive and technically demanding.
 2. Lack of interlaboratory standardization makes interpretation difficult.
 3. The practitioner may experience difficulty in interpreting the MIC and MBC results. Assessment of susceptibility or resistance depends on a knowledge of the antibiotic levels achievable at the site of infection. For example, an MIC of piperacillin of 16 $\mu\text{g}/\text{mL}$ to *Pseudomonas aeruginosa* may appear to be a high value, but a 3-g intravenous dose of piperacillin results in peak serum levels greater than 100 $\mu\text{g}/\text{mL}$. Conversely, an MIC of penicillin G of 0.5 $\mu\text{g}/\text{mL}$ to viridans streptococci may appear to indicate susceptibility, but clinical experience has documented that endocarditis due to viridans streptococci with this MIC often fails penicillin therapy.
- E. Rapid versus conventional MIC methods.** In the past several years, a variety of instrument-assisted identification and susceptibility test methods have been developed that permit generation of test results in a period of 6 to 9 hours, as opposed to the 15- to 24-hour time frame required with traditional overnight methods [33a]. These newer “rapid” methods generally have been shown to provide test results nearly as accurate as those derived from traditional overnight tests, but the newer tests are more expensive [33a]. The clinical impact of this newer technology and whether it truly facilitates faster and more cost-effective patient care is undergoing clinical study. One study suggests the rapid tests have a positive impact on patient care [33a].
- III. Antimicrobial concentration gradient methods** combine features of disk diffusion and dilution susceptibility testing.
- A. The spiral gradient endpoint method** uses an agar plate containing a continuous gradient of antibiotic concentration from the center of the plate to the edge; the test organism is applied to the plate in a radial streak, and the MIC is determined by measuring the distance of growth from the edge of the plate.
- B. The E test** (AB Biodisk, Solna, Sweden) is based on the diffusion of a continuous concentration gradient of an antimicrobial from a plastic strip into an agar medium. In 1988 this technique was created to overcome several of the disadvantages of the disk diffusion and dilution techniques and also to retain the principle of the agar dilution method by producing an accurate, reproducible, quantitative MIC result [33b] (Fig. 25.2).
1. **Procedure**[33b]
 - a. An inert thin plastic carrier strip with a predefined continuous concentration gradient of stabilized antibiotic on one side and a continuous MIC interpretive scale corresponding to a range of 15 \log_2 dilutions on the other side is used.
 - b. After an agar plate is inoculated with a broth suspension of the test organism, four to six E strips can be placed on the plate, which is incubated.
 2. **MIC result.** After incubation, an ellipse of inhibition is formed around the strip, and the MIC is read at the point where the ellipse intersects the strip edge (see Fig. 25.2). Studies evaluating E test performance compared with routine susceptibility testing methods have demonstrated excellent agreement [33b].
 3. **Potential uses.** The role the E test will play in microbiology laboratories awaits further clinical study. However, it appears to be useful especially for *in vitro* susceptibility testing of organisms for which there is not a “routine” or “standardized” approach or for **fastidious organisms**. Examples include

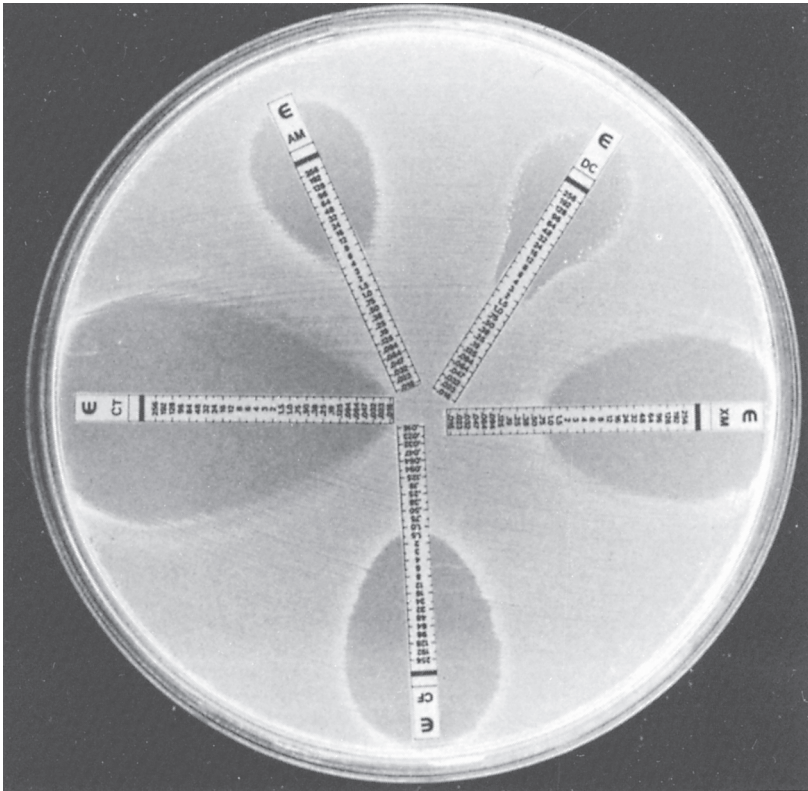

FIG. 25.2 E tests with a β -lactamase-producing *Haemophilus influenzae* strain performed with HTM agar. Antibiotic abbreviations on the E-test strips and minimum inhibitory concentration interpretations (indexed to base 1) are as follows: AM, ampicillin, 8 $\mu\text{g}/\text{mL}$; DC, doxycycline, 4 $\mu\text{g}/\text{mL}$; XM, cefuroxime, 1 $\mu\text{g}/\text{mL}$; CF, cefaclor, 2 $\mu\text{g}/\text{mL}$; CT, cefotaxime, 0.015 $\mu\text{g}/\text{mL}$. (Reprinted from Jorgensen JH, et al. Quantitative antimicrobial susceptibility testing of *Haemophilus influenzae* and *Streptococcus pneumoniae* by using the E test. *J Clin Microbiol* 1991;29:109, with permission.)

S. pneumoniae [33c], *H. influenzae*, *Neisseria* species, anaerobes (see section IV.B), enterococci, methicillin-resistant *S. aureus*, and testing for the presence and susceptibility of extended-spectrum β -lactamase-producing organisms.

4. Its major drawback may be its relatively higher cost when compared with currently available susceptibility tests. However, in certain clinical situations (e.g., in the isolation of *S. pneumoniae* from a normally sterile bodily fluid), this appears to be an easy and useful technique to determine whether the clinical isolate is susceptible, intermediately susceptible, or resistant to penicillin (see Chapter 27C).

IV. Susceptibility testing of anaerobic bacteria is not routinely available in most hospitals. In recent years, however, anaerobic susceptibility patterns are known to be less predictable than once was believed [34]. For example, 10% or more of *B. fragilis* infections may be resistant to clindamycin in many institutions [35,36]. Hospitals may elect to monitor susceptibility patterns periodically to guide antibiotic use [18,36a].

A. Susceptibility testing of specific anaerobic isolates can assist in the management of patients with selected infections [34,37], as follows:

1. **Serious anaerobic infections** such as brain abscess, empyema, bone and

joint infections, or endocarditis, especially when the anaerobe is isolated in pure culture

2. Anaerobic infections that persist or recur despite presumed appropriate empiric antibiotic therapy directed at anaerobes

B. Methods of anaerobic susceptibility testing [18,19,31,34]

1. Agar dilution susceptibility tests are performed in reference laboratories but are time consuming and impractical for most clinical microbiology laboratories.

2. Broth microdilution tests are manageable for clinical laboratories. Microdilution trays are commercially available.

3. Antimicrobial density gradient methods (e.g., the E test) are applicable to anaerobes and are simple to perform (see section **II.B**). Although expensive, these simpler tests may play an increasing role in the hospital laboratory. The E test compared favorably with the reference agar dilution method in a recent study [37a].

4. Determination of β -lactamase production. Laboratories unable to perform susceptibility tests may assay gram-negative anaerobes for β -lactamase activity, which indicates resistance to penicillins and cephalosporins. A commercial disk test is available. However, a negative result must be interpreted with caution, because resistance to β -lactam antibiotics also may be mediated by mechanisms other than β -lactamase production.

V. Susceptibility testing of antibiotic combinations *in vitro* attempts to identify antibiotic combinations that are superior to single agents (see Chapter 27A, under Principles of Antibiotic Use). A combination of antibiotics is considered to be synergistic when the effect of the combination is greater than the sum of the independent effects of each agent and antagonistic when the combined effect of the two antibiotics is less than the effect of each single antibiotic [31,38].

Such testing has been advocated for certain situations such as *P. aeruginosa* sepsis in the immunocompromised patient [39,40]; but the techniques used to assess antibiotic synergy lack interlaboratory standardization and are cumbersome and often expensive.

VI. Beta-lactamase test

A. Principle and technique. Resistance of *H. influenzae* and *N. gonorrhoeae* to the penicillin class of antibiotics may be due to plasmid-mediated β -lactamase enzymes. The development of rapid assays for β -lactamase permits an assessment of sensitivity before standard susceptibility testing results are available. Rapid acidometric, iodometric, and chromogenic cephalosporin methods are used to detect β -lactamase. Bacteria can be tested after overnight growth, and results usually are available within 30 minutes [19].

B. Clinical application

1. *H. influenzae* infections will not respond to ampicillin if the strain produces β -lactamase. Rapid testing for β -lactamase should be performed, and ampicillin should not be used if the test result is positive but can if the test result is negative. However, certain rare strains are negative by β -lactamase testing but are resistant to ampicillin by disk diffusion testing. Therefore, ideally, a negative β -lactamase test result (implying ampicillin sensitivity) should be confirmed by disk diffusion testing.

2. *N. gonorrhoeae* strains. Because of the high prevalence of β -lactamase-positive *N. gonorrhoeae* in the United States, treatment with a regimen (e.g., ceftriaxone) active against resistant strains of gonorrhea is required [41]. **Note:** Absence of β -lactamase does not guarantee susceptibility of *N. gonorrhoeae* to penicillin, because some strains may possess chromosomally mediated resistance to penicillin, which is independent of β -lactamase production (see Chapter 15).

VII. Susceptibility testing of *M. tuberculosis* is essential to the selection of appropriate antibiotic therapy, especially in the setting of increased prevalence of multidrug-resistant tuberculosis. Testing is performed on solid media or a radiometric method in liquid media (BACTEC system). In the proportion method (2–3 weeks after isolation), susceptibility is defined as growth on drug-containing medium that is less than 1% of growth on control medium. The radiometric BACTEC system measures and compares growth, by release of carbon 14, in a drug-containing vial compared with growth of the

same organism in a control vial. Results may be available within 1 week after isolation of the organism. Isoniazid, rifampin, ethambutol, and streptomycin are tested in hospital laboratories; reference laboratories perform testing for pyrazinamide, cycloserine, ethionamide, and fluoroquinolones. Susceptibility testing of mycobacteria other than *M. tuberculosis* is less commonly performed, and correlations between *in vitro* drug susceptibility of these species and *in vivo* response to therapy are not well established [42,42a]. See Chapter 11, section IV. A.

VIII. Fungal and viral susceptibility testing is not routinely performed in clinical laboratories. Testing methods and interpretive criteria are not well standardized, and these tests are considered experimental. Infectious disease consultation is advised.

Monitoring Antimicrobial Therapy

Two types of *in vitro* tests are used to monitor antimicrobial therapy: measurement of blood or bodily fluid inhibition of the responsible organism, and assay of antibiotic concentrations.

I. The serum bactericidal test determines the “killing power” of patient serum against the infecting organism. The result is expressed as the highest dilution of serum that kills and is shown schematically in Figure 25.3. **The serum inhibitory or bacteriostatic activity** is the highest dilution of serum that demonstrates a visible inhibitory effect. **The serum lethal or bactericidal activity** is similarly expressed as the highest dilution that produces a lethal effect, usually defined as a 99.9% or greater reduction of viable organisms in the initial inoculum. Bodily fluids such as CSF, urine, and synovial fluid also can be tested.

A. Standards

1. **Variables that influence interlaboratory standardization in the performance of these tests make it difficult to compare results between studies** [43,43a].
2. **Timing of sample.** Several investigators favor collection of the serum sample at peak, whereas others prefer trough levels. This remains controversial [43].

B. Clinical application. The test is the most reliable *in vitro* correlate of actual *in vivo* conditions because it accounts for other components of the antibacterial

FIG. 25.3 Dilution susceptibility testing for serum inhibitory and serum lethal activity. Serum minimum inhibitory concentration = 1:16; serum bactericidal concentration = 1:8. (Adapted from Sommers HM. Drug susceptibility testing in vitro—monitoring of antimicrobial therapy. In: Youmans GP, Paterson PY, Sommers HM, eds. *The biologic and clinical basis of infectious diseases*, 2nd ed. Philadelphia: WB Saunders, 1980, with permission.)

activity of serum in addition to the antibiotic (i.e., serum complement, opsonins, lysozymes). However, clinical applicability of the serum bactericidal titer remains to be proven rigorously [18,43,44]. **Infectious disease consultation is advised. A determination of serum bactericidal activity may prove useful in guiding therapy, particularly in the following situations:**

1. **Endocarditis.** However, the results are not necessarily predictive of survival or clinical cure, and the peak and trough bactericidal titers that best correlate with outcome are not yet clear [43,43a,45]. Although a peak titer of at least 1:8 is most frequently recommended, one study concluded that a peak titer of 1:64 or more and a trough titer of 1:32 or more were most predictive of cure; the test was a poor predictor of failure [46].
 - a. The organism is not highly sensitive to the antibiotics being used, and a synergistic combination of antibiotics might be more effective; less well established treatment regimens are used when the patient fails to improve on standard therapy; the serum bactericidal titer is high and drug toxicity is a significant risk; or the drug dose might be reduced without compromising antibacterial effect.
 - b. In acute and chronic **osteomyelitis**, serum bactericidal titers that exceed certain levels have been correlated with cure [47]. When changing to oral therapy of acute osteomyelitis in children, antibiotic doses are adjusted to achieve a bactericidal level of 1:8 or more [43a]. The usefulness in adults, remains uncertain.
 - c. In the **immunocompromised host**, maintaining an appropriate antibiotic level is correlated with successful outcome in bacteremia and soft-tissue infections [48].
 - d. For patients with acute pulmonary exacerbations of **cystic fibrosis**, peak serum bactericidal titers of 1:128 or greater against the patients' pulmonary pathogens have been correlated with favorable bacteriologic responses to therapy [49].

II. Antimicrobial levels may be obtained to assess the adequacy of the chosen dose and route of administration and to avoid toxicity [19].

A. Methods

1. **Correct timing of samples is necessary for accurate interpretation of the significance of antibiotic levels. Samples are collected without anticoagulant.**
 - a. **Peak blood levels** usually are obtained 1 hour after an intramuscular dose, 30 minutes after an intravenous infusion is over, or 1 to 2 hours after an oral dose. In renal failure, peak levels may be delayed 2 to 4 hours after an intramuscular or 1 hour after an intravenous dose.
 - b. **Trough blood levels** are obtained immediately before the next dose is due.
 - c. **Rapid processing is critical** (e.g., gentamicin is inactivated by penicillins).
 - d. The **requisition** should include the drug to be tested, other antibiotics, and timing of sample.
2. **Techniques for assay of antibiotic levels.** Bioassays (agar diffusion and broth dilution) have been largely supplanted by a variety of more accurate and reproducible methods (e.g., immunoassays and high-pressure liquid chromatography).
 - a. **Bioassays** use parallel dilution of both antibiotic standards and the patient's bodily fluid. This method cannot differentiate between the effects of two or more antibiotics in a bodily fluid. **Therefore, it is essential to submit information about combination antimicrobial therapy so that the laboratory might be able to circumvent the problem by technical manipulations** (e.g., add β -lactamase to inhibit penicillins, use multidrug-resistant indicator organisms, or remove antibiotics with cation-exchange resins). **Most bioassay systems are not as precise as other types of assays**, but the precision is adequate for clinical use.
 - b. **Immunologic assays** are presently the **most widely used**, and have gained widespread acceptance because they are rapid, accurate, specific, and easier to perform than bioassays. **Aminoglycoside** and **vancomycin** levels now are routinely available in many laboratories using the immunoassay method.

c. High-pressure liquid chromatography is a method for separating compounds; quantitation is subsequently achieved by analysis of the separated compounds. Liquid chromatographic procedures have been developed to measure almost all antibiotics in clinical specimens but are used most widely for chloramphenicol because no suitable immunoassay has been developed for this drug. Immunoassays generally are favored because they are simpler to perform.

B. Clinical application. Antibiotic levels may be considered in the following situations:

1. Pneumonia and bacteremia due to gram-negative organisms may respond more favorably to treatment when therapeutic plasma levels of aminoglycosides are achieved [50,51]. A high peak concentration of aminoglycoside relative to the MIC for the infecting organism has been correlated with improved clinical response to therapy [52]. For further discussion of the role of aminoglycoside levels, see Chapter 27I.
2. An antibiotic could have toxic side effects, particularly in the presence of altered hepatic or renal function (e.g., aminoglycosides; see Chapter 27I).
3. **An infection due to a sensitive organism may not respond to antibiotic treatment** and all other therapeutic approaches have been optimized.

C. Interpretation. It is anticipated that an infection will respond if a level of antibiotic greater than the MIC of the infecting organism can be achieved at the site of infection. However, factors other than an absolute serum level may be important (e.g., magnitude of level in comparison to MIC, duration of level above the MIC, and effect of serum protein binding). Other therapeutic modalities must always be optimized (e.g., draining abscesses, removing foreign bodies, and bolstering host defense mechanisms). See **time-dependent and concentration dependent bactericidal activity** in Chapter 27A).

26. INFECTIOUS DISEASE ASPECTS OF EMPLOYEE (OCCUPATIONAL) HEALTH: A BRIEF OVERVIEW

Keith A. Rosenbach, Sally H. Houston, John T. Sinnott,
and JoAnn Palumbo Shea

EMPLOYEE HEALTH AND SAFETY

Health-care workers (HCWs) are an important link in the control of infection. Many states already regulate minimal health and immunization requirements for employment in health-care facilities. A comprehensive employee health program should be developed using guidelines and regulations from the Centers for Disease Control and Prevention (CDC), Occupational Safety and Health Administration (OSHA), National Institute for Occupational Safety and Health, and state health departments. This discussion does not attempt to define such a comprehensive program, which has been addressed in other reports [1–5]. **Rather, the intent of this discussion is to alert the student, house officer, practicing physician, and other health-care providers about those employee health issues that overlap with infection control issues; that is, how to protect the HCW from acquiring or spreading infections in the hospital, clinic, or office setting.**

I. Employee health program

A. Major objectives of an employee health program should include the following:

1. To screen periodically to identify occupational health risks, implement preventive measures [1], and comply with respiratory agency minimal standards;
2. To provide management of occupationally related illness and communicable disease or blood-borne pathogen exposure among HCWs;
3. To monitor and investigate exposures and disease outbreaks among personnel;
4. To emphasize preventive health practices and health maintenance habits and promote individual responsibility for infection control.

B. Baseline and periodic health assessment. At the time of employment, it is useful to establish a baseline health and immunization history. If documentation of immunization is not possible, **serologic testing for rubella, rubeola, varicella-zoster virus, and hepatitis B virus (HBV)** is warranted [6]. A comprehensive medical history and physical examination is not necessary for infection-control purposes but may be required by state regulations, and it also serves as an important resource for determining preexisting medical problems. Many facilities have adopted “position-specific” screening that targets risks associated with specific tasks. Each worker’s health status should be reassessed annually and immunizations updated [1].

C. Tuberculosis control. OSHA regulations include the following. A baseline intermediate purified protein derivative (PPD) tuberculin skin test is required for all new employees whose tuberculosis status is unknown or whose reaction is negative by history. Two-step testing eliminates potential false-positive PPD conversions as a result of the booster effect [7,8] (see Chapter 11 under Tuberculosis). A current chest roentgenogram to rule out active disease is recommended for individuals exhibiting a positive reaction to PPD, with assessment for active pulmonary disease and consideration of isoniazid prophylaxis (see Chapter 11). The need for repeat PPD testing should be dictated by exposure or the prevalence of tuberculosis in the hospital population or geographic area. State regulations may also affect this interval [1]. HCWs at increased risk for exposure to tuberculosis should be PPD tested every 3 to 6 months depending on hospital risk assessment data. Potential high-risk employees include emergency department personnel, respiratory therapists, microbiology laboratory workers, pathologists, specialists in pulmonary medicine, and nurses in some settings [8–10]. For further discussion, see Chapter 11 and related references [8,9].

D. Immunization program. Immunization of hospital staff helps reduce the risk of transmissible diseases [1,6,11,12] (see also Chapter 23).

1. **Rubella.** All HCWs, regardless of age or gender, should be immune to rubella. This is a vital strategy for preventing congenital rubella syndrome, and some states have made it mandatory. Many hospitals require immunity as a

condition of employment. **New employees** without documentation of immunization after his or her first birthday **should be screened for rubella antibody and offered immunization if seronegative** [11] (see Chapter 23).

2. **Hepatitis B immunization.** OSHA requires that all employees whose job activities place them at risk for blood exposure are **offered** the hepatitis B vaccine at the employer's expense. Although prescreening is not required unless specifically requested by the employee, it may be helpful and cost effective if risk factors for hepatitis B are present [13]. For the details of hepatitis B vaccination, see Chapters 14 and 23. Postvaccination testing for antibody to HBV surface antigen should be performed to document antibody response. This will assist in determining the need for further immunization or appropriate postexposure prophylaxis [14]. OSHA mandates that employers document vaccination history (including employee refusal of vaccine) and provide training in both the prevention of exposure to blood-borne pathogens and the correct use of personal protective equipment.
3. **Influenza.** Influenza can spread quickly through a health-care facility, particularly one with a residential environment. Therefore, aggressive efforts should be made to immunize staff, particularly those with direct patient contact, in November of each year [12] (see Chapter 10). Nosocomial transmission of influenza has been demonstrated and may have dramatic effects on patient outcome [6].
4. **Rubeola.** Measles may present a significant risk to both HCWs and their patients. Persons born before 1956 are, in general, considered immune to measles. Among HCWs born after 1956, up to 14% are susceptible to measles [15,16]. The Infectious Diseases Society of America recommends that hospitals require from all HCWs evidence of measles infection or receipt of two doses of live virus vaccine [17]. If this documentation is lacking, serologic testing should be done and live measles virus vaccine should be administered at employment and repeated 1 month later for all HCWs who are not immune. Live virus vaccines are contraindicated during pregnancy [17,18] (see Chapter 23).
5. **Tetanus-diphtheria.** It is important to update tetanus-diphtheria immunization at the time of employment (if need be) and every 10 years thereafter. See detailed discussion in Chapters 4 and 23.
6. **Mumps.** Susceptible adult HCWs, especially males, are candidates for vaccination [1] (see Chapter 23).
7. **Varicella.** Knowledge of the varicella-antibody status of employees who provide direct patient care has become more important as the immunosuppressed patient population increases. Consequently, most hospitals, particularly those with large pediatric or immunocompromised populations, have initiated varicella screening of all employees. Documentation of serology will prevent unnecessary work restrictions and disruption of patient services if exposure occurs [1,6].
The live-attenuated varicella vaccine is discussed in detail in Chapter 23. Precise guidelines for the use of this vaccine in HCWs have not yet been published. Susceptible HCWs who have direct patient contact would appear to be potential candidates for this vaccine; this must be individualized until guidelines are available.
8. **Other immunizations.** Booster doses of poliomyelitis immunization are generally not indicated. Administration of oral poliovirus vaccine to an HCW is contraindicated because of the risk of transmitting the live virus. Some hospitals provide vaccine against pneumococcal pneumonia. Consideration should be given to offering hepatitis A vaccine to food handlers, hospital child-care workers, and selected research personnel (see Chapter 14).
- E. **Screening for carriage of bacterial, viral, or parasitic pathogens.** Unless an HCW is or has been epidemiologically implicated in disease transmission or has symptoms of infection, routine screening for pathogens (e.g., HBV, human immunodeficiency virus [HIV], *Salmonella* species, vancomycin-resistant enterococci, group A *Streptococcus*, *Staphylococcus aureus*, including methicillin-resistant *S. aureus*) is not indicated (see section II). However, some state or local regulations may require screening of food handlers for enteric pathogens.
- F. **Work restrictions for acute, chronic, or recurrent infections.** In certain situations, HCWs will need to be placed on work restrictions, complete or partial,

depending on the infection and risk of transmission [1]. Table 26.1 summarizes these recommendations.

G. Prophylaxis after exposure to various illnesses has been reviewed elsewhere in this volume:

1. **Hepatitis A** (see Chapters 14 and 23).
2. **Hepatitis B** (see Chapters 14 and 23).
3. **Hepatitis C**. Results have been equivocal in studies attempting to assess the value of prophylaxis with immunoglobulins against parenterally transmitted non-A, non-B hepatitis. For persons with percutaneous exposure to blood from a patient with parenterally transmitted non-A, non-B hepatitis, it may be reasonable to administer immunoglobulin (0.06 mL/kg) as soon as possible after exposure [1]. A study indicated that treatment with interferon during the acute phase prevents the development of chronic HCV infection [19]. See related discussions in section II.A.2 and Chapter 14.
4. **Meningococcal disease** (see Chapter 6).
5. **Rabies**. HCWs who have been bitten by a human with rabies or who have scratches, abrasions, open wounds, or mucous membranes contaminated with saliva or other potentially infective material from a human or animal with rabies should receive a full course of antirabies treatment [1] (see Chapter 4).

II. Occupational issues related to blood-borne disease transmission

A. Risk of transmission to HCWs

1. **HBV**. In the United States there are an estimated 1 to 1.25 million chronic carriers of HBV (hepatitis B surface antigen positive). These persons represent a continuous risk to uninfected persons. In the United States, between 200,000 and 300,000 new cases are reported annually. In part because of such figures, the CDC now recommends that all children in the United States receive hepatitis B vaccine [14] (see Chapters 14 and 23). Still, approximately 300 HCWs die annually of HBV or its complications [20]. Individuals in occupations that involve the performance of invasive procedures or frequent contact with blood are at increased risk of exposure. Surveys of personnel in high-risk occupations have shown high rates of seropositivity: between 5% and 30% or more for hospital-based physicians and laboratory personnel [11,12]. The risk for HBV infection after a single percutaneous exposure to blood contaminated with hepatitis B e antigen (HBeAg positive) is estimated to be 27% to 43%, with a 6% to 24% risk for subsequent development of clinical hepatitis [21]. **These data underscore the importance of hepatitis B immunization as a preventive measure** (see Chapter 23).
2. **Hepatitis C virus (HCV)**. Third-generation immunoassays have improved the positive predictive value of the antibody test for HCV. However, the rate of HCV transmission and risk factors for transmission remain to be determined. OSHA guidelines regarding prevention of exposure to blood-borne pathogens were intended to prevent transmission of HCV and other yet to be identified blood-borne pathogens. Contraction of HCV infection has been documented to occur via needlestick transmission [21]. The risk of transmission appears to be less than 4%, compared with up to 67% for HBeAg-positive serum [22]. Approximately 50% of those infected with HCV will go on to develop chronic liver disease with increased risk for cirrhosis and hepatocellular carcinoma [23] (see related discussions in Chapter 14).
3. **HIV**. HCWs are at low risk for acquiring HIV from their patients. However, studies and individual case reports have documented several cases of occupational transmission [24]. Currently, the risk from a single percutaneous exposure to HIV-infected blood is estimated to be approximately 0.3% (see Chapter 18). Projections of individual lifetime risk have been proposed based on the seroprevalence of HIV in the geographic area and the frequency with which an individual sustains accidental injuries that represent a risk for blood-borne disease transmission [25]. As of June 2000, the CDC had reported approximately 56 cases of documented occupationally acquired HIV and an additional 138 possible occupationally acquired transmissions among HCWs [29]. Circumstances resulting in occupational **HIV transmission have involved blood or bloody fluids only**, and transmission has occurred primarily through hollow-bore needlestick injury [20]. **Prolonged**

Table 26.1. Work Restrictions for Hospital Workers Exposed to or Infected with Selected Infectious Diseases

Disease or Problem	Relieve from Direct Patient Contact	Partial Work Restriction	Duration
Conjunctivitis, infectious	Yes		Until discharge ceases
Cytomegalovirus infections	No		
Diarrhea	Yes		
Acute stage (diarrhea with other symptoms)	No	Personnel should not care for high-risk patients	Until symptoms resolve and infection with <i>Salmonella</i> is ruled out
Convalescent stage <i>Salmonella</i> (nontyphoidal)			Until stool is free of the infecting organism on two consecutive cultures not less than 24 h apart
Enteroviral infections	No	Personnel should not care for infants and newborns	Until symptoms resolve
Group A streptococcal disease	Yes		Until 24 h after adequate treatment is started
Hepatitis, viral			
Hepatitis A	Yes		Until 7 days after onset of jaundice
Hepatitis B			
Acute	Possibly	Personnel should use barrier precautions for procedures with mucous membranes on nonintact skin	Until antigenemia resolves
Chronic antigenemia	Possibly	HCWs who are HBeAg-positive may be restricted in certain situations	Until antigenemia resolves
Hepatitis C (parenterally transmitted non-A, non-B)	No	Personnel should use barrier precautions for procedures that involve trauma to tissues or contact with mucous membranes on nonintact skin	Period of infectivity has not been determined
Herpes simplex	No		
Genital	Yes	(Note: It is not known whether gloves prevent transmission)	Until lesions heal
Hands (herpetic whitlow)	No	Personnel should not care for high-risk patients	Until lesions heal
Orofacial	Possibly	HCWs may be restricted in certain situations	

Measles Active Postexposure (susceptible personnel)	Yes Yes	Until 7 days after the rash appears From the 5th through the 21st day after exposure or 7 days after the rash appears
Mumps Active Postexposure (susceptible personnel)	Yes Yes	Until 9 days after onset of parotitis From the 12th through the 26th day after exposure or until 9 days after onset of parotitis
Pertussis Active	Yes	From the beginning of the catarrhal stage through the third week after onset of paroxysms or until 7 days after start of effective antimicrobial therapy
Postexposure (asymptomatic personnel) Postexposure (symptomatic personnel)	No Yes	Same as active pertussis
Rubella Active Postexposure (susceptible personnel)	Yes Yes	Until 5 days after rash appears From the 7th through the 21st day after exposure
Scabies	Yes	Until treated
<i>Staphylococcus aureus</i> (skin lesions) Upper respiratory infections	Yes No	Until lesions have resolved Until acute symptoms resolve
Varicella (chickenpox) Active Postexposure (susceptible personnel)	Yes Yes	Until all lesions dry and crust From the 10th through the 21st day after exposure and, if varicella occurs, until all lesions dry and crust
Zoster (shingles) Active Postexposure (personnel susceptible to chickenpox)	No, if lesions localized and covered Yes	Until lesions dry and crust, personnel should not care for high-risk patients (regardless if lesions are covered) From the 10th through the 21st day after exposure and, if varicella occurs, until all lesions dry and crust

HBsAg, hepatitis B e antigen; HCWs, health-care workers.

From Polder JA, Tablan OC, Williams WW. Personnel health services. In: Bennett JV, Brachman PS eds. *Hospital infections*, 3rd ed. Boston: Little, Brown, 1992:36-97, with permission.

contact with HIV-positive blood on nonintact skin or mucous membranes also may have transmitted the virus [24]. Several instances of HIV transmission in laboratory settings have been documented [26]. This topic has been extensively reviewed elsewhere [27].

- B. Screening employees for HBV, HCV, or HIV.** Routine preemployment or periodic screening of employees for HBV, HCV, or HIV **has been discouraged** [28]. Such testing should be linked to the provision of employee health services (i.e., screening after hepatitis B vaccine administration or as part of postexposure management). **Screening should not be used, and is in fact prohibited in some states, to exclude or modify employment in health-care settings.**
- C. Postexposure management.** Employees who have sustained percutaneous or mucous membrane or nonintact skin exposures to blood or body fluids (i.e., serous fluids) that may contain a blood-borne virus should be evaluated, counseled, and offered appropriate medical follow-up. **When possible, individuals who are the source of such exposures should be screened for HBV, HCV, and HIV. Requirements for obtaining informed consent of the source patient vary from state to state.** In the past, recommendations for testing source patients for HCV were controversial [29]. Currently, most authorities would agree that testing of high-risk patients is reasonable. Testing for HIV in exposed employees should be accompanied by appropriate pretest and posttest counseling; informed consent must be obtained [26].
1. Chapters 14 and 23 provide guidelines for **HBV postexposure prophylaxis**, which takes into consideration the HBV status of both the source individual and the employee. The CDC recommendations (June 2001) for HBV postexposure prophylaxis include hepatitis B immune globulin and/or the HBV vaccination series, after the evaluation of the HBV surface antigen status of the source, as well as the vaccination history and titers in response to the vaccine of the exposed person [30]. Once again, it is important to emphasize the need to vaccinate all unexposed HCWs for HBV because of the high risk of transmission from a needlestick injury.
 2. Gerberding and Henderson [31] recommend that an HCW exposed to HCV undergo testing for HCV antibody and liver function tests at the time of exposure. Follow-up testing should be repeated at 3 and 6 months, or sooner if the HCW becomes symptomatic [31]. Administration of serum immunoglobulin (ISG 0.06 mL/kg) to the HCW as soon as possible after parenteral exposure to a confirmed case of HCV has been suggested, but failures have been reported [29].
 - a. The CDC recommendations, June 2001, for HCV postexposure prophylaxis do not include intravenous immune globulin or antiviral agents [30]. Postexposure management involves determining the HCV status of the source and the exposed person. If the source is HCV antibody positive, then follow-up HCV testing is performed on the exposed HCW. Interestingly, one case has been reported in which an HCW did not seroconvert to HCV antibody positive after a needlestick injury involving a known HCV-infected source patient [32]. The HCW was documented by polymerase chain reaction (PCR) to have an acute HCV infection assay and has remained antibody negative at 1 year after exposure. Thus, clinical suspicion may be necessary in some cases, and liver function tests may also need to be followed.
 - b. For HCWs diagnosed in the acute phase of a HCV infection, treatment with interferon may be beneficial [19]. In one study, 44 subjects were diagnosed in the acute phase by documented seroconversion to HCV antibody positive, known or suspected exposure to HCV within the preceding 4 months, or marked elevation of serum alanine aminotransferase more than 350 U/L. All 44 subjects were HCV PCR positive and had elevated alanine aminotransferase levels. The study included subjects with different HCV genotypes. The patients resolved the HCV infection after 24 weeks of interferon alpha-2b monotherapy, preventing progression to chronic active disease. The regimen was 5 million units interferon alpha-2b subcutaneously injected daily for 4 weeks, followed by three times weekly for 20 weeks. At the end of 24 weeks, 42 of 43 (98%) subjects

had undetectable HCV RNA by the PCR-based assay. During the follow-up assays at 36 and 48 weeks, the serum from the 42 subjects remained free of detectable HCV RNA by the PCR-based assay. The level of detection is less than 600 copies/mL.

- c. The important point is to treat early, before the more difficult to treat chronic infection is established. The success rate of 98% for treating HCV in the acute phase is quite remarkable, especially when compared with the success rate in chronic HCV infections treated with the most effective regimen to date. Chronic HCV infections treated for 48 weeks with pegylated-interferon plus ribavirin eliminated the virus in only 55% of cases [33,34].
3. HCWs who have been exposed to an HIV-positive source should be offered the following:
 - a. Baseline HIV antibody testing to determine the employee's serostatus at the time of exposure and periodically thereafter (e.g., 4 weeks, 3 and 6 months) to rule out seroconversion.
 - b. Pretest and posttest counseling is required in most states to manage postexposure anxiety and to provide risk-reduction education to prevent third-party transmission during the period when seroconversion may occur.
 - c. Any HCW exposed to a potential HIV-positive source should be offered postexposure prophylaxis with antiretroviral agents to reduce the risk of transmission, including the initial period of evaluating the HIV status of the potential source. The CDC recommends a basic regimen prescribed for 4 weeks: a two-drug regimen of nucleoside reverse transcriptase inhibitors for low-risk exposures and an expanded three-drug regimen, including two nucleoside reverse transcriptase inhibitors plus a protease inhibitor or nonnucleoside reverse transcriptase inhibitor for the higher risk exposures [30] (Tables 26.2 and 26.3). When the source patient is HIV positive and the virus is known to be resistant, based on genotype or phenotype results, or suspected to be resistant, the HCW should be given an expanded postexposure prophylaxis regimen of antiretroviral agents effective against these HIV subtypes.

Emphasis must be placed on decreasing the risk of exposure to blood-borne pathogens via proper barrier techniques and appropriate handling of sharps, as well as the implementation of needle safety devices [28]. For a more detailed discussion of this topic, see the report of Beekman and Henderson [27].

D. Management of HCWs infected with HIV, HBV, or HCV. This topic has been reviewed by a number of authors [21,35–37] and is also the subject of a thoughtful editorial by Gerberding [28].

1. **HIV-infected workers.** Every industry, including health care, has HIV-positive workers at all levels. A topic of some concern is whether infected HCWs pose a risk for HIV transmission to patients. Although a potential may exist in settings where invasive procedures are performed, as of March 1996 there was only one highly publicized reported case of suspected transmission [28,38–40]. Screening of more than 19,000 patients of HIV-infected HCWs has failed to reveal another case of HIV transmission from an infected HCW to patient [41]. Currently, the CDC recommends that individual institutions establish a task force with a mandate to define exposure-prone procedures and to evaluate the competency of HIV-infected and HBeAg-positive HCWs who perform such procedures [21,42,43]. According to a CDC analysis, the risk of death from HIV or HBV infection acquired during an invasive procedure performed by an infected surgeon is similar to that of acquiring HIV infection from a transfused unit of screened blood [28].
2. **HBV-infected workers.** Hepatitis B has uncommonly been transmitted from an HCW to a patient, despite the fact that the CDC estimates that approximately 1,900 U.S. surgeons are chronically infected with HBV [37]. An unusual outbreak of HBV was described recently in patients operated on by a surgeon who was positive for HBeAg [37]. Furthermore, HBV is known to have been transmitted during invasive procedures from 34 infected HCWs to at least 350 patients in the United States and elsewhere since the early 1970s [28].

It is suggested that HCWs who perform invasive procedures know their HBV status. However, if a worker is HBeAg positive or epidemiologically linked to

Table 26.2. Recommended HIV Postexposure Prophylaxis (PEP) for Percutaneous Injuries

Exposure	Infection Status of Source			HIV Negative
	HIV-Positive Class 1 ^a	HIV-Positive Class 2 ^a	Source of Unknown HIV Status ^b	
Less severe ^d	Basic 2-drug PEP	Expanded 3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP ^e for source with HIV risk factors ^f	No PEP warranted
More severe ^e	Expanded 3-drug PEP	Expanded 3-drug PEP	Same as above	Same as above

^aHIV-positive, class 1: asymptomatic HIV infection or known low viral load (<1,500 RNA copies/mL). HIV-positive, class 2: symptomatic HIV infection, acquired immunodeficiency virus, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of PEP should not be delayed pending expert consultation, and because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

^bSource of unknown HIV status (e.g., deceased source person with no samples available for HIV testing).

^cUnknown source (e.g., a needle from a sharps disposal container).

^dLess severe (i.e., solid needle and superficial injuries).

^e“Consider PEP” indicates that PEP is optional and should be based on an individualized decision between the exposed person and the treating clinician.

^fIf PEP is offered and taken and the source is later determined to be HIV negative, PEP should be discontinued.

^gMore severe (i.e., large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient’s artery or vein).

HIV, human immunodeficiency virus.

patient transmission, work practices should be reviewed, and if modifications cannot be reasonably accommodated, work restrictions should be imposed [11,21].

3. **HCV-infected workers.** Transmission of HCV occurs principally by the parenteral route (see related discussions in Chapter 14). A recent report identifies two patients who appeared to have contracted HCV from a cardiac surgeon infected with HCV [36]. Therefore, specific guidelines to reduce risk of transmission from infected HCWs to patients remain unclear. Proper handwashing, use of approved barriers, and appropriate surgical technique with regard to prevention of exposure to sharps should be emphasized [23].

III. Education and training of all HCWs is a vital component of the infection control and employee health program. All employees should receive initial job orientation and in-service education about disease transmission, their role and responsibility for disease prevention, the infection control aspects of employee health, and the use of employee health services [1]. Employees also should receive specific training on the use of barrier precautions and preventive practices as they relate to implementation of universal precautions. Such training has been mandated by OSHA.

IV. OSHA regulations. On December 6, 1991, OSHA published its standard, "Occupational Exposure to Bloodborne Pathogens" (*Federal Register* 29 CFR Part 1910.1030). By issuing this standard, OSHA indicated that HCWs face a significant health risk as a result of occupational exposure to blood-borne pathogens such as HBV and HIV.

A. Purpose of the standard. The purpose of this standard is to minimize or eliminate occupational risk to blood-borne diseases by the provision of engineering and work practice controls, personal protective equipment, training, vaccination, and postexposure evaluation and follow-up. This standard applies to employees in all health-care facilities, including hospitals, clinics, dentists' and physicians' offices, blood banks and plasma centers, long-term care homes, hospices, clinical laboratories, funeral homes, and institutions for the developmentally disabled.

B. Components of the program

1. **Exposure control plan.** This is a written plan that identifies employees with risk of occupational exposure. It contains a schedule and method for implementation of standard requirements and postexposure evaluation procedures. The plan should be reviewed and updated annually and should be made available to all employees at risk.
2. **Methods of compliance.** The standard requires employers to implement methods and training to comply with provisions for worker protection to minimize or eliminate exposures. Areas addressed include the following:
 - a. Administration of policies and procedures;
 - b. Engineering and work practice controls;
 - c. Accessible personal protective equipment (PPE) to be used when indicated.
3. **Hepatitis B vaccination.** This standard requires that the hepatitis B vaccine is made available at no cost to all employees at risk of occupational exposure, within 10 days of initial job assignment, and after training on blood-borne pathogen exposure is completed. Employees declining vaccination must sign a declination form and may request vaccination at a later date.
4. **Postexposure evaluation and follow-up.** The employer must make a post-exposure evaluation available immediately after the exposure incident. Requirements for HIV and HBV testing of the source individual and exposed employee, provision of postexposure prophylaxis, and counseling are included.
5. **Training program.** The OSHA standard requires that all employees at risk for occupational exposure attend a training program at the time of initial employment and annually thereafter. The components of the training program include an explanation of the epidemiology and transmission of blood-borne diseases, an explanation of methods to eliminate or minimize exposures (e.g., handwashing, use of personal protective equipment), and postexposure follow-up, in addition to labeling and record-keeping requirements.
6. **Record keeping.** Records of postexposure evaluations and hepatitis B vaccination must be kept for the length of employment plus 30 years.

27. ANTIBIOTIC USE

Richard E. Reese and Robert F. Betts

A. Principles of Antibiotic Use

I. Introduction

A. Background. The benefit to society of antibiotics is one of the most important advances in medicine of the twentieth century [1]. Empiric antibiotics for specific acute infectious processes improve clinical symptoms more quickly, and the eventual outcome is improved compared with delayed or inappropriate therapy. This has been especially true in the leukopenic patient with gram-negative bacteremia (see Chapters 2 and 20) but is also true in many other infections. As a consequence, clinicians initiate antibiotics for any clinical problem that might be a bacterial infection even when symptoms are mild and often even when symptoms are probably caused by a virus. **This “standard” approach has led to a striking overuse of antibiotics, which in turn has led to the evolution of bacteria (e.g., *Streptococcus pneumoniae* or *Staphylococcus aureus*) resistant to antibiotics that previously were effective.** This approach has placed antibiotics in jeopardy of no longer being effective for infections that used to be easily controlled.

B. A different approach. Clinicians need to consider new and different approaches to patients with symptoms suggestive of an infectious illness. This approach must provide effective management for those who are most ill and at the same time not use antibiotics when they are not indicated. **Two components of this approach are especially important.**

- 1. First, of those who are seriously ill, the spectrum of the antibiotic regimen needs to include coverage of potentially resistant pathogens.** For example, in severe community-acquired pneumonia or bacterial meningitis, agents active against penicillin-resistant *S. pneumoniae* are needed (see Chapters 6 and 11). As a corollary to this, in community-acquired pneumonia it is useful to differentiate seriously ill patients from mildly ill patients (see Chapter 11).
- 2. Second, antibiotic use must be minimized for situations where the patient will not benefit from an antibiotic.** A prime example is upper respiratory tract infections (see Chapter 8).
- 3. If we can do this successfully, we will benefit our patients and prolong the useful life of the new classes of antibiotics we have been forced to use. If we are unsuccessful, the pharmaceutical industry may not have sufficient time to provide new safe and effective agents with which to treat our patients.**

II. Ten important questions to ask before selecting an antibiotic. The following 10 questions, summarized in Table 27A.1, help to provide a logical stepwise approach for antibiotic selection.

A. Question 1. Is an antibiotic indicated today, or even at all, on the basis of clinical findings?

- 1. In the seriously ill,** empiric antibiotics are indicated after obtaining cultures. Examples are meningitis, acute endocarditis, or the neutropenic patient who suddenly develops a high fever.
- 2. Although patients may be less ill than those mentioned above,** pneumonia and cellulitis are diseases for which antibiotics are indicated.
- 3. The most common situation of antibiotic overuse is** in uncomplicated upper respiratory tract infection [2] or influenza, yet antibiotics are commonly prescribed in over 50% of these situations (see Chapter 8).
- 4. For the individual who has had symptoms for 1 week or longer** and these symptoms are not rapidly accelerating, antibiotics **should not be started** until sufficient information and all possible cultures have been obtained to help guide future management. For the person with chronic symptoms, **antibiotics do not have to be started immediately** and, in fact, usually are not. Evaluate the situation and make sure all cultures have been obtained.

Table 27A.1. Important Questions to Answer Routinely Before Selecting an Antibiotic

-
1. Is an antibiotic **indicated**?
 2. Have appropriate **specimens** been obtained, examined, and cultured?
 3. **What organisms** are most likely?
 4. If several antibiotics are available, **which is best?** (This question involves such factors as drugs of choice, pharmacokinetics, toxicology, cost, narrowness of spectrum, and bactericidal compared with bacteriostatic agents.)
 5. Is an antibiotic **combination** appropriate?
 6. What are the important **host factors**?
 7. What is the best **route of administration**?
 8. What is the appropriate **dose**?
 9. Will initial therapy require **modification** after culture data are returned?
 10. What is the optimal **duration** of treatment, **and** is development of **resistance** during prolonged therapy likely to occur?
-

B. Question 2. Before antibiotics are initiated, have appropriate clinical specimens been obtained, examined, and cultured?

1. **Gram stains** are one of the most useful tools available. Has wound drainage, sterile body fluids, sputum, or abscess fluid been sent to the laboratory for Gram stain (see Chapter 25). Often this helps identify whether the pathogens are gram-positive cocci or gram-negative bacilli. Further, it requires 10^5 organisms in the specimen to be able to see them, and if there are many, there are 10^6 to 10^7 organisms present, the number that it requires to cause disease. Multiple morphotypes suggest anaerobic infection and, in the abdomen, perforation of a viscous.
2. **Site of infection cultures** (urine, sputum, wound drainage) must be obtained before starting antibiotics. **Of course, blood cultures** are almost always indicated. If the illness is low grade, three cultures can be spaced over 1 to 2 hours or even over 24 hours if subacute bacterial endocarditis is suspected. If it is an accelerating illness, three can be spaced over 20 to 30 minutes.

C. Question 3. What organisms are likely? Using clinical information and the always valuable Gram stain, an empiric regimen with good activity against the most likely pathogen(s) can be initiated. This is most important when the patient is only mildly or moderately ill and an organism may not be recovered from cultures. **For example**, if a patient presents with pneumonia and the Gram stain of the sputum shows many pleomorphic gram-negative coccobacillary organisms, therapy is aimed at *Haemophilus influenzae* and not *S. pneumoniae*. Azithromycin does not need to be added to ceftriaxone.

1. **The organ system involved** (i.e., genitourinary, pulmonary, skin, or biliary) will strongly influence the decision about whether coverage will be directed against gram-positive, gram-negative, or anaerobic organisms. Acute cellulitis is usually due to gram-positive organisms and urinary tract infection (UTI), to gram-negative organisms. However, an elderly male with a UTI and gram-positive cocci on Gram stain must be treated for either enterococcus or *Staphylococcus*.
2. **Age** may provide clues. For example, in pneumonia, certain pathogens are common in different age groups (see Chapter 11). **In the elderly**, infections may present atypically with inadequate histories, blunted signs on examination, and lack of fever; yet **morbidity rates are higher** in the elderly with infections. Pneumonia is more apt to be associated with bacteremia and slow resolution. UTI is commonly associated with bacteremia. Intraabdominal infection is more commonly associated with perforation, bacteremia, or abscess formation than in younger patients. Therefore, **in the elderly, early empiric antibiotics, broad-spectrum antibiotics, careful dosing, and assessment of drug-drug interactions are especially important** [3–5].
3. **Hospital-acquired** infections are likely to be due to gram-negative bacilli resistant to many antibiotics, *S. aureus* resistant to methicillin (MRSA), or, in certain situations, enterococci resistant to vancomycin (see Chapters 20 and 27P). Severe

nosocomial infections may be due to *Pseudomonas* species, often necessitating initial use of an aminoglycoside.

4. **Severity of illness** dictates not only whether antibiotic therapy should be initiated but also, at times, whether multiple agents or very broad-spectrum agents should be used (see related discussion under section **I.B.1**).
 5. **Prior culture data** often provide helpful clues. Do not forget to look at what was isolated last admission or in a posttreatment urine culture.
- D. Question 4. Which antibiotic among many should be chosen?**
1. Is there a **drug of choice** [6] (Table 27A.2)? If so, can this agent be used?
 2. **Are there antibiotic allergies?** The penicillin-allergic patient must be presumed to be allergic to all the penicillin derivatives unless appropriate skin tests can be done to test specifically for cross-reactivity. It is important to **consider both trade and generic names of antibiotics** when evaluating a patient's allergic history (see the discussion of penicillin allergies in Chapter 24).
 3. **Will the antibiotic penetrate** the infected area? This is especially important in meningitis, osteomyelitis, and prostatitis.
 4. **What are the potential side effects?** Some agents may be contraindicated in certain settings. Examples include the following:
 - a. **Tetracycline** use is limited to those over age 8 years who are not pregnant because of dental defects it produces.
 - b. **Fluoroquinolones** may affect cartilage formation and therefore are not currently recommended for use in prepubertal children and pregnant women (see Chapter 27G).
 5. **Bactericidal agents.** In minor infections of the healthy host, bacteriostatic agents are sufficient. However, in severe life-threatening infections (particularly bacteremia in leukopenic patients or patients with endocarditis or meningitis), bactericidal agents, which depend less on host factors, are necessary. Bactericidal agents include the penicillins, cephalosporins, aztreonam, imipenem, metronidazole for *Bacteroides*, aminoglycosides, vancomycin, and fluoroquinolones.
 6. **Cost of antibiotics**
 - a. **The cost of the antibiotic itself** is the easiest component to sort out (Appendix Table 1). **Generic preparations** should be ordered whenever possible [7], for example, generic oral trimethoprim-sulfamethoxazole (TMP-SMX). It is **essential for the clinician to recognize that the cost per day of the antibiotic itself is only one component of the cost of antibiotic administration in hospitalized patients.** Other factors are discussed later.
 - b. **Frequency of administration** per day. The more frequently the antibiotic is given (every 4 hours vs. every 8 hours vs. every 24 hours), the more expensive it is to administer in terms of personnel time and materials used. Agents with longer half-lives may be more cost effective because they are given less often. In one study, the estimated average nonantibiotic cost associated with the mixing and administration of a single intravenous (i.v.) antibiotic dose was \$3.35 [8].
 - c. **Number of antibiotics.** Multiple antibiotics usually are more expensive than monotherapy. However, sometimes two antibiotics are less expensive than one (e.g., cefazolin plus metronidazole costs less than ampicillin-sulbactam for intraabdominal infection) (see Chapter 13).
 - d. **Intravenous versus oral therapy.** The lower cost of equivalent oral agents coupled with ease of administration makes oral therapy very cost effective.
 - e. **Monitoring of serum levels.** The potential for toxicity with certain agents (e.g., aminoglycosides) is real, and the toxicity, if it occurs, may prolong the patient's hospitalization, increase the level of care of the patient (e.g., dialysis), or may be associated with increased morbidity and even mortality. Monitoring of levels is expensive. This factor should always be considered.
 - f. **Narrow versus broad spectrum of activity.** For empiric therapy in the seriously ill, antibiotics with a broad spectrum of activity are used initially. Once susceptibility data are known, it is preferable to use an agent with as narrow a spectrum as possible.
- E. Question 5. Is an antibiotic combination indicated?** In a few situations, this is appropriate.

Table 27A.2. Antibiotics of Choice for Common Pathogens

Pathogen	Antibiotic of First Choice ^a	Alternative Agents ^a
Gram-positive cocci <i>Staphylococcus aureus</i> or <i>S. epidermidis</i> ^b Non-penicillinase producing	Penicillin	A first-generation cephalosporin preferred, vancomycin, imipenem, or clindamycin; a fluoroquinolone ^c
Penicillinase producing (methicillin sensitive)	Penicillinase-resistant penicillin (e.g., oxacillin or nafcillin)	A first-generation cephalosporin, vancomycin, clindamycin, imipenem, amoxicillin-clavulanic acid, ticarcillin-clavulanic acid, ampicillin-sulbactam, piperacillin-tazobactam; a fluoroquinolone ^c
Methicillin resistant	Vancomycin with or without gentamicin with or without rifampin	Linezolid, quinupristin-dalfopristin, TMP-SMX, minocycline; a fluoroquinolone ^b
Streptococci Groups A, C, G	Penicillin	Clindamycin, a cephalosporin, ^a vancomycin, erythromycin; clarithromycin; azithromycin
Group B Enterococcus ^b	Penicillin (or ampicillin)	A cephalosporin, ^a vancomycin, or erythromycin
Endocarditis or other serious infection	Penicillin (or ampicillin) with gentamicin	Vancomycin with gentamicin; linezolid, quinupristin/dalfopristin; (see Chapter 27 P)
Uncomplicated urinary tract infection	Ampicillin or amoxicillin	A fluoroquinolone, nitrofurantoin, fosfomycin
Viridans group ^b	Penicillin G (with or without gentamicin)	A cephalosporin, ^a vancomycin
<i>S. bovis</i> <i>S. pneumoniae</i> ^b	Penicillin G See text (Chapters 6, 8, 11, 27C)	A cephalosporin, ^a vancomycin

Gram-negative cocci <i>Neisseria gonorrhoeae</i> ^b	Ceftriaxone or cefixime or ciprofloxacin or ofloxacin, or gatifloxacin see text (Chapter 16)	Cefotaxime, spectinomycin, cefoxitin (see Chapter 16)
<i>N. meningitidis</i>	Penicillin G	Third-generation cephalosporin, chloramphenicol
<i>Moraxella (Branhamella) catarrhalis</i>	Cefuroxime, a fluoroquinolone	TMP-SMX, amoxicillin-clavulanic acid; an erythromycin; clarithromycin, azithromycin, deferoxime, cefixime, third-generation cephalosporin, tetracycline
Gram-positive bacilli <i>Clostridium perfringens</i> (and <i>Clostridium</i> species) <i>Listeria monocytogenes</i>	Penicillin G, clindamycin Ampicillin with or without gentamicin	Metronidazole, imipenem, meropenem, chloramphenicol TMP-SMX
Gram-negative bacilli <i>Acinetobacter</i> ^b	Imipenem or meropenem	Tobramycin, gentamicin, or amikacin, usually with ticarcillin or piperacillin (or similar agent); TMP-SMX; a ciprofloxacin
<i>Aeromonas hydrophila</i>	TMP-SMX	Gentamicin, tobramycin; imipenem; a fluoroquinolone
<i>Bacteroides</i> ^b <i>Bacteroides</i> species (oropharyngeal)	Penicillin G or clindamycin	Cefoxitin, metronidazole, cefotetan, ampicillin, subactam, piperacillin-tazobactam, chloramphenicol
<i>B. fragilis</i> strains (gastrointestinal strains)	Metronidazole	Clindamycin; imipenem or meropenem; ampicillin-subactam; piperacillin-tazobactam; ticarcillin-clavulanic acid; cefoxitin, ^d cefotetan, ^d piperacillin, ^d chloramphenicol

(Continued)

Table 27A.2. (Continued)

Pathogen	Antibiotic of First Choice ^a	Alternative Agents ^a
<i>Campylobacter fetus</i> ^b <i>Campylobacter jejuni</i> ^b <i>Enterobacter</i> species ^b	Imipenem or meropenem Erythromycin or azithromycin; Imipenem or meropenem	Gentamicin A fluoroquinolone a tetracycline, gentamicin. An aminoglycoside and piperacillin or ticarcillin or mezlocillin; a third-generation cephalosporin; ^c TMP-SMX; aztreonam; ciprofloxacin
<i>Escherichia coli</i> ^b Uncomplicated urinary tract infection Recurrent or systemic infection	TMP-SMX ^b or ciprofloxacin (see Chapters 15, 27C, 27L) A third-generation cephalosporin ^f	A cephalosporin or a fluoroquinolone Ampicillin with or without an aminoglycoside, TMP-SMX, oral fluoroquinolones useful in recurrent infections, ampicillin-sulbactam, ticarcillin-clavulanic acid, piperacillin-tazobactam, aztreonam
<i>Haemophilus influenzae</i> (cocci bacillary) ^b Life-threatening infections Upper respiratory infections and bronchitis	Cefotaxime or ceftriaxone TMP-SMX	Chloramphenicol; cefuroxime (for pneumonia but not meningitis), meropenem Cefuroxime; cefuroxime-axetil; third-generation cephalosporin, amoxicillin-clavulanic acid, cefaclor, tetracycline; ampicillin or amoxicillin; clarithromycin; azithromycin; cefixime, a fluoroquinolone
<i>Klebsiella pneumoniae</i> ^b	A cephalosporin ^f	An aminoglycoside, imipenem or meropenem, TMP-SMX, ticarcillin-clavulanic acid, ampicillin-sulbactam piperacillin-tazobactam; aztreonam; a fluoroquinolone; amoxicillin-clavulanic acid

<i>Legionella</i> species	Azithromycin or a fluoroquinolone with or without rifampin	Doxycycline ± rifampin; TMP-SMX, erythromycin
<i>Pasteurella multocida</i>	Penicillin G	Tetracycline, cefuroxime, cefuroxime-axetil; amoxicillin-clavulanic acid, ampicillin-sulbactam, piperacillin-tazobactam
<i>Proteus</i> species, indole positive ^b	Cefotaxime, ceftizoxime ceftriaxone or cefepime ^g	An aminoglycoside; ticarcillin or piperacillin or mezlocillin; TMP-SMX; amoxicillin-clavulanic acid, ticarcillin-clavulanic acid, ampicillin-sulbactam, piperacillin-tazobactam; a fluoroquinolone; aztreonam; imipenem, meropenem
<i>Providencia stuartii</i> ^b	Cefotaxime, ceftizoxime, ceftriaxone or cefepime ^g	Imipenem or meropenem; an aminoglycoside often combined with ticarcillin or piperacillin or similar agent; ticarcillin-clavulanic acid; piperacillin-tazobactam; TMP-SMX; a fluoroquinolone; aztreonam
<i>Pseudomonas aeruginosa</i> ^b	Gentamicin or tobramycin or amikacin (combined with ticarcillin, piperacillin, etc., for serious infections)	An aminoglycoside and ceftazidime; imipenem or meropenem, or aztreonam plus an aminoglycoside; ceftipime plus an aminoglycoside; ciprofloxacin
Urinary tract infections	Ciprofloxacin	Carbenicillin; ticarcillin, piperacillin, or mezlocillin; ceftazidime; imipenem or meropenem; aztreonam, an aminoglycoside; ceftipime
<i>Burkholderia (Pseudomonas) cepacia</i> ^b	TMP-SMX	Ceftazidime, chloramphenicol, imipenem

(Continued)

Table 27A.2. (Continued)

Pathogen	Antibiotic of First Choice ^a	Alternative Agents ^a
<i>Salmonella typhi</i> ^b	Ceftriaxone or a fluoroquinolone	TMP-SMX, chloramphenicol; ampicillin, amoxicillin
Other species	Cefotaxime or ceftriaxone or a fluoroquinolone	TMP-SMX, chloramphenicol; ampicillin or amoxicillin
<i>Serratia</i> ^b	Imipenem or meropenem	Gentamicin or amikacin; cefotaxime or ceftriaxone or ceftipime; TMP-SMX; ticarcillin, piperacillin, or mezlocillin, which can be combined with an aminoglycoside; aztreonam; a fluoroquinolone
<i>Shigella</i> ^b	A fluoroquinolone	TMP-SMX; ceftriaxone; ampicillin, azithromycin
<i>Stenotrophomonas maltophilia</i> ^b	TMP-SMX	Minocycline, a fluoroquinolone
<i>Vibrio cholerae</i> (cholera)	A tetracycline	TMP-SMX; a fluoroquinolone
<i>Vibrio vulnificus</i>	A tetracycline	Cefotaxime
<i>Yersinia enterocolitica</i> ^b	TMP-SMX	A fluoroquinolone; an aminoglycoside; cefotaxime or ceftizoxime
<i>Yersinia pestis</i> (plague)	Streptomycin ± a tetracycline	Chloramphenicol; gentamicin, TMP-SMX

Note: The fluoroquinolones should be used only in adults except pregnant women. See Chapter 27G.
^aSee later individual discussions of agents for details of agent use and contraindications of use. Choice presumes susceptibility studies indicate that the pathogen is susceptible to the agent.

^bResistance may be a problem; susceptibility tests should be performed. See Chapter 25.

^cThe experience with fluoroquinolone use in staphylococcal infections is relatively limited. Resistance during therapy may occur. See Chapter 27G.

^dUp to 15–20% of strains may be resistant.

^e*Enterobacter* species may develop resistance to the cephalosporins. See discussion in Chapter 27F.

^fSpecific choice will depend on susceptibility studies. Third-generation cephalosporins and ceftipime may be exquisitely active against many gram-negative bacilli (e.g., *E. coli*, *Klebsiella* species). In some geographic areas, 20%–25% of community-acquired *E. coli* infections may be resistant to ampicillin (amoxicillin).

^gIn severely ill patients, this often is combined with an aminoglycoside while awaiting susceptibility data.

^hFormerly called *Pseudomonas maltophilia*.

TMP-SMX, trimethoprim-sulfamethoxazole.

Modified from Medical Letter. The choice of antibacterial drugs. *Med Lett Drugs Ther* 2001;43:69, with permission.

1. **Synergism.** When one antibiotic greatly enhances the activity of another, with more than an additive effect, this interaction is called **synergy** (see Chapter 25). Examples include the following:
 - a. **One antibiotic enhances the penetration of another.** It is believed that enterococci are impermeable to aminoglycosides. The synergistic interaction between **penicillin** (or ampicillin) and **aminoglycosides against enterococci** is due to penicillin altering the cell wall, allowing the aminoglycoside to penetrate the bacteria and thereby act effectively at the ribosomal level.
 - b. **An extended-spectrum penicillin (e.g., piperacillin) and an aminoglycoside are often synergistic against *Pseudomonas aeruginosa* and Enterobacteriaceae.**
 - c. **Serial inhibition of microbial growth.** Fixed combinations of TMP (80 mg) and SMX (400 g) block successive steps in the synthesis of folic acid (see Chapter 27L).
2. **In the febrile, bacteremic, leukopenic patient,** use of a synergistic combination is associated with improved outcome over a single agent [7].
3. **In infections in which multiple organisms are likely or proven** (e.g., intraabdominal or pelvic abscess), more than one antibiotic may be required for adequate treatment.
4. **Limiting or preventing the emergence of resistance.** This principle applies primarily to the treatment of tuberculosis. More than one agent is used in an attempt to prevent the replication of preexisting resistant mycobacteria. Whether or not two agents minimize the occurrence of resistance with gram-negative bacilli is unclear [9], but available data suggest they do not.
5. **β -Lactam- β -lactamase combinations** (e.g., ampicillin-sulbactam, Unasyn) are used so that the β -lactamase inhibitor protects the β -lactam antibiotic (see Chapter 27E).
6. **In the unique drug combination imipenem-cilastatin,** the enzyme inhibitor (cilastatin) prevents metabolic breakdown of imipenem by the kidney (see Chapter 27H).
7. **Disadvantages of multiple antibiotics**
 - a. **An increased risk of drug allergies or toxicity** is present when more agents are used.
 - b. **An increased risk of colonization with a resistant bacterial organism** may occur. If superinfection develops, such resistant organisms are more difficult to treat.
 - c. **Antagonism** occurs when the combined effect of two drugs is less than the effect of either drug alone; one of the drugs appears to interfere with the action of the second. How often this occurs clinically is unknown [9]. A combination of tetracycline and penicillin for treatment of meningitis resulted in a higher mortality than when penicillin was used alone, presumably due to the inhibition of growth by tetracycline, which interferes with the bactericidal action of penicillin.
 - d. **Higher costs.** Combination antibiotics often are more expensive than single agents.
 - e. **False sense of security.** Although appealing at times, the use of multiple agents to treat all possible organisms often is not possible, practical, or necessary and may be associated with an increase in side effects.
- F. **Question 6. Are there important host factors?** There may be special characteristics of the host that must be considered in choosing an antibiotic for use in individual patients.
 1. **Special risks**
 - a. A febrile person with an artificial heart valve should never receive antibiotics without first obtaining blood cultures.
 - b. A person with lymphoma or a collagen vascular disease should be approached entirely differently from a person with the same type of infection who lacks these risk factors. Pneumonia in a lymphoma patient may be cryptococcal and not pneumococcal.
 2. **Renal function.** Renal failure may affect not only the choice of antibiotic but also its dosages [10] (see discussions of individual agents). Consequently, **renal**

Table 27A.3. Major Pathways of Antibiotic Excretion

Antibiotics Primarily Excreted by the Liver ^a	Antibiotics Primarily Excreted by the Kidneys
Cefoperazone	Aminoglycosides
Chloramphenicol	Aztreonam
Clindamycin	Cephalosporins (other than cefoperazone)
Doxycycline	Imipenem
Erythromycin	Fluoroquinolones ^b
Metronidazole	Penicillin and penicillin derivatives
Nafcillin	Trimethoprim
Rifampin	Tetracycline
Sulfamethoxazole	Vancomycin

^a In renal failure, dosages usually do not need modifications. See individual chapter discussions.

^b The fluoroquinolones are excreted by the kidneys to a variable degree depending on the specific agent (see Chapter 27G).

function should be monitored in patients treated with antibiotics that are potentially nephrotoxic and primarily excreted by the kidney. **These are summarized in Table 27A.3.** Serum antibiotic levels, especially when aminoglycosides are used, should be monitored, as should serum creatinine, every 2 to 4 days.

a. Dosages of antibiotics renally excreted are modified based on the creatinine clearance.

b. The serum creatinine may not accurately reflect the patient's renal function, especially in the elderly, who may have decreased creatinine production. The **creatinine clearance is a better measure** of renal function. By modifying the equation of Cockcroft and Gault [11], it is possible to estimate the patient's creatinine clearance from the patient's age, gender, body weight (in kilograms), and serum creatinine as follows:

(1) **Male estimated creatinine clearance =**

(a) **Female estimated creatinine clearance = 85% of male value**

(b) **Some prefer to use ideal body weight,** which can be calculated as
 Male = 50 kg + 2.3 kg per each inch over 5 feet (in height)
 Female = 45.5 kg + 2.3 kg per each inch over 5 feet

(c) **In the obese patient,** we use ideal body weight to estimate the creatinine clearance.

(2) **In patients with severe hepatic insufficiency,** this formula may overestimate the creatinine clearance (see section **F.3.d**).

3. Liver function. Our understanding of modifying dosages in hepatic insufficiency is not as sophisticated as it is for renal insufficiency [12]. However, **four issues deserve special emphasis** in patients with hepatic insufficiency.

a. Aminoglycoside use in patients with cirrhosis may be associated with an increased risk of nephrotoxicity, as reviewed in Chapter 27I.

b. β -Lactam antibiotic use in one study was **associated with an increased risk of leukopenia** when standard doses of β -lactam antibiotics were used in patients with underlying liver disease [13]. The probable mechanism is impaired hepatic metabolism of the β -lactam antibiotics, resulting in bone marrow suppression of white cell precursors from excessive antibiotic concentrations. In our experience, nafcillin at standard doses is more likely to cause nephrotoxicity in subjects with cirrhosis. A reduction in dosage of β -lactam antibiotic when used in patients with significant hepatic dysfunction was proposed [13].

c. Drugs primarily metabolized by the liver (e.g., chloramphenicol, clindamycin) **need to have dose adjustments.** Other drugs to be used with caution or serum levels obtained include fluconazole, itraconazole, nitrofurantoin, and pyrazinamide [9] (Table 27A.3).

