Scaffolding Proteins in Transport Regulation

Paul A. Welling

Department of Physiology, University of Maryland School of Medicine, Baltimore, MD, USA

PDZ-PROTEINS

PDZ domains (also known as DHR domains or GLGF repeats) are ~90 amino acid, protein−protein interaction modules that bind short amino-acid motifs (4−5 residues) generally found at the extreme COOH-terminus of target proteins.[1] More rarely, PDZ domains recognize internal sequences that mimic the COOH-terminal binding motif.[2,3] The term PDZ is derived from the names of the three proteins that the structure was originally identified from (PSD 95, a post synaptic density protein), Dlg (Dropsophila Disc large tumor suppressor), and ZO-1 (zona occludens, the tight junction protein). Since its discovery as a region of sequence homology in these few proteins,[4] the PDZ domain has become recognized as one of the most common interaction modules. The human genome contains over 250 PDZ domains in nearly 100 human proteins. The structure is evolutionarily conserved, emerging largely in metazoans, perhaps to accommodate the increased signaling needs of multicellular organisms.[5]

PDZ domain containing proteins usually possess multiple protein−protein recognition modules. Because the domains act independently and allow concurrent recruitment of different binding targets, PDZ proteins function as molecular scaffolds. Indeed, PDZ proteins facilitate multi-protein complex formation, and organize expression of target proteins on specific membrane domains for a wide range of physiological processes. A growing body of work has strongly implicated PDZ proteins in targeting and clustering various receptors, channels, transporters, and signal transduction elements at specific plasma membrane domains in different cell types, including neurons,[6] muscle,[7] and the visual system.[8] PDZ proteins play especially important roles in epithelial transport processes.

CLASSES OF PDZ DOMAINS

PDZ domains have been traditionally divided into three different classes, categorized by the nature of their ligands.[1] The different ligand classes are distinguished by differences in the binding residues found at the extreme COOH of target proteins (Figure 14.1). Type I domains recognize the sequence, X-S/T-X-Φ* (where X = any amino acid; Φ = hydrophobic amino acid; * = COOH terminus). Type II domains bind to ligands with the sequence X-Φ-X-Φ*. Type III domains interact with X-D/E-X-Φ* sequences.[9,10] Binding specificity within each domain class can be conferred by the variant (X) residues, as well as residues outside the canonical binding motif, especially at the -3 and -4 positions (where 0 position is the C-terminal residue). Moreover, a few PDZ domains do not fall into any of these specific classes.[5]

Based on large-scale proteomic analysis of PDZ-ligand interactions, it has been suggested the traditional three-class definition be extended to include 16 distinct binding classes.[11] Such a classification has been proposed to predict specific interaction partners of known PDZ domains with greater fidelity than the traditional scheme.

STRUCTURAL BASIS FOR PDZ INTERACTION

In recent years, the structures of over 20 different PDZ domains have been solved at atomic resolution. Like many protein−protein recognition modules, PDZ domains are small globular structures. Comprised of six β-strands (βA-βF) and two alpha helices (αA and

(b)

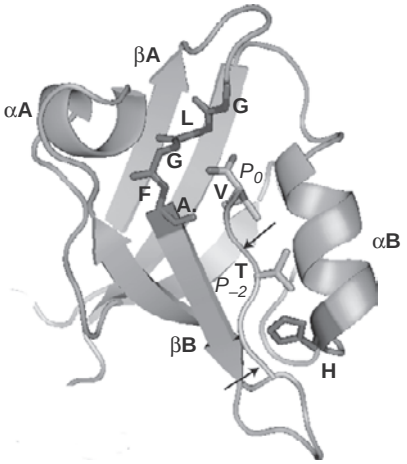

FIGURE 14.1 **PDZ-binding classes and structures.** (a) PDZ-binding motifs of the three different PDZ ligand classes are shown (X: any amino acid; Φ: hydrophobic amino acid). Residues in PDZ ligands are conventionally numbered from the final amino acid at the extreme COOH terminus, the so-called P0 position. (b) Structure of a type I PDZ domain with its ligand (third PDZ domain of PSD-95 is shown (PDB,1BFE) Doyle). The conserved GLGF motif in βA-βB linker provides a cradle of main chain amides for interaction with the terminal carboxylate group of the P0 residue. A hydrophobic pocket accommodates the hydrophobic P0 side chain. The first residue of the αB helix, a conserved histidine, forms hydrogen bonds with the P-2 threonine residue in the target protein.

αB), PDZ domains fold into a six stranded beta sandwich[12,13] (Figure 14.1). The peptide ligand inserts into a binding cleft, created by the βB strand and the αB helix, effectively forming an additional antiparallel beta strand. An extensive network of hydrogen bonds and hydrophobic interactions stabilizes binding of the peptide. For instance, the conserved glycine-leucine-glycine-phenylalanine-alanine (GLGF) motif contained within a βA-βB linker provides a cradle of main chain amides, and confers recognition of the terminal carboxylate group of the peptide.[13] A hydrophobic pocket accommodates the hydrophobic COOH-terminal residue, thereby accounting for preferential interaction with proteins ending with a hydrophobic residue (the so-called P0 position).

Binding specificity among the different binding classes is determined partly by an interaction between the P-2 residue of the target protein and the first residue of the PDZ domain αB-helix.[13] In Class I PDZ domains, a conserved histidine residue forms hydrogen bonds with the invariant P-2 serine or threonine residue in the target protein. In class II PDZ domains, this position of the PDZ domain and the P-2 residue of the target protein are usually occupied by a hydrophobic amino acid.[14]

Binding specificity within each domain class is also observed. At least three factors account for this. First, unique residues within or adjacent to the peptide-binding groove in the PDZ domain can interact with the target at sites other than the P-2 and P0 residues.[13,15–17] For example, the side chain of the P-1 target protein residue usually points away from the invariant interaction surface but, in some cases, it can bond with residues that are distinct to a particular PDZ domain.[15,17] Likewise, the P-3 side chain can make contact with unique residues in the interaction groove. Sites proximal to the archetypal, four amino acid-binding motif can also interact with regions outside the canonical-binding site, and thereby also contribute to binding specificity and affinity.[17,18] Second, because interacting residues in PDZ domains can undergo large ligand-dependent conformational changes,[19,20] variations in binding pocket flexibility may contribute to binding specificity. Such a mechanism has been proposed to explain the different binding specificity of the two highly homologous PDZ domains in NHERF1.[21] Finally, genome-wide analysis of PDZ domain binding suggests that PDZ domain selectivity is also achieved by the cellular and subcellular context of the interaction, and this may actually play a more important role than inherent binding specificity.[22]

REGULATION OF PDZ BINDING

PDZ interactions can be dynamically regulated to control the composition and stoichiometry of different multimeric complexes. Phosphorylation of the binding target is the most common mechanism. This is explained by the fact the P-2 serine or threonine in canonical type I PDZ targets can be a substrate for phosphorylation. In these cases, phosphorylation of the residue creates an energetically unfavorable PDZ ligand. For example, phosphorylation of the COOH-terminal site in the Kir 2.3 channel by Protein Kinase A inhibits its interaction with the synaptic PDZ protein, PSD-95,[23] to regulate the channel.[24] Likewise, phosphorylation of the P-2 serine in the β2 adrenergic receptor uncouples the receptor from the NHERF1 PDZ protein, and disrupts receptor recycling in the post-endocytic pathway.[25]

Phosphorylation of sites within PDZ proteins is emerging as an additional mechanism for modulating PDZ binding. Evidence for this was first provided by observations that the interaction of a PDZ protein, NHERF1 (see below), with CFTR is negatively

regulated by phosphorylation of a residue in the second PDZ domain.[26] Phosphorylation of sites in or near the first PDZ domain of NHERF1 also disrupt interaction with the Na-phosphate co-transporter, Npt2a.[27–29] Phosphorylation of sites that are involved in PDZ–PDZ protein oligomerization has also been observed.[30] This is believed to modulate the extent to which some PDZ proteins can form higher order scaffolding complexes.[31,32]

Finally, switching interactions with different PDZ proteins can differently regulate the activity and localization of target proteins. This occurs when the target has the capacity to bind to several PDZ proteins that have different properties. For example, TIP-1, a protein that consists of a single PDZ domain and lacks other protein–protein interaction modules, binds to certain target proteins to antagonize the scaffolding functions of canonical PDZ proteins.[33]

POLARIZED EXPRESSION OF PDZ PROTEINS IN EPITHELIAL CELLS

A number of PDZ proteins are preferentially expressed at polarized membrane domains or within critical sorting compartments (Figure 14.2), where they perform retention/sorting operations and organize local signaling complexes at polarized locales.[34] Examples of PDZ proteins that predominately reside at the basolateral membrane of certain intestinal and renal epithelia include syntrophin[35] (see "Dystrophin-Associated Protein Complex," below), Lin-7[36,37] (see "Lin-7/CASK/SAP97," below), the ErbB interacting protein, ERBIN,[38] and certain members of the membrane associated guanylate kinase family of PDZ proteins, such as CASK,[39] PSD-93,[40] and SAP97 (aka Discs large homolog 1[41]). Other PDZ proteins, including the sodium hydrogen exchange regulator factors (see "NHERF, "below), Shank2E,[42] and PSD-95,[40] are chiefly expressed on or near the apical membrane. Some PDZ proteins, such as zonula occludens, PALS1 (Stardust), and PATJ (Disc lost),[43] play important roles in the generation and maintenance of the tight junction.[44] Still others, like CAL, which is primarily located in the Golgi[45] or SNX27,[46] and syntenin,[47,48] which are found in endosomes, reside in biosynthetic or endocytotic sorting compartments.

A PDZ-binding motif can serve as a polarized sorting[49] or retention signal.[50] One of the first examples evolved from studies with the GABA transporters or GATs[51]; deletion of the PDZ-binding motif from the apical isoform GAT-3 caused the transporter to localize randomly to both apical and basolateral membranes.[52] Basolateral membrane expression of several membrane proteins has also been found to require a PDZ-binding motif. For instance ERBB receptors, which play crucial roles in morphogenesis and oncogenesis, interact with a basolateral PDZ protein, called ERBIN, and require a PDZ-binding motif for basolateral membrane expression.[38] ERBIN is targeted to the basolateral membrane by its leucine-rich repeat domain.[53] Efficient basolateral membrane expression of a number of transporters that interact with the basolateral PDZ protein Lin-7 also require an intact PDZ-binding site (see below).

MAGUKS, THE ARCHETYPAL PDZ SCAFFOLDS

Members of the MAGUK (membrane associated guanylate kinase) family of PDZ proteins are the archetypal PDZ scaffolds. MAGUK proteins are equipped to assemble large molecular complexes, having one to three PDZ domains, a SRC homology 3 domain (SH3), and a catalytically inactive guanylate kinase-like (GK) domain. In addition to the PDZ domains, the GK and the SH3 domains function as independent protein–protein interaction modules; GK domains recruit scaffold adaptor molecules called guanylate kinase-associated proteins or GKAPs,[54] while SH3 domains have been shown to coordinate interaction with at least one non-

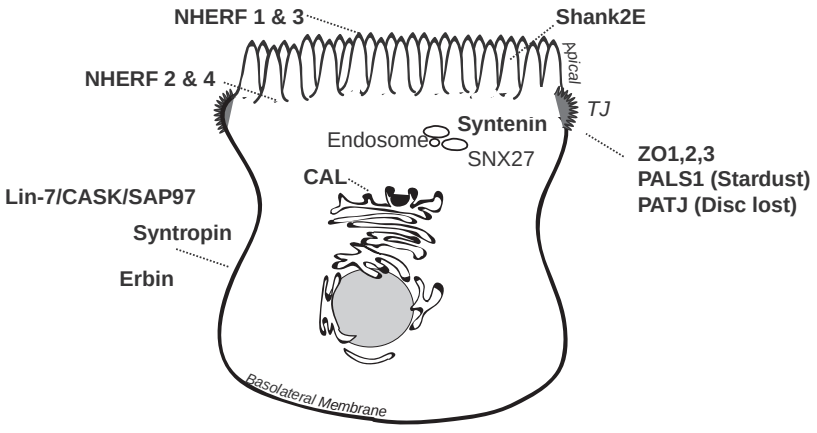

FIGURE 14.2 **Major PDZ proteins in epithelial cells.** PDZ domain containing proteins differentially localize to epithelial cell brush borders, subapical domains, endosomes, tight junctions, and basolateral membranes.

receptor tyrosine kinase.[55] The SH3 and GK domains can also interact with one another, forming a composite SH3–GK structure[56,57] that acts as an additional intermolecular protein–protein interaction domain with a binding specificity that is distinct from either SH3 or GK domains.[58]

The PSD-95 family, encoded by four genes (PSD-95/SAP90, PSD-93/Chapsyn-110, SAP102, and SAP97), exemplifies MAGUK proteins. Two of these, PSD-93[40] and SAP97 (see below), are expressed in renal epithelial cells. However, the best characterized member, PSD-95, is largely expressed in excitable tissues, and plays central roles in maintaining and modulating the strength and structure of glutamatergic synapses.[59] Generally, its properties and functions are likely to be applicable to the other MAGUKs, including those expressed in the kidney.

Like many scaffolds, PSD-95 not only contains multiple protein–protein interaction modules, it also assembles into multimers, creating an extended platform for efficient scaffolding.[60,61] These qualities, combined with palmitoylation-dependent membrane tethering and synaptic localization signals,[62] make PSD-95 ideally designed to cluster ion channels, receptors, trafficking proteins, and signal transduction machinery at the post-synaptic membrane. In doing so, PSD-95 influences trafficking, endocytosis, and activities of target proteins at the synapse.[59] Organizing local signaling complexes is one of the most important clustering functions of PSD-95. For example, the PDZ domains in PSD-95 independently interact with the calcium/calmodulin-activated nitric oxide synthase, nNOS, and NMDA (N-methyl-D-aspartate) receptors to form a ternary complex.[63,64] The organization is thought to be important for regulated synthesis of nitric oxide. Because NMDA receptors are permeable to calcium, the physical linkage of nNOS with the excitatory receptors is believed to allow nitric oxide production to be efficiently coupled to receptor activation, calcium influx, and local changes in intracellular calcium.[65] Significantly, disruption of NMDAR interaction with PSD-95 dissociates the receptors from downstream neurotoxic signaling, without blocking synaptic activity or calcium influx.[66]

Local signaling complexes that control the production of NOS in the kidney have been proposed.[67] One may involve PSD-93, the predominate MAGUK in renal epithelial cells.[40] Similar to PSD-95, PSD-93 associates with the plasmalemma via palmitoylation-dependent tethering signals,[68] where it recruits and clusters various target proteins, including nNOS.[69] In the kidney, PSD-93 is largely expressed along the basolateral membrane of the thick ascending limb, macula densa cells and the distal nephron.[40] In the macula densa, PSD-93 colocalizes with the pool of nNOS that is associated with intracellular vesicles and the basolateral membrane.[40] It remains to be tested if PSD-93 interaction with nNOS in the macula densa coordinates regulated NO production in the manner that is observed with PSD-95 at the excitatory synapse.

FORM AND FUNCTION OF PDZ PROTEIN FAMILIES IN THE KIDNEY

Apical Membrane PDZ Protein Complexes

NHERF

The Na/H exchange regulator factor PDZ proteins, NHERF, are highly expressed in the kidney and small intestine where they act as molecular scaffolds, associating with a number of transporters, channels, signaling proteins, transcription factors, and receptors to regulate apical membrane transport processes.[70,71] There is a family of four related NHERF proteins encoded by separate genes[72,73] (Figure 14.3). Originally known by many names, a unifying nomenclature has been proposed,[72,73] designating the genes as NHERF-1[74,75] (also known as Ezrin Binding Protein-50, EBP-50[76]); NHERF-2 (also known as NHE-3 kinase A (E3KARP)[77]); tyrosine kinase activator-1 (TKA) and sex-determining region of the Y chromosome (SRY-1)-interacting protein[78]; NHERF-3 (also called PDZK1,[79] Cap70,[80] DiPHOR or NaPi-Cap1[81]); and NHERF-4 (also called IKEPP,[82] DIPHOR-2, and NaPi-Cap 2[81]). Each member of the NHERF family of proteins is believed to play important roles in the regulation of transport processes within the proximal tubule, as well as other sites along the nephron, acting by three different but not mutually exclusive mechanisms. Present evidence indicates that the NHERFs function to: (1) organize local signaling complexes; (2) control apical membrane trafficking; and (3) couple apical membrane transport proteins with other PDZ-binding targets. In this way, NHERFs modulate transporter activity and/or apical abundance of transporters, channels, and receptors. Importantly, each NHERF isoform appears to have unique regulatory properties that are manifested in cell-specific manners.[83] Studies in NHERF isoform knockout-mice have begun to clarify their different physiologic roles in the renal proximal tubule, small intestine, and other epithelia.

Like other scaffolding proteins, the functions of the NHERFs are made possible by the presence of their multiple protein–protein interaction domains. NHERF-1 and NHERF-2 contain two PDZ domains and a COOH-terminal Ezrin/Radixin/Mosein/Merlin (ERM)-binding domain. The latter coordinates interaction with the ERM family of actin binding and A-kinase anchoring proteins to direct linkage with the actin cytoskeleton[84] and signal transduction machinery.[85] By contrast, NHERF-3 and

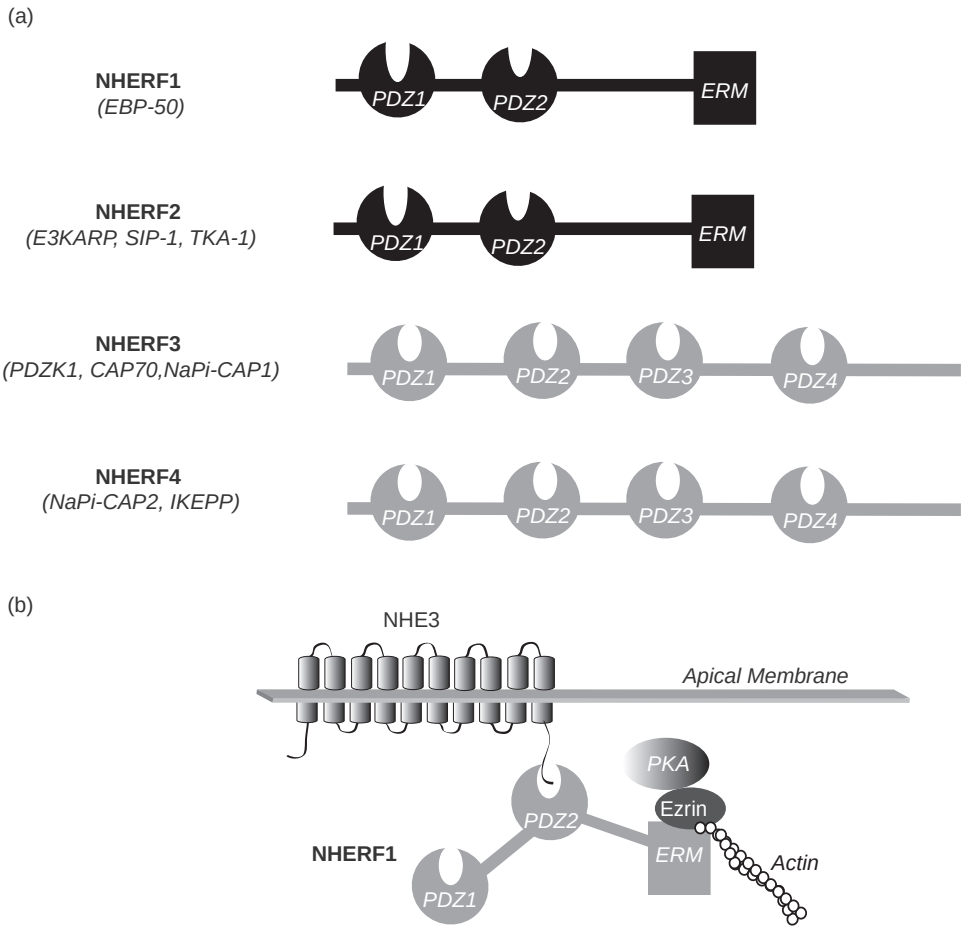

FIGURE 14.3 **NHERF.** (a) Domain architecture of NHERF family members. NHERF 1 and NHERF 2 contain two PDZ domains and an ERM-binding domain. NHERF 3 and NHERF 4 contain four PDZ domains, but no ERM-binding domain. (b) The protein–protein interaction modules in NHERF1 allow it to assemble multi-protein complexes, consisting of PDZ-binding targets (such as NHE3, shown), ezrin, and PKA.

NHERF-4 contain four PDZ domains, but no ERM domain (Figure 14.3).

NHERF proteins can also interact with one another, forming higher order protein networks. Indeed, NHERF1 and NHERF2 associate as homodimers and heterodimers.[30,86–88] Interestingly, oligomerization of NHERF-1, but not NHERF-2, is highly regulated by association with other proteins and by phosphorylation.[30] NHERF3 has been reported to interact with NHERF1 and NHERF2 to form an extensive heteromeric complex.[87] Interaction between NHERF1 and NHERF3 and ezrin is corroborative, providing a mechanism to regulate formation of a ternary scaffolding complex that contributes to the organization microvilli.[31,89,90]

NHERF in Epithelial Transport

A growing body of evidence indicates each NHERF isoform has individual and specialized activities in the kidney. It some cases, specific roles of several NHERF proteins may converge and act cooperatively to regulate target proteins. Here we review the state of knowledge about each NHERF isoform.

NHERF1 was originally discovered as a co-factor necessary for cAMP-kinase dependent phosphorylation and inhibition of NHE3, a brush border Na^+/H^+ exchanger.[74,75] Biochemical studies and work in heterologous expression systems established a likely mechanism whereby NHERF1 organizes a local PKA signaling complex, using its PDZ domains and the ERM-binding domain (Figure 14.3b). The second PDZ domain of NHERF1 directly interacts with NHE3,[91] while the ERM-binding domain simultaneously engages ezrin.[92] By acting as an A-kinase anchor protein (AKAP, see below),[85] ezrin recruits the regulatory subunit of PKA II[92] to the NHERF1 complex. Consequently, NHERF1 juxtaposes PKA with NHE3 for efficient phosphorylation of the transporter and

inhibition of Na^+/H^+ exchange. Consistent with the model, removal of the ERM-binding domain in NHERF1 disrupts formation of NHERF1−ezrin signal complex and attenuates the inhibitory effect of cAMP on NHE3 activity.[93] EPAC (the exchange protein directly activated by cAMP) also participates in the NHERF1-dependent inhibitory response in the proximal tubule, but it is not presently understood how NHERF couples EPAC to NHE3.[94]

Direct evidence that the NHERF1 signal complex is required for phospho-regulation of NHE3 has been provided by studies in NHERF1 gene knockout mice.[95] In this model, activation of PKA fails to phosphorylate and inhibit NHE3 activity in the proximal tubule.[96] The response appears to be specific to NHERF1 removal, in that other proximal tubule NHERF isoforms are not affected by NHERF1 gene ablation. Moreover, the inhibitory effect of PKA can be completely restored in NHERF1-null proximal tubule cells upon adenoviral-mediated delivery of wild-type NHERF1.[97]

The PKA coupling function of NHERF1 is believed to be widespread, with a body of work indicating that the NHERF1 can act as a nexus of signaling complex assembly for efficient phosphorylation and regulation of a variety of transporters, channels, and receptors (reviewed in [98]). For example, NHERF1 (as well as NHERF2[99]) binds to CFTR[100,101] through a PDZ interaction to potentiate PKA phosphorylation-dependent CFTR Cl(−) currents[102] in an ezrin-AKAP dependent manner.

Simultaneous PDZ-dependent recruitment of G-protein coupled receptors by NHERF proteins can further focus local signaling around NHE3 and other transport proteins.[71] For instance, studies in heterologous systems reveal that NHERF binds to the β2-adrenergic receptor (BAR2) by means of a PDZ domain-mediated interaction to recruit NHE3 and the receptor into a local signaling complex for efficient receptor-mediated regulation of sodium−hydrogen exchange. Removal of the PDZ interaction motif in the BAR2 disrupts receptor interaction with NHERF1, and markedly reduces β2-adenergic receptor-mediated regulation of NHE3 without altering activation of adenylyl cyclase.[103] Likewise, NHERF1 facilitates the assembly of a complex containing the β2-adenergic receptor, ezrin, PKA, and CFTR at the apical membrane of epithelial cells for compartmentalized and specific signaling of the channel.[104] Other examples have recently been extensively reviewed.[71]

The tandem PDZ domains in NHERF1 also provide a structural framework to link PDZ-binding transport proteins with PDZ-binding signal transduction machinery. Indeed, several different kinases,[105,106] phospholipase C isoforms,[107] and the receptor for activated C kinase, RACK,[108] have been identified as NHERF1 PDZ-binding targets. Characterization of consensus binding sequences of isolated NHERF-1 PDZ domains by phage-display, affinity selection techniques revealed that the two PDZ domains have different ligand-binding specificities, with distinct preferences for residues at the 0, −1 and −3 positions of type I PDZ ligands.[101] Thus, NHERF1 has a biochemical capacity to tether different PDZ-binding targets together. In addition, because NHERF1 interacts with itself and links with the actin cytoskeleton, formation of an extended network of NHERF1 molecules may join different PDZ-interacting proteins to the same locale. Such a mechanism has been proposed to explain NHERF1-dependent coupling of phospholipase C with the TRP4 channel.[107]

In some cases, the PDZ domains in NHERF1 can support simultaneous interaction of two identical proteins. The best-characterized example is CFTR, which interacts with both PDZ domains in NHERF1, albeit with different binding affinities.[109] In this case, NHERF1 has been reported to induce a high open probability conformation of CFTR by cross-linking the C-terminal tails of a CFTR dimer. Because CFTR binds to the two PDZ domains with different kinetics and affinities, channel gating is profoundly sensitive to alterations in NHERF1 abundance. Moreover, the composition and stoichiometry of NHERF-CFTR interactions can be dynamically regulated. Phosphorylation of NHERF1 has been found to specifically disrupt CFTR interaction with the second PDZ domain, uncoupling the tethered C-terminal tails and inducing a low open-probability conformation.[26] A similar PDZ-dependent cross-linking mechanism has been described with NHERF3.[80]

NHERF1-Dependent Apical Membrane Trafficking

In addition to co-localizing key components of signal transduction pathways, NHERF1 can also regulate cell surface expression and localization of some of its binding targets. It appears to function by controlling trafficking operations in the post-endocytic recycling pathway,[25,110] as well as by anchoring target proteins on the plasma membrane,[100,111] likely by interactions with the cytoskeleton.

Regulation of the Na-dependent phosphate transporter, Npt2a, in the proximal tubule provides a salient example. It is well-known that factors which regulate proximal tubule Pi reabsorption and Pi homeostasis do so by altering the density of Npt2a at the apical membrane. NHERF1 plays an important role in this process. Indeed, NHERF1 gene ablation causes diminished expression of Npt2a at the apical membrane and renal phosphate-wasting.[95] In the NHERF1 knockout model, the Npt2a transporter is misrouted into a subapical, intracellular compartment,[95,112] indicative of a trafficking defect.

Studies in model systems have begun to cast light on the underlying mechanism. Npt2a binds to the first PDZ domain of NHERF1 via a type 1 interaction, requiring the last three amino acids of the co-transporter.[81] These residues are also necessary for efficient apical expression of Npt2a,[111,113,114] suggesting that apical targeting and/or anchoring is specified by direct NHERF1 interaction. Apical localization of the co-transporter can be blocked by ectopic expression of truncated NHERF1 proteins, which contain the first PDZ domain and are able to interact with the transporter, but lack the ERM-binding domain. Thus, it is likely that NHERF1 coordinates localization of the co-transporter by tethering Npt2a with the actin cytoskeleton through the ERM-binding domain.[111]

Exciting recent studies reveal that PTH induced internalization and lysosomal degradation of Npt2a in the proximal tubule are coincident with phosphorylation of NHERF1, and disruption of Npt2a/NHERF1 interaction.[115] These observations strongly suggest that Npt2a−NHERF1 interactions are physiologically regulated to control Npt2a apical surface density for maintenance of calcium and phosphate metabolism. Recent live-cell imaging studies indicate NHERF1 regulates apical expression of Npt2a by a brush border retention mechanism.[116,117] A similar process controls the localization of the PTH receptor.[118] In other proteins, such as CFTR[110] and certain G-protein coupled receptors,[25,119] NHERF1 maintains surface expression by driving recycling to the cell surface after internalization.

Although NHERF1 effectively anchors NHE3 and Npt2a within the microvilli by directly interacting with the transporters and engaging the underlying microvillar cytoskeleton, the transporters have different fates in the renal proximal tubule when they disassociate from NHERF1. In NHERF1 knockout mice, localization of NHE3 is maintained within the microvilli, but Npt2a is targeted to the lysosome. By contrast, when interaction with NHERF1 become severed by physiological signaling processes (e.g., PTH-dependent), a myosin VI driven translocation process moves NHE3 and Npt2a out of the microvilli.[120–123] Because NHE3 selectively assimilates with lipid rafts, the translocated NHE3 molecules are effectively excluded from clathrin-coated pits and consequently are retained at the base of the microvilli.[121] By contrast, Npt2a transporters do not partition into rafts, and are free to be internalized once its ties with the microvillar anchor are broken.

Direct phosphorylation of NHERF1 is emerging as an important mechanism for negatively regulating PDZ-dependent binding interactions in the proximal tubule. Two residues, threonine 95 and serine 77, within the first PDZ domain are phosphorylated in response to PTH and dopamine treatment in the renal proximal tubule. This decreases the binding affinity for the Npt2a transporter, and likely contributes to the hormonal suppression of renal phosphate transport.[27–29] Additional phosphorylation-dependent mechanisms have been reported to control binding at the second PDZ domain in ways that are important for regulating microvilli assembly.[31]

NHERF2

NHERF2 appears to have different functions than NHERF1 in the kidney,[72,124] even though the two PDZ proteins share a common domain structure and NHERF2 is equally effective as NHERF1 in mediating cAMP inhibition of NHE3 in heterologous systems.[77] Unlike NHERF1, which is exclusively expressed in the human, rat, and mouse proximal tubule, expression of NHERF2 in the proximal tubule is species-specific. Found only in the mouse proximal tubule, NHERF2 predominantly localizes to a subapical, intermicrovillar compartment that is distinct from NHERF1 in the brush border.[125] Importantly, NHERF2 does not support phosphorylation-dependent inhibition of NHE3 or apical localization of Npt2a in the NHERF1 knockout model, indicating that NHERF2 does not share physiologically redundant functions with NHERF1 in the proximal tubule.[124]

The functions of NHERF2 are, in fact, better understood at sites outside the proximal tubule. In the kidney, NHERF2 is predominately expressed in the glomerulus, vas recta, and the collecting duct.[126] Physiologically important PDZ-binding partners have been identified in each of these locales. In the glomerulus, NHERF2 interacts with podocalyxin, possibly functioning to retain podocalyxin at the apical surface of the podocyte and provide a mechanism for linking this important surface sialomucin to the actin cytoskeleton.[127] NHERF2 associates with the TRPC4 channel in the descending vasa recta, where it has been suggested to control Ca^{2+} signaling[128] in a similar way that the INAD PDZ protein controls TRP in the *Drosophila* eye.[129] In the collecting duct, NHERF2 co-localizes and interacts with the ROMK channel. Studies in heterologous expression systems indicate that NHERF2 couples accessory proteins and signal transduction machinery to ROMK for efficient channel regulation and trafficking.[130]

The PDZ-binding specificity of NHERF2 also undoubtedly contributes to its unique functions as compared to NHERF1. While NHERF2 shares many of the same PDZ-binding partners as NHERF1, with nearly 60 having been identified,[70] it also interacts with several proteins that NHERF1 does not react with. These include alpha-actinin-4[131]; cGMP kinase I and II[132]; a putative Cl/HCO_3 exchanger downregulated in adenoma[133]; podocalyxin[127]; human Y-linked

testis determining gene-binding factor[78]; serum glucocorticoid stimulated kinase, SGK-1[134]; and transcriptional co-activation with PDZ-binding motif, TAZ.[135]

By organizing these unique partners into protein complexes, NHERF2 can affect functions that are distinct from NHERF1. NHERF isoform-specific regulation of NHE3 in heterologous systems provides an excellent illustration. NHERF2 uniquely confers Ca^{2+}-dependent inhibition on NHE3[136] by scaffolding the exchanger to PKCα and alpha-actinin-4.[72] NHERF1 does not support this activity, presumably because it is not capable of interacting with alpha-actinin-4. Likewise, by acting as a unique protein kinase G-anchoring protein, NHERF2 specifically confers cGMP inhibition on NHE3.[83,132] Finally, activation of NHE3 by dexamethasone requires NHERF2 rather than NHERF1.[134] In this case, the first PDZ domain of NHERF2 uniquely recruits the serum- and glucocorticoid-induced protein kinase, SGK1, into a complex with NHE3 to phosphorylate and enhance exchanger activity. Such a mechanism has been suggested to offer an explanation for glucocorticoid stimulation of sodium absorption in ileum, proximal colon, and renal proximal tubule.[134]

NHERF2-dependent scaffolding of SGK1 may also play an important role in the collecting duct for the regulation of the potassium secretory channel, ROMK.[137,138] It has been reported that NHERF2 can synergize with SGK1 to augment cell surface expression of ROMK in oocyte expression experiments.[138] Biochemical studies indicate that NHERF2 has the capacity to recruit ROMK and SGK-1 into a ternary complex by preferentially binding to the channel with the first PDZ domain,[130] while simultaneously recruiting the kinase by preferred interaction with the second PDZ domain.[134] Formation of such a complex would allow efficient phosphorylation of a residue that is required for delivery of the channel to the cell surface. Indeed, SGK1 directly phosphorylates serine 44[137] in ROMK1, creating a forward trafficking signal[139] that overrides an endoplasmic reticulum localization signal.[140,139] Together the observations suggest a potential molecular mechanism for the regulation of ROMK density by dietary potassium, whereby the NHERF2 scaffold juxtaposes the SGK-1 with ROMK for efficient phosphorylation-dependent trafficking to the apical membrane.

NHERF3

NHERF3 was first discovered as PDZK1, a PDZ domain-containing protein that is upregulated in carcinomas, and abundantly expressed in the proximal tubule brush border.[79,87,141] Significantly, the four PDZ domains of NHERF3 support interaction with many proximal tubule apical membrane transporter proteins, including Npt2a, the solute carrier SLC17A1 (NaPi-I), NHE3, the organic cation transporter (OCTN1), chloride-formate exchanger (CFEX), and the urate-anion exchanger (URAT1),[87] as well as a protein kinase A anchoring protein, D-AKAP2.[142] Based on these observations and findings that NHERF1 can interact with NHERF3, it has been suggested that NHERF3 and NHERF1 may form an extended scaffolding network in brush borders of proximal tubular cells for the regulation of transport.

Although the NHERF3-NHERF1 scaffolding network concept is an attractive hypothesis, it should be pointed out that targeted disruption of the NHERF3 gene by homologous recombination does not[143] cause global alterations in the expression or localization of most of its interacting transport proteins in the proximal tubule.[144,145] Instead, the major effects of NHERF3 gene disruption presently appear to be very specific, confined only to two interacting proteins. A selective reduction in the abundance and functional activity of the chloride-formate exchanger, CFEX, at the proximal tubule brush border is observed in NHERF3-null animals.[145] Physiologic stimulation of the NaPi-IIc isoform by dietary phosphate restriction is also impaired in NHERF3-null animals. A minor role of NHERF3 in Npt2a regulation can be provoked by physiological perturbations; while NHERF3 null animals on a normal or low phosphate diet do not exhibit alterations in Npt2a abundance or function, high dietary phosphate unmasks a modest attenuation of Npt2a levels at the proximal tubule brush border.[146] Differences in affinities of the NaPi-II isoforms for NHERF1(Npt2a) and NHERF3 (Npt2c) have been proposed to account for this behavior.[147]

NHERF4

This member of the NHERF family was originally identified in independent screens for PDZ-binding partners of the Npt2a transporter[81] and the receptor guanylyl cyclase.[82] First dubbed as NaPi Cap-2 or IKEPP (Intestinal and Kidney-Enriched PDZ Protein), it was subsequently reclassified as NHERF4 based on sequence homology modeling.[73] In the proximal tubule where it is abundantly expressed, NHERF4 localizes to a subapical region, like NHERF2, that is distinct from the brush border and NHERF1.[81] Little is known about the function of NHERF4 except that it inhibits heat stable toxin induced cGMP synthesis,[82] by a mechanism suggested to involve PDZ-dependent recruitment of inhibitory factors.[73] Roles in regulating the TRPV5 and TRPV6 calcium channels have also been described.[203] Based on its structural similarities with other NHERF forms and the site of expression in the kidney,[73] it seems likely that NHERF4 also modulates apical membrane transport and cell signaling in the proximal tubule.

Shank (SH3 Domain and Ankyrin Repeating Proteins, A.K.A Proline-Rich Synapse-Associated Protein-1/Cortactin-Binding Protein 1 (ProSAP1/CortBP1))

In addition to the established role as master scaffolds at the postsynaptic density,[148] members of the Shank (SH3 domain and ankyrin repeating proteins) family of proteins play roles as apical membrane-associated scaffolds in epithelial cells. The three known Shank genes (Shank1, Shank2, and Shank3) are expressed in a tissue-specific manner. Shank 1 is almost exclusively expressed in the brain, products of the Shank2 gene are found in brain, kidney, and liver, whereas Shank 3 is most abundantly expressed in the heart.[149] The prototypical Shank, Shank1, is a relatively large protein (> 200 KDa) containing multiple ankyrin repeats,[150] a SH3 domain, a PDZ domain, and a long proline repeat domain. A self-oligomerization domain, called a sterile alpha motif (SAM), assembles the scaffolds into head-to-tail helical sheets, forming an extensive Shank network for protein complex assembly.[151] In neurons, Shank forms a polymeric structure with another protein, Homer, to serve as a platform for assembling postsynaptic density proteins.[152] Multiple splice variants of each gene have been identified that contain different combinations of protein−protein interaction domains (Figure 14.4). For example, Shank2E, a form that is predominantly expressed in epithelial cells,[42] contains ankyrin repeats whereas the Shank2 splice form found in the brain does not.

Extensive studies in the brain provide models for Shank function in epithelial cells. It is well-established that Shank family members localize to the postsynaptic density of excitatory synapses, where they act as master scaffolds along with Homer and PSD-95.[148] Here, the Shanks physically couple the two major receptor complexes, N-methyl-d-aspartate receptors (NMDAR) and metabotropic glutamate receptors (mGluR), and recruit associated signaling proteins. They do so by concurrently engaging two different adaptors through distinct protein−protein interaction domains. The Shank PDZ domain associates with the GUK-associated protein, GKAP which, in turn, interacts with the PSD-95 complex, containing NMDA receptors.[148] At the same time, the proline rich domain of Shank interacts with another adaptor protein, Homer, to link with metabotropic glutamate receptors. Proline rich domains often serve as binding sites for SH3 (SrC homology), WW (conserved two-tryptophan domain), and EVH1 domains (enabled/vasodilator-stimulated phosphoprotein homology 1).[153] A single EVH1 domain in Homer directly interacts with a PPXXF motif in the Shank proline-rich domain, as well as with similar proline motifs in group 1 mGluR and other proteins, such as the IP3 receptor.[154] Because Homer proteins self-associate in a head-to-tail fashion, two EVH1 domains per dimer are available to bridge Shank with group 1 mGluRs. Consequently, Shank cross-links Homer and PSD-95 complexes in the PSD, presumably to couple signaling transduction pathways emanating from NMDAR and mGluR. Disruption in this synaptic scaffolding mechanism may be responsible for human disease, as mutations in SPAK2 have been associated with autism and mental retardation.[155]

More recently, Shank2 forms have been implicated in the modulation of apical membrane transport

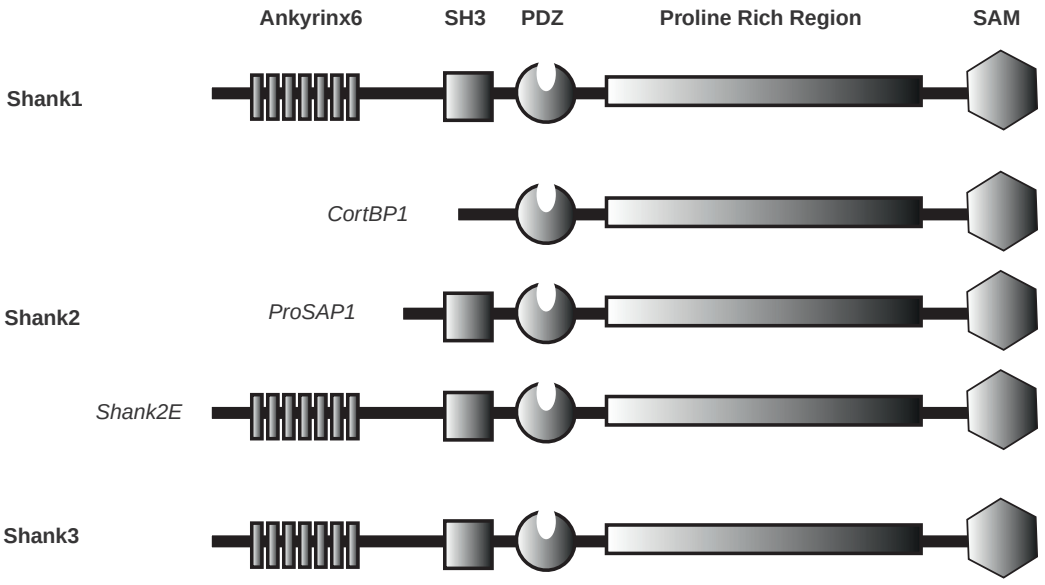

FIGURE 14.4 **Shank family members.** Domain architectures of Shank1, 2, 3, and Shank2 splice variants are shown. The major epithelial form, Shank2E, contains six ankyrin repeats, a SH3 domain, a PDZ domain, a proline rich domain, and a self-oligomerization region called a SAM domain.

processes. In the kidney, Shank2E is concentrated at the apical membrane of proximal tubule cells were it interacts with NHE3 and Npt2a, similar to NHERF1. Present evidence indicates that Shank2 and NHERF may control the activity of these transport proteins in divergent manners. Studies with NHE3 in heterologous expression systems, for example, revealed that Shank2 positively regulates NHE3 membrane expression and blunts the cAMP-dependent inhibition of NHE3, in part by antagonizing the action of NHERF1. Likewise, in pancreatic duct cells, Shank2E associates with CFTR at the apical membrane and inhibits Cl channel activity,[156] contrasting the positive effects of NHERF1 and NHERF2 on CFTR (see above). Shank2 also positively regulates NHE3 by recruiting BetaPix, a guanine nucleotide exchange factor for the Rho-GTPase.[157] Because retention and targeting of NHE3 in the apical microvilli depends on the sustained activity of Rho-GTPases,[158] the interaction between NHE3 and the Shank2-BetaPix complex may allow NHE3 trafficking to be linked to the maintenance of the microvilliar actin cytoskeleton.

Shank2E appears to regulate Npt2a in a different manner than NHERF1. In the proximal tubule, increased extracellular Pi triggers internalization and degradation of Shank2E and Npt2a in parallel, but has no effect on NHERF1 localization or abundance.[159] Combined with observations that regulated endocytosis of Npt2a is associated with disruption of Npt2a/NHERF1 interaction at the brush border,[115] one might speculate that internalization of Npt2a involves a NHERF1-to-Shank2E interaction switch. Importantly, Shank redistributes with Npt2a during regulated endocytosis,[160] and interacts with dynamin II, a GTPase that is critical for endocytic vesicle formation, via proline-rich domain interaction.[161] Thus, Shank2E is especially poised to facilitate Npt2a endocytosis and/or lysosomal trafficking, in contrast to the apparent membrane-retention and/or recycling function of NHERF1. The molecular mechanisms underlying the function of Shank2E in the proximal tubule remain to be firmly established, however. It will be interesting to learn if the activities of Shank2E in the kidney depend on scaffold adaptors, such as Homer and GKAP, as has been shown in excitatory synapses.

BASOLATERAL MEMBRANE PDZ PROTEIN COMPLEXES

The Lin-7/CASK/PSD-97 System

Lin-7 and CASK (Lin-2) are components of an evolutionarily conserved basolateral membrane scaffolding complex, important for polarized targeting and controlling cell surface density of their PDZ-binding partners. They were discovered along with another PDZ protein, Lin-10 (Lin, from abnormal cell lineage), in a genetic screen for components of the LET-23 receptor tyrosine kinase signaling pathway in *C. Elegans* vulva progenitor cells (VPC).[162] These molecules form a tripartite protein complex in VPC that interacts with a receptor tyrosine kinase, LET-23, to coordinate receptor expression on the basolateral membrane.[162–164] Importantly, null mutations in Lin-7, Lin-2 or Lin-10 cause the Let-23 receptor to become mislocalized to the apical membrane, and consequently disrupt LET-23 signaling and VPC development.

Orthologs of the *C. elegans* PDZ protein complex have been identified in mammalian tissues (Lin-7 = mLin7/Veli/MALS; Lin-2 = CASK; Lin-10 = Mint-1/X11).[37,165–167] In the mammalian kidney, a partially conserved complex, consisting of mLin-7 and CASK but not Lin-10,[19] localizes to the basolateral membrane[36,37] where it coordinates polarized expression of mLin-7-binding partners (Figure 14.5). It has been implicated in basolateral expression of the epithelial GABA transporter, BGT-1,[168] the strong inward-rectifying potassium channels, Kir 2.X,[167,169,170] the EGF-like receptor, ErbB-2/Her2,[171] and the insulin receptor substrate, p53.[172] Present evidence suggests that the mLin-7/CASK complex may offer a general mechanism for polarized expression of basolateral membrane proteins containing Type I PDZ-binding motifs.

Lin-7 acts as the upstream scaffolding molecule. It binds directly to target molecules through a Type I PDZ interaction while simultaneously engaging CASK via another protein−protein interaction module,[37,173] called a L27 domain (from Lin-2, Lin-7).[174] L27 domains, which present a number of related PDZ proteins (see PALS, below), are helical bundle structures[175,176] that mediate heterotypic assembly, important for polymerization of different scaffolds. In fact, basolateral membrane localization of Lin-7 and its PDZ-binding partners is afforded by the L27 domain and CASK interaction.[37,177,178]

CASK associates with the basolateral membrane through a web of interactions to function as the master basolateral membrane attachment factor. As a member of the MAGUK family (see above), CASK contains multiple protein−protein interactions sites, allowing it to simultaneously bind to Lin-7, extracellular matrix receptors, adhesion molecules, the actin cytoskeleton 4.1-binding proteins,[39] and another MAGUK protein, SAP-97.[173] The mLin-7 and SAP-97 L27 domains separately assemble with two L27 domains of CASK, possibly as a dimer of L27 heterodimers,[175,176] to form a mLin-7/SAP97/CASK complex.[170,173] By linking extracellular matrix receptors and the cytoskeleton, the Lin-7/CASK/SAP97 complex has the capacity to act as a stable anchor to retain Lin-7 interacting proteins on the basolateral membrane.

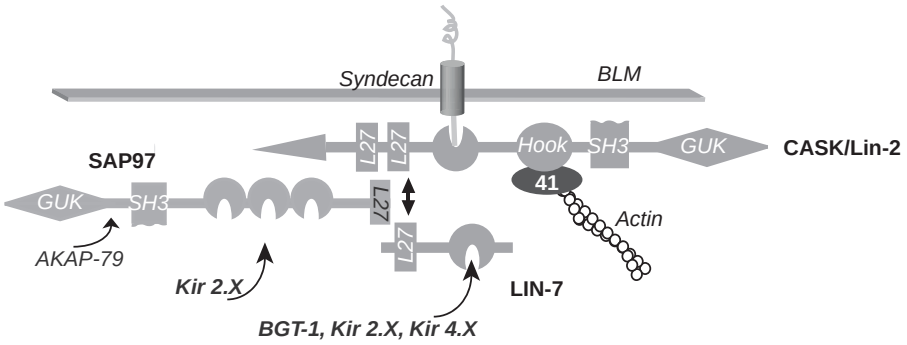

FIGURE 14.5 **Lin-7/CASK/SAP-97 complex at the basolateral membrane (BLM).** Lin-7 recruits PDZ-binding targets, such as the BGT-1 transporter and the inwardly rectifying potassium channels, Kir 2.X and Kir 4.X, to the basolateral membrane by interacting with CASK through a L27 domain interaction. CASK acts as the master anchor; it not only interacts with Lin-7, it also binds to extracellular matrix receptors, such as syndecan, through a type II PDZ interaction, while simultaneously engaging the actin cytoskeleton through a hook domain interaction with 4.1 proteins. CASK also recruits SAP-97 to the basolateral membrane through an L27 interaction. SAP-97 has the capacity to recruit PDZ-binding targets, as well as proteins that interact with the guanylate kinase (GK) and SH3 domains, such as AKAP-79.

The mammalian counterpart of Lin-10 is actually encoded by a family of proteins called the Mints or X11s.[179] Although all three members of the Mint family share C-terminal PDZ and PTB domains, only Mint-1 contains a CASK interaction domain.[165] In neuronal tissues and the heart, which express the complete Lin-7/CASK/Mint-1 complex, Mint-1 has been suggested to provide an additional membrane trafficking function. Mint-1 interacts with microtubule motors, and has been reported to transport N-methyl-D-aspartate (NMDA)-type receptor vesicles along microtubules.[180] In addition, Mint-1 interacts with Munc-18 docking machinery.[165,166,181] Importantly, mammalian epithelial cells do not express Mint-1. In its absence, the Lin-2/CASK system loses the obvious link to microtubule-mediated trafficking and fusion, suggesting that Lin-7/CASK plays a major role in retention rather than directed-delivery in renal epithelia.

Consistent with this notion, present evidence indicates that Lin-7/CASK primarily functions to retain target proteins at the basolateral membrane of mammalian epithelia. For example, Perego et al. found that removing the PDZ ligand in BGT-1 disrupted Lin-7 association in MCDK cells and dramatically increased the internalization of the transporter from the plasmalemma.[168] The retention function of Lin-7 depends on its L27 domain, which directs interaction with a cognate L27 domain in CASK.[170,177] In this way, Lin-7 acts as a PDZ-to-L27 adapter, mediating indirect association of its PDZ-binding target proteins with the larger basolateral membrane scaffold, CASK.

Although Lin-7 primarily operates as a component of a basolateral membrane retention machine in mammalian epithelial cells, it should be pointed out that disruption of Lin-7 interactions can produce a wide range of mis-localization phenotypes, depending on the Lin-7-binding partner and the types of sorting signals embedded within them. For instance, mutant BGT transporters, lacking their PDZ-binding motif, are predominately localized on the basolateral membrane. In this case, BGT-1 transporters are presumably directed to the basolateral membrane by non-PDZ-dependent sorting signals.[182] On the other hand, mutant Kir2.3 channels, lacking the PDZ-binding motif, are largely directed to an endosomal compartment, rather than the basolateral membrane,[167,177] consistent with strong endosomal targeting signals. An apical-missorting phenotype is produced by removing the PDZ-binding site from a chimeric LET-23/nerve growth factor receptor protein.[183] In this case, Lin-7 interaction may stabilize the receptor on the basolateral membrane or limit post-endocytic trafficking in such a way that it prevents transcytosis to the apical membrane.

At present, it is not known if the Lin-7/CASK/SAP97 scaffold also participates in signal complex localization and organization at the basal membrane in the way that has been described for the NHERF proteins at the apical membrane. SAP97 has been shown to recruit AKAP proteins to related PDZ protein complexes in neurons,[58] and the *Drosophila* CASK ortholog protein, Camguk, functionally modulates Ether-a-go-go potassium channels by a phosphorylation-dependent mechanism.[184] Interestingly, CASK contains an unusual CAM-kinase like domain, which can phosophorylate interacting proteins at the synapse.[185] However, it remains to be established if similar mechanisms are in place at the basolateral membrane of renal epithelial cells, which express the Lin-7/CASK/SAP97 complex.

Lin 7 Isoforms (Veli/MALS) and PALS (Partners of Lin7) in the Kidney

Three different Lin-7 isoforms, encoded by separate genes, have been identified. In mammalian systems,

these are often called Veli/MALS 1,2,3 (Vertebrate Lin-7 or Mammalian Lin Seven). Each of the MALS/Veli isoforms are expressed in the kidney, but each are differentially localized along the nephron.[36] MALS/Veli 1 is predominately expressed in the glomerulus, thick ascending limb of Henle's loop (TAL), and the distal convoluted tubule (DCT). MALS/Veli 2 is exclusively expressed in the vasa recta. MALS/Veli 3 is largely located in the proximal tubule, DCT, and collecting duct. The subcellular localization of MALS/Veli proteins can vary, depending on the isoform and the cell type. In contrast to the predominate basolateral location of MALS/Veli 1 in the TAL and DCT and MALS/Veli 3 in the DCT, MALS/Veli 1 is found diffusely throughout the cytosol of intercalated cells. In the collecting duct, MALS/Veli 3 is chiefly located on the basal membrane. Collectively, these results suggest that different MALS/Veli isoforms may carry out cell type-specific functions. MALS/Veli 1 and 2 isoforms in the thick ascending limb and distal segments appear to have the most significant capacity for a basolateral membrane targeting mechanism. MAL3/Veli 3 has been implicated in generation of polarity in the proximal tubule.[186]

The disparate subcellular localization patterns of MALS/Veli isoforms are likely to arise from at least two different factors. First, differences in the primary structures provide reason to suspect that the MALS/Velis may have specific binding preferences. In contrast to the nearly identical PDZ domains amongst the MALS/Veli isoforms, the extreme NH_2- and COOH-termini are highly divergent. Most importantly, the region believed to direct MALS/Veli subcellular localization, the L27 interaction module, exhibits only 57% amino acid identity between isoforms, raising the possibility that different isoforms preferentially bind to different L27 domain proteins. Second, cell-specific expression of Lin-7-binding partners may account for differences in isoform localization in different nephron segments and cell-types. A group of CASK-like MAUGK proteins, called PALS (Partners of Lin-7), that contain L27 hetero-oligomerization domains, have been identified as potential partners of Lin-7.[187] The different PALS might substitute for CASK under certain circumstances, forming MALS/Veli complexes with different subcellular locations and disparate functions. For instance, PALS1 targets Lin-7 to the tight junction,[188] in contrast to the basolateral membrane location of the CASK/Lin-7 complex.

Dystrophin-Associated Protein Complex

The dystrophin-associated protein complex (DPC) is a transmembrane scaffolding machine that is expressed in a variety of tissues. Extensive studies in skeletal muscle revealed the DPC serves structural and signaling functions.[189] In epithelia, the DPC localizes to the basolateral membrane (Figure 14.6), where it is organized in a manner similar to the skeletal muscle complex, functioning to compartmentalize and tether signaling and transport proteins.

In the sarcolemma, the DPC is nucleated by dystrophin, a flexible rod-like cytoplasmic protein containing multiple spectrin-like repeats. Dystrophin directly interacts with the transmembrane protein, β-dystroglycan, via a C-terminal cysteine-rich region, and connects the complex to lammin through α-dystroglycan (Figure 14.6). Because dystrophin also binds actin, it effectively links the extracellular matrix with the cytoskeleton, offering an architecture that protects the sarcolemma from shearing forces of contraction. This point is underscored by the link to disease. Specific mutations in the X-linked dystrophin have been identified that disrupt dystrophin and consequently destabilize DGC elements at the sarcolemma, producing Duchenne muscular dystrophy, the milder Becker muscular dystrophy, and X-linked dilated cardiomyopathy (reviewed in [189]).

Dystrophin also interacts with the scaffolding molecules dystrobrevin, and three isoforms of syntrophin (α1, β1 and β2), to organize local signaling complexes in muscle. The syntrophrins contain several protein−protein interaction domains, including two pleckstrin homology domains and a PDZ domain. The PDZ domains recruit a variety of proteins to the DPC, including voltage-gated sodium channels[190,191] and nNOS.[2] α-Dystrobrevin directly interacts with dystrophin via coiled-coil domains, while simultaneously binding to the syntrophins through an independent binding site.[192]

The basolateral membrane associated DRC in renal epithelial cells exhibits the same basic design as in skeletal muscle, but differs somewhat in molecular composition.[193,194] An autosomal homolog of dystrophin, called utrophin, along with less abundant C-terminal dystrophin isoforms, Dp71 and Dp140,[189] takes the place of the longer muscle-specific dystrophin in renal epithelia. In addition, differential expression of dystrobrevin and three syntrophin isoforms along the nephron give rise to nephron segment-specific DPCs with distinct molecular properties.[193] In the connecting segment and the cortical collecting duct where the DPC is especially enriched, the DPC includes utrophin, β1-/β2 syntrophin, dystrobrevin, and β-dystroglycan.[193]

Like dystrophin in muscle, utrophin directly interacts with the actin cytoskeleton in epithelial cells,[195] while associating with laminin in the extracellular matrix via the basolateral dystroglycans[196] (Figure 14.6). Thus,

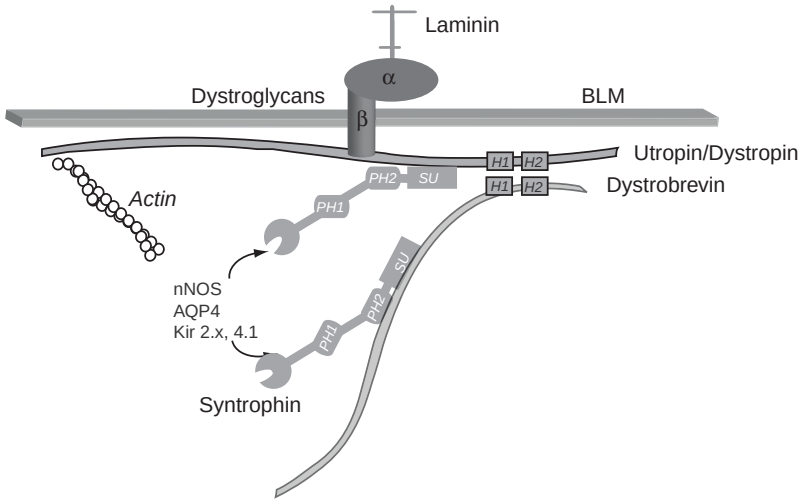

FIGURE 14.6 **The dystrophin-associated protein complex (DPC) at the basolateral membrane.** The PDZ protein, syntrophin, is recruited to the basolateral membrane via its interaction with utropin and possibly dystrobrevin, requiring one of its pleckstrin homology (PH2) domains and the syntrophin unique (SU) domain. This leaves the syntrophin PDZ domain free to recruit basolateral membrane proteins, such as the AQP4 water channel, potassium channels, Kir 2.X and Kir 4.X, as well as nNOS. Utropin/dystropin interacts with actin via N-terminal spectrin repeats, with β-dystroglycan via a C-terminal cysteine-rich region and with dystrobrevin via coiled-coiled domains (H1, H2).

utrophrin is poised to provide a secure anchoring point for polarized expression of syntrophin. Consistent with this notion, it has been reported that basolateral membrane localization of β2-syntrophin depends on its utrophin-binding activity, requiring one of its pleckstrin homology domains and the syntrophin unique (SU) domain.[35] Moreover, utrophin knockout mice exhibit a selective reduction of β2-syntrophin at renal epithelial basolateral membrane domains.[193] Syntrophins also interact with dystrobrevin via the PH and SU domains, allowing recruitment of additional syntrophin molecules to the same DPC.[197]

Importantly, the association of syntrophin with dystrobrevin, utrophin, and the basolateral membrane occurs independently of the syntrophin PDZ domain.[35] This leaves the Type I PDZ domain free to interact with proteins containing a syntrophin PDZ recognition motif. Basolateral membrane proteins, such as the inward rectifying channel proteins Kir 2.X[169] and Kir 4.X,[198] the AQP4 water channel,[199] as well as nNOS, have been shown to interact with the syntrophin PDZ-binding domain. At present, the functional relevance of these interactions in the kidney is not well-understood.