- d. When selecting a dose for a drug cleared by renal mechanisms, creatinine clearance should be estimated (just as in the elderly) even when the serum creatinine is normal [14]. In patients with underlying liver disease, a low creatinine may overestimate the creatinine clearance (two- to threefold) as measured by the inulin clearance. This may be accounted for by underproduction of creatinine resulting from diminished muscle mass or by a decreased rate of hepatic production of creatine, the substrate for the production of creatinine in muscles [14]. **In practice, for those with an estimated creatinine clearance and severe hepatic disease, we assume their estimated creatinine clearance may be approximately 50% of the calculated estimate using the above formula.**
4. **In neutropenic patients**, bactericidal agents are preferred whenever possible.
 5. **Genetic factors.** Patients with glucose-6-phosphate dehydrogenase deficiency may develop hemolysis from sulfonamides, nitrofurantoin, or chloramphenicol [9].
 6. **Pregnancy and lactation.** Certain drugs may pose special problems (e.g., the tetracyclines, which may cause hepatotoxicity in the mother and dentition problems in the infant). Because of the physiologic changes that occur in the mother during pregnancy, serum antibiotic levels are lower during gestation. Therefore in critical infections, serum levels of antibiotics may need to be monitored and compensatory dosage adjustments may be necessary [15].
 - a. **Placental transfer of antibiotics.** Whenever possible, pregnant women should avoid all drugs because of the risk of fetal toxicity. This topic has been reviewed elsewhere [15,16] and is summarized as follows:
 - (1) **Antibiotics considered safe in pregnancy** include the penicillins (with the possible exception of ticarcillin) [9], the cephalosporins, erythromycin base, and probably aztreonam.
 - (2) **Antibiotics to be used with caution** include the aminoglycosides, vancomycin, clindamycin, imipenem/cilastatin, TMP, and nitrofurantoin.
 - (3) **Antibiotics contraindicated in pregnancy** include chloramphenicol, erythromycin estolate, tetracycline, fluoroquinolones, and TMP-SMX (Bactrim, Septra). Although controversial, we would try to avoid using metronidazole because of its carcinogenic potential (see Chapter 27Q). Sulfonamides should be avoided in the last trimester of pregnancy. Some experts suggest avoiding ticarcillin, because it has been shown to be teratogenic in rodents [9] (see Chapter 27E).
 - b. **Antibiotics in breast milk.** Data regarding adverse effects in nursing neonates from maternal antibiotics are limited. If possible, nursing mothers should avoid all drugs (see section a.(1) to (3) above).
 - c. **The U.S. Food and Drug Administration's use-in-pregnancy drug-rating system is shown in Table 27A.4.** These pregnancy categories are based on the degree to which available information has ruled out risk to the fetus balanced against the drug's potential benefits to the patient. This topic has been reviewed [15].
 7. Prosthetic device infections may be difficult to eradicate (see Chapters 5 and 12).
- G. Question 7. What is the best route of administration?**
1. **Intravenous antibiotics are preferred in serious infections.** They provide high peaks with hopefully greater potential for diffusion into tissue rendered ischemic by the acute process. Many antibiotics have unpredictable oral absorption, but even in those that are very well absorbed (e.g., linezolid is 104% bioavailable), the very high peaks are not achieved (see individual chapter discussions).
 2. **Continuous versus intermittent bolus i.v. infusion.** Whether intravenously administered antibiotics should be given by continuous infusion or by intermittent bolus remains controversial [9] and is undergoing evaluation and is reviewed elsewhere [17–19].
 - a. **Continuous** infusions may result in less vein irritation and phlebitis. Results from animal model studies suggested that concentrations of penicillins and cephalosporins in fibrin clots were related to peak serum levels achieved; therefore intermittent bolus therapy seemed appropriate for endocarditis and tissue infections [9]. Recent data from animal models suggest that the clinical

Table 27A.4. U.S. Food and Drug Administration (FDA) Use-in-Pregnancy Ratings

The FDA's use-in-pregnancy rating system weighs the degree to which available information has ruled out risk to the fetus against the drug's potential benefit to the patient. The ratings, and their interpretation, are as follows:

Category	Interpretation
A	Controlled studies show no risk. Adequate well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy.
B	No evidence of risk in humans. Adequate well-controlled studies in pregnant women have not shown increased risk of fetal abnormalities despite adverse findings in animals, or, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote, but remains a possibility.
C	Risk cannot be ruled out. Adequate well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy, but the potential benefits may outweigh the potential risk.
D	Positive evidence of risk. Studies in humans, or investigational or post-marketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.
X	Contraindicated in pregnancy. Studies in animals or humans, or investigational or post-marketing reports, have demonstrated positive evidence of fetal abnormalities or risk which clearly outweighs any possible benefit to the patient.

Physicians' desk reference 56th ed. Montvale, NJ: Medical Economics, 2002:343, with permission.

effectiveness of β -lactam antibiotics is optimal when the concentration at the site of infection exceeds the minimum inhibitory concentration of the infecting organism for a prolonged time (50% of the 24-hour period) [9]. This is called time-dependent bactericidal activity. Drug levels just above those required to inhibit the organism are as effective as levels many fold above the inhibitory concentration. β -lactam antibiotics and vancomycin function by time-dependent killing [19]. Intermittent infusion remains the method used with β -lactam antibiotics.

- b. Intermittent infusions** may be preferred for antibiotics that exhibit **concentration-dependent bactericidal activity**. With these antibiotics the rate and extent of bactericidal action increase with increasing concentrations above the minimum bactericidal concentration (MBC) up to a point of maximum effect, usually 5 to 10 times the MBC [19]. The **aminoglycosides and fluoroquinolones** demonstrate concentration dependent killing [9,19]; the **higher the drug level, the greater the rate of bacterial clearance**, which slows as the drug level falls [19]. Large infrequently administered doses of concentration-dependent agents that achieve maximal concentrations at peak at the site of infection should produce optimal bactericidal effect. This is in large part the **basis for once-daily regimens of aminoglycoside** dosing, which is discussed in detail in Chapter 27I. However, clinical studies to prove this are still not available [9,19].

- 3. Oral therapy** is effective for mild to moderately severe outpatient infections and for completion of therapy of focal infections initially treated with i.v. antibiotics. In special circumstances, oral therapy is used for relatively severe infections such as TMP-SMX in *Pneumocystis carinii* pneumonia and clindamycin in osteomyelitis (see individual sections).

4. **Home i.v. antibiotics** are used in selected settings for stable infections requiring prolonged or repeated courses of i.v. antibiotics (e.g., subacute endocarditis, prosthetic joint infections, recurrent pulmonary infection in patients with cystic fibrosis, or bronchiectasis). This topic is reviewed in detail elsewhere [20]. This is a cost-effective approach to therapy that many patients obviously prefer over hospitalization.
- H. Question 8. What is the appropriate dose?** To reduce the frequency of side effects, the potential of superinfection, and the cost of therapy, the lowest dose of an antibiotic that will be effective is used.
1. **Dosage in neonates** (see Chapter 3).
 2. **Dosage in children and adults** (see discussions under individual agents).
- I. Question 9. What guides modification after culture data are available?** Once the results of cultures and antibiotic susceptibility data are available, the antibiotic regimen should be modified when possible. Some general guidelines follow:
1. Conversion from a broad-spectrum to a narrow-spectrum agent should be carried out if susceptibility data show a decreased risk of colonization and possible superinfection with resistant organisms and/or selection of resistant flora.
 2. ***S. aureus* susceptible to nafcillin.** If vancomycin was initiated, and recovered *S. aureus* organisms are susceptible to nafcillin, this narrow-spectrum agent should be used both because it is more effective and its spectrum is more focused.
 3. **Gram-negative infections.** For the individual presumptively placed on an aminoglycoside, if the identified pathogen is susceptible to a narrow-spectrum agent (e.g., ampicillin or a cephalosporin), barring allergy, a change should be made [6].
 4. **No growth or normal flora only in initial cultures.** Other diagnostic possibilities should be considered. For example, if the patient with pneumonia receiving ceftriaxone is doing poorly, other infectious agents (mycoplasma, *Mycobacterium tuberculosis*, *Legionella* species) or even noninfectious possibilities (e.g., pulmonary infarct, pulmonary vasculitis) must be considered.
 5. **Evaluation of clinical response and culture results.** It is important for the clinician to assess the clinical response of the patient before making changes based on culture results. For example, colonization with new organisms is expected with antibiotic use. **New colonization must be differentiated from new infection.** If the patient is improving and an organism resistant to the antibiotic is isolated on follow-up sputum or wound cultures, it can usually be ignored (see Chapters 11 and 4).
- J. Question 10. What is the optimal duration of therapy?**
1. **Duration.** The optimal duration of antibiotic therapy may be well established, such as a minimum of 6 weeks in osteomyelitis or relatively empiric 10 to 14 days for peritonitis. **Recommended duration** of therapy for common problems is shown in **Table 27A.5**. However, this must often be individualized. Because resistant organisms eventually colonize those who are treated for a prolonged period, it is important for the clinician to treat the patient for an adequate, but not an unnecessarily prolonged, period.
 2. **Development of resistance.** The growing problem of antibiotic resistance and its relationship to antibiotic use is discussed below under Antibiotic Resistance.
 - a. **Broad versus narrow antibiotic therapy.** What has become increasingly clear is that **using a broader spectrum agent than necessary** (e.g., a third-generation cephalosporin rather than a first-generation cephalosporin) **will result in colonization of the individual with an organism resistant to the third- rather than the first-generation cephalosporin.** If superinfection ensues, patients infected with antibiotic-resistant organisms are more likely to require hospitalization, have a longer hospital stay, and have an increased risk of death [21].
 - b. **Therefore it is particularly important for the clinician to use the new broad-spectrum agents carefully to help minimize the development of bacterial resistance** [21]. This usually involves some type of hospital-wide antibiotic control program and rational use of antibiotics. Cautious conservation is advocated in the use of new antimicrobial agents (see Antibiotic Resistance, below).

Table 27A.5. Duration of Antibiotic Therapy for Common Infections

Diagnosis	Duration of Therapy (days)
Meningococcal meningitis	7–10
Pneumococcal meningitis	10–14
<i>Haemophilus influenzae</i> type b meningitis	10–14
Streptococcal group A pharyngitis	10
Otitis media	7–10
Bacterial sinusitis	10–14
Pneumococcal pneumonia	? Optimal ^a
Gram-negative pneumonias (<i>Klebsiella</i> , <i>Enterobacter</i> , <i>Pseudomonas</i>)	? 21 ^b
<i>Mycoplasma pneumoniae</i>	14 ^c
<i>Legionella pneumoniae</i>	21 ^c
Endocarditis (nonprosthetic)	
Viridans streptococci	28
Staphylococcal	28–42
Peritonitis	10–14
Septic arthritis (nongonococcal)	14–21 ^d
Osteomyelitis (acute)	28–42 ^e

^aMost experts agree that therapy should be continued at least 3 days after the temperature returns to normal. Elderly patients may deserve 7 days of parenteral therapy.

^bDifficult to eradicate; patients may require even longer courses.

^cTo prevent relapse, a full therapeutic course should be given.

^dFour weeks of therapy may be indicated in patients with gram-negative infections, slowly responding infections (despite adequate drainage), or infections with virulent organisms such as *S. aureus*.

^eIn vertebral osteomyelitis, patients often are treated for 6 weeks.

ANTIBIOTIC RESISTANCE

Increasing bacterial resistance has been emphasized in recent reviews [2,22–28] and in the lay media. **Although an extensive discussion of this topic is beyond the scope of this chapter, several issues deserve special emphasis.** For complete related discussion, see the Centers for Disease Control and Prevention website (www.cdc.gov).

I. Background. After the introduction of sulfonamides in the middle to late 1930's and penicillin in the early 1940's, pharmaceutical companies introduced a series of antibiotics to combat resistant bacteria. These agents included, in the late 1950's, the semisynthetic penicillins to treat penicillin-resistant *S. aureus* and, in the 1960's through the 1980's, cephalosporins and aminoglycosides for hospital-acquired organisms, especially gram-negative bacilli. Vancomycin (available in 1958) has been useful in treating increasing problems associated with MRSA. **The concept of an untreatable bacterial disease is foreign to most physicians in the developing world, but if recent bacterial-resistant trends continue, it may become a reality.**

II. Current dilemma. In the past decade, there has been a **worrisome rise in resistance**, often multidrug, to **bacteria**, not only in hospital-acquired bacteria but also in community-acquired bacteria and *M. tuberculosis* in the United States and worldwide.

A. Nosocomial infections. In the past decade, gram-positive bacteria have emerged as the most frequent causes of nosocomial infection [23,26].

1. Coagulase-negative staphylococci commonly cause prosthetic device- and catheter-related infections, and 60% to 90% of strains are methicillin resistant [23].

2. MRSA accounts for 5% to 40% of *S. aureus* infections, depending on the size and type of the hospital. MRSA is occurring in individuals with no hospital contact [28] (see Chapter 27D).

3. Enterococci are the third most common nosocomial pathogen after *S. aureus* and *Escherichia coli*. In 1993 vancomycin-resistant enterococci were reported in

up to 14% of intensive care unit enterococcal isolates, a 20-fold increase since 1987 [23] (see Chapter 27P).

4. **Multidrug-resistant** *P. aeruginosa* and *Stenotrophomonas maltophilia* have become common in patients with cystic fibrosis. These organisms, as well as multidrug-resistant *Acinetobacter* species, are present in intensive care units [23].
5. Outbreaks of extended-spectrum β -lactamases *Klebsiella* species have been reported [24], presumably related to selection pressure from widespread use of late-generation cephalosporins; they usually are susceptible to imipenem.

B. Community-acquired infections

1. The increasing and ominous problem of *S. pneumoniae* resistant to penicillin [29] and other antibiotics is discussed in detail in Chapters 6, 8 11, and 27C.
2. In recent years, *Neisseria gonorrhoeae* (see Chapter 16), *Salmonella*, and *Shigella* species (see Chapter 13) have shown increasing resistance. Ampicillin-resistant *H. influenzae* and *Branhamella catarrhalis* are discussed in Chapters 8 and 11.
3. **Multidrug-resistant** *M. tuberculosis* is a serious and increasing problem in the United States and worldwide. Case fatality rates in patients infected with these organisms of 40% to 60% occur even when immunity is normal, and 80% mortality occurs in the immunocompromised [23].

III. Risk factors for emergence of resistant bacteria are partially understood and reviewed in detail elsewhere [22–28]. Several points should be emphasized.

A. Antibiotic use selects out resistant bacteria.

B. Often antibiotics are used inappropriately. In the United States, antimicrobial agents are the second most commonly used class of drugs [30,31] (second to agents used for cardiovascular disorders). In hospitals, approximately 25% to 40% of patients receive an antibiotic, accounting for nearly 25% of total drug acquisition, whereas about 15% of office-based private practice prescriptions are for antibiotics [32]. Several studies suggest that approximately 50% of antibiotic use in the United States is inappropriate (i.e., not indicated, wrong drug, wrong dose or duration). Kunin [32] reviewed this problem and potential approaches to it in detail. Guidelines are often available to help hospitals improve their use of antibiotics.

C. New antibiotics are often used excessively. Resistance develops more rapidly than anticipated because of excess use. In a relatively short time, the agent has lost its effectiveness. Kunin [22] emphasized “the pattern of discovery, exuberant use, and predictable obsolescence has been repeated after the introduction of each new antimicrobial drug.”

D. Long-term use of antibiotics may pose a greater risk for antimicrobial resistance than short-term use or prophylaxis.

E. Use of antibiotics in animals. Prolonged use either to prevent infection or to stimulate growth selects for resistant bacteria that then colonize humans through food [33–36]. Supplementing animal feed with antibiotics to enhance growth is estimated to constitute more than half the total antimicrobial use worldwide [35,36]. Subtherapeutic concentrations may help select out resistant *Campylobacter* and *Salmonella* species [33,34]. Glycopeptides in animal feed is linked to vancomycin-resistant enterococci in humans [35].

F. Microbial characteristics may facilitate the development of resistance [37].

1. The **propensity to exchange genetic material easily and/or the ability to mutate** and adapt to a changing environment are important properties of bacteria.
2. **Reservoirs** or “niches” may be important to allow the organisms to proliferate. Patients who harbor resistant organisms may be reservoirs and spreaders of resistant pathogens.
3. The **intrinsic resistance** of an organism may help facilitate resistance. Enterococci are intrinsically resistant to cephalosporins, and when cephalosporins are used excessively, these agents may facilitate increased colonization and eventual infection with enterococci.
4. The ability of an organism such as *Clostridium difficile* to survive on inanimate surfaces may allow it to spread and survive.

G. Society and environmental aspects [37]

1. **Day-care centers** allow “sharing” of many bacteria, with secondary spread to family members and other attendees.
2. **Crowding, homelessness, poor nutrition, and inadequate care** are conducive to the transmission of infectious diseases and therefore promote multidrug-resistant organisms such as *M. tuberculosis*.
3. **Poor sanitation and crowding** facilitate the spread of bacteria in developing countries.
4. **Behavioral aspects** of a society can affect the spread of bacteria, as in the sexual transmission of gonococci and disease associated with i.v. drug use.
5. **Erosion of the public health infrastructure in the United States** due to cost-containing policies has decreased public health activities such as supervised therapy for tuberculosis and surveillance of important infectious diseases [37]. For example, national surveillance of drug-resistant *M. tuberculosis* was discontinued in 1984 and was only reinstated in 1993. Surveillance of food-borne disease is inadequate in most areas of the United States, and many outbreaks go undetected. Programs have recently been instituted to correct this.
6. **Changes in food production, processing, and distribution** may compromise food safety and increase food-borne illnesses.

H. Other contributing factors [37]

1. **International travel** exposes the traveler to resistant pathogens in both developing and developed countries and allows the traveler to spread infection from one country to another.
2. As **patients live longer and undergo more immunosuppression**, a larger population is at risk for infection, invasive procedures, and antibiotic therapy.
3. **Invasive procedures** (including central venous catheters) **and foreign bodies** as a consequence of these procedures expose patients to nosocomial infectious complications.
4. **Resistant bacteria are as virulent as susceptible bacteria.** Because of the disproportionately high incidence of multidrug-resistant bacteria in hospitals, the argument has been made that resistant pathogens are dangerous only to severely ill patients [23] and overall may be less virulent, especially to “normal hosts.” This does not appear to be the case. Both methicillin-resistant and methicillin-susceptible *S. aureus* can produce toxins, and the frequency and spectrum of staphylococcal diseases caused by susceptible and resistant strains appear to be the same [23,28].

IV. Urgency of situation with multidrug-resistant bacteria. In a 1994 Rockefeller University Workshop on multidrug-resistant bacteria, the participants concluded that the epidemiologic data in the United States suggest the following:

[We have already] reached the point that health agencies should be able to (and need to) take steps to avert a potential crisis. In particular, the acquisition of resistance to vancomycin, either by MRSA or resistant *S. pneumoniae*, would create highly invasive clones that could not be controlled by any currently available chemotherapeutic agent. Indeed, the transfer and expression of vancomycin resistance to staphylococci have already been demonstrated in the laboratory, and their emergence in clinical strains may only be a matter of time [23].

Recently, vancomycin (glycopeptide) resistant *S. aureus* strains have been described clinically (see Chapter 27P).

V. Proposed solutions to the problem [23–32,38]

- A. Awareness of the problem.** Special efforts should be made to bring the issue of antibiotic resistance to the attention of microbiologists, government health authorities, physicians [23], and especially lay public in an appropriate manner. Ideally, a national and multidisciplinary approach is needed. To this end, **in 1999 the Public Health Action Plan to Combat Antimicrobial Resistance (Action Plan) was developed** by an interagency task force co-chaired by the Centers for Disease Control and Prevention, the U.S. Food and Drug Administration, and the National Institutes of Health with input from a variety of agencies, including the Department

of Agriculture, the Environmental Protection Agency, and the Department of Veterans Affairs. The *Action Plan* had input from many groups, including health agencies, health-care delivery organizations, universities, professional societies, pharmaceutical companies, agricultural producers, and consumer groups. The plan focuses on four areas: surveillance, prevention and control, research, and product development (e.g., rapid viral diagnostic tests). **The Action Plan, first annual report, and many issues related to antibiotic resistance are available at www.cdc.gov/drugresistance.** Initially domestic issues will be addressed and then eventually, the international problem of antibiotic resistance.

- B. More prudent use of antibiotics in humans and animals is critical** in developing and developed countries [22–24,31,36,39]. These are **global issues**, not ones applicable only to the United States.
 - 1.** Provider education, antibiotic control programs, shorter courses of antibiotics, and narrow-spectrum agents when feasible are all appropriate approaches. The unrealistic demand for and, at times, poor compliance with antibiotic regimens by patients must also be dealt with. Targeting obvious areas of abuse, such as antibiotic use in upper respiratory tract infection, is important (see Chapter 8).
 - 2. Appropriate pharmaceutical advertising and promotion is essential** [40,41].
 - 3.** Antimicrobial use in animals must be reviewed and improved [33–38]. For a comprehensive discussion of this topic, see a special 2002 symposium [36].
 - C. Improved surveillance.** Funding for, and interest in, surveillance systems at the state and national level declined in the 1970's and 1980's in the United States [8,9,23,42]. This needs to be and is being rectified. In recent years there has been an improvement in tracking regional and national antibiotic-resistant organisms, but more needs to be done. Better global surveillance has also been suggested [23].
 - D. Increase in funding for basic research** in mechanisms of resistance, vaccine development, and development of novel interventions is needed. By the early to mid-1990's the funding for research of bacterial disease was reduced substantially by the National Institutes of Health [23].
 - E. New antibacterial agents** [23,38,39]. With initial success of antibiotics released in the late 1980's and early 1990's, many pharmaceutical companies reduced their antibacterial research efforts in the early to mid-1990's. As a result, it is expected that fewer antibiotics will be released in the immediate future. New research in this area is needed. It is hoped that development can be expedited, possibly even with a "fast track" for new antibiotics for multidrug-resistant bacteria.
 - F. Prevention of transmission with infection control practices, improved sanitation** conditions in developing countries, and **improved care of the homeless** and those in crowded conditions also are needed. Rapid diagnostic tests and rapid treatment with effective antimicrobials also will help reduce transmission.
 - G. Hospital administrations** are encouraged to support and pursue a multidisciplinary systems oriented approach to these problems, as emphasized in a 1996 report [43]. Each hospital should establish its own strategies to optimize the prophylactic, empiric, and therapeutic use of antimicrobials in the hospital and to detect, report, and prevent transmission of antimicrobial-resistant microorganisms [43].
- VI. Summary.** To deal with this increasing problem of multidrug-resistant bacteria and reverse this trend, we agree with Dr. Levy:

The answer lies in efforts from all of us, physician, patient, microbiologist, manufacturer, public health and governmental policy officials. No one can sit back and expect someone else to solve the problem. In the past, we have relied on the pharmaceutical companies to develop new drugs to deal with resistance and they have largely succeeded. But, the ability to stay one step ahead of the bacteria has led to a complacency about the resistance problem. We can no longer maintain this attitude [39].

END OF LIFE ISSUES

Use of antibiotics for patients nearing the end of life is a topic of paramount importance [44–47]. Because in most patients with fever the physician initiates antibiotics to be certain that his or her patient does not suffer the consequences of infection, it is a natural step to

do the same for the terminally ill. However, one report from Wales in 1989 indicated that on the basis of a questionnaire of a hypothetical case of a terminally ill patient, only 16% of respondents (72/448) indicated they would use antibiotics if the terminally ill patient became febrile [47]. From observations made in the hospital, this does not seem to be the practice. Use of antibiotics in the terminally ill is not addressed in the literature. **We offer the following suggestions.**

I. For patients designated “comfort care”

- A.** Because other therapeutic agents are discontinued in comfort care patients, it is ethically reasonable to discontinue antibiotics unless their continued use is necessary for specific comfort (see section **B** below). This approach in a small way could provide not only the most rational care but also reduce resistance risks for the broader community.
- B. In special situations, directed antibiotic use with narrow-spectrum agents may be indicated for comfort.** Although therapy for a symptomatic UTI or cellulitis or pneumonia with a hacking cough may well be indicated, whether to treat or not must be individualized.
 - 1. UTI.** Usually UTI develops because of an indwelling catheter. If fever develops in this setting, it usually will resolve in 24 to 48 hours without therapy. If treatment is given, bacteria will be cleared and fever will disappear only to reappear with the next infection. Treatment may lead to greater discomfort.
 - 2. Cellulitis** with its rapidly advancing border is almost always due to a gram-positive organism and very often a penicillin susceptible β streptococcus, often group B. Rarely does a gram-negative organism produce this picture. Occasionally MRSA contributes, however.
 - 3. Aspiration** can usually be managed with good pulmonary toilet. Antibiotics often lead to *Clostridium difficile* and great patient discomfort.

II. For patients in whom broad-spectrum antibiotics are being considered, simply because the infection has developed in the hospital the issue is more complex and raises ethical issues beyond the scope of this handbook. If the clinician would not consider surgical procedures, pacemakers, or resuscitation, why use antibiotics “just in case?” We offer a few considerations.

- A.** Often resistant organisms are simply colonizers, are not very invasive, and no therapy is indicated, even with fever.
- B.** With attention to nursing measures, especially to wounds, to catheters, and to measures to avoid aspiration, excellent comfort care can be provided with use of antibiotics.
- C.** In the intubated patient where extubation is not planned, most growth from the endotracheal tube represents colonization and does not require treatment even with fever. That will disappear, like in the bladder-catheterized patient, without treatment. If infection develops, it will often progress rapidly to death, for the ultimate good of the patient.
- D.** The inserted catheters and tracheostomies make eradication of the colonizing bacteria very difficult, and often treatment leads to resistance.
- E.** In these situations we have found that an open discussion with families allows development of a plan that will provide the most comfort to the patient, citing the above factors just discussed.
- F. An ethics consultation,** if available, can help the care-giving team deal with the ethical issues raised by the question of whether or not to treat when therapy may produce more discomfort than it prevents. Although the decision to withhold broad-spectrum antibiotics can be difficult, especially if the patient is young and competent, our ethics committee has believed it is ethically defensible (appropriate) when it is weighed against community needs.

B. Prophylactic Antibiotics

I. Introduction. Use of prophylactic antibiotics involves a risk-to-benefit assessment. Two types of situations exist for use of prophylaxis. The first is to prevent postoperative infection. For the second, long-term prophylaxis is used to prevent a specific type of infection such as β streptococcus in the individual with prior rheumatic fever or pneumococcus in the splenectomized. In the tables to follow, a variety of options is summarized.

II. Short-term use in surgical procedures

A. Incidence of infection. Antimicrobial prophylaxis reduces the incidence of infection, particularly wound infection, after certain operations. However, this must be weighed against the risks of toxic and allergic reactions, emergence of resistant bacteria, drug interactions, superinfection, and cost. Studies from the literature conclude that antimicrobial prophylaxis should be used only for procedures with high infection rates, such as surgery (a) involving mucosal surfaces, so-called clean-contaminated; (b) involving implantation of prosthetic material; and (c) where the consequences of infection are especially serious.

B. Definitions. Clean surgery is any procedure where no mucosal surface is involved in the incision. Prosthetic material insertion includes any of the many situations in orthopedic surgery such as artificial joint or tendon, general surgery where meshes are used, or cardiac valve replacement. Clean-contaminated involves a mucosal surface such as oropharynx, bowel, vagina, or gallbladder, including endoscopic retrograde

cholangiopancreatography [1]. Contaminated surgery includes gun shot abdominal wounds. See Table 27B.1 for surgical procedures where prophylaxis is believed to be important [2].

C. Organisms involved. The major pathogen in postoperative clean surgery is *Staphylococcus aureus*. Potential resistant organisms such as methicillin-resistant *S. aureus* (MRSA) should be considered in clean procedures when MRSA is prevalent in an institution. With foreign body insertion, coagulase-negative staphylococcal species is more common than *S. aureus*. Gram-negative bacteria and anaerobes cause wound infections after the surgery of colon, gram-negative bacteria and β streptococcus after gynecologic surgery, and gram-negative bacteria alone after genitourinary surgery. For head and neck surgery, oral anaerobes and other normal oral flora predominate.

D. Timing of antibiotic administration. Antibiotics must be given so that good tissue levels are present at the time of the procedure and for the first 3 to 4 hours after the surgical incision. Reviews suggest that the optimal time to give an antibiotic is **30 to 60 minutes before the incision is made** [2–5]. For cesarean section it should be delayed until the umbilical cord is clamped. Stone et al. [6] showed that antibiotics given 24 hours before the procedure are no more effective than when given just before the procedure. Furthermore, if infection develops in the former, the organisms involved are more resistant than when it develops from the use of perioperative antibiotics [6].

E. Duration

1. In most instances, a single dose is sufficient. Some experts suggest continuing the antibiotics throughout the first 24 hours after surgery. For prosthetic device insertion, up to 48 hours is used.
2. If the procedure lasts several hours, redosing is suggested. For example, in colonic surgery cefotetan requires one dose every 6 to 8 hours. Therefore, it has become preferred over cefoxitin, in a long gastrointestinal procedure, because the latter must be given every 2 hours to maintain high intraoperative levels.

F. Antibiotic choices (Table 27B.1)

1. Cephalosporins are favored because of their spectrum and safety. Because cefazolin is more active against *S. aureus* than the newer cephalosporins, is less expensive, and does not suppress all bacteria, leaving a void for resistant organisms, this agent is preferred for most surgical procedures. Furthermore, cefazolin has a moderately long serum half-life. In colorectal surgery and appendectomy, cefotetan is preferred because of additional activity against bowel anaerobes (also see section E above).
2. Vancomycin is often used for antistaphylococcal activity if the patient is allergic to cephalosporins or MRSA is a major hospital pathogen and prosthetic devices are being inserted.
3. For colon surgery, metronidazole and gentamicin can be substituted for cefotetan.

III. Nonsurgical short-term prophylaxis

A. Bacterial endocarditis prophylaxis. Valve risk and procedure risk guide use. Adequate clinical trials on which to base endocarditis prophylaxis have not been done. Discussion on whether to reduce the use in this situation is ongoing. The 1997 guidelines published by the American Heart Association assist practitioners in their decision making [7].

1. At-risk cardiac lesions (Table 27B.2)

- a. Previous endocarditis, artificial valve, mitral regurgitation, aortic stenosis, or insufficiency and small ventricular septal defect are underlying lesions that require prophylaxis.
- b. **In mitral valve prolapse without regurgitation**, the risk of endocarditis is as low as that of the heart without valvular lesions so **prophylaxis is not indicated** [7,8].

2. Dental and surgical procedures at risk and recommended antibiotics are shown in Tables 27B.3 to 27B.6. In general, clean procedures do not require prophylaxis. Bacteria released are negligible. For procedures during which even low quantities (simple teeth cleaning) of bacteria are released, prophylaxis is administered to those with high risk lesions, but only high quantity release procedures

Table 27B.1. Recommended Antimicrobial Regimens

Surgical Procedure	Recommended Regimen
Biliary tract surgery	
High risk	Cefazolin 1–2 g i.v. × 1 dose or gentamicin 1.7 mg/kg i.v. q8h × 1 or 2 doses ^a
>60 yr	
Obstructive jaundice	
Acute cholecystitis	
Cholangitis	
Common duct stone	
Previous biliary surgery	
Nonfunctioning gall bladder	
Low risk	Not recommended
Gastrointestinal surgery	
Elective colorectal	Oral GI prep; Neomycin 1 g p.o. and erythromycin base 1 g p.o. given at 1 PM, 2 PM, 11 PM on day prior to surgery with or without cefoxitin 2 g i.v. q6h × 1 or 2 doses or cefotetan 2 g i.v. × 1 dose or metronidazole 500 mg i.v. and gentamicin 1.7 mg/kg i.v. q8h × 1 or 2 doses ^a (see text)
Nonelective colorectal	Cefoxitin or cefotetan or metronidazole and gentamicin ^a (at above doses)
Gastroduodenal procedures	
High risk: GI bleeding, obstruction, gastric ulcer or malignancy, decreased gastric acidity, obesity.	Cefazolin 1–2 g i.v. × 1 dose
Low risk	Not recommended
Appendectomy (perforated appendix will need full therapeutic regimen.)	Cefoxitin 2 g i.v. q6h × 1–3 dose(s) or cefotetan 2 g i.v. q12h × 1 or 2 doses or metronidazole 500 mg i.v. q8h and gentamicin 1.7 mg/kg i.v. q8h × 1–3 dose(s) ^a
Gynecological surgery	
Hysterectomy (abdominal or vaginal)	Cefazolin 1 g i.v. × 1 dose or doxycycline 200 IV × 1 dose ^a or clindamycin 900 mg i.v. × 1 dose ^a
Cesarean section	
High-risk patients (i.e., premature membrane rupture, active labor)	Cefazolin 1 g i.v. × 1 dose or metronidazole 500 mg i.v. × 1 dose ^a (after cord clamping)
Low risk	Not recommended
Therapeutic abortion	Cefazolin 1 g i.v. × 1 dose
First trimester with previous PID or midtrimester	
Head and neck surgery	
Incision through oral or pharyngeal mucosa	Clindamycin 600 mg i.v. and gentamicin 1.7 mg/kg i.v. × 1 dose or ampicillin-sulbactam
Uncontaminated	Not recommended
Neurosurgery	
CSF shunt	Not recommended
Craniotomy	Cefazolin 1 g i.v. × 1 dose or vancomycin ^b

(continued)

Table 27B.1. (Continued)

Surgical Procedure	Recommended Regimen
Orthopedics	
Closed reduction of a fracture	Not recommended
Open reduction of a fracture	Cefazolin 1–2 g i.v. × 1 dose
Prosthetic joint replacement	Cefazolin 1–2 g i.v. q6h or vancomycin i.v.; either, up to 24h
Amputation	Cefoxitin 2 g i.v. × 1 dose
Laminectomy and spinal fusion	
Hardware implantation	Cefazolin 1–2 g i.v. × 1 dose
No hardware implantation	Not recommended
Urologic surgery	
If the urine is sterile	Not recommended
If the urine is infected	Sterilize urine before surgery
Transrectal prostate biopsy	Ciprofloxacin 500 mg po or 400 mg i.v. up to 48h
Vascular and cardiothoracic surgery	
Pulmonary resection	Cefazolin 1 i.v. q8h or cefuroxime 750 mg i.v. q8h up to 48h
Prosthetic valve, CABG, pacemaker or defibrillator implant	Cefazolin 1–2g i.v. q8h or cefuroxime 1.5g i.v. q8h or vancomycin IV ^b , doses given for up to 24–48h (see text)
Cardiac catheterization	Not recommended
Peripheral vascular surgery	Cefazolin 1–2 g i.v. × 1 dose

^aAlternative in cephalosporin-allergic patient. (Gentamicin dose assumes normal renal function. See Chapter 271.)

^bFor hospitals in which MRSA commonly cause post-op wounds or in patients allergic to cephalosporins. PID, pelvic inflammatory disease; CABG, coronary artery bypass grafts; CSF, cerebrospinal fluid; GI, gastrointestinal.

Modified from Reese RE, Betts RF, Gumustop B. Prophylactic antibiotics. *Handbook of Antibiotics*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2000; and from Medical Letter. Antimicrobial prophylaxis in surgery. *Med Lett Drugs Ther* 2001;43:92, with permission.

are grounds for prophylaxis in low risk valve lesions. Amoxicillin is used for oral procedures unless penicillin allergy is an issue, and then clindamycin is used. A wallet card is available from the American Heart Association.

3. **Unresolved issues.** Although studies concluding that antibiotic prophylaxis is effective are lacking [7,8], the practice is entrenched in the United States. Failure to use prophylaxis has led to malpractice claims [9]. Some studies challenged the value of antibiotic use before dental procedures in low risk patients. Durack [9] discussed this issue in a recent editorial.

B. Influenza chemoprophylaxis is discussed in detail in Chapter 10.

C. Prophylaxis in those with total joint replacement [10–15]. Evidence to show benefit from prophylaxis is lacking. Infection with the same oral flora that cause endocarditis occurs rarely and then proximal to the original surgery. Some reviews of the data suggest that antibiotics usually add little except expense. It has been recommended that **most patients** with indwelling prosthetic joints generally **do not require antimicrobial prophylaxis** when undergoing dental, gastrointestinal, or genitourinary procedures [3]. **However, for surgery in an infected area**, including periodontal disease and drainage of abscess; **procedures with a high inoculum of bacteria**; and **procedures lasting more than 45 minutes, prophylaxis may be advisable** [13–15].

D. Bacterial meningitis. With the disappearance of *Haemophilus influenzae* type b only meningococcal disease requires prophylaxis. Only family members and intimate

Table 27B.2. Cardiac Conditions Associated with Endocarditis

Endocarditis prophylaxis recommended

High-risk category

- Prosthetic cardiac valves, including bioprosthetic and homograft valves
- Previous bacterial endocarditis
- Complex cyanotic congenital heart disease (e.g., single ventricle states, transposition of the great arteries, tetralogy of Fallot)
- Surgically constructed systemic pulmonary shunts or conduits

Moderate-risk category

- Most other congenital cardiac malformations (other than above and below)
- Acquired valvular dysfunction (e.g., rheumatic heart disease)
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with valvar regurgitation and/or thickened leaflets

Endocarditis prophylaxis not recommended

- Negligible-risk category (no greater risk than the general population)
- Isolated secundum atrial septal defect
- Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residua beyond 6 mo)
- Previous coronary artery bypass graft surgery
- Mitral valve prolapse without valvular regurgitation
- Physiologic, functional, or innocent heart murmurs
- Previous Kawasaki disease without valvular dysfunction
- Previous rheumatic fever without valvular dysfunction
- Cardiac pacemakers (intravascular and epicardial) and implanted defibrillators

From Dajani AS, et al. Prevention of bacterial endocarditis: recommendations by the American Heart Association. *JAMA* 1997;277:1794, with permission.

contacts, but not health-care workers unless they perform mouth to mouth resuscitation, should receive prophylaxis. A single 500-mg dose of ciprofloxacin is effective [16] (see Chapters 6 and 26).

E. Traveler's diarrhea. Prophylactic antibiotics are not advised for healthy travelers. Travelers to risk areas should bring antibiotics to be used if symptoms develop, as discussed in Chapters 13 and 22.

F. Oral antibiotics in the leukopenic host. Multiple studies indicate that prophylaxis given at the outset of chemotherapy does not reduce use of empiric parenteral antibiotics in neutropenic fever. However, ciprofloxacin reduces the incidence of gram-negative bacteremia, which seems to be of benefit [17]. The risks are that the frequency of ciprofloxacin resistance increases.

G. Oral fluconazole in neutropenic subjects. Daily fluconazole reduces the incidence of disseminated candidiasis but not the use of empiric parenteral antifungals. Although some studies show benefit, results in others are less convincing [18]. There is a hint that gram-negative bacteremia is increased in fluconazole recipients and observations of increased incidence of fluconazole resistant candidal infection [19].

H. Endoscopic retrograde cholangiopancreatography. Although antibiotics have often been given for this procedure, data now support their use in this setting [1].

IV. Prophylaxis of medical conditions: long-term use to prevent a specific problem

A. Recurrent urinary tract infections are discussed in Chapter 15.

B. Rheumatic fever. Prevention is discussed in detail elsewhere [20]. Either daily oral penicillin or monthly benzathine penicillin is effective. Most at risk maintain penicillin until age 35. Those who have contact with young children, such as school teachers, continue for that duration.

C. Prevention of serious infections after splenectomy [21–23]. Overwhelming infection due to encapsulated organisms such as *Streptococcus pneumoniae* and, rarely, *H. influenzae* or *Neisseria meningitidis* occur after splenectomy. How to prevent these

Table 27B.3. Dental Procedures and Endocarditis Prophylaxis

Endocarditis prophylaxis recommended ^a
Dental extractions
Periodontal procedures including surgery, scaling and root planing, probing, and recall maintenance
Dental implant placement and reimplantation of avulsed teeth
Endodontic (root canal) instrumentation or surgery only beyond the apex
Subgingival placement of antibiotic fibers or strips
Initial placement of orthodontic bands but not brackets
Intraligamentary local anesthetic injections
Prophylactic cleaning of teeth or implants where bleeding is anticipated
Endocarditis prophylaxis not recommended
Restorative dentistry ^b (operative and prosthodontic) with or without retraction cord ^c
Local anesthetic injections (nonintraaligamentary)
Intracanal endodontic treatment; post placement and buildup
Placement of rubber dams
Postoperative suture removal
Placement of removable prosthodontic or orthodontic appliances
Taking of oral impressions
Fluoride treatments
Taking of oral radiographs
Orthodontic appliance adjustment
Shedding of primary teeth

^aProphylaxis is recommended for patients with high- and moderate-risk cardiac conditions.

^bThis includes restoration of decayed teeth (filling cavities) and replacement of missing teeth.

^cClinical judgment may indicate antibiotic use in selected circumstances that may create significant bleeding.

From Dajani AS, et al. Prevention of bacterial endocarditis: recommendations by the American Heart Association. *JAMA* 1997;277:1794, with permission.

overwhelming infections, which can occur months or years after splenectomy, remains unclear and controversial. Children may be at particularly high risk, but overwhelming pneumococcal sepsis during which organisms are often seen in peripheral blood smears can also occur in adults. Recognition that adults and children are at increased risk of infection years after splenectomy has led to consideration of spleen-sparing surgical approaches after trauma.

- 1. Identification warning.** Because these patients are at risk of fulminant sepsis, we encourage each patient to have some form of personal identification such as a medical alert necklace or bracelet, or note in his or her wallet or purse indicating that he or she has undergone splenectomy. The patient's family should be aware of this potential complication. The patient's medical record should clearly indicate this information.
- 2. Vaccines.** If an elective splenectomy is performed, pneumococcal vaccine should be administered at least 2 weeks before the elective splenectomy [21]. Efficacy of **meningococcal vaccine** in this setting has not been established, but it seems to be a reasonable consideration and has been suggested [23]. A single-dose vial of the quadrivalent vaccine is available now in the United States.
- 3. Prophylactic antibiotics.** Some experts recommend penicillin V, 125 mg twice daily in children and 250 mg twice daily in adults, for at least 2 to 4 years after splenectomy. Whether to use prophylactic penicillin routinely in adults who are not otherwise compromised is a controversial issue [21–23]. We do not routinely treat adults with prophylactic antibiotics but use penicillin in adults with Hodgkin disease who have undergone splenectomy, chemotherapy, or radiation.
- 4. Early therapeutic antibiotics.** Patients can be given a supply of antibiotics for use if an acute illness develops [23]; they should also seek immediate medical

Table 27B.4. Other Procedures and Endocarditis Prophylaxis

Endocarditis prophylaxis recommended
Respiratory tract
Tonsillectomy and/or adenoidectomy
Surgical operations that involve respiratory mucosa
Bronchoscopy with a rigid bronchoscope
Gastrointestinal tract ^a
Sclerotherapy for esophageal varices
Esophageal stricture dilation
Endoscopic retrograde cholangiography with biliary obstruction
Biliary tract surgery
Surgical operations that involve intestinal mucosa
Genitourinary tract
Prostatic surgery
Cystoscopy
Urethral dilation
Endocarditis prophylaxis not recommended
Respiratory tract
Endotracheal intubation
Bronchoscopy with a flexible bronchoscope, with or without biopsy ^b
Tympanostomy tube insertion
Gastrointestinal tract
Transesophageal echocardiography ^b
Endoscopy with or without gastrointestinal biopsy
Genitourinary tract
Vaginal hysterectomy ^b
Vaginal delivery ^b
Cesarean section
In uninfected tissue
Urethral catheterization
Uterine dilatation and curettage
Therapeutic abortion
Sterilization procedures
Insertion or removal of intrauterine devices
Other
Cardiac catheterization, including balloon angioplasty
Implanted cardiac pacemakers, implanted defibrillators, and coronary stents
Incision or biopsy of surgically scrubbed skin
Circumcision

^aProphylaxis is recommended for high-risk patients; optional for medium-risk patients.

^bProphylaxis is optional for high-risk patients.

From Dajani AS, et al. Prevention of bacterial endocarditis: recommendations by the American Heart Association. *JAMA* 1997;277:1794, with permission.

attention. Oral penicillin and amoxicillin have been used. When these patients present with nonspecific febrile illnesses, often flu-like, early antibiotic therapy is rational. Ideally, appropriate cultures should be obtained, but if facilities for culture analysis are not immediately available, starting antibiotics without cultures is reasonable [21]. In community-acquired bacteremia of unclear primary focus of infection, therapy aimed at the likely pathogens should be instituted early while awaiting cultures. Ceftriaxone plus vancomycin are indicated until susceptibility data are available (see Chapter 2).

D. Prevention of recurrent cholangitis. Selected patients with a compromised biliary system such as an endoprosthesis *in situ* or history of choledochojejunostomy, hepaticojejunosomy, or sphincteroplasty who are prone to develop recurrent bouts of cholangitis may benefit from chronic daily prophylactic antibiotics. The aim of

Table 27B.5. Prophylactic Regimens for Dental, Oral, Respiratory Tract, or Esophageal Procedures

Situation	Agent	Regimen ^a
Standard general prophylaxis Unable to take oral medications	Amoxicillin Ampicillin	Adults: 2 g; children: 50 mg/kg orally 1 h before procedure Adults: 2 g intramuscularly (i.m.) or intravenously (i.v.); children: 50 mg/kg i.m. or i.v. within 30 min before procedure Adults: 600 mg; children: 20 mg/kg orally 1 h before procedure
Allergic to penicillin	Clindamycin <i>or</i> Cephalexin ^b or cefadroxil ^b <i>or</i> Azithromycin or clarithromycin Clindamycin	Adults: 2 g; children: 50 mg/kg orally 1 h before procedure
Allergic to penicillin and unable to take oral medications	<i>or</i> Cefazolin ^b	Adults: 500 mg; children: 15 mg/kg orally 1 h before procedure Adults: 600 mg; children: 20 mg/kg i.v. within 30 min before procedure Adults: 1 g; children: 25 mg/kg i.m. or i.v. within 30 min before procedure

^aTotal children's dose should not exceed adult dose.

^bCephalosporins should not be used in individuals with immediate-type hypersensitivity reaction (urticaria, angioedema, or anaphylaxis) to penicillins. From Dajani AS, et al. Prevention of bacterial endocarditis: recommendations by the American Heart Association. *JAMA* 1997;277:1794, with permission.

Table 27B.6. Prophylactic Regimens for Genitourinary Gastrointestinal (Excluding Esophageal) Procedures

Situation	Agents ^a	Regimen ^b
High-risk patients	Ampicillin plus gentamicin	Adults: ampicillin 2 g intramuscularly (i.m.) or intravenously (i.v.) plus gentamicin 1.5 mg/kg (not to exceed 120 mg) within 30 min of starting the procedure; 6 h later, ampicillin 1 g i.m./i.v. or amoxicillin 1 g orally Children: ampicillin 50 mg/kg i.m. or i.v. (not to exceed 2 g) plus gentamicin 1.5 mg/kg within 30 min of starting the procedure; 6 h later, ampicillin 25 mg/kg i.m./i.v. or amoxicillin 25 mg/kg orally
High-risk patients allergic to ampicillin/amoxicillin	Vancomycin plus gentamicin	Adults: vancomycin 1 g i.v. over 1–2 h plus gentamicin 1.5 mg/kg i.v./i.m. (not to exceed 120 mg); complete injection/infusion within 30 min of starting the procedure Children: vancomycin 20 mg/kg IV over 1–2 h plus gentamicin 1.5 mg/kg i.v./i.m.; complete injection/infusion within 30 min of starting the procedure
Moderate-risk patients	Amoxicillin or ampicillin	Adults: amoxicillin 2 g orally 1 h before procedure, or ampicillin 2 g i.m./i.v. within 30 min of starting the procedure Children: amoxicillin 50 mg/kg orally 1 h before procedure, or ampicillin 50 mg/kg i.m./i.v. within 30 min of starting the procedure
Moderate-risk patients allergic to ampicillin/amoxicillin	Vancomycin	Adults: vancomycin 1 g i.v. over 1–2 h; complete infusion within 30 min of starting the procedure Children: vancomycin 20 mg/kg i.v. over 1–2 h; complete infusion within 30 min of starting the procedure

^aTotal children's dose should not exceed adult dose.

^bNo second dose of vancomycin or gentamicin is recommended.

From Dajani AS, et al. Prevention of bacterial endocarditis: recommendations by the American Heart Association. *JAMA* 1997;277:1794, with permission.

suppressive antibiotic therapy is to prevent flare-ups of clinically overt cholangitis. Both trimethoprim-sulfamethoxazole and fluoroquinolones have been used. This topic has been reviewed elsewhere [24].

E. Recurrent otitis media. Pneumococcal prophylaxis is discussed in Chapter 8.

F. Prophylaxis in patients with acquired immunodeficiency syndrome to prevent opportunistic infections such as *Pneumocystis carinii* has recently been reviewed [25] and is discussed in Chapter 18.

G. Spontaneous bacterial peritonitis (see Chapter 13). For those with one proven episode, norfloxacin 400 mg daily taken orally has reduced the 1-year recurrence rate from 68% to 20% [26]. Despite this, ciprofloxacin is generally used. Trimethoprim-sulfamethoxazole has also been used in this setting [27]. This topic was reviewed [28].

C. Penicillin

The term **penicillin** is the generic term for a broad group of agents, including but not limited to penicillin G, penicillin V, oxacillin, nafcillin, ampicillin, ticarcillin, piperacillin, amoxicillin, and dicloxacillin. The major mechanism of action of penicillin is binding to proteins in the cell wall, called penicillin-binding protein. This binding promotes lysis of the bacteria. Thus penicillin is **bactericidal**. Penicillin has other mechanisms of action that are not fully understood.

Some penicillins are excreted primarily by the kidney by both glomerular filtration and tubular secretion; others are excreted via the liver. Penicillin is mainly eliminated via the kidney.

I. Structure [1]. The penicillin nucleus and breakdown products are shown in Figure 27C.1.

A. Structural modifications. Penicillins with differing antimicrobial activity can be synthesized from 6-aminopenicillanic acid by substitution of side chains. This results in compounds with a broader spectrum of activity, resistance to penicillinase, or stability in acid pH (important in oral preparations) and other different pharmacokinetic characteristics.

B. Common nucleus. An intact β -lactam ring (the penicillin nucleus of the molecule) is necessary for biologic activity. In addition, as a result of the common ring in the penicillins, the **potential for allergic cross-sensitivity** is high.

C. Penicillinase is a β -lactamase enzyme that splits the β -lactam ring (Fig. 27C.1, site 1). The resulting penicilloic acid is inactive against bacteria. The penicilloic acid and other breakdown molecules that result may mediate allergic reactions. The penicillins resistant to breakdown have less potential for allergic reactions. Penicillinase production is a principal mechanism of penicillin resistance in coagulase-positive *Staphylococcus aureus*, *Pseudomonas* species, and *Bacteroides fragilis* and one of the mechanisms of resistance in *Escherichia coli* and *Proteus* species. **When a penicillin is combined with a β -lactamase inhibitor (clavulanic acid, sulbactam, or tazobactam), the penicillin escapes breakdown** (see Chapter 27E).

II. Penicillin G: spectrum of activity

A. Gram-positive aerobic cocci

1. Penicillin is bactericidal against *S. pyogenes* (group A), *S. bovis*, and penicillin-susceptible *S. aureus* and against most *Streptococcus pneumoniae* and viridans streptococci. Against enterococci, penicillin G is bacteriostatic.
2. **Resistance of *S. pneumoniae* to penicillin is being seen with increased frequency** [2–6]. This topic is discussed in Chapters 8, 11, and 25.

- d. Effect of resistance on severity of illness.** In experimental animal models using Swiss mice, there is a direct correlation between reduced resistance to penicillin and reduced virulence [8]. However, in humans, antibiotic-resistant pneumococcus appears to be neither more nor less virulent than susceptible strains [9], and disease presentation and progression is equal if proper therapy is not delayed.
- e. Susceptibility of penicillin-resistant *S. pneumoniae* to other antibiotics.** For intermediate-resistant strains, the third-generation cephalosporin ceftriaxone is slightly more active (see Chapter 27F). **Also high serum levels of penicillin, ampicillin, or amoxicillin are clinically effective agents for non-central nervous system infections** [5,10,11]. **Highly resistant strains** are very often resistant to erythromycin and clarithromycin, trimethoprim-sulfamethoxazole, and tetracycline. If these drugs are considered for use, **it is imperative that susceptibility testing is performed.** Expanded-spectrum fluoroquinolones (e.g., moxifloxacin), vancomycin, linezolid, Synercid, and experimental drugs such as daptomycin or oritavancin are active against all strains regardless of degree of penicillin resistance, and imipenem is active against 90% of highly resistant organisms.
- f. Serotypes involved and clinical implications.** Currently, only six serotypes have developed intermediate or high level resistance. All but type 6A is present in the 23-valent pneumococcal capsular polysaccharide vaccine. Therefore **the pneumococcal vaccine should be aggressively promoted and routinely administered.**
- g. Clinical implications of penicillin-resistance** includes the following:
- (1) **Pneumococcal meningitis.** Until susceptibilities have returned, gram-positive organisms seen on Gram stain should be considered as high level penicillin resistant and thus resistant to third-generation cephalosporins (cefotaxime and ceftriaxone). Therapy must include vancomycin and either cefotaxime or ceftriaxone for all individuals older than age 1 month [12] (see Chapter 6).
 - (2) **Sepsis and pneumonia.** High-dose penicillin (150,000 to 200,000 units/kg/day) is effective therapy against strains resistant at the intermediate level [10]. For patients who are severely ill when high level penicillin resistance is a possibility, such as in a grandparent in contact with children who attend day care, a fluoroquinolones such as moxifloxacin or gatifloxacin or vancomycin should be used (see related discussions in Chapter 11).
 - (3) **Otitis media.** Amoxicillin is recommended for initial therapy. The *2000 Red Book* emphasizes the following [12]. Based on concentrations in middle ear fluid and *in vitro* activity, no currently available β -lactam antibiotic, including the oral cephalosporins, has better activity than amoxicillin against penicillin-resistant *S. pneumoniae*. Cefuroxime axetil, cefpodoxime, and cefprozil are the only oral cephalosporins that have comparable, but not greater, activity than amoxicillin for highly resistant strains. Recently, doses of amoxicillin of 60 to 90 mg/kg/day have been suggested to achieve middle ear concentrations active against resistant strains [12,13] (see Chapter 8).
- h. Methods to control** the rising incidence of penicillin-resistant *S. pneumoniae* are being evaluated. These include more careful use of antibiotics in the community, shorter courses of antibiotics, and use of narrower spectrum antibiotics [14,15].
- 3. Resistance of group A streptococci to penicillin** has not been observed.
- B. Gram-negative aerobes.** Penicillin remains the antibiotic of choice for *N. meningitidis* and *Pasteurella multocida* [16] but not for *N. gonorrhoeae*.
- C. Anaerobes.** Penicillin is very effective against anaerobic species [16], including *Clostridium*, *Fusobacterium*, and *Actinomyces israelii* (actinomycosis). Although penicillin is active against many *Bacteroides* species, particularly oropharyngeal strains, it is not active against some of the oral gram-negative anaerobes and

B. fragilis. If *B. fragilis* infections are suspected (e.g., intraabdominal or pelvic infections), another agent should be selected.

D. Spirochetes. Penicillin is the drug of choice for *Treponema pallidum* [16] infection (see Chapter 16) and is active against *Borrelia burgdorferi*.

III. Parenteral preparations of penicillin G (benzyl penicillin). There are three main forms of parenteral penicillin G. The pharmacokinetics differs markedly.

A. Aqueous penicillin G is available in potassium and sodium salt forms. Ordinarily, the potassium salt form is used. Aqueous penicillin is given intravenously and therefore produces **high blood levels**. Excretion is rapid, yielding undetectable penicillin blood levels 4 hours after a dose. Therefore for serious infections, the aqueous form should be given at least every 4 hours.

1. High-dose therapy. In adults with normal renal function, 3 to 4 million units every 4 hours is **used in serious infections**, such as meningitis due to susceptible organisms, in some forms of endocarditis due to mildly penicillin-resistant organisms, and in severe clostridia infections. A continuous infusion of 20 to 24 million units per day can be used [1].

2. Intermediate doses of aqueous penicillin (9 to 12 million units daily) are used in adults with aspiration pneumonia or lung abscess and in moderate to severe soft tissue infection due to group A streptococci. This dose of 9 to 12 million units/day is also used in conjunction with an aminoglycoside such as gentamicin to provide synergy against enterococci (those without high level resistance to gentamicin) and other resistant streptococci in endocarditis. This dose is active for pneumonia caused by intermediate-resistant *S. pneumoniae* (see Chapter 11).

3. Low doses. Procaine penicillin or oral penicillin is an option once the susceptibilities of the pneumococcus return. If the aqueous intravenous form of penicillin is used in known **penicillin-susceptible** pneumococcal pneumonia, the dose can be kept at 2.4 million units/day. High doses of penicillin may only increase the chances of superinfection (see prior discussion in section **II.A.2**).

4. Pediatric dose. For children, 25,000 to 300,000 units/kg/day is recommended, depending on the severity of the infection.

B. Procaine penicillin G. This repository form of penicillin has been developed to prolong the duration of penicillin in the blood. **Doses** usually are given **every 12 hours intramuscularly**. Peak levels (1–2 $\mu\text{g/mL}$) are reached in 2 to 4 hours, and detectable levels are present for 12 to 24 hours. This preparation should not be given intravenously because of the risk of procaine toxicity. To increase the peak serum levels, two separate intramuscular injections must be used. Very few clinical situations exist for its use, but procaine penicillin is used in some of the alternative regimens for syphilis (see Chapter 16).

C. Benzathine penicillin G (long acting) is an insoluble salt obtained by combining an ammonium base with penicillin G. **Very low blood levels** are achieved (approximately 0.10 to 0.15 units/mL), which persist for prolonged periods of time (i.e., 3–4 weeks). Injection-related pain limits its use. **Benzathine penicillin is used most commonly in the following conditions:**

1. Syphilis (primary, secondary, and latent), in which a prolonged blood level is necessary to kill the slowly dividing *Treponema* organisms. *T. pallidum* remains very sensitive to penicillin (MIC = 0.03 unit/mL) (see Chapter 16).

2. Rheumatic fever prophylaxis. A monthly injection will provide a serum level above that necessary to inhibit group A β -hemolytic streptococci [17].

3. Streptococcal pharyngitis. In the high-risk patient (e.g., prior rheumatic fever) or the poorly compliant patient, benzathine penicillin administration will ensure maintenance of adequate levels. Cure rates using penicillin for group A streptococcal pharyngitis are highest with a single dose of benzathine penicillin of 600,000 units in children less than 60 pounds and 1.2 million units in adults and children over 60 pounds [17].

IV. Oral penicillin. Oral penicillin G is partially inactivated by gastric acid. With a minor modification of the side chain, **penicillin V** (phenoxymethyl penicillin) is formed, and this oral congener **resists gastric acid breakdown** and therefore provides acceptable serum levels.

A. Dosage. The usual adult dosage is 250 mg (400,000 units) to 500 mg (800,000 units) every 6 hours. A 500-mg dose results in a peak level of 3 to 5 $\mu\text{g}/\text{mL}$. In children, the usual dosage is 25,000 to 100,000 units/kg/day (16 to 65 mg/kg/day) divided into doses every 6 hours.

B. Uses. Oral therapy is useful in pharyngitis, minor oral or dental infections, in minor soft tissue infections due to susceptible organisms, and for completion of courses of treatment after initial intravenous penicillin therapy. **Group A streptococci remain uniformly susceptible to all penicillins** and cephalosporins. The American Heart Association [17] and the American Academy of Pediatrics recommend a single dose of intramuscular benzathine penicillin or a 10-day course of oral **penicillin V** for group A streptococci. The suggested dose is 500 mg two or three times a day for those older than 12 years and 250 mg two or three times a day for children younger than 12 years.

C. The spectrum of activity of penicillin V is similar to that of penicillin G.

V. Allergic and toxic reactions

A. Penicillin allergy and hypersensitivity reactions. See Chapter 24 for a detailed discussion. However, several comments deserve emphasis.

1. Allergic reactions to penicillin. Adverse reactions to penicillin are estimated to occur in 1% to 10% of patients, with a fatal reaction occurring in 0.002% of patients (see Chapter 24).

a. Immediate reactions. Hypotension or bronchospasm occur within the first 2 to 30 minutes. This is due to release of histamine and other vasoactive amines. The IgE-sensitized mast cells and basophils interact with penicillin or its breakdown products. Death can ensue.

b. Accelerated reactions occur in the first 1 to 72 hours and except for laryngeal edema, which may cause asphyxia, are usually not life threatening. These reactions are also IgE mediated but not modified by IgG.

c. Serum sickness. This can develop while on therapy or more often after completion of a course. Arthritis, skin rash, and nephritis are common features. IgE and IgG acting in conjunction mediate serum sickness reaction. Skin testing done at this time will be positive.

2. Late reactions. These are the **most frequent** type of reaction and **are not immunologically mediated**. They account for 80% to 90% of reactions and occur days after initiation of therapy.

a. Morbilliform rash. No definite allergic mechanism has been demonstrated for this reaction. It is not IgE mediated. This rash cannot be predicted or diagnosed by skin tests.

b. Fever may be the only manifestation of a penicillin reaction, and its occurrence does not preclude use of penicillin in the future. However, because fever may accompany vasculitis, patients with a drug fever history require careful observation on reexposure.

c. Eosinophilia occurs with penicillin use. When the level exceeds 15% of the peripheral white blood cell count, patients may go on to more serious drug reactions (see Chapter 24).

d. Interstitial nephritis may occur at high doses with any penicillin [18], at any age, and may be a hypersensitivity reaction. Fever, hematuria, proteinuria, morbilliform rash, peripheral eosinophilia, and renal failure (50% of cases) occur several days into therapy. Some patients have eosinophils in their urine sediments, which is a helpful diagnostic clue. Renal biopsy reveals an interstitial nephritis with eosinophilic aggregations.

The offending agent should be discontinued. Whether cephalosporins can be used safely is uncertain, but we would be inclined not to use another β -lactam antibiotic.

e. Central nervous system toxicity. High blood levels lead to excessively high spinal fluid levels of penicillin. This occurs with high doses in renal failure because penicillin diffuses into the spinal fluid and then competes with the other organic acids to be transported out (see section VI.A.1). **Myoclonic twitching** is an early clue. The patient may develop **seizures**.

3. Cross-reactions (also see Chapter 24)

- a. **Other penicillins.** Patients with a history of allergy to a penicillin should be presumed to be allergic to other penicillins unless skin tests prove otherwise.
 - b. **Cephalosporins and imipenem.** In penicillin-allergic patients, studies suggest that risk of cross-allergy to a cephalosporin ranges from 5% to 15%. The more stable third-generation cephalosporins may cross-react as infrequently as 1% [1,19–21]. **When there is a history of immediate penicillin reaction, cephalosporins skin tests should be performed before their use. Patients allergic to penicillin may cross-react to imipenem.** In the patient with a history of delayed mild reaction to penicillin, cephalosporins or imipenem, in our experience, are used without difficulty [1,20,21].
 - c. **Aztreonam.** Patients allergic to penicillin can receive aztreonam without risk.
4. **Documentation of allergic history.** Because the distinction between an immediate versus a delayed allergic reaction is crucial for determining future antibiotic administration, it is important to elicit this history carefully and to document it in the patient's record.

VI. Special considerations

A. Dosage modification in renal failure

1. **High dose regimens of aqueous penicillin.** In moderate to severe renal failure and in the elderly, **to avoid central nervous system toxicity, penicillin G doses must be reduced (Table 27C.1).**
2. When **moderate intravenous doses** (i.e., 9–12 million units/day) are to be used in patients with renal failure, we tend to reduce doses proportionately (Table 27C.1).
3. With **low dose intravenous** or oral penicillin regimens, standard doses are used.

B. Hemodialysis removes variable amounts of penicillin. For a high dose regimen, reduce the dose but supplement with 500,000 units after each 6-hour dialysis (Table 27C.1). For a moderate or low dose regimen, supplement with 500,000 units

Table 27C.1. Equivalent Doses of Aqueous Penicillin G for High-dose Therapy in Renal Failure^a

Endogenous Creatinine Clearance (mL/min)	Penicillin G Dose ^b and Dose Interval ^c (units)
125	1.7–2.0 million q2h or 2.6–3.0 million q3h
60	1.8–2.0 million q4h
40	1.3–1.5 million q4h
20	800,000–1 million q4h
10	800,000–1 million q6h
0	500,000–800,000 q6h or 700,000–1.1 million q8h
<10 ^d	500,000 q8h

^aTo achieve mean blood levels equivalent to 24 million units per day in the adult with normal renal function, the above doses and dose intervals can be used in patients with renal failure. **A loading dose** of 750,000–1,200,000 units is suggested in patients with a creatinine clearance of less than 20 mL/min, and then the above doses and intervals can be followed. In patients with a creatinine clearance exceeding 20 mL/min, no loading dose is suggested.

^bThe lower dose is calculated to provide a mean serum level of 20 $\mu\text{g/mL}$ for the “average patient.” The higher dose is an overestimate.

^cAfter hemodialysis, an additional 500,000 units should be given to replace expected losses for an average full 6-h dialysis.

^dBecause the extrarenal clearance of penicillin is impaired by liver disease, in patients with hepatic and renal failure (creatinine clearance < 10 mL/min), even lower doses of penicillin G are suggested.

Adapted from Bryan CS, Stone WJ, “Comparable massive” penicillin G therapy in renal failure. *Ann Intern Med* 1975;82:189.

every other dialysis. **Peritoneal dialysis** likewise removes a variable amount of penicillin. No supplementation is provided.

C. Probenecid use. Approximately 90% of penicillin is eliminated by tubular secretion and 10% by glomerular filtration. Probenecid blocks the renal tubular secretory transport, and this in turn results in higher (usually approximately twofold) and more prolonged blood levels of penicillin.

1. Dosage. Probenecid 500 mg orally four times a day. The major side effect is gastrointestinal, but rash frequency occurs.

2. Uses. Because probenecid increases side effect frequency, **we seldom use probenecid with oral therapy.** Amoxicillin may be preferred because this agent will provide higher serum levels.

D. Penicillinase-resistant Penicillins

Penicillinase-resistant penicillins are synthesized by modifying the side chain of the common penicillin nucleus. The substituted side chain inhibits penicillinase (a β -lactamase) by preventing opening of the β -lactam ring. **These bactericidal agents are used primarily to treat penicillinase-producing *Staphylococcus aureus* [1,2].**

- I. **Available agents.** Two parenteral (nafcillin and oxacillin) and two oral (cloxacillin and dicloxacillin) agents are available. Methicillin, which is nephrotoxic, is no longer available.
- II. **Spectrum of activity**
 - A. ***S. aureus* penicillin resistant**
 1. **Methicillin-susceptible *S. aureus* (MSSA)**
 - a. ***In vitro*** The minimum inhibitory concentration (MIC) of MSSA to nafcillin or oxacillin ranges from 0.78 to 1.56 $\mu\text{g/mL}$.
 - b. **Clinical** Compared with the other agents that have activity (cefazolin, vancomycin), both nafcillin and oxacillin produce a higher cure rate [3,4]. In MSSA bacteremia, gentamicin is often used (1 mg/kg every 8 hours) in the first few days of therapy.
 2. **Methicillin-resistant *S. aureus* (MRSA) [5,6].** Although MRSA was previously considered only a nosocomial pathogen, recent data show that MRSA is becoming more common as a community-acquired pathogen [6]; see related discussion in Chapters 4 and 5.
 - a. Neither nafcillin nor oxacillin has any meaningful activity against MRSA, whose resistance is mediated by change in the penicillin binding proteins [6].
 - b. A small percent of MRSA are resistant because of a high concentration of β -lactamase. Increasing the dose of nafcillin or oxacillin can overcome this resistance.
 - B. **Other gram-positive aerobes.** Nafcillin and oxacillin are active against penicillin-susceptible *Streptococcus pneumoniae*, *S. pyogenes*, and *S. aureus*, but the MICs for these organisms are higher than for penicillin, making penicillin the preferred agent [1,4] **even for penicillin-susceptible *S. aureus*.** They are not useful in penicillin-resistant *S. pneumoniae* infections and are only minimally active against enterococci. **The penicillinase-resistant penicillins are drugs of first choice only for penicillinase-producing MSSA [4].**
 - C. **Gram-negative aerobes.** These agents are **not active against** the Enterobacteriaceae. The penicillinase-resistant penicillins are **not recommended in the treatment of gonorrhea.** For patients with infections due to *Pasteurella multocida*, penicillin is the preferred agent [4]. In animal bite wounds with mixed flora, amoxicillin-clavulanate (or ampicillin-sulbactam) is suggested (see Chapter 4).
 - D. **Anaerobes.** The penicillinase-resistant penicillins are less active than penicillin against penicillin-susceptible anaerobes and, like penicillin, are not active against *Bacteroides fragilis*.
- III. **Clinical activity parenteral preparations.** There are no adequate studies to determine which antistaphylococcal agent is more effective [1–4]. Overall, oxacillin and nafcillin are very similar and, except as noted later, are probably interchangeable. Methicillin was more commonly associated with interstitial nephritis, especially in adults; it is no longer available in the United States [2].

A. Nafcillin

1. **Dosage.** In adults, 6 g/day intravenously is recommended for moderate infections. For severe infections, 9 to 12 g/day intravenously has been suggested, but limiting the dose to 9 g/day seems to avoid excessive side effects. Because this antibiotic kills by concentration-dependent effects, the MIC simply needs to be exceeded and the 1.5-g dose is sufficient. In children, the usual dose is 100 to 200 mg/kg/day in divided doses every 4 to 6 hours. Because the half-life is short (40 minutes) and levels are undetectable at 2.5 to 3.0 hours, a 4-hour dose interval is preferred. Dosages for neonates are shown in Appendix Table 1. **Nafcillin should not be**

used in infants with jaundice. It is excreted primarily by hepatic mechanisms that may be deficient in these neonates or infants [1].

a. In renal failure and dialysis, dosage modification is not necessary [7]. **Nafcillin is an excellent choice in renal failure** when a semisynthetic penicillin is needed.

b. Hepatic failure. Dose reduction is required in hepatic failure. Even when renal function is normal, renal toxicity occurs if standard doses are used in the presence of significant hepatic dysfunction simply because high levels are exposed to the kidney.

2. Central nervous system penetration. Studies have shown adequate penetration of nafcillin into the spinal fluid, particularly when inflammation is present. Some authors suggest nafcillin is the **drug of choice in MSSA staphylococcal meningitis** [1,2].

3. Side effects. Penicillin-like allergic reactions may occur. Rarely, neutropenia has been observed. Interstitial nephritis appears to occur less frequently than with methicillin (see above). Phlebitis and/or pain often develops at the infusion site and is much more common with nafcillin than with oxacillin [1].