Several clues about the roles of transport protein interaction with syntrophin and the DPC are provided by studies in other tissues. In astrocytes, for example, α-syntrophin is required for the polarized expression of AQP4[199] and Kir 4.1[198] at end-feet membranes adjacent to blood vessels for efficient water and potassium siphoning.[200,201] It will be interesting to learn if genetic ablation of β2 syntrophin, the prevalent form in the kidney, has similar effects on AQP4 in the proximal straight tubule[202] and Kir 4.1 in the distal nephron.[203]

Utrophin knockout animals have been generated.[204] Unfortunately, expression of the shorter C-terminal dystrophin forms in the kidney compensate for the utrophin ablation, making it difficult to precisely define the functional role of the renal DPC by a genetic approach. Double utrophin/dystrophin knockout mice exhibit a fragile phenotype with complete disintegration of the DPC and premature death.[193] It will be important to determine how much of the phenotype can be attributed to impaired kidney function.

AKAP

AKAPs (A-kinase anchoring proteins) are a diverse group of molecules that function as cell signaling scaffolds. Specifically, AKAPs organize and juxtapose protein kinase A (PKA) with specific substrates and other signaling machinery at specific cellular locales. In doing so, AKAP proteins can precisely control where and when second-messengers will act on select cellular effectors. Since the first discovery of an AKAP, a microtubule anchoring protein that binds to the regulatory subunit of PKA with high affinity,[205] nearly 50 AKAP proteins have been identified. Many of them control phosphorylation of channels, receptors, and membrane transport proteins.[206] Several are suspected of modulating renal tubule transport processes.

COMMON PROPERTIES OF AKAP PROTEINS

AKAP proteins are structurally diverse, related only by general signaling functions and three common properties. First, classification as an AKAP protein requires the presence of a PKA-anchoring domain. Second, AKAPs contain cellular localization signals that provide a means to spatially organize second-messenger cascades at specific subcellular compartments. Third, AKAPs possess other protein−protein interaction domains, which specify interaction with select effectors and/or other signaling molecules. While all AKAPs have these common properties, they each have distinct targeting signals and different scaffolding

motifs. Consequently, they have specialized functions, modulating distinct intracellular signaling events.

AKAPs bind PKA by means of a small anchoring domain, comprised of a short (13–18 amino acid), amphipathic α-helix. NMR solution structures reveal that the hydrophobic side of the amphipathic helix makes numerous hydrophobic contacts within a hydrophobic surface of a four-helix bundle formed by the N-terminal domains of the PKA regulatory subunit homodimer.[208–210] Consequently, the AKAP–PKA interaction occurs with relatively high affinity (~1–10 nM). While most AKAPs interact with the RII isotypes of the PKA regulatory subunit, several AKAPs have been identified, D-AKAP1[211] and D-AKAP2,[211] which can interact with both RI and RII forms. Sphingosine kinase interacting protein (SKIP), an AKAP that is enriched in the inner mitochondrial membrane, exclusively interacts with RI.[212] Importantly, AKAP function can be disrupted by exogenous expression of a peptide mimic of the amphipathic helix.[213] Regulatory subunit isotype specific competitors have been developed.[214]

Specialized targeting sequences on anchoring proteins compartmentalize different AKAPs to distinct subcellular compartments, including plasma membrane microdomains, intracellular vesicles, nuclei, mitochondria, microtubules, and the actin cytoskeleton.[215] Certain AKAPs contain polarized trafficking signals that direct asymmetric localization in epithelial cells. AKAP2 (AKAP-KL), for example, is compartmentalized on the apical membrane[216] by its PDZ-binding motif, which specifies interaction with NHERF3.[81] Similarly ezrin, a low RII affinity AKAP, localizes to the apical membrane through a protein–protein recognition domain that directs interaction with NHERF1.[217] In many cases, different splice products of the same AKAP gene can be differentially targeted to different compartments. Splice forms of the AKAP18 gene, for instance, are expressed on opposite plasma membrane domains in epithelial cells; AKAP18-α is targeted to basolateral membranes, whereas AKAP18-β localizes to the apical membrane. In this case, a unique 23 amino acid insert in AKAP18-β acts as an apical membrane targeting determinant.[218]

As multivalent scaffolds, AKAPs can juxtapose the right combination of enzymes with their substrates. Consequently, AKAPs not only synchronize signal transduction processes, but they can also orchestrate signal termination events. The archetypal example is provided by the AKAP75/150 family, which influences the phosphorylation state of several different channels and transporters, including the Npt2a co-transporter,[219] L-type calcium channels,[220] M-type potassium channels,[221] and AMPA-type glutatamate receptors.[222,223] AKAP75 not only contains a binding site for PKA, it also directly interacts with PKC and the calcium-calmodulin-dependent phosphatase, PP2B (calcineurin).[224,225] Consequently, the same AKAP scaffold can coordinate signal transduction processes by phosphorylation as well as dephosphorylation. Thus, AKAPs can influence the balance of signal transduction and termination by differentially tethering different signaling components and effectors.[226]

Function of AKAPS in Kidney Transport Processes

AKAP-Dependent AQP2 Water Channel Shuttling

A critical role for AKAPs in water channel trafficking is strongly suggested by observations that cAMP-dependent AQP2 translocation to the cell surface can be inhibited with a synthetic peptide mimic of the AKAP amphipathic helix, which prevents binding of AKAPs to the PKA RII subunit.[227] Several different AKAPs appear to be associated with endosomal structures containing AQP2. Biochemical characterization of inner medullary collecting duct (IMCD) heavy endosomes, containing AQP2, revealed the presence of an associated multiprotein-signaling complex, composed of a 90 kD AKAP, PKA, and protein phosphatase 2a.[228] While the precise molecular identity of the 90 kD AKAP is still not certain, a smaller anchoring protein, AKAP18-δ, was subsequently discovered.[229] In the kidney, AKAP18-δ is mainly expressed in IMCD principal cells, where it appears to be confined to intracellular vesicles containing AQP2 and PKA. Observations that vasopressin recruits AKAP18-δ with AQP2 to the plasma membrane suggest that this AKAP is specifically involved in the PKA phosphorylation-dependent AQP2 translocation process. Reminiscent of the multifactoral roles of AKAP75 (see above), the AKAP-signaling complex in IMCD endosomes also contains PP2B[228] and phosphodiesterases.[230] Thus, the endosomal AKAPs in the collecting duct are also likely to participate in maintaining AQP2 in a quiescent dephosphorylated conformation in water diuresis.

AKAPs in the Proximal Tubule Apical Membrane Scaffolding Complex

Two different AKAPs, D-AKAP2 and AKPA79, have been implicated in the modulation of proximal tubule sodium phosphate transport. AKAP2 has been shown to interact with a PDZ scaffolding protein, NHERF3, at the apical membrane where it has been suggested to play an important role in the parathyroid hormone (PTH)-mediated regulation of Npt2a, involving PKA compartmentalization.[142] In a proximal tubule model, OK cells, PTH-dependent regulation of Npt2a can be uncoupled with a synthetic peptide mimic of

the AKAP amphipathic helix, indicating that an AKAP is required for PKA-dependent modulation of Npt2a regulation. In this system, AKAP79 was shown to associate with the Npt2a transporter, PKA, and the parathyroid hormone receptor.[219] Because AKAP 79 also has the capacity to interact with PDZ proteins in neuronal systems,[58] it may interact with the Npt2a co-transporter and the PTH receptor through its interaction with the apical NHERF complex.

AKAP Control of the Potassium Secretory Channel ROMK (Kir 1.1)

Studies of the renal potassium secretory channel, ROMK, in heterologous expression systems have suggested a potential role for AKAPs in the physiological regulation of potassium secretion. Because open channel gating and cell surface expression of the ROMK require direct phosphorylation by PKA[231,232] and other kinases,[137] a critical role of an AKAP has been an attractive idea. In fact, it has been reported that maximal activation of ROMK in *Xenopus* oocytes by forskolin and/or 8-bromo-cAMP-dependent kinase requires co-expression of an AKAP.[233] High basal phosphorylation of the channel in this expression system makes the effects of AKAPs modest. Nevertheless, the response appears to be AKAP specific, being dependent on AKAP-75 but not AKAP18, AKAP-2 (KL).[234] AKAP-75 is not expressed with ROMK in the thick ascending limb or collecting duct, however, so the AKAP in the kidney that interacts with ROMK still remains to be determined. Given observations that ROMK interacts with NHERF1 and 2 (see above), the ERM proteins[85] are obvious AKAP candidates.

CONCLUSION

Exciting discoveries in recent years have cast light onto the molecular mechanisms of epithelial transport modulation. The discovery of proteins that bring together physiologically appropriate assemblages of cell signaling and trafficking proteins with transport molecules for efficient regulation has been especially insightful. The molecular identities and functions of many of these scaffolding molecules in the kidney have now begun to come into focus. Still, there is much more to be learned. For example, observations that some transport proteins such as NHE1, the housekeeping sodium-hydrogen exchanger,[207] NHE3,[235] and the Na/K ATPase,[236,237] might twilight as scaffolding proteins is emerging as an intriguing possibility that we certainly will hear more about in the future. Also, with the application of powerful new tools in cell biology, genomics, and proteomics, it is likely that more scaffolding candidates will be identified. As they are, it will be important not only to continue probing into the mechanistic basis of function in model systems, but also to rigorously explore how these fascinating molecules work in their native cellular environments.

Highly conserved through phylogeny, the renin–angiotensin system (RAS) is an essential regulator of blood pressure and fluid balance. This biological system is a multi-enzymatic cascade in which angiotensinogen, its major substrate, is processed in a two-step reaction by renin- and angiotensin-converting enzyme (ACE), resulting in the sequential generation of angiotensin I and angiotensin II. Along with its importance in maintaining normal circulatory homeostasis, abnormal activation of the RAS can contribute to the development of hypertension and target organ damage.

The importance of the RAS in clinical medicine is highlighted by two sets of observations. First are associations between polymorphisms of genes encoding RAS components and cardiovascular disease.[1–6] Second, and perhaps more compelling, is the impressive efficacy of pharmacological agents that inhibit the synthesis or activity of angiotensin II. For example, angiotensin converting enzyme (ACE) inhibitors are very effective and well-tolerated anti-hypertensive agents.[7] Along with their ability to lower blood pressure, these agents also effectively prevent or ameliorate morbidity and mortality associated with cardiovascular diseases. In this regard, large clinical trials have demonstrated that ACE inhibitors improve survival in patients with congestive heart failure,[8,9] and in patients with risk factors for coronary artery disease.[10] They also slow the progression of a variety of kidney diseases, including diabetic nephropathy.[11] Angiotensin receptor blockers (ARBs), which block AT_1 receptors, are similarly effective for treating these disorders.[12–14] The purpose of this chapter is to provide an overview of the major physiological features of the RAS, focusing on its role in the kidney.

THE COMPONENTS OF THE RENIN–ANGIOTENSIN SYSTEM

Renin

The aspartyl protease renin was first isolated from the kidney by Tigerstedt more than a century ago. Renin is synthesized as a precursor protein, pro-renin, containing an additional 43 amino acids at the N-terminus that block the enzyme's active site.[15] Active renin is generated by removal of this N-terminal peptide fragment, presumably by proteases in the juxtaglomerular cells of the kidney. Whether intact pro-renin has a distinct physiological role remains to be determined; however, there is accumulating evidence suggesting specific contributions of the pro-renin molecule in some normal and disease states.[16–19]

Active renin specifically cleaves the 10 amino acids from the N-terminus of angiotensinogen to form angiotensin I. A substantial excess of angiotensinogen is present in serum, and ACE is ubiquitous in the endothelium and plasma.[20] Accordingly, in the bloodstream, the amount of renin is the rate-limiting step determining the level of angiotensin II, and thus the activity of the system. The primary source of renin in the circulation is the kidney, where its expression and secretion are tightly regulated at the juxtaglomerular apparatus by two distinct mechanisms: a renal baroreceptor[21,22] and sodium chloride delivery to the macula densa.[23–25] Through these sensing mechanisms, levels of renin in plasma can be incrementally titrated in response to changes in blood pressure and salt balance. These regulatory principles provide a basis for many of the physiological characteristics of the RAS, and regulation of renin release in the kidney will be discussed in detail below.

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00015-X

In addition to its protease activity, renin may also bind specifically to other proteins or putative receptors.[19,26–28] This binding may induce physiologically significant intracellular signaling.[27] It has been suggested that the mannose-6-phosphate receptor (M6P-R), also known as insulin-like growth factor II receptor, binds renin and pro-renin, leading to internalization and degradation.[26] Nguyen et al. reported cloning a receptor from human kidney expression library that binds renin and pro-renin specifically and with high affinity, termed the (pro)renin receptor (PRR). Binding of PRR causes a conformational change of renin that leads to increased renin catalytic activity. Similarly, binding of PRR to pro-renin causes a conformational change, resulting in an ezymatically active pro-renin without the requirement for cleavage of the pro-segment. Furthermore, binding of renin to this receptor induces a rapid and sustained activation of ERK1/ERK2, without affecting concentrations of calcium or cAMP.[27] It has been suggested that it may mediate angiotensin II-independent effects of renin, and might also indicate a functional role of pro-renin.[29] Although the physiological significance of PRR remains unclear, recent studies suggest PRR may have a role in blood pressure regulation. Transgenic rats overexpressing human PRR selectively in vascular smooth muscle cells display elevated blood pressure and heart rate.[30,31] In addition, human PRR gene polymorphism has been shown to be associated with ambulatory blood pressure in Japanese men.[32] PRR may also play a role in development. Deletion of PRR in mice results in early embryonic lethality.[33] In a family with X-linked mental retardation and epilepsy, linkage analysis identified an exonic splice enhancer in the PRR gene as the only mutation, and this resulted in the loss of the capacity of renin to phosphorylate ERK1/2.[34]

The pro-renin receptor appears to have other functions independent of the renin–angiotensin system. For example, it is found as part of a complex required for the normal function of V-ATPase in several cell lineages, including cardiac myocytes.[35] The pro-renin receptor acts as an adaptor between the Wnt receptor and V-ATPase in a Wnt/β-catenin signaling complex required for normal CNS development.[36] Thus, deletion of the pro-renin receptor gene causes a lethal phenotype at a very early embryonic stage, which contrasts significantly with the phenotype of renin knockouts,[37] indicating important functions of the receptor that are independent of its actions in the RAS. Two groups have recently described studies of mouse lines in which the pro-renin receptor was deleted specifically from podocytes. In both cases, there was a similar, dramatic phenotype characterized by disruption of the glomerular filtration barrier, with marked proteinuria and abnormal podocyte structure, perhaps due to dysregulated autophagy.[38,39] Thus, while this molecule appears to play a critical role in the kidney, much remains to be learned about its functions in normal kidney physiology and disease, including the extent to which these functions are influenced by renin or pro-renin binding.

Angiotensinogen

Angiotensinogen, the substrate for renin, is the source of all angiotensin peptides. Angiotensinogen in the circulation is derived primarily from synthesis in the liver. In humans, plasma concentrations of angiotensinogen are typically near the Km for renin,[40] so that changes in plasma concentration may influence the rate of angiotensin I generation at any given level of renin. In human hypertensive siblings, Jeunemaitre et al.[2] showed that a specific variant of the human angiotensinogen gene, M235T, was linked to hypertension, and was also associated with a modestly elevated plasma angiotensinogen concentration, about 120% of normal. They proposed that this variant of the *AGT* gene leads to an increase in plasma angiotensinogen levels and thereby eventually to increased blood pressure. However, because amino acid 235 is in a non-conserved portion of the angiotensinogen protein and variation of this amino acid does not affect protein stability, a mechanism to explain the physiological consequences of the mutation was not clear. An apparent explanation came later, when the M235T variant was found to be in linkage disequilibrium with another variant in the 5′ untranslated region of the *AGT* gene.[41] This second variant, a single nucleotide substitution in the promoter of the *AGT* gene, was associated with increased transcriptional activity of the gene.[41] Higher levels of *AGT* mRNA were found in patients carrying the variant allele.[41] The causal capacity of alterations in plasma angiotensinogen level to affect blood pressure was demonstrated in studies of mice engineered to carry from 0 to 4 copies of the *AGT* gene.[42] In these animals, there was a positive correlation between the number of *AGT* gene copies, plasma levels of angiotensinogen, and blood pressure.

In addition to its synthesis by the liver, angiotensinogen is also produced by other tissues including the brain, the immune system, and the kidney.[43] In the kidney, synthesis of angiotensinogen in proximal tubules has been well-documented,[44] and proximal tubule synthesis may be regulated in part by the end-product, angiotensin II.[45] Along with angiotensinogen, the kidney expresses all of the other components of the RAS. Accordingly, it has been suggested that regulation and functioning of autonomous "tissue" renin–angiotensin systems in the kidney, as well as

other organs, may contribute to the physiological functions of the system, especially in disease states.[46] This hypothesis has been used to explain additional complexity of the system, whereby the apparent activity of the RAS is not reflected by measured plasma levels of it major components. For example, in the broad population of patients with hypertension, diabetes, and cardiovascular disease, pharmacological antagonists of the RAS lower blood pressure and prevent end-organ damage, even in the absence of overt elevation of plasma renin levels. However, the precise nature and physiological contributions of these tissue systems has been difficult to define experimentally.

Angiotensin Converting Enzyme

Angiotensin converting enzyme (ACE) is a carboxypeptidase that generates the vasoactive peptide angiotensin II by cleaving two amino acids from the c-terminus of the inactive precursor angiotensin I.[47] There are two distinct forms of ACE, somatic and testicular, both generated by alternative splicing of a single gene.[48–50] Somatic ACE is expressed as an ectoenzyme on the surface of endothelial cells throughout the body, and is particularly abundant in lung, intestine, choroid plexus, placenta, and on brush border membranes in the kidney. A soluble form of ACE that circulates in plasma is formed by enzymatic cleavage of tissue-bound ACE at its transmembrane domain.[51] As with other components of the RAS, molecular variants of *ACE* have been proposed as candidate genes in hypertension, cardiovascular, and kidney diseases.[52] Insertion (I) and deletion (D) polymorphisms of the human *ACE* gene are common, and have been associated with altered levels of ACE in plasma.[53,54] In some cohorts, but not others, these *ACE* gene variants have been linked to differing susceptibilities to hypertension, cardiovascular, and renal diseases.[52,55]

In addition to angiotensin I, other biologically active peptides are substrates for ACE. Perhaps the most important of these is bradykinin.[56] ACE degrades bradykinin into an inactive peptide, representing a significant biological pathway for bradykinin metabolism *in vivo*[57]; in older literature, ACE was referred to as kininase II. Since bradykinin has vasodilator and natriuretic properties,[56] it has been suggested that one mechanism of blood pressure reduction with ACE inhibition is blockade of this kininase activity. This was clearly demonstrated by Brown and associates, who showed that the anti-hypertensive efficacy of ACE inhibitors is attenuated by simultaneous administration of a bradykinin receptor antagonist.[58]

Using genome-based strategies, homologs of ACE have been identified.[59–61] One of these, ACE2, exhibits more than 40% identity at the protein level with the catalytic domain of ACE.[59,60] Similar to ACE, ACE2 is expressed on the surface of certain endothelial cell populations. However, compared to the ubiquitous distribution of ACE, the expression pattern of ACE2 is more limited, with most abundant expression in kidney followed by heart and testis.[59,60] Their substrate specificities also differ; ACE2 hydrolyzes angiotensin II with high efficiency, but has much lower activity against angiotensin I.[59,62] Hydrolysis of angiotensin II by ACE2 generates another peptide with putative biological actions: angiotensin 1-7.[62] Accumulating evidence indicates that this peptide causes vasodilation, natriuresis, and may promote reduced blood pressures[63] via the Mas receptor.[64] It has been further suggested that ACE2 may be a major pathway for synthesis of angiotensin 1-7.[65] Thus, the functions of ACE2 may be determined by its distinct actions to metabolize angiotensin II and to generate angiotensin 1-7.

Although the precise physiological role of ACE2 is not clear, it was originally identified and cloned from a cDNA library prepared from ventricular tissue of a patient with heart failure.[59] Initial studies in ACE2-deficient mice have suggested a role for ACE2 in cardiac function[364,365] and in blood pressure regulation.[66] More recent work by many groups has demonstrated roles for ACE2 in renal diseases, such as diabetic and non-diabetic kidney disease,[67–70] and hypertension[67,71,72] in both experimental models and human cohorts.

A third member of the ACE gene family, collectrin, was identified as a gene that is upregulated in the subtotal nephrectomy model of chronic kidney disease.[73] Collectrin is highly homologous to the transmembrane portion of ACE2, but lacks the carboxypeptidase domain.[61] Its physiological functions are emerging[74,75] and appear to regulate amino acid transport by the kidney.

Angiotensin Receptors

The biological actions of angiotensin II are mediated by cell surface receptors that belong to the large family of 7 transmembrane receptors.[7,76] The angiotensin receptors can be divided into two pharmacological classes, type 1 (AT_1) and type 2 (AT_2), based on their different affinities for various non-peptide antagonists (Figure 15.1). Studies using these antagonists suggested that most of the classically recognized functions of the RAS are mediated by AT_1 receptors.[76] Gene targeting studies have confirmed these conclusions.[77]

AT_1 receptors from a number of species have been cloned[78–80] and two subtypes, designated AT_{1A} and

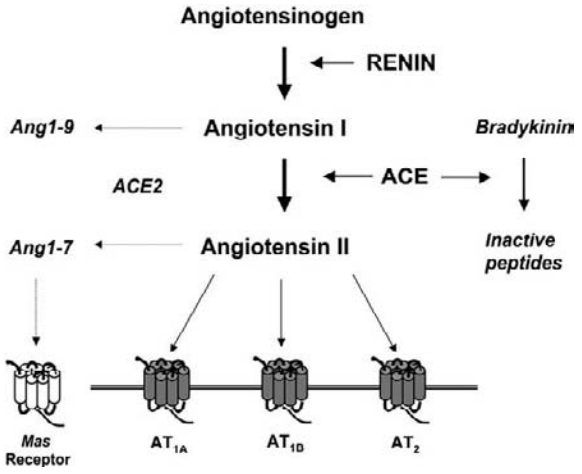

FIGURE 15.1 Angiotensinogen is cleaved by renin to form angiotensin I, which is then cleaved by angiotensin-converting enzyme (ACE) to form angiontesin II, the major effector molecule of the RAS. The biological effects of angiotensin II are mediated by the G-protein-coupled seven-transmembrane cell surface receptors AT1 and AT2. Angiotensin II is hydrolyzed by angiotensin-converting enzyme 2 (ACE2), a homologue of ACE. This hydrolysis results in the generation of the angiotensin 1–7 peptide, the actions of which are mediated by the *Mas* receptor. After: *Le, TH and Coffman TM. Targeting genes in the renin-angiotensin system. Current Opinion in Nephrology and Hypertension 2008, 17:57-63. Lippincott Williams & Wilkins.*

AT_{1B}, have been identified in rat[81–83] and mouse.[84] In the classical view, AT_1 receptors signal through $G_{\alpha q}$-linked signaling pathways involving phospholipase C, IP3, and increases in intracellular calcium.[85] However, the AT_1 receptor has also been linked to JAK/STAT activation,[86] as well as β-arrestin-dependent pathways linked to ERK activation.[87–89] In addition, recent studies have shown that the AT1 receptor has the capacity to transactivate the EGF receptor, which may be independent of ligand.[90,91] This pathway may contribute to chronic kidney injury.[92]

The murine AT_1 receptors are products of separate genes and share substantial sequence homology.[83,93,94] AT_{1A} receptors predominate in most organs, except the adrenal gland and regions of the CNS, where AT_{1B} expression may be more prominent.[93,95,96] A single report has suggested that AT_{1B} receptors might also exist in man,[97] but this has not been confirmed in the unpublished work of several independent groups, and the consensus view is that there is no human counterpart to the murine AT_{1B} receptor. Thus, the AT_{1A} receptor is considered the closest murine homolog to the single human AT_1 receptor.

The binding signatures of the AT_{1A} and AT_{1B} receptors are virtually identical,[98] and it was difficult to discriminate their *in vivo* functions pharmacologically. Experiments using gene targeting have provided insights into the discrete functions of the two AT_1 receptor genes.[99,100] Although the AT_{1B} receptor has a unique role to mediate thirst responses in the CNS,[101] AT_{1A} receptors have the predominant role in determining the level of blood pressure,[102–104] and in mediating vasoconstrictor responses.[99,102] The phenotype of markedly reduced blood pressures and profound sodium sensitivity in mice lacking the AT_{1A} receptor[102,105] underscores its importance in blood pressure control.

Pharmacological and genetic studies have confirmed that virtually all of the classically recognized functions of the RAS are mediated by AT_1 receptors. Until recently, little was known about the physiological role of AT_2 receptors. AT_2 receptors are found in abundance during fetal development,[106,107] but their expression generally falls after birth. However, persistent AT_2 receptor expression can be detected in several adult tissues including the kidney, adrenal gland and the brain, and absolute levels of AT_2 receptor expression may be modulated by angiotensin II and certain growth factors.[108] AT_2 receptors appear to signal by coupling to $G_{\alpha i2}$ and $G_{\alpha i3}$ proteins.[109] Using site-directed mutagenesis, the intermediate portion of the third intracellular loop of the AT_2 receptor was found to be necessary for normal receptor signaling.[110,111] Moreover, it has been suggested that activation of AT_2 receptors stimulates bradykinin, nitric oxide, and guanosine cyclic 3′,5′-monophosphate (cGMP),[112,113] and these pathways may mediate actions of the receptor to promote natriuresis and blood pressure lowering. Finally, there is also evidence to support HETEs as second messengers for AT_2 receptors in the kidney, leading to ERK1/2 phosphorylation.[114]

Targeted disruption of the mouse *Agtr2* gene did not cause a dramatically abnormal phenotype. These animals clearly manifest increased sensitivity to the pressor actions of angiotensin II.[115,116] One of the AT_2 deficient lines manifested increased baseline blood pressure and heart rate.[115] Interestingly, behavioral changes were also observed in AT_2-deficient mice. They had decreased spontaneous movements and rearing activity,[115,116] and impaired drinking response to water deprivation.[116] Transgenic mice that overexpress the AT_2 receptor gene under control of a cardiac-specific promoter have decreased sensitivity to AT_1-mediated pressor and chronotropic actions.[117] Moreover, the pressor actions of angiotensin II are significantly attenuated in these transgenic mice. This attenuation was completely reversed following pretreatment with a specific AT_2 receptor antagonist. Taken together, these data suggest that a primary function of the AT_2 receptor may be to negatively modulate the actions of the AT_1 receptor. Along similar lines, the recently described non-peptide agonist, compound 21, has been used to uncover additional functions of the AT_2 receptor, which appear quite diverse. Studies with this agonist regarding blood pressure have been

variable, but it appears to have minimal effect on blood pressure in normal situations; the potential to affect blood pressure in disease states may be different.[118]

Aldosterone

Aldosterone is a steroid hormone synthesized in the zona glomerulosa (ZG) of the adrenal gland. The two dominant regulators of aldosterone synthesis and release are angiotensin II and the level of serum potassium.[119] The RAS-dependent component of aldosterone regulation is triggered by binding of angiotensin II to AT_1 receptors in the ZG.[119] Stimulation of aldosterone release by angiotensin II contributes to enhanced sodium reabsorption and anti-natriuresis. Independently of angiotensin II, hyperkalemia can control the release of aldosterone through a process that involves the membrane depolarization of ZG cells.[120,121] In addition, adrenocorticotropic hormone (ACTH) can stimulate aldosterone via its G-protein coupled receptor.[121] Elevations in ACTH influence aldosterone production only during short-term stress, as this response is attenuated with persistent exposure to ACTH. In contrast, angiotensin II and potassium can both exert a chronic, sustained stimulation of aldosterone generation by the zona glomerulosa.[122]

The classically recognized effects of aldosterone to influence sodium handling in the distal nephron are mediated by aldosterone binding to the mineralocorticoid receptor (MR). The MR is a 107 kD protein that acts as a transcription factor to regulate gene expression in target tissues. The molecular mechanisms used by the MR to drive epithelial sodium channel (ENaC) function in the collecting tubule have been reviewed recently.[123] Cortisol actually exhibits a higher affinity for the mineralocorticoid receptor than aldosterone, but locally expressed 11ß-hydroxysteroid dehydrogenase type 2 "protects" the MR by converting cortisol to cortisone, which does not activate the MR.[124] The binding of aldosterone to the MR in the principal cell of the collecting tubule epithelium induces transcription of the α-subunit, the multimeric coupling of the α-, β-, and γ-subunits of the EnaC, and the translocation of the ENaC complex to the luminal surface of the tubule.[125,126] Aldosterone-induced expression of the αENaC-subunit, in particular, follows a diurnal variation pattern that depends on the circadian transcription factor Period1.[127]

Aldosterone stimulates ENaC transcription and activity largely through the upregulation of serum- and glucocorticoid-regulated kinase 1 (sgk1).[128–130] At the transcriptional level, Sgk1 phosphorylates ALL1-fused gene from chromosome 9 (Af9), which in turn blocks the repressor effects of the histone H3 Lys79 methyltransferase disruptor of telomeric silencing alternative splice variant a (Dot1a) on αENaC gene transcription.[131] At the post-translational level, Sgk1 phosphorylates Nedd4-2, causing ENaC proteins to remain in the apical membrane of the principal cell.[132,133] Once inserted into the luminal membrane of the principal cell, ENaC permits cellular uptake of intraluminal sodium, generating an electronegative potential in the distal tubular lumen which favors secretion of potassium from the principal cell into the urinary filtrate via the renal outer medullary potassium channel (ROMK). Sgk1 may also phosphorylate ROMK, similarly increasing its apical density, further facilitating the kaliuresis induced by aldosterone.[134] In addition, aldosterone appears to directly increase ROMK expression.[135] Finally, aldosterone modulates sodium transport in the distal nephron independently of ENaC by enhancing expression and activity of the thiazide-sensitive Na-Cl co-transporter (NCC). Sgk-1 mediates this effect by phosphorylating serine/threonine kinase with-no-lysine 4 (WNK4), thereby diminishing the inhibitory effects of WNK4 on NCC activity.[136] Through these pathways, the MR regulates sodium and potassium transport within the mineralocorticoid-responsive segments of the distal nephron.

Recent human phenotyping studies and animal studies using gene-targeting strategies have confirmed the contribution of the MR to tubular function and salt balance. For example, in humans with a mutation leading to a constitutively active MR, early onset hypertension develops,[137] whereas heterozygosity for an inactivating mutation of the MR leads to salt-wasting, hypotension, metabolic acidosis, and hyperkalemia.[138] Mice genetically deficient for the MR similarly develop severe salt-wasting that leads to neonatal death,[139] whereas mice with genetic deletion of the MR restricted to the principal cell waste salt and lose body weight only when exposed to a low-sodium diet,[140] suggesting that at baseline the late distal convoluted tubule and early connecting tubule may be able to compensate for a lack of ENaC activity in the distal nephron. Alternatively, the discrepancy in phenotypes between the global and conditional knockout mice may be due to discrete functions of aldosterone to modulate solute transport in the proximal tubule[141,142] and/or medullary thick ascending limb.[143] Mutations that activate the ENaC may cause hypertension,[144–146] whereas global inactivation of the subunits of the ENaC in mice causes sodium-wasting, potassium retention, and early mortality, and in humans pseudohypoaldosteronism type 1 with severe salt-wasting.[147] In contrast, inactivation of the α-ENaC gene only in the collecting duct does not impair sodium and potassium balance,[148] again indicating that the regulation by aldosterone of ENaC in the latter regions of

the distal convoluted tubule and/or the connecting tubule may also contribute to sodium and fluid homeostasis.[149]

In addition to its physiologic effects on renal solute handling, aldosterone has the capacity to mediate direct cellular injury in the kidney.[150] In this regard, pathologic functions of aldosterone in non-tubular renal compartments become increasingly relevant. For example, aldosterone impairs vascular reactivity by diminishing expression of glucose-6-phosphate in the endothelium[151] and mediates direct vascular injury via a placental growth factor-dependent pathway.[152] In mesangial cells, aldosterone activates sgk-1, NF-kB, and MAP kinases, leading to cellular proliferation, generation of oxidative stress, and connective tissue growth factor expression.[153–155] Emerging evidence suggest aldosterone may also promote oxidative stress and apoptosis directly within podocytes.[156,157] Consistent with these pathologic effects of aldosterone in several cell lineages of the kidney glomerulus, human studies have now demonstrated a role for aldosterone blockade in ameliorating the progression of proteinuric kidney disease.[158]

Integrated Actions of the RAS in the Kidney

The important role of the kidney in regulation of blood pressure has been long recognized,[159] and the relationship between alterations in systemic blood pressure and changes in renal sodium excretion is well-documented.[160] For example, an elevation in perfusion pressure in the renal artery results in a rapid increase in sodium and water excretion by the kidney, so-called "pressure natriuresis".[160] Based on such observations, Guyton and co-workers suggested that whenever arterial pressure is elevated, activation of this pressure-natriuresis mechanism will cause sufficient excretion of sodium and water to return systemic pressures to normal.[161] They further hypothesized that the substantial capacity for sodium excretion by the kidney provides a compensatory system of virtually infinite gain to oppose processes, including increases in peripheral vascular resistance, which would tend to increase blood pressure. It follows that defects in renal excretory function would therefore be a pre-requisite for sustaining a chronic increase in intra-arterial pressure.

The RAS has potent actions to modulate pressure-natriuresis relationships in the kidney[162,163] and these actions shape the characteristics of RAS-dependent blood pressure regulation in normal physiology and in disease states. For example, as depicted in Figure 15.2, chronic infusion of angiotensin II causes a shift of the pressure natriuresis curve to the right, suggesting that when the RAS is activated, higher pressures are required to excrete an equivalent sodium load[164] (Figure 15.2). Conversely, administration of ACE inhibitors or ARBs shifts the curve to the left, meaning that natriuresis is facilitated at lower levels of blood pressure (Figure 15.2). The basic features of endogenous control of the RAS are consistent with these homeostatic functions. As shown in Figure 15.2, the system is activated at low levels of salt intake, stimulating renal sodium reabsorption and conservation of body fluid volumes and blood pressure. In contrast, with high sodium intake, the system is suppressed, facilitating natriuresis.

REGULATION OF RENIN

As discussed above, the concentration of renin in plasma is the rate-limiting step in the production of angiotensin II. Accordingly, the activity of the RAS in the circulation is largely determined by the factors that regulate renin. The kidney is the major source of renin, where its generation and secretion are primarily controlled by renal perfusion pressure and by the luminal delivery of sodium chloride to the macula densa in the distal nephron. The major features of these regulatory processes are described in the sections that follow.

Sources of Renin

The major source of renin in the circulation is the kidney. Following bilateral nephrectomy, plasma levels of renin and angiotensin II fall precipitously.[165] In the kidney, the location of renin-expressing cells varies from development through adulthood, and in response to homeostatic challenges. During embryonic development, renin-expressing cells are found in the undifferentiated metanephric mesenchyme.[166] In the fetal kidney, these cells are present in the large intrarenal arteries, glomeruli, and interstitium.[166] In the adult kidney, renin expression is primarily restricted to granular cells which are modified smooth muscle cells within the juxtaglomerular apparatus (JGA). The JGA is located in the region where the afferent arteriole enters the glomerulus.[167,168] As shown in Figure 15.3, the JGA is a highly organized structure composed of three distinct anatomical parts: granular cells, the macula densa, and the extraglomerular mesangial cells.[169] The macula densa is a specialized tubular area that marks the transition from the ascending loop of Henle to the distal tubule lying in direct contact with the vascular pole of the glomerulus from which it originated.[169] By light microscopy, the unique characteristics of the macula densa epithelial cells can be discerned by their narrow, columnar shape and apparent

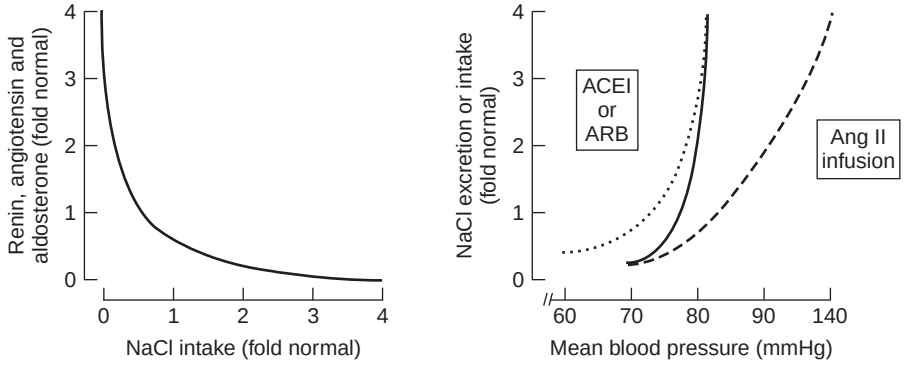

FIGURE 15.2 Chronic infusion of angiotensin II causes a shift of the pressure natriuresis curve to the right. Conversely, administration of ACE inhibitors or ARBs shifts the curve to the left. FIGURE 15.3 The juxtaglomerular apparatus (JGA). Integration of the regulated secretion of renin is carried out at the JGA. There are three major pathways regulating the secretion of renin by granular cells at the JGA: the baroreceptor, the macula densa mechanism, and direct stimulation by the sympathetic nervous system. The renal baroreceptor monitors renal perfusion pressure and signals an increase in renin when renal perfusion pressure falls. In the macula densa mechanism, macula densa cells sense the decrease in chloride ions in the filtrate in the distal tubule, thereby stimulating release of renin. Increased activity of renal sympathetic nerves directly stimulates renin release via activation of adrenergic receptors. Sympathetic innervation also modulates both the baroreceptor and macula densa mechanisms. After: *Francois H and Coffman TM. Prostanoids and blood pressure: which way is up? J Clin Invest. 2004; 114(6):757-759. American Society for Clinical Investigation.*

accumulation of nuclei, distinguishing them from cells in the adjacent parts of the distal tubule.[167] By electron microscopy, the basement membrane of the macula densa appears to be fused with the vacular component, and continuous with the basement membranes surrounding the granular and agranular cells in the extraglomerular mesangium.[167] As described below, the macula densa acts as a sensor of chloride concentration in the distal tubule, providing signals that are important for control of renin.[169] The anatomical organization of the JGA facilitates the regulation of renin secretion in response to critical environmental cues.

Although JG cells are clearly the primary source of renin in the adult kidney, studies by Gomez and associates suggest that renin-expressing cells are not terminally differentiated, but can be recruited during periods of homeostatic pertubations such as dehydration and hypotension. For example, in angiotensinogen-deficient mice, renin is expressed extensively along the entire length of the afferent arteriole and intrarenal arteries.[170] Similarly, in mice subjected to a low-sodium diet combined with captopril treatment, renin-expressing cells can be found throughout the length of the afferent arteriole, in the glomerular and

extraglomerular messangium, and in the glomerular capsule.[170] Studies by Lalouel and associates suggest that renin is also present in the connecting tubule, at least in the mouse kidney. Moreover, their studies indicate that renin expression in the connecting tubule may be regulated by sodium intake.[171] Although its physiological role is unclear, it has been suggested that renin expressed in the distal nephron may contribute to regulation of angiotensin peptide concentrations in the tubular lumen.

Expression of renin outside the kidney has also been documented. Levi and associates have recently shown that mast cells express renin mRNA and contain large quantities of renin protein, apparently within the secretory granules.[172] Mast cell-derived renin can efficiently convert angiotensinogen to angiotensin I after mast cell degranulation.[172] Moreover, release of renin by cardiac mast cells can be triggered by ischemia, producing pathophysiologic consequences such as release of norepinephrine and generation of cardiac arrhythmias.[173] Taken together, this work has suggested that resident mast cells in the heart and perhaps other organs, upon appropriate stimulation, are capable of generating ample quantities of renin to activate the RAS locally, and thereby affect organ function. Furthermore, it appears the factors controlling renin release from mast cells will be quite different from those that regulate JG cells, and are likely to involve signals associated with inflammation and injury.[174] Nonetheless, it remains to be determined whether this alternative pathway for RAS activation plays any major role in physiology or disease pathogenesis.

Baroreceptor Regulation of Renin Release

The baroreceptor theory was developed to explain observations that renin secretion is directly stimulated by reduced renal perfusion. This theory was first developed in the context of experimental observations that granularity of the JG cells was inversely correlated with the magnitude of renal perfusion pressure.[175] Since then, numerous studies have shown that renin secretion is inversely related to renal perfusion pressure or pulse amplitude.[21,176–179] This relationship is preserved in denervated kidneys[180,181] and in isolated perfused kidneys with a non-functioning macula densa mechanism.[182–184] Thus, the baroreceptor is an independent mechanism for controlling renin, residing within the kidney and clearly separate from regulation by the sympathetic nervous system.[179] In renovascular hypertension, the baroreceptor is the primary mechanism for stimulating renin release. In the presence of a critical stenosis of the renal artery, renal perfusion pressure drops, stimulating renin and generating hypertension.[185]

While the independent nature of the baroreceptor mechanism and its localization to the kidney has been clearly established, identification of its precise nature has been elusive. Various models have been proposed to explain the mechanism for pressure sensing and consequent signal transduction, including direct stretch of the JG cells due to transmural pressure across the afferent arteriole[22,186] or indirect pathways involving secondary release of autocoids.[187] Some of these candidate soluble factors include nitric oxide[188–190] and prostanoids,[191,192] which are stimulatory or endothelins, which are inhibitory.[193]

Gene-targeting in the mouse has been utilized to examine the role of some of these mediators in the baroreceptor response. In one study, genetic deletion of endothelial nitric oxide synthase (eNOS) had no effect on renin release in response to change in renal perfusion pressure, suggesting that eNOS-derived nitric oxide is not a mediator of the baroreceptor–renin coupling.[194] On the other hand, the absence of the IP receptor, the single known receptor for PGI_2 (prostacyclin), conferred substantial resistance to hypertension and hyperreninemia after unilateral renal artery stenosis.[195] This suggests an absolute requirement for PGI_2 in triggering renin release after baroreceptor activation. A number of questions remain concerning the mechanism and cell lineages controlling synthesis of key mediators such as prostacyclin, and the cellular targets for these mediators affecting renin release.[196]

Over the past 40 years, much deliberation has been rendered regarding the existence and location of a baroreceptor for renin release. The mechanism by which renal perfusion pressure regulates renin secretion remains poorly understood. However, this mechanism appears to be dependent on extracellular calcium concentration. Kurtz and colleagues demonstrated that when the extracellular level of calcium is lowered, the inhibitory effect of renal perfusion pressure on renin release is abolished.[197] A potential mediator in this process may involve connexin proteins that form gap junctions between JG cells and adjacent endothelial cells. Disruption of connexin40 (Cx40) in the mouse, either through gene deletion or point mutation, results in hyperreninemia and hypertension, and loss of pressure control of renin release[198,366-368]; similar to the effect observed with the lowering of extracellular calcium concentration.[197] Other connexin proteins have been demonstrated to also play a role in renin release. Connexin45, another gap junction protein, can replace the function of connexin40, since genetic substitution of the coding region of connexin40 by connexin45 resulted in the attenuation of hypertension and near normalization of the pressure control of renin secretion.[200] Replacement of connexin43 by connexin32 in

the mouse resulted in decreased renin levels that did not change in response to a high-salt diet and protection from hypertension induced by a 2-kidney-1clip model.[201] A consensus remains to be established regarding whether connexin proteins (and which one (s)), are indeed the elusive baroreceptor, but the evidence suggests that connexins play an essential role in the regulation of renin release in response to change in perfusion pressure. Future studies are required to determine whether these connexins interact in coordination with other mediators mentioned above in the baroreceptor response.

Macula Densa Mechanism for Renin Regulation

The second major pathway for physiological regulation of renin is the so-called macula densa mechanism, whereby cells at the macula densa sense a reduction in chloride ions in the filtrate of the distal tubule, triggering renin release.[25] In this circumstance, release of renin and the consequent generation of angiotensin II are believed to serve as a mechanism for enhancing renal sodium reabsorption in states of fluid volume depletion. The anatomical association of the macula densa with the JG cells stimulated the first speculation by Goormaghtigh of its physiological function.[202] As mentioned above, the macula densa is made up of specialized epithelial cells at the terminal portion of the thick ascending limb. Their basolateral membrane is in contact with glomerular mesangial cells which, in turn, are contiguous with granular cells in the JGA.[24] The role of the macula densa in renin regulation was initially hypothesized by Vander in 1967,[169] and there is now general consensus that this mechanism provides a control of renin secretion that is directly determined by sodium chloride delivery to the distal nephron.[203,204] Moreover, several studies indicate that chloride flux through the Na-K-2Cl transporter (NKCC2) regulates the signaling pathways linked to renin secretion.[205,206] Increased chloride delivery to the MD inhibits, whereas reduced chloride delivery stimulates, renin release.[23,197,207]

In addition to the well-studied NKCC2 transporter, the Na^+/H^+ exchanger isoform 2 (NHE2) expressed on the apical surface of the macula densa also plays a role in renin release, perhaps through its effect on macula densa cell volume. A recent study by Peti-Peterdi and colleagues demonstrated that NHE2-deficient mice have significant mechanisms responsible for increased renin levels which are macula-densa specific,[208] since these mice have been characterized to have normal blood pressure.[209]

Several candidate signaling pathways linking distal tubule solute concentration to control of renin have been proposed. These include adenosine, nitric oxide, and prostanoids.[210] The most compelling current evidence suggests that MD stimulation of renin involves activation of cyclo-oxygenase (COX)-2[211] constitutively expressed at high levels in the macula densa, generating the prostanoid PGE_2.[212,213] PGE_2 then activates an EP receptor on granular cells in the JGA to stimulate renin release.[214] The EP4 receptor is likely the major EP receptor that mediates the actions of PGE2 in this process. Facemire et al. demonstrated that EP4 receptor-deficient mice display a ~70% reduction in renal renin expression and plasma renin concentration compared to wild-type mice after treatment with furosemide.[215] In contrast, deletion of EP2 receptors in the mice has no effect on renin stimulation by furosemide. Interestingly, this study also suggested that the source of PGE2 in this pathway is not dependent on microsomal PGE synthases 1 and 2 (mPGES1, mPGES2). The capacity for prostaglandins to directly stimulate renin secretion has been long recognized.[216,217] Moreover, studies using specific inhibitors and COX-2 deficient mice have clearly demonstrated the importance of COX-2 in the macula densa pathway.[218,219] In addition, the activity of various components of this system has been demonstrated in the isolated perfused macula densa segments[220] and JG cell lines.[221] However, at least one study[195] has failed to confirm a non-redundant role for individual EP receptors for PGE_2 in furosemide-stimulated renin release *in vivo*.

Initial evidence suggesting a role for adenosine in MD signaling came from studies using the selective A1AR antagonist 8-cyclopentyl-1,3-dipropylxanthine. The major effect of the inhibitor was to attenuate the actions of increasing luminal NaCl concentrations to inhibit renin release.[222] Later studies using A1AR-deficient mice confirmed that the role of adenosine is primarily restricted to the arm mediating inhibition of renin release. In A1AR-deficient mice, renin-inhibitory actions of enhanced sodium chloride delivery to the macula densa are blocked, whereas stimulation of renin secretion caused by reduced sodium chloride transport at the macula densa is unaffected.[223]

Macula densa cells express high levels of neuronal nitric oxide synthase (nNOS).[224,225] The role of NO in regulation of renin was first tested using nonselective inhibitors of nitric oxide synthesis, which attenuated renin release stimulated by reduced luminal sodium chloride concentrations.[226,227] The specific roles of the individual NOS isoforms have been examined using mice with targeted deletion of nNOS or eNOS. In these studies, activation of the macula densa pathway was achieved by administration of NKCC2 blocking loop diuretics *in vivo* and in isolated perfused mouse kidneys. Deficiency of either nNOS or eNOS alone did not significantly affect macula densa-dependent renin secretion,[228] while nonspecific NOS blockade attenuated renin stimulation by loop diuretics. This suggests that nitric oxide plays a permissive, rather than a

primary, role in the macula densa control of renin release.[228]

Short Loop Feedback: Regulation of Renin by Angiotensin II

Angiotensin II also contributes to the regulatory pathways for renin and may control its own synthesis by activating AT_1 receptors, highly expressed at the JGA, thereby suppressing renin release.[229,230] Evidence supporting the existence of this so-called short-loop feedback mechanism includes studies in the isolated perfused kidney, where infusion of angiotensin II suppresses renin release.[179] Administration of ACE inhibitors and angiotensin receptor blockers increases renin mRNA expression and causes JGA hypertrophy.[231] Similarly, mice lacking AT_{1A} receptors also develop marked JGA hypertrophy.[103,230] However, in *Agtr1a*$^{-/-}$ chimeric mice,[103] and in kidney cross-transplantation experiments,[232] JGA hypertrophy correlated with blood pressure, but not with the absence of AT_1 receptors at the JGA, indicating a significant role for baroreceptor mechanisms in this response. Nonetheless, a role for the short-loop feedback mechanism to alter the sensitivity of baroreceptor or MD mechanisms would be consistent with current data.

Role of Sympathetic Nerve Activity

The capacity for sympathetic nerve activation to stimulate renin has been long recognized. For example, β-adrenoceptors are abundant in the JGA of kidneys from various species.[233] Furthermore, numerous studies have demonstrated that β-adrenergic agonists stimulate renin release.[234] Chronic renal nerve activation also stimulates renin,[235,236] along with its affects to modulate renal blood flow and tubular function. In experiments controlling for these factors, a clear relationship between increasing renal sympathetic nerve activity and renin secretion is maintained.[237,238] However, as discussed above, renal denervation does not abolish the capacity of the baroreceptor[181,239] or macula densa mechanisms to stimulate renin.[182–184] Accordingly, it appears likely that β-sympathetic tone has a modulatory, rather than primary, role in regulation of renin. Recently, a randomized controlled clinical trial demonstrated that renal sympathetic denervation is more effective than medical management alone in patients with resistant hypertension.[240] The original report did not mention any measurement of renin, but it will be of significant interest to determine the effect of the procedure on plasma renin levels in patients who did or did not have a significant reduction in blood pressure.

Regulation of Cellular Release of Renin

At the JGA, renin is stored in cytoplasmic granules within granular cells. In response to activating stimuli, renin is released into the circulation by exocytosis. This process of renin secretion is carried out by fusion events between the secretory granules and cell membrane of afferent arterioles.[241] Furthermore, the extent of secretory activity or exocytosis can be assessed using electrophysiological techniques that directly measure cell membrane capacitance of single mouse JG cells.[242] The control mechanisms for renin, described above, act by triggering this exocytotic pathway. Compared to the relative wealth of available information about physiological regulation of renin, much less is known about the precise intracellular pathways involved in renin secretion, and how these mechanisms are controlled in the granular cell. The general consensus is that the environmental signals regulating renin act through a limited number of intracellular second messengers, including calcium and cyclic AMP.[214,243]

The cyclic AMP pathway appears to be the major trigger for cellular release of renin. In a variety of experimental models, maneuvers causing an elevation of intracellular concentrations of cyclic AMP cause rapid stimulation of renin secretion.[243,244] In this regard, most of the documented secretagogues for renin, including PGE_2, PGI_2, dopamine, and β-adrenoreceptor, act via 7 transmembrane receptors linked to G_s-proteins that increase cyclic AMP levels in JG cells.[244] The specific biochemical pathways by which cyclic AMP acts to stimulate renin secretion are unclear, but likely involve protein kinase A, since inhibition of protein kinase A attenuates the stimulatory effect of β-adrenoreceptors on renin secretion.[190]

By contrast, increases in intracellular calcium levels may inhibit renin release. For example, experimental maneuvers that reduce intracellular calcium concentration stimulate renin release.[243] Moreover, several mediators with putative actions to inhibit renin release, such as angiotensin II, α-receptor agonists, vasopressin, and endothelins, have receptors that couple to G_q-proteins, and activation of these receptors by ligand increases intracellular calcium concentrations in JG cells.[214,243] The inhibitory effect of calcium on renin release appears to be mediated by protein kinase C, since stimulation of protein kinase C inhibits renin secretion,[245–247] whereas blockade of protein kinase C attenuates the inhibitory effect on renin secretion.[245–247] There is also evidence that the effects of calcium on renin release are mediated in part by a calmodulin-dependent process, since inhibition of calmodulin activity stimulates renin secretion.[248,249] Antagonistic interactions between the cyclic AMP and intracellular

calcium may ultimately determine the final consequences of extracellular signals on renin release.[243,250]

Regulation of Renin Gene Expression

The steady-state activity of the RAS is generally reflected by renin mRNA levels in the kidney. During chronic stimulation of the RAS, for example, upregulation of renin gene expression is required to sustain over time the enhanced release of renin protein by the JGA. Understanding of tissue-specific control of renin gene expression has been complicated by the difficulty of developing tractable cell culture preparations derived from JG cells. Thus, transgenic mice have been used extensively to assess *in vivo* regulation of renin gene expression.[251,252] Using this approach, minimal segments of the human renin gene sufficient to recapitulate temporal- and cell-specific patterns of gene expression have been identified.[251,252]

There is strong sequence conservation of 5′ proximal promoter regions between the renin genes of the human, rat, and mouse.[253] This region contains a cyclic AMP (cAMP) response element (CRE),[254–256] which is required for cAMP stimulation of transcription.[254,257] In addition, there are at least seven transcription factor-binding sites within the proximal promoter, including a binding site for HOX proteins that play critical roles in specifying positional information along embryonic axes.[253] The renin promoter is relatively weak in isolation,[254,257,258] but is strengthened up to 80-fold by a distal enhancer element.[259,260] This enhancer contains at least eleven transcription factor-binding sites responsive to a variety of signal transduction pathways.[261] Inhibitory factors, including endothelin-1, angiotensin II, mechanical stretch, and inflammatory cytokines, may act through target sequences within the enhancer.[261]

Post-transcriptional mechanisms also play a key role in determining steady-state renin mRNA levels. cAMP appears to be a critical mediator in this process. For example, in cell systems, cAMP has only a modest effect in inducing renin gene transcription of the renin gene, but nonetheless it causes marked induction of renin mRNA levels.[262] This augmentation is associated with enhanced stability of renin mRNA.[263] cAMP also increases levels of RNA-binding proteins targeting the 3′UTR of the human renin gene,[264] suggesting a potential mechanism for its effects to promote renin mRNA stability.

Control of Renal Hemodynamics by the RAS

Angiotensin II, acting via its AT_1 receptor, is a potent vasoconstrictor. Stimulation of AT_1 receptors in vascular smooth muscle cells initiates a signaling cascade including increased intracellular calcium concentration and alterations in cytoskeleton, inducing contraction with consequent increases in vascular resistance.[265] Studies in mice deficient in both the AT_{1A} and AT_{1B} receptor isoforms have confirmed the importance of AT_1 receptors in this response.[102,100] The pressor response to acute angiotensin II infusion is completely abolished in these double-knockout animals[100]; whereas response to another pressor agent, epinephrine, is not affected. These vasoconstrictor actions of angiotensin II play a central role in maintaining circulatory homeostasis in a number of tissues, including the kidney. In the kidney, the hemodynamic actions of angiotensin II impact renal blood flow, glomerular filtration rate, excretion of salt and water, and progression of renal damage in disease states.

Glomerular Microcirculation

The coordinated regulation of resistances in the afferent and efferent arterioles plays a critical role in determining and maintaining the glomerular filtration rate (GFR). The RAS has potent effects on glomerular hemodynamics. Angiotensin II causes constriction of both the afferent and efferent arterioles. However, the effect of high levels of angiotensin II is to induce a more profound constriction of the efferent arteriole.[266–268] The reasons for this disproportionate effect of angiotensin II on the efferent arteriole are not clear, but may include differences in levels of AT_1 receptor expression,[269] modulating actions of vasodilators such as prostaglandins and nitric oxide on preglomerular vessels[270,271] or differences in calcium responses to angiotensin II in the afferent versus efferent arterioles.[272–274] In mice, the AT_{1A} and AT_{1B} receptor isoforms have distinct actions in the glomerular circulation. Both AT_{1A} and AT_{1B} receptors contribute to the afferent arteriolar response to angiotensin II, whereas the efferent arteriolar response is mediated exclusively by AT_{1A} receptors.[275]

The overall effect of angiotensin II on glomerular hemodyamics is a predominant increase in post-glomerular resistance, resulting in an increase in glomerular hydrostatic pressure. These actions serve to protect GFR in states of intravascular volume depletion. Because angiotensin II also simultaneously reduces renal blood flow, there will be a coincident increase in filtration fraction, and a decrease in peritubular capillary pressure[276] promoting an increase in sodium reabsorption in the proximal tubule.[277,278] The importance of angiotensin II in maintaining GFR when renal perfusion is threatened is illustrated by the effect of ACE inhibitors in patients with critical bilateral renal artery stenosis or critical stenosis in the renal artery of a single functioning kidney. When blood pressures in such patients are reduced to equivalent levels with

a non-specific vasodilator, such as nitroprusside, compared to an ACE inhibitor, the ACE inhibitor causes a much more marked deterioration in GFR.[279,280]

The glomerular hemodynamic responses to angiotensin II may be modified significantly by other circulating factors. For example, the vasoconstrictor actions of angiotensin II may be substantially augmented in the presence of elevated adenosine levels.[281–285] This can occur in pathologic states including malignant hypertension, renal artery stenosis, and in some experimental models of renal ischemia.[286–288] When both angiotensin II and adenosine are present at high concentrations, there is a dramatic increase in preglomerular resistance that does not occur with either agent alone. Other mediators, such as prostanoids[289] and nitric oxide, may also modulate the actions of angiotensin II in the glomerular microcirculation, particularly in disease states such as diabetes.[290] In angiotensin II-induced hypertension, for example, nitric oxide attenuates afferent arteriolar constriction.[291]

In kidney disease, abnormal activation of the RAS and coincident increases in glomerular hydrostatic pressure have been suggested to contribute to progressive renal injury.[292,293] For example, in the remnant kidney model of chronic kidney disease, post-glomerular resistances are increased, and this is associated with increased glomerular hydrostatic pressures.[294,295] This abnormal glomerular hemodynamic pattern is reversed with RAS blockade. These observations formed the basis of the rationale for using ACE inhibitors or angiotensin receptor blockers in chronic kidney diseases. Reduction of glomerular hemodynamic pressure may be a key mechanism explaining the renoprotective effects of these agents in diseases such as diabetic nephropathy.[11,13,14]

Renal Medullary Circulation

Along with its effects on the glomerular circulation angiotensin II, acting through AT_1 receptors, has important regulatory functions in the renal circulation in general. In the mouse, regulation of renal blood flow by angiotensin II is primarily mediated by AT_{1A} receptors.[296] Moreover, effects of AT_1 receptors to modulate blood flow in the medulla significantly impact the kidney's excretory capacity for sodium.[297] In this regard, it has been suggested that regulation of medullary blood flow by angiotensin II represents a critical pathway for modulating the pressure-natriuresis response discussed earlier in the chapter.[161,276] Thus, regulation of medullary blood flow by the RAS is likely to be a key pathway used by the kidney to maintain blood pressure homeostasis.