B. Oxacillin

1. Dose is similar to nafcillin and should be limited to 1.5 g every 4 hours in adults and older children.

a. Renal failure. Because oxacillin is excreted mainly by the liver and somewhat by the kidney, in renal failure doses do not have to be modified. **The exception is the individual with hepatic failure. Hemodialysis and peritoneal dialysis** do not remove oxacillin [7].

b. Hepatic failure (see section A.1.b)

2. Side effects. Oxacillin-related **hepatitis** in prolonged intravenous use has been described [8]. Therefore **weekly liver function tests are advisable for patients receiving prolonged therapy.** *Clostridium difficile* diarrhea may occur. Interstitial nephritis may occur with oxacillin use, but it is less frequent than after methicillin use (see section A.3). Neutropenia also occurs.

IV. Oral preparations (cloxacillin, dicloxacillin)

A. Indications for use. Oral penicillinase-resistant penicillins often are considered the oral drugs of choice for known or highly suspected penicillin-resistant mild staphylococcal infections. They are useful in treating soft tissue infections due to susceptible *S. aureus* or mixed *S. aureus* and *S. pyogenes* (group A streptococci). However, the first-generation oral cephalosporins have less frequent gastrointestinal side effects and are therefore often preferred over cloxacillin or dicloxacillin (see section C).

B. Agents available. These are better absorbed in the fasting state.

1. Cloxacillin is available in a solution (125 mg/5 mL) and in 250- and 500-mg capsules. Usual dosage in children is 50 to 100 mg/kg/day and in adults, 1 to 2 g/day divided into four equal doses.

2. Dicloxacillin is available as a suspension (62.5 mg/5 mL) and in 125- and 250-mg capsules. The usual dosage in children is 25 to 50 mg/kg/day; in adults, the usual dosage is 1 to 2 g/day divided into four equal doses. The higher dose range may be preferable for adequate antistaphylococcal activity.

C. Side effects. Mild **gastrointestinal symptoms** are common; often the standard oral dosages (e.g., 500 mg every 6 hours in adults) cannot be tolerated. Furthermore, the poor taste of the oral suspension may adversely affect compliance in children [9]. A first-generation oral cephalosporin is better tolerated and therefore often preferred. If severe or persistent diarrhea occurs, antibiotic-related diarrhea must be considered.

E. Broad-spectrum Penicillins and β -Lactam- β -Lactamase Combinations

Several side-chain modifications of penicillin have been made to provide enhanced activity of the broad-spectrum penicillins (Table 27E.1).

I. Aminopenicillins: ampicillin and amoxicillin [1,2].

A. Spectrum of activity. In addition to being active against penicillin-susceptible organisms, **ampicillin** is more active than penicillin against enterococci, *Listeria monocytogenes*, and β -lactamase-negative *Haemophilus influenzae*.

1. **Drug of choice:** For *L. monocytogenes*, group B streptococci (*S. agalactiae*), *Proteus mirabilis*, and *Eikenella corrodens* [3].
2. **Useful when proven active:** Many *Escherichia coli*, *Salmonella* species, and *Shigella* species are susceptible, so that ampicillin is a good choice once susceptibility studies are available [3]. About 50% of *E. coli* are susceptible but far fewer *Salmonella*.
3. **Predictably inactive:** Ampicillin should not be used for penicillinase-producing *Staphylococcus aureus* or β -lactamase-positive *H. influenzae* or *Moraxella catarrhalis*.
4. **Amoxicillin:** Only available for oral use. It is closely related to ampicillin in both chemical structure and antibacterial activity. Amoxicillin provides twice the serum level of oral ampicillin. Amoxicillin is given three times a day rather than the four times a day for ampicillin. Consequently, **amoxicillin has replaced oral ampicillin** [1,2], except that ampicillin is still preferred for susceptible *Shigella* species [3].
5. **The combination of amoxicillin-clavulanate (Augmentin) is discussed separately** in section III.B.

Table 27E.1. Available β -lactamase Inhibitors and β -lactam Antibiotic Combinations

Active Antibiotics	β -Lactamase Inhibitor	Trade Name	Comment
Amoxicillin	Clavulanate	Augmentin	Only as oral agent
Ticarcillin	Clavulanate	Timentin	Only parenteral
Ampicillin	Sulbactam	Unasyn	Only parenteral
Piperacillin	Tazobactam	Zosyn	Only parenteral; most active antibiotic <i>in vitro</i>

B. Clinical usage

1. **Ampicillin intravenously** should be limited to those situations where susceptibilities are known. It is an excellent choice for susceptible enterococcal or group B streptococcal infections.
2. **Use is discouraged in combination therapy for the following:**
 - a. **Pyelonephritis** with an aminoglycoside. Pyelonephritis due to enterococcus is uncommon, except in older men, and usually is relatively mild. For gram-negative organisms other single agents make more sense.
 - b. **Intraabdominal infections.** Though used in combination with gentamicin and clindamycin for intraabdominal and gynecologic infections, use of three antibiotics increases the side effect potential and is inconvenient. The same coverage can be provided by piperacillin/tazobactam.
3. **Amoxicillin**, available as an **oral agent only**, is used for the following:
 - a. **Acute otitis media**, as discussed in Chapter 8.
 - b. **Acute sinusitis persisting for 10 days or longer** (see Chapter 8).
 - c. **Exacerbation of chronic bronchitis**, as discussed in Chapter 8.
 - d. **Susceptible pathogens in nonbacteremic urinary tract infection (UTI).**
 - e. "Step-down" therapy after completion of intravenous ampicillin (see section 1).
 - f. Oral prophylactic antibiotic regimens to prevent endocarditis after dental manipulations (see section **B**, above, and Chapter 12).

C. Dosage**1. Ampicillin**

- a. **Intravenous. In adults**, 6 to 12 g daily is given depending on the organism involved and the severity and site of the infection. In adults with moderately severe infections, 1 g should be given every 4 to 6 hours. The half-life is about 120 minutes. For more severe infections, 1.5 g every 4 hours may be necessary and, in *Listeria meningitis* in the adult, 2 g every 4 hours is used. **In children**, the usual dosage range is 100 to 200 mg/kg/day in divided doses every 6 hours. Neonatal doses are shown in the Appendix Table.
- b. **Oral.** The usual adult dose is 250 to 500 mg every 6 hours **on an empty stomach**. In children, 50 to 100 mg/kg/day in divided doses every 6 hours is suggested. Amoxicillin has replaced oral ampicillin.
- c. **Intramuscular.** Ampicillin can be given intramuscularly, but intravenous is preferred.
- d. **Renal failure.** Because ampicillin is excreted by the kidney, dosage is modified in patients with significant renal impairment, particularly when high dose regimens are used. If the creatinine clearance is 10 to 50 mL/min, the standard dose can be given every 6 to 12 hours. If the creatinine clearance is less than 10 mL/min, the standard dose can be given every 12 to 24 hours [4].
- e. **Dialysis.** Ampicillin is partially removed by hemodialysis. After dialysis, a supplemental dose is required. Peritoneal dialysis does not significantly lower ampicillin serum levels. For oral therapy, 250 mg every 12 hours has been used [4].
- f. **Pregnancy.** Ampicillin crosses the placenta and should be used conservatively in pregnancy.
- g. **Nursing mothers.** Ampicillin is excreted in human milk. The neonate could be sensitized by ampicillin in the mother's milk, so this agent should be used conservatively in nursing mothers.

2. Amoxicillin

- a. **Adults and children.** Since its introduction, the adult dose has been 250 to 500 mg every 8 hours, and the fasting state is not essential. More recently, **the suggested adult dose has been increased to 1.0 g every 8 hours.** In children, 20 to 40 mg/kg/day is given in divided doses every 8 hours. An oral suspension is available with 250 mg/5 mL and 125 mg/5 mL. **For otitis media in children, the high-dose regimen is discussed in Chapter 8.**
- b. **Renal failure.** If the creatinine clearance is 10 to 50 mL/min, the standard dose can be given every 12 hours. If the clearance is less than 10 mL/min, the standard dose can be given every 24 hours [4].

- c. **Dialysis.** Dosage is as described for ampicillin; see the preceding discussion. In chronic ambulatory peritoneal dialysis patients, 250 mg every 12 hours has been suggested [4].
- d. **Pregnancy.** The package insert notes that safety for use in pregnancy has not been established.
- e. **Nursing mothers.** Amoxicillin is excreted in human milk (see section 1.g, above).

D. Adverse effects of ampicillin (and amoxicillin)

1. These are similar to those described under penicillin discussed previously in this chapter.
2. **Rash.** Epstein-Barr virus infection (mononucleosis), acute lymphocytic leukemia, or cytomegalovirus infection increases the risk for an ampicillin (or amoxicillin) maculo papular rash to 60% to 100%. This does not appear to be mediated by IgE [5] and should not be interpreted as an allergic reaction. Morbilliform rashes, occurring unassociated with Epstein-Barr virus, are more common with ampicillin (amoxicillin) than with penicillin for unclear reasons [5].

II. Extended-spectrum penicillins. The carboxypenicillins include **carbenicillin (only oral available)** and **ticarcillin** and ureidopenicillins, **piperacillin**. They were introduced for more resistant gram-negative bacteria, including *Pseudomonas aeruginosa* [1,2].

A. Spectrum of activity

1. **Gram negative.** This group of antibiotics is active against many but not all Enterobacteriaceae, most *P. aeruginosa*, and other nosocomial gram-negative bacteria. Susceptibility testing is required. The extended-spectrum penicillins are synergistically active when used in conjunction with aminoglycosides. They are inactive against β -lactamase producing *Haemophilus* species, *N. gonorrhoea*, and *Moraxella catarrhalis*.
2. **Gram positive.** Activity mimics that of ampicillin. The ureidopenicillins (not the carboxypenicillins) are active against ampicillin-susceptible enterococci at doses used for gram-negative bacilli. They are inactive against both *Staphylococcus aureus* and penicillin-resistant *Streptococcus pneumoniae*.

B. Overview of uses

1. For susceptible pathogens, prospective comparative studies have failed to demonstrate clinical superiority of one of these agents over another [1,2]. Except against *P. aeruginosa*, these agents are not “**drugs of choice**” [3].
2. For severe *P. aeruginosa* infection (e.g., pneumonia, sepsis), **monotherapy** with these agents is associated with the rapid emergence of resistance that requires any one of these to be combined with an aminoglycoside to decrease that likelihood of selecting resistant organisms. [1–3].
3. For hospital-acquired gram-negative organisms, including *P. aeruginosa*, one of these agents is combined with an aminoglycoside. Often the combination is synergistic (see discussions in Chapters 2 and 20).
4. These agents are active against anaerobes, including bowel anaerobes, but are considered “second-line” agents.
5. One of these agents combined with an aminoglycoside has historically been a useful combination for empiric therapy of the febrile neutropenic patient (see Chapter 20).

C. Which agent?

1. **Ticarcillin versus piperacillin.** Generally, the pharmacy and therapeutics committee of each hospital selects one of these agents for routine use.
 - a. **Piperacillin compared with ticarcillin** has lower sodium load per daily dose, is more active *in vitro*, and has less acquired platelet dysfunction, thereby reducing the likelihood for bleeding after surgery and/or in patients with renal failure [6]. However, the bactericidal mechanism may be more effective for ticarcillin.
 - b. **Because piperacillin** overall is about four times more active against *P. aeruginosa* than is ticarcillin [2], **piperacillin** is generally preferred because the situation in which they are most often used is when *P. aeruginosa* is the likely or the proven cause of the infection.

D. Dosages

1. **Adults.** Because of a relatively short half-life in normal renal function, the dose interval should be 4 hours, and a dose of 3 g is reasonable. Piperacillin, due to its nonlinear pharmacokinetics, may be dosed as 4 g every 6 hours. For UTI, 6 g/day can be used.
2. **Children.** In children 12 years of age or older, 200 to 300 mg/kg/day intravenously (not to exceed the adult daily dose) in divided doses every 4 (or sometimes 6) hours is suggested. Dosages for children younger than 12 years have not been established, and the safety of this agent in neonates is not known.
3. **Renal failure.** No dose reduction is necessary until the creatinine clearance is less than 50 mL/min. If the creatinine clearance is 10 to 50 mL/min, 3 to 4 g is given every 6 hours, and if less than 10 mL/min, 3 to 4 g is given every 8 hours [4].
 - a. **Hemodialysis.** Because dialysis removes 30% to 50% of the serum levels, a dose of 2 g every 8 hours, with a supplemental 1-g dose after hemodialysis, is recommended. A 3- to 4-g dose every 8 hours with a dose after dialysis has been used with piperacillin [4].
 - b. **With peritoneal dialysis** the doses for renal failure less than 10 mL/min can be used [4].
4. **For both hepatic and renal insufficiency occurring together,** 3.0 g per day is given, and ideally, levels monitored.
5. **Pregnancy.** This is a category B agent (see Chapter 16). Because there are no well-controlled studies in pregnant women, this drug should be used during pregnancy only if clearly needed.
6. **Nursing mothers.** These drugs are excreted in low concentrations in milk; therefore caution should be exercised when these agents are administered to nursing mothers.
7. **Cost** data are shown in Appendix Table 1.
8. **Side effects.** The side effects seen with penicillin may occur with these agents.
 - a. Hypokalemia occurs less commonly with piperacillin than with carbenicillin [1,2].
 - b. Platelet dysfunction is uncommon with piperacillin [1,2].

III. β -Lactam- β -lactamase combinations: an overview

A. Background. Because structural modification of the penicillin side chain has limitations, new strategies of extending the antibacterial spectrum of the penicillin family were explored. Because the primary mechanism of bacterial resistance to penicillins is through β -lactamase (enzyme) production, inactivation of these enzymes was the next logical step [1,2]. Therefore a β -lactamase inhibitor (e.g., clavulanate, sulbactam, or tazobactam) was combined with certain extended penicillins. These β -lactamase inhibitors bind **irreversibly to the β -lactamase** (plasmid mediated) and the bound β -lactamase cannot hydrolyze the penicillin [7]. Hence, the penicillin is free to interact with the penicillin binding proteins and exerts its antibacterial effect [2]. The benefit is provided only when the bacterial resistance is the result of β -lactamase production [1]. Worldwide, more than 90% of *S. aureus* and *B. fragilis* are β -lactamase producers [8].

B. Spectrum of activity

1. **Susceptible.** The inhibitors are effective against β -lactamases produced by *S. aureus*, *H. influenzae*, *M. catarrhalis*, *Bacteroides* species, many *Escherichia coli*, and Enterobacteriaceae.
2. **Resistant.** Some species of *Enterobacter*, *Citrobacter*, *Serratia*, *Morganella*, and *Pseudomonas*, among others, produce β -lactamases that are usually chromosomally encoded and are not inhibited by these β -lactamase inhibitors [2].
3. **Determinant of antimicrobial activity.** The *in vitro* activity of the active antibiotic is very important. For example, piperacillin/tazobactam activity against gram-negative organisms is greater than that of ticarcillin/clavulanate or ampicillin/sulbactam because of the relative greater activity of piperacillin [8]. If the mechanism of resistance is to the penicillin and not mediated by β -lactamase, these antibiotics are not effective. As such, methicillin-resistant

S. aureus (MRSA), high level penicillin-resistant pneumococcus, and vancomycin-resistant enterococci are resistant to the β -lactam- β -lactamase combination.

C. Oral agents. Amoxicillin-clavulanate (Augmentin) is the only oral combination agent available.

1. Activity. Separate susceptibility testing must be performed with the combination. Clavulanic acid inhibits the β -lactamase of *S. aureus*, *N. gonorrhoeae*, *H. ducreyi*, *M. catarrhalis*, and *H. influenzae* (10%–30% of these organisms are β -lactamase positive). In addition, clavulanic acid inhibits β -lactamase produced by many gram-negative bacilli, including *E. coli*, *Klebsiella*, and *Proteus* species. Therefore the combination of amoxicillin-clavulanate is active against amoxicillin-susceptible and many previously amoxicillin-resistant organisms. This includes 97% to 100% of oxacillin-susceptible *S. aureus*, most streptococci (including most enterococci), *N. gonorrhoeae*, *H. influenzae*, *E. coli*, and *Klebsiella* species. It is not active against the β -lactamase produced by *Enterobacter* species, *Pseudomonas* species, and *Serratia* species. High level penicillin-resistant *S. pneumoniae* are resistant to amoxicillin-clavulanate.

2. Pharmacokinetics

- a.** Both components are **well absorbed**. Peak levels occur at 1 hour, independent of meals, antacids, or milk.
- b.** The drugs penetrate peritoneal and pleural fluids well. **Very high urine levels** are achieved compared with modest serum levels. There is only fair penetration into pulmonary secretions; therefore higher doses are necessary in pulmonary infections.

3. Clinical uses

- a. Human and animal bite wounds.** Because of the polymicrobial nature of these infections, **this agent is the drug of choice** in this setting (see detailed discussion in Chapter 4).
 - b. Alternate therapy in acute otitis media.** Amoxicillin remains the drug of choice in this setting, but for patients who fail amoxicillin or as initial therapy in areas with very high resistant rates of *H. influenzae*, Augmentin is very effective [9,10] (see related discussions in Chapter 8).
 - c. Acute bacterial sinusitis** can often be managed with amoxicillin, but amoxicillin-clavulanate is preferred in some situations (see Chapter 8).
 - d. UTI.** Although the fluoroquinolones and trimethoprim-sulfamethoxazole are commonly used in UTI, for susceptible pathogens amoxicillin-clavulanate provides another possible oral agent; it is not used for uncomplicated UTI caused by amoxicillin-susceptible organisms.
 - e. Pulmonary infections.** It is useful in exacerbation of chronic bronchitis and in mild community-acquired pneumonia in children and adults (see Chapters 8 and 11). (N.B. It is not active against *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, or *Legionella*.)
 - f. Other considerations** include mild diverticulitis (see Chapter 13) and wound infections due to susceptible pathogens.
- 4. Dosages.** This agent **should be administered** at the start of a meal to decrease the incidence of gastrointestinal (GI) side effects. It is available in the United States only in an oral form.
- a. Oral chewable tablets** are in doses of **250 mg amoxicillin and 62.5 mg clavulanate; 125 mg amoxicillin and 31.25 mg clavulanate** are for pediatric use.
 - b. Oral suspension** is available in doses of 125 mg amoxicillin and 31.25 mg clavulanate/5 mL, 250 mg amoxicillin and 62.5 mg clavulanate/5 mL, and 400 mg amoxicillin and 57 mg clavulanate/5 mL.
 - c. Adult-sized tablets:** 250 mg amoxicillin and 125 mg clavulanate given three times a day, 500 mg amoxicillin and 125 mg clavulanate given three times a day, and 875 mg amoxicillin and 125 mg clavulanate given every 12 hours.
- Note: Two of the 250-mg amoxicillin/125-mg clavulanate tablets should not be taken at one time, because the double dose of clavulanate is more likely to cause GI toxicity. To provide a 500-mg dose, give one 250-mg amoxicillin/125-mg clavulanate tablet with one 250-mg generic tablet of amoxicillin. **The**

chewable tablets and adult tablets have different amoxicillin-to-clavulanate ratios, as noted above, and should not be interchanged.

- d. **For adults** the usual dose is one 250-mg tablet every 8 hours or one 500-mg tablet every 12 hours. For more severe infections and respiratory tract infections, one 875-mg tablet every 12 hours or one 500-mg tablet every 8 hours is advised. (**N.B.** The every 12 hour regimen is associated with fewer GI side effects.)
- e. **Children. Suspension or tablets for children: For otitis media when there is amoxicillin failure**, higher doses of the amoxicillin component are advised, 80 to 90 mg/kg/day, using the new formulation to keep the dose of clavulanate at about 10 mg/kg/day [10]. Before the era of increasing penicillin resistance, regimens used 40 to 45 mg/kg/day of the amoxicillin component (see Chapter 8). For sinusitis, lower respiratory tract infections, and more severe infections, the amoxicillin component of 45 mg/kg/day divided every 12 hours or 40 mg/kg/day divided every 8 hours has been used. For less severe infection 25 mg/kg/day divided every 12 hours or 20 mg/kg/day divided every 8 hours has been suggested. **Children weighing 40 kg or more can follow adult dose regimens.** The adult-sized 250-mg tablet should not be used unless the child weighs more than 40 kg.
- f. **Renal failure.** The package insert does not suggest dose modification if renal failure is modest (i.e., creatinine clearance of more than 30 mL/min). With a creatinine clearance of less than 30 mL/min, do not use the 875-mg tablet. With a creatinine clearance of 10 to 30 mL/min, use 250 or 500 mg every 12 hours, depending on the severity of the infection. With creatinine clearance of less than 10 mL/min, use 250 or 500 mg every 24 hours, depending on the severity of infection. **Hemodialysis patients** should receive 250 or 500 mg every 24 hours, depending on the severity of infection. Patients should receive an additional dose during and at the end of dialysis.
- g. **Pregnancy.** This is a category B agent (see Chapter 16). Because there are no adequate and well-controlled studies in pregnant women, this agent should be used during pregnancy only if clearly needed. The combination has been safe in pregnant women with bacteruria or UTI.
- h. **Nursing mothers.** Because amoxicillin is excreted in breast milk, the package insert suggests exercising caution if this agent is administered to a nursing woman.

5. Side effects

- a. The usual side effects of penicillin can occur with amoxicillin-clavulanate.
- b. **GI side effects**—nausea, vomiting, diarrhea, and abdominal cramps—occur in 10% or more of patients [10]. These are related in part to the dose of clavulanate (i.e., more symptoms at higher doses) and can be **minimized if the drug is taken at the start of a meal** [1,10]. **Also, the every 12 hour regimens** are associated with fewer side effects than the every 8 hour regimens (see section C.4.e).

6. Cost. This is a relatively **expensive** agent (see Appendix Table 1).

D. Intravenous β -lactam and β -lactamase combinations

1. Ampicillin-sulbactam (Unasyn) was approved in 1987.

- a. ***In vitro* activity.** Sulbactam inhibits many bacterial β -lactamases, thereby extending the activity of ampicillin. The combination *in vitro* is active against β -lactamase-producing strains of *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, many anaerobes (including *B. fragilis*), *E. coli*, *Proteus* species, *Klebsiella* species, *Acinetobacter calcoaceticus*, *S. aureus*, and *S. epidermidis*.
 - (1) **Ampicillin-sulbactam is not active against MRSA, *P. aeruginosa* and certain Enterobacteriaceae strains (*Serratia*, *Enterobacter*, and *Citrobacter* species)** (see section III.B.3).
 - (2) ***E. coli*: Approximately 20% to 25% or more of *E. coli*** (including community-acquired) **are resistant** to this combination [10]. Most of these *E. coli* strains have minimal inhibitory concentrations that are very close to the breakpoint concentration for determining susceptibility (≤ 8 $\mu\text{g/mL}$). Although the clinical significance of this laboratory

observation is unknown, a study in an animal model of infection caused by an ampicillin-sulbactam-resistant isolates of *E. coli* found the agent to be ineffective [11]. Overall, not as many gram-negative bacilli are inhibited by ampicillin-sulbactam *in vitro* as by many cephalosporins or other intravenous β -lactam- β -lactamase combinations (Table 27E.2).

- b. Pharmacokinetics** of ampicillin are not altered by the coadministration of sulbactam. **Excretion**, of both components, is primarily in the urine. **Tissue levels** are achieved in extravascular fluids, bile, and peritoneal and cerebrospinal fluids.
- c. Clinical uses** [1–3]. This agent has been very useful, especially in the **mixed aerobic and anaerobic** infections, including mild to moderately severe community-acquired intraabdominal infection, aspiration pneumonia, community-acquired pneumonia (although it does not cover *Legionella* or *Mycoplasma*), UTI, pelvic infection, deep neck infection, and soft tissue infection, including diabetic foot infection.
- d. Dosage**
- (1) **Adults.** The **usual dose** for mild to moderate infection is **1.5 g** (1 g ampicillin plus 0.5 g sulbactam) **every 6 hours** if renal function is normal. **In severe infection and/or most intraabdominal infections**, 3 g (2 g ampicillin and 1 g sulbactam) every 6 hours is used. **It is important to adjust doses in the elderly and those with renal dysfunction** to avoid excess serum levels and to provide cost-effective dosing (Table 27E.3).
 - (2) **Pediatrics.** The package insert notes that the safety and effectiveness of ampicillin-sulbactam has been established for pediatric patients 1 year of age and older for skin and soft tissue infections. The dose used in children is 300 mg/kg/day divided up every 6 hours.
 - (3) **In renal failure**, the elimination of ampicillin and sulbactam is similarly affected, and dose modification is necessary (Table 27E.3).
- e. Special considerations**
- (1) **Pregnancy.** This is a category B agent (see Chapter 16). Because there are no adequate studies in pregnant women, this drug should be used during pregnancy only if clearly indicated.
 - (2) **Nursing mothers.** Low concentrations of this combination are excreted into breast milk. Therefore caution should be exercised when ampicillin-sulbactam is administered to a nursing woman.
 - (3) **Contraindicated in ampicillin-allergic patients.** Because this agent contains ampicillin, it is contraindicated in patients allergic to ampicillin or other penicillins (unless skin testing is performed). This seems obvious but is **a concern if physicians order antibiotics by a trade name (Unasyn) rather than its generic name.** This concern also applies to the combination of ticarcillin-clavulanate (Timentin) and piperacillin-tazobactam (Zosyn), discussed later.
- f. Side effects.** These are the same as those known to occur with ampicillin [2].
- (1) **Ampicillin skin reactions. Rashes are common. Many are not allergic** (see Chapter 24).
 - (2) **Minor enzyme elevations** (serum aspartate aminotransferase and alanine aminotransferase) occur in approximately 6% of recipients.
 - (3) Ampicillin-sulbactam may have a marked **effect on oral flora**, leading to *Clostridium difficile* colitis.
- g. Cost** (see Appendix Table 1)
- h. Conclusion.** Although it is a very popular agent for polymicrobial infections, diabetic foot ulcer infections, mild to moderate community-acquired intraabdominal and pelvic infections, mixed aerobic/anaerobic soft tissue infections, selected cases of aspiration pneumonia, and severe UTI, there are drawbacks. The antibiotic is often selected in situations where *E. coli* is anticipated, yet 20% to 40% of *E. coli* are resistant, making this a less than optimal choice. Other agents with greater *E. coli* activity are more

Table 27E.2. Comparison of *In Vitro* Susceptibility Data

Organism	Number Tested	Antimicrobial	Percent Susceptible
<i>Escherichia coli</i>	10,942	Piperacillin-tazobactam	91.5
		Ticarcillin-clavulanate	88.8
		Ampicillin-sulbactam	65.4
		Cefoxitin	96.1
		Cefotetan	99.3
		Ceftriaxone	99.2
		Imipenem	99.7
		Aztreonam	98.1
		Ciprofloxacin	99.0
<i>Klebsiella pneumoniae</i>	4,405	Piperacillin-tazobactam	90.9
		Ticarcillin-clavulanate	91.3
		Ampicillin-sulbactam	75.2
		Cefoxitin	90.3
		Cefotetan	97.4
		Ceftriaxone	95.2
		Imipenem	99.6
		Aztreonam	94.1
		Ciprofloxacin	94.5
<i>Proteus mirabilis</i>	3,822	Piperacillin-tazobactam	96.2
		Ticarcillin-clavulanate	95.0
		Ampicillin-sulbactam	90.4
		Cefoxitin	94.7
		Cefotetan	97.7
		Ceftriaxone	98.5
		Imipenem	82.9
		Aztreonam	91.7
		Ciprofloxacin	96.6
<i>Serratia marcescens</i>	1,392	Piperacillin-tazobactam	86.9
		Ticarcillin-clavulanate	84.3
		Ampicillin-sulbactam	9.1
		Cefoxitin	16.7
		Cefotetan	94.3
		Ceftriaxone	85.8
		Imipenem	90.5

		Ticarcillin-clavulanate	98.1
		Ampicillin-sulbactam	98.0
		Cefoxitin	98.1
		Ceftriaxone	98.4
		Imipenem	98.7
Ciprofloxacin	91.7		

(continued)

Table 27E.2. (Continued)

Organism	Number Tested	Antimicrobial	Percent Susceptible
<i>Streptococcus agalactiae</i> (group B)	701	Piperacillin-tazobactam	98.2
		Ticarcillin-clavulanate	97.0
		Ampicillin-sulbactam	99.6
		Cefoxitin	96.6
		Ceftriaxone	97.0
		Imipenem	99.4
		Ciprofloxacin	92.9
<i>Streptococcus faecalis</i>	2,624	Piperacillin-tazobactam	94.7
		Ticarcillin-clavulanate	23.2
		Ampicillin-sulbactam	97.0
		Cefoxitin	2.1
		Ceftriaxone	7.0
		Imipenem	95.5
		Ciprofloxacin	62.5

Adapted from Murray PR, et al. and the In Vitro Susceptibility Surveillance Group. Multicenter evaluation of the in vitro activity of piperacillin-tazobactam compared with eleven selected β -lactam antibiotics and ciprofloxacin against more than 42,000 aerobic gram-positive and gram-negative bacteria. *Diagn Microbiol Infect Dis* 1994;19:111, with permission.

rational. We **would not use** ampicillin-sulbactam as monotherapy for patients with severe or life-threatening intraabdominal infection or mixed aerobic/anaerobic soft tissue infections but prefer a combination of antibiotics in this setting (e.g., a third-generation cephalosporin and metronidazole or piperacillin/tazobactam). **See section D for how this agent compares with similar β -lactam/ β -lactamase combinations;** piperacillin-tazobactam may be preferred. In addition, we would not use this agent alone for severe nosocomial infections, because many hospital-acquired gram-negative bacteria, including *E. coli* and *Klebsiella* species, may be resistant; *Pseudomonas* species are also resistant. An aminoglycoside could be combined with it. It should not be used to treat methicillin-resistant staphylococcal infections. Ampicillin-sulbactam has not been studied extensively for treatment of infections in immunocompromised patients [12].

2. Ticarcillin-clavulanate (Timentin) [1,2,7]

a. **Spectrum of activity** is very similar to that for ampicillin-sulbactam (see section A.1) except

Table 27E.3. Ampicillin-sulbactam Dosages in Patients with Renal Impairment

Creatinine Clearance (mL/min)	Recommended Dosage
>50	1.5–3.0 g q6h
30–50	1.5–3.0 g q6–8h
15–29	1.5–3.0 g q12h
5–14	1.5–3.0 g q24h

In patients undergoing hemodialysis, preliminary data suggest the ampicillin will be partially removed (approximately 60%) but not the sulbactam. One could therefore give a supplemental dose of ampicillin after dialysis or time the daily dose of ampicillin-sulbactam so that it is given after dialysis.

- (1) The concerns with *E. coli in vitro* susceptibilities are not as prominent with ticarcillin-clavulanate. Nevertheless, many hospital-acquired *E. coli* are resistant.
 - (2) Enterococci are less susceptible than to ampicillin-sulbactam or piperacillin-tazobactam.
 - (3) This agent is active against many strains of *P. aeruginosa* but is not as active as piperacillin-tazobactam (Table 27E.2).
- b. Clinical uses.** This combination is effective for a variety of polymicrobial infections with susceptible pathogens, including intraabdominal infection, pelvic infection, osteomyelitis, pneumonia, bacteremia, UTI, and skin and soft tissue infections.
- c. Pharmacokinetics.** The half-life of each agent is approximately 1 hour, necessitating a 4- to 6-hour dose interval. Ticarcillin is excreted primarily by the kidney, producing very high urine levels. Dosage adjustments in significant renal failure are required. The combination penetrates tissues well.
- d. Dosages**
- (1) **Adults.** Ticarcillin-clavulanate is available in vials containing 3 g ticarcillin and 0.1 g clavulanic acid as the potassium salt. The usual dosage for systemic infections is one 3.1-g vial every 4 to 6 hours. For moderately severe gynecologic infections, a 3.1-g dose every 6 hours and for severe infection, 3.1 g every 4 hours. For patients weighing less than 60 kg, the recommended dose is 200 to 300 mg/kg/day (based on the ticarcillin content) divided every 4 to 6 hours. A vial containing 3 g ticarcillin and 0.2 g clavulanic acid is also available. This has been used in UTIs, with a dosage of 3.2 g given every 8 hours, per the package insert, when renal function is normal.
 - (2) **Children** (≥ 3 months). In children weighing less than 60 kg, 50 mg/kg based on the ticarcillin component is administered as follows: For mild to moderate infections, a dose every 6 hours and for severe infections, dose every 4 hours. In children weighing more than 60 kg: For mild to moderate infections, 3.1 g every 6 hours and for severe infections, 3.1 g every 4 hours.
 - (3) **In renal failure**, in adults use a normal loading dose. Thereafter, for a creatinine clearance of 30 to 60 mL/min, 2 g every 4 hours; for a creatinine clearance of 10 to 30 mL/min, 2 g every 8 hours; and for creatinine clearance less than 10 mL/min, 2 g every 12 hours. If there is hepatic dysfunction as well, then the latter dose is given every 24 hours. For hemodialysis, give 2 g every 12 hours supplemented with 3.1 g after each dialysis, and for peritoneal dialysis give 3.1 g every 12 hours.
- e. Penicillin allergy precludes the use of this agent** unless skin testing is done.
- f. Pregnancy.** This is a category B agent. Because there are no adequate and well-controlled studies in pregnant women, the package insert suggests this agent should be used during pregnancy only if clearly indicated.
- g. Nursing mothers.** It is not known whether this agent is excreted in human breast milk, but it should not be used in nursing women unless necessary.
- h. Side effects** are similar to those for penicillin, ampicillin, and/or ticarcillin. See prior discussions. The potential for hypokalemia and for platelet abnormalities exists.
- i. Cost** (see Appendix Table 1)
- j. Conclusion.** The main indication for ticarcillin-clavulanate is for polymicrobial infections with susceptible aerobic and anaerobic infections. Because of its safety and activity against possible etiologic organisms, this is used frequently in obstetrics/gynecology services for pelvic and intraabdominal infections. **There are insufficient data** to use it as monotherapy for severe or life-threatening infections or for severe nosocomial infections, because many hospital-acquired gram-negative bacteria may be resistant. In febrile neutropenic cancer patients, ticarcillin-clavulanate has been evaluated primarily

in combination with an aminoglycoside [12–15]. Other options are available in this setting (see Chapter 20). **See section D above** for a comparison of β -lactam- β -lactamase combinations. Piperacillin-tazobactam may be preferred.

3. Piperacillin-tazobactam (Zosyn) became available in the United States in 1993 [7,12,13].

a. Spectrum of activity. Of the available β -lactam/ β -lactamase antibiotics, piperacillin-tazobactam is the most active *in vitro*, in large part reflecting the enhanced *in vitro* activity of piperacillin over ampicillin and ticarcillin (see section III.A.4). This agent has an *in vitro* spectrum of activity comparable with that of imipenem-cilastatin and superior to that of ceftazidime, ticarcillin-clavulanate, and ampicillin-sulbactam [12] (Table 27E.2).

(1) **Gram-positive aerobes.** This combination is active against *S. pyogenes*, *S. agalactiae*, *S. pneumoniae* (not highly penicillin-resistant strains), and methicillin-susceptible *S. aureus*. Although it is active against *Enterococcus faecalis*, it is not active against *E. faecium* and MRSA [12]. However, in an animal model, piperacillin/tazobactam is excreted into the bile in sufficiently high concentrations to prevent colonization after *E. faecium* oral challenge, whereas cefepime does not prevent colonization after this challenge [16].

(2) **Enterobacteriaceae.** Most community-acquired Enterobacteriaceae (e.g., *E. coli*, *Klebsiella* species) are susceptible, but because of poor activity of piperacillin-tazobactam against many of the class 1 β -lactamases, *E. aerogenes*, *E. cloacae*, *Citrobacter* species, *Serratia* species, and *P. aeruginosa* may be resistant (Table 27E.2) (see section III.B.3).

(3) **Other gram-negative bacteria.** Piperacillin-tazobactam has excellent activity against *H. influenzae*, *M. catarrhalis*, *Yersinia enterocolitica*, and *Plesiomonas shigelloides* but not *Salmonella* species or *Stenotrophomonas maltophilia*.

(4) **Anaerobes.** Piperacillin-tazobactam has good activity against *B. fragilis* (but less than that of imipenem), *Bacteroides* species, and *Clostridium perfringens* [17]. Oral anaerobes are usually susceptible to penicillin and piperacillin. Although some reviewers conclude there are no significant differences between the activity against anaerobes of piperacillin-tazobactam and other β -lactamase inhibitor combination agents [12], other reviewers have concluded that piperacillin-tazobactam inhibits a broader spectrum of anaerobes than does ampicillin-sulbactam and ticarcillin-clavulanate [18].

b. Pharmacokinetics. Preparations contain an 8:1 ratio of piperacillin to tazobactam; tazobactam does not interfere with the pharmacokinetics of piperacillin. Renal excretion accounts for 50% to 60% of the administered dose. Doses must be reduced in patients with a creatinine clearance of less than 40 mL/min [17]. As noted earlier, piperacillin is excreted into the biliary tract in sufficient concentration to inhibit *E. faecium*, reducing the likelihood of colonization of the GI track in the orally challenged animal [16].

c. Clinical use. Piperacillin-tazobactam has been used in **polymicrobial infections**. Early clinical studies have been summarized [17–19]. The combination is approved for use in moderate to severe infections with susceptible pathogens and appears effective in the following situations:

(1) **Intraabdominal infections** (especially appendicitis, including cases complicated by rupture or abscess). The combination appears as effective as imipenem or clindamycin plus gentamicin [2].

(2) **Pelvic infections** in women.

(3) **Mixed aerobic skin and soft tissue** infections, including diabetic foot infections.

(4) **Community-acquired pneumonia.** This is not a usual agent; however, its activity against β -lactamase-producing *H. influenzae*, *Klebsiella pneumoniae*, *P. aeruginosa*, *Acinetobacter calcoaceticus*, and *Moraxella*

catarrhalis makes it a useful agent when Gram stain shows pure gram-negative organisms or when the patient has recently been hospitalized and returns for admission. However, this agent is not active against *Mycoplasma* or *Legionella* [17].

- (5) **Nosocomial pneumonia.** When **Gram stain shows gram-negative organisms**, this agent, used in conjunction with an aminoglycoside pending susceptibilities, is an excellent choice [17]. Alternative therapy should be used if Gram stain shows gram-positive cocci in clusters.
- (6) **Clinical investigation.** Piperacillin-tazobactam both with and without an aminoglycoside has been used for empiric therapy of the febrile leukopenic patient without a focal infection [14,15,17]. It is not listed as a drug of choice in this setting [15]. Currently a study comparing it with cefepime as monotherapy is underway. The potential for piperacillin/tazobactam to prevent colonization with vancomycin-resistant enterococci because of high biliary concentrations is a key point of evaluation in that study [16].

d. Dosages

- (1) **Adults.** The **usual dose is 3 g/0.375 g every 6 hours** if the creatinine clearance is higher than 40 mL/min. For empiric therapy nosocomial pneumonia, the package insert suggests a 3.375-g dose every 4 hours along with an aminoglycoside to ensure activity against *P. aeruginosa*. If *P. aeruginosa* is not isolated, then the aminoglycoside can be discontinued. **If *P. aeruginosa* is isolated, then piperacillin alone can be used with an aminoglycoside because** in documented pseudomonas infection, tazobactam does not enhance the activity of piperacillin against this pathogen [17]. **An alternate approach for high dose** therapy is to use a 4.5-g vial (piperacillin 4 g and tazobactam 0.5 g) every 6 hours, along with an aminoglycoside for empiric therapy of nosocomial infections and possible pseudomonas infection [18].
- (2) **Children.** As of 2002, the package insert indicates the safety and efficacy in pediatric patients has not been established.
- (3) **Renal failure. Dose reductions are shown in Table 27E.4.** For patients receiving **hemodialysis**, the maximum dose of piperacillin-tazobactam is 2 g/0.25 g every 8 hours. Because hemodialysis will remove 30% to 40% of the dose in a 4-hour dialysis, one additional dose of 0.75 g can be given after dialysis. **In chronic ambulatory peritoneal dialysis**, approximately 10% of the piperacillin dose is recovered [17]. Until further guidelines are available, in chronic ambulatory peritoneal dialysis patients select the dose as if the creatinine clearance is less than 10 mL/min (Table 27E.4).
- (4) **In cirrhosis** or other hepatic disease, no dosage modifications are required [17].
- (5) **Pregnancy.** This is a category B agent (see Chapter 16). There are no adequate and well-controlled studies with piperacillin-tazobactam in pregnant women. Therefore the drug should be used during pregnancy only if clearly indicated [12].
- (6) **Nursing mothers.** Piperacillin is excreted in low concentrations in human breast milk; whether tazobactam is in human breast milk has not

Table 27E.4. Piperacillin-tazobactam Dosages in Renal Failure

Creatinine Clearance (mL/min)	Recommended Dosage Regimen
>40	12 g/1.5 g/day in divided doses of 3.375 g q6h
20–40	8 g/1.0 g/day in divided doses of 2.25 g q6h
<20	6 g/0.75 g/day in divided doses of 2.25 g q8h

From *Physician's desk reference*, 56th ed. Montvale, NJ: Medical Economics, 2002:1893, with permission.

been studied. Therefore the package insert suggests that caution should be used if this agent is administered to a nursing woman.

e. Side effects. The toxicity of piperacillin-tazobactam is similar to that of other penicillins and β -lactam antibiotics [17–19]. The most common side effects include the following:

- (1) GI disorders, primarily diarrhea and nausea, occur in 4.6% of recipients.
- (2) Skin reactions occur in 2.2% of recipients. Fewer than 1% have a rash.
- (3) No significant hepatic or renal dysfunction has been noted in early reports.
- (4) Mild hypokalemia can occur, presumably due to the nonresorbable anions presented to the distal tubules, which cause an increase in the pH and a secondary loss of potassium ions.

4. Ticarcillin-clavulanate versus ampicillin-sulbactam versus piperacillin-tazobactam. The optimal agent for selected polymicrobial infections has not been clearly delineated in the medical literature. None of these β -lactam- β -lactamase combinations is listed as the antibiotic of first choice for any specific pathogen [3]. In a review [12], the authors concluded that “because of its broad spectrum of antibacterial activity, it [piperacillin-tazobactam] appears to be the best suited for treatment of mixed infections.” In a 1996 summary of piperacillin-tazobactam, after an extensive review of the literature, the authors concluded, “The proven and theoretical advantages of piperacillin-tazobactam in comparison with those of ticarcillin-clavulanate appear to more than offset the modest difference in cost between the two compounds” [18].

a. When one of these drugs is indicated, we would offer the following considerations:

- (1) For situations in which *E. coli* is a likely pathogen, because 20% to 25% are resistant to ampicillin-sulbactam, piperacillin-tazobactam is advised, although ticarcillin-clavulanate may be a reasonable alternative if one of these agents is to be used.
- (2) Because cefazolin is effective against most community-acquired *E. coli* strains, the more expensive β -lactam- β -lactamase inhibitor combinations should be used selectively. For community-acquired intraabdominal or pelvic infections, the most cost-effective cefazolin-metronidazole combination is reasonable (see Chapter 13).
- (3) **Piperacillin-tazobactam can be used selectively** in the following situations:
 - (a) Severe (limb-threatening) diabetic foot ulcer infections, as discussed in Chapters 4 and 5.
 - (b) Selected patients with severe head and neck infections.
 - (c) As monotherapy in nosocomial pneumonia not acquired in an intensive care unit and where risk for *P. aeruginosa* infection is low and it is desirable to avoid an aminoglycoside.
 - (d) Selected intensive care unit nosocomial pneumonia. While awaiting cultures, it is advisable to combine it with an aminoglycoside. Piperacillin and an aminoglycoside combination is more cost effective.
- (4) **Serious nosocomial infections.** None of these agents should be used as monotherapy for known or highly suspected severe *P. aeruginosa* infection.
- (5) **Versus imipenem.** For the situation in which monotherapy is indicated and there is a choice between one of these β -lactam- β -lactamase combinations and imipenem, most institutions reserve imipenem for those patients who may have or develop resistant pathogens.

E. Drug resistance to β -lactam- β -lactamase inhibitor compounds has been reviewed recently [7]. The extended spectrum β -lactamase-producing bacteria are resistant to these agents. The most common organisms carrying this resistance are *E. coli* and *Klebsiella* species. The frequency with which these are found depends on the total gram use of expanded spectrum cephalosporin antibiotics [7]. Carbapenem antibiotics (see Chapter 27H) are selected in infections caused by extended spectrum β -lactamase-producing bacteria instead of the combinations discussed in this chapter [6]. Piperacillin/tazobactam-resistant *P. aeruginosa* have also emerged. A

predisposing risk factor appears to be the quantity of ciprofloxacin use. This factor needs to be considered when treating ventilator-associated pneumonia caused by *P. aeruginosa* [20].

F. The Cephalosporins

The cephalosporins [1–3] are **bactericidal** agents that inhibit bacterial cell wall synthesis. They are widely used agents because they are safe, familiar to the clinician, and active against penicillinase-producing methicillin-susceptible *Staphylococcus aureus* (MSSA). They can be used for patients with delayed penicillin allergies. Unless special skin tests can be performed, **cephalosporins should be avoided in patients with a history of an**

immediate severe reaction to a penicillin (or cephalosporin), such as anaphylaxis or angioedema (see section IV.A).

I. Introduction

A. Agents available. The currently available cephalosporins are shown in Table 27F.1.

The goal of this chapter is to summarize and to emphasize a limited number of agents that are particularly useful and have withstood the test of time.

1. From a historical standpoint, it is useful to note that the different “generations” of parenteral cephalosporins had a logical sequence of development by the pharmaceutical industry [1].

a. The first-generation agents are active against MSSA, penicillin-susceptible *Streptococcus pneumoniae*, and other common gram-positive bacteria, such as streptococci groups A and B and viridans streptococci, and many community-acquired gram-negative bacteria. These agents remain active and useful against these pathogens.

b. Second-generation agents, cefamandole and later cefuroxime, were developed, in part, because of their activity against ampicillin-susceptible and -resistant *Haemophilus influenzae* (and *Moraxella catarrhalis*). They maintained activity against *S. pneumoniae*. Cefoxitin was the first cephalosporin to have activity against bowel anaerobes, especially *Bacteroides fragilis*; it was also active against *Neisseria gonorrhoeae*, including penicillinase-producing strains. Although still useful, these agents enjoy less popularity than in the past, for reasons to be discussed.

c. Third-generation agents can be divided into two subsets. One type, ceftazidime, was initially touted as having enhanced gram-negative activity, including activity against hospital-acquired pathogens such as *Pseudomonas aeruginosa*. This still holds. The other had excellent activity against community type bacteria but was not nearly as active against hospital-acquired organisms. Once-daily ceftriaxone has significant gram-positive activity and has found many clinical roles in those admitted from home but not for hospital-acquired gram-negative organisms.

d. Cefepime has sometimes been called a **fourth-generation agent** [3], but it may be better summarized as a “hybrid” of cefotaxime (which has similar activity to ceftriaxone) and ceftazidime, two third-generation agents. In many

Table 27F.1. The Major Cephalosporins

First Generation	Second Generation	Third Generation
Parenteral	Parenteral	Parenteral
Cephalothin (Keflin)	Cefamandole (Mandol)	Cefotaxime (Claforan)
Cefazolin (Ancef, Kefzol)	Cefoxitin (Mefoxin) ^a	Cefoperazone (Cefobid)
Cephapirin (Cefadyl)	Cefuroxime (Zinacef)	Ceftizoxime (Cefizox)
Cephradine (Velosef)	Cefotetan (Cefotan) ^a	Ceftriaxone (Rocephin)
		Ceftazidime (Fortaz, Tazidime, or Tazicef)
		Cefepime (Maxipime) ^b
Oral	Oral	Oral
Cephalexin (Keflex)	Cefuroxime axetil (Ceftin)	Cefixime (Suprax)
Cephradine (Velosef, Anspor)	Cefprozil (Cefzil)	Cefpodoxime (Vantin)
Cefadroxil (Duricef)	Loracarbef (Lorabid) ^a	Ceftibuten (Cedax)
	Cefaclor (Ceclor)	Cefdinir (Omnicef)
		Cefditoren pivoxil (Spectracef)

^aA cephalosporin-like antibiotic.

^bSome authors have referred to this agent as a fourth-generation cephalosporin; see text.

Table 27F.2. Pharmacokinetic Properties of Parenteral Cephalosporins (in Adults)

	Half-Life (h)	Standard Dose (g)	Usual Dose Interval (h)	Half-Life (h) in End-Stage Renal Disease
Cephalothin	0.6	1.0–2.0	4	10
Cefoxitin	0.9	1.0–2.0	4–6–8	10–22
Cefotaxime	1.0 ^a	1.0–2.0	6–8	3
Cefuroxime	1.0	0.75–1.5	6–8	15–20
Cefazolin	1.8	1.0	6–8	18–36
Cefoperazone	1.8	2.0	6–8	2
Ceftizoxime	1.8	2.0	8	25–35
Ceftazidime	1.8	1.0–2.0	8	16–25
Cefepime	2.0	1.0–2.0	12	14
Cefotetan	4.5	1.0–2.0	12	12–35
Ceftriaxone	7.0	1.0–2.0	24 ^b	12–15

^aCefotaxime has a half-life of 1 h in persons with normal renal function but is metabolized to a desacetyl derivative, which has a half-life of 1.6 h and possesses significant antimicrobial activity and may interact synergistically with the parent compound [1].

^bFor non-central nervous system infections; for meningitis doses are given q12h. See text.

centers, cefepime has replaced ceftazidime because it includes the latter's activity and extends it.

2. The cephalosporin "antibiotic market domination" of the late 1980's has been diminished somewhat by the advent of the newer quinolones released in the late 1980's and the newer macrolides (clarithromycin and azithromycin) released in the early 1990's.

B. Side effects. Cephalosporins are **well tolerated**. Their side effects are reviewed in section **IV** except for special considerations with an individual agent, which are discussed under that agent.

C. Pharmacokinetics data are summarized in Table 27F.2. Like the penicillins, the antimicrobial effects of the cephalosporins depend on maintaining concentrations of active drug above the minimum inhibitory concentration (MIC) of the infecting organism for 50% of the 24-hour period (**time-dependent killing**; see Chapter 25).

D. Resistance issues

1. **Mechanisms of action and bacterial resistance.** Penicillin binding proteins are targets of the cephalosporins that exert their antimicrobial effect by interfering with the synthesis of peptidoglycan, a major component of the bacterial cell wall [2]. The three most common mechanisms that mediate resistance are (a) production of enzymes, β -lactamases, to inactivate drugs before they reach the penicillin binding proteins; (b) alteration of the penicillin binding proteins; or (c) changes in the outer membrane that limit the ability of the drug to reach the target [2].

- a. **β -Lactamase production.** Some of the β -lactamases are plasmid mediated by plasmids that are transferred between bacteria. Some are inducible and are chromosomally mediated. These inducible enzymes develop in certain species (*Enterobacter* species, *Citrobacter* species, *P. aeruginosa*). Clinically, this phenomenon manifests as treatment failure and emergence of drug-resistant organisms despite initial susceptibility to the cephalosporin used [1,2].

"**Extended-spectrum β -lactamases**" have recently been described, especially with nosocomial *Klebsiella pneumoniae*. They confer high level resistance to all β -lactams. However, *in vitro* testing indicated resistance mainly to ceftazidime but suggested susceptibility to other cephalosporins when used in clinical situations tends to be resistant [2].

- b. **Alteration of penicillin binding proteins.** Gram-positive organisms such as *S. pneumoniae* or *S. aureus* represent excellent examples of this resistance development.

- c. **Porin alterations and resistance.** *P. aeruginosa* very quickly changes its porins to exclude drugs like ceftazidime.
- 2. **Antibiotic pressure and resistance.** Because hospitalized patients are compromised, there is a tendency to initiate antibiotics such as ceftazidime or cefepime at the first sign of instability. As a result, organisms that are merely colonizers and not causing infection become resistant. Furthermore their excess use tends to select for vancomycin-resistant enterococci [4]. When true disease develops, they do not respond to the selected antibiotic.
- 3. **Intrinsic resistance.** Some organisms are always resistant to cephalosporins (e.g., all enterococci, *Listeria monocytogenes*, and the organisms of nonbacterial pneumonia [*Legionella*, *Mycoplasma*, and *Chlamydia* species]) [2].

II. Rational approach to use of intravenous preparations

A. First generation. Cefazolin (Ancef, Kefzol) is the most commonly used agent. It can be given intravenously (i.v.) or intramuscularly every 6 to 8 hours rather than every 4 to 6 hours, which other first-generation agents require.

- 1. **This first-generation agent has activity against MSSA** and is active against most community acquired gram-negative organisms. Therefore it is useful in the following:
 - a. **Routine surgical prophylaxis.**
 - b. Known or suspected **MSSA**, but not methicillin-resistant *S. aureus* (MRSA) infections. There is some evidence that about 50% of **MSSA** that appear to be susceptible to cefazolin, produce a β -lactamase that has high activity against cefazolin. Although appearing susceptible by disk, when these organisms are present at concentrations above 10^6 /mL, the infection they are causing responds less well to cefazolin than it does to nafcillin.
 - c. An alternative agent for penicillin-susceptible *S. pneumoniae*, *S. pyogenes*, viridans streptococci, and *S. agalactiae* (streptococci group B).

2. **Infection caused by community-acquired gram-negative organisms** (e.g., *E. coli*, *K. pneumoniae*, etc.), such as cholecystitis and in initial cases of community-acquired pyelonephritis.

The combination of cefazolin (active against gram-negative organisms) and metronidazole (active against bowel anaerobes) is a very cost-effective regimen for community-acquired intraabdominal infections (see related discussion in Chapter 13).

- 3. **Situations in which to avoid cefazolin.** Cefazolin does not penetrate the cerebrospinal fluid adequately and is not indicated in meningitis. **All cephalosporins are inactive against enterococci and therefore are not indicated in enterococcal endocarditis.** However, in most mixed aerobic and anaerobic intraabdominal infections, enterococci do not require specific antimicrobial treatment (see Chapter 13).
- 4. **Pregnancy and nursing.** All cephalosporins, both intravenous and oral, are category B agents and should be used in pregnancy only when clearly indicated. They are all excreted into the breast milk and could sensitize the newborn.

5. **Dosing** (Table 27F.3).

6. **Side effects** (see section IV)

7. **Cost** (see Appendix Table)

B. Second-generation cephalosporins

- 1. **Cefamandole (Mandol)** use has largely been replaced by cefuroxime or third-generation cephalosporins. From a **historical standpoint**, it is important to emphasize that **this agent was associated with a significant risk of hypoprothrombinemia** (more than 10% of recipients), **presumably related to the N-methylthiotetrazole (NMTT) side chain**, which interferes with prothrombin synthesis. Although controversial, **similar concerns persist in newer agents (e.g., cefotetan) that have this same side chain.**
- 2. **Cefuroxime (Zinacef, Kefurox)** was introduced in the middle to late 1980's and has replaced cefamandole. Because of its spectrum of activity (see section a, below), it is used for respiratory infections in some centers. In 1993, the American Thoracic Society [5] favored its use in empiric therapy of community-acquired pneumonia (CAP), especially in adults with comorbid illness. However, with the

Table 27F.3. Typical Dosages and Summary of Parenteral (i.v.) Cephalosporins

Agent	Common Adult Single i.v. Dose ^a	Usual Dose Interval in Normal Renal Function ^b (h)	Typical Total Adult Daily Dose (g)	Pediatric Dose	Dose Interval (h) with Decreased Creatinine Clearance			CSF Penetration	Potential for Bleeding Side Effects	
					<50	30–49	10–29			
					<10	<10	<10			
First generation										
Cefazolin (Ancef, Kefzol)	0.5–1 g	8	1.5–3.0	25–100 mg/kg/d; divided into q6–8h equal doses	8	12	24	24–48	Poor	In renal failure
Second generation										
Cefoxitin (Mefoxin)	2 g	6–8	6–8	80–160 mg/kg/d; divided into q4–6h doses	6–8	8–12	12–24	24 ^c	Poor	
Cefuroxime (Zinacef)	750 mg–1.5 g	8	2.25–4.5	75–100 mg/kg/d; divided into q8h	8	8	12	24	Modest	No
Cefotetan (Cefotan)	1–2 g	12	2–4	Not advised	12	12	24	48	Poor	Yes
Third generation										
Cefotaxime (Claforan)	1–2 g	8 ^d	3–6	50–180 mg/kg/d; divided into q6 ^h	8 ^d	8–12	12	24	Excellent	No
Ceftriaxone (Rocephin)	1–2 g ^f	24 ^f	1–2	In meningitis, loading dose of 75 mg/kg and then 100 mg/kg/d (not to exceed 4 g/d) divided q12h. In other infections, 50–75 mg/kg/d (not to exceed 2 g) divided q12h or once-daily doses	24 ^g	24 ^g	24 ^g	See text	Excellent	No

Ceftazidime (Fortaz, Tazidime, Tazicef) Expanded spectrum or fourth generation Cefepime (Maxipime)	1–2 g	8	3–6	90–150 mg/kg/d; divided q8h (to maximum 6 g/d)	8	12–24 ^a 24–48 ^a 48–72 ^a	Excellent	No
	1–2 g	12 ^b	4	50 mg/kg/dose q12h ^h if over 2 months of age	Usual; see text		Modest	

^a Doses suggested for moderately severe infections; higher dose in severe infection.

^b Or: in patients with creatinine clearance > 50 mL/min.

^c Dose is also reduced 50%. See text.

^d Dose interval for cefotaxime in children is usually q6h.

^e Higher dose range of cefotaxime used in meningitis. Use adult dosages in children weighing > 50 kg. Neonatal dosages shown in Chapter 3.

^f In meningitis, 2 g q12h is advised (see text). In less severe infections, 1 g daily may be used. See text.

^g In CNS infections, a q12h regimen is preferred. See text.

^h In neutropenic patients, a higher dose regimen is used: 2 g q8h in adults, and 50 mg/kg/dose q8h in children.

recent increased incidence of penicillin-resistant *S. pneumoniae* and the *in vitro* data suggesting cefuroxime is not an optimal agent for this pathogen, its role as of 2002 has undergone considerable reassessment (see Chapters 11 and 27C).

a. *In vitro* activity

- (1) **Gram-positive organisms.** Cefuroxime is very active against group A and B streptococci and viridans streptococci but not enterococci. Generally, cefuroxime is less active against MSSA than cefazolin, but cefuroxime is still active, with an MIC₉₀ ≤ 1.6 μg/mL. **In a recent *in vitro* study of more than 1,500 respiratory isolates of *S. pneumoniae*, cefuroxime was active against 99.1% of penicillin-susceptible strains, 53% of penicillin intermediate susceptible strains, and none of the high level penicillin-resistant strains [6]** (see related discussions in Chapter 11).
- (2) **Gram-negative organisms.** Cefuroxime is very active against ampicillin-susceptible or -resistant *H. influenzae* and *M. catarrhalis* as well as *Neisseria meningitidis*, *N. gonorrhoeae* (including penicillinase producers), and *Pasteurella multocida*. It is active against many community-acquired gram-negative bacteria (e.g., *E. coli*, *Klebsiella* species, etc) but is less active *in vitro* than the third-generation cephalosporins against gram-negative bacteria. Many hospital-acquired gram-negative organisms and most *Pseudomonas* species and *Providencia* species are resistant.
- (3) **Anaerobes.** Cefuroxime is not as active as cefoxitin or cefotetan against bowel anaerobes. Practically speaking, we would not rely on cefuroxime for anaerobic activity.
- (4) ***Borrelia burgdorferi*** (agent of Lyme disease) are susceptible.

b. Pharmacokinetics (Table 27F.2)

c. Clinical uses. Cefuroxime has commonly been used for CAP [7], postinfluenza pneumonia, orbital cellulitis, complicated sinusitis, and epiglottitis. However, it is now less favored in these clinical settings due to increasing antimicrobial resistance of the organisms causing these syndromes (see section **a**, above). Oral cefuroxime (cefuroxime axetil, Ceftin) is considered one of the drugs of choice for early Lyme disease (i.e., erythema chronicum migrans) [8].

d. Doses (Table 27F.3)

e. Pregnancy and nursing mothers. Category B.

f. Cost (See Appendix Table 1)

g. Side effects (see section IV)

3. Cefoxitin (Mefoxin) is a cephamycin antibiotic (cephalosporin-like) that has enhanced anaerobic activity.

a. *In vitro* activity

- (1) **Gram-positive bacteria.** Cefoxitin is slightly less active than the first-generation agents.
- (2) **Gram-negative bacteria.** Cefoxitin remains active against many community-acquired gram-negative bacteria but is not active against many hospital-acquired gram-negative bacteria (e.g., *Pseudomonas* species, *Enterobacter cloacae*). It is active against *N. gonorrhoeae*, including penicillinase producers.
- (3) **Anaerobes.** Cefoxitin is active *in vitro* against 80% to 90% of strains of *B. fragilis* at clinically achievable concentrations, although in well-established anaerobic infections, cefoxitin may not be as effective *in vivo*. **Generally, cefoxitin is viewed as the cephalosporin with the best activity *in vitro* against oral and bowel anaerobes.**

b. Pharmacokinetics (Table 27F.2)

c. Clinical uses

- (1) **Community-acquired mild to moderate intraabdominal infections.** Cefoxitin has been useful in the management of mixed gastrointestinal (GI) flora infections, especially before an abscess develops. Cefoxitin remains a useful agent in diverticulitis, very early appendix rupture, and early to mild bowel perforation before *B. fragilis* has become established in high titers. However, there are many antibiotic options for these infections,

including ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam (see Chapter 13). **Cefoxitin and the β -lactam- β -lactamase inhibitor combinations are expensive. Thus a combination of cefazolin and metronidazole** for mild to moderate community-acquired intraabdominal infections (see Chapter 13) and pelvic infections that do not involve *N. gonorrhoeae* is an alternative (see section (2), below).

- (2) **Pelvic infections.** Because cefoxitin is active against *N. gonorrhoeae*, many gram-negative bacilli, and most anaerobes, it has been clinically successful in a variety of pelvic infections, early pelvic abscesses, and pelvic inflammatory disease regimens [9] (see Chapter 16).
- (3) **Mixed aerobic/anaerobic soft tissue infections** may respond well to cefoxitin. The best results may occur when the duration of illness, before initiation of antibiotics, is short. Cefoxitin has been used in mixed-flora foot infections in diabetic patients; it is not active against enterococci whose role in this setting is often unclear (see Chapter 4).
- (4) **Note. Cefoxitin should not be relied on as monotherapy** in very ill patients with bacteremia due to *B. fragilis*, because cefoxitin may not be active against 5% to 15% of these isolates. **The same is true for hospital-acquired intraabdominal sepsis** that is often caused by resistant gram-negative bacteria.

d. **Dosing** (Table 27F.30)

e. **Pregnancy and nursing mothers** (see section II.A.4)

f. **Side effects** (see section IV)

g. **Cost** (see Appendix Table)

4. **Cefotetan (Cefotan)** has been promoted as a cost-effective **cefoxitin-like agent** with good anaerobic activity because cefotetan can be given every 12 hours rather than every 6 to 8 hours.

a. ***In vitro* activity**

- (1) **Gram-positive organisms.** Cefotetan is two to four times less active than cefoxitin [10].
- (2) **Gram-negative aerobes.** *In vitro*, cefotetan is more active than cefoxitin against enteric gram-negative bacilli but less active than the third-generation cephalosporins. It is active against gonococci but is inactive against many hospital-acquired gram-negative organisms, including many strains of *Enterobacter* species and most strains of *P. aeruginosa* and *Acinetobacter* species.
- (3) **Anaerobes.** Cefotetan is considered comparable with cefoxitin *in vitro* against *B. fragilis* but is less active against other species within the *B. fragilis* group [1].

b. **Side effects. Interference with prothrombin synthesis.** Cefotetan contains the NMTT side chain, which may be related to an increased incidence of hypoprothrombinemia (see section II.B.1). The exact incidence of this with cefotetan is unclear. Of interest, the package insert warning for cefotetan (but not cefoxitin) indicates that cefotetan “may be associated with a fall in prothrombin activity and possible subsequent bleeding. Those at increased risk include patients with renal or hepatobiliary impairment or poor nutritional status, the elderly, and patients with cancer. Prothrombin times should be monitored and exogenous vitamin K administered as indicated” [10]. Barza [10] concluded that this needs to be considered when choosing between these agents.

c. **Other side effects** (see section IV)

d. **Clinical use** of cefotetan

- (1) For young otherwise healthy women with pelvic infections, endometritis, pelvic inflammatory disease, or mild to moderate community-acquired intraabdominal infections, cefotetan is reasonable. A similar view was presented in a publication of clinical practice guidelines. The Committee on Antimicrobial Agents of the Canadian Infectious Disease Society suggested that cefotetan could be considered an alternative single agent for prophylaxis of infection in patients undergoing elective bowel surgery.

It may be used to treat patients with acute pelvic inflammatory disease and endometritis, but hypoprothrombinemia in debilitated patients is a concern [11].

(2) Cefotetan's useful role in **GI surgical prophylaxis** is reviewed in Chapter 27B.

(3) **For patients with underlying risk factors for hypoprothrombinemia (see section b), we do not recommend using cefotetan.**

e. Dosing (Table 27F.3). The safety and efficacy in children has not been established.

f. Pregnancy and nursing mothers (see section II.A.4)

g. Cost (see Appendix Table 1)

5. Cefonicid (Monocid). This agent is no longer available in the United States.

C. Third-generation cephalosporins are useful in several settings, as shown in Table 27F.4. These agents are drugs of choice for only a limited number of organisms (Table 27F.4).

1. In vitro activity

a. Gram-positive aerobes [12,13]

(1) ***S. pneumoniae***. Cefotaxime, ceftizoxime, and ceftriaxone are very active against the highly and intermediate susceptible organisms but less so against penicillin-resistant ***S. pneumoniae***. In one large *in vitro* report, ceftriaxone was found to be active against 92% of intermediate level but only 27% of high level penicillin-resistant strains [6,13].

(2) ***S. aureus***. The first- and some second-generation cephalosporins are at least two- to fourfold more active than cefotaxime, ceftizoxime, and ceftriaxone against penicillin-susceptible *S. aureus* and against some, but not all, β -lactamase-producing strains. When considering cefotaxime, ceftizoxime, or ceftriaxone in suspected sepsis in which staphylococci cannot be excluded, any of these three cephalosporins would provide the necessary activity against staphylococci [12]. In patients with documented severe MSSA infections (e.g., endocarditis), an oxacillin or nafcillin or ceftazolin is preferable.

(3) **Coagulase-negative staphylococci**. If the organisms are methicillin-resistant, a cephalosporin is not recommended, even if the *in vitro* data suggest that a cephalosporin may be active. If methicillin susceptible, cephalosporins are potential agents, although vancomycin often is used.

(4) **Group A streptococci**. Some third-generation cephalosporins (cefotaxime, ceftizoxime, and ceftriaxone) are very active against these pathogens, with MICs less than 0.03 $\mu\text{g/mL}$, comparable with benzyl penicillin and, in fact, more active than ceftazolin or cefoxitin.

(5) **Group B streptococci (*S. agalactiae*)** are also very susceptible to cefotaxime, ceftizoxime, and ceftriaxone, with an MIC comparable with penicillin G and lower than ceftazolin. **Groups C and G streptococci** are also very susceptible to the aforementioned third-generation agents.

(6) **Most viridans streptococci and *Streptococcus bovis*** have lower MICs for these third-generation agents than the first- or second-generation cephalosporins. This has implications in alternate endocarditis therapeutic regimens (e.g., ceftriaxone once daily).

(7) **Inactive *L. monocytogenes*, enterococci, MRSA, and, as mentioned above, most high level penicillin-resistant *S. pneumoniae*** are resistant.

b. Gram-negative aerobes [12,14]

(1) ***H. influenzae*** (and other *Haemophilus* species) and ***N. gonorrhoeae*** are very susceptible to the third-generation cephalosporins, including strains that produce β -lactamases.

(2) ***N. meningitidis*** and ***M. catarrhalis*** likewise.

(3) **Community-acquired Enterobacteriaceae**. The excellent *in vitro* activity of the third-generation cephalosporins against gram-negative organisms is a major advantage of these agents over the first- and second-generation cephalosporins. Bacteria resistant to the older cephalosporins

Table 27F.4. Common Uses of Third-Generation Cephalosporins

Setting	Agent Commonly Used	Comment
Gram-negative enteric meningitis (e.g., <i>E. coli</i> , <i>Klebsiella</i> species)	Cefotaxime, ^a Ceftriaxone, Ceftazidime	An unusual clinical problem. Seen in neonates, or post neurosurgery.
Bacterial meningitis	Cefotaxime, ^a ceftriaxone ^b	Excellent for <i>H. influenzae</i> , ^b <i>N. meningitidis</i> , and penicillin-susceptible <i>S. pneumoniae</i> . For penicillin-resistant <i>S. pneumoniae</i> need vancomycin (see Chapters 6 and 27) and for <i>Listeria monocytogenes</i> need ampicillin or TMP-SMZ.
Febrile neutropenic patient without a focal source	Ceftazidime, cefepime ^c	Ceftazidime not active against gram (+) cocci. If there is a Hickman catheter infection, would need to add i.v. vancomycin until culture data are available. Cefepime not active against MRSA. Also see Chapter 2. Once-a-day dose.
<i>S. viridans</i> endocarditis	Ceftriaxone	For synergy (e.g., in pneumonia) combined with an aminoglycoside.
<i>P. aeruginosa</i> activity	Ceftazidime, cefepime	Ceftazidime has little gram-positive activity. Ceftriaxone not active against <i>P. aeruginosa</i> .
Broad-spectrum activity (see text)	Ceftriaxone (cefepime also an option)	Ceftazidime has little gram-positive activity. Ceftriaxone not active against <i>P. aeruginosa</i> .
Gram-negative pathogens (e.g., <i>E. coli</i> , <i>K. pneumoniae</i> ; indole-positive <i>Proteus</i> , <i>P. vulgaris</i> ; <i>Morganella morganii</i> ; <i>Providencia stuartii</i> , <i>Serratia</i> species)	Ceftriaxone, cefotaxime, ceftazidime; cefepime	Active against most community-acquired gram negatives. Certain hospital-acquired gram negatives may be resistant.
<i>N. gonorrhoeae</i> infections	Ceftriaxone ^b	See Chapter 16.
<i>Pseudomonas pseudomallei</i>	Ceftazidime ^b	Rare problem.
<i>Haemophilus ducreyi</i> (chancroid)	Ceftriaxone ^b	Azithromycin is also an agent of choice.
<i>Borrelia burgdorferi</i> (Lyme disease)	Ceftriaxone	See <i>Med Lett Drugs Ther</i> 2000;42:37

^aFor neonates, use cefotaxime, not ceftriaxone. See text.