The mechanisms controlling medullary blood flow in the kidney are complex. As in the glomerulus, vasodilator effects of mediators such as nitric oxide and prostanoids act to counterbalance the actions of angiotensin II. For example, a subpressor dose of angiotensin II, which by itself has a negligible effect on the medullary circulation, significantly reduces medullary blood flow when combined with the NO inhibitor L-NAME.[298] Cortical blood flow is unaffected in this circumstance. Nitric oxide also protects medullary blood flow during chronic infusion of angiotensin II.[299] In the outer medulla, angiotensin II stimulates NO production by tubular epithelium, potentially as a compensatory mechanism, and this may be an example of "tubulo-vascular cross-talk," whereby the effects of angiotensin II on tubular epithelium may modify its vasoconstrictor actions.[300] Similarly, renal prostaglandins also appear to modulate pressure natriuresis by altering renal medullary hemodynamics.[301] These hemodynamic changes from the inhibition of prostaglandin production lead to increased chloride reabsorption in the loop of Henle and collecting duct.[302,303]

Alterations in the balance of angiotensin II and NO in the medulla may have significant consequences on systemic blood pressure regulation. For example, angiotensin II-stimulated NO production is impaired in Dahl-sensitive hypertensive rats,[263,304,305] and attenuated generation of NO in kidneys of these animals is associated with reduced medullary blood flow.[306,307] Furthermore, delivery of L-NAME directly into the renal medulla of Dahl salt-sensitive rats reverses the hypertensive actions of angiotensin II,[305] as does intravenous infusion of L-arginine.[308]

RENAL EPITHELIAL ACTIONS OF THE RAS

Along with its hemodynamic actions, angiotensin II may modulate fluid and solute excretion through two distinct pathways: (1) an indirect pathway involving stimulation of aldosterone release from the adrenal gland; and (2) through direct effects of AT_1 receptors expressed by renal epithelia.[162]

In the adrenal cortex, activation of AT_1 receptors stimulates the release of aldosterone[119] which in turn promotes sodium reabsorption by binding to mineralocorticoid receptors in the mineralocorticoid-responsive segments of the distal nephron.[125] The biology of the aldosterone system is described elsewhere, and historically was thought to be the major effector system used by the RAS to control renal sodium handling.[123] Direct actions of angiotensin II in the kidney were defined later using isolated perfused tubules[309–314] and micropuncture studies.[315–318] Using these approaches, renal epithelial responses to angiotensin II were documented in several nephron segments. However, it has been

difficult, in the intact animal, to separate the effects of AT_1 receptors in renal epithelium from other renal and systemic effects of angiotenson II, and to determine their contribution to integrated control of blood pressure. Nonetheless, recent studies using renal cross-transplantation and regional genetic deletion clearly indicate significant, non-redundant contributions of AT_1 receptors within the kidney to determining the level of blood pressure.[232,319] Activation of AT_1 receptors in the nephron can have physiologic or pathophysiologic effects depending on the clinical context. For example, stimulation of AT_1 receptors in the proximal tubules helps to prevent circulatory collapse at baseline by promoting sodium retention,[319] whereas the accumulated stimulation of AT_1 receptors on tubular cells that occurs over the span of a normal lifetime downregulates pro-survival genes including sirtuin 3, such that AT_1 receptor deficiency is associated with enhanced longevity in mice.[320] In the next section, we will provide an overview of tubular actions of the RAS.

Tubular Effects of Angiotensin II

Proximal Tubule

Direct actions of angiotensin II in the proximal tubule are perhaps the best characterized. These actions were first implied in whole animal studies,[321–323] and then were specifically defined using *in vitro* perfused proximal tubules[313] and micropuncture studies.[317] Taken together, these studies suggest that angiotensin II, acting through AT_1 receptors on the basolateral surface of proximal tubules, promotes sodium reabsorption by coordinately stimulating the sodium-proton anti-porter on the luminal membrane along with the sodium-potassium-ATPase on the basolateral surface.[310,313,317] These actions result in enhanced basolateral sodium bicarbonate flux.[310] In addition, although angiotensin II is thought to regulate renal water handling primarily through actions in the collecting tubule (discussed below), data are emerging to suggest that AT_1 receptor activation also modulates proximal tubular expression of the aquaporin 1 channel, heretofore considered to be constitutively expressed.[324]

The capacity for proximal tubular actions of the RAS to influence blood pressure was first demonstrated in elegant experiments by Sigmund and associates.[325] In these studies, isolated co-expression of human renin and angiotensinogen in the proximal tubule caused hypertension without any detectable increase in circulating angiotensin II levels. In more recent work from this group, overexpression of the type AT_1 receptor in the proximal tubule raised baseline blood pressure levels.[326] Inversely, Gurley and colleagues showed that deletion of AT_1 receptors selectively from the proximal tubular epithelium using a Cre/loxp approach reduces the baseline level of blood pressure by diminishing fluid reabsorption from the proximal tubule, and protects from angiotensin II-induced hypertension by mitigating sodium reabsorption.[319] These studies also illustrated that angiotensin II regulates the abundance of key apical membrane sodium transporters, as AT_1 receptor deletion in the proximal tubule allowed the downregulation of the NHE3 exchanger and the NaPi2 co-transporter, thereby facilitating hypertension-induced natriuresis.[319] Complementary studies in a rat model demonstrated that angotensin II directs these transporters to redistribute within the luminal membrane microvilli of the proximal tubular cell to promote sodium and water reabsorption.[327]

AT_1 receptors are also present on the luminal brush border of the proximal tubular epithelium.[328–330] Moreover, angiotensin II is secreted into, and endocytosed from, the proximal tubular lumen where its levels may not correlate with plasma angiotensin II levels.[331–333] It has been suggested that control of angiotensin II generation in this luminal compartment might provide separate regulation of epithelial function that is independent of the systemic RAS.[334] Moreover, activation of AT_1 receptors on the luminal membrane of the proximal tubular cell can promote sodium reabsorption, in part through a G_i-protein-mediated reduction in cyclic AMP.[313,317,333] There is some evidence for an independent regulation of luminal concentrations of angiotensin II. For example, although both whole kidney and proximal tubular angiotensin II levels are elevated in response to reduced renal perfusion,[335] angiotensin II levels in proximal tubular fluid are not suppressed with acute volume expansion, and may even increase in this setting.[335,336]

The net effect of angiotensin II on bicarbonate handling in the proximal tubule appears to be neutral. Coordinating with its stimulation of the apical membrane sodium-proton exchanger, angiotensin II enhances the activity of the sodium-bicarbonate co-transporter on the basolateral surface of the early proximal tubule.[310,313] As such, angiotensin II acts as a potent stimulus for proximal acidification, coupled to reclamation of bicarbonate from the early proximal tubule.[310,337,338] Nevertheless, the resulting reduction in delivery of bicarbonate to the late proximal tubule leads to less bicarbonate reabsorption in that segment. Moreover, at higher concentrations, angiotensin II paradoxically inhibits sodium-bicarbonate transporter activity,[339] such that overall the bicarbonate concentration in the urinary filtrate reaching the distal convoluted tubule is not altered by angiotensin II stimulation.[340] Thus, the contribution of the RAS to acid–base regulation is primarily mediated by aldosterone in the distal nephron.[341–345]

Loop of Henle

Compared to the proximal tubule, the functions of angiotensin II in the medullary thick ascending limb (MTAL) are not as well-characterized. AT_1 receptors are expressed on both the luminal and basolateral membranes of the MTAL epithelium.[346,347] *In vitro* studies addressing the role of angiotensin II in MTAL ion transport suggest that cellular responses may differ, depending on the local concentrations of angiotensin II.[348,349] At lower concentrations of angiotensin II, inhibition of the sodium-potassium-chloride co-transporter (NKCC2) may be seen,[348,349] whereas stimulation of NKCC2 can be seen at higher concentrations.[348] *In vivo* microperfusion experiments have also demonstrated physiological consequences of angiotensin II in the MTAL, including increased bicarbonate transport out of the urinary filtrate.[350] This heightened bicarbonate flux is likely due to an increase in sodium–hydrogen exchange, as has been observed in the proximal tubule, suggesting that angiotensin II increases sodium reabsorption from the MTAL. These data are consistent with the finding that *in vivo* administration of angiotensin II leads to heightened expression of both the NHE3 sodium-hydrogen exchanger and NKCC2 in the MTAL.[351]

Distal Nephron

SOLUTE TRANSPORT

Although angiotensin II indirectly influences distal and collecting tubular function through the generation of aldosterone, more recent studies have demonstrated that angiotensin II also has direct effects in modulating ion flux along the distal nephron. As in other nephron segments, all the elements of the RAS are present along the distal nephron, and relatively high concentrations of angiotensin II can be detected in the tubular fluid of these segments.[171,330,332] Angiotensin II, acting via AT_1 receptors, stimulates sodium–hydrogen exchange in the cortical and outer medullary collecting tubule by increasing the density of the vacuolar sodium-hydrogen-ATPase in the apical membrane of the type A intercalated cell, which in turn leads to an increase in bicarbonate reabsorption.[315,316,352,353] On the apical membrane of the principal cells in the cortical collecting duct (CCD), luminal angiotensin II stimulates amiloride-sensitive sodium transport by increasing activity of the epithelial sodium channel (ENaC) through an AT_1 receptor-dependent mechanism.[312,318] Furthermore, activation of AT_1 receptors on the basolateral membrane of CCD cells stimulates the activity of potassium channels via a nitric oxide-dependent pathway.[354] As the distal nephron ultimately determines urine flow and composition, actions of angiotensin II to modulate sodium handling at this site may impact blood pressure homeostasis.[164,312]

WATER HANDLING

Recent studies suggest a role for the RAS in the control of urinary concentrating mechanisms and free water handling. For example, the complete absence of angiotensinogen, ACE or AT_{1A}/AT_{1B} receptors in mice is associated with atrophy of the renal papilla and a marked urinary concentrating defect.[230,355,356] Mice lacking AT_{1A} receptors are also unable to generate maximally concentrated urine, despite having apparently normal renal papillae.[357] These animals generate vasopressin normally in response to water restriction, but are resistant to dDAVP.[357] Administration of an AT_1 receptor-antagonist to wild-type mice, and even selective deletion of AT_1 receptors from the collecting duct using a Cre/loxp approach, recapitulates this urinary concentrating defect.[357,358] Similarly, AT_1 receptor blockade also blunts the maximal urine concentrating capacity in DDAVP-challenged rats, and this effect is associated with reduced expression of aquaporins-1 and -2.[359] In the medullary collecting duct, angiotensin II upregulates gene expression for the V_2 vasopressin receptor, and the expression and apical membrane targeting of the aquaporin-2 channel.[360–363] These effects are mediated through a protein kinase A-dependent pathway.[360] Thus, direct effects of angiotensin II on expression of water channels and perhaps vasopressin receptors may contribute to its actions on renal water handling.

RENAL SYMPATHETIC NERVES

Introduction

One of the first observations of a potential neural control of kidney function was made by Claude Bernard in the middle of the 19th century, who reported a unilateral diuresis following section of the greater splanchnic nerve of the anesthetized dog.[17] However, the critical role of the sympathetic nervous system in the control of renal function was long questioned due to the views of Homer Smith,[244] who regarded the renal innervation to be of little importance in determining the function of the kidney. It was not until the 1960s that the innervation of the kidney and its regulation of renal function came under detailed scrutiny. Over the following three-to-four decades a wealth of information has been generated and concepts developed which have provided the foundation for how the renal sympathetic nerves regulate all aspects of vascular, tubular, and secretory functions of the kidney, both normally and in pathophysiological states of cardiovascular diseases. A number of major reviews have brought together the most significant pieces of information about the renal sympathetic nerves over this period.[51,52,58,189] This knowledge is now being translated into therapeutic approaches in man, particularly in relation to hypertension, heart failure, and renal disease.[53,234] The recent reports by Esler and co-workers[76,172,173,234] that bilateral renal denervation in patients with resistant hypertension resulted in a profound and sustained (≥2 years) reduction in blood pressure reinforces the important contribution of the autonomic control of the kidney in determining cardiovascular homeostasis and how it may be involved in pathophysiological states. These findings are set to reinforce the drive to gain knowledge of both the efferent and afferent innervations of the kidney, and to stimulate the development of further therapeutic avenues to modulate the neural control of the kidney.

NEUROANATOMY, PHARMACOLOGY, AND PHYSIOLOGY

Extrinsic Innervation

The efferent innervation of the kidney comprises pre-ganglionic fibers which arise from spinal segments T_{11}–L_3, and traverse to both pre-vertebral (thoraco-lumbar sympathetic chain) and para-vertebral ganglia (aortico-renal, splanchnic, coeliac, superior mesenteric ganglia) which give rise to the post-ganglionic fibers. There is great species variation in the overall contribution from the various ganglia, for example, with 80% arising from the ipsilateral para-vertebral ganglia (T_{11}–L_2) in the rat and hamster, but only 50% for the cat and monkey (T_{11}–L_3).[58] Figure 16.1 gives a brief outline of these different neural pathways. Tracer studies with horseradish peroxidase and herpes virus have been used to demonstrate the neural pathways for the sympathetic innervation. The pre-ganglionic sympathetic nerve fibers in the rat are primarily located in the intermediolateral column of the spinal cord, from T_9–T_{13}, suggesting that they descend three to four segments before exiting the spinal column at T_{11}–L_3. A number of nuclei within the central nervous system project to these intermediolateral areas of the spinal cord, including the raphe nuclei, rostral

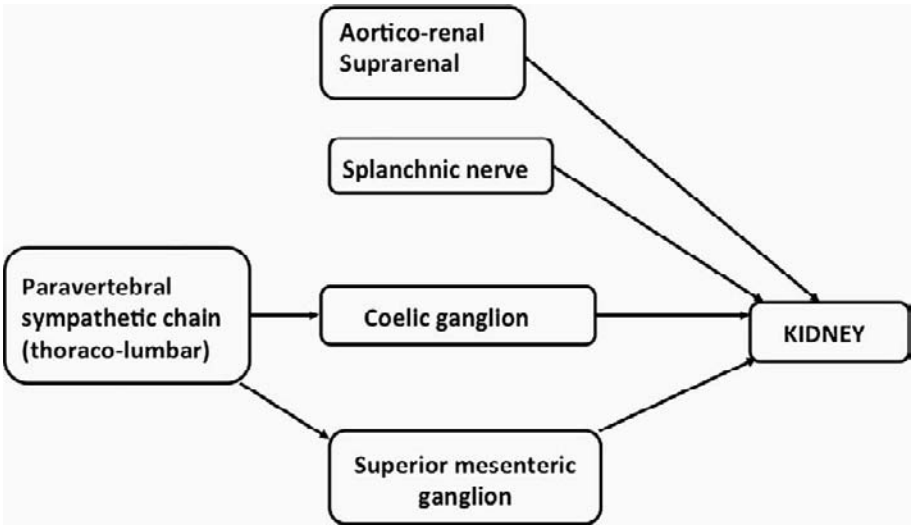

FIGURE 16.1 **This shows the main ganglia providing the sympathetic post-ganglionic fibers which innervate the kidney.**

venterolateral medulla, an A5 group, and the paraventricular hypothalamic nucleus.[42] Together, there is a view that descending projections from the supra-spinal systems are the primary regulators of sympathetic outflow to the kidney.

There has been a continuing evaluation of the size and type of nerves forming the efferent innervation of the kidney. Analyses performed in the rabbit utilizing electron microscopy have demonstrated two types of nerve fibers with different diameters in the renal cortex,[49,183] suggesting that different functionalities may exist within these different nerve populations. Detailed counts of fiber number and diameter in the rat[67,233] have found that the majority of the fibers are unmyelinated (96%) with the remainder being myelinated. The average diameter of the unmyelinated fibers was approximately 1.3 μm, and while DiBona and colleagues[67] reported a bimodal distribution, this was not observed in the report of Sato and co-workers.[233] More recently, Fazan and colleagues[81] investigated the situation in the mouse and found that, although the nerve fibers had a similar mean diameter, 0.76 ± 0.02 μm, compared to the rat, the distribution was clearly unimodal. Together, these observations provide no consistent support for the argument that different nerve fibers are directed towards the innervation of specific cell types (vascular, epithelial or granular) in order to control selected functions.

Intrinsic Innervation

The sympathetic nerves generally traverse from the ganglia, running alongside the renal artery, and enter the hilus of the kidney where they begin to divide, with smaller nerve bundles approximately following the major divisions of the blood vessels. The sympathetic nerves begin to divide into smaller bundles which penetrate and form a network throughout the cortical and juxta-medullary areas. Early studies by Barajas and co-workers[9,10] demonstrated discrete neuro-effector junctions present at the afferent and efferent arterioles, the granular cells of the juxtaglomerular apparatus, the proximal and distal tubules, and the thick limb of the ascending limb of the loop of Henle. This group of investigators, utilizing electron microscopy, went on to show that the sympathetic nerves were typical autonomic fibers having varacosities associated with the neuro-effector junctions that contained dense cored vesicles. Using a tritiated noradrenaline radiographic approach they[9,10] clearly showed the presence of noradrenaline, and although there was a suggestion that acetylcholine esterase was present, there was no indication that the fibers were cholinergic. Later, more detailed studies indicated that there was a variation in the number of neuro-effector junctions along the nephron, with the greatest number being at the proximal tubule, fewer at the thick ascending limb of the loop of Henle, and the smallest number at the distal tubules and collecting duct.[58] Interestingly, when calculated as the density of neuro-effector junctions per unit length, the density was found to be greatest in the thick ascending limb of the loop of Henle and progressively less in the distal and proximal tubules.[9,10] There is also a regional variation, with the innervation being greatest along the cortico-medullary border and becoming less in the outer cortex and deeper regions of the medulla. This regional variation in innervation density is paralleled in both the vascular and tubular structures. Figure 16.2 illustrates the cell types where neuro-effector junctions have been described and the functions they may regulate.

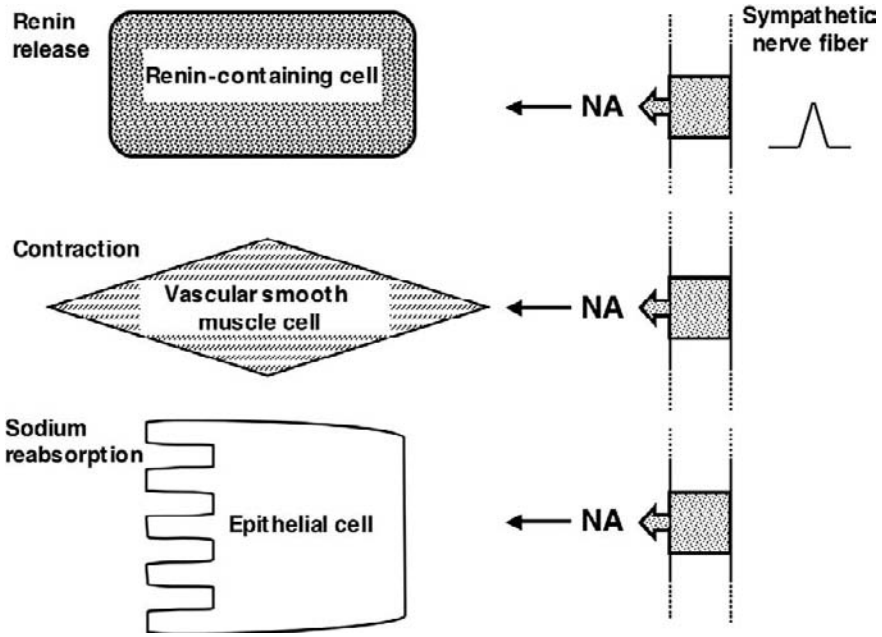

FIGURE 16.2 **Neuro-effector junctions are formed at the renin-containing cells, the vascular smooth muscle cells (interlobular arteries, afferent, and efferent arterioles) and the epithelial cells of the proximal tubule, thick ascending limb of the loop of Henle, and the distal tubule.** Noradrenaline (NA) is contained in granules within varicosities which are exocytosed following passage of an action potential.

Pharmacology

Neurotransmitters

A large body of evidence from biochemical and pharmacological studies indicates that the primary neurotransmitter arising from the sympathetic innervation is noradrenaline. Functional studies have shown that renal denervation, in the initial stages, is associated with a marked decrease in noradrenaline content of some 95%,[58] while activation of the renal sympathetic nerves results in an elevation in noradrenaline production or spillover into the renal venous blood.[75,76] The role of dopamine and potential dopaminergic nerve-mediated influences remains unclear, as all adrenergic nerve varicosities contain dopamine as an intermediary in noradrenaline biosynthesis, but there is little evidence that dopamine acts as a neurotransmitter[58] in the neural regulation of either renal hemodynamic function, renin release or fluid reabsorption.

Adrenoceptors

Multiple types of adrenoceptors are present within the kidney mediating the actions of noradrenaline released from the nerve varicosities, and a range of α_1- and α_2-adrenoceptors subtypes exist along the renal vasculature and nephrons. At a functional level, stimulation of the α-adrenoceptors causes a vasoconstriction of vascular smooth muscle and reabsorption of fluid at tubular epithelial cells. Stimulation of β-adrenoceptors increases renin release at the juxtaglomerular granular cells. A number of molecular biological and cloning investigations have defined α_1-adrenoceptors into α_{1A}-, α_{1B}-, and α_{1D}-subtypes, α_2-adrenoceptors into α_{2A}-, α_{2B}-, and α_{2C}-subtypes, and β-adrenoceptors as β_1-, β_2-, and β_3-subtypes, all of which are G-protein coupled receptors comprising a superfamily of membrane proteins that signal the actions of adrenaline and noradrenaline.[251] The α_1-adrenoceptors utilize a range of signaling pathways including activation of phospholipases A and C, mobilization of intracellular calcium stores, as well as opening of voltage-dependent and independent calcium channels[225] which results in a rapid vascular smooth muscle contraction. Interestingly, noradrenaline binding to α_1-adrenoceptors also activates the MAP kinase pathways which, in the longer term, are responsible for regulating growth and hypertrophy of the vascular smooth muscle.[263] There are reports that α_{1A}- and α_{1B}-adrenoceptors are present to a similar degree in the cortex and outer stripe of the medulla, while in the inner stripe of the medulla the α_{1B}-adrenoceptor subtype appears to predominate.[83] However, in terms of hemodynamic functionality, α_{1A}-adrenoceptors are more effective than the α_{1B}-adrenoceptor subtypes in causing renal vasoconstriction.

α-Adrenoceptors are also present on the epithelial cells of the nephron, where they modulate fluid reabsorption. There is evidence, at least in the proximal tubule, that α_1-adrenoceptor stimulation engages both the phospholipase C and MAP kinase[264] pathways, but these signal to different end-points, that is to the sodium/hydrogen exchanger, isoforms-1 (NHE1) and isoform-3 (NHE3), respectively.[179] At the more distal sections of the nephron, the distal tubule and collecting duct, α_2-adrenoceptors are the primary subtype, and in this segment their activation results in a decrease in cAMP which blunts the action of other factors signaling through this pathway. A key example is AVP,[223] which stimulates both water reabsorption

and ENaC insertion in this region where these actions are blunted by α_2-adrenoceptor agonists.[8] β_1-adrenoceptors are found primarily on the granular renin-containing cells of the afferent arteriole, and their activation stimulates adenylyl cyclase which increases intracellular levels of cAMP. The β_2-adrenoceptors found on the tubules, primarily collecting duct, also utilize cAMP production as the signaling molecule, but their function at this site has not been resolved.

PHYSIOLOGY

Activation of the various signaling pathways via ligand binding to the adrenoceptors increases fluid reabsorption at the level of the proximal tubule. In the proximal tubule, the catecholamines stimulate Na/K-ATPase at the basolateral membrane,[4] resulting in increased sodium reabsorption from the tubular lumen across the apical membrane. There is evidence from micropuncture studies,[212] as well as *in vitro* studies,[180] that the sodium−hydrogen exchanger is activated, particularly isoform 3 (NHE3), the isoform primarily responsible for the regulation of sodium entry into the epithelial cells at the proximal tubule.[179,180] The NHE3 protein in the proximal tubule appears to be present in the microvillae, either incorporated into the plasma membrane[273] where it is likely to be active or internally in the subapical vesicles, where it is considered to be inactive in terms of a transporting protein. The mechanisms involved in the translocation of the NHE3 from the plasma membrane into the subapical vesicles are complex[197] and require the interaction of a number of proteins (NHERF1, myosin VI, ezrin, raft, non-raft, and myosin). McDonough[197] has recently reviewed the evidence showing that when blood pressure is elevated acutely[273] or when the sympathetic nervous system is reflexly activated there is increased movement of NHE3 into the subapical compartment where the transporter is inactive. McDonough and co-workers have put forward the concept that translocation of the NHE3 into the subapical regions is a key element whereby sodium reabsorption may be regulated by catecholamines, both in the short-term as well as over a longer timeframe, thereby contributing to cardiovascular homeostasis.[197,198]

Autocrine and Paracrine Influences on Neurotransmission

The interstitium of the kidney contains a complex milieu of hormones and factors which may vary across the cortex and medulla, but can determine the level of functions of all cell types, vascular smooth muscle, renin containing, and epithelial cells. There are modulator influences at the neuro-effector junction which can come into play and influence the amount of noradrenaline released in response to depolarization caused by the passage of an action potential. An outline of potential interactions with various agents is illustrated in Figure 16.3.

Adrenoceptors

At an early stage it was recognized that pre-synaptic α_2-adrenoceptors were able to act in an auto-inhibitory fashion, whereby when activated by noradenaline released into the neuro-effector junction, they decreased neurotransmitter release caused by subsequent depolarizations. There is evidence that this situation pertains at the kidney. α_2-adrenoceptors are present in the kidney,[18,19] and their blockade enhances noradrenaline release and renal nerve induced vasoconstriction in the dog.[113] In the rabbit[109] blockade of α_2-adrenoceptors peripherally has little effect on renal nerve-induced vasoconstrictions, but potentiates the renal nerve-mediated antidiuresis and antinatriuresis.

Angiotensin II

A second important neuro-modulator is angiotensin II, which is present in the renal interstitium at high levels in conditions of increased endogenous angiotensin II production.[122,211,243] Activation of pre-synaptic AT-1 receptors facilitates the release of noradrenaline. This was first reported by Boke and Malik[21] using the isolated perfused rat kidney. They found that renal nerve-induced catacholamine release into the renal vein was facilitated when angiotensin II was added to the perfusate. At a functional level, studies in the anaesthetized rat using both direct and reflex activation of the renal nerves, at levels which had little or no effect on renal hemodynamics, caused decreases in fluid excretion which were blocked in the presence of an angiotensin-converting enzyme inhibitor,[102] and restored following administration of exogenous angiotensin II.[129] Similar observations were reported by Veelken and colleagues[258] in the conscious rat, where administration of the AT1-receptor antagonist ZD 7155 blunted the renal nerve-dependent antidiuresis and antinatriuresis in response to an air-jet stress test. Together, these findings support the view that at both renal vascular and epithelial cell neuro-effector junctions occupation of pre-synaptic AT1 receptors enhances neurotransmission. It would seem that these receptors are fully occupied, even at low endogenous levels of angiotensin II[256,258] and under normal conditions the facilitation is maximal but when production is prevented, then neurotransmission will be blunted. There may be other interactions at the post-synaptic membranes of the epithelial cells. Quan and colleagues[228,229] demonstrated that the ability of angiotensin II

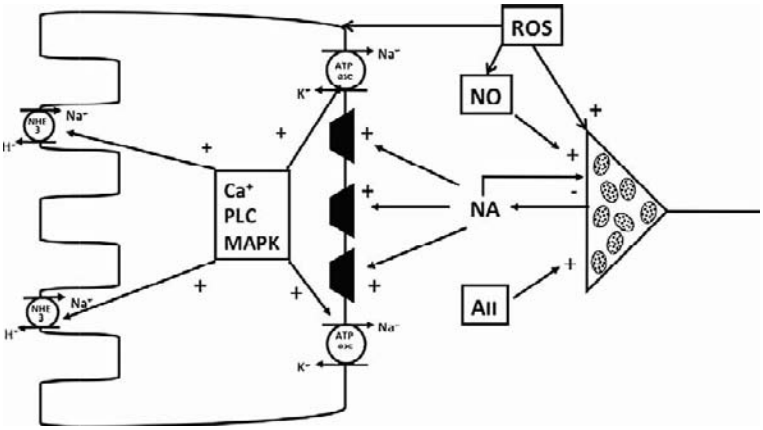

FIGURE 16.3 **Noradrenaline (NA) acts on the epithelial cells to activate phospholipase C, increases intracellular calcium (Ca^+) which initiates MAP kinase signaling pathways stimulating both the apical sodium–hydrogen exchanger isoform 3 (NHE3) and the basolateral sodium/potassium-ATPase.** Noradrenaline exerts an auto-inhibitory feedback action on further release (−) while nitric oxide (NO) and angiotensin II (AII) exert an action (+) to increase the amount of noradrenaline release on passage of each action potential. Reactive oxygen species (ROS) appear to directly facilitate noradrenaline release and indirectly to modulate the action of NO.

to stimulate proximal tubule fluid reabsorption was blunted following acute renal denervation, but augmented if the renal sympathetic nerves were stimulated at low levels not affecting filtration rate. A comparable interaction was reported by Abdulla and co-workers,[1,2] who found that the renal vasoconstriction caused by close renal arterial infusion of angiotensin II was blunted following acute renal denervation. Thus, these observations demonstrate that angiotensin II has modulatory activities at the neuro-effector junction, both pre-synaptically and post-synaptically, which determine the effectiveness of the neural control of renin release, fluid reabsorption, and vascular tone in the kidney.

Nitric Oxide

A third potentially important factor determining noradrenaline release, and hence its impact on functional end-points, is nitric oxide (NO). All isoforms of nitric oxide synthase (NOS), endothelial (eNOS), neuronal (nNOS), and inducible (iNOS) are present in the kidney. eNOS has been found along the vasculature and glomerular capillaries,[7,194] nNOS is present in the renal nerves,[156,181] at low concentrations along the tubules[24] and high concentrations in the macula densa,[7] while iNOS is expressed constitutively in the medulla.[142] It is possible that in the environment of the neuro-effector junction, NO may have both pre-synaptic and post-synaptic actions, and this probably contributes to the conflicting findings which have been reported. Thus, in the anaesthetized dog, the low level renal nerve stimulated noradrenaline output was enhanced following NOS inhibition and suppressed in the presence of an NO donor, consistent with an inhibitory pre-synaptic action.[71,188] In contrast in the rat, NOS blockade suppressed renal nerve mediated noradrenaline output and neurally induced renal vasoconstriction.[253,259] In terms of the influence of NO on renal nerve stimulated increases in sodium reabsorption, there is a lack of consistency. It is evident that NOS inhibition increases, and exogenous NO decreases, proximal tubule fluid reabsorption,[72,213] suggesting an inhibitory action of NO on reabsorptive processes. Importantly, this action of NO is only evident if the renal nerves are intact.[266] In an apparent conflict with these studies are the findings that renal nerve-induced increases in fluid reabsorption are prevented by NOS blockade, consistent with a facilitating action of NO.[268] In attempting to clarify these differing reports, it is possible that NO could act in two ways, directly within the post-synaptic cell, either vasculature or epithelial cells, where it may blunt the neurally controlled cell function, or indirectly by facilitating neurotransmitter release. The differing balances between these two sites of action may simply reflect how the NO generating systems may be activated by the various experimental conditions of the investigations.

Reactive Oxygen Species

The generation of cellular energy results in the production of reactive oxygen species which comprise radicals that can damage both nuclear and cytoplasmic proteins and phospholipids. A raised output of reactive oxygen species is recognized as a state of oxidative stress that is associated with a range of metabolic and cardiovascular diseases. Reactive oxygen species comprise superoxide anions, H_2O_2, and other reactive radicals which are able to influence both neurotransmission and the responsiveness of the target cells to the neurotransmitter. The actions of the reactive oxygen species may be either direct or indirect, as a consequence of their ability to reduce the bioavailability of NO. There are reports that systemic infusion of tempol, a synthetic diffusible superoxide dismutase mimetic which scavenges superoxide anions,[239,272] reduced blood pressure and renal sympathetic nerve activity to the same extent before and following NOS blockade. These findings would be compatible with the argument that in states of oxidative stress, for example hypertension, increased production of superoxide anions could enhance the activity of the sympathetic nervous system, and hence the level at

which it influences kidney function. The enzymes NAD(P)H and superoxide dismutase are present in both the cortex and medulla of the kidney,[133] with the level of the latter being somewhat higher in the medulla. This group[133] demonstrated that oxidative stress increased the activity of NAD(P)H, but not superoxide dismutase, in the cortex but not the medulla. This would suggest that in renal oxidative stress whereas superoxide anion generation would increase, the level of scavenging would remain unaltered, implying greater activity of the reactive oxygen species. This is important in terms of renal sympathetic nerve activity, as Shokoji et al.[239] demonstrated that direct application of tempol or DETC, a blocker of superoxide dismutase, directly onto renal sympathetic nerve fibers decreased and increased nerve traffic, respectively. These findings imply that oxidative stress in the kidney can itself alter the level of reactive oxygen species in the local environment, which may directly affect the level of renal sympathetic nerve activity and renal nerve-dependent function.

CONTROL OF THE RENAL CIRCULATION

Activation of Renal Sympathetic Nerves

The earliest studies by Cohnheim and Roy[38] using a renal plethysmograph, demonstrated that renal volume was decreased following asphyxia or when the cut ends of the renal nerves were stimulated. Indeed, these early plethysmographic studies also identified the spinal origin of the vasoconstrictor fibers. The advent of the modern flowmeters to measure renal blood flow dynamically allowed studies in anaesthetized dogs, cats, rabbits, and rats[58] which convincingly demonstrated that direct electrical stimulation of the renal nerves caused frequency related reductions in renal blood flow. Furthermore, reflex activation of the renal sympathetic nerves, either as a consequence of activation of the baroreceptor reflex by reduction in carotid sinus pressure[54,69] or activation of the somatosensory system[45,255] resulted in a renal nerve-mediated reduction in renal blood flow. Together, these reports indicate that renal nerves cause contraction of the vascular smooth muscle of the resistance vessels, thereby reducing blood flow. While the innervation of the afferent arteriole would cause a reduction in renal blood flow because it is the major resistance bed within the kidney, the impact and relative importance of a neurally induced vasoconstriction at the efferent arteriole is less clear cut in terms of its overall contribution to the reduction in renal blood flow. Luff and co-workers[49,183] were able to identify at the ultrastructural level two types of fibers in the rabbit that were differentially distributed, one type solely innervating the afferent arteriole and a second type evenly distributed to both afferent and efferent arterioles, which they argued enabled an independent regulation of the two resistance vasculatures. However, an alternative view is that because of the differing wall thicknesses and lengths of the afferent and efferent arterioles, even if both vessels constricted to a similar degree, the efferent arteriolar constriction would have a greater impact on glomerular filtration pressure,[48,50] and hence filtration rate.

A number of studies have reported a disparity in the magnitudes of the reduction in renal blood flow and glomerular filtration rate produced by renal nerve stimulation. Studies in the anaesthetized rabbit,[108] cat,[131] and rat[102] demonstrated that modest neurally induced reductions in renal blood flow (of 15–20%) were accompanied by either no change or a small 2–5% reduction in glomerular filtration. However, if angiotensin II activity was reduced by converting enzyme inhibitors, angiotensin II type 1 (AT-1) receptor blocking drugs or β-adrenoceptor antagonists, the neural impact on glomerular filtration rate became greater, with the magnitude of reductions in glomerular filtration rate becoming roughly proportionate with renal blood flow.[128] These reports gave rise to the important concept that the renal nerves, indirectly via locally produced angiotensin II acting at the efferent arteriole, could ensure that over a modest range of variation in renal blood flow, the glomerular filtration rate, and hence filtered load presented to the nephrons, was maintained at a relatively constant level.

Renal Denervation

An important question is whether under basal, unstressed conditions the renal sympathetic nerves have a tonic influence on basal blood flow through the kidney. The reasons for this uncertainty reside in the manner of the experimental studies, whether anaesthetized or conscious preparations were used, the degree of surgical stress and type of anaesthesia used, and, to a degree, the species under study. Thus, in a number of reports in the anaesthetized rat, there was very little change in renal blood flow following acute renal denervation.[58] However, in these studies there was often a relatively long period of time between basal measurements, the surgical manipulation and denervation of the kidney, and the post-surgery measurements, with the result that it was difficult to determine whether changes had taken place. In an attempt to resolve this issue, Kompanowska-Jezierska and colleagues[141] inserted an electro-cautery wire around the bulk of the nerves, and instantaneous denervation occurred when

a current was passed to destroy the neural tissue. Under these conditions, it was found that over the first 10 to 20 minutes an increase of some 20% in blood perfusing the outer cortex occurred when measured by laser Doppler flowmetry, suggesting there was sufficient activity within the renal nerves to decrease basal renal blood flow. This view was to a degree supported by the conscious rabbit reports of Malpas and co-workers,[190] who found that seven days after renal denervation, renal blood flow was some 55% to 65% higher in the denervated compared to the innervated kidney, the large difference most likely indicative of greater basal sympathetic outflow in the rabbit.

The studies of Miki and co-workers[277] using the conscious rat showed that while basal renal blood flow in the groups of animals with either intact or denervated kidneys could not be distinguished, an increase in renal sympathetic nerve activity during grooming and movement caused a proportionate decrease in blood flow to the intact kidneys of some 15%, whereas that to the denervated kidneys tended to increase in line with blood pressure. The relationship between renal blood flow and stress-induced activation of the sympathetic nervous system was the basis of the study undertaken by Brod and co-workers.[25] They demonstrated in man that, in the unstressed state, administration of an adrenergic blocking drug, dibenamine, had no effect on para aminohippurate (PAH) clearance (effective renal plasma flow), but if the patients were tense, anxious, and stressed, the dibenamine administration was associated with a rise in PAH clearance compatible with the view that there was a tonic renal nerve-induced reduction in renal blood flow. Thus, the degree of tonic influence of the renal sympathetic nerves on basal hemodynamics is dependent on the level of stress impinging on the subjects, and in the normal conscious state the renal sympathetic nerves have relatively little impact.

Neural Regulation of Intra-Renal Hemodynamics

Measurement of Intra-Renal Hemodynamics

The measurement of blood flow through the cortical and medullary regions of the kidney is difficult and fraught with technical limitations. Videomicroscopic techniques have been used to evaluate blood flow through single vasa recta vessels.[41] The limitation of many techniques used such as the Rhubidium-86 methodology is single estimations from one kidney,[107] the H_2-washout method is the accuracy of curve fitting of the data,[5,6] and the trapping of labeled microspheres in glomerular is only two to three measurements per kidney.[37] More recently, there has been greater use of laser-Doppler technology, which allows continuous measurements of blood perfusion through the cortex and medulla of the same kidney. The limitations of this technique are that the values recorded are not flow, but are a flux measurement derived from the product of the velocity as well as the number of red cells moving through the volume of tissue illuminated by the laser. Consequently, the values arising from this technique represent qualitative rather than quantitative evaluations of blood flow.

Activation of the Renal Nerves

There have been a series of investigations addressing how and whether the renal sympathetic nerves may differentially regulate blood flow through the cortex and medulla. Early studies in this area applying the H_2-washout approach in the anaesthetized dog[5,6] indicated that adrenergically-mediated decreases in flow were of comparable magnitude in both cortical and medullary regions. Similar findings were reported using the Rhubidium-86 methodology,[107] in that stimulation of the renal sympathetic nerves caused equivalent decreases in flow through both cortex and medulla. By contrast in later reports, Rudenstam et al.[231] used laser-Doppler flowmetry in the rat and observed a relative resistance of medullary perfusion to decrease in response to renal sympathetic nerve stimulation. Evans and co-workers,[74,97,177] using the same technique in the anaesthetized rabbit, demonstrated smaller reductions of the perfusion in the medulla than in the cortex or total renal blood flow. Further studies in rabbits[96] showed that the magnitude of reduction was similar across the medullary region, irrespective of the depth at which measurements were made (inner or outer medulla). This, to a degree, contrasts with the findings in the anaesthetized rat,[259] where the inner medullary perfusion was less responsive than the outer medullary area to renal nerve stimulation. The reasons underlying the differences reported in the sensitivity of the two vascular regions (cortex versus medulla) to adrenergic stimulation are unclear, but they may reside in the differing characteristics of the afferent and efferent arterioles (which may also vary between outer and inner cortical regions), possible variations in innervation density, species variation or the mix of paracrine and autocrine factors residing in the interstitium in these different regions. The potential interactions of all these factors have been considered in detail in recent reviews.[78,79]

CONTROL OF RENAL TUBULAR SOLUTE AND WATER TRANSPORT

Renal Denervation

Claude Bernard[17] first noted that section of the splanchnic nerve of the anaesthetized dog caused an

increase in urine flow. Questions arising from this finding were whether the raised fluid excretion was due indirectly to an increase in glomerular filtration rate, whether it was the result of a direct action on the tubular reabsorptive processes of the epithelial cells or a combination of these mechanisms. This problem was addressed by Bonjour and co-workers[22] using the anaesthetized dog, who convincingly demonstrated that the elevated urine flow and sodium excretion subsequent to the section of the renal sympathetic nerves was independent of any changes in glomerular filtration rate. They concluded that the raised fluid excretion reflected a direct influence of the nerves on tubular function. Thereafter, this view was supported by a series of reports using micropuncture techniques which directly examined reabsorptive rates along accessible segments of the nephron. Bello-Reuss and colleagues[14,15] observed in the anaesthetized rat that section of the splanchnic nerves had a minimal effect on single nephron glomerular filtration rate, but was associated with significant decreases in both absolute and fractional sodium and water reabsorption at the proximal tubule. These conclusions were supported by other investigators at that time, using comparable techniques to directly measure tubular function.[252,267,268]

Renal Nerve Stimulation

The removal of the influence of the renal sympathetic nerves represents only one way of illustrating their action, and to fully appreciate their influence a corresponding series of studies were necessary in which the renal nerves were activated. In a ground-breaking study, LaGrange and co-workers,[175] using the anaesthetized dog, found that direct electrical stimulation of the nerves at levels that were sub-threshold for changing either renal blood flow or glomerular filtration rate, caused a 30–40% fall in water and sodium excretion, which was interpreted as a direct action of the renal nerves on tubular fluid reabsorption. A similar situation was found to exist in the rabbit[108] and rat,[132] in that electrical stimulation of the renal nerves at levels subthreshold for decreasing renal blood flow, decreased both urine flow and sodium excretion. These observations were supported by micropuncture studies which more directly evaluated the tubular actions of the nerves. These studies[16] demonstrated that the absolute and fractional sodium and water reabsorption of the proximal tubule was increased by low frequency direct electrical stimulation of the renal nerves which was without effect on single nephron filtration rate. Moreover, DiBona and Sawin[62] found in the anaesthetized rat that low frequency stimulation of the renal nerves, at rates which did not alter renal blood flow or glomerular filtration rate, also increased fluid reabsorption at the thick limb of the ascending loop of Henle.

Thus, there is a large body of information which substantiates the view that the renal sympathetic nerves, when activated at low rates which have minimal effects on renal hemodynamics, have a direct action on the transport processes of the epithelial cells of the proximal tubule and the thick ascending limb of the loop of Henle. The situation regarding the distal tubule and the collecting duct has not been investigated in depth, primarily because of the technical hurdles required to evaluate reabsorption in these segments *in vivo*. Interestingly, Bankir and colleagues[8] have reviewed evidence for the concept that activation of vasopressin V2 receptors along the collecting duct not only increases water abstraction, but also activates epithelial sodium channels (ENaC) in the principal cells of this nephron segment. The EnaC-mediated antinatriuresis takes place in association with V2-induced increases in cAMP, and occurs at high plasma levels of vasopressin typically seen in pathophysiological states. The possibility arises that activation of α_2-adrenoceptors along this nephron segment,[222,223] which are known to suppress cAMP, could interact with vasopressin to determine the level not only of water retention, but also of the sodium due to ENaC insertion. The relationship between vasopressin and adrenoceptor activation at this nephron segment remains a source of investigation.

NEURAL CONTROL OF RENIN RELEASE

Renin Containing Cells

Renin Production

The granular cells of the juxtaglomerular apparatus contain renin. These cells are found in the afferent arterioles at increasing density as the vessel approaches the glomerulus.[98] The origin of these cells has been examined in a study by Sequeira-Lopez et al.[236] using single cell PCR and double immunostaining combined with lineage markers. By transplanting embryonic kidneys between genetically lineage marked mice containing cells for renin, smooth muscle, and endothelial cells with wild-type mice, they showed two distinct populations of cells expressing either renin or smooth muscle cell markers, but never both in the same cell. During the course of maturation, the renin cell began to express the smooth muscle cell markers, suggesting that renin cells could progress into smooth muscle cells and, if required, back into renin cells. Importantly, it appears that the transformation the other way round cannot happen, that is, the smooth muscle cells do not transform into renin cells.[220,236] The situation seems to be that when demand for renin is high, for example as a consequence of

reduced renal perfusion pressure or following a low dietary sodium intake, some smooth muscles will transform back into renin producing cells. Expression of the renin gene generates a specific mRNA which translates into a large protein, pre-pro-renin, which then undergoes processing to generate pro-renin.[98] The pro-renin then undergoes one of two fates, it can be secreted constitutively in an unchanged form, which represents "inactive" renin or it is incorporated into the secretory granules, where it undergoes further modification into mature renin. The secretion of renin occurs when exocytosis of the granules is stimulated. The exocytosis of the granular cells is regulated by two main intracellular signaling molecules, cAMP which stimulates renin release and intracellular calcium ion concentration (Ca^{2+}) which inhibits renin secretion.

Renin Cell Electrophysiology

The membrane potential of the granular cells is determined by a variety of ion channels influenced by cAMP and Ca^{2+}. Large conductance calcium-sensitive voltage-activated channels (BKa) are opened by increased intracellular cAMP, resulting in hyperpolarization. L-type voltage-dependent calcium channels ($Ca_v1.2$) which inhibit cAMP-mediated exocytosis.[85,86] The normal physiological process is one where the cAMP stimulation of renin granule exocytosis is protected against activation of L-type calcium channel by the hyperpolarization that results from the cAMP induced opening of the BKa. In this way, renin secretion can occur in a regulated manner independent of intracellular Ca^{2+}. These relationships and interactions are illustrated in Figure 16.4.

There are three primary intracellular signaling pathways which interact to determine the rate of renin secretion: cAMP; cGMP; and cytosolic calcium. Good evidence exists[13] that cAMP is the key signaling molecule. In mice with deletion of the G-protein $G_{s\alpha}$ in juxtaglomerular cells,[30] plasma renin is low and the mice are unresponsive to stimuli such as β_1-adrenoceptor stimulation which utilize cAMP. On the other hand in intact mice, challenges that stimulate adenyl cyclase or suppress phosphodiesterase enzymes result in increased renin release. The role of intracellular calcium in the regulation of renin secretion is only now becoming clear.[235] Angiotensin II-, endothelin-, and ADH- receptor-mediated increases in intracellular calcium suppress the exocytosis of the renin granules. Indeed, the intracellular calcium levels are inversely proportional to those of cAMP, that is, as intracellular calcium decreases there is an increase in cAMP and renin release, and *vice versa*.[98,221] It would seem that adenylyl cyclase isoforms 5/6 are inhibited by increased intracellular calcium, thereby determining the rate of cAMP generation. Taken together, the scenario put forward[235] is that cAMP is the primary intracellular signaling molecule eliciting renin release, and this occurs through activation of β_1-adrenoceptors. The other factors and mechanisms, which exert their actions via changes in calcium entry into the granular cells and therefore the activity of adenyl cyclase 5/6, will serve to modulate the sensitivity of the cAMP-dependent pathways for renin secretion.

Activation of the Renal Nerves

The stimulation of renal secretion and the exocytosis of the granules are regulated through three main routes, the renal baroreceptor mechanism, the macula densa and the renal sympathetic nerves. Many of the early investigations utilized either electrical stimulation or reflex activation of the renal sympathetic nerves, and showed that plasma renin activity or renin

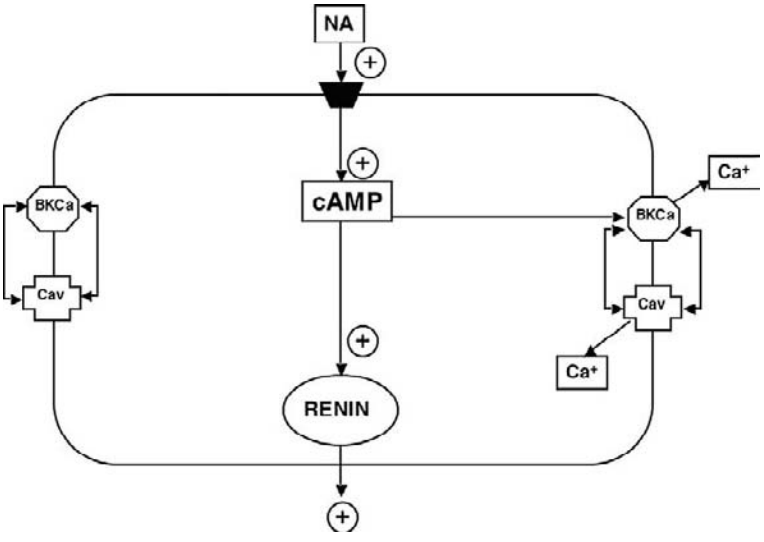

FIGURE 16.4 **Noradrenaline-adrenoceptor on a renin-containing cell to increase (NA) stimulates intracellular cAMP which then initiates exocytosis of renin-containing granules, releasing renin.** At the same time, cAMP acts at the BKCa channel to cause a hyperpolarization which to a degree suppresses the CaV channel offsetting calcium entry, an effect tending to inhibit renin secretion.

secretion was increased[58,143] which could be prevented by administration of β-adrenoceptor antagonists. Often interpretation of these findings was complicated by the concomitant reductions in renal blood flow and glomerular filtration rate which could have also contributed to the rise in renin release. The reports by Kopp et al.[143] and Osborn et al.[215] demonstrated that electrical stimulation of the renal sympathetic nerves at low frequencies producing no or small decreases in renal blood flow resulted in increases in renin release that were prevented by administration of a β_1-adrenoceptor antagonist in anesthetized dogs. This view of renin release from the granular cells being due to a direct action of neurally released noradrenaline has been supported by comparable observations in the rabbit and rat, as well as man.[128,269]

It is now clear that the neurally-induced renin release is associated with a rise in renal renin mRNA. This effect becomes measurable at relatively high levels of renal nerve stimulation over an extended period of time, of approximately an hour, causing large increases in plasma renin activity.[207] Interestingly, a number of reports have indicated that cAMP stimulates renin gene expression by binding to an enhancer region upstream of the gene,[218,240] as well as increasing the stability of renin mRNA.[221,242,261] The mechanisms involve cAMP-dependent phosphorylation mediated by ERK kinases.[98] Thus, the nerve-mediated increase in cAMP may act in several ways, first to cause an immediate release of renin as a result of exocytosis of the granules; second to increase renin gene expression; and third to cause a stabilization and prolongation of the action of renin mRNA, all actions to ensure that sufficient renin is available and stores are replenished.

Neural and Non-Neural Interactions and Renin Release

A number of early observations gave rise to the concept that a background level of renal nerve activity was necessary to allow the differing renin releasing mechanisms to operate normally. It was the initial studies of Stella et al.[248] in the anaesthetized cat that demonstrated that increased renin secretion as a result of reductions in renal perfusion pressure or renal blood flow were blunted in the denervated compared to the innervated kidneys. Furthermore, Johns[130] demonstrated that during reflex activation of the sympathetic nervous system following reduction of perfusion pressure at the carotid sinus, the magnitude of renin release when renal perfusion pressure was reduced was greater in the innervated than denervated kidneys. These findings were extended by Holdaas et al.[114] and Osborn et al.[216] using the anaesthetized dog, who found that furosemide-induced renin release was enhanced when the renal sympathetic nerves were intact compared to that obtained when the kidneys were denervated. Indeed, Kopp and DiBona[160] clearly demonstrated in the dog that the relationship between the magnitude of renin released in response to a particular level of electrical stimulation of the renal nerves was dependent on the prevailing level of renal perfusion pressure. The mechanisms involved at the cellular level remain undefined.

INTEGRATION OF RENAL NERVE ACTIVITY AND FUNCTION

Recruitment of Functionalities

An important consideration after having defined the exact mechanisms by which the renal nerves exert their influence on the different end-points of kidney function, renin release, fluid reabsorption, and renal hemodynamics, is the relationship between the recruitment of these functionalities under normal conditions. At low levels of renal nerve stimulation, which is subthreshold for changing fluid reabsorption and renal hemodynamics, there is an increase in renin secretion. At somewhat higher levels of renal nerve activation, but again sub-threshold for impacting on renal hemodynamics, not only are there larger increases in renin secretion, but there is also an antidiuresis and antinatriuresis which has been demonstrated in the anaesthetized dog, rabbit, and rat.[58] It is clear that the renal nerve-induced sodium and water retention under these conditions reflects a direct action on proximal tubule reabsorptive processes, as described in micropuncture studies using the anaesthetized rat.[16,266,267] At high levels of renal nerve stimulation, the raised renin release and fluid retention is enhanced, but is now accompanied by a reduction in renal blood flow and, depending on the actual level of stimulation, a decrease in glomerular filtration rate.[58] Indeed, this progressive recruitment of renal functionalities has been shown to occur in man in an elegant study by Wurzner et al.[269] who used lower body negative pressure (LBNP) to reflexly activate the sympathetic nervous system. They found that as LBNP was progressively reduced, there were associated proportionate increases in plasma noradrenaline and plasma renin activity, while sodium excretion was only reduced at the lowest LBNP used. During these challenges neither renal blood flow nor glomerular filtration rate were changed. The way in which these functionalities are recruited is illustrated in Figure 16.5.

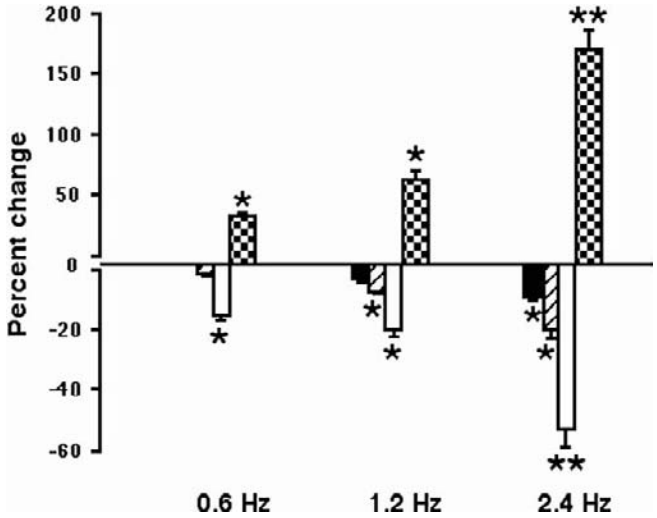

FIGURE 16.5 **At the lowest level of renal nerve stimulation (0.6 Hz), there are significant increases in plasma renin activity (stippled bars) and decreases in sodium excretion (open bars), but no effect on either renal blood flow (hatched bars) or glomerular filtration rate (filled bars).** As the frequency of stimulation is increased there are larger increases in all variables, particularly the decreases in renal hemodynamics which become significant. Importantly the frequency–response relationships are much steeper for plasma renin activity and sodium excretion than for renal blood flow or glomerular filtration rate. *(Modified from ref. [109].)*

There are two important considerations which arise from this pattern of responses. At low levels of renal sympathetic nerve activity, the major impact will be on renin release and sodium and water reabsorption. At these low levels of activity there will only be small increases in circulating renin (50–70%) and reductions in sodium excretion of some 20–40%. However, if these effects persist over a long timeframe, they could have a profound impact on extracellular fluid volume, and thereby on the level at which blood pressure is set. Again, it is worth reiterating that these renin releasing and sodium retaining responses can occur with little evidence of major reductions in renal hemodynamics.

By contrast, when renal sympathetic nerve activity is raised to higher levels by major stressors (for example emotional challenges, severe exercise), then blood flow through the kidney will be markedly reduced. However, it is important to emphasize that these are short acting events, and therefore they are likely to have only minor influences on overall cardiovascular homeostasis.

Patterns of Electrical Stimulation of the Renal Nerves

Patterns of Efferent Activity

The concepts of how the renal nerves influence kidney function have been based largely on experiments in which the sympathetic nerves to the kidney have been dissected out, placed on electrodes, and stimulated using square wave pulses of defined width and voltage at increasing frequencies and constant current delivery. It has been recognized that this pattern of stimulation bears no relation to that passing down the nerves naturally to reach the kidney. Indeed, multifiber nerve recordings have shown the signal to be composed of a bursting nature where larger or smaller numbers of fibers fire together in a coordinated or disparate fashion, with the result that complex patterns are generated. The issue is whether the effectiveness or impact of the nerves on one or more functions might be different if they were stimulated in a way more representative of that occurring under natural conditions.

Lacroix et al.[176] and Nilsson et al.,[210] using isolated mesenteric and nasal vessels, demonstrated that larger sympathetically-mediated vasoconstrictions were produced using high frequency bursts of impulses compared to the delivery of the same number of impulses as a continuous train. This was to a degree reinforced by the observations of Hardebo,[103] who found that the high frequency bursting pattern caused a greater release of noradrenaline from cerebral vessels than that achieved with the same number of impulses delivered as a continuous stream. Thus, the amount of neurotransmitter released can be influenced by the exact pattern of stimulation used.