^bAgent considered a "drug of choice" [5].

^cIn patients at high risk for severe infection (including patients with a history of recent bone marrow transplantation, with hypotension at presentation, with underlying hematologic malignancy or with severe or prolonged neutropenia) the package insert notes monotherapy may not be appropriate. Insufficient data exist to support efficacy in such patients.

and, at times, even the aminoglycosides are often susceptible to the third-generation cephalosporins. *E. coli* is usually very susceptible to the third-generation agents. Most *Klebsiella* species and *P. mirabilis* remain susceptible.

- (4) **Hospital-acquired gram-negative organisms.** Even hospital-acquired gram-negative organisms that are resistant to first- and second-generation agents and even occasionally to aminoglycosides are usually susceptible to specific third-generation drugs [14]. *E. coli*, *Providencia*, *Citrobacter* species, and *P. vulgaris* generally are inhibited by very low concentrations. Occasionally, nosocomial strains of *Klebsiella* species isolated in the United States are resistant (and these usually are susceptible to imipenem). *Enterobacter* species, especially *E. cloacae*, which are important nosocomial pathogens, is a major weakness of the third-generation cephalosporins. Approximately 10% to 30% of *E. cloacae* may initially be resistant to the third-generation cephalosporins, but even the isolates of *E. cloacae* with MICs of 1 $\mu\text{g}/\text{mL}$ or less contain subpopulations of organisms that are easily selected for resistance to the third-generation cephalosporins (see section I.D.2). Presumably, the general use of cephalosporins, including the first- and second-generation cephalosporins, has caused the increase in isolation of this species over the last two decades. Also, *C. freundii* similarly develops resistance, although it has not become as prominent a nosocomial pathogen.

- (5) **Susceptibility tests for hospital gram-negative organisms.** Because of the variability of *in vitro* susceptibility data, testing is needed for each third-generation cephalosporin that may be used. For *P. aeruginosa*, cefepime, which has largely replaced ceftazidime and cefoperazone, can be considered a potential agent. Because cefoperazone is less active (and has the NMTT side chain), we believe that cefepime is the better third-generation cephalosporin for these situations [14]. Cefepime MIC₉₀ for *P. aeruginosa* is 8 $\mu\text{g}/\text{mL}$, signifying only modest activity. Some *Burkholderia cepacia* strains are inhibited by ceftazidime.

- c. **Anaerobes.** The activity of the third-generation cephalosporins against anaerobes was summarized elsewhere [12], but a few points deserve emphasis. The anaerobic activity of cefotaxime, ceftizoxime, and ceftriaxone is suitable for respiratory pathogens (i.e., oral anaerobes). None of the third-generation agents is considered a drug of first choice for bowel-related *B. fragilis* [12], although cefotaxime has been very effective in clinical situations [15]. Cefoxitin and cefotetan are more active *in vitro* against anaerobes than most but not all [11] third-generation agents.

2. **Pharmacokinetics** is shown in Table 27F.2.

3. **Dosages** are shown in Table 27F.3, including doses in renal failure.

4. **Pregnancy and nursing mothers** (see section II.A.4)

5. **Clinical use: third-generation agents for community acquired infection**

- a. **Ceftriaxone (Rocephin)** is a widely used agent both due to its broad spectrum of activity and its long half-life, allowing for every 24-hour dosing in non-central nervous system (CNS) infections (Table 27.F.2). It has been effective against serious infections and is the primary agent for CAP.

(1) **Dosing (Table 27F.3).** For non-CNS infections, in adults a single dose given once daily is preferred, usually 1 g every 24 hours. For CNS infections (e.g., meningitis, brain abscess), maximal doses are used, 2 g every 12 hours in adults. In children, with meningitis or severe infection, use every 12 hour regimen.

(2) **Renal failure.** Ceftriaxone has dual renal (60%) and hepatic (40%) excretion; in renal failure, hepatic excretion increases [2]. Dose adjustments are not necessary in renal failure [1,2]. If both hepatic and renal failure is present, half-life is prolonged. If serum levels are not available and ceftriaxone is clearly the agent of choice, 500 mg every 24 hours for non-CNS infections in adults [1] is used though serum monitoring is preferred.

For patients on hemodialysis, the package insert suggests serum levels be monitored.

- (3) **Side effects are discussed in section IV. Rarely**, ceftriaxone may cause “sludge” to form in the gallbladder, especially in children, causing “**biliary pseudolithiasis.**” Associated symptoms may include nausea, vomiting, and right upper quadrant abdominal pain [16].
 - b. Cefotaxime (Claforan)** was the first third-generation cephalosporin introduced and is still the **preferred agent in neonates**, both because of greater experience and because it does not interfere with bilirubin metabolism in the neonate. Otherwise, ceftriaxone has for the most part replaced cefotaxime because of the single daily dose. The one exception is for bowel-perforated intraabdominal infections for which the parent drug cefotaxime plus its desacetyl breakdown product are very effective [15].
 - c. Ceftizoxime (Ceftizox)** must be given every 8 to 12 hours for severe infections and every 4 hours for life-threatening infections. **It has largely been replaced by ceftriaxone given once daily.**
- 6. Clinical use: third-generation agents for hospital-acquired infection**
- a. Cefepime (Maxipime)** is an expanded-spectrum cephalosporin released in 1996 [13,14,17,18].
 - (1) ***In vitro* activity.** It has activity against gram-positive organisms comparable with cefotaxime and activity against gram-negative aerobic organisms comparable or superior to ceftazidime. Cefepime is less active against MSSA than ceftazolin. Among the antibiotics with activity against *P. aeruginosa*, it has more frequent *in vitro* activity than ceftazidime [14]. One of the mechanisms by which it might impart resistance is by inhibiting adherence of the organism to epithelial cells [19]. However, some strains are susceptible to ceftazidime and not to cefepime [20]. It is not active against enterococci, MRSA, *B. fragilis*, or high level penicillin-resistant *S. pneumoniae* [13].
 - (2) **Pharmacokinetics** (Table 27F.2)
 - (3) **Approved indications** include therapy of susceptible pathogens in (a) uncomplicated and complicated urinary tract infection (UTI) [10], (b) uncomplicated skin infections, (c) moderate to severe pneumonia [13], and (d) empiric therapy for the febrile neutropenic patient [21–23]. (**N.B.** The package insert does not list meningitis as an indication for use.)
 - (4) **Dosages**
 - (a) **For adults** usually 1 to 2 g i.v. (or intramuscularly) every 12 hours, depending on the severity of infection. At 2 g every 12 hours, time above the MIC of *P. aeruginosa* for 60% to 70% of a 24-hour period [24]. In the febrile leukopenic patient, 2 g every 8 hours is advised [21–23].
 - (b) **For children** more than 2 months of age. If weight is less than 40 kg, 50 mg/kg/dose every 12 hours for most infections but every 8 hours in the febrile neutropenic patient. Maximum dose per day should not exceed adult doses. If weight is more than 40 kg, adult doses can be used.
 - (c) **Renal failure.** Normal doses are indicated for a creatinine clearance of more than 60 mL. **If the creatinine clearance is 30 to 60 mL/min and the interval selected is every 12 hours**, give the usual dose every 24 hours; for a creatinine clearance of 10 to 30 mL/min, give 50% of the usual dose every 24 hours; for a creatinine clearance of less than 10 mL/min, give 25% of the usual dose every 24 hours. **If the interval selected is every 8 hours** and the creatinine clearance is 30 to 60 mL/min, give the usual dose every 12 hours; for a clearance of 10 to 30 mL/min give the usual dose every 24 hours; and for a clearance of less than 10 mL/min, give 50% of the usual dose every 24 hours.
 - (5) **Side effects** (see section IV)
 - (6) **Cost** (see Appendix Table 1)

(7) **Summary.** Many institutions have replaced ceftazidime with cefepime. As with other broad-spectrum agents (e.g., imipenem, piperacillin-tazobactam), if these agents are used excessively, bacterial resistance will presumably develop. This is especially true in those associated with a foreign body. It has been suggested that emergence of resistance of *E. cloacae* and other gram-negative organisms with inducible β -lactamase potential will not be as common as it has been with ceftazidime [3].

b. Ceftazidime (Fortaz, Tazidime, or Tazicef) and cefepime are the most active cephalosporins against *P. aeruginosa*. **Ceftazidime has poor activity against gram-positive aerobes.** It has in many institutions been replaced with cefepime, but its niche involves therapy against known or potential *P. aeruginosa* infection, including the following:

- (1) **Febrile neutropenic patients** without an obvious source of infection [22,25] (see Chapter 20).
- (2) ***P. aeruginosa* meningitis.** In this rare problem, infectious disease consultation is advised.
- (3) **In combination with an aminoglycoside for *P. aeruginosa* tissue or bloodstream infections in a patient with a delayed penicillin allergy.**
- (4) **Nosocomial pneumonia** when a Gram stain or culture has ruled out *S. aureus*. In this setting resistance can develop on therapy (e.g., with hospital-acquired *Enterobacter* species).
- (5) **Malignant external otitis**
- (6) **Cystic fibrosis.** Early lower respiratory tract infections in cystic fibrosis patients.

D. Cefoperazone (Cefobid) is not quite as active as cefepime against *P. aeruginosa* and contains the NMTT side chain, which appears associated with hypoprothrombinemia (see section II.B.1) **We do not favor the use of this agent.**

III. Oral cephalosporins (Table 27F.5). Although **these are expensive agents** (see Appendix Table), they are commonly used. Adults will have less GI upset with cephalixin or cephadrine than with oral antistaphylococcal agents (dicloxacillin). In children, taste and aftertaste are important in compliance. In one report, oral cephalosporin suspensions were more "acceptable" than other agents [26]. In general, these agents are rapidly and thoroughly absorbed [2].

All these agents are category B in pregnancy and all are excreted in breast milk (see section II.A.4). **The indications and uses** for these agents have been **summarized in** Tables 27F.4 and 27F.6 It is helpful to summarize these agents as first-, second-, and third-generation agents.

A. First-generation oral agents are useful for mild to moderately severe penicillin- and methicillin-susceptible *S. aureus* and group A streptococcal infections of the skin and soft tissue and susceptible UTI pathogens.

1. Cephalixin (Keflex) is well absorbed, but because of the relatively high MICs of the susceptible gram-negative organisms, **this agent is not useful in soft tissue infections due to gram-negative bacteria.** For UTI, even for uncomplicated UTI, a 7-day course, not 3-day course, is advised (see Chapter 15).

a. Dosage. When treating significant *S. aureus* soft tissue infection in adults, a dose of 1,000 mg every 6 hours is used initially and the course completed with 500 mg every 6 hours [27]. This dose is required to provide adequate serum levels because cephalixin is excreted very rapidly. The suggested adult dose for UTI is 250 to 500 mg every 6 hours. In children, 25 to 50 mg/kg/day is divided into four equal doses. In streptococcal pharyngitis, a twice daily regimen at the UTI dose can be used.

b. In renal failure with creatinine clearance less than 10 mL/min, the interval is prolonged to every 12 hours [24,29]; for dialysis patients, a single dose of 500 mg daily suffices and is an excellent regimen to complete treatment of a MSSA infection. When creatinine clearance is 10 to 50 mL/min, a dose is given every 8 to 12 hours, depending on disease severity and renal failure.

c. Side effects (see section IV)

Table 27F.5. Oral-Cephalosporins

Agent	Indication	Comment
<p>First generation Cephalexin (Keflex), or Cephadrine (Anspor, Velosef)</p>	<p>Mild/minor soft-tissue infections due to methicillin-susceptible <i>S. aureus</i> and/or <i>S. pyogenes</i> (strep A). Susceptible UTI. Alternative in strep pharyngitis.^a</p>	<p>Use an adequate dose since activity against <i>S. aureus</i> is modest and excretion is rapid. See text. Probably prudent to use 7-day course for uncomplicated UTI rather than 3-day course. These are relatively expensive agents. See Appendix Table.</p>
<p>Second generation Cefuroxime (Ceftin), or Cefprozil (Cefzil), or Loracarbef (Lorabid)</p>	<p>Alternative therapy in otitis media, sinusitis, bronchitis. See Chapter 8. Cefuroxime axetil (Ceftin) has been used in Lyme disease. Alternate therapy in early selected cases of community-acquired pneumonia (CAP). See Chapter 11. Alternate therapy for <i>H. influenzae</i> and <i>M. catarrhalis</i> therapy in otitis media</p>	<p>Cefaclor falling out of favor in children, for it may cause serum sickness. Oral cefuroxime has a poor taste vs “bubble-gum” flavored cefprozil, which is b.i.d. dosing.</p>
<p>Third generation Cefixime (Suprax)</p>	<p>Susceptible UTI or mild soft-tissue infections due to susceptible pathogens. Alternate for uncomplicated GC therapy. No unique niche. No unique role. No unique role. Possible alternative in flares of bronchitis. No unique role. No unique role.</p>	<p>Less active against <i>S. pneumoniae</i> and not active for <i>S. aureus</i>. Do <i>in vitro</i> susceptibility data to show activity. See Chapter 16.</p>
<p>Cefpodoxime (Vantin) Ceftibuten (Cedax)</p>		<p>See text.</p>
<p>Cefdinir (Omnicef) Ceftitoren (Spectracef)</p>		<p>See text. See text. See text.</p>

^aAlthough second- and third-generation cephalosporins have been used for strep pharyngitis, the first-generation agents are the most cost effective. UTI, urinary tract infection; GC, gonococcal infection.

Table 27F.6. Common Clinical Uses of Oral Cephalosporins

Setting	Particularly Useful Agents	Comments
Soft-tissue infections, cellulitis	First-generation agent preferred (e.g., cephalexin, cephhradine)	When <i>S. aureus</i> and streptococci activity is desired. Agents provide poor gram-negative tissue levels. (Cefixime, cefibuten, and cefditoren have poor <i>S. aureus</i> activity; good gram-negative activity.)
Otitis media	Cefprozil	Useful in delayed penicillin-allergic patients and when ampicillin-resistant <i>H. influenzae</i> are known or highly suspected. See Chapter 8.
	Cefixime, cefibuten, and cefditoren	Have less activity against <i>S. pneumoniae</i> , so do not use for initial empiric therapy; are used for possible <i>H. influenzae</i> and <i>M. catarrhalis</i> infections.
Sinusitis	Cefuroxime axetil (adults)	Especially if cannot use less expensive agents (i.e., TMP-SMZ, amoxicillin). See Chapter 8.
Bronchitis	Cefprozil (children or adults) Cefuroxime, cefprozil	Alternative agents for delayed penicillin-allergic patients or patients on rotating antibiotic regimens. See Chapter 8. Cefixime and cefibuten are not as active against <i>S. pneumoniae</i> .
Streptococcal pharyngitis	First-generation agent	Most cost-effective alternative in the penicillin-allergic patient when a macrolide is not used. See Chapter 8.
Urinary tract infection	Cephalexin, cephradine Cefaclor, cefuroxime Cefixime	When susceptibility data support use. For uncomplicated UTI, a 7-day (not 3-day) course is preferred. See Chapter 15.
Community-acquired pneumonia, mild and typically when >55 y.o.	Cefuroxime	For completion of therapy when intravenous cefuroxime has been used (see text); selected cases for oral therapy. (See Chapter 11.)

- d. **Pregnancy and nursing mothers** (see section II.A.4)
 - e. **Cost** (see Appendix Table)
2. **Cephadrine (Anspor, Velosef)** is considered equivalent to cephalexin and may be preferred if available locally at a lower cost than cephalexin.
- a. **Dosages:** same as for cephalexin.
 - b. **In renal failure**, if the creatinine clearance is more than 50 mL/min, a normal dose is given every 6 hours. If the clearance is 10 to 50 mL/min, 50% of the usual dose is given at normal intervals. With a creatinine clearance of less than 10 mL/min, 25% of the usual dose is given at usual intervals. A dose is advised after dialysis. In chronic ambulatory peritoneal dialysis (CAPD), doses similar to those with a creatinine clearance of less than 10 mL/min can be used [28,29].
 - c. **Side effects** (see section IV)
 - d. **Cost** (see Appendix Table)
 - e. **Pregnancy and nursing mothers** (see section II.A.4)
3. **Cefadroxil (Duricef)** is a very expensive agent with no unique niches. **We do not advocate its use.**
- B. Second-generation oral cephalosporins** have enjoyed immense popularity primarily for upper respiratory (acute otitis media, sinusitis) and lower respiratory tract infections (acute exacerbations of chronic bronchitis, early CAP) (see Chapters 8 and 11). They are active against penicillin-susceptible *S. pneumoniae*, and some of them are active against some intermediate penicillin-resistant *S. pneumoniae* but not high level penicillin-resistant *S. pneumoniae*. They are also active against *M. catarrhalis* and *H. influenzae*—including β -lactamase-positive pathogens, streptococci group A—and have modest activity against MSSA. **All these agents are relatively expensive.** For streptococcal pharyngitis in the allergic patient, if a cephalosporin is indicated, a first-generation agent (e.g., cephalexin) is preferred (see Chapter 8).
1. **Cefuroxime axetil (Ceftin)** has an unpalatable taste, including the suspensions, and therefore an **alternate agent (e.g., cefprozil) seems prudent in children** in an attempt to improve compliance. It is active against β -lactamase-positive and-negative *M. catarrhalis*, *S. aureus*, group A and B streptococci, penicillin-susceptible *S. pneumoniae*, and some intermediate-level penicillin-resistant *S. pneumoniae* (see Chapters 8 and 11). In adults, oral cefuroxime has been used to complete therapy initiated with parenteral cefuroxime (see section II.B.2) and as an alternative agent for sinusitis or bronchitis, especially in an allergic patient (see Chapter 8).
- a. **Dosage.** For children more than 13 years of age and adults, 250 to 500 mg twice daily, depending on the severity of infection. In early Lyme disease (erythema chronicum migrans) use 500 mg twice daily.
 - b. **In mild or moderate to even severe renal failure**, usual doses are given [28,29].
 - c. **Cost.** This is expensive (see Appendix Table). (Pregnancy and nursing, see section II.A.4).
 - d. **Side effects** (see section IV)
 - e. **Pregnancy and nursing mothers** (see section II.A.4)
2. **Cefprozil (Cefzil)** has similar *in vitro* activity as cefuroxime axetil. Because it is available in a bubble-gum-flavored suspension and can be **given twice daily**, it is commonly used in **otitis media** when there is amoxicillin allergy or when amoxicillin has failed. It also can be used in **sinusitis and acute exacerbations of chronic bronchitis**.
- a. **Dosage.** Cefprozil is available as a 250- or 500-mg tablet as well as a liquid bubble-gum-flavor oral suspension of 125 mg/5 mL and 250 mg/5 mL. **In adults** with exacerbations of bronchitis, 500 mg twice daily is given. In sinusitis, a similar dose could be used. **In children** (6 months to 12 years) 15 mg/kg every 12 hours is suggested per package insert.
 - b. **Renal failure.** If the creatinine clearance is over 30 mL/min, use standard doses. For a creatinine clearance less than 30 mL/min, use 50% of the standard

dose at normal intervals. Because cefprozil is partially removed after dialysis, a dose should be given after completion of dialysis. In CAPD, use doses as if creatinine clearance was less than 10 mL/min [28,29].

c. **Cost** (see Appendix Table)

d. **Side effects** (see section IV)

e. **Pregnancy and nursing mothers** (see section II.A.4)

3. **Loracarbef (Lorabid)** has a cephalosporin-like structure. Its spectrum of activity is similar to cefuroxime axetil and cefprozil. Loracarbef has been used especially in acute otitis media, sinusitis, acute bronchitis, and selected cases of CAP similar to the indications for cefuroxime axetil and cefprozil. **It has no special niches and we seldom use it.**

a. **Dosing.** The ingestion of food will decrease and delay the peak serum concentration; **doses should be given 1 hour before or 2 hours after meals.** The suspension is more rapidly absorbed than the capsules, and the **suspension is recommended for otitis media.**

Loracarbef is available in 200-mg pulvules and a suspension (100 mg/5 mL and 200 mg/5 mL). **In adults** and children 13 years of age or more, for acute exacerbations of chronic bronchitis, CAP, sinusitis, and uncomplicated pyelonephritis, 400 mg every 12 hours has been suggested. **In children** (6 months to 12 years), for otitis the suspension preparation at 30 mg/kg/day in divided doses every 12 hours.

b. **In renal failure.** When creatinine clearance is 10 to 49 mL/min, a normal dose at twice the usual dose interval is given (i.e., every 24 hours). In patients with creatinine clearance of less than 10 mL/min who are not undergoing hemodialysis, the usual dose can be given every 3 to 5 days [24]. Patients undergoing hemodialysis should receive a supplemental dose after dialysis. For patients with CAPD, there are no data. Dose as if creatinine clearance is less than 10 mL/min [28,29].

c. **Side effects** (see section IV)

d. **Cost** (see Appendix Table 1)

e. **Pregnancy and nursing mothers** (see section II.A.4)

4. **Cefaclor (Ceclor)** produces serum sickness in children (see section IV), and 10% to 15% or more of ampicillin-resistant *H. influenzae* are resistant to cefaclor. Furthermore, its activity against *S. pneumoniae* is inferior. **Consequently, there is very little use for this agent** [1].

C. **Third-generation oral cephalosporins** are expensive and occasionally useful in the allergic patient and in the special circumstances discussed later. Because most microbiology laboratories can only perform susceptibility data on a limited number of agents, the susceptibility data of these agents often are not available. **We use these agents in a very limited fashion.**

1. **Cefixime (Suprax)** is more active than other oral cephalosporins against many gram-negative organisms (*E. coli*, *Klebsiella* species, *P. mirabilis*, and *S. marcescens*) but has no useful activity against *Pseudomonas* species, many strains of *Enterobacter* species, and *Acinetobacter* species. It is very active against *N. gonorrhoeae*, *H. influenzae*, and *M. catarrhalis*, including β -lactamase producers. However, **it is not active against *S. aureus*** and has decreased activity against *S. pneumoniae* when compared with other oral cephalosporins [1]. Cefixime is not active against anaerobes.

a. **Clinical use.** The exact role for this agent introduced in 1989 is still evolving. It can be considered especially in [1] **uncomplicated gonococcus infection** [9] (see Chapter 16) and ***H. influenzae* or *M. catarrhalis* otitis media infections**, but because cefixime is not as active against *S. pneumoniae* (a common pathogen in otitis), **cefixime is not a first-line agent for otitis**; it has been used when amoxicillin has failed (see Chapter 8) **In selected cases of UTI or gram-negative soft tissue infections**, when susceptibility data allow, cefixime may occasionally be useful, especially when allergies preclude using more conventional less expensive regimens. When it was first introduced, the general consensus was that it offered little. A recent study comparing cefixime to intravenous antibiotics in low risk febrile neutropenic patients

with negative blood cultures, cefixime fared well [30]. Further studies are awaited.

- b. **Dosing.** The oral suspension is absorbed more rapidly and completely than the tablets and is preferred in the treatment of otitis media. Tablets are available in 200 and 400 mg; the oral suspension contains 100 mg/5 mL. **In adults and children older than 12 years of age**, 200 mg twice daily or 400 mg once daily is suggested. **In children** more than 6 months of age, 8 mg/kg/day of the suspension once daily or two divided doses are suggested.
 - c. **Renal failure.** If the creatinine clearance is 10 to 50 mL/min, 75% of the standard dosage at the standard interval is given. Patients whose clearance is less than 10 mL/min or patients on CAPD may be given half the standard dose at the standard interval. Patients on hemodialysis can be given 300 mg after dialysis [28,29].
 - d. **Side effects** (see section IV)
 - e. **Pregnancy and nursing mothers** (see section II.A.4)
 - f. **Cost** (see Appendix Table)
2. **Cefpodoxime (Vantin)** was approved in 1992. It is modestly active against MSSA, MIC₉₀ = 2.0 µg/mL, and against common respiratory pathogens, including penicillin-susceptible *S. pneumoniae*; *H. influenzae*, and β-lactamase-positive or-negative *M. catarrhalis*, and *Streptococcus* groups A and B. It is active against many Enterobacteriaceae but not against *Enterobacter*, *Serratia*, *Morganella*, or *Pseudomonas* species. It has been used in UTI, CAP, acute otitis, bronchitis, and single-dose therapy of uncomplicated gonorrhea.
- a. **Dosing.** Both 100- and 200-mg tablets and an oral suspension (50 mg/5 mL and 100 mg/5 mL) are available. **In adults** and children 13 years of age or more, 200 mg every 12 hours for moderately severe infection is used. **For children** (6 months to 12 years), the dose is 10 mg/kg/day divided every 12 hours (maximum 400 mg/day) for 10 days for otitis media. The oral suspension has a bad taste that can effect compliance in children.
 - b. **In renal failure**, the dose interval can be changed [28,29]. If the creatinine clearance is 10 to 50 mL/min, a standard dose can be given every 16 hours; if the creatinine clearance is less than 10 mL/min, a standard dose can be given every 24 to 48 hours. In patients undergoing hemodialysis, 200 mg after dialysis only is suggested. For patients undergoing CAPD, dose as if the creatinine clearance is less than 10 mL/min [28,29].
 - c. **Pregnancy and nursing mothers** (see section II.A.4)
 - d. **Comment.** Shortly after its release, the *Medical Letter* reviewed this agent and concluded the following: “Cefpodoxime is a broad-spectrum oral cephalosporin that offers no clear advantage over previously available drugs for the treatment of any infection” [31]. In the woman with many antibiotic allergies, when susceptibility data allow, it may be useful in selected episodes of UTI.
3. **Ceftibuten (Cedax)** was approved in late 1995. The *in vitro* activity of this “third-generation” oral agent is similar to that of cefixime in that it has **enhanced activity against many Enterobacteriaceae, but many gram-positive organisms are resistant** (including *S. aureus*, *S. agalactiae*, and viridans streptococci). Ceftibuten has limited activity against *S. pneumoniae*. Specifically, strains of pneumococci that are intermediate or high level penicillin resistant are ceftibuten resistant. Anaerobes are not susceptible. Ceftibuten is not active against *Acinetobacter* species and *Pseudomonas* species. Susceptibility data are available [32].
- a. Although approved for pharyngitis and tonsillitis, less expensive agents are available. It should not be used for empiric therapy of otitis media because it is not active against many pneumococcal infections. Ceftibuten is a consideration for acute bacterial exacerbations of chronic bronchitis due to susceptible *H. influenzae* and *M. catarrhalis* especially.
 - b. **Dosages.** Ceftibuten is available in 400-mg capsules and a suspension (90 mg/5 mL and 180 mg/5 mL). **Adults and children more than 12 years of age** are given 400 mg once daily. **Children more than 6 months of age**

should receive 9 mg/kg/day as a single dose up to a maximum of 400 mg/day. The **suspension must be administered 2 hours before or 1 hour after a meal.**

- c. Renal failure.** If creatinine clearance is between 10 to 50 mL/min, 50% of the usual dose is given every 24 hours; if the creatinine clearance is less than 10 mL/min, 25% of the usual dose is given every 24 hours [28,29]. In patients undergoing hemodialysis, a single 300-mg dose or 9 mg/kg (maximum of 300 mg) should be administered at the end of each hemodialysis session. There are no data for CAPD patients as of early 2000; use doses as if creatinine clearance is less than 10 mL/min [28,29].

d. Pregnancy and nursing mothers (see section II.A.4)

- e. Comment.** So far, this agent has no unique niches. Cefditaben is another agent that could be used for acute exacerbations of chronic bronchitis, especially when a once-daily regimen is highly desirable or as an agent to rotate with other antibiotics in this setting. A recent review [3] and the *Medical Letter* [33] did not give this agent a very good report; in its review in 1996 the *Medical Letter* [33] concluded “ceftibuten is an expensive new oral cephalosporin that seems like a poor choice for the indications for which it is being marketed. In particular, recommending a drug for use in acute otitis media except when caused by pneumococcus makes no sense; pneumococcus are a frequent cause of otitis media and in clinical practice, the pathogen is usually not identified.”

4. Cefdinir (Omnicef) was approved for use in mid-1998 and reviewed [2,34,35].

- a. In vitro activity** [34]. Cefdinir is similar to cefpodoxime in antibacterial activity. Cefdinir is active against MSSA; penicillin-susceptible *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and *N. gonorrhoeae*; and many gram-negative bacteria but not against *Pseudomonas* species.

Cefdinir is not active against MRSA, atypical pathogens (*Legionella*, *Mycoplasma*, *Chlamydia*), enterococcus, and many anaerobes. It is not active against high level penicillin-resistant *S. pneumoniae*, and we view its activity against intermediately penicillin-resistant *S. pneumoniae* as inadequate. In one report, the MIC₉₀ of cefdinir against these strains was 3.1 μg/mL, with the average peak serum levels after a 600-mg dose of only 2.9 μg/mL [36].

- b. Pharmacokinetics.** Cefdinir is absorbed somewhat slowly from the GI tract with bioavailability of the capsules of only about 20% and 25% for the suspension. Food does not affect absorption. The drug is not metabolized and is excreted in the urine [36]. Because children find it to have a smell and taste they enjoy, compliance may be good.

- c. Approved uses** include therapy of susceptible pathogens in acute maxillary sinusitis, otitis media, acute exacerbations of chronic bronchitis, CAP, and skin infections and for pharyngitis in young children.

- d. Dosages** per package insert are as follows: **For adults**, 300 mg every 12 hours or 600 mg every 24 hours (the once-daily regimen is not advised in pneumonia or skin infections). **For children** (6 months to 12 years of age), 7 mg/kg every 12 hours or 14 mg/kg every 24 hours.

- e. Renal failure.** For patients with creatinine clearance less than 30 mL/min the package insert suggests the following: **In adults**, 300 mg once a day; **in children**, 7 mg/kg (up to 300 mg) given once a day. **In hemodialysis, which removes cefdinir**, the above reduced doses can be given every other day, with a dose after dialysis.

f. Pregnancy and nursing mothers (see section II.A.4)

- g. Side effects.** Like other oral cephalosporins, cefdinir is well tolerated. Diarrhea and vaginal candidiasis are the most common side effects [34].

- h. Cost.** This is an expensive agent: cost to the pharmacist for 10 days in an adult is \$67 [34] for the 300 mg every 12 hour regimen (see Appendix Table).

- i. Summary.** In a review, the *Medical Letter* concluded the following: “cefdinir is an oral third-generation cephalosporin similar to cefpodoxime. **Older, better established drugs are preferred**” [34]. However, in a recent symposium,

discussants concluded that the acceptability in children provides an alternative for a child who has failed penicillin for strep throat [35].

5. **Cefditoren pivoxil** (Spectracef) is a new oral third-generation cephalosporin approved by the U.S. Food and Drug Administration in late 2001. The drug has been used in Japan for 7 years [37].

a. ***In vitro* activity.** This is similar to cefdinir and cefpodoxime.

b. **Pharmacokinetics.** Cefditoren is well absorbed, with peak levels achieved in 1.5 to 3 hours. The drug's half-life (1.6 hours) permits dosing every 12 hours. It is excreted mainly by the kidneys. The inactive metabolite pivalate is eliminated by the kidneys in combination with carnitine as pivaloylcarnitine (see section e.(2), below).

c. **Approved clinical uses in adults or children 12** or more years of age include therapy of acute exacerbation of chronic bronchitis, pharyngitis/tonsillitis, and uncomplicated skin and soft tissue infection.

d. **Dosage.** 200-mg tablets should be taken with meals (absorption is increased with fatty meals). For pharyngitis and skin infections, 200 mg every 12 hours is advised; for exacerbation of acute bronchitis, 400 mg every 12 hours is advised.

e. **Adverse effects.** For short-term use, this agent is generally well tolerated.

(1) Common adverse side effects include diarrhea, nausea, and vaginal candidiasis.

(2) Cefditoren decreases serum concentrations of carnitine, which is the substrate for carnitine acyltransferases involved in fatty acid metabolism and transport of long-chain fatty acids into mitochondria. In normal patients, the significance of this is unclear, and 7 to 10 days after stopping the drug, serum carnitine levels normalize. Patients with disorders of fatty acid metabolism associated with carnitine deficiency can develop progressive muscle weakness and rhabdomyolysis, but neither has been reported with cefditoren use [37].

(3) **Cefditoren tablets** contain sodium caseinate, a milk protein. Therefore these **should not be given to patients with milk hypersensitivity** [37].

f. **Drug interactions.** Absorption can be reduced when cefditoren is taken with antacids with magnesium or aluminum or H₂ receptor agonists such as ranitidine [37].

g. **Cost.** As with other third-generation cephalosporins, a 10-day supply of cefditoren is expensive, although cefditoren is less expensive than cefdinir or cefpodoxime [37] (see Appendix Table).

h. **Summary.** Cefditoren has no unique clinical niche. In early 2002 the *Medical Letter* concluded the following: "it offers no clinical advantage over cefdinir or cefpodoxime, but it costs less" [37]. Older cephalosporins (e.g., cephalixin for skin infections and cefuroxime for acute exacerbation of chronic bronchitis), the *Medical Letter* went on to conclude, "that have narrower spectrums of activity are as effective as cefditoren for the approved conditions. They are less likely to promote emergence of resistance. Penicillin remains the drug of choice for streptococcal pharyngitis or tonsillitis" [37].

IV. Side effects of cephalosporins. Both oral and intravenous formulations are very well tolerated.

A. **Primary allergic reactions.** There is approximately a 1% to 3% incidence of primary allergic reactions to cephalosporins: urticarial and morbilliform rashes, fevers, eosinophilia, and serum sickness. Anaphylaxis is rare, occurring in less than 0.02% of recipients [2]. In individuals with a history of penicillin allergy, risk of an allergic reaction to cephalosporin is up to eight times higher than in those without that history. However, if the history-positive individual is tested and is negative, that excess risk disappears [38] (see Chapter 24). If skin tests are unavailable, the following approach is suggested:

1. **With a history of an immediate reaction to penicillin** (i.e., anaphylaxis, bronchospasm, hypotension, etc.), **cephalosporins should be avoided** [39].

2. **In the patient with a delayed mild reaction** (e.g., morbilliform rash) **to penicillins, cephalosporins are commonly used with caution.** The risk with the

third-generation cephalosporins in this setting is as low as 1%, similar to those without that history [40].

3. **Serum sickness has been observed more in recipients of cefaclor** [40] and with cefprozil [41,42]. Loracarbef may have a risk of serum sickness because its structure is similar to cefaclor.

B. Nephrotoxicity is infrequent with cephalosporin monotherapy [1,2]. Interstitial nephritis has occurred as a hypersensitivity response.

C. Hematologic effects

1. **Positive Coombs reactions** are relatively common (3%) while on high-dose parenteral therapy [2]. Although hemolytic anemia is quite uncommon, it occurs after cefotetan use [43,44].

2. **Granulocytopenia** and/or **thrombocytopenia** are rare complications. With severe underlying hepatic dysfunction, various β -lactam antibiotics, including the cephalosporins, have been associated with leukopenia; lower doses of β -lactam antibiotics should be used [45].

3. **Hypoprothrombinemia** associated with NMTT side chain is discussed in sections **II.B.1** and **II.B.4**. It has also been described with cefazolin use in patients with renal failure because of the side chain similar in structure to NMTT in cefazolin.

D. Phlebitis with intravenous use is reported in 1% to 2% and is related more to the known risks of intravenous catheters than to a particular thrombogenic potential of the cephalosporins [2].

E. Ethanol intolerance. Disulfiram-like reactions (flushing, tachycardia, nausea, vomiting, headache, hypotension) have been described with patients receiving **cefoperazone**, **cefotetan**, and cefazolin. The reaction may be related to the NMTT structure. Patients receiving these agents should be advised *not* to consume alcohol or alcohol-containing medications [1,2].

F. Clostridium difficile diarrhea may occur more often in recipients of second- and third-generation cephalosporins [46], including the oral third-generation agents.

G. Fluoroquinolones

Quinolone antibiotics have been available since the mid-1960's [1–5]. Thousands of different quinolone structures have been synthesized, but fewer than 10 U.S. Food and Drug Administration (FDA)-approved agents are clinically useful [2]. Quinolones can be categorized based on spectrum of antibacterial activity **as shown in Table 27G.1** [4]. The more recently introduced third- and fourth-generation fluoroquinolones are referred to as “expanded-spectrum” fluoroquinolones, in contrast to the earlier second-generation agents such as ciprofloxacin.

Because bacterial resistance to the first-generation quinolones (nalidixic acid, oxolinic acid, cinoxacin) developed rapidly and they are no longer used, they are not mentioned further. The second-generation agents (norfloxacin and ciprofloxacin, followed by ofloxacin) were released between 1986 and 1992. These agents have been very useful clinically for gram-negative or

Table 27G.1. Classification of Quinolones

Third and fourth generation ^c
Levofloxacin ^d
Sparfloxacin
Gatifloxacin ^e
Grepafloxacin ^f
Trovafoxacin ^f
Moxifloxacin ^e

^aWithdrawn. See text.

^bMost potent against *Pseudomonas*.

^cMore potent against *Pneumococcus* and/or anaerobes than were earlier compounds.

^dAlthough classified by some as second-generation agent [2], because of its expanded spectrum against *S. pneumoniae*, including penicillin-resistant strains (see Chapter 11), it seems appropriate to view this as a third-generation agent.

^eMost active *in vitro* against *S. pneumoniae*. See text.

^fMore potent against anaerobes but rarely indicated. See text.

Modified from Walker RC. The fluoroquinolones. *Mayo Clin Proc* 1999;74:1030.

mycobacterial infection, but they lack consistent activity against gram-positive cocci such as *Streptococcus pneumoniae* and anaerobes. The recently introduced expanded-spectrum third- and fourth-generation fluoroquinolones, which include sparfloxacin, levofloxacin, gatifloxacin, and moxifloxacin, were introduced after 1997 (Table 27G.1). The third- and fourth-generation quinolones have enhanced gram-positive activity, including penicillin-susceptible and penicillin-resistant *S. pneumoniae*, and modest anaerobic activity. They also have gram-negative activity, except for pseudomonas, and activity against the nonbacterial organisms that cause pneumonia, such as *Mycoplasma pneumoniae*, as well as against *Legionella pneumophila*. This spectrum, plus excellent bioavailability, good tissue penetration, long serum half-life, and safety, have made the fluoroquinolones very attractive agents. **The challenge for the health-care provider is to limit their use to clinical settings that call for their enhanced spectrum.** By doing so, the clinician will reduce the rate of resistance selection. These steps will lengthen the useful life of these agents.

In this chapter the terms “fluoroquinolones” and “quinolones” are used interchangeably.

I. An overview of the fluoroquinolones

- A. Structure.** Many structural modifications can be made to the basic synthetic nucleus to achieve specific goals such as enhanced gram-positive or anaerobic activity.
- B. Mechanism of action** is reviewed elsewhere [4]. Fluoroquinolones **inhibit DNA gyrase**, a bacterial enzyme essential for DNA replication, and thus inhibit DNA supercoiling. They promote gyrase-mediated double-stranded DNA breakage at specific sites.
- C. In vitro activity of the fluoroquinolones** is summarized in Table 27G.2 [4].
 - 1. Gram-positive bacteria.** Compared with the earlier quinolones, gatifloxacin, moxifloxacin, and to a lesser degree levofloxacin have enhanced activity against *S. pneumoniae*, including penicillin-susceptible and moderately and highly penicillin-resistant strains [6,7] (see Chapters 8, 11, and 27C). However, against penicillin-susceptible *S. pneumoniae*, penicillin is as active *in vitro* as are the quinolones. Some strains of *S. aureus* are susceptible to quinolones, but against methicillin-susceptible *S. aureus*, similarly nafcillin is as active as fluoroquinolones [7] (Table 27G.2) and methicillin-susceptible *S. aureus* is far less likely to develop resistance to nafcillin.
 - 2. Gram-negative bacteria.** All the fluoroquinolones are very active against gram-negative cocci and bacilli, which cause infections in community-residing individuals, including organisms like *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Escherichia coli*. Recently, however, a study of sex workers in the Philippines demonstrated that *Neisseria gonorrhoeae* has developed high level resistance to ciprofloxacin; from 1994 through 1996 to 1997, resistance of gonococcal isolates increased from 9% to 49% [8]. This led to a significant number of clinical failures. Against *Pseudomonas aeruginosa* and other hospital gram-negative organisms, the activity of quinolones can be summarized as follows: ciprofloxacin > levofloxacin = gatifloxacin = moxifloxacin = ofloxacin. Sparfloxacin is not approved for pseudomonas.
 - 3. Anaerobes.** Gatifloxacin and moxifloxacin have some activity. Trovafloxacin is the most active *in vitro* [5] and has been approved for use in anaerobic infections; however, it is rarely used (see later discussion). The others have limited activity against anaerobes.
 - 4. Chlamydia/Mycoplasma.** The recently introduced fluoroquinolones are active against *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *C. trachomatis*. Ofloxacin is active against *C. trachomatis* (Table 27G.2).
 - 5. Legionella pneumophila.** Ciprofloxacin is quite active, as are the third- and fourth-generation fluoroquinolones. Ofloxacin, though active, is less so.
 - 6. β -Lactam-resistant organisms. All fluoroquinolones lack significant activity against methicillin-resistant *S. aureus*, vancomycin-resistant enterococci, and multidrug-resistant nosocomial gram-negative organisms (e.g., *Stenotrophomonas maltophilia*).**
 - 7. Miscellaneous. In foreign body infection,** there is laboratory evidence that quinolones are relatively more active against bacteria attached to foreign bodies than are the β -lactams. Furthermore, the quinolones adhere to such

MSSA, methicillin-sensitive *S. aureus*; MRSA, methicillin-resistant *S. aureus*; CRSA, ciprofloxacin-resistant *S. aureus*. Modified from O'Donnell JA, Gelone SP. Fluoroquinolones. *Infect Dis Clin North Am* 2000;14:489 for data on levofloxacin, moxifloxacin, and gatifloxacin; and from Garey KW, Amsden GW. Trovofloxacin: an overview. *Pharmacotherapy* 1999;19:21 for data on ciprofloxacin and ofloxacin.

foreign bodies as ureteral stents at concentrations that exceed the minimum inhibitory concentration of possible infecting organisms [9]. This has led to their use in artificial joint infection, sometimes combined with rifampin (see related discussions in Chapters 5 and 27R).

D. Pharmacokinetics

1. **Oral absorption.** Fluoroquinolones are **well absorbed** [1–4,10]. In obese subjects, weight-adjusted dosing yielded higher serum concentrations but similar tissue fluid concentrations compared with those occurring in nonobese subjects receiving standard doses [11]. **Certain drugs taken concomitantly will interfere with the absorption of quinolones.** If antacids, sucralfate, magnesium, aluminum, iron, zinc, calcium, or didanosine are taken together with an oral fluoroquinolone, absorption of the latter is reduced.
 2. **Intravenous (i.v.) preparations** are available for ciprofloxacin, ofloxacin, trovafloxacin, levofloxacin, gatifloxacin, and moxifloxacin. **Oral regimens provide similar serum levels** as the more expensive i.v. formulations, and thus oral should be used preferentially [1,2]. The i.v. formulations are indicated for patients who cannot take anything by mouth or have active nausea and vomiting. If enteral nutrition is possible, patients can be on oral therapy [1,2].
 3. **Tissue penetration.** Fluoroquinolones penetrate tissue well, including lung, bronchial mucosa, kidney, prostate, bone, and the genital tract.
 4. **Renal excretion varies** [2]. All quinolones require dose reduction in the setting of both renal and hepatic dysfunction.
 - a. **Levofloxacin and ofloxacin** depend entirely on renal excretion; dosage modification is required in renal failure.
 - b. **Ciprofloxacin, sparfloxacin, and gatifloxacin:** moderate dosage adjustments are necessary in renal failure.
 - c. **About 50% of moxifloxacin** is metabolized in the liver; dosage reduction is not necessary.
 - d. **Trovafloxacin** is eliminated entirely by the hepatic route. No dosage change is necessary except in hepatic failure.
 5. **Concentration-dependent killing.** Like gentamicin, fluoroquinolones have “**concentration-dependent killing**” and postantibiotic effect against gram-negative organisms [2,10] (see Chapter 25). If high peak serum concentration to minimum inhibitory concentration ratios are achieved, some experts believe the emergence of resistant bacteria may be reduced [12] (also see section V.B).
 6. **Drug interactions** are discussed in section F.4.
 7. **Topical solutions** are available for certain eye and ear infections (see Chapters 7 and 8 and section II.B.12.f).
- E. Adverse reactions.** Fluoroquinolones are well tolerated [1,2,13–15]. Although the clinical impression has been that side effects may be more common in the elderly (i.e., those older than 65 years of age), recently that opinion has been challenged [15]. **Side effects have recently been reviewed [13,14] and include the following:**
1. **Gastrointestinal symptoms,** primarily nausea but also anorexia, vomiting, and/or diarrhea, occur in about 5% or more. *C. difficile* diarrhea occurs but is uncommon, perhaps because of the quinolones minimal effect on anaerobic flora [13].
 2. **Cutaneous reactions,** including nonspecific rashes and urticaria, occur in 1% to 2%. **Sparfloxacin** has **increased rates of phototoxicity** (see section III.C.1).
 3. **Hepatotoxicity.** Liver function test abnormalities and hepatic toxicity are minimal in the commonly used quinolones. The exception is trovafloxacin [1,3,14], which has been associated with severe hepatotoxicity. During the 18 months after the release of this drug, several cases of severe liver toxicity, including acute liver failure and some deaths, were reported. In mid-1999, the FDA recommended that trovafloxacin should be used only for life-threatening or limb-threatening infections with initial i.v. therapy started in an inpatient setting; see related discussions under section III.C.2.
 4. **Central nervous system symptoms** occur in 1% to 4% of patients, mainly the elderly. The most common symptoms are headaches (mild), slight dizziness, mild sleep disturbance, and alteration of mood with agitation, anxiety, or depression.

Seizures have rarely been reported and may occur in patients receiving other medications simultaneously, such as nonsteroidal antiinflammatory agents with any quinolone: theophylline with ciprofloxacin and moxifloxacin with metronidazole.

5. **QT prolongation with torsades de pointes** has been described with the use of some of the quinolones. This is an evolving area of interest, and up to date information is available from two excellent websites, *www.qtdrugs.org* and *www.Torsades.org*, which provide listings of drugs with this possible complication and current references for drugs that may prolong the QTc interval and/or may be associated with torsades. In recent discussions of this topic [16,16a], the authors conclude that moxifloxacin, levofloxacin, and gatifloxacin **should not be used in patients with risk factors predisposing them to prolonged QTc interval and therefore torsades**. Risk factors included female gender; presence of underlying cardiac disease, including congestive heart failure; advanced age; hypokalemia; hypomagnesemia; and use of concomitant drugs known to prolong the QTc interval such as the class Ia (e.g., quinidine, procainamide) and III antiarrhythmics such as amiodarone or sotalol [17].

See section III. under individual agents also.

6. **Tendon rupture** [10]. Postmarketing data suggest that quinolone use may be associated with tendon rupture, primarily the Achilles tendon (unilateral or bilateral) but also in the shoulder and hand. *In vitro* studies indicate that ciprofloxacin interferes with collagen synthesis. Tendon rupture is more common in men over age 50 and in those on steroids. **Therefore at the first sign of tendon pain or inflammation, quinolone should be discontinued** and exercise avoided until the tendonitis has subsided. This topic has recently been reviewed [18].

7. **Drug interactions** (see section F.4)

F. Precautions in use [19–24]

1. **Do not use in patients allergic to either the early analogues** (e.g., nalidixic acid, oxolinic acid, or cinoxacin) or other fluoroquinolones.
2. **Avoid systemic use in children.** Fluoroquinolones produce cartilage erosion in young animals. The clinical importance of this has not been demonstrated. Although topical preparations have been used in ear and eye infections (see section II.B.12.f), the *Red Book* [20], Centers for Disease Control and Prevention [25], and other experts [19,21] do not recommend systemic (oral or i.v.) fluoroquinolones for use in children with the following exceptions [1,2,19–21,26]:
 - a. **Cystic fibrosis** patients, because the benefits are believed to outweigh the potential risks. Investigations of ciprofloxacin use in this setting have demonstrated no adverse effects [19].
 - b. **In special circumstances** fluoroquinolones may be justified in children younger than 18 years when alternatives are not available [20,21]. For a detailed discussion see the *Red Book* [20]. For children over 45 kg, the Centers for Disease Control and Prevention policy is that adult quinolone regimens can be used and adult doses are advised [25].
 - c. Topical agents have been used in eye and ear infections (see Chapter 7 and section II.B.12.f).
3. **Avoid in pregnancy and nursing mothers** because of the potential effect on developing cartilage (see section 2). The fluoroquinolones are **category C** agents (see Chapter 27A).
4. **Drug interactions**
 - a. **Antacids** containing magnesium or aluminum markedly diminish absorption. This effect is minimized if the antacid is taken 2 to 3 hours after the fluoroquinolone. **Other multivalent metal cations** impair absorption (see prior discussion in section D).
 - b. **Theophylline levels** are **increased by ciprofloxacin**. See individual agents.
 - c. **Caffeine.** Fluoroquinolones, especially **ciprofloxacin, can increase caffeine levels**. Avoid fluoroquinolones late in the evening with a heavy caffeine load.
 - d. **Warfarin.** Whether a warfarin–fluoroquinolone interaction occurs remains

unanswered [22]. Close monitoring of prothrombin time while on warfarin and fluoroquinolones seems prudent.

- e. Cyclosporine.** Interaction of cyclosporine and fluoroquinolones is unclear. Monitoring of serum concentrations of cyclosporine and measures of renal function has been suggested [22].

G. Cost. In general, fluoroquinolones are expensive agents (see Appendix Table).

II. Clinical indications

A. Drugs of choice. Although the fluoroquinolones have an FDA-approved indication for many infections, they are drugs of choice **only for the following** [23]:

1. *Salmonella* or *Shigella* species
2. *Neisseria gonorrhoeae* (with ceftriaxone and cefixime)
3. *P. aeruginosa* urinary tract infections (UTIs)
4. *Legionella* species rifampin (azithromycin is also a drug of choice) N.B. For indications 1 to 3 above, many fluoroquinolones are effective, but ciprofloxacin has often been used for *Legionella* infections.

B. Common empiric uses, but not antibiotic of choice. They are used when the infecting organism is suspected to be resistant to the preferred agent or if the illness is severe (Table 27G.3). Certain issues need special emphasis.

1. **UTIs.** Most uncomplicated community-acquired UTI is due to pathogens susceptible to trimethoprim-sulfamethoxazole (TMP-SMX), so this is usually the preferred agent. However, as discussed in Chapter 27L, the incidence of TMP-SMX resistance for community-acquired *E. coli* is rising and is 15% to 20% in some regions of the United States. Hence, in some areas of the United States and for pyelonephritis or for UTI in diabetics, use ciprofloxacin until susceptibility data are available. Ciprofloxacin is preferred for anyone if *P. aeruginosa* is suspected. **See the related discussions in Chapters 15 and 27L.** The fluoroquinolones are very useful for complex UTI due to susceptible pathogens and many but not all nosocomial UTI.

Table 27G.3. An Overview of the Fluoroquinolones

Setting	Suggested Agent ^a	Related Discussions
UTI	Ciprofloxacin	Chapter 15
Prostatitis	Ciprofloxacin	Chapter 15
Urethritis/PID	Ofloxacin	Chapter 16
Intraabdominal infection	Ciprofloxacin + metronidazole, (or clindamycin)	Chapter 13
Traveler's diarrhea	Ciprofloxacin	Chapter 13
Bacterial diarrhea	Ciprofloxacin	Chapter 13
Diabetic foot infections	Ciprofloxacin and anaerobic therapy in advanced infections	Chapter 4
CAP	Moxifloxacin, ^{b,c} or gatifloxacin, ^{b,c} or levofloxacin ^{b,c}	Chapter 11
Nosocomial pneumonia	Choice guided by susceptibility data. See text.	Chapter 11
Selected cases of sinusitis, refractory otitis, acute exacerbations of COPD (see text)	Moxifloxacin, ^b or gatifloxacin, ^b or levofloxacin ^{b,c}	Chapter 8
Septic arthritis, osteomyelitis ^d	Ciprofloxacin	Chapter 5

^aSeems prudent to use the narrowest-spectrum fluoroquinolone that will do the job.

^bOptimal agent is unclear. See text sec. III.B.3 and III.B.9.

^cAn advanced-generation fluoroquinolone, with activity against penicillin resistant *S. pneumoniae* is preferred. This agent is also active against common CAP pathogens and atypical pathogens.

^dPrimarily due to susceptible gram negatives. See Chapter 5.

2. **Prostatitis.** TMP, TMP-SMX, and the fluoroquinolones all penetrate the prostate well. Based on susceptibility data and/or side effect profile, fluoroquinolones are often used in this setting [24], although both TMP and TMP-SMX are more cost effective (see Chapter 15).
3. **Urethritis/cervicitis/pelvic inflammatory disease.** **Ofloxacin** is currently the preferred fluoroquinolone [25,26] and the agent with which there is the most experience (see Chapter 16).
4. **Intraabdominal infections.** Ciprofloxacin plus metronidazole (or clindamycin) provides good gram-negative and anaerobic activity, respectively. The many other antibiotic options one can use in this setting are discussed in Chapter 13.
5. **Traveler's diarrhea.** The fluoroquinolones (ciprofloxacin) are preferred (see Chapters 13 and 22).
6. **Diabetic foot infections** and therapeutic options are discussed in **Chapter 5**. There has been the greatest clinical experience with ciprofloxacin in this setting, and it remains the most active currently available fluoroquinolone against *P. aeruginosa*.
7. **Refractory sinusitis/otitis media.** When antibiotic therapy is indicated, amoxicillin remains the agent of choice for acute sinusitis and otitis media. When this agent fails or in the patient with multiple antibiotic allergies, moxifloxacin or gatifloxacin, with activity against penicillin-resistant *S. pneumoniae*, may be indicated (see Chapter 8).
8. **Acute exacerbation of chronic bronchitis** can usually be treated with less expensive and narrower spectrum antibiotics (see **Chapter 11**). Occasionally, in the allergic patient or with culture-proven resistant pathogens, a 5-day course of either moxifloxacin or gatifloxacin that are active against *S. pneumoniae* and *Haemophilus* species is reasonable.
9. **Community-acquired pneumonia (CAP)** is **discussed in Chapter 11**. The advanced-generation fluoroquinolones such as moxifloxacin or gatifloxacin and, to a lesser degree, levofloxacin are active against the common pathogens causing CAP, including penicillin-susceptible or -resistant *S. pneumoniae*, *H. influenzae*, *M. catarrhalis* and the atypical organisms, including *Mycoplasma* and *Chlamydia* species and *Legionella pneumophila* [6,7,27]. Consequently, these advanced quinolones have become very popular in the therapy of CAP. They are included as agents of possible choice in the therapeutic guidelines for CAP [28]. To avoid the rapid development of bacterial resistance, fluoroquinolones should be used judiciously in CAP [29]. See related discussion in section **V.B** and in Chapter 11.
 - a. **Macrolides** remain agents of choice for CAP in those under 50 years of age.
 - b. Advanced fluoroquinolones are useful in patients with known or highly likely penicillin-resistant *S. pneumoniae* pneumonia and/or if very ill with pneumonia and multilobar disease, requiring intensive care unit care while awaiting susceptibility data and other information (see Chapter 11). These agents are indicated in other selected cases.
10. **Nosocomial pneumonia** usually occurs in ventilated patients, so-called ventilator-associated pneumonia.
 - a. When fever develops in the patient on a ventilator, very frequently the cause is far from clear. It has recently been shown that in the patient who did not fulfill the criteria for definite pneumonia, ciprofloxacin, initiated at the onset of the fever, could be safely stopped after 3 days instead of continuing a full 7 to 10 days. When this was done, the patients had equal or better outcome [30] compared with those in whom the drug was continued for 7 to 10 days. **In those with clear-cut ventilator-associated pneumonia, initial empiric therapy** often involves combination therapy (e.g., antipseudomonal penicillin and an aminoglycoside) until culture data are available. An advanced fluoroquinolone (with or without) aztreonam may be useful in the allergic patient. See related discussions in Chapter 11.
 - b. **For completion of therapy** an oral fluoroquinolone can often be used; the agent selected will depend on culture data, if available, or local susceptibility patterns and trends.

11. **Septic arthritis and osteomyelitis** due to susceptible pathogens, primarily gram-negative organisms, have been treated with fluoroquinolones, most commonly ciprofloxacin (see Chapter 5). More recently, ciprofloxacin with rifampin has been shown to be effective in staphylococcal infections of artificial hips. **The quinolone was chosen to be combined with rifampin** because of the quinolone's superior activity against gram-positive organisms attached to foreign material. However, when ciprofloxacin is used by itself, development of resistance, and clinical failure, is common [31]. See related discussions in section I.C.7 and Chapters 5 and 27R.

12. **Miscellaneous**

- a. **Meningococcal carrier state.** Ciprofloxacin is a drug of choice (see Chapter 6).
- b. **Cat scratch disease**, due to *Bartonella henselae*, has been treated with ciprofloxacin [32], although azithromycin is listed as the drug of choice for this pathogen [23], with ciprofloxacin listed as an alternative agent.
- c. **Fever of unclear etiology in the leukopenic patient.** In an attempt to avoid hospitalization or minimize the hospital stay, oral antibiotics are being evaluated in these patients. Ciprofloxacin, which is very active against gram-negative organisms, combined with an agent for gram-positive organisms such as amoxicillin-clavulanate, has been studied [33–35]. For the hospitalized patient, ciprofloxacin plus piperacillin appears to be useful [36]. See related discussions in Chapter 20.
- d. **Mycobacterial infections** are sometimes treated with fluoroquinolones [32,37] (see Chapter 11). Infectious disease and/or pulmonary consultation is advised.
- e. **Patients with cystic fibrosis** and pulmonary colonization/infection with *Pseudomonas* have been treated with ciprofloxacin (see section I.F.2).
- f. **Selected ear infections in children have been treated with topical agents.** Ciprofloxacin HC otic suspension has been used for **otitis externa** (see Chapter 8) and ofloxacin otic solution has been approved for use in otitis externa, **chronic suppurative otitis media**, and the otorrhea of acute otitis media that occurs **in children with tympanostomy tubes** 1 year of age and older. The use of these topical agents has been reviewed in detail in a recently published symposium devoted to this topic [38].

III. **Brief comment on individual agents.** Although several agents are available, in the past decade of using these antibiotics, **certain common practices and special niches have often evolved** that have allowed the clinician to use selected agents effectively while eliminating other agents (Table 27G.3). In addition to the general comments made in section I, we emphasize the following:

A. **Second-generation agents**

1. **Norfloxacin (Noroxin)**, available in 1986, provides good urinary and gastrointestinal levels but does not provide acceptable serum levels or nonrenal tissue levels. It is potentially a useful agent in uncomplicated UTI, traveler's diarrhea, and for spontaneous bacterial peritonitis prophylaxis in cirrhosis. **It has been replaced by ciprofloxacin**, even for the latter indications.
2. **Ciprofloxacin (Cipro)** was released in late 1987 and **remains a very useful agent. It remains more active against *P. aeruginosa* than any other fluoroquinolone.** However, it is not as active against penicillin-susceptible or -resistant pneumococci or against anaerobes, as are the third- and fourth-generation agents. Ciprofloxacin can raise theophylline and caffeine levels and causes central nervous system symptoms in the elderly but is otherwise well tolerated (see section I.E).
3. **Ofloxacin (Floxin)** was released in 1990. In the review in *Medical Letter* the contributors concluded that ofloxacin "appears to be equivalent to ciprofloxacin" for UTI, prostatitis, skin and soft tissue infections, lower respiratory tract infections, and "can be used for chlamydial infections" [39]. Ofloxacin is active against *C. trachomatis*, and there is considerable experience with its use for these infections. It has therefore achieved a special niche in the therapy of **nongonococcal urethritis, where it remains the quinolone of choice and is part of some**

of the regimens for pelvic inflammatory disease [25] (see Chapter 16). Ofloxacin **does not interfere with theophylline or caffeine** metabolism as may ciprofloxacin. It is not approved for osteomyelitis.

B. Third- and fourth-generation agents: expanded spectrum. There are three currently available agents in common use, levofloxacin, moxifloxacin, and gatifloxacin. The latter two were approved in late December 1999 for use in CAP, acute bacterial exacerbations of chronic bronchitis, and acute sinusitis [6,7,41–45]. Both agents are active against *Legionella* species and *M. pneumoniae* and both have less than optimal activity against some anaerobes. Neither drug affects the cytochrome P450 enzyme system [41]. Because of the potential **for prolongation of the QT interval** with both of these agents [41], while awaiting further clinical experience **we believe it is prudent to limit their use in patients who have other risk factors for QT prolongation. See related discussion under section I.E.5.**

1. Levofloxacin (Levaquin) became available in late 1997 [40]. This expanded-spectrum fluoroquinolone **has good activity against penicillin-resistant *S. pneumoniae*** (see Chapter 11) **and other CAP pathogens.** However, the minimum inhibitory concentration of *S. pneumoniae* is very close to the maximum achievable serum levels, and in some experts' opinions this fact may be contributing to the development of resistance in quinolones [3,12] (also see section V.B). It has been used in selected cases of CAP and selected cases of refractory sinusitis, otitis in adults, and acute exacerbations of chronic obstructive pulmonary disease (see Chapter 8). It is also used in some of the regimens for sexually transmitted diseases (e.g., nongonococcal urethritis, gonococcal (GC) urethritis, pelvic inflammatory disease regimens, etc.) [25]. The oral formulation is extremely well absorbed. **Oral and i.v. formulations are 99% bioequivalent.** One dose per day is needed; the dose interval is prolonged in renal failure.

2. Moxifloxacin (Avelox) has improved gram-positive activity over levofloxacin [40,41,45], including penicillin-resistant *S. pneumoniae*, but is less active against Enterobacteriaceae than ciprofloxacin and has little activity against *Pseudomonas* species. In addition to the indications listed in section B above, it is approved for use in uncomplicated skin and soft tissue infections due to susceptible *S. aureus* or *Streptococcus pyogenes*.

a. Dosage. In adults, 400 mg orally is given once daily, without dose adjustment in renal failure. It does not interfere with theophylline or warfarin and has a low propensity for phototoxicity and central nervous system side effects.

b. Side effects (see section I.E)

c. Cost (see Appendix Table 1)

3. Gatifloxacin (Tequin) has similar *in vitro* activity [6,7,41,42] to moxifloxacin. In a recent report, gatifloxacin was about fourfold more active *in vitro* against *S. pneumoniae* than levofloxacin [42]. In addition to the respiratory tract infections listed under section 3 above, gatifloxacin is approved for use in uncomplicated and complicated UTI and for uncomplicated gonococcal infections (see Chapter 16).

a. Dosage. Oral tablets and an i.v. preparation are available. The usual adult dose is 400 mg orally or intravenously every 24 hours with reduction if the creatinine clearance is less than 40 mL/min (Table 27G.4).

b. Cost (see Appendix Table)

4. Levofloxacin versus moxifloxacin versus gatifloxacin. The optimal quinolone for use in CAP due to known or highly suspected penicillin-resistant *S. pneumoniae* is unclear as of mid-2002. There is more clinical experience with levofloxacin, but as discussed in earlier sections either gatifloxacin or moxifloxacin provides a greater therapeutic ratio that may be advantageous. The precise risk of QTc-related problems with any of these agents continues to undergo study and awaits further clinical experience. Clinically significant QTc prolongation appears to be rare and, when it occurs, may be more likely to take place in patients with more than one risk factor associated with QTc prolongation (see section I.E.5). Therefore, in patients with more than one risk factor for QTc prolongation, we would favor using an alternative class of antibiotic (see Chapter 11).

Table 27G.4. Dose Adjustments in Renal Failure

	Creatinine Clearance (mL/min)			Hemodialysis (HD)	CAPD
	>50	10–50	<10		
Ciprofloxacin	100% ^a	50–75% ^a	50% ^a	250 mg p.o. or 200 mg i.v. q12h	250 mg p.o. q8h or 200 mg i.v. q8h
Ofloxacin	100% ^a	200–400 mg q24h	200 mg q24h	100–200 mg after HD	Same as for creatinine clearance <10 mL/min
Levofloxacin	100% ^a	250 mg q24–48h after usual 500-mg initial dose	250 mg q48h after usual 500-mg initial dose	Same as for creatinine clearance <10 mL/min	
Gatifloxacin	100%	^b	^b	^b	^b
Moxifloxacin	100%	100%	100%	^c	^c

^aRefers to % of usual dose, when renal function is normal.

^bFor gatifloxacin, if the creatinine clearance is <40 mL/min, an initial dose of 400 mg can be given followed by subsequent doses (beginning day 2) of 200 mg q.d. A similar regimen is advised for patients on hemodialysis or undergoing CAPD.

^cDosages in hemodialysis and CAPD have not been studied yet per 2002 package insert.

Modified from Aronoff GR, et al, eds. *Drug prescribing in renal failure: dosing guidelines for adults*, 4th ed. Philadelphia: American College of Physicians, 1999; and *Physicians desk reference*, 56th ed. Montvale, N.J: Medical Economics Co, 2002, with permission.

Because these are evolving issues, at this point we would advise discussing the optimal agent with an infectious disease subspecialist, especially if there are risk factors associated with QTc prolongation.

C. Rarely used or recently withdrawn agents include the following.

1. **Sparfloxacin (Zagam)**. This agent was introduced in late 1997. A generic preparation is available but because this agent has been associated with significant problems with photosensitivity and QT prolongation with torsades, **we would use an alternate quinolone.**
2. **Trovofloxacin (Trovan)** was approved for use in early 1998. *In vitro*, this agent is active against pathogens causing CAP, many gram-negative bacilli, and anaerobes. It has good bioavailability, and both oral and i.v. formulations are available. **Because of the hepatotoxicity discussed previously (see section I.E.3) and the availability of other quinolones or other classes of antibiotics, we do not use this agent.** We would not suggest using trovafloxacin unless in a special circumstance and in consultation with an infectious disease specialist. Therefore this agent is not discussed further. Of interest, trovafloxacin is not listed as an important quinolone in the recent *Medical Letter* [23].
3. **Enoxacin** has been **withdrawn.**
4. **Lomefloxacin (Maxaquin)** was released in 1992, but patients on this agent had **moderate to severe phototoxic reactions.** This agent has been **withdrawn.**
5. **Grepafloxacin (Raxar)** was approved for use in late 1997. It was associated with prolongation of the QT interval, and in late 1999 it was voluntarily **withdrawn** from the market due to severe cardiovascular adverse reactions [14].

IV. Dosages of fluoroquinolones

A. With normal renal function, see Table 27G.5.

B. In renal failure, see Table 27G.4.

V. Miscellaneous

A. Cost. In general, the fluoroquinolones are **expensive** agents (see Appendix Table). Nevertheless, they may be cost-effective agents if they can shorten the hospital stay, or the oral form is used to avoid hospitalization for i.v. antibiotic administration, or early switch from the i.v. formulation to the oral form is carried out.

B. Resistance to fluoroquinolones [2,8,46–52]. With widespread use of the fluoroquinolones, selective pressure is exerted, particularly in intensive care and specialized care units in hospitals [2]. This has resulted in the emergence of quinolone-resistant bacteria [2]. Resistance develops by mechanisms of reduced drug penetration, altered regulation of active efflux mechanisms [2,3], and DNA gyrase mutations.

1. Nosocomial pathogens

a. Methicillin-resistant *S. aureus* is resistant to available fluoroquinolones or will become so with use in a patient.

b. *P. aeruginosa*. Resistance is common with infections involving a foreign body, such as a Foley catheter or a tracheostomy, or with prolonged use as occurs in cystic fibrosis respiratory infections. At this time approximately 15% to 30% of *P. aeruginosa* are resistant to all available fluoroquinolones.

c. *Serratia marcescens*, other *Pseudomonas* species, and *Acinetobacter* species often are resistant. *S. maltophilia* is resistant, even when laboratory tests report susceptibility. In a recent report [48], 56% of extended-spectrum β -lactamase-producing *E. coli* and *Klebsiella pneumoniae* isolates were resistant to the fluoroquinolones.

2. Community-acquired resistance of bacteria has been uncommon. Recently, pneumococci with decreased susceptibility to quinolones have been described [50], and treatment failures with levofloxacin have occurred [51,52]. Some experts believe that recent exposure to a fluoroquinolone should be a contraindication to the use of another fluoroquinolone for the empiric treatment of CAP [51,52]. Although fluoroquinolone-resistant *N. gonorrhoeae* have been isolated in the Far East, such strains fortunately have only been rarely isolated in the United States [8,49]. There is concern that resistance may increase due to use of fluoroquinolones in

Table 27G.5. Dosages in Normal Renal Function

Ciprofloxacin p.o. ^a		
UTI		
Acute, uncomplicated	100 mg p.o. bid	× 3 days
Mild and moderate	250 mg p.o. bid	10–14 days
Severe, complicated, pyelonephritis	500 mg p.o. bid	14 days
Prostatitis	500 mg p.o. bid	2–4 weeks. See text
Intraabdominal infection ^b	500 mg p.o. bid	10–14 days
Traveler's diarrhea	500 mg p.o. bid	3 days
Bacterial diarrhea	500 mg p.o. bid	5–7 days ^c
Susceptible lower respiratory tract gram negatives (e.g., hospital-acquired pneumonia)	500–750 mg p.o. bid	At least 14 days total treatment. See text.
Septic arthritis, osteomyelitis due to susceptible pathogens	500–750 mg p.o. bid	See Chapter 5.
Ofloxacin (p.o./i.v.)		
Acute, uncomplicated urethral and cervical gonorrhea	400 mg, single dose	1 day
Nongonococcal cervicitis/urethritis due to <i>C. trachomatis</i>	300 mg bid	7 days
Mixed infection of the urethra and cervix due to <i>C. trachomatis</i> and <i>N. gonorrhoeae</i>	300 mg bid	7 days
Acute pelvic inflammatory disease ^d	400 mg bid	14 days
Levofloxacin (p.o./i.v.)		
CAP	500 mg q24h	10–14 days
Susceptible lower respiratory infections in hospitalized patients	500 mg q24h	10–14 days
Selected cases of sinusitis, bronchitis	500 mg q24h	5–7 days
Gatifloxacin (p.o./i.v.)		
CAP	400mg q24h	7–14 days
Selected cases of Sinusitis	400mg q24h	10 days
Bronchitis in COPD	400mg q24h	5–7 days
Moxifloxacin (p.o./i.v.)		
CAP	400mg q24h	10 days
Selected cases of Sinusitis	400mg q24h	10 days
Bronchitis In COPD	400mg q24h	5 days

^aCiprofloxacin can be given i.v.: for mild to moderate UTI 200 mg i.v. q12h; for severe or complicated UTI 400 mg q12h. Doses given over 60 min. A 500-mg p.o. dose and a 400-mg i.v. dose provide similar serum levels.

^bNeeds to be combined with an anaerobic agent (e.g., metronidazole or clindamycin). See Chapter 13.

^cTyphoid fever is treated with 10 days.

^dOfloxacin is combined with metronidazole. See details of therapy of PID in Chapter 16.

both human and animal food [47]; quinolone-resistant *Salmonella* species have been isolated [53,54].

H. Unique β -Lactam Antibiotics: Monobactams and Carbapenems (Aztreonam, Imipenem, Meropenem, and Ertapenem)

- I. **Aztreonam (Azactam)** is the first clinically useful monobactam. It is active against most of the gram-negative aerobes without the nephrotoxicity of aminoglycosides [1].
 - A. **Mechanism of action.** Aztreonam binds to the penicillin binding proteins of **bacterial walls**.
 - B. ***In vitro* activity.** Aztreonam is **unique among the β -lactam antibiotics because it is active only against gram-negative aerobes**.
 1. **Gram-negative aerobes**
 - a. **Highly susceptible organisms** include β -lactamase and non- β -lactamase-producing strains of *Haemophilus influenzae* and *Neisseria gonorrhoeae*, as well as *N. meningitidis*.
 - b. **Most Enterobacteriaceae** are inhibited by less than 1 $\mu\text{g/mL}$ [1], except for resistant strains shown in section **d** below.
 - c. ***Pseudomonas aeruginosa***. Aztreonam inhibits 50% at 4 $\mu\text{g/mL}$ and 90% at 16 to 32 $\mu\text{g/mL}$; concentrations required to inhibit usually are twofold greater than those for ceftazidime [2]. At least 12% of strains of *P. aeruginosa* are resistant [3,4]. The combination of aztreonam and piperacillin (or mezlocillin) is synergistic against some strains of *P. aeruginosa* and *Enterobacter* species but not as frequently as piperacillin plus an aminoglycoside [5,6].
 - d. **Resistant strains** typically include *Citrobacter freundii*, *Enterobacter aerogenes*, some *E. cloacae*, *Legionella pneumophila*, and *Acinetobacter* species. Cefoxitin antagonizes the activity of aztreonam against *Enterobacter* species. [1].
 2. **Gram-positive aerobes:** little or no activity.
 3. **Anaerobes:** little or no activity.
 - C. **Pharmacokinetics** [1,6].
 1. **Absorption.** Aztreonam is poorly absorbed after oral administration but can be given intramuscularly (i.m.) or intravenously (i.v.).
 2. **Excretion** is primarily by the **kidneys** and doses are reduced in renal failure.
 3. **Penetration/distribution.** Aztreonam penetrates body fluids well but has limited penetration into the cerebrospinal fluid. After i.v. infusion of 0.5-, 1-, and 2-g doses, mean peak serum levels of more than 60, 160, and 250 $\mu\text{g/mL}$, respectively, are achieved [1]. Urinary concentrations are very high with urinary concentrations of more than 250 $\mu\text{g/mL}$ and more than 700 $\mu\text{g/mL}$ achieved 4 to 6 hours after a single i.v. 500-mg or 1-g dose, respectively, in patients with normal renal function [1].
 - D. **Clinical role.** Because aztreonam is active against gram-negative aerobes only, combination therapy is necessary for mixed infections with gram-positive organisms and/or anaerobes. Aztreonam has been successfully used in the following [1,6]:
 1. **Urinary tract infection** as single agent for susceptible gram-negative organisms.
 2. **Intraabdominal** (including peritonitis) and/or **pelvic infections in combination with antianaerobic agents** such as clindamycin or metronidazole [7].
 3. **Bacteremia.** For empiric therapy, additional coverage is necessary. Once a gram-negative bacteria is isolated, this becomes an excellent choice.

Table 27H.1. Aztreonam Intravenous Dosage Guidelines (Normal Renal Function)

Type of Infection	Dose ^a	Frequency (Hours)
Adults^b		
Urinary tract infections	500 mg or 1 g	8 or 12
Moderately severe systemic infections	1 g	8
Severe systemic or life-threatening infections	2 g	6 or 8 ^c
Pediatric patients^b		
Mild-to-moderate infections	30 mg/kg	8
Moderate-to-severe infections	30 mg/kg	6 or 8

^aHigher doses are used in more severe infection.

^bMaximum recommended dose is 8 g/day.

^cIn systemic or severe *P. aeruginosa* infections 2 g q6–8h is suggested.

^dMaximum recommended dose is 120 mg/kg/day.

Modified from *Physicians' desk reference*, 56th ed. Montvale, NJ: Medical Economics Data, 2002, with permission.

4. **Gram-negative pneumonia** due to susceptible pathogens [8]. Because some nosocomially acquired *P. aeruginosa* may be resistant to aztreonam, an aminoglycoside is initially preferred until susceptibility data are available.
5. **Skin and soft tissue** infection after the gram-negative organism is identified.
6. **Bone and joint** infections due to susceptible pathogens have been treated with aztreonam i.v. Usually an oral fluoroquinolone is preferred in this setting.
7. **Febrile neutropenic patients** have been treated with aztreonam combined with an aminoglycoside. Vancomycin is added for patients when gram-positive infection is suspected (e.g., patients with central venous catheters or chemotherapy ports) (see Chapters 2 and 20).
- E. **Dosing.** Aztreonam may be administered **i.v. or i.m.** The i.v. route is recommended for patients requiring more than 1 g per dose and in those patients with bacteremia, abscess, peritonitis, or other severe or life-threatening infections.
 1. **Adult and pediatric** (more than 9 months of age) **dosages are summarized in Table 27H.1.**
 2. **Renal failure** dose reduction is shown in Table 27H.2.
 - a. **Doses for patients on hemodialysis** are similar to those whose clearance is <10 mL/min. Thereafter, one-eighth of the initial dose (or 500 mg) is given after each hemodialysis [9].

Table 27H.2. Dosing of Aztreonam in Renal Failure

Estimated Creatinine Clearance	Adult Dose	Pediatric Dose
>30 mL/min	See Table 27H.1	See Table 27H.1
10–30 mL/min	Initial dose as in Table 27H.1, then give half of the usual dose at the standard interval	Insufficient data ^a
<10 mL/min	Initial dose as in Table 27H.1, then one quarter the usual dose at the usual fixed interval	Insufficient data ^a

^aAs per the 2002 package insert, there are insufficient data to support recommendations for dosing aztreonam in renally impaired pediatric patients.

- b. Chronic ambulatory peritoneal dialysis (CAPD).** Dosing guidelines followed for a clearance less than 10 mL/min can be followed [9].
- 3. Penicillin-allergic or cephalosporin-allergic patients.** For patients with immunologically mediated reactions to penicillins or cephalosporins there is little risk of cross-sensitivity. Repetitive courses of aztreonam may rarely provoke a hypersensitivity reaction [10].
- 4. Pregnancy.** Aztreonam is a category B agent; it should be used during pregnancy only if clearly indicated.
- 5. Nursing mothers.** Aztreonam is excreted in breast milk. The package insert suggests consideration should be given to temporary discontinuation of nursing and use of formula feedings while the mother receives aztreonam.
- F. Toxicity** [1,6]. Aztreonam is a safe agent with side effects similar to other β -lactams.
- 1. Serious nephrotoxicity or ototoxicity has not been reported. Aztreonam is promoted for the treatment of gram-negative aerobic infections as safer than the aminoglycosides.**
 - 2. Adverse reactions** of rash, nausea, diarrhea, eosinophilia, and mild hepatic transaminase elevations have been seen as with other β -lactam antibiotics.
- G. Cost** (see Appendix Table 1). Although monotherapy costs compared with third-generation cephalosporins are competitive, aztreonam is much more expensive than gentamicin or tobramycin; thus combination therapy with aztreonam is more expensive.
- H. Summary. Guidelines for the optimal use of aztreonam continue to evolve** [1,6,11]. In moderate to severe nosocomial infections, aminoglycoside therapy for gram-negative organisms for the initial 48 to 72 hours while awaiting cultures is prudent unless an aminoglycoside is contraindicated. Once susceptibility data are back, if the organism is resistant to cephalosporins and quinolones but susceptible to aztreonam, aztreonam could be used. The development of resistance while on therapy is usually not a concern with aminoglycosides but with aztreonam is not fully delineated. If the approach just outlined is used, the risk of resistance may be minimized. There may be an increased incidence of *Clostridium difficile* diarrhea associated with the common use of advanced cephalosporins. Aztreonam appears to be associated less often with these problems and therefore may be an appealing alternative. Because aztreonam is active only against gram-negative bacilli, when it is used empirically for mixed infections, combination therapy will be necessary, thereby increasing costs. In some circumstances, an aminoglycoside may still be the preferred agent as, for example, in combination therapy against enterococcus and *Listeria monocytogenes* and in combination with anti-*Pseudomonas* penicillin in severe *P. aeruginosa* infections.
- II. Imipenem (Primaxin),** a carbapenem released in 1985, has a very broad spectrum of activity. It is combined with cilastatin, a potent enzyme inhibitor, which prevents the inactivation of imipenem in the kidney by inactivating enzymes in the brush border cells. This ensures good urinary concentrations. Cilastatin also appears to have a "nephroprotective" effect [1,6].
- A. Mechanism of action.** Imipenem binds with high affinity to penicillin-binding proteins, causing lysis of many gram-positive and gram-negative bacteria. Its ability to penetrate the cell membrane of multiple gram-negative bacilli and its resistance to β -lactamases produced by gram-positive and gram-negative bacilli help explain its broad spectrum [1].
- B. In vitro activity** [12]. Some resistance has developed over time [1,13].
- 1. Gram-positive aerobes**
 - a. Very susceptible,** with a minimum inhibitory concentration (MIC)₉₀ typically of 0.1 μ g/mL or less: penicillin-susceptible *Streptococcus pneumoniae*, group A and B streptococci, *Streptococcus bovis*, methicillin-susceptible *Staphylococcus aureus*, *S. saprophyticus*, intermediate penicillin-resistant *S. pneumoniae*, and many high level resistant strains [1,6] (see Chapters 11 and 27C).
 - b. Moderately susceptible.** Amoxicillin-susceptible enterococci usually are susceptible, with the MIC₉₀ of susceptible *Enterococcus faecalis* approximately

1 to 3 $\mu\text{g/mL}$. Imipenem is bacteriostatic against susceptible enterococci. Imipenem-aminoglycoside combinations may be synergistic against *E. faecalis*. However, many strains of *E. faecium* are resistant to imipenem.

- c. **Resistant.** Methicillin-resistant *S. aureus* (MRSA), coagulase-negative staphylococcus, *Corynebacterium JK*, and vancomycin-resistant enterococci (VRE) are resistant to imipenem.

2. Gram-negative aerobic bacteria

- a. **Enterobacteriaceae.** In an early review of more than 8,000 isolates, three levels of imipenem activity were recognized [14]. An MIC_{90} of 1.0 μg or less (very susceptible) was seen with *Escherichia coli*, *Klebsiella* species, *Salmonella*, *Shigella* species, *Citrobacter diversus*, *Hafniae alvei*, and *Yersinia enterocolitica*. *Enterobacter* species, *C. freundii*, and *Serratia* species have MIC_{90} of approximately 1 to 2 $\mu\text{g/mL}$ (susceptible). An MIC_{90} of 2 to 4 $\mu\text{g/mL}$ (less susceptible) is noted, especially with the *Proteus* species. Although some Enterobacteriaceae has developed resistance to imipenem, it remains more active than noncarbapenem β -lactam antibiotics [1,13].

- b. ***Pseudomonas*.** The MIC_{90} for *P. aeruginosa* is typically higher (e.g., 5 $\mu\text{g/mL}$ in more than 1,600 strains in early testing) [14]. Although some strains have developed resistance to imipenem over time, in one 1996 report of more than 6,600 intensive care unit isolates, 87% of strains were susceptible to imipenem. Against these same strains, 89%, 93%, and 65% of strains were susceptible to amikacin, tobramycin, and gentamicin, respectively [13].

Similar MICs were noted for *P. fluorescens*. Imipenem may show synergism with tobramycin or other aminoglycosides against *P. aeruginosa* [1,6]. Risk factors for imipenem-resistant *Pseudomonas* have recently been reviewed [15].

- c. ***Burkholderia cepacia* and *Stenotrophomonas maltophilia* are resistant. The latter produces a β -lactamase that easily hydrolyzes imipenem.** *Acinetobacter calcoaceticus* species are usually quite susceptible, but nosocomial infections due to resistant species can occur.

- d. **Community-acquired pathogens.** The MICs for β -lactamase-positive and-negative *N. gonorrhoeae* are identical and similar to *N. meningitidis*. They have a MIC_{90} of less than 0.20 $\mu\text{g/mL}$, and *H. influenzae* with a MIC_{90} of 0.6 $\mu\text{g/mL}$ are very susceptible. Although imipenem is active *in vitro*, it is not considered appropriate treatment for *Legionella* pneumonia because of the intracellular location of the organism [1,6].

C. Pharmacokinetics

1. **Intravenous or i.m.** but not oral route is available. Lower serum levels are reached after i.m. doses. In adults of average size with normal renal function, 500- and 1,000-mg doses i.v. provide peak serum levels of 30 to 40 and 60 to 70 $\mu\text{g/mL}$, respectively [1].
 2. **Excretion** is primarily by the kidneys, and doses must be reduced in renal failure. Little of the drug is found in the feces, so there is relatively little impact on bowel flora; *C. difficile* diarrhea has been reported (see section F.3).
 3. **Penetration/distribution.** Imipenem-cilastatin penetrates body fluids well, with at least modest penetration of the inflamed meninges.
- D. **Clinical role.** Imipenem-cilastatin is especially useful in infections caused by pathogens resistant to other agents or for infections that would otherwise require multiple antibiotics. It is particularly useful in complex nosocomial infections [1,5].

1. See Table 27H.3 for a summary.

2. Miscellaneous uses

- a. **Eye infections.** Its broad spectrum leads to its use for some eye infections [16] (see Chapter 7).
- b. **Acute necrotizing pancreatitis.** Imipenem is detected in high concentrations in pancreatic tissue but not in the bile. It has been used to try to prevent or treat pancreatic infections, but other choices seem better for biliary sepsis [17] (see Chapter 13).
- c. ***Nocardia*.** Alternate agent for *Nocardia* infections. It may be useful in selected infections due to high-level resistant *S. pneumoniae* (see Chapters 11 and 17).

Table 27H.3. Clinical Use of Imipenem (or Meropenem)

For **serious nosocomial infections** (e.g., bacteremia, pneumonia, complex UTI, severe perineal soft tissue infection, osteomyelitis), **especially** those **involving resistant organisms**, or polymicrobial infections (mixed anaerobes, aerobic, gram-positive and -negative, especially for diabetics)^a

Used as an alternative to combination therapy for complex **nosocomial intraabdominal infections**, thus avoiding ototoxic and nephrotoxic effects of aminoglycosides^b

For *Pseudomonas* infections caused by organisms resistant to other antipseudomonal β -lactam agents but, where possible, use in combination with an aminoglycoside.

Monotherapy in **febrile granulocytopenic patients** (see Chapter 20).

A **“drug of choice”** for severe nosocomial *Enterobacter* or *Serratia* or *Acinetobacter* spp., and *C. freundii* infections; also for *Campylobacter fetus* infections [8].

When not to use imipenem (or meropenem)

Not alone in treatment of serious *Pseudomonas* infections^c especially pneumonia

Not for most community-acquired infections

Not for surgical prophylaxis

Not for methicillin-resistant staphylococcal infections or VRE

Not alone in therapy for serious enterococcal infections (*E. faecalis*)

Not in therapy for non-aeruginosa pseudomonal infections

^aEditors' note: We “save for use” imipenem and meropenem for when cultures reveal or are likely to reveal resistant pathogens in someone usually already on antibiotics or who has recently received antibiotics. *C. freundii*, *Acinetobacter*, and *Enterobacter* species. may be resistant to other antibiotics.

^bEditors' note: Not for mild to moderate community-acquired infections where less broad agents are effective (e.g., cefazolin combined with metronidazole, cefoxitin, cefotetan, ampicillin-sulbactam, ticarcillin-clavulanate). See Chapter 13. Particularly useful in hospital-acquired intraabdominal infections in which resistant organisms may be involved.

^cEditors' note: For susceptible *P. aeruginosa* infections, an antipseudomonal penicillin and an aminoglycoside are preferred. (See Chapter 27I.)

Modified from Sobel JD. Imipenem and aztreonam. *Infect Dis Clin North Am* 1989;3:613, with permission.

d. Prophylaxis. Imipenem is not advised for prophylaxis because of the risks of promoting antimicrobial resistance. However, when a hospitalized patient who has had many courses of antibiotics requires surgery, it is reasonable to consider this possibility.

E. Dosages. For a given patient, the dose of imipenem **depends on the severity of infection, renal function, and weight of the patient** (with dose reductions if the patient weighs less than 70 kg). The dose of imipenem-cilastatin refers to the amount of the imipenem [1].

1. A table for dosages for adults of less than 70 kg and different degree of renal dysfunction is in the package insert and the *Physicians' desk reference*, which is readily available.

a. Serious infections in adults weighing 70 kg with normal creatinine clearance, 500 mg every 6 hours are suggested [1,6]. For life-threatening infections, 1 g every 6 to 8 hours has been used.

b. Adults under 70 kg: 25 mg/kg/day divided every 6 hours has been suggested [1].

c. Renal failure. Fifty percent of the usual dose is given when creatinine clearance is between 10 to 50 mL/min and 25% of the usual dose when the creatinine clearance is less than 10 mL/min [9]. **Hemodialysis** removes 40% to 70% of the imipenem, so half a dose is given after dialysis. In patients undergoing **CAPD**, dosages are given as above in patients with a creatinine clearance of less than 10 mL/min [9].

2. Children. Intravenous imipenem has recently been approved. **For those older than 3 months,** the recommended dose is 15 to 25 mg/kg/dose i.v. every 6 hours

(to a maximum of 2 g daily). Higher doses have been used in children with pseudomonas infections and/or cystic fibrosis. See package insert for use in children less than 3 months. For neonates, see Chapter 3. For children less than 30 kg with impaired renal function there are no data.

3. **Central nervous system infections. Imipenem is not advised** because of the risk of seizures. See related discussions of meropenem in section IV.
4. **Pregnancy.** Imipenem is **category C**. The package insert indicates there are no adequate and well-controlled studies in pregnant women. Therefore this agent should be used during pregnancy only if the potential benefit justifies the potential risk to the mother and fetus.
5. **Nursing mothers.** It is not known whether imipenem is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when this agent is administered to a nursing woman.

F. Side effects and toxicity. Overall, imipenem is well tolerated [1,6].

1. **Seizures** have occurred in less than 1% but occur more frequently in patients with closed head trauma, with a previous history of seizures, after neurosurgery, and if high doses and decreased renal function were present. **Dosage reduction in the elderly and in renal insufficiency is indicated.** If a seizure, tremor, or myoclonus occurs, need for imipenem should be reassessed and anticonvulsant therapy should be considered. **Imipenem use in patients with closed head injury or with meningitis is usually avoided; meropenem is preferred in these patients.** Whether seizures occur more often than with other antibiotics, when proper doses are used, is not established [1,6] (see section 5).
2. **Allergic reactions** such as drug fever, pruritus, rash, and urticaria are uncommon. **Patients allergic to penicillin should be skin tested before imipenem use** [18]. In addition, imipenem should be avoided or administered under close monitoring to patients with a history of IgE-mediated hypersensitivity to other β -lactam antibiotics, although the exact incidence of cross over allergy is unknown [19,20].
3. **Gastrointestinal symptoms** occasionally occur. Decreasing the infusion rate or the dose decreases nausea and vomiting [1]. *C. difficile* diarrhea occurs.
4. **Nephrotoxicity and hepatotoxicity are rare.**
5. **Drug interactions.** Seizures have been reported in patients receiving **ganciclovir** and imipenem. These drugs should not be used concomitantly unless the benefit outweighs risks. **Probenecid** increases imipenem concentrations. Avoid concomitant use. **Imipenem may induce β -lactamases that inactivate** other β -lactams [1,6].

G. Resistance can develop especially against *P. aeruginosa* [15]. In severe infections due to this pathogen, monotherapy with imipenem should be avoided.

H. Cost. This is an expensive agent but may be competitive if it replaces multiple other agents (see Appendix Table 1).

III. Ertapenem (Invanz) is a new i.v. carbapenem agent released in early 2002 [21].

A. Mechanism of action. Like other β -lactam antibiotics, ertapenem inhibits bacterial cell wall synthesis. It is relatively resistant to hydrolysis by β -lactamases, including extended-spectrum β -lactamases.

B. In vitro activity. Ertapenem has a narrower spectrum of activity than imipenem or meropenem.

1. **Gram-positive aerobes.** Although active against many gram-positive aerobes, ertapenem is less active than imipenem. Although active against MSSA, group A streptococcus, penicillin-susceptible *S. pneumoniae*, and many strains of intermediate resistant pneumococci, it has **little activity against highly penicillin-resistant pneumococci, MRSA, or *Enterococcus faecium* or *faecalis*** [21].
2. **Gram-negative aerobes.** Ertapenem is more active than imipenem and similar to meropenem against **Enterobacteriaceae, but unlike imipenem and meropenem ertapenem has little or no activity against *P. aeruginosa* or *Acinetobacter* species** [21]. It is not active against *Stenotrophomonas maltophilia*.
3. **Anaerobes.** Ertapenem has good activity against most anaerobes, including *B. fragilis* [22]

4. **Miscellaneous. Ertapenem is not active against “atypical” respiratory pathogens** such as *Mycoplasma pneumoniae*, *Legionella* species, or *Chlamydia* species.

C. Pharmacokinetics

1. **Half-life.** Ertapenem has a **longer half-life than imipenem/meropenem:** 4 hours versus 1 hour. Therefore, **ertapenem has** been approved for a **once-daily dose** regimen [21].
2. **Metabolism/excretion.** Ertapenem is partly metabolized by hydrolysis and 80% is excreted by the kidney [21].

D. Clinical role [21]

1. **U.S. Food and Drug Administration approved uses.** Based on early clinical studies, ertapenem was approved for **once daily i.m./i.v.** therapy of complicated intraabdominal infections, urinary tract infection, skin and skin structure infections, acute pelvic infections, and community-acquired pneumonia.
2. As discussed in previous chapters on the above infections, there are already many commonly used regimens for each of these infections. The potential usefulness of this broad new agent must be weighed against the likelihood of selecting our resistance and greater expense, compared with other regimens. **See section H below for a summary of its potential role.**

E. Dosing

1. In adults, 1 g i.v. or i.m. is recommended [21].
2. **In renal failure,** the dose should be reduced by 50% in patients with a creatinine clearance less than 30 mL/min. For patients on chronic hemodialysis, the dose should be given 6 hours before dialysis; if given less than 6 hours before, an extra dose of 150 mg should be given after dialysis [21].
3. **In children,** the safety and efficacy of ertapenem have not been established and therefore should not be used in patients less than 18 years old.
4. **Pregnancy.** This is a category B drug and should be used only if clearly indicated during pregnancy.
5. **Nursing mothers.** Ertapenem is excreted in breast milk and should be given to nursing mothers only when clearly indicated.

- F. Toxicity.** In early reports, ertapenem has generally been well tolerated. Diarrhea, nausea, vomiting, increased serum aminotransferase levels, and local complications at the infusion site, including phlebitis, have occurred. Seizures have occurred in 0.5% of patients.

- G. Cost** (see Appendix Table). Ertapenem is less expensive than imipenem, meropenem, and piperacillin-tazobactam [21].

H. Summary. The precise role of ertapenem awaits further clinical experience with this agent.

1. **In their 2002 review, the *Medical Letter* concluded the following** [21]: “ertapenem is a broad-spectrum, once-daily, parenteral antibiotic that offers better anaerobic coverage than ceftriaxone and fewer doses per day than piperacillin/tazobactam (and related agents) and other drugs used to treat infections that may involve anaerobes. It might be a good choice for home treatment of some infections (since given once daily), but offers no advantage over ceftriaxone for treatment of community-acquired bacterial pneumonia. Unlike imipenem and meropenem, ertapenem is not active against *Pseudomonas* and *Acinetobacter*; and therefore **should not be used for empiric treatment of nosocomial infections.**”
2. This new agent does not solve the clinician’s problem of treating resistant pathogens. This agent is not active against many hospital-acquired gram-negative organisms (including *Pseudomonas*, *Acinetobacter* species), MRSA, high level penicillin-resistant pneumococci, and enterococci, including VRE. Also, ertapenem is not active against atypical respiratory pathogens.

- IV. Meropenem (Merrem)** is a new i.v. carbapenem, approved in 1996, which is **very similar to imipenem.** Meropenem has been reviewed elsewhere [1,6,23–28]. Meropenem is stable to human renal dehydropeptidase and therefore can be given without cilastatin.

A. Susceptibilities. *In vitro*, it is similar to **imipenem**. It is slightly more active against gram-negative organisms, whereas imipenem is slightly more active against gram-positive organisms (1,16,18). Whether these minor *in vitro* differences have clinical relevance is unknown, but no differences have been detected in the initial comparative trials [1].

1. Gram-positive organisms. Meropenem, like imipenem, is active *in vitro* against many penicillin-resistant *S. pneumoniae*, including many high level resistant forms. Meropenem is not active against MRSA, *E. faecium*, and VRE strains of enterococci.

2. Gram-negative organisms include *S. maltophilia* and some strains of *P. aeruginosa*.

B. Pharmacokinetics. The pharmacokinetics of meropenem is similar to those of imipenem [1,5]. Only an i.v. formulation is available. About 70% of each dose is recovered in the urine. Hemodialysis removes most of the drug. Its serum half-life is about 1 hour, so it is given every 8 hours. Meropenem reaches therapeutic concentrations in the cerebrospinal fluid in patients with meningitis [26].

C. Clinical role. Meropenem has been **approved for** i.v. therapy as follows [1,6,26]:

1. Intraabdominal infections in adults and children over 3 months of age.

Complex mixed aerobic and anaerobic and nosocomial infections [27,29].

For mild to moderate community-acquired abdominal infections, other options are available. (Imipenem is chosen in adults unless possibly in a patient with recent seizures or there is renal failure, where dose modification is easier with meropenem.)

2. Bacterial meningitis in children more than 3 months of age, although meropenem has been used [29,30] and is approved for susceptible *H. influenzae*, *S. pneumoniae*, and *N. meningitidis* in children. A third-generation cephalosporin is preferred because of greater experience (see Chapter 6). For a case of known *S. pneumoniae* resistant to penicillin but susceptible to meropenem, **meropenem provides an alternative agent to vancomycin** (see Chapter 6), and meropenem is preferred over imipenem.

3. Other. Meropenem has been shown to be effective in a variety of clinical conditions, including pneumonia, febrile neutropenic patients, bacteremia, and complex urinary tract infection [1].

D. Dosages

1. Adults. The usual dose is 1 g i.v. every 8 hours. In the management of febrile neutropenic adult patients 1 g every 8 hours was as effective as 2 g every 8 hours of ceftazidime alone and/or ceftazidime and amikacin [1]. In bacterial meningitis, 2 g every 8 hours has been effective [1].

2. In pediatrics, for intraabdominal infections 20 mg/kg (maximum of 1 g) every 8 hours and for meningitis 40 mg/kg (maximum 2 g) every 8 hours. Patients more than 50 kg can be given adult doses.

a. Renal failure. If the creatinine clearance is 26 to 50 mL/min, the regular dose is given every 12 hours. If the creatinine clearance is 10 to 25 mL/min, one-half of the usual dose is given every 12 hours. If the creatinine clearance is less than 10 mL/min, one-half of the usual dose is given every 24 hours. As of mid-2000, the package insert indicates no dose recommendations for pediatric patients with renal failure (i.e., no experience).

b. In dialysis. As of mid-2000, there is inadequate information regarding the dose of meropenem in patients on hemodialysis and peritoneal dialysis, per the package insert.

3. In hepatic disease, the package insert indicates no dosage adjustments are needed (in adults).

4. In pregnancy. The package insert notes this is a **category B** agent and should be used during pregnancy only if clearly needed.

5. In nursing mothers. It is not known if this agent is excreted in human milk. Caution should be exercised when i.v. meropenem is administered to a nursing woman.

E. Side effects. There are differences in the tolerability of imipenem and meropenem [1].

1. **Meropenem is unlikely to cause seizures** that have been reported with imipenem [26,31].
2. Meropenem has been less likely to cause nausea and vomiting as well as inflammation at the i.v. site compared with imipenem [1].
3. The frequency and severity of adverse events with meropenem does not seem to escalate at higher doses as with imipenem [1].
4. Rashes, diarrhea, and reversible increases in aminotransferase enzymes have occurred as with other β -lactam antibiotics [1,6,26].

F. Cost. Meropenem is an **expensive** i.v. agent to use, even more so than imipenem [26] (see Appendix Table).

G. Summary. In their review, the *Medical Letter* concluded the following [26]: "meropenem is an expensive new parenteral antibiotic similar to imipenem, possibly with less potential for causing seizures. Meropenem, like imipenem, could be used for treatment of hospital-acquired infections that may be resistant to other antibiotics [27]. For treatment of intraabdominal infections or bacterial meningitis, meropenem generally offers no clear advantage over less costly older drugs."

We would add that except for very selected cases of meningitis in which meropenem may be useful (infectious disease consultation is advised in these difficult cases), the indications for meropenem are the same as those for imipenem (see section **II.D**). In selected patients, the decreased side effects with meropenem may be important.

I. Aminoglycosides

The role of aminoglycoside antibiotics in clinical medicine has decreased somewhat as third-generation cephalosporins, aztreonam, and fluoroquinolones have become available [1]. Nevertheless, because of the rare development of bacterial resistance, the low incidence of *Clostridium difficile* diarrhea, the low risk of allergic reactions, the better understanding of their toxicity, and cost considerations, the aminoglycosides remain very useful. **These agents are, in most instances, bactericidal.** However, the precise mechanism through which the aminoglycosides cause bacterial cell death remains unclear [2]. They penetrate the cell wall and membrane and bind irreversibly to the 30S bacterial ribosome. The most commonly used aminoglycosides are gentamicin, tobramycin, and amikacin, so these agents are emphasized here [1–3]. Netilmicin is no longer manufactured in the United States.

I. Introduction: important principles of aminoglycoside use

A. When? Aminoglycosides are active against almost all aerobic gram-negative rods.

1. Community versus nosocomial infections. Although aminoglycosides are active against community-acquired gram-negative bacteria, cephalosporins are preferred for empiric use. **In contrast, aminoglycosides are particularly useful in hospital-acquired infections,** especially for *Pseudomonas* species. A change to aztreonam after initial aminoglycoside treatment of a gram-negative bacteria when prolonged therapy is contemplated reduces toxicity. Ciprofloxacin is useful empirically when most gram-negative

Table 27I.1. Aminoglycoside Activity

Typically Active Against	Not Usually Active Against
<i>Acinetobacter</i> species ^a	
<i>Citrobacter</i> species ^a	
<i>Enterobacter</i> species ^a	
<i>Escherichia coli</i> ^b	<i>Pseudomonas (Burkholderia) cepacia</i>
<i>Klebsiella</i> species ^b	
<i>Morganella morganii</i> ^b	<i>Stenotrophomonas maltophilia</i> ^c
<i>Proteus</i> species ^b	
<i>Providencia</i> species ^b	
<i>Pseudomonas aeruginosa</i> ^d	
<i>P. fluorescens</i>	
<i>Serratia</i> species ^b	
<i>Yersinia enterocolitica</i>	

^aAlthough aminoglycosides may be active *in vitro*, imipenem or meropenem are viewed as “drugs of choice” [3].

^bAlthough aminoglycosides are active *in vitro*, cephalosporins usually preferred [3].

^cFormerly called *Pseudomonas maltophilia* or *Xanthomonas maltophilia*.

^dAminoglycosides, often in combination with piperacillin, are drugs of choice for severe infections. For UTIs, ciprofloxacin (a quinolone) preferred [3].

organisms occurring in that setting are susceptible or after the offending bacteria has been isolated and tested.

- 2. Modifying initial therapy.** Regardless of the circumstances under which the aminoglycoside is initiated, if the isolated pathogen is susceptible to a narrow-spectrum agent, appropriate modifications should be made.

B. Special problems with aminoglycoside use

- 1. Toxicity. The aminoglycosides have considerable intrinsic toxicity, both nephrotoxicity and eighth nerve.** Risk factors for toxicity include older age, treatment with aminoglycosides for more than 2 weeks, and the concurrent use of other ototoxic toxic or nephrotoxic agents. This risk of toxicity must be considered, especially with use for any extended time (>7 days) (see section VI). Aminoglycoside toxicity is rare before 7 days.
- 2. Toxic-therapeutic ratio.** The margin between effective and toxic concentrations is narrow.
- 3. Monitoring of serum levels.** Serum levels must be measured to ensure effective levels and minimize toxicity. This topic is discussed in detail in section V.

II. *In vitro* activity (Note peak serum levels are 8 ug/ml for gentamicin and tobramycin and 25 ug/ml for amikacin)

A. Gram-negative aerobes (Table 27I.1)

- 1. Community-acquired gram-negative organisms.** All aminoglycosides are equally active in proportion to achievable serum levels.
- 2. Hospital-acquired gram-negative organisms.** In general, tobramycin *in vitro* is two to four times more active than gentamicin against *Pseudomonas aeruginosa*, although the clinical implications of this are unclear. Against *Serratia* species, gentamicin has two to four times the bactericidal activity of tobramycin. For other nosocomial organisms, the aminoglycosides are equally active in proportion to achievable serum levels [1]. Against organisms resistant to one or more aminoglycosides, amikacin is the most frequently active, tobramycin is the next, and gentamicin is the least frequently active.

- B. Gram-positive aerobes.** The aminoglycosides have some activity against some organisms (e.g., staphylococci) but **alone are never the preferred agents** [3]. Gentamicin, together with ampicillin or penicillin, usually is **bactericidal against enterococci**. However, in recent years, at major medical centers, there has

Table 27I.2. Expected Peak and Trough Levels of Respective Aminoglycosides (in $\mu\text{g/mL}$) with Conventional or Individualized Dosing

	Peak ^{a,b}	Trough ^c	Toxic ^b
Gentamicin	6–10	1–2	>10
Tobramycin	6–10	1–2	>10
Amikacin	15–30	5–10	>35

These ranges for peak and trough concentrations are used commonly, but their exact implications remain controversial, as reviewed by McCormack JP, Jewesson PJ. A critical reevaluation of the “therapeutic range” of aminoglycosides. *Clin Infect Dis* 1992;14:320.

^a Drawn one-half hour after a half-hour i.v. infusion. See text. For pneumonia therapy, the higher levels of peaks are desirable.

^b These peak toxic levels are with conventional dosage regimens. With once-a-day dosages, higher acceptable peak levels will routinely be achieved. See text.

^c Level just before next dose.

been an increasing incidence of high level gentamicin-resistant enterococci. These enterococci are resistant to more than 2,000 $\mu\text{g/mL}$ of gentamicin and therefore to the combination of gentamicin and penicillin. In one report, 26% of enterococci demonstrated high level gentamicin resistance [2]. The details of this problem and alternative therapeutic approaches are reviewed elsewhere [4].

C. Anaerobes are not susceptible.

D. *Nocardia* is susceptible to amikacin [3].

E. Mycobacterium. Most *Mycobacterium tuberculosis* are susceptible to streptomycin and amikacin; most *M. avium-intracellulare* isolates are susceptible to amikacin [3].

III. Pharmacokinetics

A. Gentamicin and tobramycin have similar pharmacokinetics; therefore standard doses, peak levels achieved, and serum half-lives are essentially the same (Table 27I.2). Amikacin is a semisynthetic kanamycin derivative with pharmacokinetics nearly identical to those of kanamycin. The **intravenous route is preferred**, but the intramuscular route can be used if hypotension or thrombocytopenia is absent.

B. Variation in pharmacokinetics. There is striking variation in the volume of distribution and rate of excretion of aminoglycosides in individual patients with normal renal function [5]. **Thus it is important to monitor serum levels in all patients regardless of volume status or renal function** (see section V) to ensure adequate levels. Peak and trough level measures can be repeated every 3 to 4 days if the patient is stable. In a patient who has major changes in hydration status or renal function, levels have to be repeated more frequently (Table 27I.2).

1. Peak levels [1] are measured 30 minutes after completion of an intravenous infusion or 45 to 60 minutes after intramuscular injection. In renal failure, the peak sample is drawn 120 to 150 minutes after the intramuscular dose, because the drug continues to be absorbed and not excreted. **Peak serum level** is obtained to ensure that enough drug was administered for therapeutic efficacy. A peak level is obtained after the first or second maintenance dose or after dosage adjustments.

2. Trough levels are obtained just before the next dose. If trough levels are elevated, the dose needs to be reduced or the dose interval prolonged. In renal failure, the trough level should ideally be obtained after the same dose in which the peak was measured.

- C. Aminoglycoside excretion is entirely renal**, mandating dose reductions in renal failure.
- D. Tissue penetration.** Aminoglycosides achieve reasonable concentrations in bone, synovial fluid, and peritoneal fluid. Urinary concentrations are high and usually exceed serum concentration by 100 times in patients with normal renal function [2]. There is limited penetration into the central nervous system and probably intraabdominal abscesses [1]. Drug levels in bronchial secretions are poor [2].
- IV. Clinical use** [1,2]
- A. Aminoglycosides as drugs of choice** for specific pathogens [3]
- 1. For *P. aeruginosa* infections other than urinary tract infection (UTI)**, an aminoglycoside is combined with piperacillin or similar antibiotic except in delayed penicillin allergy where cefepime is often substituted. In *P. aeruginosa* UTI, ciprofloxacin is preferred [3].
 - 2. Gentamicin is used in combination** with another agent to achieve synergy with: (a) penicillin, ampicillin, or vancomycin against gentamicin-susceptible enterococci or viridans streptococci [1,2]; (b) ampicillin against *Listeria monocytogenes*; (c) an extended-spectrum penicillin (e.g., piperacillin) against *P. aeruginosa* and susceptible *Enterobacter* species (see section 1 above); (d) vancomycin and rifampin against *S. epidermidis* prosthetic valve infection; (e) ampicillin (or vancomycin) for endocarditis prophylaxis in high-risk patients before genitourinary or gastrointestinal procedures; (f) an antistaphylococcal penicillin for right-sided endocarditis caused by *S. aureus*; and (g) doxycycline for brucellosis [1–3].
 - 3. Amikacin** has been used in certain atypical mycobacterium infection. Amikacin (plus clarithromycin) is the drug of choice for *M. fortuitum* complex infections [3].
 - 4. Streptomycin (or gentamicin)** is an agent of choice for *Yersinia pestis* (plague); streptomycin remains a useful agent for *M. tuberculosis* therapy and for *M. kansasii* infections.
- B. Other situations.** Gentamicin is a primary agent. Tobramycin or amikacin are alternates [3].
- 1. As empiric therapy in life-threatening community-acquired gram-negative infections.**
 - 2. Infections occurring in a hospital setting or in a patient who has recently been hospitalized;** an aminoglycoside is indicated while awaiting culture data.
 - a. In most community hospitals** where resistance to gentamicin is uncommon, we favor gentamicin because it is less expensive. An exception is the patient who has already received gentamicin and is possibly infected with a relatively resistant gram-negative bacterium. Until susceptibility data are available, tobramycin or amikacin are the preferred agents.
 - b. Amikacin versus gentamicin** [1]. **In large medical centers or specialized areas** (e.g., intensive care units, burn units) where the frequency of resistance to gentamicin, tobramycin, or netilmicin may be high, amikacin is preferred until susceptibility data are available. If gentamicin resistance is low (e.g., 1%–5%), gentamicin is the most rational cost-effective choice unless the patient has recently received gentamicin. In that instance amikacin should be used while awaiting culture results. Amikacin is the aminoglycoside of choice for the treatment of gentamicin-resistant gram-negative bacteria [2,6].
 - c. Note.** If a patient is potentially at high risk for aminoglycoside toxicity (e.g., in hepatic failure or is frail and elderly; see section VI.A.4), an alternate should be considered (e.g., aztreonam).
 - 3. In the leukopenic febrile patient** with no obvious focus of infection, an aminoglycoside and an extended-spectrum penicillin (e.g., piperacillin) have commonly been used (see Chapter 20).
 - 4. For susceptible pathogens in which a less toxic agent is unavailable,** aminoglycosides have been used effectively to treat susceptible gram-negative

organisms causing UTI, bone and joint infections, pneumonia, and sometimes gram-negative bacillary endocarditis.

5. **In nosocomial intraabdominal infections** (see Chapter 13). Resistant gram-negative organisms are present when peritonitis develops in a patient who has been in the hospital.
 6. **For therapy for organisms that may develop resistance to monotherapy with a third-generation cephalosporin** such as *Enterobacter cloacae*, *Citrobacter freundii*, and *Acinetobacter* species. In this setting, an aminoglycoside is often combined with an extended-spectrum penicillin (e.g., piperacillin) for synergy. However, imipenem or meropenem is preferable for nosocomially acquired *Acinetobacter* species and some *Enterobacter* species [3].
- C. **Aminoglycoside effectiveness** is not optimal in the following situations [1]:
1. **In lower respiratory tract infections**, the low pH of bronchial secretions may decrease the activity of aminoglycosides. One cannot **rely on aminoglycosides alone** in major lower respiratory tract infections such as *Pseudomonas* pneumonia.
 2. **Sterilization of abscesses** with aminoglycosides may be difficult because of poor activity in the presence of the low pH, anaerobic conditions, and bivalent cations.
 3. **Prostatitis**. Aminoglycosides do not achieve useful levels in prostate tissue.
- V. **Aminoglycoside dosing**. Numerous dosage regimens have been proposed, but studies showing that one method is clearly superior are not available. **What is widely accepted is that in the very ill patient, giving a routine conventional dose (e.g., 1.5 mg/kg every 8 hours) to adults with normal renal function is not an acceptable dose regimen** because of the variability in levels achieved. Zaske et al. [5] emphasized this when they studied more than 200 surgical patients. In that carefully done study in patients with normal renal function, if this standard approach was used, 47% of the patients would be underdosed and 14% would be overdosed.
- Three acceptable approaches** are single daily dose regimens for short-use duration, individualized dosing with a pharmacokinetics model, and conventional dosing with serum levels used to adjust doses by someone skilled in the use of aminoglycoside.
- A. **Single daily aminoglycoside dosing** has been evaluated in several settings [7–14].
1. **The underlying principles** of this approach include the following:
 - a. **Concentration-dependent killing**. The rate of bactericidal killing by aminoglycosides increases as the antibiotic concentration is increased (see Chapter 25) and the increased killing persists for a prolonged period. In addition, data suggest that once daily dosing is less toxic than thrice daily dosing, although this could be the more effective level achieved initially [5].
 - b. **Postantibiotics effect (PAE)** is persistent suppression of growth after short antibiotic exposure. Aminoglycosides demonstrate a PAE against aerobic gram-negative bacilli both *in vitro* and in animal models. The duration of the PAE correlates with the height of the peak. PAE remains after the serum level falls below the minimum inhibitory concentration. In the animal model with normal neutrophils, the presence of neutrophils doubled the duration of the *in vivo* PAE [7]. The importance of the PAE in humans has not been completely studied.
 - c. Nephrotoxicity and probably ototoxicity are related to time-dependent drug accumulation. **Single daily dosing (SDD) seems less toxic** than multiple doses, perhaps because little or no tissue accumulation occurs during the several hours when serum levels are low before the next infusion [13] or perhaps because higher levels are guaranteed to occur initially [5].
 2. **Clinical studies** have been summarized in detail elsewhere [7–14]. SDD appears to be comparable and in some cases superior in efficacy to traditional aminoglycoside dosing. However, in the studies of SDD, therapy has been for short duration plus a second effective agent has been part of the regimen and most study subjects have been under 55 years of age.

Table 271.3. Exclusions for Using Single Daily Dosing

Moderate to severe renal insufficiency (creatinine clearance < 40 mL/min)
Serious burns (> 20% body surface area)
Ascites
Severe sepsis syndrome
Cystic fibrosis
Fluid overload postoperatively
Dialysis
Neonates/children
Pregnant patients
Documented invasive <i>P. aeruginosa</i> infection in neutropenic patients
Patients receiving other nephrotoxic agents (amphotericin B, cis-platinum, radiocontrast material, nonsteroidal anti-inflammatory drugs)
Endocarditis
Mycobacterial disease
Patients needing protracted courses, >7 days ^a
Patients with significant underlying hepatic disease ^b

^aFor example, in *P. aeruginosa* pneumonia in which the patient may need 2–3 weeks of antibiotics.

^bSee text. We try to avoid aminoglycosides in these patients.

Modified from Gerberding JL. Aminoglycoside dosing: timing is of the essence. *Am J Med* 1998;105:256, with permission.

3. Limitations of use of SDD (Table 271.3)

- a. **In reduced creatinine clearance**, high-dose aminoglycoside treatment will produce sustained serum concentrations, drug accumulation, and increased potential for toxicity. Therefore these patients have been excluded from published trials [12].
- b. **Situations of uncertain volume of drug distribution or clearance** [12], including ascites, sepsis syndrome, severe burns, cystic fibrosis, or recipients of large volumes of fluid infusion.
- c. **Pregnant women, children, and neonates**. There are incomplete data for SDD [12].
- d. **Endocarditis (e.g., enterococci)**. Animal studies reveal SDD regimens are inferior [13].
- e. **Prolonged SDD regimens**. Because there are limited data on the toxicity, we prefer individualized dosing in patients needing aminoglycosides for more than 7 days.
- f. **Significant underlying hepatic disease (e.g., cirrhosis)**. In general, **we try to avoid aminoglycosides here** because of the risk of nephrotoxicity. If they must be used, infectious disease consultation and individualized dosing are suggested.

4. Dosing regimens for gentamicin and tobramycin. Doses used have ranged from 5 to 7.5 mg/kg infused over 60 minutes [12]. For older subjects, the lower dose regimen of 5 mg/kg is favored [6,7]. For the younger subject, the higher dose is reasonable.

- a. **Ideal body weight (IBW) in kilograms** [15]: If the weight is more than 20% to 30% over IBW, an obese dosing weight is used.

(1) To estimate IBW

Women = 45 kg + 2.3 kg per inch of height over 5 feet

Men = 50 kg + 2.3 kg per inch of height over 5 feet

For example, for a male patient 5 ft 10 in. tall, an estimated IBW would be 50 + 2.3[10], or 50 + 23 = 73 kg

- (2) **For weight more than 20% above IBW**, an obese dosing weight (ODW) is more reliable [15].

ODW = IBW + 40% (of excess weight; i.e., actual weight minus IBW)

Table 27I.4. Once-daily Aminoglycoside Maintenance Dosing Regimens for Gentamicin and Tobramycin

Estimated Creatinine Clearance (mL/min)	Dose in mg/kg (Given q24h) Over 60 Min
>80	5
60–80	4
50–60	3.5
40–50	2.5
<40	Individualized pharmacokinetics advised

Modified from Gilbert DN. Aminoglycosides. In: Root RK, et al., eds. *Clinical infectious diseases: a practical approach*. New York: Oxford University Press, 1999:273–284, with permission.

For example, an obese woman has a wound infection requiring gentamicin or tobramycin. Her actual weight is 100 kg; her ideal weight is 60 kg.

Obese dosing weight

$$= \text{IBW} + 20\% (100 \text{ minus } 60)$$

$$= 60 + 20\% (40) = 60 + 8$$

$$= 68 \text{ kg, and this weight can be used in Table 27I.4.}$$

b. For estimating the creatinine clearance for doses, a modification of the equation of Cockcroft and Gault is used (see Tables 27I.4 and 27I.5).

- 5. Dosing in patients with renal dysfunction.** One convenient method is to determine the half-life and then give one-half the dose every half-life. However, data are not available to ensure the superiority of that method over extension of the interval [13] (see Tables 27I.4 and 27I.5).

a. Prolonging the dose interval. See detailed guidelines for this approach [13].

b. Single daily dose with lowering the total daily aminoglycoside dose.

For patients with mild to moderate renal insufficiency, this approach is less cumbersome. Here, it is important to document that the 18-hour serum concentration is low ($<2 \mu\text{g/mL}$ for gentamicin or tobramycin) or undetectable [12]. Gilbert [13] suggested that if the gentamicin or tobramycin serum level is more than $1 \mu\text{g/mL}$ at 18 hours, one should repeat serum creatinine and recalculate the estimated creatinine clearance and reassess the dose.

Table 27I.5. Once-daily Aminoglycoside Dosing Regimen for Amikacin

Estimated Creatinine Clearance (mL/min)	Dose in mg/kg (Given q24h) Over 60 Min
>90	15
70–90	12
50–70	7.5
40–50	4.0
<40	Individualized pharmacokinetics advised

Modified from Gilbert DN. Aminoglycosides. In: Root RK, et al., eds. *Clinical infectious diseases: a practical approach*. New York: Oxford University Press, 1999:273–284, with permission.

6. **Serum monitoring** in SDD continues to undergo evaluation.
 - a. A **trough** level before the second or third dose is advised. Troughs should be less than 1 $\mu\text{g/mL}$; if not, extend the dose interval (see section 5.b). **Troughs** can be repeated every 48 to 72 hours.
 - b. **Peak** levels are not indicated, except in severe sepsis where clearance is very rapid.
 7. **Summary.** Unless contraindicated (see Table 27I.3), “the available data are sufficient to establish this strategy (i.e., SDD or extended dosing) as a standard approach for most serious infections where aminoglycoside treatment is indicated” [9].
- B. Pharmacokinetics model (Table 27I.3 and see section V.A.4)**
1. Zaske and colleagues devised a formula for the pharmacokinetics of aminoglycosides in individual patients with either normal or impaired renal function [5,16]. A **loading dose** is given (see section C.1 below). Subsequently, timed serum samples are used to determine the volume of distribution and the half-life of the aminoglycoside. Using a kinetic model, the appropriate dose needed to achieve a desired peak and trough is calculated. Acceptable peak and trough levels can be maintained by adjusting doses and dose intervals. (See Table 27I.2 for desirable levels.)
 - a. Because of the **variations in the volume of drug distribution** and the patient’s ability to excrete aminoglycosides, there is marked variation in levels achieved with conventional dosing (see section C below). The patient’s age, renal function, state of hydration, presence or absence of fever, and degree of obesity affect serum levels. **Individualized dosing allows adjustment for each patient** by measuring serum levels and calculating the aminoglycoside’s half-life.
 - b. **Patients with shorter half-lives.** Higher and more frequent doses are required to maintain adequate aminoglycoside peaks and to avoid prolonged periods of subtherapeutic levels. The converse is true for those with longer half-lives [5].
 - c. **Protracted therapy required.** The pharmacokinetic model is favored over SDD (Table 27I.3).
- C. Conventional dosing, careful level monitoring, and dose adjustment [10,12]**
1. **Loading dose**, independent of creatinine clearance, achieves therapeutic plasma levels rapidly. **IBW** in kilograms is used for adult patients. In the patient weighing 20% more than IBW, an obese weight is calculated as per section V.A.4. First, calculate the IBW/ODW for the patient. **For gentamicin and tobramycin**, use a loading dose of 2 mg/kg. **For amikacin**, a dose of 7.5 mg/kg is suggested.
 - a. **Children.** A loading dose of 2 to 2.5 mg/kg is suggested for gentamicin and tobramycin. For amikacin, 5 to 7.5 mg/kg has been used (maximum of 500 mg).
 - b. **Neonates** (see Chapter 3)
 2. For **maintenance doses**
 - a. **Adult, normal serum creatinine.** Gentamicin or tobramycin at 1.0 to 1.7 mg/kg/dose is given at an 8-hour interval in young to middle-aged patients and every 12 hours in older patients. The low dose is used for UTI and the higher dose is used for tissue or bloodstream infections. For amikacin 5 mg/kg is given every 8 hours up to middle age and every 12 hours in older patients.
 - b. **Children.** Aminoglycosides are eliminated more rapidly, so the follow-up doses are the same as the loading dose (2 to 2.5 mg/kg/dose of gentamicin or tobramycin) given every 8 hours. The dose of amikacin is 5 to 7.5 mg/kg (maximum of 500 mg) given every 8 hours.
 - c. **Renal failure. Two options exist and** the optimal approach is unclear. **The usual dose interval can be prolonged or doses can be given every half-life.** Serum monitoring after the first dose and at 48 hours is essential;

this dosing regimen is only an estimate. Further dosing can be adjusted as needed by someone experienced in aminoglycoside use to maintain appropriate peaks and troughs (Table 27I.2).

(1) **Prolonging the interval. For gentamicin and tobramycin:** Multiply the serum creatinine by 8 to estimate the interval. If the serum creatinine is 2.0, the maintenance dose can be given (serum creatinine of 2×8) every 16 hours (every 18 hours for convenience). **For amikacin:** Multiply the serum creatinine by 9, that is, creatinine is 2.0 and the interval is 18 hours.

(2) **Dosage every half-life.** This avoids very prolonged intervals of low serum trough levels, and half the dose can be given at the estimated half-life interval. For example, if the serum creatinine is 3.5, for gentamicin the estimated prolonged interval is $8 \times 3.5 = 36$ hours; 50% of the dose can be given every 18 hours (i.e., at half the extended interval). **In renal failure we prefer "individualized dosing" (see section B above).**

Dosing based on **nomograms** alone is **not advised**.

D. Overview of methods of dosing aminoglycosides. Until further studies clarify this issue, a reasonable approach for those patients in whom it is not clear if they are infected with an aminoglycoside-requiring organism to dose aminoglycosides using a once daily regimen for empiric short courses (e.g., 3–5 days). If an aminoglycoside is genuinely required in the very ill patient and in certain complex patient settings where SDD is contraindicated (Table 27I.3), individualized dosing is preferable and may also be superior for courses longer than 7 days.

E. Hemodialysis reduces levels by approximately 50%. One-half of the dose is given after dialysis. Because the duration of dialysis and type of dialysis machine affect the amount of drug removed, **monitoring serum aminoglycoside levels is necessary**.

F. Peritoneal dialysis. One-third to one-half of a usual single dose is administered daily. Serum aminoglycoside levels are advised.

G. Direct administration into infection sites. Aminoglycosides have been administered into the site of infection to gain benefit of activity while at the same time avoiding their toxicity.

1. Chronic ambulatory peritoneal dialysis. Aminoglycosides in peritoneal dialysis fluid are used for chronic ambulatory peritoneal dialysis peritonitis but not for systemic infections. Because of the diffusion of an aminoglycoside across the peritoneum, serum levels of the aminoglycoside should be monitored. Infectious diseases consultation is recommended for these complicated patients [17].

2. Aerosolized aminoglycosides have been used in special settings: in cystic fibrosis patients with *P. aeruginosa* in their sputum [18–23], to prevent early colonization with *P. aeruginosa* in cystic fibrosis [21] and to treat selected cases of purulent *P. aeruginosa* tracheobronchitis without pneumonia in elderly patients [19], and as adjunctive therapy for persistent smear positive pulmonary tuberculosis [23]. Infectious disease consultation is advised.

3. Artificial joint cement or gentamicin beads. After removal of infected artificial joints, cement containing tobramycin has been used in anticipation of later artificial joint replacement. In addition, gentamicin-containing bead chains have been inserted into infected osteomyelitis cavities and have demonstrated a high success rate and virtually no toxicity [24].

VI. Toxicity. Hypersensitivity reactions are uncommon. Important side effects include the following [1,2,25]:

A. Nephrotoxicity occurs at the level of the proximal tubule, but how injury or death of proximal tubule cells results in a decrease in the glomerular filtration rate is uncertain. The overall incidence of aminoglycoside nephrotoxicity is about 5% to 10% [1,2]. **Serum creatinine levels** should be obtained every 2 to 4 days in patients receiving aminoglycosides.

1. Definition. Initial creatinine was normal: nephrotoxicity is either the elevation of creatinine to 1.5 or higher or an absolute increase of 0.4 mg/dL. Initial serum

creatinine is elevated but less than 3.0 mg/dL: nephrotoxicity is an increase of at least 0.5 mg/dL. Initial creatinine exceeded 3.0: a rise in serum creatinine of more than 1.0 mg/dL defines nephrotoxicity [25].

2. **Manifestations.** A rising blood urea nitrogen and creatinine, proteinuria, or oliguria or nonoliguric renal failure. Changes are **usually reversible with discontinuation**. Progression to dialysis is uncommon.
 3. **Comparative toxicity.** No proof exists that gentamicin is more toxic than tobramycin [1,2].
 4. **Risk factors** are [1,2,25] as follows:
 - a. **Concomitant liver disease.** In particular, when prothrombin time is prolonged due to liver disease or in patients with known hepatorenal syndrome. Use other options if possible.
 - b. **Concomitant drug use.** Vancomycin, amphotericin B, cyclosporine, furosemide, nonsteroidal antiinflammatory agents, and foscarnet appear to increase the frequency of nephrotoxicity.
 - c. **Other risk factors.** Advanced age, previous courses of aminoglycosides (within 1 year), greater total dose of aminoglycoside, and prior renal disease may be associated with toxicity.
 5. **Prevention** of nephrotoxicity is not fully understood. Considerations are as follows:
 - a. **Use aminoglycosides only when indicated and for the shortest appropriate course.**
 - b. **Management of fluid status:** Correct hypovolemia and/or congestive heart failure.
 - c. **Avoid with underlying liver disease** (see section 4 above).
 - d. **SDD regimens** for short courses of therapy.
 - e. **Individualized dosing** for longer courses (>7 days) of therapy (see sections V.A and V.B).
 - f. **Monitoring of levels** is appropriate. However, even when levels are maintained at those that are recommended, toxicity may still occur [26].
 - B. **Ototoxicity is frequently irreversible** [1,2,25] and may appear during or after therapy. Repeated exposure engenders cumulative risk. Older patients are at greater risk for ototoxicity. A given patient may develop cochlear damage, vestibular damage, or, rarely, both.
 1. **Cochlear (auditory) toxicity.** Audiometric studies show that 2% to 14% of recipients demonstrate hearing loss, but clinically detected hearing loss is uncommon. Patients particularly at risk to develop clinical signs are those who have received a high cumulative dose or a protracted course of aminoglycosides. **In general**, if renal function is normal, **routine audiograms are not recommended**. In a cooperative patient who needs protracted aminoglycoside therapy (e.g., more than 2 weeks), serial audiograms are reasonable. **Serum levels should be monitored carefully and adjusted. Protracted courses of aminoglycosides should be avoided whenever possible.**
 2. **Vestibular dysfunction** manifested by nausea, vomiting, vertigo, dizziness, and unsteady gait with nystagmus is more difficult to evaluate in ill patients but presumably is related to the same predisposing factors that cause auditory toxicity. This appears to occur in 1% to 3% of patients and is usually irreversible.
 3. **Interruption of therapy.** If a patient develops symptoms of hearing loss, tinnitus, vertigo, or nystagmus, the aminoglycoside should be discontinued and the situation reevaluated.
 - C. **Neuromuscular paralysis**, though rare, has occurred after intraperitoneal lavage (no longer used or recommended) or after rapid intravenous bolus therapy, particularly in the setting of myasthenia gravis or concurrent use of succinylcholine or curare. This is usually reversible.
- VII. **Cost.** Gentamicin is less expensive than all other aminoglycosides and cephalosporins. A daily dose for SDD costs under \$5 and monitoring costs are lower. Hospitals have estimated that SDD administration may reduce hospital costs of aminoglycoside administration 50% to 60% [2]. Amikacin is the most expensive aminoglycoside (see Appendix Table).

VIII. Resistance

- A. Gram-negative organisms.** With the exception of streptomycin, aminoglycoside resistance **evolves very slowly** [1,2], but use is eventually followed by the development of resistance. When gentamicin resistance of nosocomial gram-negative organisms exceeds 10%, it is reasonable to use amikacin, especially if resistant blood isolates have been detected.
- B. Mechanisms in gram-negative organisms. Diffusion mediated resistance.** Changes in porins of the cell wall restrict diffusion into the cell. This may be aminoglycoside specific. The minimum inhibitory concentration increases, but use with a β -lactam may still mediate synergy. **Inactivation of the aminoglycoside** inside the cell by six specific enzymes. All of these enzymes inactivate gentamicin; five of the six inactivates tobramycin, and one of the six inactivates amikacin.
- C. High level gentamicin-resistant enterococci** have increased significantly [2] (see section II.B).
1. **Clinical significance.** These enterococci are potentially very important nosocomial pathogens because of intrinsic cephalosporin resistance. Their epidemiology is very similar to that of methicillin-resistant *S. aureus* and of multidrug-resistant gram-negative bacilli. Therefore all enterococci isolated from normally sterile body fluids (e.g., blood) or serious wound infections should be tested for **high level aminoglycoside resistance**, as well as ampicillin and vancomycin susceptibility.
 2. **Therapy.** Optimal therapy is unclear; **infectious disease consultation is advised.**

IX. Other aminoglycosides are used less frequently and are discussed only briefly.

- A. Streptomycin** was introduced in 1944 and was effective against many gram-negative bacteria and *M. tuberculosis*. Gram-negative resistance to streptomycin is now prevalent. Hospital pharmacies can order streptomycin by calling 1-800-254-4445 (Monday through Friday 8:30 A.M. to 5 P.M. EST).
1. **Current uses**
 - a. **Tularemia.** Streptomycin (or gentamicin) is the drug of choice for susceptible strains of *Francisella tularensis* [3].
 - b. **Antituberculous therapy.** Although its use has diminished, it is still used [3].
 - c. **Uncommon diseases** in which streptomycin is a drug of choice or alternative drug [3] are brucellosis (with tetracycline), glanders *Pseudomonas (Burkholderia) mallei*, and plague due to *Yersinia pestis*. Streptomycin has been used for treatment of endocarditis due to those strains of enterococci exhibiting high level resistance to gentamicin but preserved susceptibility to streptomycin [2]. Streptomycin may be used as an alternate agent in rat-bite fever due to *Streptobacillus moniliformis* or *Spirillum minus* [3] or in granuloma inguinale.
 2. **Dosage.** With normal renal function, for tularemia or plague, 500 to 1,000 mg intramuscularly every 12 hours can be used. In children, 20 to 30 mg/kg/day is given and divided into every 12 hour doses.
 - a. **Renal failure.** Ototoxicity is the risk. Therefore, gentamicin with monitoring of levels is an acceptable alternative or the dose of streptomycin must be reduced. One approach [27] is to give a 1-g loading dose and then prolong the interval. If the creatinine clearance is 10 to 50 mL/min, use a dose interval of 24 to 72 hours. If the creatinine clearance is less than 10 mL/min, use a dose interval of 72 to 96 hours. Streptomycin is removed by hemodialysis and peritoneal dialysis. If streptomycin must be used in dialysis, monitoring of serum levels using the disk diffusion method is a possibility. Obtain infectious disease consultation.
 - b. **Tuberculosis therapy** (see Chapter 11)
 3. **Toxicity.** Avoid streptomycin in patients older than 55 years if an alternate agent is available.
 - a. **Ototoxicity.** When given 2 g daily for more than 60 days, most patients develop vestibular toxicity. The incidence is reduced by half if the dosage

is reduced to 1 g daily. Deafness can occur. Risks include impaired renal function, old age, and prolonged therapy.

b. Nephrotoxicity is much less common with streptomycin than with the other aminoglycosides.

c. Hypersensitivity reactions include rash and drug fever.

B. Paromomycin (Humatin). Paromomycin sulfate is structurally related to streptomycin. It is too toxic for parenteral administration. It is available in an amorphous powder with a saline taste [28]. Because it is not absorbed from the intestinal tract, it can be used safely as alternative therapy for symptomatic infections due to *Entamoeba histolytica* [29] and has been used in patients with acquired immunodeficiency syndrome infected with the protozoa *Cryptosporidium parvum* [29].

1. Pharmacokinetics. Although paromomycin is poorly absorbed from the gastrointestinal tract, impaired gastrointestinal motility or ulcerations may facilitate absorption of the drug. Therefore paromomycin must be administered with caution to patients with ulcerative intestinal lesions. Accumulation may occur in patients with impaired renal function, making the drug contraindicated in this setting.

2. Uses for parasitic infections. Paromomycin is a drug of choice for a symptomatic carrier of *E. histolytica* and *Dientamoeba fragilis* infections. It is also an alternative agent for infections due to *Giardia lamblia* [29]. **Cryptosporidiosis in acquired immunodeficiency syndrome.** In a recent study, paromomycin was found to be no more effective than placebo [30]. Hence it is no longer indicated for therapy [29].

3. Side effects [18]. Anorexia, nausea, vomiting, epigastric burning, cramps, and diarrhea are the most frequent. Rash, eosinophilia, and headache and overgrowth of *Candida* may occur.

J. Clindamycin

Clindamycin, introduced in 1966, is an important antibiotic for intraabdominal or pelvic infections involving anaerobes [1,2]. In addition, it is a second-line alternative agent in penicillin-allergic patients for the treatment of susceptible gram-positive infections. Depending on the bacterial species, inoculum of bacteria, and concentration of antibiotic available, clindamycin is bactericidal for some organisms but generally is bacteriostatic. Clindamycin inhibits protein synthesis at the ribosomal level.

I. Spectrum of activity

A. Gram-positive aerobes. Clindamycin is active against group A streptococci, and in necrotizing fasciitis it is the drug of choice (see section III.D below). It is also active against most *Staphylococcus aureus* strains. **Of hospital isolates, at least 5% to 20% of strains of *S. aureus* are resistant to clindamycin** [1,3,4]. The emergence of clindamycin-resistant *S. aureus* has been noted in clindamycin-treated patients, especially when the organisms initially had erythromycin resistance at the onset of treatment. **Clindamycin-susceptible but erythromycin-resistant organisms should be considered resistant to clindamycin.** Some methicillin-resistant strains of *S. aureus* are susceptible to clindamycin, but this must be documented

in the microbiology laboratory before treatment. Clindamycin is not active against enterococci. Although active against penicillin-susceptible *Streptococcus pneumoniae*, the susceptibility of penicillin-resistant *S. pneumoniae* strains is variable. In some areas, penicillin-resistant pneumococci remain clindamycin-sensitive, but in many areas penicillin-resistant pneumococci are clindamycin resistant. It is prudent that clinicians routinely review the susceptibility patterns of *S. pneumoniae* in their locale (see Chapters 11 and 27C).

- B. Anaerobes.** Clindamycin is active against gram-positive and gram-negative anaerobes, including most *Bacteroides fragilis* and *Clostridium perfringens* strains. In the past decade, susceptibility data have shown increasing resistance of *Bacteroides* species to clindamycin at many but not all institutions. For example, in a report from six hospitals in Chicago, rates of resistance within this one city varied from 0 to 20% [5]. Other data suggest that 6% to 11% or more of *B. fragilis* isolates are resistant to clindamycin [1–3,6]. Approximately 10% to 20% of clostridial species, other than *C. perfringens*, and 10% to 20% of peptococci strains are resistant [1,2].
- C. Gram-negative aerobes.** Clindamycin has **no useful activity** against gram-negative aerobes.
- D.** Clindamycin is not active against *Mycoplasma pneumoniae* but is against certain strains of *Toxoplasma gondii*, *Babesia microti*, *Pneumocystis carinii*, and some malarial species [1,2,4].

II. Pharmacokinetics

- A. Oral and parenteral.** Clindamycin is well absorbed from the gastrointestinal tract (i.e., 90%), and food does not decrease its absorption. Therapeutic blood levels can be achieved by the oral, intramuscular, or intravenous route.
- B. Tissue penetration.** Clindamycin penetrates most body tissues well, including sputum, bile, bone, prostate, and pleural fluid, but not the cerebrospinal fluid. It crosses the placenta.
- C. Metabolism and excretion.** Clindamycin is metabolized primarily by the liver. **In severe hepatic insufficiency, the half-life of clindamycin is prolonged to 8 to 12 hours; therefore doses of clindamycin should be reduced** in severe liver or combined liver and renal failure [7].

Enterohepatic circulation of clindamycin and its metabolites can lead to a prolonged antimicrobial presence in stool, with changes in gut flora lasting up to 2 weeks after discontinuation of clindamycin. Some have suggested that perhaps this accounts for clindamycin causing *C. difficile* diarrhea [4].

III. Indications for use [1,2,4].

Although, except for *Bacteroides* species, it is not generally considered the drug of choice for any other organism, it has become recognized as the drug of choice for certain clinical situations discussed below.