Electrical Activation with Frequency Enriched Stimuli

HEMODYNAMICS AND FUNCTION

The question therefore arises as to whether the effectiveness or impact of the renal sympathetic nerves could be influenced by the pattern of the stimulation parameters. This was investigated by DiBona and Sawin[66] in the anaesthetized rat using a complex computer generated stimulus pattern basically of a sine wave, within which was embedded a randomly generated white noise signal. The patterned stimulus was designed to approximate that which the kidney might normally be expected to receive. The authors used two levels of intensities, one impacting on renal hemodynamics and one at a lower level which only influenced excretory function. Importantly, they showed that for the same integrated voltage applied to the nerves, the magnitude of reduction in renal blood flow was greater with the sinusoidal patterned stimulus than with the square wave stimulus at all frequencies tested. This data is presented in Figure 16.6, where there is a clear shift of the frequency–response curve to the left with the sinusoidal stimuli compared to the square wave stimuli. In a similar way, application of sub-threshold stimuli for changing renal hemodynamics had no effect

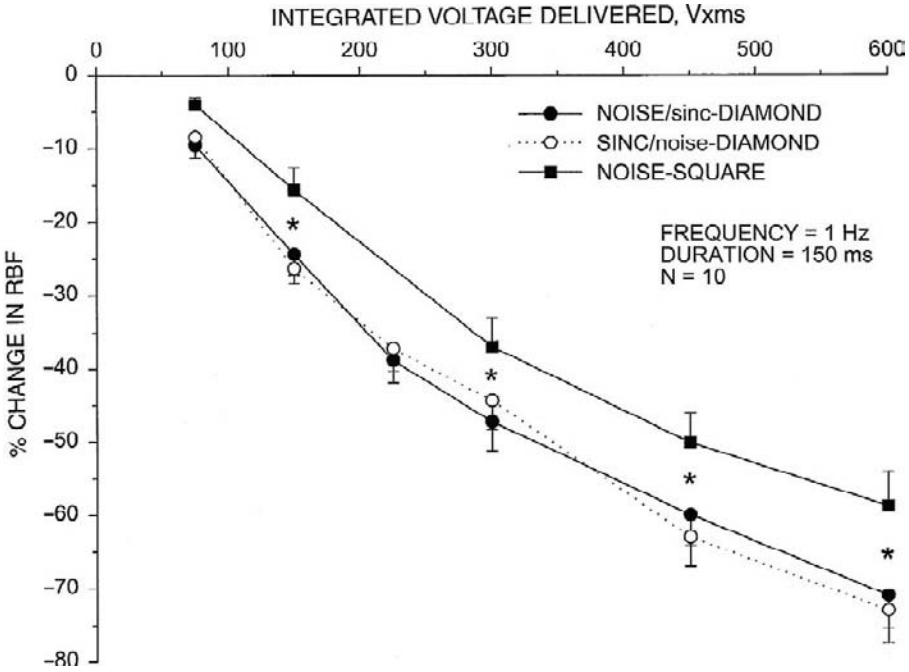

FIGURE 16.6 This figure *(taken from* ref. *[66] with permission)* demonstrates that delivery of an electrical stimulus as a square wave pulse (NOISE-SQUARE) is less efficient in decreasing renal blood flow (RBF) at every integrated voltage step compared with stimuli delivered as a sinusoidal wave containing either noise (NOISE/SINC-DIAMOND) or fixed frequency within the sinusoidal wave (SINC/NOISE-DIAMOND).

on sodium excretion if delivered in a square wave form, but did cause an antidiuresis and antinatriuresis at the same integrated voltage if the sinusoidal signal was used, and this is illustrated in Figure 16.7. Thus, together these reports serve to emphasize that the way in which the neural signals are delivered into the kidney can determine the impact on end-organ function.

HEMODYNAMICS

Malpas and colleagues,[95,191,192] using the anaesthetized rabbit, investigated whether the bursting pattern of naturally occurring renal nerve activity could in any way determine the dynamic regulation of renal blood flow. Utilizing a similar patterned stimulus, i.e., a sine wave of varying voltage within which square wave pulses were embedded, as against steady square wave pulses, they showed that the frequency of the sine wave could determine the degree of reduction in renal blood flow, even though the total current delivered was the same.[191] The authors proposed that the low frequency pulses in renal sympathetic nerve activity were likely to result in an enhanced dynamic gain to allow the renal blood flow to respond rapidly to normal everyday variations in blood pressure. Interestingly, this hypothesis was not supported by an investigation in the rat[63] in which the renal nerves were similarly stimulated with sine wave modulation with embedded high frequency pulses. These investigators found that there were reductions in renal blood flow with superimposed low frequency oscillations, but that the magnitude of these vasoconstrictor responses were not altered when basal tone was increased by exogenous administration of noradrenaline or angiotensin II. The reasons why there is a disparity between these reports are unclear, but may reflect a fundamental difference in the regulation of the renal vasculature in the rabbit versus the rat.

Analysis of Renal Nerve Activity

The central mechanisms involved in the generation, regulation, and analysis of the sympathetic outflow have been reviewed in detail by Malpas.[189] It has become possible to resolve the frequency and amplitude components, phase relationships, and coherence between renal sympathetic nerve activity, renal blood flow, and blood pressure. These techniques have been applied to gain insight into how low levels of renal sympathetic nerve activity may influence renal function. It is evident that renal sympathetic nerve activity is at a level which tonically reduces renal blood flow, at least, in the rabbit.[96,190] Moreover, following power spectral analysis of the renal blood flow signal it has become apparent that at a spectral frequency range above 0.6 Hz in the renal sympathetic nerve signal, the nerves exert a tonic vasoconstrictor action on the renal vasculature.[191] However, the lower frequency power spectral peaks, below 0.6 Hz, cause slow cycles of vasoconstriction and vasodilation which, it has been argued, may enhance the responsiveness of the vasculature to other stimuli to allow renal blood flow and glomerular filtration rate to dynamically adapt to ensure constancy of filtered load, and hence fluid processing by the nephron.[192] Indeed, it has been emphasized that this role of the renal nerves is integral to the maintenance of cardiovascular homeostasis.[12]

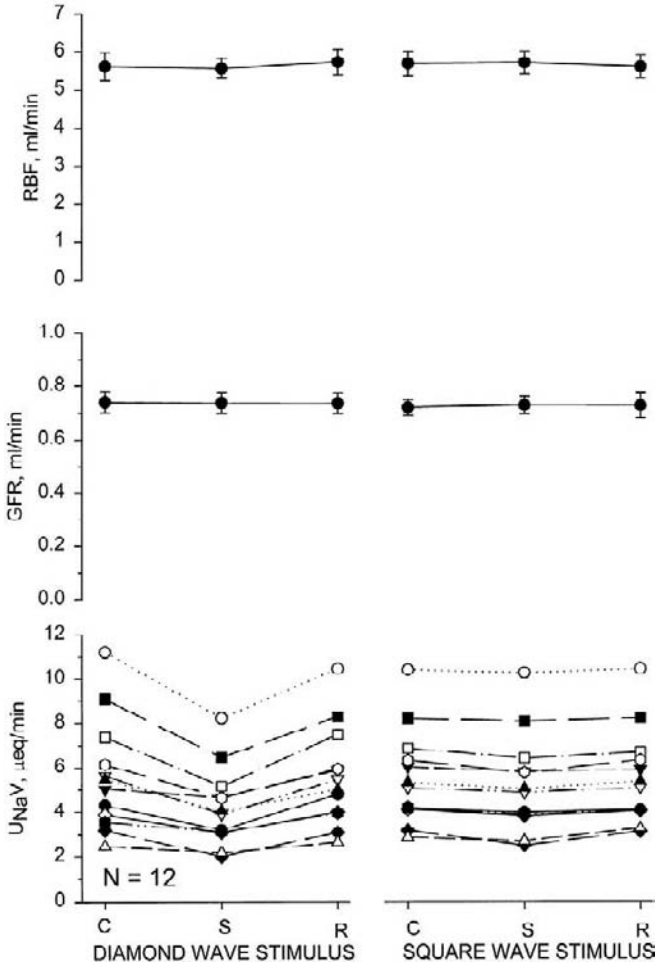

FIGURE 16.7 **Electrical stimulation of the renal sympathetic nerves with the diamond wave stimulus, which had no effect on either renal blood flow (RBF) or glomerular filtration rate, (GFR) significantly decreased sodium excretive (UNAV), whereas delivery of the same integrated voltage as a square wave stimulus was without effect on any of the measured variables.** *(Taken with permission from ref. [66].)*

The situation in the rat appears somewhat different, as many reports[58] demonstrate that under basal conditions the renal sympathetic nerves have a much smaller, if any, influence on basal renal blood flow. DiBona and Sawin[61,65] evaluated the transfer function gain between blood pressure and renal blood flow under a variety of conditions where renal sympathetic nerve activity was removed or enhanced. There was a characteristic pattern to the transfer function gain under basal conditions. The transfer function gain decreased below zero over the frequency range 0.02 and 0.06 Hz, which was taken to represent a slower tubuloglomerular feedback mechanism of autoregulation, and increased above zero with a plateau region over the higher frequency range 0.1 to 0.2 Hz, which was taken to reflect the myogenic component of autoregulation. They found that acute denervation had little impact on the overall pattern of transfer function gain over the whole frequency range.[61] In contrast, in two pathophysiological states, congestive heart failure and in the spontaneously hypertensive rat where basal renal sympathetic nerve activity is elevated, transfer function gain was suppressed over both these frequency ranges, but was relatively normalized following acute renal denervation.[63] The authors concluded that in the rats with elevated renal nerve activity, the coupling between blood pressure and renal blood flow was overridden such that autoregulation of renal blood flow was impaired. These authors went on to show that this effect was mediated via angiotensin II, as blockade of angiotensin AT1 receptors with losartan depressed the transfer function gain in rats fed on low or normal dietary sodium intake, but not a high dietary sodium intake.[59,63] Indeed, the outcome of these studies indicated that the renin–angiotensin system enhanced the tubuloglomerular feedback component of autoregulation, but not the myogenic component, and that the elevated angiotensin II increased the efficiency of transfer of the neural signal to control the renal vasculature.

Reflex Regulation of the Renal Nerves

Activity within the renal sympathetic nerves represents an integration of a number of sensory inputs arising from different regions of the body by the central nervous system. Malpas has recently reviewed the central mechanisms regulating sympathetic outflow to the periphery, including that to the kidney.[189] The changing output of renal sympathetic nerve activity represents a means by which renal functionalities, that is, renin release, sodium reabsorption, and renal hemodynamics are regulated at an appropriate level. The different sensory systems sending information into the central nervous system are shown in Figure 16.8.

Cardiovascular Baroreceptors

HIGH PRESSURE BARORECEPTORS

A number of early studies demonstrated that the high pressure baroreceptors in the carotid sinuses exerted an important influence on the neural regulation of the kidney. Studies undertaken in anaesthetized and conscious dogs in which carotid sinus pressure was reduced mechanically[94,278] or as a consequence of periods of head up tilt[54,201,202] increased renal nerve activity, renin secretion, and caused a renal nerve-dependent antidiuresis and antinatriuresis with relatively little change in renal hemodynamics. This means that during everyday activity, the baroreflex control of blood pressure will impact on kidney function; renin

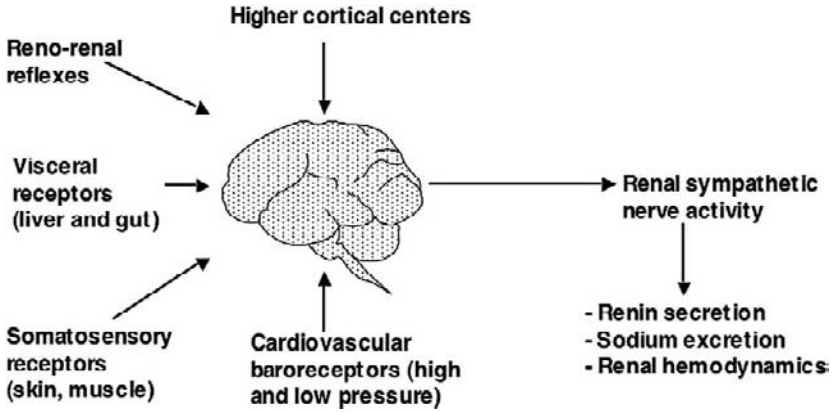

FIGURE 16.8 **The figure summarizes the input from different sensory system which are integrated by the central nervous system to determine the degree of renal sympathetic nerve activity to regulate renin secretion, sodium excretion and renal hemodynamics.**

release and sodium and water retention to a greater degree than vasomotor tone. However, what has become evident from the conscious rat studies of Miki and colleagues, is that the baroreflex control of renal sympathetic nerve activity is shifted towards a higher blood pressure as muscle activity increases, for example during grooming and exercise on a treadmill.[204,206,277]

LOW PRESSURE BARORECEPTORS

The low pressure baroreceptors are contained in the cardiopulmonary areas, and are mechanosensitive nerves embedded in the atria and great veins (superior and inferior venae cavae and pulmonary vein) which respond to stretch. Activation of these sensory nerves by inflation of balloons in the left atria results in a reflex decrease in renal sympathetic nerve activity associated with a rise in water and sodium excretion.[90,178] While many of these studies were undertaken in anaesthetized preparations, DiBona and Sawin[68] demonstrated in the conscious rat that volume expansion decreased and volume depletion increased renal sympathetic nerve activity. These observations correlated with a key report by Miki et al.[201] in the conscious dog showing that head-out total body water immersion, a maneuver that shifts fluid into the more central compartments of the cardiovascular system, caused a reflex renal sympatho-inhibition associated with a diuresis and natriuresis. The cardiopulmonary receptors were demonstrated to be essential in this reflex, as following chronic cardiac denervation both the renal sympatho-inhibition and excretory responses were markedly blunted when these dogs were subjected to the water immersion challenge.[202]

Somatosensory System

There are mechanosensory nerve fibers in the joints and tendons, chemosensitive nerves within the muscle tissue itself depolarized by metabolites.[127,128] The skin contains nociceptors and thermoreceptors. Each of these classes of sensory nerves sends important afferent information into the central nervous system to be integrated. At the level of the kidney, an early study by Thames and Abboud[255] demonstrated that sciatic nerve stimulation caused profound reductions in renal blood flow. In the anaesthetized rat, electrical stimulation of the brachial nerves, application of capsaicin subcutaneously to depolarize afferent nerve endings or inhalation of noxious fumes[45,46,279] caused increases in renal sympathetic nerve activity and a renal nerve-mediated antidiuresis and antinatriuresis with little change in renal hemodynamics. Interestingly, the magnitude of the renal sympathetic nerve activity responses is under tonic inhibitory control by the cardiopulmonary receptors, as suggested by studies showing that activation of the cardiopulmonary receptors blunts the sympatho-excitatory and antinatriuretic responses to capsaisin-induced activation of the afferent nerves.[279] These studies illustrate the point that the somatosensory system does provide an important input to the brain, but its impact is modulated by input from the cardiovascular baroreceptors.

Visceral System

Less well-studied, but nonetheless important, are the chemo- and mechano sensory nerves in the visceral system. In early studies, Weaver and co-workers[262] demonstrated that activation of chemosensitive nerve fibers in the small intestine of the cat, by bradykinin, caused a reflex activation of the renal sympathetic nerves. Furthermore, they demonstrated that the effectiveness of this sensory input from the gut was under a tonic inhibitory influence from both the low and high pressure cardiovascular baroreceptor.

Chemo- and mechanosensory nerves are also present within the liver, where they modulate renal sympathetic nerve activity and renal nerve mediated fluid excretion.[110,111,171,205] A reduction in plasma sodium concentration in the hepatic portal vein, but not hepatic artery, resulted in increased adrenaline secretion, indicative of a sympatho-excitation, which was blocked by

denervation of the hepatic portal vein.[110,111] Moreover, infusion of a hypertonic solution in the hepatic portal vein[205] caused a renal sympatho-inhibition and a renal nerve-dependent increase in sodium and water excretion. Taken together, these observations lay the foundation of important reflexes whereby food and fluid absorption from the gut initiates an appropriate neural regulation of kidney function to ensure that sodium and water homeostasis is maintained.

The spleen has also been found to be a source of sensory information which can modulate renal sympathetic nerve activity and its functional end-points. Hamza and Kaufman[99–101] reported that an increase in splenic venous pressure resulted in small rises in blood pressure and reductions in renal blood flow, with the latter being prevented following surgical section of the renal sympathetic nerves. It can be speculated that this relationship becomes important in portal hypertension and liver cirrhosis in eliciting a reflex renal sympatho-excitation which will contribute to the sodium retention associated with these disease states.

Higher Cortical Centers

The role of psychological stress in regulating renal sympathetic nerve outflow and renal function is less clear-cut and far more difficult to study. Nonetheless, chronically instrumented rats have been used and subjected to a range of challenges to engage the higher cortical centers. An arousal stimulus of an air jet stress has been found to reflexly increase renal sympathetic nerve activity along with a renal nerve-dependent antinatriuresis and antidiuresis.[64,258] However, studies to determine potential control by the cardiovascular baroreceptors of physiological stresses have been difficult to achieve in conscious studies. Nonetheless, the recent observations of Miki and his group have revealed a number of important findings. First, it was apparent that renal sympathetic nerve activity was lower during rapid eye movement sleep than in non-rapid eye movement sleep and became higher as the level of physical activity rose, from quiet awake to grooming.[277] At the same time, there was an adaptation of the baroreflex to function over a higher blood pressure range as the activity of the animal increased.[277] Second, during treadmill exercise,[204] there was an increased sensitivity of the baroreflex relationship, which they interpreted as important in buffering the raised blood pressure under conditions of increased muscular activity. This group has also evaluated the cardiovascular changes induced during "freezing" behavior, when conscious rats are exposed to a high level of white noise.[203,276] Under these conditions, there was a minimal change in blood pressure, but heart rate decreased while renal sympathetic nerve activity increased, and lumbar sympathetic nerve activity did not change. The alterations in renal sympathetic nerve activity and heart rate during the freezing behavior were largely prevented by prior sino-aortic denervation, which indicated their important contribution to this pattern of responses. Thus, the cardiovascular and sympathetically-mediated responses during the freezing behavior prepare the animal for an active response to the threatening situation. Taken together, it is apparent that in all these different behavioral states central command exerts an important differential regulatory influence on the baroreflex control of sympathetic outflow to many organs, including that to the kidney.

Reflex Control of Selective Functions

Attention has been focused on whether the renal innervation could selectively regulate either renal hemodynamics or tubular fluid reabsorption or renin secretion. The findings of Luff et al. in the rabbit[183] and DiBona and Sawin in the rat[67] demonstrated that two types of structurally different nerve fibers exist within the nerve bundles and within the kidney itself. Evidence has been produced in the rabbit, where glomerular capillary pressure was measured as an indirect estimate of pre- and post-glomerular resistances.[48–50] Using an angiotensin II clamp, to remove any confounding influences of changes in endogeneous angiotensin II levels, a hypoxic challenge increased glomerular filtration pressure. The authors' interpreted these observations as reflecting a selective neural regulation post-glomerular vascular resistance, possibly via one of the subtypes of nerve fiber, independent of the renin–angiotensin system.

DiBona and colleagues[51,67] using the rat analyzed the strength-duration relationship during direct electrical renal nerve stimulation in relation to renal blood flow, urine flow, and sodium excretion. They found a higher stimulation threshold for the nerve fibers involved in regulating renal blood flow than for those involved in regulating fluid excretion. Moreover, activity in single sympathetic fibers innervating the kidney could be selectively modified by different reflexes. Thus, stimulation of arterial baroreceptors, central chemoreceptors, and thermoreceptors activated a large proportion (88%) of spontaneously active fibers, whereas thermoreceptors only increased the firing rate of those fibers which had no spontaneous activity. In a different series of studies, examining patterns of renal sympathetic nerve activity by evaluating the peaks of activity and time between peaks, DiBona and co-workers were able to show that although somatosensory (pinch) and heat stimuli resulted in similar increases in total renal sympathetic nerve activity, it was only the heat stimulus that caused a decrease in renal blood flow. The authors took these responses to indicate that two different stimuli could result in a distinctly

different control of sympathetic outflow regulating renal hemodynamics.

It would seem that there is a small, but persuasive, body of evidence for the view that there may be a degree of selectivity of functional control in the neural control of the kidney. There is a need for more investigation of this particular topic.

Central Nervous System

Central Processing

The processing of this sensory information within the central nervous system to generate an appropriate level of sympathetic outflow, not only to the kidney but to other organs, is complex and attention has been directed towards the cardiovascular baroreceptors which exert a major influence on autonomic control.[44] The sensory information from both the high and low pressure baroreceptors pass to the nucleus tractus solitarius (NTS) for initial processing, and subsequently via multiple pathways to the caudal and rostral ventrolateral medulla (CVLM and RVLM) where a complex interaction takes place before the pre-ganglionic fibers are stimulated. The way in which the major sensory inputs feed into these pathways is illustrated and summarized in Figure 16.9.

The situation regarding the somatosensory and visceral systems and their inputs to the areas regulating the autonomic nervous system are much less defined. The somatosensory system appears to have a direct input at three levels, NTS, CVLM, and RVLM,[42] but the actions exerted at each of these sites, whether excitatory or inhibitory, and the neurotransmitters involved, have not been resolved.

There is now a body of evidence that autonomic control is organized in a patterned manner. Micro-injection of glutamate onto the RVLM elicited an increase in cardiac, splenic, and renal sympathetic nerve activities that were very different in magnitude.[195,196] In conscious rat studies there is a relatively low degree of autonomic control of lumbar sympathetic nerve activity during treadmill exercise or in the freezing behavior,[203,204,276] whereas there are large dynamic responses in renal sympathetic nerve activity. There is also a clear differential control of cardiac and renal sympathetic outflow in the conscious sheep. Thus, following an infusion of hypertonic saline icv, renal sympathetic nerve activity markedly decreased, whereas cardiac sympathetic nerve activity did not change.[195] By contrast, in a model of pacing-induced heart failure, there was a large elevation in cardiac sympathetic, but not renal sympathetic, nerve activity. It was also reported in conscious rats[275] that icv infusion of angiotensin II reduced renal, but not lumbar, sympathetic nerve activity. A fuller analysis of the evidence has been presented by Malpas[189] in a recent review. The exact way in which information from each sensory system is integrated to provide an appropriate output of renal sympathetic nerve activity and neural control of renal function in order to ensure cardiovascular homeostasis remains to be explored.

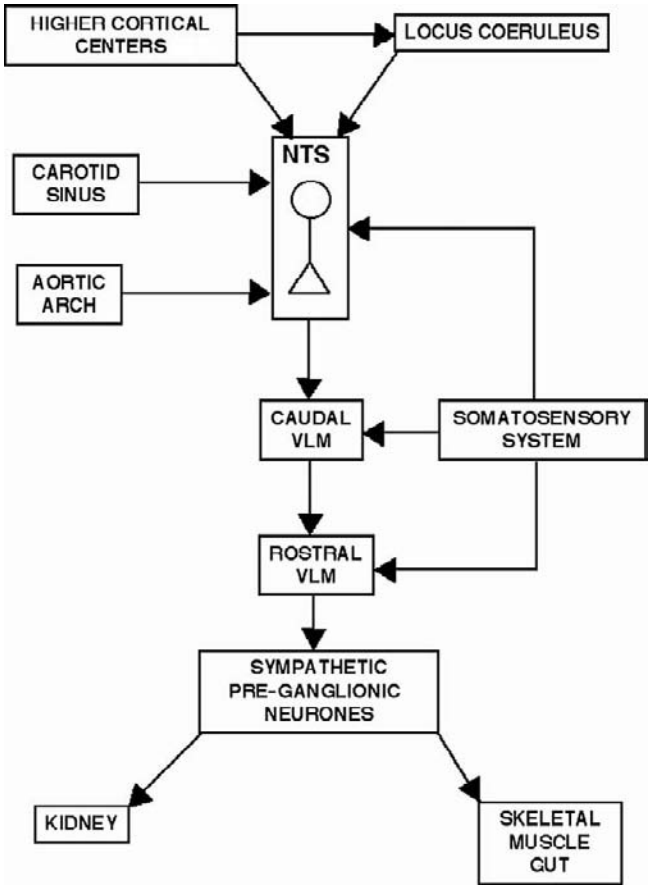

FIGURE 16.9 **This illustration indicates how input from the baroreceptors, somatosensory system, and higher cortical centers act at the nucleus tractus solitarus (NTS), which feeds into the caudal and rostal venterolateral medulla (CVLM and RVLM).** This determines the level of excitability of pre-ganglionic neurones and thereby sympathetic outflow to the kidney and other vascular beds.

Brain Angiotensin II

ANGIOTENSIN II AND AUTONOMIC PATHWAYS

There is accumulating evidence that the renin–angiotensin system and angiotensin II can influence the reflex responses in sympathetic nerve activity generated by the central nervous system. This can arise in two ways, either via circulating angiotensin II or by means of angiotensin II generated locally within the brain at specific nuclei. Moreover, angiotensin II receptors have been demonstrated in many regions of the brain, and particularly at those nuclei involved with cardiovascular control.[3] It is now accepted that in the

areas of the circumventricular organs the blood–brain barrier is leaky,[200] enabling angiotensin II to act on nuclei within this region which have been shown to contain a high density of angiotensin II receptors. At these sites the peptide is able to influence fluid balance; it stimulates drinking, induces ADH release, and causes increased sodium reabsorption and renin release.[199] The second route whereby angiotensin II may influence autonomic control is that generated within the brain itself, as all components of the renin–angiotensin system are present, that is renin, angiotensinogen, converting enzyme, and angiotensin II receptors.[265] It is also necessary to emphasize that immunocytochemical, *in situ* hybridization studies, and mRNA measurements of angiotensin II receptors and angiotensinogen have shown them to be present or their genes expressed at those nuclei involved with autonomic control, that is the NTS, RVLM, and CVLM, and the paraventricular nucleus (PVN),[199] as well as those other nuclei of the subfornical organ and the area postrema which are most likely subject to the action of circulating angiotensin II. Neurophysiological studies have shown that local administration of angiotensin II onto the NTS and RVLM is excitatory and produces a sympathetically-mediated pressor response, but when applied to the CVLM it causes a sympatho-inhibition[43,105]; thus, angiotensin II may have different actions and consequences depending on its site of production and action.

BRAIN ANGIOTENSIN II AND NEURAL CONTROL OF THE KIDNEY

The functional role played by angiotensin II within the brain in modulating autonomic control, both normally and in pathophysiological states, is only now being elucidated. There are now a number of reports showing that the baroreflex control of renal sympathetic nerve activity was suppressed by angiotensin II in conscious normotensive Wistar rats,[120] and enhanced in the spontaneously hypertensive rat (SHR).[117,174] In terms of the somatosensory reflex, angiotensin II within the central nervous system is important, in that losartan given icv blocked the renal nerve-mediated antinatriuresis and antidiuresis resulting from nociceptor stimulation[118] and angiotensin II icv restored the renal nerve-dependent functional responses[119] which could be correlated with marked changes in the pattern with which energy was distributed within the renal nerve signal.[127,279] The central issue which arises is to understand which factors could affect the level of angiotensin II within the central nervous system which would then impact on the degree of autonomic control exerted peripherally and particularly at the kidney. Indeed, it is important to distinguish between acute bolus administration of angiotensin II administered systemically and the application of the peptide as an icv infusion which may be associated with increases in blood pressure and a renal sympatho-excitation.

The level of dietary sodium intake can modulate this very important link between the autonomic control of the cardiovascular system and brain angiotensin II. An early report by Huang and Leenen[117] demonstrated that raised levels of dietary sodium intake in normotensive rats from four to eight weeks-of-age, led to an increase in baroreflex gain associated with a resetting to a higher pressure for renal nerve activity, but not for heart rate. The importance of dietary sodium intake during development has been reinforced by the studies of Osborn and his group,[27,214] who showed that in rats fed a high-salt diet from four to eight weeks-of-age, low dose infusion of angiotensin II into the brain (icv) over five days caused a sustained increase in blood pressure associated with a renal nerve-dependent antinatriuresis. This was not observed in rats fed a normal or low-salt diet. Further evidence for this role of the renal sympathetic nerves was reported by Houghton and co-workers[115,116] who found that a bolus injection of angiotensin II icv had vasopressor and renal sympatho-excitatory actions, the magnitudes of which were enhanced in rats fed a high-sodium diet over the period of growth and development that was in part mediated by vasopressin release both systemically and within the spinal cord.

This influence of dietary sodium intake on the contribution of angiotensin II in the brain on central pathways regulating renal sympathetic nerve activity has received some attention. DiBona and co-workers[56,57] using rats subjected to a low, normal or high dietary sodium intake for two weeks, microinjected an AT-1 receptor antagonist onto the RVLM, and observed a decreased blood pressure and a shift in the baroreflex gain curve for renal nerve activity to a lower pressure in the animals fed a low-sodium diet, but not in those animals fed the normal or high-sodium intakes. Furthermore, it was evident that administration of an AT-1 receptor antagonist to the RVLM blunted the increases in blood pressure, heart rate, and renal sympathetic nerve activity produced by bicuculline, a GABA receptor antagonist, injected onto the PVN. Importantly, the renal sympathetic nerve responses to the bicuculline administration into the PVN were enhanced in the rats subjected to the low-sodium diet, but blunted in those fed the high salt intake.[55]

Together, these findings highlight the importance of the brain renin–angiotensin system and the significance of angiotensin II in determining the sensitivity of neural pathways regulating sympathetic outflow to the kidney. They also emphasize how alterations in dietary sodium intake may impact on these neural control pathways, which may reset kidney function to a level which could predispose the individual to a hypertensive state.

Neural Regulation of the Kidney in Man

Knowledge of the sympathetic nerve control of the kidney in experimental animals under normal physiological conditions is now extensive in relation to the regulation of renal hemodynamics, renin secretion, and tubular sodium reabsorption. Indeed, although not touched upon in this chapter, there is an extensive body of work in relation to the role of the renal sympathetic nerves in pathophysiological states.[53,58,124,189] However, knowledge of the importance and significance of the renal sympathetic nerves in man remains a relatively unexplored area, although their contribution to cardiovascular and renal diseases is increasingly recognized and alluded to above in different sections. The most striking demonstration of their importance in man has come in a report by Krum et al.,[172,173] who utilized an angioplasty catheter inserted into the renal arteries with a probe at the tip which emitted radiofrequencies with sufficient intensity to disrupt the renal nerves passing alongside the renal artery. In a group of patients with hypertension that was resistant to conventional drug based therapy, bilateral ablation of the renal nerves in this way resulted in a reduction in systolic blood pressure of some 30 mmHg which was maintained for at least 24 months after the manoeuvre. Currently, these initial observations are being further investigated in randomized multicenter trials. DiBona and Esler[53] have emphasized that the knowledge gained from the experimental studies is now being successfully translated into therapeutic approaches, and that the role of the renal sympathetic nerves in heart failure, renal failure, and metabolic diseases of diabetes and obesity will now be explored.