- A. Intraabdominal/pelvic infections.** *Bacteroides fragilis* plays an important role in these infections. Traditionally, clindamycin is listed as a drug of choice [8] for *Bacteroides* species, but many infectious disease experts have turned to metronidazole. It must be combined with an agent active against gram-negative organisms. In the animal model with well-established intraabdominal abscess due to *B. fragilis*, metronidazole is superior to clindamycin. In endocarditis or other intravascular infection due to *B. fragilis*, metronidazole, a bactericidal agent, is preferred.
- B. For mixed aerobic and anaerobic soft tissue infections** (e.g., perineum), clindamycin has an advantage over metronidazole in that clindamycin is also active against group A or B streptococci and *S. aureus* as well as anaerobes, whereas metronidazole is not. In polymicrobial infections in adults, it is combined with an anti-gram-negative agent (e.g., ciprofloxacin).
- C. Alternative drug in allergic patients.** For patients allergic to both penicillin and cephalosporins, clindamycin is an effective alternative for susceptible aerobic gram-positive cocci (e.g., *S. aureus*, *Streptococcus pyogenes*) causing skin and soft tissue infection. For *S. aureus* endocarditis or a staphylococcal bacteremia of unknown source, a bactericidal agent such as a vancomycin is required. Clindamycin is considered a second-line alternative agent for penicillin-susceptible *S. pneumoniae*. Testing using a clindamycin disk can identify high level macrolide resistant pneumococci [9].

- D. Necrotizing fasciitis.** This disease is caused by invasive group A streptococcal that often leads to streptococcal toxic shock syndrome, and bacteremia [10]. Clindamycin is more effective in the animal model and is thought more effective in the clinical situation, perhaps because of its activity against nongrowing organisms against which penicillin appears to be less active because the penicillin binding protein is not expressed [11,12]. Furthermore, clindamycin appears to interfere with toxin production [13] (see discussions in Chapters 2 and 4). Initial therapy for these infections combines penicillin with clindamycin until susceptibilities return. **The same thinking applies in severe cellulitis** of an extremity (see discussion in Chapter 4).
- E. Osteomyelitis.** Clindamycin penetrates bone very well, so it is a useful alternative for susceptible organisms in the allergic patient and has been used in carefully monitored oral programs. Some pediatric infectious disease experts use it as a first-line agent in childhood osteomyelitis due to susceptible pathogens.
- F. Lung abscess.** These infections are usually related to poor dental hygiene. For aspiration of oral anaerobes, penicillin has historically been the drug of choice, although clindamycin is also favored. Some experts favor clindamycin for those who are seriously ill with this problem, to ensure coverage for anaerobes that may be resistant to penicillin.
- G. Diabetic foot infections.** Clindamycin, combined with an agent with good activity against aerobic gram-negative rods (e.g., ciprofloxacin), is commonly used.
- H. Miscellaneous uses**
- 1. Alternative for endocarditis prophylaxis for oral/dental procedures** (see Chapters 12 and 27B).
 - 2. Odontogenic infections.** A dental source that contains anaerobic streptococcus may lead to Ludwig's angina, maxillary sinusitis, and retropharyngeal and parapharyngeal abscesses with a major anaerobic component. Clindamycin is favored over penicillin or metronidazole.
 - 3. Posttraumatic endophthalmitis** due to *Bacillus cereus*. Clindamycin has fairly good penetration into the eye.
 - 4. Chronic sinusitis or chronic otitis.** Culture data have implicated anaerobic organisms.
 - 5. Bacterial vaginosis** usually is treated with metronidazole, but topical clindamycin as clindamycin ovules once at bedtime for 3 days is an alternative [14].
 - 6. Streptococcal group A pharyngitis, recurrent.** For susceptible β streptococcus clindamycin is the most effective agent in recurrent disease or for penicillin allergic patients.
 - 7. Acne vulgaris.** A 1% topical clindamycin gel and lotion has been used in this setting.
 - 8. Other.** Clindamycin has been used in special settings, including central nervous system toxoplasmosis (in combination with pyrimethamine), *Pneumocystis carinii* pneumonia in acquired immunodeficiency syndrome (with primaquine, when standard therapy has failed), and babesiosis [15] and malaria regimens.
- IV. Route and dosage**
- A. Oral. In children,** the recommended oral dosage is 10 to 25 mg/kg/day divided into every 6 hour doses or for mild to moderately severe infections; 20 to 30 mg/kg/day in four divided doses has been used. In severe infections in children, such as osteomyelitis, 30 to 40 mg/kg/day (up to 50 kg of body weight) divided into every 6 hour doses has been used. **In adults,** 300 to 450 mg every 6 to 8 hours can be given, depending on the severity of the illness. However, some patients may have many gastrointestinal side effects at the 450-mg regimen.
- B. Parenteral**
- 1. In adults** 600 mg every 8 hours is usually recommended. For tubo-ovarian abscess and possibly in the therapy of morbidly obese patients, 900 mg intravenously every 8 hours is preferred.
 - 2. In children** older than 1 month, 20 to 40 mg/kg/day is suggested, divided into every 6 to 8 hour doses.
 - 3. In neonates,** doses are summarized in Appendix Table 1.

- C. Clindamycin 2% vaginal cream**, 5 g intravaginally once daily for 7 days [7] (see Chapter 16).
- D. In renal failure, no change in the dosage** is required. Clindamycin is **not removed by either peritoneal dialysis or hemodialysis** [16].
- E. In hepatic insufficiency**, the half-life is prolonged. **Doses should be reduced**, the dosage interval prolonged, or, if possible, an alternative agent should be used (see discussion in section II.C). Patients with moderate to severe liver disease should be given about half the usual dose, and further reductions may be necessary if the patient also has renal disease [2].
- F. Pregnancy.** This is a category B drug (see Chapter 27A). The package insert suggests that this drug should be used in pregnancy only if clearly indicated. Limited data have not revealed adverse effects on fetal development [4].
- G. Nursing mothers.** Clindamycin is detected in breast milk. Because of the potential for adverse reactions in neonates, the package insert suggests that the decision to discontinue the drug should be made, taking into account the importance of the drug to the mother.
- H. Potential for antagonism** exists with the macrolides and chloramphenicol, which also act at the ribosomal level and may competitively inhibit the action of each other. These drugs **should not be used in combination** with clindamycin.
- I. Cost.** Clindamycin is a relatively expensive agent (see Appendix Table).

V. Side effects

- A. Gastrointestinal.** Diarrhea is the most significant adverse reaction due to clindamycin [4].
 - 1. Antibiotic-associated diarrhea** occurs in up to 20% of patients receiving clindamycin, presumably because of alternations of anaerobic bowel flora [4].
 - 2. *C. difficile* diarrhea** can occur as a side effect of any antibiotic [17]. The incidence of clindamycin-induced *C. difficile* diarrhea in hospitalized patients varies considerably by institution [4]. The overall incidence is presumably less than 1%, unless there are nosocomial outbreaks within a given institution. When this occurs, restriction of clindamycin use has been beneficial [18]. It is much less common in outpatients receiving clindamycin.
 - 3.** Anorexia, nausea, vomiting, flatulence, bitter taste, and abdominal distention can occur [2]. **A metallic taste** in the mouth when clindamycin is given parenterally occurs infrequently.
- B. Allergic reactions**, eosinophilia, rashes, (with fever), and, rarely, anaphylaxis occur [1,2,4,19].
- C. Hepatotoxicity.** Minor reversible elevations of hepatocellular enzymes are frequent.
- D. Nephrotoxicity.** Clindamycin does not cause significant renal toxicity.
- E. Bone marrow suppression.** Neutropenia and thrombocytopenia have been reported.

K. Chloramphenicol

Chloramphenicol has been available since 1949. Because of the rare case of irreversible fatal aplastic anemia that is associated with its use, chloramphenicol should be used only when clearly indicated. In Third World countries, because it is readily available, inexpensive, and efficacious in many serious infections [1,2], it is widely used. In the United States, however, chloramphenicol is rarely used, and most young physicians are completely unfamiliar with the drug.

I. Mechanism of action. Chloramphenicol inhibits protein synthesis at the ribosomal level. Although active against *Staphylococcus aureus*, group B streptococci, and Enterobacteriaceae, chloramphenicol is bacteriostatic against these organisms. However, against meningeal pathogens, *Haemophilus influenzae*, penicillin-susceptible *Streptococcus pneumoniae*, and *Neisseria meningitidis*, chloramphenicol is bactericidal [3].

II. Spectrum of activity [1,2]. Chloramphenicol has a broad-spectrum antibiotic active against many gram-positive and gram-negative bacteria, rickettsiae, chlamydiae, and mycoplasma. However, **it is not listed as the drug of first choice for any common pathogen** [4].

A. Gram-positive bacteria. Many gram-positive cocci, both aerobic and anaerobic, are susceptible to chloramphenicol, although the minimum inhibitory concentrations are relatively high. Alternate agents are preferred. Chloramphenicol is not considered a drug of choice against enterococci or staphylococci. Methicillin-resistant *S. aureus* usually is resistant to chloramphenicol. However, with the recent increase in vancomycin-resistant enterococci, which are resistant to most available antibiotics (see Chapter 27P), there is renewed interest in chloramphenicol, because it is active *in vitro* against many strains of vancomycin-resistant enterococci, probably because of its previous infrequent use [5].

B. Gram-negative bacteria. *N. meningitidis* and almost all *H. influenzae* strains are susceptible. Chloramphenicol has variable activity against other gram-negative

bacilli; therefore susceptibility studies are necessary. *Salmonella* species are often susceptible. *Pseudomonas* species are resistant.

C. Anaerobes. Chloramphenicol has **excellent activity against gram-positive and gram-negative anaerobes**, including *Bacteroides fragilis* [1,2].

D. Miscellaneous. Chloramphenicol is active against the rickettsiae that cause Rocky Mountain spotted fever, Q fever, and typhus, and it is active against *Ehrlichia chaffeensis* (4).

III. Pharmacokinetics [1,2]

A. Absorption. Chloramphenicol is rapidly absorbed orally, although variable absorption occurs in children. It penetrates body tissues well, including the spinal fluid and the unobstructed biliary tree. **Approximately 30% to 50% of serum levels appear in the cerebrospinal fluid** in both the inflamed and noninflamed meninges [1,2].

B. Inactivation. Chloramphenicol is metabolized and inactivated primarily in the **liver** by glucuronyl transferase.

C. Excretion. In renal failure, the plasma half-life of the biologically active free chloramphenicol is not prolonged. Consequently, chloramphenicol is given in normal doses in renal failure [6].

IV. Toxicity

A. Dose-related bone marrow reversible suppression may occur in any patient on chloramphenicol. Anemia, reticulocytopenia, and neutropenia can occur. Occasionally, only thrombocytopenia occurs. Bone marrow suppression is increased substantially in patients with ascites or jaundice [2]. This **suppression** is due to a direct pharmacologic effect of the antibiotic.

1. Monitoring patients

a. Serial blood counts. A complete blood cell count and platelet assessment every 2 or 3 days is suggested. If suppression occurs, the dose should be reduced and drug reassessed. If the bone marrow suppression progresses, usually the drug is discontinued.

b. Serum levels. Direct bone marrow toxicity is related to levels of free chloramphenicol. **Therapeutic levels are between 10 and 20 $\mu\text{g}/\text{mL}$. The risk of direct bone marrow suppression increases when unconjugated (free drug) levels exceed 25 $\mu\text{g}/\text{mL}$ [1]. Serum should be monitored, especially in neonates and with prolonged use.**

2. Recovery. Complete recovery, **in this reversible form**, occurs approximately 2 weeks after stopping the chloramphenicol.

B. Aplastic anemia is rare, occurring only in 1 in 25,000 to 40,000 courses of chloramphenicol, **and usually is fatal**. The precise mechanism is unknown, but there is a genetic predisposition. The aplasia is not dose related and can become manifest weeks to months after use. Whether topical ophthalmic use of chloramphenicol can cause aplasia remains controversial [7].

C. Gray baby syndrome. Premature infants and newborns younger than 2 weeks have immature hepatic and renal function. Chloramphenicol accumulates in the blood of these infants, which can cause vasomotor collapse and death especially when higher doses of the drug are used. This is the so-called gray baby syndrome. **Therefore chloramphenicol should be avoided in the premature infant and in the first 2 weeks of life except in extreme life-threatening situations, in which decreased doses should be used and serum levels monitored.**

D. Glucose-6-phosphate dehydrogenase deficiency. Chloramphenicol may precipitate hemolysis in patients with a severe deficit of glucose-6-phosphate dehydrogenase [1].

V. Clinical indications. Chloramphenicol is not listed as the drug of first choice for any common pathogen [4]. **Because this agent is used so infrequently, before use, discuss with an infectious disease subspecialist.** The package insert clearly notes the pharmaceutical manufacturer's warning that chloramphenicol **"must not be used when less potentially dangerous agents will be effective."** Because of the availability of less toxic antibiotics, chloramphenicol is seldom used except in special settings or in the allergic patient.

A. Potential important indications for chloramphenicol use include the following:

1. **Alternative for life-threatening *H. influenzae* infections.** The third-generation cephalosporins are the drugs of choice in the empiric therapy of meningitis and acute epiglottitis in children [4]. If there is an allergic history that precludes the use of a cephalosporin, chloramphenicol is an acceptable alternative.
2. **Brain abscess.** Chloramphenicol may be used in selected cases.
3. **Alternative agent in severe anaerobic infection.**
4. **Alternative drug [4] in *Salmonella typhi* infections,** brucellosis, glanders (*P. pseudomallei*), plague, *Chlamydia psittaci* infections (psittacosis), tularemia, and intraocular infections due to susceptible pathogens.
5. **Rickettsial infections** Rocky Mountain spotted fever, endemic typhus (murine), scrub typhus, epidemic typhus (louse-borne), and Q fever. **Chloramphenicol may be the preferred agent when the patients require parenteral therapy, in young children, and in pregnancy** when a tetracycline cannot be used. Infectious disease consultation is advised.
6. **In susceptible infections due to vancomycin-resistant enterococci,** chloramphenicol may provide a possible alternative [5,8,9], although the availability of linezolid and quinupristin/dalfopristin have led away from the use of chloramphenicol.

VI. Route and dosage

A. Neonatal doses. Serum levels should be monitored in neonates. Infectious disease consultation is advised in this setting.

B. Children and adults

1. **Intravenous.** The usual dosage is 50 to 100 mg/kg/day in divided 6-hour doses, with a maximum dose of 1.5 g every 6 hours. Serial blood cell counts should be monitored (see section IV.A.1). Because children vary greatly in their ability to metabolize the drug, monitoring of levels is important [2].
 - a. **In renal failure, hemodialysis, or peritoneal dialysis,** no dosage adjustments are required [6].
 - b. **Hepatic failure.** If chloramphenicol must be used, serum levels should be monitored. In adults, an initial loading dose of 1 g followed by 500 mg every 6 hours sometimes is suggested; the course should be limited to 10 to 14 days [1].
2. **Oral chloramphenicol** is no longer available in the United States, although it is available in some countries (e.g., Mexico).
3. **Drug interactions.** Chloramphenicol can prolong the half-life of chlorpropamide, phenytoin, tolbutamide, and warfarin derivatives. The prothrombin time of patients receiving anticoagulation therapy must be closely monitored [2].

L. Sulfonamides and Trimethoprim-Sulfamethoxazole

I. Sulfonamides. Sulfonamides were the first effective systemic antibacterial drugs used in humans and were initially introduced in the late 1930's. The sulfonamides, which are primarily **bacteriostatic**, act by interfering with bacterial synthesis of folic acid [1].

A. Pharmacokinetics. Sulfonamides generally are used in the oral form. They are metabolized in the liver by acetylation and glucuronidation. Free drug and its metabolites are excreted by the kidney. Preparations less apt to become crystallized in urine have attained more widespread use. Sulfonamides compete for binding sites on plasma albumin. By so doing they may increase blood levels of unconjugated bilirubin (see section **I.E**).

B. Spectrum of activity. Routine disk antibiotic susceptibility testing is unreliable. Because testing is not used, susceptibilities of most organisms are unknown. Many community-acquired *Escherichia coli* are susceptible, particularly to levels achieved in the urine. The sulfonamides also are active against many strains of *Neisseria meningitidis*, *Chlamydia*, *Toxoplasma*, and some *Nocardia* species. **A sulfonamide alone is not the drug of first choice for any bacterial pathogen** [2]. Sulfonamides have *in vitro* activity against *Streptococcus pyogenes* and have been used to prevent recurrent rheumatic fever [3], but they are not advised for treatment of streptococcal pharyngitis.

C. Current clinical uses

1. **Situations in which sulfonamides are useful** include the following:

- a. *Toxoplasma gondii* infections (e.g., sulfadiazine with pyrimethamine).
- b. *Nocardia asteroides* infections respond well to sulfonamides. Trimethoprim-sulfamethoxazole (TMP-SMX) often is listed as the agent of choice [2].

2. **Miscellaneous indications** for sulfonamide use are the following:

- a. **Rheumatic fever prophylaxis** [3]. Although sulfadiazine is effective as prophylaxis, it is ineffective in established streptococcal pharyngitis infections.
- b. *Chlamydia trachomatis pneumonia*. Alternate agent.
- c. **Otitis media prophylaxis**. Sulfonamides have been used in selected patients to prevent recurrences (see Chapter 8).
- d. *E. coli*. Because at least 25% to 35% of strains that cause cystitis are resistant to sulfonamides, sulfonamides are no longer the agents of choice for empiric therapy of initial uncomplicated urinary tract infection (UTI) (see section **II**) [1].

D. Preparations available and dosage regimens [1–4]. Sulfonamides are acetylated or glucuronated in the liver. These inactive metabolites and free drug are actively secreted into the urine [4]. Sulfonamide dosage is reduced for creatinine clearance of less than 50 mL/min; no dosage modification is necessary with hepatic impairment [4]. Sulfonamides penetrate pleural, peritoneal, synovial, and cerebrospinal fluid (CSF); they cross the placenta and are detectable in breast milk.

1. **Short-acting** preparations usually are given four (and sometimes six) times daily.

- a. **Sulfisoxazole** (e.g., Gantrisin, Azo Gantrisin) are no longer listed in the *Physicians' Desk Reference* and are not discussed here.
- b. **Pediazole**. This is a fixed combination of sulfisoxazole and erythromycin. Use of combinations when a single drug will do exposes the individual to excess toxicity.
- c. **Sulfadiazine** (e.g., Neotrizine) is less soluble in urine and therefore less suitable for use in UTI. It is less protein-bound than sulfisoxazole, which yields good blood and CSF levels. It is useful for **nocardial infection, toxoplasmosis, or for rheumatic fever prophylaxis** in the penicillin-allergic patient. Although it has a longer half-life than sulfisoxazole, sulfadiazine is given four times daily. The usual dose in adults is a 2-g loading dose with a maintenance dose of 1 g four times per day. For the treatment of toxoplasmosis or nocardiosis infectious disease consultation is advisable.

- d. Triple sulfa drug** (Trisem) usually is made up of sulfadiazine and two other sulfa preparations. Theoretically, each drug maintains its solubility in the urine to decrease the chances for crystalluria. In adults, the usual dose is 1 g four times daily.
- 2. Intermediate-acting sulfonamides** are given two or three times daily. **Sulfamethoxazole** (e.g., Azo Gantanol) is given twice daily and has been used in UTI. Because it can cause crystalluria, it is important to ensure a high urine output. The dose in adults is 2 g followed by 1 g twice daily. In children older than 2 months, the initial dose is 50 mg/kg, then 25 to 30 mg/kg per dose is given twice daily. **Sulfamethoxazole combined with trimethoprim is available as cotrimoxazole (Bactrim, Septra) (see section II).**
 - 3. Long-acting sulfonamides** are **no longer recommended** because these preparations have the capacity to produce hypersensitivity reactions (e.g., Stevens-Johnson syndrome), which then become a prolonged problem. The exception is sulfadoxine, which is a component of Fansidar, which is still used in some antimalarial regimens (see section III).
 - 4. Topical sulfonamides** [5]. Mafenide acetate (Sulfamylon) is used on burns to help prevent bacterial colonization, particularly by pseudomonas. Its use has been limited by the side effect of metabolic acidosis. Silver sulfadiazine (Flamazone) has fewer side effects and is used extensively for burns. Outbreaks of silver-resistant infections may ultimately limit its usefulness [5]. Sulfonamides are used also in ophthalmic preparations and in vaginal suppositories and creams.
 - 5. Sulfasalazine** (Azulfidine) is used in the treatment of ulcerative colitis.
- E. Toxicity** [4,5]
- 1. Pregnancy and neonates.** Sulfonamides should not be used in the last trimester of pregnancy (especially the last month) because they are transplacentally transmitted and compete for bilirubin-binding sites on plasma albumin, increasing the risk for kernicterus. Sulfonamides are **not recommended for therapy in neonatal infections or in nursing mothers** because the neonate's hepatic enzyme system may be immature.
 - 2. Hematology.** Sulfonamides should be **avoided in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency**, because hemolysis can be precipitated. However, one study showed that G6PD-deficient patients who received TMP-SMX did not have hemolytic reactions during therapy [6]. Anemia, leukopenia, or thrombocytopenia occurs with sulfonamide use, especially in those with folate deficiency.
 - 3. Hypersensitivity reactions** with rashes, vasculitis, erythema nodosum, erythema multiforme, and Stevens-Johnson syndrome can occur. These were particularly common with the long-acting compounds, which are no longer recommended.
 - 4. Gastrointestinal disturbances** with nausea, vomiting, and diarrhea occur in 3% to 5% of patients.
 - 5. Renal dysfunction** due to tubular deposition of sulfonamide is now rare.
- F. Important drug interactions.** Sulfonamides may displace drugs from albumin-binding sites, increasing the clinical effect of the displaced drug [5].
- 1. Oral anticoagulants.** Sulfonamides compete for albumin-binding sites and, in effect, increase the activity of a given anticoagulant dose. Therefore **doses of oral anticoagulants** (e.g., warfarin sodium) **should be reduced** and serial prothrombin times monitored.
 - 2. Methotrexate.** Because sulfonamides displace methotrexate from its bound protein, **risk of methotrexate toxicity increases. Therefore sulfonamides should be avoided.**
 - 3. Oral hypoglycemic agents.** The hypoglycemic effect of sulfonylureas may be exaggerated by sulfonamides, although the precise mechanisms for this are unclear.
 - 4. Methenamine** compounds should not be given concomitantly with sulfonamides because there is an increased risk of insoluble urinary precipitate formation.
- G. Sulfonamide use in renal failure.** Because sulfonamides are excreted by way of the kidney, in renal failure **doses must be reduced or dose intervals prolonged** [7].

FIG. 27L.1. Mechanism of action of trimethoprim-sulfamethoxazole. Most bacteria cannot use exogenous folate but must make their own folate for nucleic acid synthesis. Trimethoprim-sulfamethoxazole can sequentially block the formation of tetrahydrofolic acid and thereby interfere with cell replication.

II. TMP-SMX [1,5,8,9], formerly called **cotrimoxazole**, is available commercially as **Bactrim or Septra as well as in generic** preparations. This unique preparation was specifically formulated to include a combination of agents that would inhibit activity in two sequential steps of bacterial metabolism. It became available in the United States in 1973. The combination has two theoretic advantages: It decreases the chances of bacterial resistance and the combination may act synergistically. The combination is available in oral and intravenous forms. The regular tablets contain 80 mg TMP and 400 mg SMX to provide an ideal blood ratio of 1:20 for optimal synergy. However, it is noteworthy that in different body fluids, the ratios of TMP to SMX are virtually never 1:20, so the value of the ideal ratio in the blood is uncertain. **Alone, each agent is bacteriostatic, but together they are bactericidal and synergistic *in vitro*.** Currently, sulfonamides are used most frequently in this combination [5].

A. Mechanism of action. TMP-SMX sequentially blocks two steps in the synthesis of folic acid by bacteria (Figure 27L.1).

B. Pharmacokinetics [1,4,5]. Oral TMP-SMX is well absorbed. Peak serum levels occur 1 to 4 hours after ingestion. The intravenous preparation provides excellent blood levels. Serum half-lives of TMP and SMX are 8 to 10 hours and 10 hours, respectively [4]. TMP-SMX is excreted primarily by the kidneys, so doses must be reduced in renal failure. **Because the pH of the urine dictates which component is excreted more rapidly in renal failure, this makes dosage selection difficult.** Excretion occurs over several hours, and this permits twice-daily dosing. Each drug is distributed widely and can be detected in most tissues of the body. This agent penetrates the CSF well (20%–40% of serum levels). Concentrations of TMP in prostatic fluid usually are at least three times those of the serum concentration [1].

C. Spectrum of activity. TMP by itself has a wide spectrum of activity against gram-positive and gram-negative bacteria (see Chapter 27M). SMX is less active alone, but it enhances the activity of TMP when combined with it.

1. **Gram-positive cocci.** TMP-SMX is active against most *Staphylococcus aureus*, *S. epidermidis*, penicillin-susceptible *S. pneumoniae* strains, and viridans streptococci. In a survey of penicillin-resistant strains of *S. pneumoniae* in Atlanta, Georgia, published in 1995, 75% of the isolates resistant to penicillin were resistant to TMP-SMX [10] (see related discussions in Chapter 11). This agent is active against many methicillin-resistant *S. aureus* species. Despite the apparent *in vitro* sensitivity of methicillin-resistant *S. aureus*, some reviews emphasize that clinical success with TMP-SMX therapy for methicillin-resistant *S. aureus* is extremely variable and unpredictable [8]. It is not useful clinically against enterococci.
 2. **Gram-negative bacilli and cocci**
 - a. **Enterobacteriaceae are usually susceptible**, although a higher percent of these and of *Salmonella* and *Shigella* species are now resistant than in the past.
 - b. *Haemophilus influenzae* (ampicillin-susceptible and ampicillin-resistant) and *Moraxella catarrhalis* are usually susceptible. TMP-SMX has activity against *Pasteurella multocida* [11], although it is usually not listed as an alternative agent for this pathogen [2].
 - c. *Stenotrophomonas* (formerly *Xanthomonas maltophilia*) are susceptible. Even when they are labeled resistant, a slightly higher dose will be clinically effective. *Burkholderia cepacia* (formerly *P. cepacia*) are usually susceptible.
 - d. *Pseudomonas aeruginosa*. TMP-SMX is **not active**.
 3. **Anaerobes.** TMP-SMX is not particularly active against anaerobes, including *Bacteroides fragilis* [1,9].
 4. **Miscellaneous** [1,2,9].
 - a. TMP-SMX is active against *Listeria monocytogenes*, *Yersinia enterocolitica*, *Aeromonas* species, *Legionella micdadei*, and *Legionella pneumophila*.
 - b. *Pneumocystis carinii* (a parasite) is susceptible but resistance has been noted [12], the meaning of which is uncertain.
 - c. **Many Nocardia** species are susceptible.
 - d. *Treponema pallidum* is resistant.
 5. **Resistance to TMP-SMX** has recently been reviewed [8,13].
 - a. **Bacterial resistance** to both TMP and SMX has developed, although there are significant geographic variations. Resistance to the sulfonamides is usually more common than is resistance to TMP. In developed and developing countries, levels of resistance to TMP-SMX for *S. pneumoniae* range from 10% to 50%. In the United States, for *H. influenzae* over 30% and for *M. catarrhalis* from 2% to 50% of strains are resistant to TMP-SMX. Many penicillin-resistant pneumococci are also resistant to TMP-SMX [13]. Because of increasing resistance, TMP-SMX is no longer the drug of choice for *Salmonella* species or *Shigella* species [2,13]. **At least 30% to 35% of nosocomial urinary pathogens are resistant to TMP-SMX** [8]. In recent reports of susceptibility studies in **community-acquired acute uncomplicated cystitis** in women aged 18 to 50 years, **the incidence of resistance of *E. coli* has risen to 16% to 20%** [14–16]. This rise in resistance in community-acquired *E. coli* now has affected empiric antibiotic therapy for uncomplicated cystitis (see section **D.1.a** below and Chapter 15).
 - b. *P. carinii*. TMP-SMX has been widely used to prevent infections in underlying human immunodeficiency virus (HIV) infection [17]. Selection pressure caused by prolonged use of TMP-SMX in this setting has been associated with an increase in the levels of resistance to TMP-SMX among clinically important bacterial species infecting HIV patients [13]. Furthermore, TMP-SMX resistant strains of *P. carinii* have been isolated but only from cases that were treated successfully [12]. Because resistance to TMP-SMX is in large part governed by resistance to TMP, this topic is discussed further in Chapter 27M.
- D. Indications for use** [1,2,8,9]. **TMP-SMX is the first-line drug [2] for the treatment of infections caused by *Burkholderia cepacia*, *S. maltophilia*, *Nocardia* species, and *P. carinii* as well as *Y. enterocolitica* or *Aeromonas* species.** TMP-SMX has been extensively used in the treatment of acute bronchitis and upper respiratory

infections. Of concern, however, has been increasing TMP-SMX resistance amongst strains of *H. influenzae* and *S. pneumoniae*. It is important for clinicians to know the susceptibility of these common respiratory pathogens to TMP-SMX in their local practice environment.

1. UTIs. See related discussion in Chapter 15.

- a. **Acute initial uncomplicated UTI.** Because many strains of community-acquired *E. coli* are resistant to sulfonamides alone and amoxicillin (ampicillin), for empiric therapy of community-acquired uncomplicated UTI, TMP-SMX is often preferred [2]. However, with community-acquired *E. coli* showing an increased frequency of resistance to TMP-SMX (see section C.5.a above) and up to 8% of strains of *S. saprophyticus* resistant to TMP-SMX [14], these factors must be considered in empiric therapy of cystitis [14–16], and especially pyelonephritis. Although we still commonly use empiric TMP-SMX in the healthy young female with an uncomplicated UTI, if the patient has underlying diabetes or repetitive infections or a possible early pyelonephritis, we would favor a quinolone.
- b. **Pyelonephritis.** Because TMP-SMX penetrates tissue well, it is a useful agent in this setting **for susceptible pathogens [14–16]**, especially because it can be given both intravenously and orally. **If the Gram stain of unspun urine reveals gram-positive cocci, suggesting enterococci, TMP-SMX should not be used.**
- c. **Recurrent UTI in adult women.** In women prone to recurrent UTI, TMP-SMX has helped decrease the rate of recurrence, presumably in part by decreasing colonization at the periurethral area [1]. However, enterococcal colonization may result. An alternative regimen is a short course of self-administered antibiotic with a twice-daily dose of TMP-SMX for 3 days at the onset of symptoms.
- d. **Prostatitis recurrent UTI in men.** In the absence of other genitourinary pathology, men with recurrent UTI often have chronic **bacterial prostatitis**. [18,19]. Organisms in the prostate are extremely difficult to eradicate, because most antibiotics do not penetrate the prostate well. TMP-SMX penetrates the prostatic fluid and is very useful in these patients. Often trimethoprim by itself is used. The fluoroquinolones also are useful in this setting.
- e. **Postcoital antibiotic prophylaxis for recurrent UTI** with TMP-SMX has been shown to be a safe, effective, and inexpensive approach to management in carefully selected young women with recurrent UTI [20].

2. Respiratory infections

- a. ***P. carinii*.** TMP-SMX is considered the drug of choice in children and adults, with or without HIV, for the treatment and prevention of ***P. carinii* pneumonia (PCP)** [17,21,22]. A high incidence of adverse effects occurs in patients with acquired immunodeficiency syndrome (AIDS) who are treated with TMP-SMX, especially when maximal doses are used (see related discussion in section G.2). Usually the starting dose for PCP is 20 mg/kg/day TMP equivalent, which can be reduced to 10 mg/kg/day TMP over 48 to 72 hours. This reduced dose remains effective and a decrease in incidence of side effects occurs.
- b. **Acute exacerbations of chronic bronchitis.** Because TMP-SMX is active against penicillin-susceptible *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*, it is a useful agent in this setting [1,5] or as part of a rotating antibiotic regimen (see Chapter 8).
- c. **Pneumonia.** For susceptible gram-negative pathogens, intravenous TMP-SMX has been used for lower respiratory tract infections [5]. TMP-SMX is an alternative agent for *L. micdadei* and *L. pneumophila* infections when erythromycin or a fluoroquinolone cannot be used [2].
- d. **Acute otitis media.** TMP-SMX has been used as an alternative agent for acute otitis media, especially if ampicillin-resistant *H. influenzae* is a concern (see Chapter 8).
- e. **Sinusitis.** With the advent of penicillin (and TMP-SMX) resistant *S. pneumoniae*, TMP-SMX may be less effective for sinusitis therapy (see Chapter 8).

3. Gastrointestinal infections. See Chapter 13 for additional discussion.

- a. **Shigellosis.** TMP-SMX resistance has increased significantly. Thus, TMP-SMX should be used for bacterial enteritis caused by *Shigella* strains only if susceptibility is known [2].
- b. **Salmonella.** Although ceftriaxone or a quinolone are drugs of choice for *S. typhi* or other *Salmonella* species infections requiring treatment, TMP-SMX is an excellent alternative agent [2].
- c. **Traveler's diarrhea.** In the past, TMP-SMX was the most common agent used to treat traveler's diarrhea. Now the fluoroquinolones often are preferred in adults because TMP resistance has become common.
- d. **Spontaneous bacterial peritonitis.** Prevention in patients with underlying cirrhosis is discussed in Chapter 13.
- e. **Meningitis.** Gram-negative bacillary meningitis caused by organisms (e.g., *Enterobacter cloacae*, *Serratia marcescens*) only **moderately susceptible** or resistant to **third-generation cephalosporins** or (*P. cepacia*, *Acinetobacter* species) may be candidates for TMP-SMX treatment if the organisms are susceptible [1,5,9,23]. TMP-SMX is an alternate agent in meningitis due to *L. monocytogenes* [2] when ampicillin cannot be used.

4. Neutropenic patients. Although TMP-SMX has been used for **prevention of infection**, a recent panel of experts concluded that use of TMP-SMX should be avoided in this setting [9,24].

5. Miscellaneous

- a. **Endocarditis.** TMP-SMX has been used as an alternative agent for susceptible pathogens causing bacteremia or endocarditis [1,5]. Infectious disease consultation is advised.
- b. **Nosocomial infections.** Gram-negative nosocomial infections due to bacteria resistant to many antibiotics may be susceptible to TMP-SMX (e.g., *Enterobacter*, *Klebsiella*, and *Proteus* species), and patients will respond to this therapy. *Burkholderia cepacia* infections that have relapsed or failed other agents often have responded well to TMP-SMX. **Before using TMP-SMX for these types of infections, *in vitro* data should show susceptibility.**
- c. **Nocardia.** TMP-SMX is an important agent for these infections and sometimes is viewed as the agent of choice [2].
- d. ***Y. enterocolitica* and *Aeromonas* species infections** can be treated with TMP-SMX.
- e. **Brucellosis.** TMP-SMX is an alternative agent for brucellosis [2].
- f. **Renal transplantation recipients.** Prophylaxis with TMP-SMX significantly reduces the incidence of bacterial infection after renal transplantation (especially infection of the urinary tract and bloodstream), can provide protection against PCP, and is cost beneficial [25]. Patients appear to tolerate this regimen well in this setting [25].
- g. **Prevention of infection in patients with chronic granulomatous disease.** TMP-SMX prophylaxis is useful in the prevention of infectious complications [1,9].
- h. ***Mycobacterium marinum*.** TMP-SMX is an alternative agent [2].
- i. **Gastrointestinal infections** TMP-SMX is viewed as the drug of choice for *Cyclospora*, *Isospora*, and **coccidian parasites** in HIV-infected patients [16,26].

E. Dosage forms available

1. **Oral. Single strength** tablets contain 80 mg TMP and 400 mg SMX. **Double strength** tablets contain 160 mg of TMP and 800 mg SMX. There are unflavored and cherry-flavored **suspensions** containing 40 mg TMP and 200 mg SMX per 5 mL.
2. **Parenteral.** An intravenous form of TMP-SMX is supplied in 5-mL ampules that contain 80 mg TMP and 400 mg SMX. The intravenous preparation is recommended for the following: (a) **severe UTI** in patients who are vomiting or otherwise too ill to take an oral medication, (b) patients with severe **PCP**, (c) **severe *Shigella* infections**, and (d) certain serious multiresistant enteric gram-negative bacillary infections in which TMP-SMX is active *in vitro*. Infectious disease consultation is advisable in this setting. The intravenous form has also been

used in the treatment of pneumonia, bacteremia, meningitis, and other serious infections.

For severe or complicated UTI, due to known susceptible organisms, 8 to 10 mg/kg/day (based on the TMP component) is recommended. The dose is divided into an every 6 or 12 hour schedule until the patient improves enough to allow oral therapy (Table 27L.1).

- F. Preferred route.** Because TMP-SMX is well absorbed, **the oral route is usually preferred** unless the patient has nausea, is vomiting, is taking nothing by mouth, or is critically ill. If intravenous therapy is initially used, one can often switch to oral therapy when the patient improves. Adequate fluid intake should be encouraged to prevent sulfonamide crystalluria [1].
- 1. See Table 27L.1.**
 - 2. In children, TMP-SMX is not recommended for infants less than 2 months** of age because of the risk of kernicterus. For otitis media and other infections 8 mg/kg TMP (and 40 mg/kg SMX) per 24 hours is given in two divided doses every 12 hours for 10 days (see Chapters 3 and 8) (Table 27 L.2). An identical dosage is given for 5 days for shigellosis.
 - 3. In pregnancy**
 - a. TMP-SMX is not recommended at term** because sulfonamides cross the placenta and may cause kernicterus.
 - b. TMP-SMX is a category C drug** (see Chapter 27A). It is generally not recommended for use in pregnancy unless the benefits justify the risks to the fetus [5] (see section G.4 below).
 - 4. Nursing mothers.** Because sulfonamides are excreted in human breast milk and may cause kernicterus, avoid the **use** of TMP-SMX for nursing mothers (see section G.4).
 - 5. In renal failure, dosages must be modified.** The optimal approach is not well defined. The package insert suggests that standard doses can be used for a creatinine clearance of more than 30 mL/min. For a creatinine clearance of 15 to 30 mL/min, half the usual dose is suggested. For a creatinine clearance of less than 15 mL/min, use is not recommended.
 - a.** In a recent review [9], the author suggested (a) usual doses for a creatinine clearance of more than 50 mL/min, (b) 50% of the standard dose be given every 12 hours or the standard dose of 18 to 24 hours if the creatinine clearance is 10 to 50 mL/min, and (c) a standard dose every 24 hours if the creatinine clearance is less than 10 mL/min. Because TMP-SMX is **removed by hemodialysis**, standard doses can be administered after dialysis, with perhaps a supplemental fractional dosing provided on nondialysis days [9]. Infectious disease input is advised. Adults on chronic ambulatory peritoneal dialysis should receive the equivalent of one double strength tablet every 48 hours [5].
 - 6. In significant hepatic failure, TMP-SMX should be avoided.**
- G. Toxicity and side effects.** Although skin rashes are common, this combination **usually is well tolerated**, even for prolonged periods. Reactions occur either to the TMP (see Chapter 27M) or, more commonly, to the sulfonamide component (see section I.E). Adverse reactions have been reviewed [1,4,9,27]. **In patients with AIDS, drug toxicity** (rash, fever, neutropenia, thrombocytopenia, and transaminase elevation) **occurs more frequently** [28] than in non-AIDS patients, but dose reduction and the use of corticosteroids, commonly used in PCP, may help reduce these reactions.
- 1. Mild gastrointestinal symptoms**, including nausea, vomiting, diarrhea, cramps, and similar symptoms, occur in 3% to 3.5% of patients [21] and are the most frequent adverse effects [8].
 - 2. Skin rashes are relatively common**, occurring in 3% to 5% [1,9]. They are usually typical drug eruptions with a **diffuse maculopapular rash or mild toxic erythema**. Most rashes are benign and resolve with discontinuation of therapy. However, exfoliative dermatitis, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur. An increased frequency of rashes occurs in AIDS patients receiving TMP-SMX [28]. With a history of cutaneous sensitivity or other

Table 27L.1. Dosing of TMP-SMX

Indication	Dosage ^a /Day (Normal Renal Function)	Duration and Comments
Uncomplicated cystitis in women	1 DS bid	For 3 days
Conventional therapy in UTI, UTI in elderly	1 DS bid	For 7–10 days
Pyelonephritis	i.v. or p.o., 1 DS bid p.o.	For at least 14 days. See text for i.v. doses. For children use dose as in acute otitis media.
Prophylaxis of recurrent UTI in women	½ or 1 SS every other night or ½ SS tab nightly qhs	Typically for at least 6–12 mo; the urine should be sterilized first. See Chapter 15.
Prostatitis	1 DS bid	For 3–4 weeks or more. See Chapter 15.
Acute exacerbations of COPD	1 DS bid	Usually for 5–7 days. See Chapter 8.
Acute otitis media (AOM)	In children > 2 mo, TMP 8 mg/kg/day and SMX 40 mg/kg/day given in divided doses q12h See Table 27L.2	5 days to 10 days. See Chapter 8.
Sinusitis	1 DS bid in adults. In children, see AOM doses	Usually for 10 days. See Chapter 8.
Pneumonia	i.v. initially (see text)	After improvement, switch to po, 1 DS bid in adults, duration must be individualized. See Chapter 11.
<i>Salmonella</i> , <i>Shigella</i> when susceptible	Dosages used for UTI	For 5 days
Traveler's diarrhea	1 DS bid	For 3 days in adults. Many <i>E. coli</i> now resistant to TMP-SMX. See text and Chapter 22. Quinolones usually preferred unless contraindicated.
Susceptible, gram-negative meningitis ^b	10 mg/kg/day (based on TMP component) i.v. divided q6h ^b	Probably for 2 weeks. Infectious disease consultation advised.
Bacteremias and nosocomial infections	i.v. 8–10 mg/kg/day (based on TMP component) divided q6 or q12h schedule.	Go to oral doses when patient improves.
Prevention of <i>Pneumocystis carinii</i> pneumonia (PCP) in immunocompromised e.g., AIDS ^c	1 DS p.o. qd or 1 SS p.o. qd	While CD4 count is <200/μL or oropharyngeal candidiasis
Therapy of PCP	Initially, begin at 5 mg/kg of TMP component q6h for 3–5 days, then q8h for another 3–5 days, then 4 mg/kg of TMP q8h component until course completed.	Total course of 21 days. By tapering doses, side effects may be minimized. In very ill patients, i.v. therapy is initially used and converted to oral therapy as the patient improves.

^aDS, double-strength tablet; SS, single-strength tablet. The DS tablet of TMP-SMX is a large tablet; some patients may prefer two of the smaller SS tablets.

UTI, urinary tract infection; COPD, chronic obstructive pulmonary disease.

Table 27L.2. Pediatric Dosages of TMP-SMX for UTI, Otitis Media, Shigellosis, and the like^a (Pediatric Suspension)

Weight		Dose (q12h)	
Ibs.	Kg	Teaspoonfuls	Tablets
22	10	1 tsp. (5 mL)	—
44	20	2 tsp. (10 mL)	1 tablet ^b
66	30	3 tsp. (15 mL)	1 ½ tablets
88	40	4 tsp. (20 mL)	2 tablets or 1 DS tablet

^aFor children 2 months of age or older.

^bAuthor's note: tablet = single strength.

DS, double strength; UTI, urinary tract infection.

Physicians' desk reference, 56th ed. Montvale, NJ: Medical Economics Data, 2002, with permission.

TMP-SMX intolerance, desensitization has been successful with oral desensitization protocols [9,29–31].

- 3. Bone marrow and peripheral blood.** Megaloblastic bone marrow changes are uncommon except in those patients with preexisting depleted folate stores (e.g., alcoholics, the elderly, pregnant women, malnourished patients, and patients receiving phenytoin). Except for bone marrow transplant recipients in whom engraftment may be delayed, occasionally in pediatric patients, and in AIDS patients, severe hematologic reactions to TMP-SMX are rare [27]. Thrombocytopenia occurs as it does with sulfonamide use. Although neutropenia has been attributed to TMP-SMX, the precise relationship to drug therapy is difficult to determine, as neutropenia (a) is common in randomly sampled young children (control subjects); (b) is seen with viral illnesses for which the patient, especially children, may receive antibiotics; and (c) in reviews has been seen with similar frequency in patients receiving amoxicillin therapy [1]. Further studies are necessary to clarify this question. If neutropenia occurs in a patient receiving TMP-SMX, it is prudent to discontinue the TMP-SMX and use an alternative agent.

Use of folinic acid. It has been suggested that concomitant administration of folinic acid may reverse the antifolate effects of TMP-SMX, especially in patients not infected with HIV, without interfering with its antimicrobial effect (see **Chapter 18**). In one report, adjunctive folinic acid with TMP-SMX for PCP in AIDS patients was associated with an increased risk of therapeutic failure and death [32]. Therefore empiric addition of folinic acid in this setting is not advised [32].

Hemolysis may rarely be precipitated with TMP-SMX use in patients with G6PD deficiency (see section **I.E.2**). However, in one study, G6PD-deficient patients who received TMP-SMX did not have hemolytic reactions during therapy [6]. In patients with AIDS who receive TMP-SMX for PCP, dose reduction may help reduce bone marrow suppression.

- 4. Pregnancy and lactation.** Because of the teratogenic effect seen in animal studies, TMP-SMX is generally contraindicated in pregnant [5] or lactating women. Furthermore, because the sulfonamide component displaces bilirubin from albumin-binding sites and may therefore increase the risk of kernicterus, TMP-SMX is contraindicated in infants younger than 2 months and in pregnant women near term.
- 5. Drug-drug interactions.** The sulfonamide-related interactions are reviewed in section **I.F.** and include interactions with oral anticoagulants and oral hypoglycemic agents. We try to avoid using sulfonamides, including TMP-SMX, in patients receiving warfarin. If TMP-SMX is used, prothrombin times should be monitored. Often the dose of warfarin will need to be reduced. TMP-SMX may prolong the half-life of phenytoin.

Methotrexate concentrations can be increased, and toxicity may ensue as a result of displacement from plasma-binding sites [9]. A review of drug interactions has recently been published [33].

6. **Nephrotoxicity** does not appear to be a significant side effect [1]. Clinically insignificant elevations of creatinine can occur with TMP (see Chapter 27M).
7. **Hyperkalemia** may occur in patients with AIDS during treatment for PCP with TMP-SMX (see discussion in **Chapter 18**).
8. **Local thrombophlebitis** uncommonly occurs with intravenous administration.
9. **Acquisition of resistance** is discussed in Chapter 27M.

H. Cost (see Appendix Table)

- III. **Fansidar** tablets are a combination of pyrimethamine (25 mg), a folate antagonist, and sulfadoxine (500 mg), a long-acting sulfonamide. This combination is still used in some antimalarial treatment regimens [21].

M. Trimethoprim

Trimethoprim (TMP) not in combination with sulfamethoxazole (SMX) is available and is approved for use in uncomplicated urinary tract infections (UTIs) [1–3].

- I. **Mechanism of action.** By inhibiting dihydrofolate reductase, TMP interferes with the production of tetrahydrofolic acid in bacterial cells (see Fig. 27L.1).
- II. **Spectrum of activity.** TMP is bactericidal against many gram-positive aerobic cocci and many species of gram-negative bacteria, except *Pseudomonas aeruginosa* and other *Pseudomonas* species [3]. Enterococci usually are resistant. It is **active against community-acquired urinary tract pathogens** such as *Escherichia coli*, *Proteus mirabilis*, *Klebsiella pneumoniae*, and *Enterobacter* species. Most anaerobes and *Chlamydia* species are resistant [2]. Its spectrum of activity is **very similar to that of the TMP-SMX combination**.
- III. **Pharmacokinetics.** TMP is **well absorbed** from the gastrointestinal tract. It is excreted primarily unchanged in the urine. Urinary concentrations are considerably higher than in blood. Dosage must be altered in renal failure. **TMP penetrates prostatic** and vaginal secretions well [1,3]. It achieves high tissue levels in the kidney [3] and is excreted in breast milk. This drug increases the half-life of phenytoin.

IV. Dosage

- A. **Oral.** TMP is available in 100-mg doses. The effectiveness of TMP as a single agent in children younger than 12 years has not been established. The safety of TMP in infants younger than 2 months of age has not been demonstrated.
- B. **In renal failure,** the interval is adjusted. For creatinine clearance of 10 to 50 mL/min, the usual dose is given every 18 hours, and for creatinine clearance less than 10 mL/min, the usual dose can be given every 24 hours [4].
- C. **Pregnancy.** TMP is a **category C agent** (see Chapter 27A) and should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus (see section **VI.B.6**).
- D. **Nursing mothers.** TMP is excreted in human breast milk. Because TMP may interfere with folic acid metabolism, caution should be exercised for a nursing woman (see section **VI.B.6**).

V. Current clinical uses

- A. **Uncomplicated UTI.** Some experts prefer TMP alone to TMP-SMX because of equal spectrum and less common adverse effects [5]. A 3-day regimen is preferred over one dose. Adult dose is 100 mg every 12 hours or 200 mg every 24 hours for 3 or 10 days.
- B. **Recurrent UTI** in women. TMP has been used in suppressive regimens of 100 mg at bedtime [1,2,5]. Urine should be sterilized before suppressive therapy is started (see Chapter 15).
- C. **Prostatitis.** TMP, 100 mg every 12 hours or 200 mg every 24 hours is given for 4 to 12 weeks. It is effective for both acute and chronic prostatitis [1,2,5]. It is especially useful in the sulfa allergic. TMP-SMX and oral fluoroquinolones are alternative agents (see Chapter 15).
- D. **Traveler's diarrhea.** TMP, 100 mg twice daily for 3 or, at most, 5 days has been effective [6]; quinolones are preferred (see Chapters 13, 22, and 27G, section **II.B.5**).
- E. ***Pneumocystis carinii*.** TMP cannot be substituted for TMP-SMX. A combination of **dapsone and TMP**, 200 mg every 8 hours **is effective for moderate *P. carinii*** in acquired immunodeficiency syndrome (AIDS) [7,8] (see Chapter 18).

VI. Potential problems and adverse effects

- A. **Resistance to TMP.** The topic of TMP and TMP-SMX has been reviewed [9–13] (see also **Chapter 27L, section II.C.5**). TMP resistance governs whether there is resistance to the combination. Resistance of *Escherichia coli* has been occurring with increasing frequency. For example, from 1978 to 1981, *E. coli* resistance to TMP rose modestly from 2% to 6% in Boston, from 8% to 30% in Paris, and to even higher rates (40%) in developing countries [9,11] (25%–68% in South America, Asia, and Africa [10]). In some developing countries, antibiotics are often available without prescription, and TMP is used as monotherapy. Resistance to *Salmonella typhi* is worldwide. Also, resistance of *Shigella* species, of methicillin-resistance *S. aureus*, and, recently, *S. pneumoniae* to TMP has become more common [3]. In two recent studies, it was shown that prior exposure to antibiotics, especially to TMP, predicted that organisms causing a current UTI would be resistant to TMP [12,13]. See related discussion in Chapters 15 and 27L.
- B. **Adverse effects.** TMP is well tolerated in standard regimens.
 1. **Skin rashes** have been noted in approximately 3% of patients, compared with 6% of patients receiving TMP-SMX [1] when conventional doses are used. In high dose regimens, TMP is associated with a higher incidence of rashes and other adverse drug effects [14].
 2. **Anaphylaxis** has been described after TMP use [15,16]. **For a history of a delayed diffuse rash from TMP-SMX**, unless there was an immediate reaction associated, it is reasonable to use TMP alone as sulfonamides cause rashes more commonly.
 3. **Hyperkalemia** [17–20] is seen commonly in patients with AIDS who are treated with high doses of TMP-SMX or TMP and dapsone and has occurred in hospitalized patients without AIDS who were treated with TMP-SMX. TMP is a sodium channel inhibitor and functions as a potassium-sparing diuretic agent.
 4. **Bone marrow effects.** TMP is a weak human folic acid metabolic inhibitor, particularly in the elderly or alcoholic folate-deficient patient [1,5]. Megaloblastic

anemia, neutropenia, and thrombocytopenia have been described with prolonged use. The administration of 10 mg of folinic acid daily prevents this side effect, presumably without reducing the antibacterial activity of TMP, but folinic acid is expensive. However, adjunctive folinic acid with TMP-SMX for *P. carinii* pneumonia in AIDS patients was associated with an increased risk of therapeutic failure and death in one series [21]. Folinic acid must be used cautiously.

5. **Modest evaluations of serum creatinine** levels may occur in patients receiving TMP, but these are probably clinically insignificant [14]. **Abnormal liver function tests** can occur [22].
6. Teratogenicity of TMP in humans has not been clearly established. **It seems prudent to use an alternate agent in pregnancy and nursing women** [2].
7. **Drug interaction.** TMP may predispose to **phenytoin** toxicity by increasing free levels of phenytoin [5].

C. **Cost** (see Appendix Table)

N. Macrolides: Erythromycin, Clarithromycin, and Azithromycin*

Erythromycin and the semisynthetic derivatives of erythromycin, clarithromycin and azithromycin, have structural modifications to improve tissue penetration and broaden their spectrum of activity [1–4] and are available in the United States. The macrolides inhibit RNA-dependent protein synthesis by reversibly binding to the 50S ribosomal subunits of susceptible microorganisms. Although generally bacteriostatic, they may be bactericidal under certain conditions or against certain microorganisms [1,3]. Because the structure of the macrolides differs from that of β -lactams, macrolides are useful for patients who are allergic to β -lactams.

ERYTHROMYCIN

I. Spectrum of activity. Erythromycin's spectrum includes many gram-positive bacteria, some gram-negative bacteria, mycoplasma, chlamydiae, treponema, and rickettsiae.

A. See Table 27N.1.

B. Aerobic bacteria. Certain points deserve emphasis.

1. Gram-positive organisms

- a. Erythromycin is usually active against **group A streptococci (GAS)**. In the United States, until recently less than 5% of GAS were resistant to erythromycin [5,6]. Resistance of GAS to erythromycin in some countries has been a problem (e.g., Finland). In 2002, a sudden outbreak was reported of a macrolide-resistant GAS in which 48% of throat isolates were resistant to erythromycin. Given these findings, an editorial encouraged research to document prevalence of macrolide resistance throughout the United States so that individual physicians know the likelihood of erythromycin-resistant GAS in their local area [7].
- b. Penicillin-susceptible *Streptococcus pneumoniae* are susceptible to erythromycin, but many penicillin-resistant strains are also resistant *in vitro* to macrolides. The exact clinical significance of this remains debated [8] (see Chapters 8 and 11). Strains resistant to one macrolide are resistant to all macrolides [1].
- c. Many other streptococci are susceptible (groups B, C, G, etc.), but **group D (enterococci) is resistant**.
- d. **Methicillin-susceptible *Staphylococcus aureus*** are often susceptible to erythromycin, but resistance may emerge during therapy [9]. Interestingly, the *Medical Letter* does not list the macrolides as alternative agents for methicillin-susceptible *S. aureus* [10]. **Methicillin-resistant *S. aureus* (MRSA)** are resistant to macrolides.
- e. **Erythromycin** is the drug of choice for *Corynebacterium diphtheriae* and **alternative agent** for *Bacillus anthracis* (anthrax) [10].

2. Gram-negative organisms

- a. Erythromycin is an **agent of choice** for *Campylobacter jejuni*, *Bordetella pertussis* (whooping cough), bacillary angiomatosis caused by *Bartonella henselae*, and trench fever caused by *B. quintana*. [10].
- b. Erythromycin is an **alternative agent** for *Haemophilus ducreyi* (chancroid), *Eikenella corrodens*, and *Moraxella catarrhalis* [10].

*Adapted from Reese ER, Betts RF. Macrolides: erythromycin, clarithromycin, and azithromycin. In: Reese RE, Betts RF, Gumustop B, eds. *Handbook of antibiotics*, 3rd ed. Philadelphia: Lippincott Williams and Wilkins, 2000:468–492.

Table 27N.1. *In Vitro* Activity of the Macrolides

Organism	Mean MIC ₉₀ (mg/L) ^a		
	Erythromycin (≤0.5 mg/L) ^b	Clarithromycin (≤2 mg/L) ^b	Azithromycin (≤2 mg/L) ^b

^aValues for MIC cutoff for susceptibility. MIC of clarithromycin alone; 14-hydroxy metabolite of clarithromycin may contribute to antimicrobial activity. All MICs broth dilution, inoculum 10⁻⁴–10⁻⁶; at least 10 strains from each source.

^bRecommended susceptibility breakpoints.

^cRecommended breakpoint ≤8 mg/L.

^dRecommended breakpoint ≤4 mg/L.

GU, genitourinary; MIC, minimal inhibitory concentration; MIC₉₀, minimal concentration that will inhibit 90% of clinical isolates; MRSA, methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *Staphylococcus epidermidis*; MSSA, methicillin-sensitive *Staphylococcus aureus*; MSSE, methicillin-sensitive *Staphylococcus epidermidis*; STD, sexually transmitted disease; subsp, subspecies.

Modified from Alvarez-Elcoro S, Enzler MJ. The macrolides: erythromycin, clarithromycin, and azithromycin. *Mayo Clin Proc* 1999;74:613.

- c. Most strains of *H. influenzae* [3] are resistant to erythromycin [1], and thus it is not viewed as an alternative agent for this pathogen, although clarithromycin and azithromycin are considered active against respiratory isolates of *H. influenzae* [10].
 - d. **Enterobacteriaceae** such as *Escherichia coli* and *Klebsiella* species are resistant.
- C. Anaerobes. Erythromycin has activity against some species of gram-negative anaerobes, but *Bacteroides fragilis* strains and *Fusobacterium* species usually are resistant [9].**
- D. Nonbacterial pathogens**
1. **Mycoplasma. Erythromycin is active against *Mycoplasma pneumoniae* and is a drug of choice for this pathogen as well as the drug of choice for *Ureaplasma urealyticum* [10].**
 2. **Chlamydiae.** Erythromycin is active against *Chlamydia trachomatis* and *C. pneumoniae*.
 3. **Spirochetes.** Erythromycin is active against *Borrelia burgdorferi*, the causative agent of Lyme disease. Azithromycin and clarithromycin are alternative agents for this pathogen [10]. It also is active against *Treponema pallidum* but seldom is used for this purpose.
- II. Pharmacokinetics [1-4,9,11]**
- A. Oral absorption.** Erythromycin is acid labile. In the stomach, it rapidly decomposes to two inactive metabolites, one of which may contribute to gastrointestinal (GI) side effects. As a result of this instability and depending on the salt form, the rate of absorption may be unpredictable (35% ± 25%) [11]. Preparations for oral use have been synthesized with a goal of diminishing destruction by gastric acid and promoting better absorption [9].
1. Food in the stomach may decrease absorption of some forms.
 2. Average serum levels achieved by the available oral preparations are similar; therefore no single oral formulation of erythromycin offers a clear advantage in adults [9].
 3. In children, erythromycin estolate has better bioavailability than the ethylsuccinate [9].
 4. Four hours after an oral dose of 500 mg, peak serum concentrations are 1 to 2 μm/mL [1].
- B. Intravenous (i.v.).** Serum concentrations 1 hour after 500 mg to 1 g i.v. are approximately 10 to 15 μg/mL [1]. Erythromycin should not be administered intramuscularly. Intravenous preparations should be used to treat serious infections requiring erythromycin.
- C. Half-life and excretion.** The serum half-life of erythromycin is approximately 1 to 2 hours, and levels persist for approximately 6 hours [1,3]. Because erythromycin is excreted primarily in the bile, this fact must be considered in patients with liver disease. Dose reduction is not necessary in mild to moderate renal failure.
- D. Miscellaneous**
1. As a single agent, erythromycin provides **adequate middle-ear levels for penicillin-susceptible *S. pneumoniae* and *S. pyogenes***, but these levels probably are not adequate to eradicate *H. influenzae* consistently [9].
 2. **Erythromycin crosses the placenta**, but it is not known to be teratogenic. It is a category B agent (see Chapter 27A and section IV.F). It also is excreted into breast milk [1].
 3. **Synovial fluid.** Limited data from patients with septic arthritis suggest that erythromycin penetrates the synovial fluid poorly [9].
 4. **Brain tissue and cerebrospinal fluid (CSF).** Because of limited preparation, we would not use erythromycin in central nervous system infections.
- III. Indications for use**
- A. Erythromycin is considered a drug of choice [10] in the following infections:**
1. ***Mycoplasma pneumoniae* pneumonia.** Tetracycline can also be used, but erythromycin is nearly 50 times more potent than tetracycline against *M. pneumoniae* *in vitro* [9].

2. ***Chlamydia trachomatis* pneumonia**, in newborns. Erythromycin is also used for *C. trachomatis* conjunctivitis or pelvic infections, especially during pregnancy [9].
3. **Miscellaneous**. Erythromycin is also used in whooping cough, for both therapy and prophylaxis; *Campylobacter jejuni* infections; *Corynebacterium diphtheriae* infections or carrier states; *B. henselae*, the agent of bacillary angiomatosis [10,13]; and *Ureaplasma urealyticum* infections (e.g., urethritis).

B. Other indications

1. **Community-acquired pneumonia (CAP)**. Erythromycin, and especially azithromycin, have been commonly used in mild to moderate CAP, especially when it occurs in young to middle-aged adults. (See related discussions in Chapter 11 and under azithromycin later in this chapter.)
2. ***Legionella* infections**. Erythromycin was the first agent used. It has been replaced by azithromycin [10].
3. **Surgical prophylaxis, before elective GI procedures**. Oral erythromycin has been used with oral neomycin in (see Chapter 27B).
4. ***Lymphogranuloma venereum* and *C. trachomatis*** [12]. It is used in both of these infections (see Chapter 16).

C. Erythromycin is not recommended for the following:

1. **Meningitis or endocarditis**.
2. **For dental/oral procedures for infective endocarditis prophylaxis** because of GI intolerance and unpredictable blood levels (see Chapter 27B).

D. Erythromycin as an alternative in the penicillin-allergic for the following conditions:

1. **Group A streptococcal (GAS) pharyngitis** (see Chapter 8 [7]).
2. ***Streptococcus pneumoniae* pneumonia (penicillin-susceptible strains)** (see Chapter 11).
3. **Minor staphylococcal skin infections**. Resistance to erythromycin may develop with its use over time, and erythromycin alone is not advised for deep-seated staphylococcal infections [9].
4. **Rheumatic fever prophylaxis** [14].
5. **Miscellaneous**. Erythromycin has been used in early syphilis.

IV. Preparations available and dosage

A. Oral forms

Several oral preparations are available: erythromycin base, stearate salt, ethylsuccinate ester, and the estolate form. Although the blood levels achieved vary somewhat, when the agents are used against very sensitive organisms, these minor differences are not clinically significant [1]. Also, no one formulation causes substantially less GI upset than others [1]. (The newer macrolides have less GI intolerance.)

1. **Children**. Erythromycin estolate is more bioavailable than erythromycin ethylsuccinate [15]. It rarely causes hepatitis, and it appears to be better absorbed, better tolerated, and more effective than ethylsuccinate [15]. Absorption is not affected by food [9].
2. **Adults**. Erythromycin estolate is no longer recommended because of the associated incidence of **cholestatic hepatitis** [9].

B. Oral dosages

1. **Adults**. The dose is 250 to 500 mg every 6 hours. Higher doses cause intolerable GI symptoms.
2. **Children**. The usual dose is 30 to 50 mg/kg/day divided into every 6 hour doses. In infants younger than 4 months, 20 to 40 mg/kg/day divided into doses every 6 hours has been suggested. Erythromycin estolate and erythromycin ethylsuccinate are the most widely used preparations, because they are both tasteless and available in suspensions.

C. Parenteral forms of erythromycin are available (e.g., erythromycin lactobionate 1–4 g/day, divided every 6 hour doses) for more serious infections requiring higher blood levels or for inability to take oral medications. Intravenous use may be associated with **thrombophlebitis**. This may be avoided by dilution in at least 250 mL of fluid [9] and infusion over 40 to 60 minutes into a large peripheral vein or through a central venous line. For children, 50 mg/kg/day is recommended, divided every

- 6 hours. Avoid intramuscular use. Intravenous azithromycin, which can be given once daily, is preferred for patients more than 16 years of age (see later discussion).
- D. Topical.** Erythromycin gel or solution 1.5% or 2% applied twice daily for treatment of acne skin lesions. An ophthalmic ointment is used for bacterial conjunctivitis.
 - E. Renal failure.** In moderate renal failure, dose modification is not necessary [9,16]. With a creatinine clearance of 10 mL/min or less, **the drug may accumulate** and toxic side effects occur [1] (e.g., **transient hearing loss**) [3]. Therefore in severe renal failure, 50% to 75% of dose can be given at standard intervals [16]. **Erythromycin is not removed by peritoneal dialysis or hemodialysis [16].**
 - F. Pregnancy.** **Erythromycin estolate should not be used in pregnancy** (see section VI.A.3). Other erythromycin agents are safe in pregnancy; they are category B agents (see section II.D).
 - G. Nursing.** **Erythromycin is excreted in breast milk;** caution should be exercised when erythromycin is administered to a nursing woman.
 - H. Hepatic insufficiency.** Erythromycin is metabolized primarily by the liver. It should be avoided in patients with severe liver disease. If absolutely needed, **dosages should be reduced and serum levels should be monitored.**
 - I. Cost** (see Appendix Table 1)
- V. Toxicity and side effects.** Erythromycin is considered one of the least toxic commonly used antibiotics [1,3,9], but drug-drug interactions may occur.
- A. GI side effects.** With oral use, epigastric distress is common, **as is diarrhea, but** both can be diminished by taking the drug with meals. Symptoms often improve if the dose is reduced. GI symptoms can occur with oral and i.v. therapy [9]; a slow i.v. infusion (e.g., more than 60 minutes) may help to decrease the i.v. use associated nausea and vomiting, which may be seen more frequently in patients younger than 40 years [1].
 - 1. Newer macrolides.** Because of these GI side effects, the newer macrolides are often preferred, and of these azithromycin appears to have the fewest GI side effects (see later).
 - 2. Erythromycin in diabetic gastroparesis [17,18].** Although, the GI side effects are due to the GI motility-stimulating effect of the macrolides, erythromycin may have therapeutic value in this clinical entity.
 - 3. Infantile hypertrophic pyloric stenosis.** Recent data suggest an association between systemic erythromycin use in infants (especially those <2 weeks of age) and subsequent infantile hypertrophic pyloric stenosis. Therefore, erythromycin should be used with prudence in early infancy [19].
 - B. Allergic reactions.** **Rash, fever, and eosinophilia are uncommon, generally mild,** and occur in approximately 0.5% to 2.0% of treated patients; rashes are usually maculopapular but sometimes urticarial. Fixed drug eruptions, contact dermatitis, and anaphylaxis occur rarely. The risk appears to be higher in patients allergic to other antibiotics [20].
 - C. Cholestatic hepatitis** is rare and, although associated with the estolate preparation in adults, usually after approximately 10 days of use [1] occurs with other erythromycins.
 - D. Deafness,** which occurs most frequently in elderly patients with renal failure receiving a high-dose [9], usually reverses several days after decreasing or discontinuing erythromycin.
 - E. Clostridium difficile diarrhea** occurs rarely with the use of erythromycin [9].
 - F. Drug interactions**
 - 1. Erythromycin inhibits the metabolism** of numerous drugs presumably mediated by interfering with cytochrome P450 enzyme [1,3]. As a result, blood levels increase of theophylline, warfarin, carbamazepine, cyclosporine, triazolam, alfen-tanil, bromocriptine [3,9], and the “statins.” Macrolide antibiotics inhibit CYP3A4 enzyme systems.
 - a. Statins.** Erythromycin increases plasma concentrations of lovastatin, simvastatin, and atorvastatin. Because these interactions are sufficient to increase **the risk of myopathy and/or rhabdomyolysis,** the doses of these statins should be reduced by 50% during treatment with erythromycin or other macrolides [21]. Because pravastatin does not undergo CYP450 metabolism

and fluvastatin is metabolized by the CYP2C9 isoenzyme, statin-macrolide drug interactions do not occur with these statins, and no dosage modification is necessary when using macrolides with pravastatin or fluvastatin [21].

b. Theophylline. The dose should be reduced by 25% to 40% to compensate.

c. Carbamazepine doses may require a 50% reduction.

2. Digoxin. Erythromycin may improve digoxin absorption in some patients because it apparently inhibits one or more bacteria in the bowel that can break down some of the administered digoxin before it is absorbed [1].

3. Prolonged QT interval. Because erythromycin, especially i.v., may produce a long QT syndrome, erythromycin should probably be avoided in patients with a history of prolonged QT syndrome, especially drug induced [22]. Rarely, i.v. erythromycin has caused cardiac rhythm disturbances in premature infants [23].

4. Cisapride (Propulsid). Rare cases of serious cardiovascular adverse events—including torsade de pointes, other ventricular arrhythmias, and cardiac arrest—have occurred when these agents have been given concomitantly.

VI. Resistance to macrolides. This topic recently has been reviewed [24] and is beyond the scope of this chapter. However, a few clinical points deserve emphasis.

A. Cross-resistance. As previously stated, resistance to one macrolide implies cross-resistance to other macrolides [1,2,24].

B. GAS resistance to macrolides has occurred in the United States (see section **I.B.1** [6]).

C. Penicillin-resistant *S. pneumoniae*. In general, the higher the rate of penicillin resistance, the higher the rate of macrolide resistance. For example, only 4% of the penicillin-susceptible isolates were resistant to clarithromycin, but 34.8% and 60.1% of the penicillin intermediate and highly resistant strains, respectively, were macrolide resistant [2].

D. Country to country comparisons. Wide variations in the levels of resistance of certain pathogens to macrolides occur from country to country or within countries [24].

E. Stable susceptibility. Of interest, intracellular pathogens such as *Legionella*, *Chlamydia*, and *Mycoplasma* species are seldom resistant to macrolides [24].

CLARITHROMYCIN (BIAXIN)

Clarithromycin differs chemically from erythromycin by having an O-methyl substitution at position 6 of the macrolide ring. Its spectrum of activity is similar to that of erythromycin, except for enhanced *H. influenzae* activity and activity against atypical mycobacterium. It has better pharmacokinetics, including once and twice daily doses [25–27].

I. In vitro activity. This is similar to erythromycin except as noted later (Table 27N.1).

A. Aerobes

1. Gram-positive bacteria resistant to erythromycin are resistant to clarithromycin (e.g., MRSA, high level penicillin-resistant and many intermediate level *S. pneumoniae*).

2. Gram-negative bacteria

a. *H. influenzae*. Clarithromycin is more active *in vitro* than erythromycin, in part due to the additive effect of its active metabolite, 14-OH clarithromycin, which *in vitro* decreases the minimum inhibitory concentration against these organisms [1,3]. The clinical significance of this is unclear [3].

b. *M. catarrhalis* strains are susceptible.

c. Enterobacteriaceae. Clarithromycin is not an active agent against these pathogens.

B. Anaerobes. Clarithromycin activity like erythromycin [27] is only modest.

C. Miscellaneous

1. *M. pneumoniae*. Similar to that of erythromycin.

2. *H. pylori*. Clarithromycin is also active.

3. Mycobacteria. Clarithromycin is active against *M. avium* complex (MAC), *M. chelonae*, *M. chelonae abscessus*, and other atypical mycobacteria [1,3]. Clarithromycin is a drug of choice for MAC [28] and *H. pylori* and an alternative

for *S. pyogenes*, *M. catarrhalis*, *H. influenzae* (upper respiratory strains), and *B. burgdorferi* [10].

4. ***Ureaplasma urealyticum***. Clarithromycin is active.

II. Pharmacokinetics

A. **Absorption**. Clarithromycin is acid stable and well absorbed orally with an absolute bioavailability of about 50% [1,3]; its absorption is better and more reliable than erythromycin [1,2]. When taken with meals, bioavailability increases [26]. There is no i.v. preparation.

B. **Half-life**. The half-life of oral clarithromycin and its 14-OH metabolite is approximately 3 to 4 hours, which allows a twice daily dose schedule. An **extended release tablet** (Biaxin XL) is available, which allows a **once daily** schedule.

C. **Distribution**. Clarithromycin **penetrates tissue well**, including lung, kidney, liver, nasal mucosa, and tonsils [27], **but not into the CSF** of humans adequately. Clarithromycin and its OH metabolite penetrate middle-ear effusions adequately, with antibiotic concentrations exceeding the minimum inhibitory concentrations of the most susceptible otitis pathogens.

D. **Metabolism and elimination**. Clarithromycin is metabolized extensively in the liver by the hepatic cytochrome P450 enzyme system, and the excretion of clarithromycin and the 14-OH metabolite is by renal mechanisms [3] (see section **V.E**).

III. Indications for use in adults

A. Approved uses in adults

1. **Upper respiratory tract infections**. Clarithromycin has been used to treat (a) GAS pharyngitis, although penicillin is the agent of choice (see Chapter 8); (b) acute maxillary sinusitis (see Chapter 8); (c) acute exacerbation of chronic bronchitis (see Chapter 8); and (d) mild CAP, especially in the young to middle-aged adult (see Chapter 11).

2. **MAC**. Clarithromycin has been useful in the prevention and treatment of MAC infections in patients with acquired immunodeficiency syndrome (AIDS). This topic is reviewed in detail elsewhere [1,3,10,28–30].

3. ***H. pylori*** has been effectively treated with clarithromycin and omeprazole [1,3,10,31].

4. ***S. pyogenes* or *S. aureus*** susceptible uncomplicated skin and skin structure infections [26]. More conventional therapy such as erythromycin, dicloxacillin, or oral first-generation cephalosporins may be more cost effective. In the penicillin-allergic patient or the patient who has GI side effects from erythromycin, clarithromycin provides a useful alternative but azithromycin may be even better tolerated.

B. Approved uses in children [32–35]

1. **Pharyngitis, tonsillitis, acute maxillary sinusitis, or mild CAP** (due to mycoplasma, susceptible *S. pneumoniae*, or *C. pneumoniae*).

2. **Skin and soft tissue infections**, when the susceptibilities are known.

3. **Otitis media**. Clinical trials in the treatment of otitis media have shown similar efficacy for clarithromycin, amoxicillin, amoxicillin-clavulanate, and cefaclor.

C. **Rapidly growing atypical mycobacterial infections, Lyme disease, or toxoplasmosis**. Investigation is ongoing [1,3,36]. Clarithromycin is listed as an agent for Lyme disease [10].

IV. Dosages. Administer with or without meals.

A. **Adult dosages**. A dose of 250 to 500 mg twice daily is used depending on the severity of infection. The Biaxin XL film tablets are available in 500 mg, and two tablets are given once daily with food for acute maxillary sinusitis and for 7 days for acute exacerbation of chronic bronchitis.

B. **Pediatric dosage**. For children 6 months of age or older, 15 mg/kg/day divided every 12 hours for 10 days is recommended. Suspensions are available with 125 mg/5 mL and 250 mg/5 mL.

C. **Renal failure**. When the creatinine clearance is 10 to 50 mL/min, 75% of the usual dose is suggested. If creatinine clearance is less than 10 mL, use 50% to 75% of the usual dose [16]. **After hemodialysis**, some sources suggest a dose, although data are limited. **In chronic ambulatory peritoneal dialysis**, no dose adjustments are necessary [16].

- D. Hepatic failure.** No dose adjustments. There is an increase in renal clearance [9].
- E. Pregnancy.** Clarithromycin is a category C drug (i.e., used only if there is no alternative) (see Chapter 16). Clarithromycin has demonstrated adverse effects on pregnancy and embryo fetal development in animals. High doses of clarithromycin have caused cardiovascular anomalies in rats, cleft palates in mice, and fetal growth retardation in monkeys [37]. There are no adequate and well-controlled studies in pregnant women. Clarithromycin should be used in pregnancy only if the potential benefit justifies the potential risk to the fetus. **If pregnancy occurs while on this drug, the patient should be apprised of the risks.**
- F. Nursing mothers.** The package insert notes that it is not known whether clarithromycin is excreted in human breast milk, and caution should be exercised when administering clarithromycin to a nursing mother because clarithromycin is excreted in the milk of lactating animals and other drugs of this class are excreted in human milk.
- V. Toxicity and side effects.** Clarithromycin is relatively nontoxic [3,38].
- A. GI.** Occasionally, clarithromycin in standard doses causes nausea, diarrhea, abdominal pain, and metallic taste [3] but fewer GI side effects than erythromycin [39].
- B. Hepatic, renal, or hematologic.** No significant toxicity appears to occur [38] with clarithromycin. Minor hepatic enzyme elevations can occur. In fewer than 1% of recipients, leukopenia and prothrombin time prolongation have been noted.
- C. Headache** may occur in up to 2% of recipients [38].
- D. High-dose regimens.** For therapy of MAC in AIDS patients or of atypical mycobacterial infections in the elderly, more adverse reactions, (nausea, vomiting, metallic taste, abnormal liver function blood tests, and central nervous system side effects) may occur [3].
- E. Drug interactions [1,3].** As with erythromycin, drug interactions with clarithromycin are extremely important [3].
- 1. Hepatic P450 system** Because clarithromycin inhibits **the hepatic P450 system**, it may result in increased levels of multiple medications metabolized by the liver [3].
 - a. Carbamazepine.** Concomitant administration of clarithromycin and carbamazepine causes a major change in carbamazepine levels.
 - b. Caffeine, nicotine, and midazolam,** as well as other potential interactions, including those discussed in section **V.F** under erythromycin, above [3].
 - 2. Antiretrovirals.** Clarithromycin lowers zidovudine levels. Similar interactions occur with other antiretroviral agents [3] (see Chapter 19).
- F. Cost.** Oral clarithromycin is a relatively expensive agent (see Appendix Table 1).

AZITHROMYCIN (ZITHROMAX)

Azithromycin was approved in 1991 and developed to overcome the shortcomings of erythromycin such as GI intolerance, low bioavailability, and somewhat limited spectrum of activity [1,3]. It is an azalide antibiotic. Its nuclear structure differs from that of erythromycin in that the lactone ring contains a nitrogen atom. This molecular rearrangement has resulted in a compound with remarkable and **unique properties** [40], including high and sustained tissue antibiotic levels, which are much greater than the serum antibiotic levels. It has a prolonged tissue half-life, decreasing the doses per course of therapy and duration of therapy [1,3]. It also has an expanded *in vitro* spectrum of activity. Azithromycin inhibits protein synthesis, in a similar manner to erythromycin.

- I. Spectrum of activity.** The broad-spectrum *in vitro* activity of azithromycin is summarized in Table 27N.1. If erythromycin is active against pathogens, azithromycin is also, but azithromycin is also more active against some organisms (e.g., *H. influenzae*).
- A. Gram-positive aerobes.** Azithromycin is active against erythromycin-susceptible *S. aureus* (approximately 80% of strains), *S. pyogenes*, many *S. pneumoniae*, *S. agalactiae*, and coagulase-negative staphylococci, but overall erythromycin and clarithromycin are more active against these gram-positive cocci. Enterococci usually are resistant [26]. Strains of these organisms resistant to erythromycin will be resistant to azithromycin, including many intermediate and most high level

penicillin-resistant *S. pneumoniae* (see Chapters 11 and 27C). MRSA strains are resistant to erythromycin and azithromycin. In addition, azithromycin is two- to eightfold **less active than erythromycin against staphylococci and streptococci** [37].

- B. Gram-negative aerobes.** Most gram-negative bacteria are intrinsically resistant to the macrolides because of the inability of the macrolide to penetrate the outer cell membrane effectively. Azithromycin appears to be able to penetrate the outer membrane better than erythromycin and therefore has activity against some gram-negative organisms normally resistant to erythromycin [41].
- 1. *H. influenzae*, *M. catarrhalis* and *Neisseria* species** Azithromycin is severalfold more active against *H. influenzae* than is erythromycin or clarithromycin. It is also more active than erythromycin against *M. catarrhalis* and *Neisseria* species.
 - 2. Enterobacteriaceae.** Azithromycin is not active against *E. coli*, *Klebsiella* species.
 - 3. Nonfermenters such as *Pseudomonas* species, [42].** It is not active.
 - 4. *H. pylori*.** Azithromycin is active against *H. pylori*, although not listed as an alternative agent for these infections [10].
 - 5. Gastroenteritis pathogens.** It is active against *Shigella* species and *C. jejuni* [10] **but not *Salmonella*.**
- C. Anaerobes.** Azithromycin inhibits some anaerobes similar to erythromycin but is not useful against bowel anaerobes [10].
- D. Miscellaneous**
- 1. *Legionella* species [3].** Azithromycin is the most active macrolide against *Legionella* species. (The fluoroquinolones and azithromycin are viewed as the agents of choice for *Legionella* infections [10].) See Chapter 11.
 - 2. Most *B. burgdorferi* strains** are inhibited by 0.015 $\mu\text{g/mL}$, suggesting azithromycin is more active *in vitro* than erythromycin or clarithromycin [26].
 - 3. *Mycoplasma pneumoniae*** is very susceptible at 0.25 $\mu\text{g/mL}$ [26], as are *C. pneumoniae* [43].
 - 4. Sexually transmitted pathogens.** *C. trachomatis*, *U. urealyticum*, *N. gonorrhoeae*, and *T. pallidum* are susceptible to azithromycin [3].
 - 5. Atypical mycobacterium** are overall more susceptible to clarithromycin than azithromycin or erythromycin [3].
 - 6. *Babesia microti* [44].** Azithromycin is active against this agent.
 - 7. *Chlamydia pneumonia* and coronary arteries.** This is undergoing intense investigation [45].
- E. Resistance.** Resistance to erythromycin implies cross-resistance with azithromycin [26,42]. See related discussion under Erythromycin, section VI.
- II. Pharmacokinetics.** For adults, **both an oral and i.v. formulation are available** (see section IV). For children less than 16 years of age, only the oral formulation is approved as of mid-2002.

Compared with other available antimicrobial agents, azithromycin has unique pharmacokinetic properties. It yields high and sustained tissue levels in excess of serum levels. This involves active movement from the serum into the intracellular sites. Therefore for tissue infections azithromycin can provide excellent antibiotic levels.

- A. Absorption.** Azithromycin is more stable than erythromycin at various pH ranges seen in the stomach, and approximately 37% of a single capsule dose is absorbed, compared with 25% absorption of erythromycin [46]. Although adsorption of the capsular formation of azithromycin was decreased in the presence of food, the new tablet formation is equally absorbed in the fasting or fed state [3].
- B. Tissue kinetics [27,46].** The unique pharmacokinetic profile of azithromycin reflects a rapid and extensive uptake from the circulation into intracellular compartments followed by slow release [3].
- 1. Serum levels** are lower than those of erythromycin or clarithromycin [1,3].
 - 2. Tissue levels.** Azithromycin penetrates tissues rapidly and extensively to yield very high steady-state tissue concentrations that exceed serum levels by 10- to 100-fold [1,3] (e.g., lung [100-fold], sputum [30-fold], cervix [70-fold], and skin [35-fold]) [3].

3. **Intracellular accumulation.** Azithromycin is rapidly and highly concentrated in a number of cell types, including polymorphonuclear leukocytes, monocytes, alveolar macrophages, and fibroblasts [46].
 - a. **Polymorphonuclear leukocyte function** is not affected by antibiotic uptake [46]. By migrating to sites of infection, these polymorphonuclear leukocytes may play a role in the transport of azithromycin to the actual site of infection. **Azithromycin is released spontaneously and slowly from phagocytes (and fibroblasts).**
 - b. **Tissue concentrations** do not peak until 48 hours after administration and persist for several days afterward [41].
 4. **Half-life.** The average tissue half-life is between 2 and 4 days.
 5. **Tissue persistence.** With recommended dosages daily for 5 days, therapeutic concentrations of azithromycin persist at the tissue level for 5 days or more after the completion of therapy.
 6. **Aqueous humor or CSF.** Very little or none of the drug is detectable in aqueous humor or CSF, although azithromycin is widely distributed in brain tissue [3].
- C. Metabolism and excretion [1,3]
1. **Eliminated unchanged.** Most of the absorbed dose of azithromycin is eliminated unchanged principally in the feces [3]. **Urinary excretion** of the unchanged drug is **minor**.
 2. **Liver disease.** No dosage modification is necessary for patients with class A or B cirrhosis [3].

III. Indications for use

A. Approved uses in adults

1. **CAP** due to *S. pneumoniae*, *Mycoplasma*, *H. influenzae*, and *C. pneumonia*. Mild to moderate CAP is commonly treated with oral regimens of azithromycin in young to middle-aged adults. For hospitalized patients, the i.v. formulation, approved for *S. pneumonia*, *M. pneumoniae*, *M. catarrhalis*, *S. aureus*, and *L. pneumophilia*, is used initially (see related discussions in Chapter 11). **N.B. For very ill hospitalized patients, because azithromycin often is not active against high level penicillin-resistant *S. pneumoniae* and many intermediate level resistant strains, monotherapy with azithromycin is not advised** (see Chapter 11).
2. **Acute exacerbation of chronic bronchitis** has successfully been treated with azithromycin, which is active against common pathogens, including most *S. pneumoniae*, *M. catarrhalis*, and *H. influenzae* (see related discussions in Chapter 8).
3. **Pharyngitis/tonsillitis due to GAS.** Azithromycin is an alternative to first-line therapy (i.e., penicillin) for the allergic [1,3]. Erythromycin-resistant strains of GAS will be resistant to azithromycin. (Of note, the package insert suggests susceptibility tests with azithromycin for GAS should be performed in this setting.) This topic is discussed in detail in Chapter 8. When compliance is a major concern, one dose daily for 5 days may be useful. Other alternative regimens are less expensive (see Chapter 27A, Tables 27A.2 and 27A.3).

Data establishing the **efficacy of azithromycin in the prevention of subsequent rheumatic fever** are not available [3]. Overall, we believe that azithromycin will have a very limited role in this setting [1].

4. **Methicillin-susceptible *S. aureus*, GAS, or group B streptococci** uncomplicated skin and soft tissue infections. Similar efficacy is achieved with 5 days of azithromycin or 10 days of cephalexin [26].
5. **Sexually transmitted disease [12] (see Chapter 16)**
 - a. **Urethritis and cervicitis** due to *C. trachomatis* can be treated with azithromycin. For *N. gonorrhoeae*, other agents are preferred.
 - b. ***H. ducreyi*** (chancroid) genital ulcer disease has been treated with azithromycin.
 - c. **Pelvic inflammatory disease** due to *N. gonorrhoeae*, *C. trachomatis*, and *M. hominis* have been treated initially with the i.v. formulation. (i.v. azithromycin 500 mg for 1 or 2 days followed by 250 mg orally daily to complete a 7-day course). If anaerobic microorganisms are suspected, an antianaerobic

agent (e.g., metronidazole) is added [3]. However, experience with this regimen compared with other Centers for Disease Control and Prevention regimens for pelvic inflammatory disease is summarized in Chapter 16 [12].

6. **Pharyngitis and tonsillitis (see discussion in section B.3 below).**
7. **Currently unapproved uses (as of early 2002).** Conventional uses of azithromycin include the following; the clinical studies supporting the use of azithromycin in these settings are reviewed elsewhere [3].
 - a. **Sinusitis**, especially acute maxillary [26].
 - b. **For MAC.** Azithromycin (1,200 mg once per week) is effective in preventing the first episode of MAC in AIDS patients at risk (i.e., CD4 count $<50 \mu\text{L}$). Because azithromycin does not have major drug interactions, it is preferred over clarithromycin [3,30]. For therapy of **established disseminated MAC in AIDS patients**, studies suggest that combination regimens including clarithromycin convert blood cultures to negative more quickly and more often than azithromycin-containing regimens [3].
 - c. **Infective endocarditis prophylaxis.** Either clarithromycin or azithromycin is an alternative in patients allergic to penicillin and who require antibiotic prophylaxis before oral, dental, esophageal, or respiratory procedures [3] (see Chapter 12).
8. For investigational uses, see section C.
- B. **Approved uses in children.** The oral suspension for pediatric use was approved by the U.S. Food and Drug Administration in 1995; it is approved for children more than 6 months of age. The i.v. preparation of azithromycin is approved, per the package insert, for children more than 16 years of age.
 1. **Acute otitis media** caused by *S. pneumoniae*, *H. influenzae*, or *M. catarrhalis* (see Chapter 8).
 2. **Mild CAP** due to *S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, and *H. influenzae*.
N.B. Even the package insert emphasizes that **azithromycin should not be used in moderate to severe pneumonia or in children with risk factors such as cystic fibrosis, nosocomial pneumonia, known or suspected bacteremia, immunodeficiency, or illness sufficiently severe to require hospitalization.**
 3. **Pharyngitis/tonsillitis** due to GAS infection as an alternative when first-line therapy cannot be used (see related discussion section III.A.4).
- C. **Investigational uses** have recently been reviewed [3,36].
 1. **Lyme disease (*B. burgdorferi*)** in which azithromycin is listed as an alternative agent [10], although its precise role remains to be established [3].
 2. ***Shigella* infections.** Azithromycin has been shown to be very active *in vitro* against *Shigella* species and is a potential alternative agent [10].
 3. ***H. pylori*.** The role of azithromycin for the treatment of this pathogen remains to be determined; it is not approved [3] or recommended [10] even though clarithromycin is useful for *H. pylori* eradication (see section III.A.3 under Clarithromycin).
 4. ***Bartonella* infections (e.g., bacillary angiomatosis, cat scratch):** azithromycin is listed as an alternate agent [10].
 5. **Secondary prevention antibiotic treatment trials for coronary artery disease (CAD).** There is considerable interest in the potential causative role of *C. pneumoniae* in CAD and the prevention of this with antibiotics. Because azithromycin is active against this pathogen and penetrates tissue well, there are two large CAD treatment trials underway to see if azithromycin can help reduce cardiac events in chronic CAD. Results are not expected until late 2003 [43].
 6. **Miscellaneous areas of clinical investigation** [3] include the use of azithromycin in malaria prophylaxis, toxoplasmosis therapy, *Babesia microti* infection, and trachoma therapy.
 7. **Babesiosis.** A recent report indicates a regimen of atovaquone and azithromycin is as effective as a regimen of clindamycin and quinine and is associated with fewer adverse reactions [44].

Table 27N.2. Dosages of Azithromycin

	Setting	Dose/Route	Duration
Adults	CAP (community-acquired pneumonia)	i.v. 500 mg 1–3 days ^a then p.o. 250 mg qd	Usually 5 days total
	<i>Legionellosis</i>	i.v. 500 mg 1–7 days ^b	Usually 7 days
	Acute bronchitis	Z pack	5 days total
	Pharyngitis	Z pack	5 days total
	Uncomplicated skin infections	Z pack	5 days total
	STDs		
	Urethritis	1 g p.o.	Once only. See text and Chapter 10.
	Cervicitis	1 g p.o.	Once only. See text and Chapter 10.
	Chancroid	1 g p.o.	Once only. See Chapter 10.
	PID	See text	
	Sinusitis	Z pack	
	MAC Prevention	1,200 mg once weekly	While CD4 counts depressed (<50 cells/UL)
Therapy	Infectious disease consult suggested		
SBE prophylaxis	See Chapter 15		
Children (over 6 mo)	Acute otitis media (AOM)	10 mg/kg day 1 followed by 5 mg/kg on days 2–5	5 days
	Mild CAP	Same as AOM	5 days
	Pharyngitis	12 mg/kg day 1–5 (not to exceed 500 mg daily) ^c	5 days

^aFor mild, early CAP, a standard Z pack is often used. See text.

^bPrecise guidelines not available. For moderate to severe cases, i.v. and/or oral therapy for 7 days presumably provides 21 days of tissue levels and therefore a 7-day course seems prudent. For patients doing very well, i.v. may be converted to oral, 250–500 mg qd, to complete 7-day course.

^cFailures at 10 mg/kg daily for 5 days have been reported. Therefore a higher dose is suggested. Penicillin is the preferred agent. See Chapter 8.

STDs, sexually transmitted diseases; MAC, *Mycobacterium arium* complex; SBE, subacute bacterial endocarditis.

IV. Dosages

A. See Table 27N.2

- Azithromycin** is available as a 250-mg tablet (or capsule) commonly distributed in a “Z pack” containing six tablets for a standard 5-day regimen in adults (two tablets [500 mg] day 1 and then one 250-mg tablet daily on days 2–5). Tablets can be taken with or without food. Capsules should not be taken with food.
- The flavored oral suspension** comes in 100 mg/5 mL and 200 mg/5 mL. The suspension should be given 1 hour before or 1 hour after meals.
- For MAC prophylaxis**, 600-mg tablets are available.
- Nongonococcal urethritis**. A 1-g oral suspension single dose packet is also available and should be taken in the fasting state.

- 5. Intravenous azithromycin.** A dose of 500 mg i.v. once daily is infused over at least 60 minutes in patients 16 years of age and older [47].
- B. Pregnancy.** Azithromycin is a category B agent (i.e., used only if clearly needed) (see Chapter 27A). It does not produce abnormalities in pregnant animals.
 - C. Nursing mothers.** The package insert indicates that it is not known whether azithromycin is excreted in human breast milk and that caution should be exercised when azithromycin is administered to a nursing woman. However, it should be presumed that azithromycin is in human breast milk because it is present in the milk of lactating animals and because other macrolides are excreted into human breast milk [26].
 - D. Renal failure.** No dosage adjustments are necessary in renal failure, including situations in which patients are on hemodialysis or chronic ambulatory peritoneal dialysis [16].
 - E. Erythromycin allergy.** In the rare patient who has a history of a severe allergic reaction to erythromycin, until further data are available azithromycin should be avoided.
 - F. Drug interactions** have been reviewed in detail elsewhere [48]. Human clinical and pharmacokinetic studies have shown no major drug-drug interactions between azithromycin and numerous other agents, including carbamazepine, theophylline, midazolam, terfenadine, zidovudine, or cimetidine [3]. This is a distinct advantage of azithromycin over erythromycin and clarithromycin. **Coadministration of antacids does not affect absorption of azithromycin [3].**
 - G. Limitation.** Because azithromycin typically produces low serum levels, we believe this precludes its use as a potential alternative agent in the allergic prone patient with endocarditis, although little data exist on this topic.
- V. Toxicity and side effects.** Initial studies in about 4,000 adults and 2,000 children indicate this is a very well-tolerated agent [27,49], and continued extensive clinical experience supports this.
- A. GI complaints** are far less common than erythromycin and less so than clarithromycin. Diarrhea, nausea, and mild abdominal discomfort can occur, more so with higher doses.
 - B. Central nervous system.** Mild headache and dizziness can occur.
 - C. Ototoxicity, severe liver toxicity, or nephrotoxicity** do not seem to occur with conventional dosing [49]. In high-dose regimens (e.g., for therapy of atypical mycobacterium), reversible dose-related hearing loss has been described [1].
 - D. Rash** appears to be uncommon.
- VI. Cost** (see Appendix Table 1)
- A. Although a typical Z pack** (actual wholesale price) is about \$37, this is often competitive and at times less expensive than other conventional regimens. Also, the convenience of once daily doses for only 5 days enhances compliance and satisfaction.
 - B. Intravenous azithromycin**, 500 mg daily, costs about \$24 per day. This is about as much as i.v. generic erythromycin drug acquisition costs per day (i.e., for four 500-mg doses), but it is more cost-effective to give i.v. azithromycin daily versus the every 6 hour regimen for erythromycin.
- VII. An overview of the macrolides**
- A. For i.v. use.** Because there is no i.v. clarithromycin and because i.v. azithromycin is more cost effective and lacks the drug interactions seen with erythromycin, **we favor i.v. azithromycin** when i.v. therapy is used in patients older than age 16.
 - B. Oral macrolide therapy**
 1. Generic oral erythromycin is still the most cost-effective regimen **and 250 mg four times a day for 10 days (average wholesale price) is about \$7.25 versus the \$37 (average wholesale price) of the azithromycin Z pack.** However, the GI side effects of erythromycin, four times a day dosing schedule often for 10 to 14 days, and drug interactions must be balanced with the ease and fewer side effects of azithromycin.
 2. **Azithromycin is preferred** to maximize compliance and/or minimize GI side effects and/or minimize drug interactions. **Azithromycin can be used in pregnant women.**

- 3. Clarithromycin** can be given twice daily but still requires conventional durations of therapy and has the potential of multiple drug interactions. It must be avoided in pregnancy, if possible. It is the macrolide of choice for *H. pylori* eradication regimens and for combination therapy of MAC bacteremia in AIDS patients (see prior discussions).

O. Tetracyclines

Discovered more than 50 years ago, the tetracyclines remain one of the most widely prescribed antibiotic classes in the United States, especially by office-based physicians [1,2]. **Bacteriostatic** tetracyclines act by interfering with protein synthesis at the ribosomal level. The superior pharmacokinetic properties, enhanced compliance, lesser toxicity, and reasonable cost of doxycycline make it the tetracycline of choice (see section **II**).

I. Spectrum of activity

A. Tetracyclines, especially doxycycline, are active against a wide variety of pathogens [1–14] (Table 27O.1).

1. Community-acquired respiratory tract pathogens, including *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Mycoplasma*, *Legionella*, and *Chlamydia*

Table 27O.1. Broad-spectrum Activity of Tetracyclines [13,14]

Table 270.2. Commonly Used Oral Tetracyclines in Adults

Name	Usual Capsule Dose (mg)	Usual Interval Between Doses (h)	Usual Total Daily Dose (mg) (See Text)	Approximate Cost (Dollars) for 10 Days ^a
Short acting Tetracycline hydrochloride ^b	250–500	6 (without food) ^c	1,000–2,000	2.50–5.00
Long acting Doxycycline hyclate ^d	100	12–24 (with or without food)	200	\$14.00 (generic form 100 mg bid)
Minocycline ^e	100	12 (with or without food)	200	—

^a Approximate actual wholesale price in 2000.

^b Trade names include Achromycin, Panmycin, Sumycin, Tetracyn.

^c No food in preceding 2 h.

^d Trade names include Vibramycin, Doroyx, Doxycin.

^e Trade name is Minocin.

species [4] and penicillin-susceptible *Streptococcus pneumoniae* (see section 3 below).

2. Although any of the available agents (Table 270.2) can often be used, against some organisms doxycycline and minocycline are the more potent [2].

a. **Doxycycline** is more active against the following:

- (1) *S. pneumoniae* [4,5], including most intermediate penicillin-resistant strains. Strains resistant to tetracycline are often susceptible to doxycycline [5].
- (2) *M. fortuitum* and *M. chelonae* [2].

b. **Minocycline** is more active against

- (1) *S. aureus*, including many strains of methicillin-resistant *S. aureus* and coagulase-negative staphylococci [2].
- (2) *M. marinum* [2].

B. Tetracyclines are not reliably active against *Neisseria gonorrhoeae* or *Bacteroides fragilis*. They are active against parasites such as *E. histolytica* and *Plasmodium falciparum* [6].

II. **Pharmacokinetics.** Oral tetracyclines are used for most infections except for treatment of pelvic inflammatory disease (PID) (see Chapter 16), where the intravenous route is often used.

A. **Gastrointestinal (GI) absorption.** These agents are incompletely absorbed from the GI tract. Absorption is impaired by milk, aluminum hydroxide, calcium, magnesium (e.g., in antacids), or iron preparations. The tetracyclines combine with the metallic ion calcium or magnesium, forming inactive chelates. Absorption is improved, even with the better adsorbed doxycycline, if the antibiotic is taken 1 hour before or 2 hours after meals [2].

B. **Blood levels.** Following the above, therapeutic blood levels are achieved. The twice daily dosing of doxycycline improves compliance (Table 270.2).

1. **Short-acting agents.** **Tetracycline** is preferred over oxytetracycline and is cost effective.

2. **Long-acting agents** can be given once or twice daily.

a. **Doxycycline** half-life (15–18 hours), permits dosing every 12 to 24 hours, improving compliance.

b. **Minocycline** has a similar half-life.

c. Both are dosed at 200 mg and then 100 mg once or twice daily.

C. **Distribution.** The tetracyclines diffuse reasonably well into sputum, urine, and peritoneal and pleural fluids. Levels in synovial fluid and sinuses approach serum

concentrations. Because of its lipophilic properties, doxycycline yields higher concentrations in the brain and cerebrospinal fluid than other tetracyclines. This supports its use for oral therapy for Lyme disease [7].

D. Excretion. Tetracyclines are excreted via **the urine** except for doxycycline, which is excreted (90%) in the feces. **Hepatic failure** does not lead to elevated serum levels of the tetracyclines. However, these drugs have been noted to cause hepatotoxicity.

E. Drug interactions [2]

1. **Anticonvulsants** (e.g., carbamazepine, barbiturates, phenytoin) induce hepatic microsomal metabolism of tetracyclines, decreasing tetracycline serum concentrations.
2. **Cholestyramine and colestipol** can reduce GI absorption of tetracycline.
3. **Warfarin anticoagulation** may be potentiated by tetracyclines. Prothrombin time should be monitored.
4. **Oral contraceptive** efficacy may be decreased with concurrent use of tetracyclines.

III. Indications for use. Because of their broad-spectrum nature (Table 270.1), these agents are useful in several settings [1,2,7,8] (Table 270.3).

IV. Contraindications to use [1,2]

A. Pregnancy and lactation. Tetracyclines (including doxycycline) are **category D** agents (see Chapter 27A). Tetracycline may cause hepatotoxicity in pregnant women. Furthermore, it is transferred across the placenta and has caused **dental deformities and dental discoloration in children** whose mothers received tetracycline while pregnant. Tetracycline is excreted in breast milk. Therefore, the **tetracyclines should be avoided by pregnant or lactating women.**

B. Children less than 8 years old. Except in patients with Rocky Mountain spotted fever or ehrlichiosis, tetracycline should be given only when there is no alternative [1].

V. Dosages. The doxycycline twice daily dosing improves compliance. Doxycycline is usually preferred [1,2] unless minocycline is needed for its unique susceptibility profile (see section I.A).

A. Route. Generic tetracycline or doxycycline usually is given **orally** as capsules or tablets, but liquid forms are available. Oral preparations should be taken **while fasting.**

B. Dosage regimens

1. **Oral.** The common oral preparations available are shown in Table 270.2.

a. Tetracycline

- (1) **In adults**, 250 to 500 mg as the hydrochloride every 6 hours, or four times a day, can be used.
- (2) **In children more than 8 years of age**, 20 to 40 mg/kg/day is divided into every 6 hour doses.

b. Doxycycline

- (1) **In adults**, start with 200 mg initially or 100 mg every 12 hours and then 100 mg every 12 to 24 hours, depending on the severity of the infection. **Oral drug has the same bioavailability as does intravenous [8].**
- (2) **In children older than 8 years of age** who weigh less than 45 kg, 4.4 mg/kg is given on the first day, divided into two doses given at 12-hour intervals, followed by 2.2 mg/kg/day as a single dose or divided into every 12 hour doses. Adult regimens can be used for children weighing more than 45 kg.

c. Minocycline is used as an **alternative therapy** for *Nocardia* or methicillin-resistant *S. aureus*. Infectious disease consultation is advised. If renal function is normal, 100 mg twice daily has been used in adults.

d. In renal failure, doxycycline is preferred. Neither **peritoneal dialysis** nor **hemodialysis** alters the half-life of doxycycline. Dosage changes are not needed in renal failure or post-dialysis [9].

2. **Parenteral (tetracycline hydrochloride** is no longer commercially available).

a. Doxycycline is used intravenously in selected patients in PID regimens, in Lyme disease, and occasionally in other settings. Because of pain associated

Table 270.3. Major Clinical Conditions for Which Tetracyclines May be Used^a

Respiratory infections
Community-acquired pneumonia in an outpatient setting
Atypical pneumonia (<i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i> , psittacosis)
Acute exacerbation of chronic bronchitis
Legionellosis ^b
Genital infections
<i>Chlamydia trachomatis</i> (nongonococcal urethritis, pelvic inflammatory disease, epididymitis, prostatitis, lymphogranuloma venereum)
Granuloma inguinale ^b
Syphilis ^b
Systemic infections
Rickettsiae (Rocky Mountain spotted fever, endemic and epidemic typhus, Q fever)
Brucellosis in combination with rifampin (or streptomycin)
Lyme borreliosis
Ehrlichiosis
Relapsing fever (<i>Borrelia recurrentis</i>)
<i>Vibrio</i> (cholera, <i>V. vulnificus</i>, and <i>V. parahaemolyticus</i>)
Tularemia ^b
Bacillary angiomatosis (bartonellosis) ^b
Leptospirosis ^b
Other (local and systemic) infections
Methicillin-resistant <i>Staphylococcus aureus</i> and <i>S. epidermidis</i> ^b (minocycline) when vancomycin or other agents are not considered appropriate
<i>Pasteurella multocida</i> ^b
<i>Mycobacterium marinum</i> ^b
<i>Helicobacter pylori</i> (in combination with bismuth subsalicylate and metronidazole or clarithromycin)
<i>Yersinia pestis</i> (combined with streptomycin)
Other conditions
Acne vulgaris
Malaria [8]
Prophylaxis of mefloquine resistant <i>Plasmodium falciparum</i> malaria [8]
Therapy of certain forms of malaria

^a Tetracyclines are a drug of choice for the infections that are in **boldface**.

^b Infections for which a tetracycline is an acceptable alternative to standard agents.

Modified from Smilack JD. The tetracyclines. *Mayo Clin Proc* 1999;74:727, with permission.

with intravenous infusion, doxycycline should be administered orally when possible even when the patient is hospitalized. For adults and for children older than 8 years weighing more than 45 kg, 200 mg day 1 is given in one or two divided infusions, followed by 200 mg every 24 hours or 100 mg every 12 hours. In children older than 8 years who weigh less than 45 kg, 4.4 mg/kg is given on day 1 in two divided doses at 12-hour intervals and then 2.2 mg/kg/day once daily subsequently. **In PID regimens**, oral doxycycline 100 mg twice daily is often used to complete a 14-day course [10]. However, its continued use is under question because of lower efficacy [11] (see Chapter 16). Nonetheless, data from a recent study indicate no difference in reproductive outcome between women randomized to inpatient or outpatient treatment [11].

VI. Toxicity and side effects [1,2]

A. Teeth and bone. Tetracycline can cause depression of bone growth, permanent gray-brown discoloration of the teeth, and enamel hypoplasia when given during tooth

development. However, more than a single course seems to be required to produce this effect.

- B. Hypersensitivity** reactions such as anaphylaxis, urticaria, and rashes are uncommon. **Toxic photosensitivity reactions** consisting of a red rash on areas exposed to intense sunlight can occur with all tetracyclines. Patients receiving doxycycline, especially high doses, should avoid intense sun exposure or use sunscreens with a protection factor of 18 or above.
- C. GI effects** are usually minor. Epigastric distress and nausea can occur after oral administration, and these symptoms are somewhat dose related. Esophageal ulcerations can occur with doxycycline. To minimize this, give oral doses with adequate amounts of fluid.
- D. Accentuated prerenal azotemia.** Tetracyclines appear to aggravate preexisting renal failure by inhibiting protein synthesis.
- E. Benign intracranial hypertension.** This rare entity is seen in women on tetracycline.
- F. Hepatitis** occurs after high intravenous doses or in pregnant women as acute fatty necrosis.
- G. Skin pigmentation changes and blue-black oral pigmentation** changes can occur with prolonged minocycline use.
- H. Thrombophlebitis** can occur with intravenous use.
- I. Vestibular** side effects, including dizziness, ataxia, and vertigo, can occur with minocycline.
- J. Superinfections with candida** of the oral and anogenital region occurs.

P. Vancomycin, Quinupristin/Dalfopristin, and Linezolid

With the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA) (see Chapters 4 and 12) and penicillin-resistant *S. pneumoniae* (see Chapter 11), vancomycin has become an extremely important agent [1–3]. Because of clinicians' concern about the above organisms, vancomycin is used very frequently when the need may not really exist. This excessive use has contributed to the emergence of vancomycin-resistant *Enterococcus faecium* (VREF), vancomycin, (glycopeptide) intermediate *S. aureus* (GISA) and now even vancomycin completely resistant *S. aureus* (see section II). **Prudent use of vancomycin is essential to preserve the effectiveness of this important antibiotic.**

I. Spectrum of activity. Vancomycin is active **only** against **gram-positive bacteria**, particularly aerobes. There is no cross-resistance between vancomycin and penicillin [1].

A. Gram-positive bacteria. Except for enterococci and MRSA, vancomycin is bactericidal.

1. Staphylococci. Vancomycin is active against MRSA, coagulase-negative staphylococci (SSCN), and methicillin-susceptible *S. aureus* (MSSA), but not as active as nafcillin against the latter.

2. Enterococci. Vancomycin is **bacteriostatic against** *Enterococcus faecalis*, but in combination with **gentamicin it is bactericidal**, except for those that are high level gentamicin-resistant (see Chapter 27I). A common clinical dilemma is when to treat enterococcus. It is a pathogen with very low virulence. It occurs as part of mixed aerobic/anaerobic flora in intraabdominal (see Chapter 13) and in pelvic (see Chapter 16) and surgical wound infections or in superficial cultures in diabetic foot infections (see Chapter 5). In these situations, **enterococci usually do not require specific treatment** (see Chapter 13).

By contrast there are situations where enterococci need to be treated. *E. faecalis* occasionally is involved in osteomyelitis (see Chapter 5). It also causes urinary tract infection in older men. Bacteremias or endocarditis due to *E. faecalis* may follow gynecologic or genitourinary or gastrointestinal (GI) procedures or occur as a complication of a focal infection at these sites, but this is relatively uncommon [8] (see Chapter 12). *E. faecalis*, susceptible to vancomycin but not to ampicillin, infrequently causes nosocomial bacteremia.

3. Streptococci. Vancomycin is bactericidal against *Streptococcus pyogenes*, group C and G streptococci, viridans streptococci, and *S. pneumoniae*, including multidrug and high level penicillin-resistant strains [2] (see Chapter 11).

4. Miscellaneous: Vancomycin is active against *Corynebacterium JK* and *Clostridium difficile*.

B. Gram-negative bacteria. Vancomycin has no clinically useful activity [1].

C. Anaerobes. Although vancomycin has some activity against *Clostridium* species and anaerobic streptococci, it is not used as an agent for anaerobic infections [1].

II. Vancomycin resistance.

A. Enterococcus. VREF has emerged and is increasing in frequency in the intensive care unit (ICU), in the bone marrow transplant unit, and in hospital locations where patients with leukemia are treated. *E. faecium* is discussed further later in this chapter under quinupristin-dalfopristin (Q-D) and linezolid. It is resistant by virtue of containing one of the resistance determinants vanA, vanB, vanD, vanE, vanF, or vanG.

B. S. aureus

1. In 1997, S. aureus with intermediate levels of resistance to vancomycin—also referred to as GISA because vancomycin is a glycopeptide antibiotic, with a minimum inhibitory concentration (MIC) of 6 $\mu\text{g}/\text{mL}$ or more—was first isolated [4]. GISA are intermediately susceptible because the organism secretes an extracellular product, d-alanine-d-alanine, that binds vancomycin, not permitting it to reach the vancomycin-binding site. These organisms do not contain the resistance binding moieties found in VREF.

2. However, in a report published in early July 2002, a *S. aureus* that **had an MIC of 32 $\mu\text{g}/\text{mL}$** was isolated from a patient who had received vancomycin and other antibiotics. After treatment of an infection with a vancomycin-containing regimen, the *S. aureus* was repeatedly isolated, with **an MIC of more than 128 $\mu\text{g}/\text{mL}$** [5]. Unlike previous GISA, this *Staphylococcus* **contained the vanA resistance determinant**. Widespread use of vancomycin presumably contributes to the emergence of these resistant staphylococci.
3. **Patients** with documented GISA, and especially those strains with the vanA resistant determinant, **need to be isolated** to prevent nosocomial spread, and isolates should be reported through state and local health departments to the Centers for Disease Control and Prevention [6,7]. **Infectious disease consultation is advised for patients colonized or infected with GISA or with true vancomycin-resistant *S. aureus*.**

III. Pharmacokinetics [1,2]. Vancomycin demonstrates **time-dependent bactericidal activity** rather than concentration-dependent bactericidal activity [2] (see Chapter 25).

A. Intravenous (i.v.) preparation. Intramuscular vancomycin causes severe pain and is not advised.

1. **Therapeutic levels** are achieved in synovial, ascitic, pericardial, and pleural fluids after i.v. administration [1,2]. **Bile levels are low**, and ocular penetration is poor. Low bile levels help explain why vancomycin has little meaningful activity against *C. difficile* when given i.v. **Vancomycin penetrates inflamed meninges variably** [1,2]. Adequate cerebrospinal fluid (CSF) levels cannot be ensured [12].
2. **Peritoneal dialysis fluid.** Penetration is unpredictable. In dialysis-related peritonitis, the intraperitoneal route is recommended and convenient [13].
3. **Renal excretion.** Vancomycin is excreted primarily by glomerular filtration. **The dose must be reduced in renal failure. Vancomycin is not removed by dialysis.** The **half-life** of vancomycin in adults with normal renal function is 4 to 8 hours and in anuria, 7 to 12 days.
4. **Liver metabolism.** The liver also contributes to a lesser extent in the disposition of vancomycin. Dose adjustments may be needed with severe liver dysfunction [2].

B. Oral preparation. Vancomycin is **poorly absorbed** [1,2]. Very high stool concentrations are achieved after oral administration, making this agent active against *C. difficile* diarrhea and staphylococcal enterocolitis.

IV. Indications for use. Clinicians should be aware that vancomycin is less rapidly bactericidal and thus **less effective than β -lactam agents for β -lactam-susceptible staphylococci** (e.g., MSSA). Furthermore, because the use of vancomycin is a risk factor for colonization/infection with VREF and/or GISA [4–6], **prudent use of vancomycin is emphasized** [6,14]. **Guidelines for proper use of vancomycin should be a part of a hospital's quality improvement program** and should include the participation of the pharmacy and therapeutics committee, infection control, and infectious disease, medical, and surgical staffs.

A. **Vancomycin use is appropriate for the following infections** caused by β -lactam-resistant **gram-positive bacteria**. Those infections include the following [1–3]:

1. **MRSA. Vancomycin is treatment of choice** [15]. At times, gentamicin and/or rifampin are added for synergy [15] (see Chapters 4, 5, and 12). To achieve greatest success, some experts suggest troughs of no less than 15 $\mu\text{g}/\text{mL}$ should be maintained.
2. **Bacterial meningitis in adults or in children older than 1 month, with gram-positive cocci suggestive of *S. pneumoniae*** [15,16] on Gram stain **or in those patients believed to be at risk for pneumococcal meningitis** (see Chapter 6). Vancomycin is added to cefotaxime or ceftriaxone, until susceptibility data are available, specifically to cover intermediate and high level **penicillin-resistant *S. pneumoniae***. Because penetration of vancomycin in adult CSF may be compromised by steroid use, **some experts will also add rifampin** until susceptibility data are available [12,15,16] (see Chapter 6).

Outside the central nervous system, high-dose β -lactams or newer second-generation fluoroquinolones (e.g., gatifloxacin) are alternatives even for high-level resistant **penicillin-resistant *S. pneumoniae*** (Chapter 11).

3. **SSCN infections.** Surveys indicate that 35% to 65% of SSCN isolates are resistant to methicillin. Vancomycin, sometimes combined with gentamicin and/or rifampin, is the treatment of choice for these infections. Vancomycin combined with rifampin is effective in prosthetic device infections and CSF shunt infections. It also is effective against SSCN nosocomial infections in intensive care nurseries [1].
 4. **Selected febrile neutropenic patients.** Whether to use vancomycin empirically in this setting is an area of **clinical debate** (see section **D.3** below and Chapter 20). Generally agreed on situations for use **for 72 hours pending cultures are as follows:** an epidemiologic situation of **β -lactam-resistant viridans streptococci**, when the treated subject has known colonization with MRSA, when more than one blood culture has yielded gram-positive bacteria (see section **D.2** below) but susceptibility data are pending, or if the situation is life-threatening [17,18].
 5. **Central catheter infections.** When catheter exit site has clear-cut surrounding cellulitis, empiric vancomycin is used while awaiting culture results (see [17] and Chapter 2).
 6. **Corynebacterium infections** such as endocarditis of prosthetic valves or CSF shunt infections, especially if penicillin resistant such as the JK bacillus.
 7. **Miscellaneous**
 - a. **MRSA hemodialysis shunt infections.**
 - b. Chronic ambulatory peritoneal dialysis is often complicated by SSCN **peritonitis** [12] (see Chapter 13).
 - c. For the rare **staphylococcal enterocolitis**, oral vancomycin is indicated.
- B. Vancomycin is used in patients with a history of anaphylaxis or severe reactions to β -lactam antimicrobials** for the following:
1. **Serious *S. aureus* (coagulase-positive) infections.**
 2. **Endocarditis** due to enterococci or to viridans streptococci or other susceptible streptococci, (e.g., *S. bovis*). Because vancomycin is bacteriostatic against enterococci, vancomycin plus an aminoglycoside is required (see Chapter 12).
 3. ***S. aureus* or other gram-positive bacterial central nervous system infections.** The penetration of vancomycin into the CSF is variable. Infectious disease consultation is advisable to help adjust doses and/or monitor CSF drug levels.
- C. Prophylaxis**
1. **Endocarditis.** The American Heart Association recommends vancomycin for patients at risk who are amoxicillin-allergic and are undergoing GI or genitourinary manipulations, in patients with an artificial heart valve, or in other high-risk patients undergoing dental procedures (see Chapters 12 and 27B).
 2. **Implantation of prosthetic devices.** A single dose administered immediately preoperatively with a repeat dose if the procedure lasts more than 6 hours is sufficient to reduce attack rate of **MRSA or SSCN** (see detailed discussion in Chapter 5).
- D. Vancomycin use is discouraged for the following situations** [11,14,19,20]:
1. **Routine surgical prophylaxis** (see Chapter 27B).
 2. **SSCN single positive blood culture out of several** drawn in the same time frame. This is almost always either a contaminant or clinically unimportant bacteremia.
 3. **Culture-negative neutropenic fever.** There is a higher rate of rash and abnormal liver function tests and no obvious benefit if vancomycin is continued when there is no microbiological reason for its use [21–23]. Most of those who do develop positive blood cultures requiring therapy aimed at gram-positive organisms, which is a small minority of the febrile group, do as well if vancomycin is started after the blood culture data become available as when it is used empirically.

4. **Systemic or i.v. catheter “lock” prophylaxis** to prevent infection or colonization of indwelling central or peripheral intravascular catheters or vascular grafts.
 5. **Selective decontamination of the digestive tract.**
 6. **Eradication of MRSA colonization.**
 7. **Treatment of *C. difficile* diarrhea.** Although oral vancomycin is often selected either when there is relapse of *C. difficile* diarrhea after metronidazole therapy or when *C. difficile* diarrhea is severe and potentially life-threatening, there is no proof that it is superior to metronidazole for these purposes. Because of the concern for selecting VREF and because i.v. vancomycin does not achieve levels in the bowel, vancomycin is not the primary treatment of *C. difficile* diarrhea (see Chapter 13). Oral metronidazole remains the drug of choice in this setting (see Chapter 27Q).
 8. **Prophylaxis** for very low birth weight infants.
 9. **Prophylaxis** for patients on continuous ambulatory peritoneal dialysis.
 10. **Treatment (chosen for dosing convenience)** of β -lactam-sensitive gram-positive infections in patients who have renal failure.
 11. **Vancomycin solution** for topical application or irrigation.
- V. **Continued inappropriate use of vancomycin has contributed to the emergence of VREF, GISA, and the recent vancomycin completely resistant *S. aureus*** (see section II.B.2).
- A. Despite published Centers for Disease Control and Prevention guidelines (see section IV), several investigators have reported that **30% to 80% of vancomycin used in hospitals is inappropriate** [24–26].
 - B. **Vancomycin is often part of empiric antibiotic regimens, especially in hospitalized patients**, because of concern for MRSA and SSCN line-associated bacteremia [26].
 1. Vancomycin use could be controlled better by infection control measures to reduce MRSA rates and central-line infections [26], thereby reducing the need to use vancomycin so frequently.
 2. **Infection control practices**, include the following [26]:
 - a. **Better handwashing** and more use of the “user-friendly” soapless/waterless soaps.
 - b. **New technology** (e.g., new i.v. catheters bonded with antiinfectives) are undergoing clinical evaluation.
- VI. **Dosage**
- A. **Intravenous** [1,2]
 1. **Adults**
 - a. **One gram every 12 hours.** A convenient and cost-effective dosage regimen in subjects with **normal renal function** is 1 g every 12 hours (over 2 hours to avoid red man syndrome; see section VIII.A).
 - b. **Mayo Medical Center vancomycin dosing nomogram (Table 27P.1).** Conventional dosing mentioned in section 1 above does not take into account variability in patient’s weight and renal function. **In obese** patients, ideal body weight can be used to determine the creatinine clearance, but actual total body weight is used in dose calculations [2] (see section C.2 below).
 - c. **Combined vancomycin and aminoglycoside.** Some authorities recommend either a reduced dose of 500 mg every 8 hours or, preferably, pharmacokinetic monitoring.
 - d. **Prophylaxis in cardiac surgery.** Some authors favor a single 15-mg/kg preoperative dose (see Chapter 12).
 2. **Children and neonates.** There is less experience with the use of vancomycin in children. For infants and children with non-central nervous system infections, 10-mg/kg doses i.v. over 60 minutes every 6 hours (40 mg/kg/day) often are suggested. In central nervous system infections, 15 mg/kg doses i.v. over 60 minutes every 6 hours are suggested to attain peak serum concentrations between 30 and 40 μ g/mL [12]. **In neonates**, close monitoring of vancomycin serum levels is important to ensure therapeutic efficacy without toxicity (see Chapter 3 for dose regimens in neonates).

Table 27P.1. Mayo Medical Center i.v. Vancomycin Dosing Nomogram^{a,b}

Creatinine Clearance	Dosing Interval
>80	Every 12 h
65–80	Every 12 to 18 h
50–64	Every 24 h
35–49	Every 24 to 36 h ^c
21–34	Every 48 h ^c

^aUse a dose of 15 mg/kg (actual body weight). The dosing interval is based on renal function. It can be estimated by using the estimated creatinine clearance. See Chapter 27A, and the table above.

^bIf the estimated renal function is near the border of two dosing intervals, it may be reasonable to begin with the more aggressive interval; the dose can then be modified if necessary according to serum levels.

^cPatients with serious infection in whom the initial dosing interval is >24 h should have serum level monitoring performed before steady state to ensure that the levels are not subtherapeutic. It may be advisable to measure a random level about 24 h after the first dose. This level can be interpreted with respect to the seriousness of the infection to determine whether the dosage regimen needs to be modified.

Modified from Wilhelm MP, Estes L. Vancomycin. *Mayo Clin Proc* 1999;74:928.

B. Oral. An oral preparation is available but its appropriate use is extremely limited.

- 1. For *C. difficile* diarrhea** in adults [1], 125 mg every 6 hours for 10 to 14 days is as effective a regimen as 500 mg orally four times a day. In children, the dose is 40 mg/kg/day in four divided doses (see Chapter 13). Metronidazole is the preferred drug, as discussed in Chapters 13 and 27Q.
- 2. For staphylococcal enterocolitis**, 500 mg every 6 hours in adults has been suggested. It is unclear whether this entity really exists.

C. Doses in renal failure. In renal failure, maintenance doses must be reduced.

- 1. The Mayo Clinic Center vancomycin dosing nomogram** can be used (Table 27P.1). However, nomograms may not work well in anuric patients or patients with rapidly changing renal function; serum drug level monitoring is useful in these patients (see section VII).
- Figure 27P.1 shows a very useful nomogram designed to achieve peak and trough concentrations of 30 and 7.5 $\mu\text{g/mL}$, respectively. After an **initial loading dose of 25 mg/kg** (infused at 500 mg/h), the vancomycin **maintenance** dose remains constant at **19 mg/kg** (infused at 500 mg/h), but the dosage interval depends on the creatinine clearance. **Doses are based on actual total weight**, not ideal patient weight. (See Chapter 27A for instructions on estimation of **creatinine clearance based on ideal body weight**.)
- 3. Individualized dosing.** Ideally, vancomycin dosage can be “individualized” based on serum concentrations, using pharmacokinetic consultation. Initial vancomycin dosage is calculated on a per body weight basis with the use of the nomogram (see section 2 above). Adjustments are made to attain peak serum levels of 30 to 40 $\mu\text{g/mL}$ and trough levels of 5 to 10 $\mu\text{g/mL}$. For treatment of **MRSA, troughs of 15 $\mu\text{g/mL}$** have been recommended by some experts.
- 4. Hemodialysis or peritoneal dialysis does not remove significant amounts of vancomycin.** Individualized dosing is preferred in this setting, with a loading dose of 25 mg/kg infused at 500 mg/h and maintenance dose of 19 mg/kg every 5 to 7 days. If on day 5 the level is less than 10 $\mu\text{g/mL}$ (<16 $\mu\text{g/mL}$ for MRSA) a maintenance dose is given. If on day 5 the level is more than 10 $\mu\text{g/mL}$ (more than 18 $\mu\text{g/mL}$ for MRSA), the maintenance dose can be given usually on day 7. When treating MRSA, it seems prudent to keep the trough 15 or possibly even as high as 20 $\mu\text{g/mL}$.

FIG.27P.1. Nomogram for vancomycin dosage in patients with renal failure. (From Matzke GR, et al. Pharmacokinetics of vancomycin in patients with varying degrees of renal function. *Antimicrob Agents Chemother* 1984;25:433, with permission.)

D. Intraperitoneal administration. Vancomycin dosage is discussed elsewhere [13].

E. Vancomycin administration into the CSF. Because of the somewhat variable vancomycin CSF penetration, for inadequately responding meningitis, intrathecal injection is a consideration. This has been reviewed [12]. **Infectious disease consultation is advised.**

VII. Monitoring serum vancomycin. The theoretical optimal serum level range for vancomycin is **peaks of 20 to 40 μg/mL and troughs of 5 to 10 μg/mL** [2], but some experts, as noted, suggest troughs of **15 μg/mL if treating MRSA.**

A. Vancomycin pharmacokinetics is sufficiently predictable that adequate serum drug concentrations can be obtained by empiric dosing methods (e.g., see section III). These take into account the patient's age, weight, and renal function. This is especially true when renal function is normal. Therefore, **routine serum monitoring is not advised** [27,28]. In a thoughtful editorial comment on vancomycin serum level monitoring, Moellering [28] suggested a limited number of clinical settings in which following serum or body fluid levels of vancomycin may be prudent:

1. **Vancomycin/aminoglycoside combination** administration.
2. **Anephric patients** undergoing hemodialysis with systemic infection and receiving infrequent doses of vancomycin.
3. **Patients receiving higher than usual doses of vancomycin** such as treatment of high level penicillin-resistant *S. pneumoniae* meningitis.
4. **Patients with rapidly changing renal function.**
5. **In addition, we would monitor levels early in therapy of those with MRSA** infection as noted above in an attempt to ensure a trough of about 15 μg/mL.

Note: Vancomycin serum monitoring is indicated, especially initially to be certain that you have achieved adequate serum concentrations.

B. In a review [2], the authors emphasize that **if monitoring is done, only trough levels** are needed. Maintaining adequate trough levels may correlate with a better outcome. Furthermore, if nephrotoxicity is, in fact, related to trough levels, nephrotoxicity can be avoided.

VIII. Toxicity [1–3]

- A. Red man syndrome.** If vancomycin is infused too rapidly, it may cause flushing of the face, neck, or torso; pruritus; or hypotension [29]. This is a **nonimmunologically mediated** histamine release precipitated by the hyperosmolarity associated with the rapid infusion of vancomycin. Rapid bolus infusions also can cause pain and muscle spasms of the chest and back.
1. **Infusion rate. To avoid these reactions, infuse vancomycin slowly, at 500 mg/h.**
 2. **Clinical implications.** Because red man syndrome is **not immunologically mediated**, it does not preclude continued use. **Bronchospasm and angioedema are not part of red man syndrome and suggest a true allergic reaction to vancomycin.**
- B. Rashes** other than red man syndrome occur in approximately 5% of patients. Stevens-Johnson syndrome may occur rarely. **Anaphylaxis** has been described with vancomycin use.
- C. Nephrotoxicity** is very uncommon. Currently available purified parenteral preparations are very well tolerated. Only when **another drug with nephrotoxic potential** such as an aminoglycoside **is used simultaneously** is there significant risk of these toxicities. If there is renal failure or vancomycin is used with an aminoglycoside, monitoring levels of both antibiotics will decrease the risk of toxicity.
- D. Ototoxicity** is a potential side effect, is relatively **uncommon**, and **occurs with very high serum levels** (>80 $\mu\text{g/mL}$) or in combination with aminoglycosides or other ototoxic drugs. Serum level monitoring as in section **VII.B** above will avoid this [1].
- E. Phlebitis** at the site of infusion **can be minimized if the vancomycin is diluted in 100 to 200 mL dextrose and water or saline and infused slowly** at a rate not exceeding 15 mg/min.
- F. Fever and chills** after i.v. administration are uncommon but occur occasionally.
- G. Neutropenia** can occur, especially with prolonged use, and agranulocytosis has been described [30]. **Blood counts weekly are indicated with prolonged vancomycin therapy.**

IX. Cost. Oral vancomycin is **expensive** (see Appendix Table).

TEICOPLANIN

Teicoplanin (Targocid) is an antibiotic chemically similar to vancomycin but with important differences responsible for the unique physical and chemical properties of the complex. Although widely used in Europe for the treatment of gram-positive infections, teicoplanin was an investigational agent in the United States until late 1995, and at that point **clinical investigations were suspended**. As of mid-2002, we are not aware of “compassionate-use” availability of this agent in the United States. This agent is discussed elsewhere [3].

QUINUPRISTIN/DALFOPRISTIN (SYNERCID) [31]

- I. Introduction.** Quinupristin/dalfopristin (Synercid) **is a combination of two antibiotics and is the first agent from a new class of antibiotics called streptogramins. In September 1999, it was given accelerated approval by the U.S. Food and Drug Administration for bloodstream infections due to VREF [31–33]. This was based on a demonstrated effect on a surrogate end point that is likely to predict clinical benefit, the ability to clear VREF from the bloodstream.**
- II. The problem.** Vancomycin-resistant enterococci, usually *E. faecium* (VREF). It is important to be aware of the new problem posed by this organism.
- A. Incidence.** VREF are being isolated more frequently [10,11,34,35], especially in larger hospitals. From January 1989 through March 1993, nosocomial VREF increased 20-fold. During this time, ICU isolates increased from 0.4% to 13.9% [36]. Now about 50% of enterococci isolates from ICUs are VREF [9]. Initially, **all strains of VREF were identical to one another**, carrying the *vanA* resistance determinant. This indicates that **resistance was not induced in the treated patient but instead that the VREF was transmitted from one antibiotic-treated individual to another.**

B. Clinical problems

1. **Colonization is more common with VREF than infection.** Because VREF colonizes the GI tract, **cultures of either stool or rectal swabs are the best way to identify carriers**, with stool cultures being superior.
 - a. **Infection control.** Because “person to person” and “fomites to person” spread is critical in maintaining a reservoir, **infection control practices must be followed diligently.** Acquisition of infection occurs from thermometers and from personnel and is closely related to proximity to colonized and, even more so, infected patients (see Chapter 20). **Handwashing and change of gloves between every patient are mandatory.** Gowns probably add an additional measure of protection, but studies are inconclusive.
 - b. **Investigational observations.** Preliminary data suggest that if VREF is given orally to animals or human volunteers, simultaneous administration of piperacillin reduces the potential to colonize because of the high biliary levels piperacillin produces. The levels are sufficient to inhibit the organism and prevent establishment of colonization. By contrast, cephalosporins do not prevent colonization in this model. However, once colonization is established, antibiotics with antianaerobic activity lead to higher fecal titers of VREF and hence to its potential to spread or cause disease. **Prudent use of all antibiotics, including vancomycin, may help decrease the incidence of VREF.** This has led some to speculate that the use of piperacillin-tazobactam, when treatment of gram-negative bacteria is needed, in the ICU may reduce VREF colonization; this will require careful study.
2. **Infection. Patients infected with VREF often are very debilitated and have had prolonged hospitalizations.** They have **often received multiple antibiotics**, including vancomycin [1–3,34–36]. Individuals with VREF bacteremia have a higher death rate than those with susceptible enterococcal bacteremia [34,35]. **Two specific groups at risk to develop VREF infection are patients who have undergone liver transplants and patients with hematologic malignancy.** Colonization (see section B.1 above) precedes infection. **In liver transplant patients**, once enterococci colonize the gut they migrate and find an ecological niche in the biliary tract. A major complication of liver transplant is hepatic artery thrombosis. Because the peribiliary duct anatomic areas of the liver are served only by the hepatic artery and not simultaneously by the portal system, this leads to necrosis of those areas. Abscess forms due to the necrosis. If that individual has previously been colonized with VREF, it replicates to high titer when antibiotics active against gut flora suppress competing bacteria. **In the patient with leukemia**, when antibiotics are administered for neutropenic fever, other flora are suppressed and VREF emerges, enters the bloodstream through the gut compromised by mucositis, and then disseminates.

III. Use of Q-D for VREF and other gram-positive infections

- A. **Mechanism of action.** The two antibiotics work synergistically by interfering with protein synthesis: Dalfopristin inhibits the early phase, whereas quinupristin interferes with the late phase of protein synthesis. Resistance is associated with resistance to both components. However, if the staphylococcus is resistant to macrolide-lincosamide-streptogramin B, Q-D is less efficacious than if the organism is susceptible to macrolide-lincosamide-streptogramin B [37]. Clindamycin susceptibility appears to identify organisms susceptible to macrolide-lincosamide-streptogramin B [38].
- B. **In vitro activity.** Q-D is not active against gram-negative organisms.
 1. Q-D is **bacteriostatic against VREF and may be bactericidal against MSSA and group A streptococcus (GAS), but it is not active against *E. faecalis*.**
 2. Q-D also is active against *Streptococcus pneumoniae*, regardless of penicillin susceptibility; MRSA; *S. agalactiae*; *Corynebacterium jeikeium*; *S. epidermidis*; and group C β hemolytic streptococcus.
 3. *Ureaplasma urealyticum*, *Mycoplasma pneumoniae*, and *Mycoplasma hominis* are susceptible *in vitro* [39].
 4. *Borrelia* and *Leptospira* species are susceptible *in vitro* [40].

- C. Pharmacokinetics.** Synercid consists of 30% quinupristin and 70% dalfopristin, each of which is converted into several active major metabolites.
- 1. Elimination half-lives** of quinupristin and dalfopristin are less than 1 hour.
 - 2. Biliary excretion**, and hence fecal excretion, constitutes the major elimination of both parent drugs and their metabolites.
 - 3. Renal failure.** Doses do not require modification in renal failure.
 - 4. Cytochrome P450 3A. Q-D is a major inhibitor of the activity of cytochrome P450 3A4 isoenzyme and can interfere with the metabolism of other drugs** (see section V.G).
- IV. Indications for use** [32,41–43]
- A. VREF infection.** Q-D is approved for **serious or life-threatening infections associated with VREF**. Because of the difficulty in eradicating these infections, **infectious disease consultation is advised**.
 - B.** Skin and skin structure infections caused by MSSA or GAS. Although approved for this use, other very active agents are available for these infections (see Chapter 4), and we do not suggest using Q-D in this setting unless there is VREF bacteremia associated with MSSA or GAS wound infection. Infectious disease consultation is advised.
 - C. MRSA.** Although U.S. Food and Drug Administration approval has not been issued, success is reported using Q-D when vancomycin has failed. It may find a role also in GISA and vancomycin-resistant *S. aureus*.
- V. Dosages and administration.** Only an i.v. preparation is available.
- A. Dose ranges.** The dose is diluted in at least 250 mL D5W and infused over 60 minutes.
 - 1. VREF.** An i.v. dose, infused over 1 hour, of 7.5 mg/kg every 8 hours is recommended with duration dependent on clinical response.
 - 2. For complex skin and skin structure infections,** 7.5 mg/kg every 12 hours i.v. for 7 days is suggested.
 - B. Pediatric use.** The safety and efficacy in those under 16 has not been established.
 - C. Pregnancy.** Q-D is a **category B** agent (see Chapter 27A). It should be used during pregnancy only if clearly needed.
 - D. Nursing.** Q-D is excreted in milk in animals; it is not known if it is excreted in human breast milk. Caution should be exercised administering Synercid to nursing women.
 - E. In renal failure** no dosage adjustment is required, including patients undergoing dialysis.
 - F. In hepatic failure,** no special dose changes are recommended at this time, but only preliminary data are available.
 - G. Drug interactions**
 - 1. Cytochrome P450 3A4. Q-D significantly inhibits cytochrome P450 3A4 metabolism of cyclosporin A, midazolam, nifedipine, and terfenadine.** Therefore concomitant administration of these or other drugs metabolized by the cytochrome P450 enzyme system may result in increased plasma concentrations of these drugs. **Monitoring levels** of cyclosporin is indicated.
 - 2. QTc prolongation potential.** Q-D itself does not seem to increase the QTc interval. However, **medications metabolized by cytochrome P450 3A4 that prolong the QTc interval should be avoided when using Q-D.** For up-to-date drug information on drugs that may affect the QTc interval, see www.qt.org, and for drugs associated with drug interactions causing torsades, see www.torsades.org
 - 3. Other serum drug level increases. Examples of drugs whose concentrations may be raised by concomitant use of Q-D** have been summarized in the package insert and **include** the following: antihistamines (astemizole, terfenadine); anti-human immunodeficiency virus (non-nucleoside reverse transcriptase inhibitors [NNRTI] and protease inhibitors; e.g., delavirdine, nevirapine, indinavir, zalcitabine); antineoplastic agents: vinca alkaloids (e.g., vinblastine), docetaxel, and paclitaxel; benzodiazepams (midazolam, diazepam); calcium channel blockers; HMG-CoA reductase inhibitor; cholesterol-lowering agents (statins);

cisapride; cyclosporine; tacrolimus; methylprednisolone; carbamazepine; quinine; disopyramide; and lidocaine.

VI. Side effects

- A. **Arthralgia** and/or **myalgias** are common. These are the number one reason that the drug is discontinued. Reducing the dose helps [44].
- B. **Intravenous site inflammation, pain, edema, and local reactions** are common and if severe may be reduced by increasing the infusion volume to 500 or 750 mL of D5W.
- C. **Hyperbilirubinemia** is relatively common.
- D. **GI side effects** (nausea, vomiting, diarrhea) occur in a small percent (<5%).

LINEZOLID (ZYVOX): A NEW PROTEIN SYNTHESIS INHIBITOR ANTIBIOTIC

Linezolid belongs to a **new class of antibiotics, the oxazolidinones**. It was approved in early 2000. It interferes with bacterial protein synthesis by binding at the 50S ribosomal area but at a site different from that to which erythromycin binds [32,45–48].

I. Spectrum of activity [31] and related issues

- A. **Gram-positive bacteria.** It is active against all *S. aureus*, including MRSA; VREF; *S. faecalis*; and penicillin-resistant or -susceptible *S. pneumoniae* [49].
 1. It is **bacteriostatic** for most gram-positive bacteria, although it may be bactericidal against pneumococcus.
 2. **Serum inhibitory levels** for these organisms range from 0.5 to 2.0 $\mu\text{g/mL}$.
- B. **Gram-negative aerobes.** Linezolid is not active against gram-negative aerobes.
- C. **Miscellaneous.** *In vitro*, it is also active against *Legionella pneumophila*, *M. pneumoniae*, and *C. pneumoniae*.
- D. **Resistance.** VREF resistance develops in liver transplant patients who are continuously on this drug [50]. Resistant organisms are transmitted person to person [51]. MRSA resistance to linezolid has been described. [52].

II. Pharmacokinetics

- A. **Oral drug is 100% bioavailable.** Intravenous or oral administration yields the same serum levels. The oral and i.v. doses are 600 mg yielding serum levels approximating 20 $\mu\text{g/mL}$.
- B. **Dose interval** is every 12 hours.
- C. **Hepatic or renal failure.** There is **no dose modification** for hepatic or renal failure.
- D. **Bone levels** are about 50% of serum levels [53]. **CSF penetration** is poor, but penetration into **skin and soft tissue** is excellent.

III. Clinical results. These studies have been carried out in multicenter trials. Usually studies were designed as initial i.v. followed by oral therapy.

- A. ***S. aureus***—soft tissue infection or pneumonia
 1. **MSSA. Oxacillin/dicloxacillin versus linezolid:** Cure rates were similar [54].
 2. **MRSA soft tissue, pulmonary, and urinary tract infection.** Vancomycin versus linezolid were compared. Linezolid was as effective as vancomycin against MRSA with similar clinical cure rates and similar microbiologic eradication [55]. In a nosocomial pneumonia study in which several but not all isolates were MRSA, linezolid plus aztreonam was as effective as vancomycin plus aztreonam [56].
- B. ***S. pneumoniae*.** Trials have compared i.v. with oral linezolid versus ceftriaxone followed by oral cefixime.
 1. **Nonbacteremic pneumonia.** Linezolid was equally effective to ceftriaxone. In a pediatric trial, linezolid was quite successful.
 2. **Bacteremic pneumonia.** Linezolid was more effective than ceftriaxone ($p < 0.01$). Most cases were caused by penicillin-susceptible *S. pneumoniae*.
- C. **Enterococcus. In trials against VREF,** linezolid was effective in treating urinary tract infection, soft tissue infection, extravascular body fluid infection such as ascites, and source unknown bacteremia. Linezolid has been effective in cases where Q-D has failed [57]. Case reports of efficacy in VREF endocarditis are reported [58]. Linezolid is also active against *E. faecalis*.

IV. Side effects and toxicity

- A. **GI.** GI side effects that did not result in drug cessation were more common than in vancomycin-treated subjects. Both diarrhea and nausea and/or dyspepsia were manifest. An occasional patient cannot continue oral linezolid because of severe nausea, but most tolerate the drug to the end of the treatment course [55].
 - B. **Rash** has not been prominent with linezolid and in one study occurred less frequently than occurred with vancomycin [56].
 - C. **Hematologic** [59–61]. Thrombocytopenia has been observed in those treated for more than 3 weeks but is reversible on drug cessation in those where it has occurred. The frequency is low. Mild neutropenia was observed in one study of treatment of pneumonia in children but did not lead to cessation of drug. Mild reversible neutropenia and thrombocytopenia are certainly not totally unexpected in a drug whose action interferes with protein synthesis. Reversible red blood cell aplasia has been described.
 - D. **Monoamine oxidase inhibition** [62]. Because of its biochemical structure there was concern that linezolid could pose a risk with certain dietary products. However, this has not been borne out with clinical experience or with studies in normal volunteers.
 - E. **Drug interactions** [63]. When linezolid is administered in conjunction with pseudoephedrine or phenylpropanolamine, a minimal increase in both blood pressure and serum levels of the coadministered drugs was observed but no serious adverse events developed. When administered in conjunction with dextromethorphan, a serotonin uptake inhibitor, there was only minimal change in the clearance of a metabolic breakdown product of dextromethorphan. There was no change in the pharmacokinetics of linezolid. **There is no anticipated interaction between CYP 450 drug-drug interactions.**
- V. **Indications for Use** [31,55,59–61,64]. Because of the **high expense** of linezolid and the need to **use it only when clearly indicated** so that resistance will be minimized, **infectious disease consultation is advised before prescribing** this agent. This is a very expensive agent (see Appendix Table).
- A. **MRSA soft tissue infection** is a primary indication for its use. Compared with vancomycin it is similarly effective, and linezolid offers the advantage of switch to oral therapy with the potential for shorter hospital stay and reduced risk of line-related infection [55]. Although resistance has been reported [52], if appropriated debridement is carried out accompanying the antibiotic this risk is probably small. MRSA resistant to vancomycin has also been observed [4,5], so special attention to management of the MRSA infections, regardless of what antibiotic is chosen, is very important.
 - B. **VREF infection.** Considerable experience and success has been reported [31].
 - C. **Probable or known severe pneumococcal pneumonia** in a β -lactam highly allergic individual [60].
 - D. **MRSA osteomyelitis.** Data are limited. Tissue levels in bone and hematoma are promising [53]. In a large series of patients treated under emergency use protocol, linezolid treatment resulted in cure of osteomyelitis due to either MSSA or MRSA [64]. Although linezolid is effective against MSSA, there are other available drugs with which to treat that infection.

AN INVESTIGATIONAL DRUG FOR GRAM-POSITIVE INFECTIONS: DAPTOMYCIN (CIDECIN)

- I. **Mechanism of action** [64]. Daptomycin is a novel lipopeptide antibiotic derived from the fermentation of *Streptomyces roseosporus*. It belongs to a new class of antibiotics. Daptomycin appears to kill bacteria by a mode of attack at more than one site that is rapid and distinct from resistance mechanisms against usual organisms. It may inhibit peptidoglycan biosynthesis, it disrupts cell membrane permeability, it reduces synthesis of lipoteichoic acids, and it may even disrupt trans-membrane electrochemical gradient.
- II. **Resistance potential.** *In vitro* evaluation indicates that it has an extremely low resistance potential ($<10^{-10}$) for *S. aureus* when challenged at eight times the MIC value.

III. Spectrum of activity [65]

A. Gram-positive aerobes. Daptomycin is active against all gram-positive cocci, including MSSA; MRSA; enterococcus, including VREF; *S. pneumoniae*; and SSCN species. MIC for *S. aureus* is 1 $\mu\text{g/mL}$ and for enterococci is 2 $\mu\text{g/mL}$.

B. Gram-negative bacteria. It has no activity against gram-negative bacteria.

IV. Pharmacokinetics

A. Bactericidal activity. Vancomycin exhibits time-dependent bactericidal activity. By contrast, daptomycin demonstrates **concentration-dependent bactericidal activity** (see Chapter 25). Its rate of bactericidal activity is faster than vancomycin.

B. Serum levels. At a dose of 4 mg/kg/dose C_{max} is approximately 54.6 $\mu\text{g/mL}$.

C. Excretion. The major route of excretion is of unmetabolized drug via the kidney. There are very limited data on dose reduction in renal failure.

V. Side effects and toxicity

A. Muscle enzyme changes. In a small proportion of treated individuals, creatine phosphate kinase levels become elevated after 2 weeks of therapy. Usually the individual is asymptomatic and creatine phosphate kinase levels return to normal on drug cessation.

B. Other side effects. Preliminary data suggest no renal, hepatic, or bone marrow toxicity, but the number of individuals receiving the drug is limited.

VI. Clinical experience

A. Skin and soft tissue. Efficacy appears similar to conventional agents.

B. Bacteremia. Daptomycin sterilized blood cultures in all (of a small number) of treated individuals and its use was associated with a high cure rate.

VII. Summary. This is an interesting new antibiotic that is currently undergoing phase III clinical trials for *S. aureus* and *E. faecium* bacteremia.

Q. Metronidazole

Metronidazole, introduced in 1959, has become an extremely important agent for the treatment of anaerobic infections [1–4]. It inhibits DNA synthesis, regardless of the growth phase of the organism, and is rapidly bactericidal.

I. Spectrum [2–4]

A. Anaerobic activity

1. **Gram-negative anaerobes.** Metronidazole is bactericidal against *Bacteroides fragilis*, other *Bacteroides* species, and *Fusobacterium* species [1,2].
2. **Gram-positive anaerobes.** Against some gram-positive anaerobes, including *Clostridium perfringens* and *C. difficile*, metronidazole is very active. The activity against anaerobic gram-positive cocci is much more variable, with resistance in up to 50% of tested isolates [2]. Strains of *Actinomyces* and *Propionibacterium* (e.g., *P. acnes*) are resistant [2].

B. Aerobic activity. *Gardnerella (Haemophilus) vaginalis* and *Helicobacter pylori* are susceptible to metronidazole. However, unlike clindamycin, metronidazole is not active against gram-positive aerobic bacteria such as *Staphylococcus aureus* and β streptococcus group A.

C. Parasites. Metronidazole is very active against *Entamoeba histolytica*, *Giardia lamblia*, and *Trichomonas vaginalis*.

II. Resistance. Susceptible bacteria rarely develop resistance. During a 10-year period at the Mayo Clinic, no increase in resistance occurred among *Bacteroides* or *Fusobacterium* species [2].

III. Pharmacokinetics [1–4]

A. Oral absorption. Metronidazole is **very well absorbed**. Serum levels are similar after equivalent oral and intravenous doses [1,2]. Metronidazole can be taken with food.

B. Tissue penetration. Metronidazole has **excellent penetration** into almost all sites and provides therapeutic levels in bone, unobstructed biliary tract, cerebrospinal fluid, brain abscess contents, empyema fluid, hepatic abscesses, middle ear, pelvic tissue, and vaginal secretions.

C. Metabolism and excretion. Metronidazole is metabolized primarily in the liver and excreted in the kidney. Dose reductions are advised in severe renal failure [5].

D. Placenta and breast milk. Metronidazole readily crosses the placenta and penetrates breast milk.

IV. Clinical uses

A. Drug of choice. Metronidazole is indicated for *C. difficile*, *Bacteroides* species, susceptible *H. pylori*, and *G. vaginalis* [6]. In addition, it is the drug of choice for *Entamoeba histolytica*, *Giardia lamblia*, and other less common parasites [7] (Table 27Q.1).

B. Anaerobic infections. Metronidazole alone or in combination is indicated for the following:

1. **Mixed aerobic/anaerobic soft tissue or intraabdominal and pelvic infections:** with antiaerobic antibiotics. (See related discussions in Chapters 13 and 16.)

Table 27Q.1. Metronidazole Dosage Regimens

Indication	Route of Administration	Adult Dosage ^a
Susceptible anaerobic infections	i.v.	Loading dose of 15 mg/kg, then 7.5 mg/kg q6h. For the average adult (70 kg) a 1-g load followed by 500 mg q6h.
	p.o.	1–2 g/day in 2–4 doses q6–12h. For the average-sized adult, 500 mg q6–8h is often used.
<i>C. difficile</i> diarrhea	p.o.	500 mg tid or 250 mg qid for 10 days [7a]
	i.v. (see text)	500 mg q6–8h
<i>Trichomonas</i> vaginitis	p.o.	2 g in a single dose or 500 mg bid × 7 days
Bacterial vaginosis (nonspecific vaginitis, <i>Gardnerella vaginalis</i> vaginosis)	p.o.	500 mg bid for 7 days
	Topical	See footnote ^b
Giardiasis	p.o.	250 mg tid for 5 days ^c
Amebiasis (intestinal or extraintestinal)	i.v. or p.o.	500–750 mg tid for 10 days ^d

^aDosages must be modified if creatinine clearance <10 mL/min or if there is significant hepatic dysfunction. See text.

^bA 0.75% vaginal gel formulation of metronidazole (MetroGel-Vaginal) is available in a 70-g tub-and packaged with a 5-g vaginal applicator. The dose is 5 g intravaginally bid for 5 days. For use of metronidazole in pregnancy see reference 10 and Chapter 16.

^cIn children, giardiasis has been treated with 5 mg/kg/dose tid for 5 days.

^dIn amebiasis therapy, after 10 days of metronidazole, iodoquinol, 650 mg tid for 20 days, is recommended in adults. The pediatric dose of metronidazole is 35–50 mg/kg/day divided into three doses for 10 days; iodoquinol, 30–40 mg/kg/day (max. 2 g) in three divided doses, given (after completion of metronidazole) for 20 days.

Modified from Mathisen GE, Finegold SM. Metronidazole and other nitroimidazoles. In: Gorbach SL, Bartlett JG, Blacklow NR, eds. *Infectious diseases*. Philadelphia: WB Saunders, 1992:262; and Medical Letter. Drugs for parasite diseases. *Med Lett Drugs Ther* 2002;44:1 (April 2002), with permission.

2. *B. fragilis* bacteremia with endocarditis or other vascular infections. Metronidazole is bactericidal against *B. fragilis*. It is active against the 5% to 15% of isolates of *B. fragilis* that are resistant to clindamycin. Metronidazole costs less than clindamycin and is associated with less *C. difficile* diarrhea than clindamycin. **It is the agent of choice.**

3. Brain abscess. Metronidazole penetrates brain abscesses and is bactericidal. It is used with anti-gram-positive antibiotics.

4. Antibiotic-associated diarrhea due to *C. difficile*. Metronidazole is the drug of choice. [1,2,6,8] (see Chapter 13). Oral therapy is more effective and less expensive than intravenous therapy, but intravenous therapy may be effective in patients who cannot receive oral therapy.

5. Tetanus. Some data suggest metronidazole, not penicillin, may be the preferred agent [6,9].

6. Anaerobic pleuropulmonary infections. Failures have occurred, perhaps because these infections are polymicrobial [2] and because microaerophilic streptococci are resistant [1,4].

C. Other infectious agents

1. Trichomoniasis and bacterial vaginosis [10] (see Chapter 16) and **Giardiasis** (see Chapter 13).

2. Amebiasis [7].

3. *H. pylori* in peptic ulcer disease [1–4,6].

4. Miscellaneous. Metronidazole is adjunctive to debridement in severe **gingivitis and**

- a. **Bacterial overgrowth conditions** such as Crohn disease and the perineal disease associated with **Crohn disease** [1,2].
 - b. **Periodontitis**, including those with human immunodeficiency virus infection [2].
5. **Topical metronidazole gel** is an effective and safe therapeutic agent for **rosacea**. A 0.75% vaginal gel formulation is available for treatment of bacterial vaginosis (see Chapter 16).
- V. **Use in pregnancy.** Metronidazole has been shown to have **carcinogenic potential**. It is carcinogenic in mice and rats. The precise risk for humans is unclear and remains controversial. Metronidazole has not been shown to be teratogenic. However, many experts agree metronidazole use in the second and third trimesters of pregnancy should be restricted to those patients in whom alternative treatment has been inadequate. The use of metronidazole in the first trimester should be carefully evaluated because metronidazole crosses the placenta barrier and its effects on human fetal organogenesis are not known. The **pros and cons of using metronidazole in pregnancy**, especially the first trimester, have **recently been reviewed** [11]. In his commentary, the reviewer emphasizes that the “preponderance of published human experience does not support a teratogenic effect in any trimester” [11]. He believes that pending further data, metronidazole should be avoided in the first trimester except for serious or life-threatening infections. After organogenesis is complete, metronidazole could be considered for significant infections when other equally effective options are not available or are contraindicated [11]. In a recent report, investigators found no increase in late incidence of cancer after short-term metronidazole use in more than 5,000 women followed for a median of more than 12.5 years [12]. **Because metronidazole is excreted into breast milk, nursing should be discontinued during and for 2 days after therapy**[1].
- VI. **Preparations and doses.** Seriously ill patients should receive metronidazole intravenously. Because blood levels are comparable after intravenous and oral drug, oral is indicated when clinically reasonable [1,2].
- A. **Adult dosage regimens** (Table 27Q.1). The intravenous dose is infused over 60 minutes. Because of the relatively long half-life of metronidazole, oral doses can be given every 6, 8, or 12 hours, although higher doses, given at one time, may be associated with more gastrointestinal side effects.
 - B. **Renal failure.** No dose modification is needed, except with creatinine clearance of less than 10 mL/min, where a 50% reduction in the usual dose is suggested [5] to prevent the accumulation of toxic metabolites. A dose after hemodialysis, but not peritoneal dialysis, is recommended because of drug removal. Furthermore, some sources suggest a 50% dose reduction for patients undergoing chronic ambulatory peritoneal dialysis [5].
 - C. **In significant hepatic impairment, doses** should be **reduced** by at least 50% [1,2].
 - D. **Pediatrics.** The safety and efficacy of metronidazole in pediatric patients has not been established except in the treatment of amebiasis. [7].
- VII. **Adverse effects.** In general, metronidazole is well tolerated [1,2].
- A. **Alcohol intolerance.** Because of a disulfiram-like effect (i.e., nausea, vomiting, headaches), alcoholic beverages should not be consumed while taking metronidazole [13].
 - B. **Peripheral neuropathy**, manifested as numbness and tingling of the extremities, may occur in those on long-term therapy. This is usually reversible if the drug is stopped [2]. **Seizures**, encephalopathy, or cerebellar dysfunction are rare. Some advise caution with a history of central nervous system disorders. If neurologic symptoms develop on therapy and there is no other obvious cause, metronidazole should be stopped [2].
 - C. **Anticoagulation interference.** Metronidazole can potentiate the effect of warfarin.
 - D. **Miscellaneous.** **Mild gastrointestinal symptoms** of nausea, abdominal discomfort, and diarrhea can occur. Patients complain of a **metallic unpleasant taste** while on oral therapy. Metronidazole may be a cause of **acute pancreatitis**.
- VIII. **Cost.** Generic oral formulations are inexpensive (see Appendix Table 1).

R. Rifampin, Rifapentine, and Rifabutin

RIFAMPIN (RIFADIN) [1–4]

Rifampin, discovered in 1965, inhibits DNA-dependent RNA polymerase by binding to the subunit of the enzyme, thus interfering with protein synthesis [1]. Rifampin is bactericidal. Resistant strains of bacteria have altered RNA polymerase that is not inhibited by rifampin [1].

I. Spectrum of activity. Rifampin is a **broad-spectrum** agent active against bacteria, mycobacteria, and chlamydiae [1,2]

A. Bacteria. The *in vitro* activity of rifampin as a single agent is summarized in Table 27R.1.

B. Mycobacteria. Most strains of *Mycobacterium tuberculosis* are susceptible to rifampin, but **resistant strains have been isolated** with greater frequency in recent years [3,4]. The susceptibility of other mycobacteria is variable: *M. kansasii* and *M. marinum* are susceptible, whereas *M. fortuitum* and *M. chelonae* are resistant [1]. (See related discussions in Chapter 11.)

C. Chlamydiae. Many species of *Chlamydia*, particularly *C. trachomatis*, are susceptible.

II. Resistance. Monotherapy. Rapid emergence of resistant bacteria occurs with monotherapy [1]. Except for short-term **prophylaxis**, rifampin should not be used alone [1].

III. Pharmacokinetics and preparations. Rifampin is red-orange in color in the crystalline state. The **oral** form is well absorbed from the gastrointestinal (GI) tract in the fasting state. In late 1989, an **intravenous preparation** of rifampin became available for use when the oral route is not an option; this preparation should not be given intramuscularly [1,2].

*Adapted from Reese RE, Betts RF. Rifampin, rifapentine, and rifabutin. In: Reese RE, Betts RF, Gumustop B, eds. *Handbook of antibiotics*, 3rd ed. Philadelphia: Lippincott Williams and Wilkins, 2000: 527–541.

Table 27R.1. *In Vitro* Activity of Rifampin

Organism	MIC ₉₀ (μg/mL) ^a
Gram positive	
<i>Staphylococcus aureus</i> ^b	0.015
<i>S. epidermidis</i> ^b	0.015
<i>Streptococcus pyogenes</i>	0.12
<i>S. pneumoniae</i> (penicillin susceptible)	4.0
<i>Viridans streptococci</i>	0.12
<i>Enterococcus faecalis</i>	16.0
<i>J K diphtheroids</i>	0.05
<i>Listeria monocytogenes</i>	0.25
<i>Clostridium difficile</i>	≤0.2
<i>C. perfringens</i>	≤0.1
<i>Peptococcus, Peptostreptococcus species</i>	1.6
<i>Propionibacterium acnes</i>	≤0.1
Gram negative	
<i>Neisseria gonorrhoeae</i>	0.5
<i>N. meningitidis</i>	0.12
<i>Moraxella (Branhamella) catarrhalis</i>	0.03
<i>Haemophilus influenzae</i>	0.5
<i>H. ducreyi</i>	0.03
<i>Legionella pneumophila</i>	0.03
<i>Brucella species</i>	1.25
<i>Escherichia coli</i>	16.0
<i>Klebsiella pneumoniae</i>	32.0
<i>Enterobacter species</i>	64.0
<i>Pseudomonas aeruginosa</i>	64.0
<i>Bacteroides fragilis</i>	0.8
<i>B. melaninogenicus</i>	0.2

Source: Modified from Craig WA. Rifampin and related drugs. In: Gorbach SL, Bartlett JG, Blacklow NR, eds. *Infectious diseases*. Philadelphia: WB Saunders, 1992:265–266.

^aMIC₉₀ = concentration below which 90% of tested organisms are inhibited.

^bIn most cases, the MIC for methicillin-resistant strains is similar to those for methicillin-susceptible strains (1).

- A. Distribution.** Body fluids and tissue levels are similar to those observed in serum. Therapeutic concentrations are obtained in serum, urine, saliva, bone, pleura, pancreatic juice, and cerebrospinal fluid [1,2].
- B. Metabolism.** Rifampin is cleared from the circulation primarily by hepatic metabolism and biliary excretion. Its half-life is 2 to 5 hours and is prolonged in hepatic disease, perhaps more so with jaundice. **In renal failure**, only modest dose adjustments are advised (see section **VI.B**).
- C. Peak serum concentrations** after an oral dose of 600 mg or 10 mg/kg are variable but usually are in the range of 7 to 15 μg/mL [1].
- IV. Clinical use.** Rifampin has U.S. Food and Drug Administration approval only for treatment of patients with tuberculosis and carriers of *N. meningitidis* [4].
- A. Tuberculosis.** Rifampin is an important agent in the treatment of *M. tuberculosis* and for some of the atypical mycobacteria [5–7]. Rifampin or rifampin plus pyrazinamide are options for chemoprophylaxis of tuberculosis. One hesitates to use this in contacts of human immunodeficiency virus (HIV)-infected subjects because of the high risk of the index case having infection with multidrug resistant *M. tuberculosis* [6–9]. Because of the risk of drug-drug interactions of rifampin in HIV-infected patients on antiretroviral therapy, rifabutin is preferred for these patients (see section **VI.D.2** and Chapter 11).

- B. Bacterial meningitis contacts.** Rifampin has been used successfully in eradicating the carrier state of close **contacts of meningococcal or *Haemophilus influenzae* meningitis**. This is one of the rare uses of rifampin as monotherapy, but the use is legitimate because it is used for a very short time. See the rationale and specific recommendations in Chapter 6.
- C. Investigational studies.** When rifampin is used alone for specific infections, resistance rapidly develops. Thus there has been increased interest in the **use of rifampin with other antibiotics to avoid this** and yet take advantage of its excellent *in vitro* activity [10–12].
- 1. Methicillin-resistant *Staphylococcus aureus* (MRSA)**
 - a. MRSA nasal carriage.** Rifampin in combination with a second agent (e.g., trimethoprim-sulfamethoxazole) has been used to try to eradicate nasal carriage of MRSA [13]. Topical nasal mupirocin has also been used to eradicate MRSA nasal carriers [14]. See the related discussion in Chapter 27D.
 - b. MRSA infections.** Vancomycin is the therapy of choice [5] (see Chapter 27P). There are no data to support the routine addition of rifampin to vancomycin, but if there is an inadequate response to vancomycin alone, then the addition of rifampin, gentamicin, or both should be considered [5]. In his review, Farr [12] emphasized that rifampin resistance has been reported during therapy for MRSA infections with rifampin plus vancomycin, and the addition of gentamicin to the regimen may help prevent the development of rifampin resistance.
 - 2. Endocarditis.** Rifampin has been studied particularly in **endocarditis** due to *S. aureus* and *S. epidermidis* [12]. For *S. aureus*, there are conflicting *in vitro* data, because antagonism may be seen with combination therapy [15,16]. Infectious disease consultation is advised. Bactericidal levels should be compared before and after adding rifampin. **In the animal model of endocarditis** caused by MRSA, the combination of vancomycin with rifampin was significantly more effective than vancomycin alone [15]. In the same model with *S. epidermidis*, the addition of gentamicin or rifampin to vancomycin was beneficial, even though *in vitro* synergistic studies may not predict a beneficial effect [15]. See related discussions in Chapter 12.
 - 3. Legionella infections.** In severe pneumonia caused by *Legionella pneumophila* or other *Legionella* species, rifampin has often been combined with a macrolide, usually azithromycin, or a fluoroquinolone [5,10]. See related discussion in Chapter 11.
 - 4. Cerebrospinal fluid shunt infections.** In combination with vancomycin, rifampin has been used to treat staphylococcal coagulase-negative infections [17]. See discussion in Chapter 6.
 - 5. Chronic osteomyelitis** due to *S. aureus* has been treated with a combination of nafcillin and rifampin [1,2]. This complex and difficult problem is discussed elsewhere [12]. In these difficult cases, infectious disease consultation is advised (see Chapter 5).
 - 6. Brucella infections.** Prolonged therapy with doxycycline plus rifampin has a clinical response similar to that of tetracycline plus streptomycin [1,5,10].
 - 7. Orthopedic implant infections.** Patients with prosthetic device infections have been treated with rifampin-containing antibiotic combinations [18–20]. In a 1998 report, patients with stable implants and short duration of staphylococcal infection (<21 days) were treated with initial debridement and intravenous antibiotics. If patients could then tolerate long-term therapy with 3 to 6 months therapy of rifampin-ciprofloxacin, cure of the infection without device removal was commonly achieved [20–22]. Only patients with quinolone-susceptible staphylococci should be candidates for this form of therapy [22]. See related discussions in Chapter 5.
 - 8. Penicillin-resistant *S. pneumoniae* meningitis** merits therapy with vancomycin. Some experts have suggested that rifampin may be added [5]. If cefotaxime or ceftriaxone is used, rifampin in combination may improve results [23] (see Chapters 6, 11, 27C, and 27P).

9. Miscellaneous uses include combination therapy with penicillin for eradication of group A streptococcal carrier states and combination regimens for severe cat scratch disease [11].

V. Adverse reactions. Adverse reactions of rifampin often are classified into four types [2]:

- A. Immunosuppression.** In animal and *in vitro* studies, rifampin has been shown to suppress the secretion of migration inhibition factor by lymphocytes, the response of lymphocytes to stimulation by nonspecific mitogen, and the production of antibody by cultured lymph node cells. The precise implications of these studies for humans are unclear [12]. In addition, patients tuberculin skin test reactivity may be diminished by rifampin therapy.
- B. Immunologic reactions**
- 1. Allergic or hypersensitivity reactions** such as drug fever, skin rashes, and eosinophilia are uncommon.
 - 2. A flu-like syndrome** with fever, malaise, and headache can occur, particularly with irregular administration. It is very infrequent with daily or twice weekly tuberculosis regimens. Renal failure, thrombocytopenia, hemolysis, and the hepatorenal syndrome can occur in this flu-like syndrome [12]. Interstitial nephritis is a rare complication. Most patients improve with supportive care and withdrawal of the agent. Presumably, the risk of these reactions can be reduced if the doses are given on a regular schedule.
 - 3. Red-orange coloring of the urine, saliva, feces, sweat, and tears.** The most common side effect observed with rifampin is a harmless orange-red discoloration of the urine (see section III). Permanent staining of soft contact lenses can occur during rifampin therapy [1]. Patients should be forewarned of this to prevent unnecessary anxiety.
 - 4. Hepatotoxicity** has been seen in patients with overdose, prior hepatic disease, and concurrent use of hepatotoxic agents (e.g., halothane anesthesia). For patients with mild liver function test abnormalities, rifampin must be used with caution. Liver function tests ideally should be monitored carefully if the drug is used. For nonmycobacterial infections, if there is no underlying hepatic dysfunction, serial liver function tests are not routinely recommended.
 - a. Isoniazid and rifampin.** There is some concern about whether this combination increases hepatotoxicity. In one review, Craig [1] emphasized that although elevated liver enzyme values are observed in approximately 5% to 10% of recipients of rifampin, "hepatitis occurs in only 0.15% to 0.43%. The incidence of hepatitis rises to 2.5% with multiple drug regimens for tuberculosis. However, most studies suggest that rifampin does not enhance hepatotoxicity of isoniazid" [1].
 - b. Rifampin and pyrazinamide.** The new guidelines for use in treatment of latent tuberculosis infection (+PPD) were published in 2000 [8] (see Chapter 11).
 - (1) In these 2000 recommendations, for contacts of patients with isoniazid-resistant rifampin-susceptible tuberculosis, rifampin and pyrazinamide given daily for 2 months was one option [8].
 - (2) Unexpected severe hepatotoxicity developed in some recipients. This option is no longer advised for HIV-negative patients [24]. In addition, for those patients who are still candidates for the rifampin-pyrazinamide combination therapy, careful monitoring was advised [24] (see Chapter 11).
 - 5. Renal injury** is uncommon [12].
 - 6. Exudative conjunctivitis**, which is reversible with drug cessation, has been reported.
- C. Drug interactions.** Rifampin induces increased hepatic excretion of a number of drugs by stimulating an increase in activity of hepatic microsomal cytochrome P450-related enzymatic reactions and other compounds metabolized by the liver [1,2,12]. The interactions of rifampin have been reviewed in detail [25–28]. The **drugs that may interact with rifampin are summarized from these reports in Tables 27R.2 through 27R.6**, respectively.

Table 27R.2. Previously Described Rifampin Drug Interactions,^a Part I

Drug	Comments
Anticoagulants, oral ^b	Increase anticoagulant dose based on monitoring of prothrombin time
β -Blockers	May need to increase propranolol or metoprolol dose
Chloramphenicol	Monitor serum chloramphenicol concentrations; increase dose if needed
Contraceptives, oral ^b	Use other forms of birth control; document patient counseling in chart
Cyclosporine ^b	Monitor serum cyclosporine concentrations; increased dose will likely be needed
Digitoxin ^b	Monitor serum digitoxin concentrations; monitor for arrhythmia control and signs and symptoms of heart failure; increase dose if needed
Digoxin	Monitor serum digoxin concentrations; monitor for arrhythmia control and signs and symptoms of heart failure; clinically significant interaction most likely in patients with decreased renal function
Glucocorticoids ^b	Increase glucocorticoid dose twofold to threefold with concomitant rifampin therapy
Ketoconazole ^b	Avoid this combination if possible; monitor serum ketoconazole concentrations; increase dose if needed; space rifampin and ketoconazole doses by 12 h
Methadone ^b	Increase methadone dose with concurrent rifampin therapy; control withdrawal symptoms
Phenytoin ^b	Monitor serum phenytoin concentrations; increase phenytoin dose if needed
Quinidine ^b	Monitor serum quinidine concentrations; monitor for arrhythmia control; increase dose if needed
Sulfonylureas	Increase sulfonylurea dose based on blood glucose control; monitor blood glucose with discontinuation of rifampin therapy
Theophylline ^b	Monitor serum theophylline concentrations; increased dose will likely be needed
Verapamil ^b	Use alternative agent to verapamil if possible, because even very large increase in oral verapamil may not be sufficient; monitor serum verapamil concentrations; monitor patient for clinical response

^aCarefully adjust doses when rifampin is discontinued; enzyme induction effect is gradually reduced over 1–2 weeks. For details see Borchering SM, Baciewicz AM, Self TH. Update on rifampin drug interactions. *II. Arch Intern Med* 1992;152:711.

^bMajor clinical significance is well established.

From Borchering SM, Baciewicz AM, Self TH. Update on rifampin drug interactions. *Arch Intern Med* 1992;152:711, with permission.

1. Antiretroviral therapy. Of the available rifamycins, rifampin is the most potent CYP450 inducer, followed by rifapentine and then rifabutin, which has substantially less activity as an inducer [28,29]. Although this topic is reviewed in detail elsewhere, a few points deserve special emphasis. Also see related discussions in Chapter 19.

a. Protease inhibitors and nonnucleoside reverse transcriptase inhibitors. Drug-drug interactions occur with rifamycins, principally because of the induction or inhibition of the cytochrome CYP450 enzyme system. For example, if a protease inhibitor is administered with rifampin, blood

Table 27R.3. Rifampin Drug Interactions,^a Part II

Drug	Comments
Antacids	May need to space rifampin and aluminum hydroxide doses apart by several hours; more study needed
Haloperidol	Monitor serum haloperidol concentrations; alter dosing regimen if needed; limited initial study indicates serum concentrations and half-life are reduced by about 50%
Tocainide	Monitor arrhythmia control; increase dose if needed; 1 trial in healthy subjects found nearly 30% decrease in tocainide serum half-life
Disopyramide	Monitor arrhythmia control; increase dose if needed; initial study indicates decrease in disopyramide serum half-life of about 50%
Propafenone	Monitor plasma propafenone concentrations; monitor arrhythmia control; increase dose if needed
Ciprofloxacin	No interaction noted in humans to date; more study needed
Dapsone	Decrease serum concentrations; studies needed in patients with <i>Pneumocystis carinii</i> pneumonia
Fluconazole	May need to increase fluconazole dose; monitor signs and symptoms of infection; one trial in healthy subjects found 22% decrease in fluconazole serum half-life
Nifedipine	Monitor clinical response; may need to increase dose; controlled study needed
Diltiazem ^b	Consider alternative agent to diltiazem if possible, because even very large increase in oral diltiazem may not be sufficient; may monitor serum diltiazem concentrations (see Table 27R.2 regarding similar interaction with verapamil); monitor clinical response
Diazepam	Monitor clinical response; may need to increase diazepam dose; 300% increase in diazepam oral clearance has been reported

^aAgents available in the United States; for each interaction, carefully adjust doses when rifampin is discontinued; enzyme induction effect is reduced gradually over 1–2 weeks.

^bMore study needed in patients; probably of major clinical significance.

From Borchering SM, Baciewicz AM, Self TH. Update on rifampin drug interactions. *Arch Intern Med* 1992;152:711, with permission.

concentrations of the protease inhibitor decrease markedly and most of the antiviral activity decreases as well [29] (see Chapter 19). **Rifabutin is a less potent inducer with less of an effect** on the drug levels of antiretrovirals (Table 27R.5).

b. Rifabutin is preferred. Because rifampin markedly lowers the blood levels of these antiretrovirals, which results in suboptimal antiretroviral therapy, rifampin is always contraindicated [29] (see Chapter 19).

c. Rifapentine is not recommended as a substitute for rifampin because its safety and effectiveness have not been established for the treatment of patients with HIV-related tuberculosis [29].

2. Oral contraceptives. As shown in Table 27R.2, **rifampin impairs the effectiveness of oral contraceptives**; this topic has recently been reviewed [30].

D. Thrombophlebitis can occur with the parenteral form [11].

VI. Dosages and precautions

A. Dosages. Capsules are available in 150- and 300-mg sizes. The oral regimen is preferred and is given 1 hour before or 2 hours after meals. For special needs, a liquid suspension can be made according to the package insert. The same dose per day is given orally or intravenously.

Table 27R.4. Rifampin Drug Interaction,^a Part III

Type of Drug	Comments
Clarithromycin	Monitor signs and symptoms of infection; more study needed.
Delavirdine	Avoid concomitant use if possible.
Doxycycline	Monitor clinical response and serum doxycycline concentrations; increased dosage may be needed.
Itraconazole	Monitor clinical response; increased dosage will likely be needed.
Midazolam	Monitor for decreased efficacy; increase dosage as necessary.
Nifedipine	Alternative class of agents should be considered; monitor clinical response; dosage increase may be needed. ^b
Nortriptyline	Monitor clinical response and serum nortriptyline concentrations.
Pefloxacin	Moderate rifampin induction effect; pending further research, no dosage adjustment recommended.
Protease inhibitors	Most significant decreases in serum concentrations seen with saquinavir mesylate, indinavir sulfate, and nelfinavir mesylate; ritonavir appears to have less reduction in serum concentrations; adjust dosage as necessary.
Tacrolimus	Monitor serum tacrolimus concentrations and clinical responses; increased dosage may be needed.
Triazolam	Monitor for decreased efficacy; increase dosage as necessary.
Zidovudine	Monitor clinical response; increased dosage may be necessary.

^aCarefully adjust dosage when rifampin use is discontinued. Enzyme induction effect is gradually reduced during a 1- to 2-week period or longer. Based on small numbers of reports; further studies are needed for most of these agents.

^bSee also verapamil (Table 27R.2) and diltiazem (Table 27R.3).

From Stayhorn VA, Baciewicz AM, Self TH. Update on rifampin drug interactions, III. *Arch Intern Med* 1997;157:2453, with permission.

1. **Tuberculosis:** A single daily dose of 10 mg/kg up to 600 mg for adults and 10 to 20 mg/kg, not to exceed 600 mg/day, for children is used. The same doses are used in the intermittent regimen [2]. See detailed discussion in Chapter 11.
2. **In meningococcal meningitis and *H. influenzae* meningitis contacts,** dose regimens are discussed in Chapter 16.
3. **Doses for other regimens**
 - a. ***S. epidermidis* prosthetic valve endocarditis.** Vancomycin given in combination with rifampin (300 mg every 8 hours) and gentamicin (1.0–1.3 mg/kg every 8 hours) is advocated in adults [31]. All three drugs are given for 2 weeks, and vancomycin and rifampin are continued for an additional 4 weeks (see Chapter 12).
 - b. **Prosthetic device infections.** Rifampin 450 mg every 12 hours [16] and 300 mg every 8 to 12 hours have been used (see Chapter 5). Another antibiotic such as ciprofloxacin or vancomycin is always used.
- B. Renal failure.** Dose modifications are suggested [32]. For a creatinine clearance of 10 to 50 mL/min, 50% to 100% of the usual dose is suggested. For a creatinine clearance of less than 10 mL/min or for the patient on chronic ambulatory peritoneal dialysis, 50% of the usual dose is suggested [32].

Table 27R.5. Percentage by Which Rifampin and Rifabutin Lower the AUC of PIs and NNRTIs

	Indinavir	Nelfinavir Mesylate	Saquinavir Mesylate	Amprenvir	Ritonavir	Ritonavir and Lopinavir	Efavirenz	Nevirapine	Delavirdine Mesylate
Rifampin	89	32	84	82	35	75	25	34	96
Rifabutin	32	32	40	15	0	0	0	16	80

AUC, area under the concentration–time curve; PI, protease inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor.

Table 27R.6 Updated Rifampin Drug Interactions,^a Part IV

Type of Drug	Comments
Controlled drug interaction studies	
Selective serotonin receptor (5-HT ₃) antagonist	Monitor clinical response, increase dose if needed; use another agent if needed
Bupirone hydrochloride	Monitor clinical response; increased dose will likely be needed or use another agent if possible
3-Hydroxy-3-methylglutaryl coenzyme A reductase inhibitors	Monitor lipid panel; increased dose will likely be needed for simvastatin; further research needed for other agents in this class
Metronidazole	Monitor for decreased clinical response; increase dose if needed or use another agent if possible
Opiates (morphine or codeine)	Monitor pain control and clinical response; increased dose may be needed in extensive metabolizers; use another agent if possible; may be associated with ethnic variability
Propafenone hydrochloride	Monitor clinical response; increased dose may be needed or use another agent if possible
Tamoxifen citrate or toremifene citrate	Monitor clinical response; increased dose likely needed
Zolpidem tartrate	Monitor clinical response; increased dose may be needed or use another agent if possible
Potential interactions based on case reports^b	
Clozapine	Monitor clinical response; increase dose if needed or use another agent if possible
Levothyroxine sodium	Monitor thyrotropin level; increase dose likely needed
Sertraline hydrochloride	Monitor clinical response; increase dose if needed

^aCarefully adjust dosage when rifampin use is initiated and discontinued. The enzyme induction is gradually reduced during a 1- to 2-week period or longer when rifampin therapy is discontinued. Based on the small number of reports, further studies are needed for most of these agents.

^bControlled study is needed to establish the importance and extent of the interaction.

C. Pregnancy. Rifampin is a **category C** agent (see Chapter 27A). Rifampin crosses the placenta readily and is teratogenic in animals. There are no adequate and well-controlled studies in pregnant women in terms of the effects on the fetus. The package insert emphasizes that rifampin should be used during pregnancy only if the potential benefits justify the potential risks to the fetus [4]. Rifampin has been used to treat severe cases of tuberculosis in pregnant women [1]. Rifampin is not recommended for pregnant women who are contacts of infected patients with *H. influenzae* meningitis. Pregnant women in close contact with an index case of *N. meningitidis* can be treated with ceftriaxone (see the related discussion in Chapter 6).

D. Nursing mothers. Because of the potential for tumorigenicity of rifampin shown in animal studies, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother [4].

E. Liver disease. The use of rifampin in patients with liver disease is not recommended except in case of necessity; in such patients, the drug's half-life usually is doubled [1].

F. Drug interactions (see section V.C and Table 27R.6)

RIFAPENTINE (PRIFITIN)

Rifapentine (Priftin) is a long-acting analogue of rifampin that became available in late 1998 for oral use, with at least one other drug, in the treatment of pulmonary tuberculosis. It inhibits DNA-dependent RNA polymerase [33].

- I. **Activity.** Rifapentine is active against *M. tuberculosis*, but strains resistant to rifampin are also resistant to rifapentine. Rifapentine is also active against *M. avium* and *Toxoplasma gondii* [33].
- II. **Pharmacokinetics.** Rifapentine is well absorbed, especially when taken with food. It is excreted mostly in the feces (70%). It is metabolized to a desacetyl form that is microbiologically active, contributing 40% of the drug's overall activity [33].
- III. **Clinical trials.** Only limited data are available so far about the clinical efficacy of this agent in pulmonary tuberculosis regimens [33]. Further clinical studies are needed before the precise role of this agent is clarified. See related discussions in Chapter 11.
- IV. **Dosage.** Tablets of 150 mg are available. The recommended dosage of rifapentine in adults is 600 mg twice weekly (with at least 72 hours between doses) for the first 2 months of therapy and then 600 mg once a week, always in combination with other antituberculosis drugs [33].
- V. **Adverse effects.** Like other rifamycins, rifapentine causes red-orange discoloration of body fluids and stains contact lenses. In clinical trials with isoniazid, rates of adverse reactions were similar to those with rifampin and rifapentine. The only adverse effect that occurred more often with rifapentine than with rifampin was hyperuricemia when the drug was given twice weekly [33] (see related discussions under Rifampin, above).
- VI. **Drug interactions** (see related discussion in section V.C under Rifampin). In terms of other drugs, until further experience is available, it seems prudent to assume rifapentine may have the same drug interactions as rifampin (see above discussion under Rifampin).
- VII. **Conclusion.** In its February 1999 review of this agent, the *Medical Letter concluded*: "rifapentine has the advantage over rifampin of requiring only twice-weekly doses for initial therapy of tuberculosis and once-weekly doses during the continuous phase of treatment. **It is not clear that rifapentine in the dosages currently recommended is as effective as rifampin. Until more data become available, rifampin is preferred**" [33]. We concur with this conclusion (see related discussions in Chapter 11).

RIFABUTIN (ANSAMYCIN)

Rifabutin (Mycobutin) [34–43] is a semisynthetic ansamycin approved in 1992 for the prevention of disseminated *Mycobacterium avium* complex (MAC) in patients with advanced HIV infection [39]. It also is used in regimens to treat disseminated MAC [5]. Because of the concerns with drug-drug interactions in HIV-infected patients on antiretroviral drugs, rifabutin is preferred over rifampin in therapy of tuberculosis [29] (see section V.B.2 under Rifampin). Rifabutin is active against most strains of MAC isolated from HIV-positive and HIV-negative people. The minimal inhibitory concentration (MIC)₉₀ of MAC is typically approximately 2 $\mu\text{g}/\text{mL}$ [1]. Rifabutin is also active against all rifampin-sensitive *M. tuberculosis* strains and about one-third of rifampin-resistant strains [12].

- I. **Pharmacokinetics.** The drug is taken up by all tissues and is especially concentrated in the lungs, where levels may be 10 times higher than in the serum [12]. Rifabutin has excellent solubility in lipids, which results in good intracellular penetration; cerebrospinal fluid concentrations are about 50% of those in the serum [42].
 - A. **Bioavailability.** Rifabutin is absorbed rapidly, and absolute bioavailability is in the range of approximately 20% [1].
 - B. **Metabolism** is similar to that for rifampin. The elimination half-life is long (45 hours), and as a result of a very large volume of distribution, average plasma concentrations remain relatively low after repeated standard doses [34]. Animal models suggest rifabutin has less of an effect on hepatic microsomal enzyme activity than rifampin [28,29] (see section V.B under Rifampin).
- II. **Clinical studies**
 - A. **Therapy of *M. tuberculosis* in HIV-infected patients on antiretroviral drugs.** (See related discussion in section IV.A and V.C under Rifampin.) In these patients, rifabutin is preferred [28,29].
 - B. **MAC.** [39,42] Rifabutin is used as an **alternative regimen to prevent MAC** in patients with HIV infection. This topic has been reviewed elsewhere [39], but

prophylaxis should be considered for HIV-infected adults and adolescents who have CD4⁺ lymphocyte counts of less than 50/mm³. **Clarithromycin or azithromycin are the preferred prophylactic agents** with rifabutin as an alternate. Because the combination of clarithromycin and rifabutin is no more effective than clarithromycin alone and is associated with a higher rate of adverse effects than either agent alone, this combination should not be used [39]. Disseminated MAC should be ruled out before starting prophylaxis (i.e., with a negative blood culture for mycobacterium). Because treatment with rifabutin could result in the development of resistance to rifampin in persons who have active tuberculosis, tuberculosis should be excluded before rifabutin is used for prophylaxis [39].

- C. **MAC therapy.** Rifabutin has also been used in **therapeutic regimens** for disseminated MAC in patients with acquired immunodeficiency syndrome [5,36,38]. Infectious disease consultation is advised.

III. Dosages.

A 150-mg capsule is available.

- A. **MAC prophylaxis.** When patients with advanced HIV cannot tolerate clarithromycin or azithromycin, 300 mg administered orally once daily is recommended [39]. If there is a propensity to nausea, vomiting, or other GI upset, 150 mg twice daily is given with meals.

- B. **Treatment of disseminated MAC** with rifabutin 300 to 450 mg orally daily has been suggested, along with clarithromycin or azithromycin and/or ethambutol and/or ciprofloxacin [5,40,42]. Because of the potential side effects at higher doses (see section IV), 300 mg/day of rifabutin may be a rational compromise [41]. Infectious disease consultation is suggested. For *M. tuberculosis*, see regimens in Chapter 11.

- C. **Pediatric use.** The safety and effectiveness of rifabutin for prophylaxis of MAC in children have not been established, per the package insert. However, preliminary recommendations suggest consideration of rifabutin for children infected with HIV and depressed CD4⁺ cell counts who cannot tolerate clarithromycin or azithromycin [39,42]. Candidates for prophylaxis include the following CD4⁺ thresholds (cells/ μ L): children 6 years of age or more, less than 50; children aged 2 to 6 years, less than 75; children aged 1 to 2 years, less than 50; and children below 12 months of age, less than 750 [39]. A liquid formulation of rifabutin is under development. The drug can be mixed with foods such as applesauce for administration to children [42]. A dosage of 5 mg/kg of rifabutin has been used per package insert.

- D. **Pregnancy.** Rifabutin is viewed as a **category B** agent (see Chapter 27A). The package insert suggests that rifabutin should be used in pregnant women only if the potential benefit justifies the potential risk to the fetus. Chemoprophylaxis for MAC should be administered to pregnant women and other adults and adolescents [39]. However, because of general concern about administering drugs during the first trimester of pregnancy, some providers may choose to withhold prophylaxis during the first trimester. **Azithromycin is the agent of choice for prevention of MAC in pregnancy** (see Chapter 27N). Experience with rifabutin in this setting is limited [39].

- E. **Nursing mothers.** It is not known whether rifabutin is excreted in human breast milk. The package insert suggests that a decision should be made about whether to continue nursing or discontinue rifabutin, taking into account the importance of the drug to the mother. (See Chapter 27N regarding the association between macrolide use in infants and hypertrophic pyloric stenosis.)

- F. **In renal failure** no dosage modifications are necessary. Neither hemodialysis nor chronic ambulatory peritoneal dialysis requires dosage adjustment [32].

- G. **In hepatic dysfunction**, the package insert does not currently advise any dosage modifications.

IV. Side effects.

Rifabutin is generally well tolerated at the prophylaxis dose of 300 mg/day. Rash, GI intolerance, and neutropenia are seen in 2% to 4% of recipients [4]. In therapeutic regimens for MAC and at higher doses (e.g., 600 mg/day or more), adverse effects can be seen in most patients, especially leukopenia, GI intolerance, diffuse polyarthralgia syndrome (19%), and **anterior uveitis** (6%) [41,43]. Use of rifabutin may cause an orange-brown discoloration of urine, feces, saliva, tears, and soft contact lenses [42].

Rifabutin is metabolized in the liver and induces activity of the hepatic cytochrome P450 enzyme group, which may lead to pharmacokinetic interaction with other drugs administered concurrently [42]. The extent to which this occurs, compared with rifampin, is discussed in section **V.D** under Rifampin. Concurrent administration of fluconazole or clarithromycin can increase serum concentrations of rifabutin by 80% to 100% and potentially increase toxicity (e.g., increase the risk of uveitis) [43].

- V. Investigational uses.** Rifabutin is undergoing clinical investigation for the treatment of Crohn disease [44]. It is also being used in multiple drug regimens designed to treat difficult to eradicate *H. pylori* infections [45].

S. Spectinomycin

Spectinomycin (Trobicin) was approved in 1971. The structure of spectinomycin is similar, but not identical, to aminoglycosides and inhibits ribosomal protein synthesis. It is bactericidal against gonococci. **Spectinomycin is used only as an alternative agent for *Neisseria gonorrhoeae*** [1–4].

- I. Indications.** Alternative regimens for gonococcal infections (see Chapter 16).
- A. Uncomplicated urethral, endocervical, or rectal infections.** When the drugs of choice (cephalosporin or quinolone) cannot be used, spectinomycin is an alternative [1–4]. It is active against penicillin-resistant strains of gonococci. In published trials, cure rates of 98.2% of uncomplicated urogenital and anorectal injections have been achieved with spectinomycin [2].
- B. Treatment of gonococcal infections in pregnancy.** Pregnant women who cannot tolerate cephalosporins can be treated with spectinomycin [2].
- C. Disseminated gonococcal infections.** Patients who are allergic to β -lactams and quinolones (or for whom quinolones are contraindicated) can be treated with spectinomycin [2].
- II. Contraindications and limitations to use** [1–4]
- A. Pharyngeal gonococcal infection.** Spectinomycin is ineffective against this infection, probably because the drug is not secreted in saliva in adequate concentrations.
- B. Incubating syphilis.** Spectinomycin will not abort incubating syphilis and may actually prolong the incubation period. Thus syphilis serology at the time of treatment and again in 2 to 3 months to rule out this associated diagnosis is indicated.
- C. Nonspecific urethritis** (nongonococcal urethritis). At least 50% of cases that are not susceptible to spectinomycin are due to *Clostridium trachomatis*.
- III. Actual or potential resistance.** Spectinomycin does not produce sustained high bactericidal levels in blood. Resistant strains have occurred in the United States and elsewhere [4]. Prior data suggest that extensive use of spectinomycin in initial gonococcal therapy might lead to the emergence of spectinomycin-resistant gonorrhea [5]. Careful use of spectinomycin has also been emphasized in a report by Boslego et al. [6]. After only 3 years of using spectinomycin as the primary treatment for uncomplicated gonococcal urethritis in U.S. military men in the Republic of Korea, more than 8% of recipients were treatment failures [6] (see Chapter 16).
- IV. Route and dosage.** Spectinomycin **intramuscularly** is well absorbed. In uncomplicated anogenital gonococcal infection, 2 g spectinomycin is given as a single dose in men or women and in children, 40 mg/kg (maximum 2 g) [2]. As an alternative agent in disseminated gonococcal infection, 2 g intramuscularly every 12 hours can be used [2]; optimal duration is not well defined, but a 7-day course seems prudent [2].
- In renal failure,** no dose adjustment is required. Neither hemodialysis nor chronic ambulatory peritoneal dialysis removes spectinomycin [7]. It is relatively expensive (see Appendix Table).
- V. Toxicity** appears very limited, perhaps because the total dose is low. There are no known serious adverse reactions.
- VI. Conclusions.** Spectinomycin has a **limited but useful role in gonococcal infections**. The best use of this agent is in the treatment of gonorrhea in persons who cannot tolerate or be treated with cephalosporins or quinolones [2].

T. Urinary Antiseptics

Urinary antiseptics are agents that concentrate in the urine but do not produce therapeutic levels in the serum. Therefore these agents are useful only in the **prevention or therapy of lower urinary tract infection** (UTI) but are not indicated for pyelonephritis or associated systemic infection [1–3]. This unique feature has **advantages, including** reduced suppression of normal flora compared with other antimicrobials used for UTI, decreased rates of resistance, low rates of yeast overgrowth, and minimization of teratogenic risk and fetal toxicity [3].

- I. **Nitrofurantoin** inhibits various enzymes within bacteria, and nitrofurantoin intermediates also damage DNA directly, leading to DNA strand breakage [2,3].
 - A. **Spectrum of activity.** Nitrofurantoin is active against most *Escherichia coli*, *Enterobacter* and *Klebsiella* species. *Pseudomonas* species are resistant, as are most *Proteus* species. Nitrofurantoin also is active against gram-positive bacteria that sometimes produce a UTI, such as enterococci or coagulase-negative staphylococci [1–3]. Of note, some isolates of vancomycin-resistant enterococci remain susceptible to nitrofurantoin, and this agent may be useful in the treatment of selected patients with lower UTI caused by this difficult to treat organism. Infectious diseases consultation is recommended for these patients.
 - B. **Pharmacokinetics.** Nitrofurantoin is well absorbed from the gastrointestinal (GI) tract, but it **does not reach therapeutic concentrations in tissue, only in urine**. Bioavailability increases when taken with food. Therapeutic **urinary concentrations** of the drug are present for up to 6 hours. Tubular reabsorption provides levels in renal medullary tissue. The liver is the principal site of metabolic inactivation [2,3].

The drug is contraindicated in renal failure (i.e., creatinine clearance of less than 50 mL/min) [4] because adequate urinary antibiotic levels may not be achieved and serum levels increase in renal failure, presumably increasing the toxicity of this agent. In alkaline urine, the antibacterial effect of nitrofurantoin is decreased; therefore the urine should not be alkalinized [2].
 - C. **Resistance.** Nitrofurantoin's *in vitro* activity has remained stable despite four decades of use. This has been explained in part by its broad mechanisms of action, high oral bioavailability, and low concentrations at mucosal surfaces [3].
 - D. **Preparations.** All are equally active, and sections 1 and 2 below have similar pharmacokinetics.
 1. **Furadantin** is the **microcrystalline** form and has been available since 1953.
 2. **Macrodantin** is the macrocrystalline form. It appears to be associated with a **lower incidence of GI side effects** [2]. This is the preferred agent.
 3. **Nitrofurantoin monohydrate** (75 mg) macrocrystals (25 mg) (Macrobid) is a slow-release formulation, in a capsule, equivalent to 100 mg nitrofurantoin.
 4. An intravenous preparation of nitrofurantoin is no longer available.
 - E. **Uses.** Nitrofurantoin is used in the treatment of susceptible uncomplicated (lower) UTI or the prophylaxis of recurrent UTI [1–3,5]. Cure rates for lower UTI range from 70% to 95%. Nitrofurantoin **should not be used for symptomatic upper UTI or complex UTI** in which therapeutic levels of antibiotic may not be attained at the site of infection [1–3].

1. **Therapy** for 3 to 7 days at 100 mg twice daily taken with meals in adults with normal renal function is suggested [3]. **In children** older than 1 month of age, 5 to 7 mg/kg/day is given in divided doses four times a day, commonly for 7 days. **Therapy in pregnancy** is discussed in section 5. In lower UTI due to **susceptible enterococci**, nitrofurantoin may provide an alternative **agent** for the ampicillin-allergic patient [5].
 2. **UTI prophylaxis.** Macrochantin has been given daily at bedtime or after coitus as a single 50- or 100-mg dose to women with recurrent uncomplicated UTI (see Chapter 15). In children older than 1 month of age, 1 to 2 mg/kg/day in one daily dose has been used. Prolonged use requires periodic clinical assessment for pulmonary and neurologic toxicity as well as complete blood count and transaminase determinations [3] (see section F).
 3. **If creatinine clearance** is less than 50 mL/min, **the drug is contraindicated** [4] (see section B).
 4. **In hepatic failure**, the drug should be avoided because of its association with hepatotoxicity.
 5. **In pregnancy**, caution should be used; this is a **category B agent** (see Chapter 27A). This topic has been reviewed elsewhere [3,6]. Nitrofurantoin is considered a safe and effective agent when ampicillin (amoxicillin) cannot be used because of allergies or resistance. However, a single 200-mg dose of nitrofurantoin for asymptomatic bacteriuria has been associated with a failure rate of 27%, similar to other single dose failure rates. Symptomatic bacteriuria (acute cystitis) or relapse after single dose has been treated with nitrofurantoin 100 mg two to four times a day for 3 to 7 days [3,6]; more experience is available with 7 days [6]. Follow-up urine cultures are important. Suppressive therapy may be indicated if a repeat course of therapy does not sterilize the urine [6]. Nitrofurantoin is safe in pregnancy postcoital or nightly at a dose of 50 mg [3].
- F. Toxicity.** The side effects of nitrofurantoin have been well documented and reviewed in detail elsewhere [7]. **GI irritation** is the **most common** side effect, with anorexia, nausea, and vomiting. This may be decreased by using the macrocrystalline preparation (Macrochantin) and may be dose related [1,3]. Serious adverse reactions have occurred at approximately 28 per million treatment courses [3,7]. **Because major adverse events are more common in the elderly**, with reduced renal function of aging, we agree with the recommendation that **nitrofurantoin is rarely warranted in people 60 years of age or more** [3]. The **frequency of these serious adverse reactions** in more than 120 million treatment courses is shown in Table 27T.1; some reactions are fatal.

Table 27T.1. Nitrofurantoin and Serious Adverse Events

Adverse Event	Patients Worldwide	Incidence ^a (Reactions/Million Treatment Courses)
Acute pulmonary	1,138	9.4
Subacute pulmonary	22	0.2
Chronic pulmonary	281	2.3
Miscellaneous pulmonary	283	2.3
Hepatic	312	2.6
Neurologic	847	7.0
Hematologic	500	4.1
Total	3,383	27.8

^aBased on 121.43 million courses of therapy.From Darcy P. Nitrofurantoin. *Drug Intell Clin Pharmac* 1985;19:540-547; and Dow G, Ronald AR. Miscellaneous drugs. In: Root RK, et al., eds. *Clinical infectious disease: a practical approach*. New York: Oxford University Press, 1999, with permission.

1. **Pulmonary reactions are the most common severe problem** [1–3,7,8].
 - a. **Acute pneumonitis** with fever, cough, and eosinophilia may occur after a few hours or days of therapy. On chest roentgenography, pulmonary alveolar-interstitial infiltrates or pleural fluid is seen. This pneumonitis probably is hypersensitivity phenomenon and is rapidly reversible by discontinuing treatment. Acute reactions do not generally progress to chronic reactions [1–3]. Corticosteroids may be used in patients with severe reactions [3].
 - b. **Subacute** presentations are less likely to have fever and eosinophilia and are slower to resolve. **Chronic** pulmonary reactions with interstitial infiltrates are rare and occur when the drug has been prescribed for more than 6 months [3]. This latter syndrome has an **insidious onset** (malaise, cough, dyspnea on exertion). Fever and eosinophilia are seen less frequently. This reaction presumably represents a cumulative toxic drug effect. In some cases, improvement occurs with discontinuation [1–3]. A beneficial effect of corticosteroid therapy has not been convincingly demonstrated in patients with chronic nitrofurantoin pulmonary reactions [2]. Histopathology reveals chronic pneumonitis and fibrosis [3].
2. **Polynuropathies** (ascending sensorimotor) with demyelination and degeneration of sensory and motor nerves may occur, more often in patients with renal failure or on chronic therapy [1–3]. The mechanisms are unclear, but it is believed to be related to a direct toxic effect of the drug. Sensory symptoms usually begin within 6 weeks of starting therapy followed by motor neuropathy; total recovery occurs in one-third of cases, with partial recovery in one-half [3]. **The drug should be stopped if early signs of a neuritis, such as paresthesias, develop.**
3. **Hepatic reactions** are rare and of two types [1–3].
 - a. **Acute cholestatic hepatitis** with fever, rash, eosinophilia, and jaundice. This appears to be immunologically mediated and resolves with discontinuation of nitrofurantoin [1–3].
 - b. **Chronic active hepatitis** has an insidious onset after prolonged therapy (more than 6 months). Recovery is seen in most patients if the nitrofurantoin is discontinued.
 - c. **Monthly liver function tests** for patients on chronic nitrofurantoin are suggested by some [9].
4. **Bone marrow depression** or megaloblastic anemia may occur. **In patients with glucose-6-phosphate dehydrogenase deficiency, acute hemolysis may be precipitated.** However, based on one report, clinically important hemolytic reactions appear to be rare [10].
5. **Maculopapular rashes, urticaria, and angioneurotic edema** occur in 1% to 5% of recipients [3]; these resolve rapidly with discontinuation of therapy.
6. **In children**, there has been concern that the side effects of nitrofurantoin may outweigh the benefits. However, it has been concluded that **serious adverse reactions in children are rare** and that most patients recovered from their reactions once the drug was discontinued. Therefore **nitrofurantoin remains potentially useful** in pediatric patients [11,12].

G. Contraindications to use [3]

1. **Renal insufficiency** (see section I.B)
2. **Children less than 1 month** of age (nitrofurantoin can cause hemolysis)
3. **Pregnant woman near delivery** (to avoid transplacental transfer at the time of birth)

II. Methenamine [2,3] is not an active antibacterial agent but has been used as a urinary antiseptic since 1895 [3]. It has the advantage of economy, tolerability, minimal effect on GI flora, and absence of bacterial resistance [3]. With the emergence of bacterial resistance, this is a **potentially useful UTI suppressive agent**.

- A. Mechanism of action.** Under acid pH, methenamine is hydrolyzed to form formaldehyde and ammonia. **Formaldehyde is the active agent** that yields protein denaturation. It is bacteriostatic at low and bactericidal at higher levels [3]. Formaldehyde formation depends on several factors:

1. **Acid environment.** For hydrolysis to occur, an acid pH is required. Ideally, the **urine pH must be 6.0 or less [2]**. In many patients, in the absence of diuresis, the pH of the urine is low enough to liberate free formaldehyde. Fluid restriction may also help (see section **D**).
 2. **Kinetics.** At least 2 to 3 hours are necessary to generate adequate concentrations of formaldehyde. Therefore **in a patient with a chronic indwelling bladder catheter, it is not surprising that it is ineffective [13]**. However, this agent may be helpful for patients with prostatic hypertrophy where retention provides adequate contact time. The same is true for preventing UTI in patients with neurogenic bladders who are in a program of intermittent catheterization and bladder retraining [14].
 3. **High dosage.** Adequate doses of methenamine are needed to provide sufficient formaldehyde.
- B. Spectrum of activity.** If sufficient formaldehyde is generated, **all bacteria are susceptible, and bacteria do not become resistant.**
- C. Pharmacokinetics.** Methenamine is well absorbed from the GI tract and is excreted into the urine. Under ideal urine pH, only 2% to 20% is converted into free formaldehyde. Because ammonia is also generated, **the agent is contraindicated in hepatic insufficiency [2]**.
- D. Preparations available.** Therapeutically available agents combine methenamine with acids to help acidify the urine. These include methenamine mandelate (Mandelamine) and methenamine hippurate (Hiprex or Urex). However, in the usual recommended doses, these organic acids generally are inadequate to acidify the urine [2]. Methenamine alone has been given with large doses of ascorbic acid (2–6 g daily) to achieve the desired result.
- Fluid restriction** has been suggested as a more useful method to **acidify urine**. This acts to reduce voiding frequency, acidify the urine, and allow more formaldehyde generation. **Patients should be asked to reduce voiding frequency and restrict fluids to 1,200 to 1,500 mL/day so that the urine specific gravity is maintained at a level of 1.015 or greater [3]**.
- E. Uses.** Methenamine and ascorbic acid (or methenamine hippurate [15]) are used primarily in **chronic suppressive therapy** for patients without an indwelling catheter. They are **not indicated for acute UTI**. This regimen may be particularly useful in partial obstruction. **It is important to sterilize the urine initially with another agent [16]**. In UTI due to *Proteus* species it may be impossible to achieve adequate pH levels because of the high urinary pH generated.
- F. Dosage**
1. In **adults**, 1 g of methenamine mandelate or methenamine hippurate orally two to four times a day. Fluid restriction is useful to provide adequate acidification (see section **D**). Ascorbic acid (e.g., 1 g orally four times a day) may be given in an attempt to acidify the urine adequately and keep the pH less than or equal to 6.0. Ideally, urine pH should be monitored daily or every other day. Higher doses of ascorbic acid may be necessary when reduction of the pH to 6 is not achieved with 4 to 6 g daily.
 2. **For children between 6 and 12 years of age**, the dose is 500 mg to 1 g twice daily. A suspension (methenamine mandelate 500 mg/5 mL) is available for younger children; for children less than 6 years of age, the usual dose is 250 mg per 30 pounds of body weight orally four times a day [2].
 3. **In renal failure**, limited guidelines are available. Methenamine alone is nontoxic and urinary methenamine is readily converted to formaldehyde in the azotemic state [3]. Methenamine-acid combinations are not advised if the creatinine clearance is less than 50 mL/min [4]. They may exacerbate acidosis or precipitate in renal tubules.
 4. **In patients with gout or hyperuricemia, these agents should be avoided.** Acidification of the urine and the use of acid salts may promote uric acid crystals and calculi formation.
 5. **Methenamine and sulfonamides contraindicated.** The latter may precipitate when formaldehyde is released (see Chapter 27L).

- 6. In hepatic insufficiency, methenamine should not be used** because of the ammonia produced [2], which may induce or exacerbate hepatic encephalopathy.
- 7. In pregnancy,** the safety of methenamine and its salts has not been established [3].
- G. Toxicity.** Methenamine generally is well tolerated, especially in children [3]. Minor GI side effects, such as gastric discomfort, nausea, and vomiting, occur, especially at high doses. With prolonged high doses, some patients note urinary frequency, dysuria, and hematuria, perhaps due to formaldehyde irritating the mucosal lining of the genitourinary tract. The dysuria often diminishes with continued use as the mucosa becomes less sensitive.
- III. Fosfomycin tromethamine (Monurol)** was approved in the United States in 1997 **for single dose oral treatment of uncomplicated susceptible *Escherichia coli* and *Enterococcus faecalis* UTI in women.** The drug interferes with the formation of bacterial cell wall [17].
- A. Spectrum of activity.** Fosfomycin is moderately active *in vitro* against *E. coli* and many other gram-negative bacteria, as well as some strains of *S. saprophyticus* and most enterococci [17,18] that cause community-acquired uncomplicated UTI. In addition, vancomycin-resistant enterococci are susceptible to fosfomycin [19,20]. *Pseudomonas* species are usually, but not always, resistant [17].
- B. Pharmacokinetics.** Oral fosfomycin is rapidly absorbed and is excreted unchanged in the urine, reaching bactericidal concentrations that persist for 24 to 48 hours or longer [3,17,21].
- C. Clinical trials.** There are three randomized trials in women with uncomplicated UTI comparing a single 3-g dose of fosfomycin with nitrofurantoin (50 mg four times a day for 7 days) or norfloxacin (400 mg twice daily for 5 days) or cephalexin (500 mg four times a day for 5 days). Eradication rates with fosfomycin were similar to those with norfloxacin and nitrofurantoin and superior to those with cephalexin [17]. Additional data in more than 1,000 patients found that a single dose of fosfomycin was less effective than 7 days of ciprofloxacin or 10 days of trimethoprim-sulfamethoxazole [17].
- D. Dosage. A single oral dose of 3 g is used** for uncomplicated UTI in women over age 17. The \$25 cost to the pharmacist [17] is more expensive than 3 days of standard therapy (see Chapter 15). The dose that has been used in *Pseudomonas* infection is 1 sachet every other day for 3 days.
- 1. Pediatric use.** Safety and efficacy in children under 12 years of age have not been established.
 - 2. In renal failure,** no special recommendations are available in the 2002 package insert [4].
 - 3. Pregnancy.** This is a **category B** agent (see Chapter 27A). There are no adequate and well-controlled studies in pregnant women per the package insert.
 - 4. Nursing.** The package insert indicates it is not known whether fosfomycin is excreted into human breast milk; a decision should be made about whether to discontinue nursing or not after administering the drug, taking into account the importance of the drug to the mother.
- E. Adverse effects.** Fosfomycin is generally well tolerated, with diarrhea the most common side effect (9%). Vaginitis can occur [17].
- F. Overview.** In their 1997 review, the *Medical Letter* concluded: "A single dose of fosfomycin is **moderately effective** for treatment of uncomplicated UTI in women and should improve compliance; but it is **expensive**. How the new drug compares with a three-day course of TMP-SMX, an effective regimen that costs much less, has not been established" [17]. Fosfomycin may play a useful role in some settings where compliance is a major issue. Fosfomycin is an alternative for uncomplicated UTI in women due to susceptible enterococci [5].
- An interesting recent report revealed that many vancomycin-resistant enterococci are susceptible *in vitro* to fosfomycin [18]. Because the drug is safe, because it would not induce dangerous resistance, and because there are not many options for this, it is certainly reasonable to attempt therapy with this agent for that problem (see Appendix Table).

IV. Cranberry juice may be useful in the prophylaxis of UTI [3], and its **benefit** has been demonstrated in **elderly women** in whom prophylaxis with 300 mL of cranberry juice cocktail per day significantly reduced bacteriuria and pyuria compared with those receiving placebo [22]. Its mechanism of action has been attributed to the inhibition of bacterial adherence [3]. However, recent Cochrane Database reviews emphasized that further properly designed studies are indicated before concluding that cranberry juice is efficacious. [23,24] (see related discussion in **Chapter 15**).