AFFERENT RENAL SENSORY NERVES

Introduction

Not much focus has previously been placed on the afferent sensory innervation of the kidney and its physiological importance in the cardiovascular regulation compared to the efferent renal sympathetic innervation of the kidney. However, recent studies in man showing long-term depressor effects following renal nerve ablation which reduces both efferent and afferent renal nerve activity have highlighted a possible role for the afferent renal nerves in hypertension.[53] As will be discussed in more detail below, in healthy animals activation of the afferent renal sensory nerves elicits an inhibitory renorenal reflex response consisting of increases in afferent renal nerve activity, the nerve signals going from the kidney to the neuraxis, causing decreases in efferent renal sympathetic nerve activity which in turn result in a natriuresis (Figure 16.10). Available evidence would suggest that in many pathological conditions the nature of the renorenal reflexes is switched from being of an inhibitory to an excitatory nature (*vide infra*).

NEUROANATOMY

In the kidney, the majority of the afferent renal nerves containing substance P and calcitonin gene-related peptide (CGRP) are located in the renal pelvic wall,[147,156,182] where their circumferential orientation make them ideally suitable for sensing stretch (Figure 16.11). The majority of the renal sensory nerves are unmyelinated.[139]

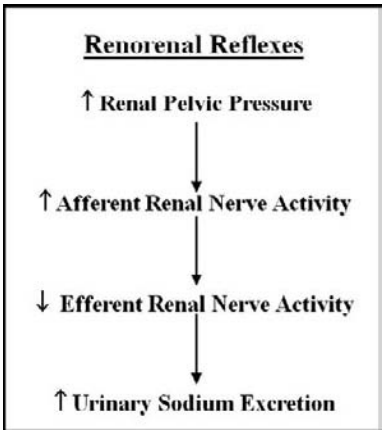

FIGURE 16.10 **Increasing renal pelvic pressure ≥3 mmHg stretches the renal pelvic wall, leading to activation of the afferent renal mechanosensory nerves.** The increase in afferent renal nerve activity leads to decreases in efferent renal nerve activity, which in turn increases urinary sodium excretion, i.e., a renorenal reflex mechanism.

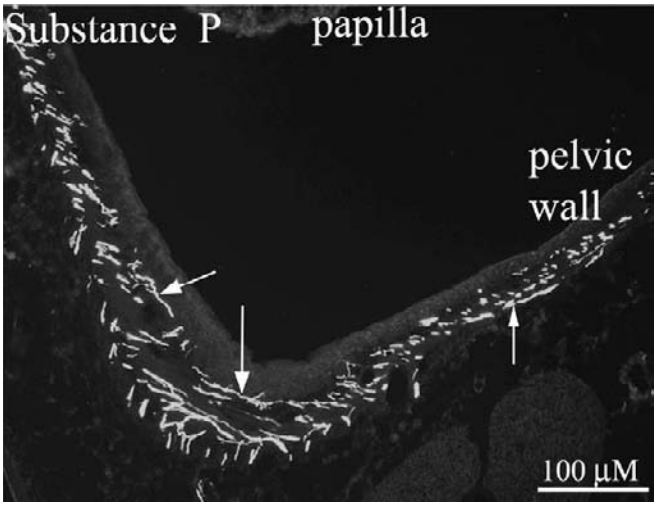

FIGURE 16.11 **In the kidney, the majority of the substance P containing nerve fibers (arrows) is located in the muscular layer of the renal pelvic wall.**

Depending on the species, the cell bodies of the afferent renal nerves are located in ipsilateral dorsal root ganglia (DRG) from T_6-L_4, with predominance in $T_{12}-L_3$.[58] Viral tracing studies combined with dorsal rhizotomy (DRX) at $T_{10}-T_{13}$ have provided evidence for the afferent renal nerves projecting from the DRG to the ipsilateral dorsal horn mainly in Laminae I, III–V,[36] where they synapse with interneurons projecting to sites within the central nervous system which are associated with cardiovascular regulation, including nucleus tractus solitarius, rostral ventrolateral medulla, subfornical organ, and paraventricular nucleus of hypothalamus.[247] There is also evidence for a monosynaptic projection of the afferent renal nerves to areas within the brainstem.[270]

Stimulation of the afferent renal nerves may activate spinal and supraspinal pathways.[29,35,138,241] Electrical stimulation of the afferent renal nerves results in widespread decreases in efferent renal sympathetic nerve activity, including renal, cervical, and cardiac nerves, in association with decreases in arterial pressure.[232] A majority of the neurons in the ventral lateral medulla that decrease their activity in response to afferent renal nerve stimulation also respond to stimulation of the central portion of the aortic nerves, with a decrease in efferent renal sympathetic nerve activity.[232] These neurons are also responsive to inputs from the carotid sinus nerves.[254] In addition, activation of the afferent renal nerves alters the activity of vasopressin and oxytocin neurons in the paraventricular nucleus of hypothalamus in rats,[35] resulting in increases in arterial pressure and plasma vasopressin and oxytocin concentrations. These effects are abolished by prior denervation of the stimulated kidney.

The convergence of the afferent signals from the renal and carotid sinus nerves on neurons in several brain areas involved in cardiovascular control[26,82,247] provides an anatomical basis for possible interactions among the afferent signals deriving from various organs, including the kidney.

Two classes of renal sensory nerves have been identified neurophysiologically: renal mechanosensory nerves responding to stretch of the renal pelvic wall; and renal chemosensory nerves responding to renal ischemia and/or changes in the chemical environment of the renal interstitium. The electrophysiology of the renal sensory nerves has previously been reviewed extensively.[58,249] Isotonic saline volume expansion results in a differential activation of renal mechano- and chemosensitive nerves.[33] Whereas volume expansion increased the activity of mechanosensitive nerves, it decreased the activity of the chemosensitive nerves, type R2 chemoreceptors. Stretch is associated with an increase in muscle spindle cell membrane sodium permeability, resulting in an inward flux of sodium and depolarization.[121,217] The afferent renal nerve activity responses to increased renal pelvic pressure are reduced by renal pelvic administration of amiloride and lidocaine,[165,169] agents known to reduce sodium influx by different mechanisms. Conversely, inhibition of Na^+-K^+-ATPase by ouabain increases the afferent renal nerve activity response to increased renal pelvic pressure.[170] These studies suggest that changes in intracellular sodium concentration may modulate the responsiveness of renal pelvic mechanosensitive nerves.

RENORENAL REFLEXES

The identification of a reflex originating in one kidney and affecting contralateral renal function was first demonstrated in the early 1980s. In healthy normotensive animals, the afferent renal nerves were activated by increases in renal pelvic pressure of a magnitude ≥ 3 mmHg, commonly seen during high urine flow rate,[33,88,151] suggesting that the afferent renal nerves were tonically active in conditions of high-sodium diet and/or volume expansion. Supporting this argument were studies in anesthetized volume expanded rats showing that increases in ipsilateral urinary sodium excretion produced by total, i.e., efferent plus afferent, unilateral renal denervation were accompanied by decreases in contralateral urinary sodium excretion. The contralateral antinatriuresis was caused by increases in contralateral efferent renal sympathetic nerve activity; this is called a renorenal reflex response[39,60] (Figure 16.12). Because unilateral renal denervation results in an ipsilateral diuresis and natriuresis, total (ipsilateral plus contralateral) urine flow rate and urinary sodium excretion are unchanged. Thus, the afferent renal nerves exert tonic inhibitory effects on contralateral efferent renal sympathetic nerve activity.

Selective Afferent Renal Denervation: Dorsal Rhizotomy

The overall importance of the natriuretic inhibitory renorenal reflexes can be evaluated by selective bilateral afferent renal denervation produced by dorsal rhizotomy (DRX) at T_9-L_1. Cutting the dorsal roots from T_9-L_1 interrupts the afferent renal neural input to the central nervous system.[70] Both DRX and sham-DRX rats are able to establish external sodium balance on both a normal dietary sodium intake and a four-fold higher dietary sodium intake. However, this is achieved at markedly different levels of arterial pressure.[150] On a normal or low-sodium diet, the levels of mean arterial pressure are similar in DRX and sham-DRX rats.[126,150] However, the process of achieving external sodium balance while consuming an increased dietary sodium intake resulted in a mean arterial pressure in DRX rats

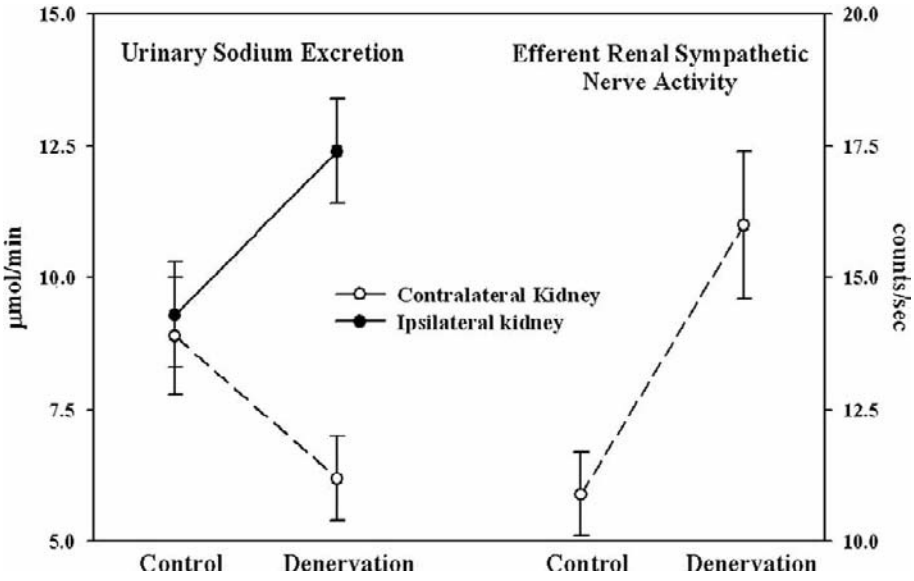

FIGURE 16.12 **In normotensive healthy rats, denervation of one kidney (ipsilateral kidney) results in increases in ipsilateral urinary sodium excretion, and decreases in contralateral urinary sodium excretion.** The decreases in contralateral urinary sodium excretion are the result of increases in contralateral efferent renal sympathetic nerve activity, i.e., the afferent renal nerves exert a tonic inhibition of sympathetic nerve activity to the contralateral kidney. *(Modified from ref. [58].)*

that was some 30 mmHg greater than that in sham-DRX rats[150] (Figure 16.13). These findings support the view that the afferent renal nerves are tonically active in high-sodium dietary conditions.[151] Thus, the afferent renal nerves are essential for achieving sodium balance during increased dietary sodium intake. Rats lacking intact afferent renal innervation can only achieve sodium balance at the cost of increased mean arterial pressure. Thus, afferent renal denervation leads to salt-sensitive hypertension. Among the mechanisms contributing to the development of salt-sensitive hypertension in DRX rats are increased efferent renal sympathetic nerve activity and increased responsiveness of efferent renal sympathetic nerves to various sympathetic stimuli due, at least in part, to impairment of the arterial baroreflex function.[164]

Wang and co-workers have presented evidence for salt-sensitive hypertension in rats neonatally treated with capsaicin to destroy the sensory innervation of all organs.[260] The salt-sensitive hypertension in DRX rats would suggest that the lack of intact afferent renal innervation in the capsaicin treated rats may contribute to the increased arterial pressure in these rats when fed a high-sodium diet.

Activation of Renal Mechanosensory Nerves: Physiological Conditions

The inhibitory nature of the afferent renal nerves in healthy normal rats has been further demonstrated in studies examining the functional responses to activation of the afferent renal nerves. The renal mechanosensory nerves respond to stretch of the smooth muscle layer in which many of the sensory nerves are embedded. Studies in cats showed that the increased urine flow rate produced by volume expansion resulted in parallel increases in renal pelvic pressure and afferent renal nerve activity.[88] Importantly, the activation threshold of the mechanosensory nerves was <5 mmHg above baseline pelvic pressure, suggesting that the renal pelvic mechanosensory nerves are activated by increases in renal pelvic pressure within the physiological range and below that required for sensation of pain. Studies to examine the mechanisms involved in the activation of the renal sensory nerves in the absence of changes in the renal circulation utilized a fluid-filled ureteral catheter elevated to different levels above the kidney. These studies, performed in rats, showed that graded increases in renal pelvic pressure resulted in graded increases in afferent renal nerve activity, with the activation threshold being between 3 to 5 mmHg,[170] i.e., a similar activation threshold as that produced by volume expansion. The increase in afferent renal nerve activity produced bilateral decreases in efferent renal sympathetic nerve activity and increases in urinary sodium excretion[166,169,187] (Figure 16.10). Ipsilateral renal denervation blocks the increases in urinary sodium excretion, demonstrating that stimulation of renal mechanosensory nerves activates an inhibitory bilateral renorenal reflex mechanism. The afferent renal nerves are not responsive to NaCl concentrations within the physiological range, as shown by lack of increases in afferent renal nerve activity in response to renal pelvic perfusion with NaCl at <900 mM.[170]

The natriuretic nature of the renorenal reflexes would suggest that this reflex mechanism contributes to total body sodium and fluid volume balance by assisting in the excretion of sodium and water. In this case, it would be expected that this reflex mechanism would be enhanced or upregulated during conditions

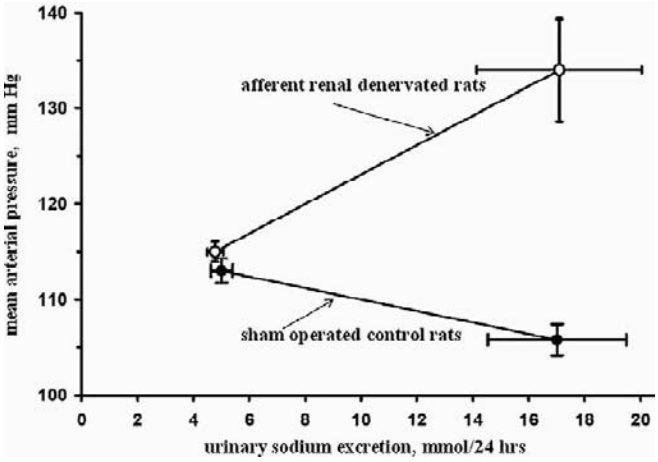

FIGURE 16.13 **Recording mean arterial pressure in conscious rats fed either normal or high-sodium diet for three weeks following dorsal rhizotomy at T_9-L_1 to remove the afferent renal innervation showed markedly elevated mean arterial pressure in the afferent renal denervated rats fed a high-sodium diet compared to the sham-operated litter mates.** Mean arterial pressure was similar in the two groups of rats fed normal sodium diet. Thus, afferent renal denervated rats are characterized by salt-sensitive hypertension. *(Modified from references [53,152]).*

of sodium and volume-loading. Indeed, studies examining the responsiveness of the renal mechanosensory nerves in rats fed various sodium diets showed that, in comparison to low-sodium dietary intake, high-sodium dietary intake enhances the renorenal reflex responses.[151] At every level of renal pelvic pressure, the increases in both afferent renal nerve activity and urinary sodium excretion were greater in rats fed high-sodium diet compared to rats fed low-sodium diet (Figure 16.14). Importantly, in rats fed high-sodium diet, the threshold of activation of the renal mechanosensory nerves was 2–3 mmHg, suggesting that the afferent renal nerves are tonically active in high-sodium dietary conditions.

Interaction between Efferent and Afferent Renal Nerve Activity

Not only is the renal pelvic wall innervated by afferent sensory nerves, but it is also innervated by efferent sympathetic nerves which are in close contact with the sensory nerves in the renal pelvic wall[157] (Figure 16.15). These findings provide anatomical support for a functional interaction between the efferent and afferent renal nerves. As discussed above in normotensive rats, activation of the afferent renal sensory nerves leads to decreases in efferent renal sympathetic nerve activity and natriuresis, an inhibitory renorenal reflex response.[166] However, not only do increases in afferent renal nerve activity decrease efferent renal sympathetic nerve activity, but increases in efferent renal sympathetic nerve activity increase afferent renal nerve activity[157,163,158] (Figure 16.16). The increased afferent renal nerve activity will, in turn, decrease efferent renal sympathetic nerve activity via activation of the renorenal reflexes, a negative feedback mechanism, to maintain low-level efferent renal sympathetic nerve activity (Figure 16.17). Similar to the responsiveness of the renal mechanosensory nerves being modulated by dietary sodium, the interaction between efferent renal sympathetic nerve activity and afferent renal nerve activity is also modulated by dietary sodium. Reflex increases in efferent renal sympathetic nerve activity results in much larger increases in afferent renal nerve activity in rats fed high-sodium diet than in rats fed low-sodium diet (Figure 16.14).

Thus, in high-sodium dietary conditions, the enhanced afferent renal nerve activity responses to increases in efferent renal sympathetic nerve activity and/or increases in renal pelvic pressure would lead to enhanced inhibitory renorenal reflex control of efferent renal sympathetic nerve activity to minimize sodium retention. Conversely, in low-sodium dietary conditions, the suppressed afferent renal nerve activity responses to increases in efferent renal sympathetic nerve activity and/or increases in renal pelvic pressure would result in little or no inhibition of efferent renal sympathetic nerve activity, which eventually would lead to sodium retention. It is important to note that these are physiologically appropriate responses to changes in dietary sodium in the overall goal of maintaining sodium balance.

Mechanisms Involved in Activation of Renal Mechanosensory Nerves

SUBSTANCE P

Substance P is produced in the neural cell bodies in the dorsal root ganglia and transported along the afferent nerves towards the peripheral nerve endings, where it is stored in vesicles and released in response to various stimuli. The presence of substance P-containing sensory nerves in the renal pelvic wall[156] (Figure 16.11) suggested a role for this neuropeptide in the activation of the renal sensory nerves. Single unit recordings of afferent renal nerve activity showed that the same single nerve fiber could be activated by increases in renal pelvic pressure and substance P administered directly into the renal pelvic area, suggesting an important role for substance P in the inhibitory renorenal reflex responses to increased renal pelvic pressure.[185] Substance P is released from the renal pelvic sensory nerves by a calcium (Ca^{2+})-dependent mechanism requiring influx of Ca_i^{2+} via N-type Ca_i^{2+} channels in response to prostaglandin E_2 (PGE_2),[146] a known activator of sensory neurons.[31,112,257]

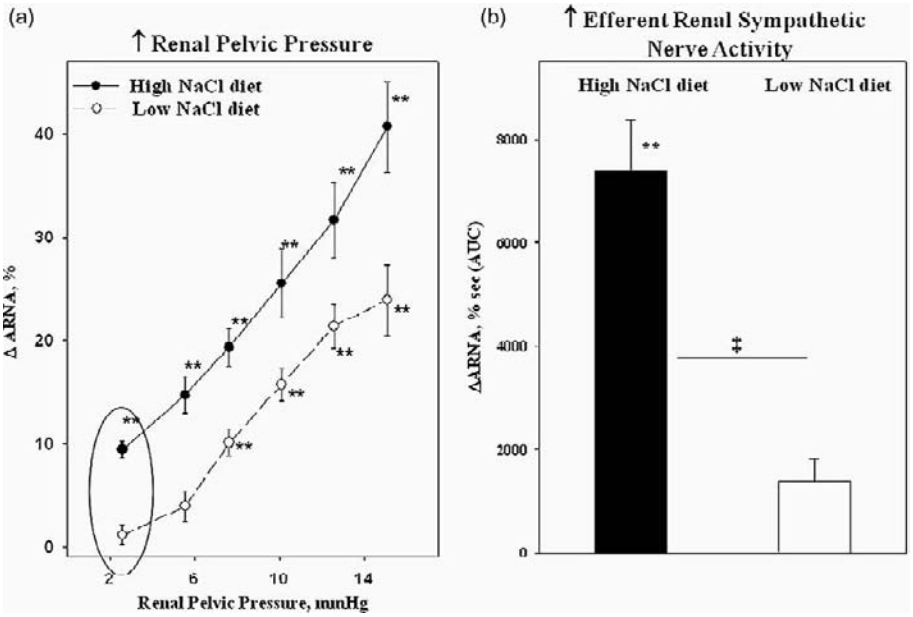

FIGURE 16.14 **High-sodium diet enhances the afferent renal nerve activity (ARNA) responses to increases in renal pelvic pressure (a) and reflex increases in efferent renal sympathetic nerve activity produced by thermal cutaneous stimulation (b).** The activation threshold for the renal mechanosensory nerves is 2–3 mmHg in rats fed high-sodium diet suggesting that the afferent renal nerves are tonically active in high-sodium dietary conditions. *(Modified from references [151,158].)*

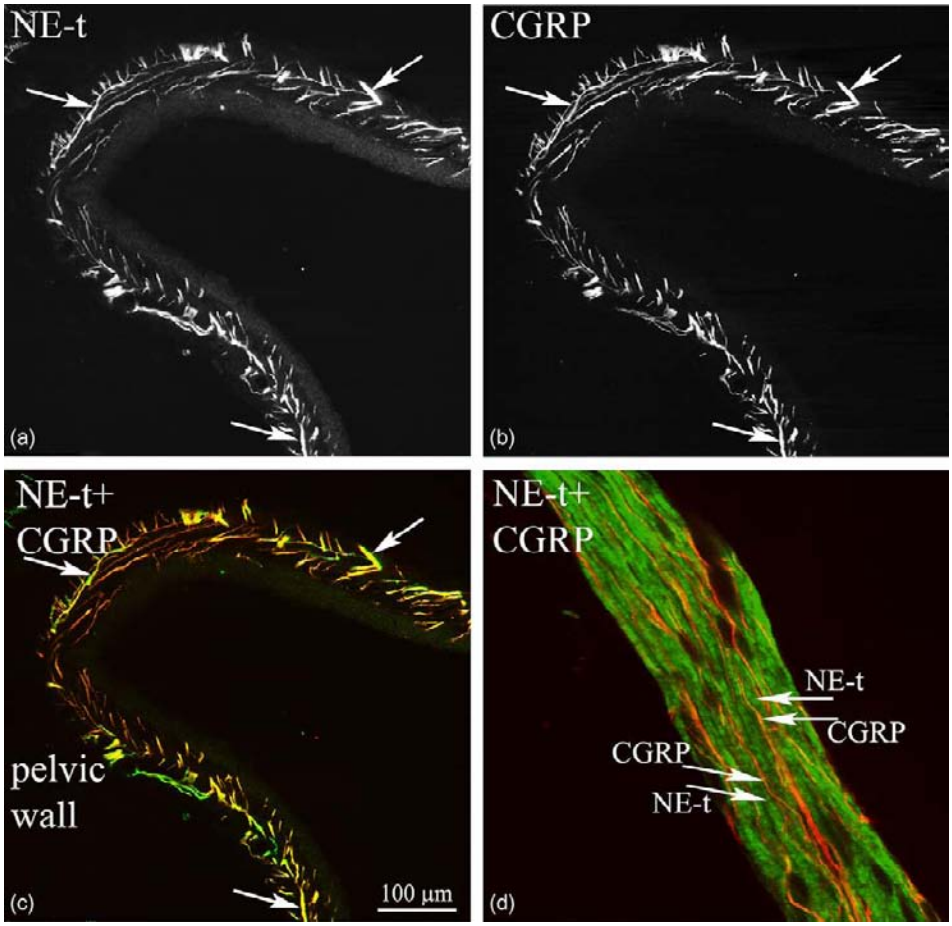

FIGURE 16.15 **Applying antibodies against the norepinephrine transporter (NE-t) and the neuropeptide calcitonin gene-related peptide (CGRP) to kidney tissue to identify sympathetic and sensory nerve fibers, respectively (arrows) showed that the sympathetic nerves in the renal pelvic wall (a); are in close contact with the sensory nerves (b); as indicated by the color yellow (c).** Higher magnification showed that the sympathetic and sensory nerves are separate fibers in close contact in the same nerve bundle (d). *(Modified from reference [157].)*

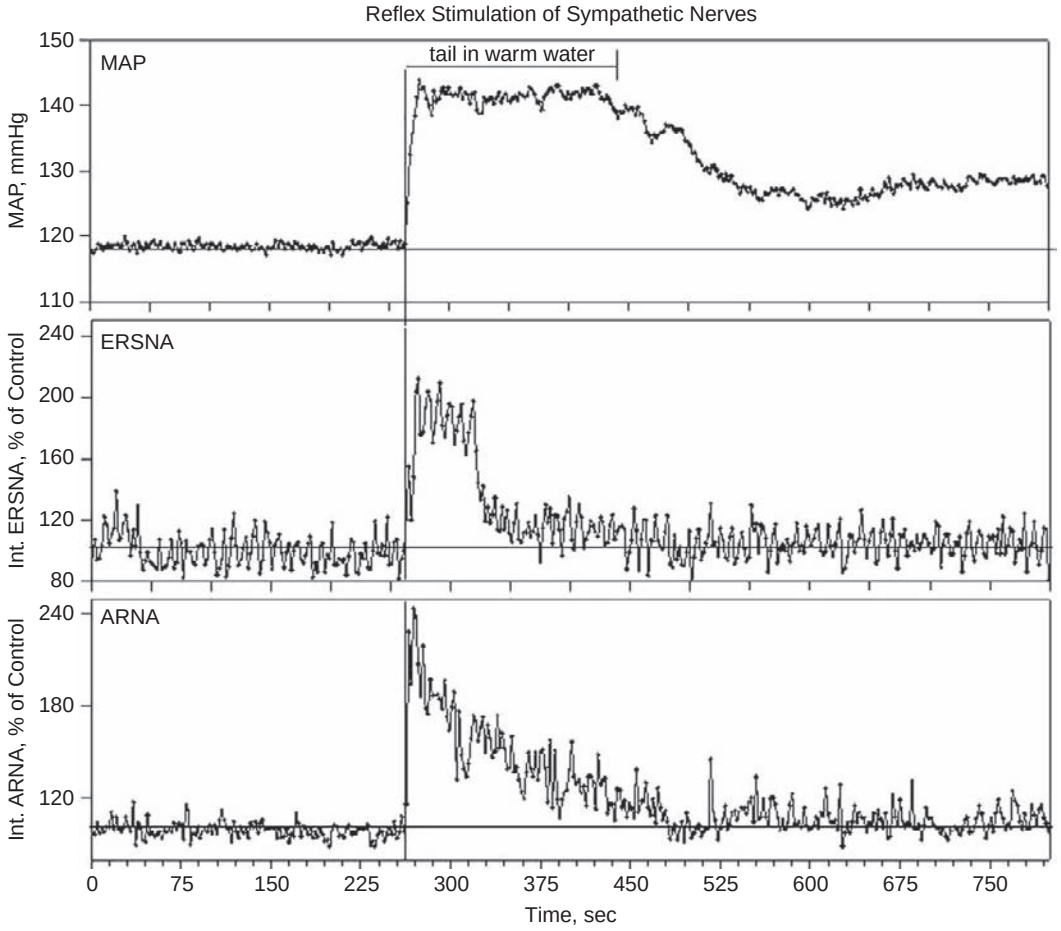

FIGURE 16.16 **Thermal cutaneous stimulation by placing the rat's tail in 47°C water results in a general increase in sympathetic nerve activity, as indicated by the increases in mean arterial pressure (MAP) and efferent renal sympathetic nerve activity (ERSNA).** The increases in ERSNA produced the increases in afferent renal nerve activity (ARNA), see text for further details. *(Modified from reference [157].)*

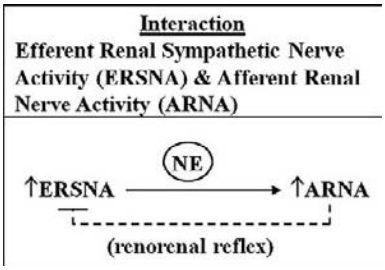

FIGURE 16.17 **There is a reciprocal interaction between efferent renal sympathetic nerve activity (ERSNA) and afferent renal nerve activity (ARNA).** Increases in ERSNA increase ARNA, the increase in ARNA would in turn decrease ERSNA via activation of the inhibitory renorenal reflexes in the overall goal of maintaining low ERSNA to minimize sodium retention. Norepinephrine (NE) is involved in the ERSNA-induced increase in ARNA.

Functional support for a role of substance P in the activation of renal pelvic sensory nerves is derived from *in vivo* studies showing that activation of renal mechanosensory nerves results in renal pelvic release of substance P.[155,161,162] Renal pelvic administration of substance P receptor antagonists abolishes the renorenal reflex responses to increased renal pelvic pressure.[167]

On the other hand, the role of CGRP in the activation of renal sensory nerves is unclear. Although CGRP is colocalized with substance P in the majority of the sensory nerves in the renal pelvic wall and released in response to stimuli that also release substance P,[154,156] blocking CGRP receptors does not reduce the responsiveness of the afferent renal nerves to various stimuli. Rather, available evidence would indicate that CGRP plays a role in delaying the catabolism of substance P, thereby prolonging the effects of neurally released substance P.[92,93]

There is considerable evidence for the transient receptor potential vanilloid type 1 (TRPV1) channels in the renal pelvic wall which, upon activation, elicits a similar inhibitory renorenal reflex response as activation of renal mechanosensory nerves. The TRPV1 channels are nonselective cation channels that can be activated by capsaicin, resiniferatoxin, noxious heat or a low pH. In the kidney,

activation of the TRPV1 channels by capsaicin or a capsaicin analog activates renal mechanosensory nerves resulting in increases in substance P release, afferent renal nerve activity, and a contralateral natriuresis. The physiological importance of the TRPV1 channels is currently not known, although it has been proposed that they serve as an integral part of the mechanosensory nerve complex.[84,280]

PROSTAGLANDIN E_2 (PGE_2)

There is considerable evidence for prostaglandins (PGs) enhancing the responsiveness of various sensory nerve fibers.[208,219] The kidney, especially the renal medulla, is an active PG-producing tissue.[23] A role for PGs in renal sensory receptor activation by reduced renal perfusion pressure was demonstrated by the finding that PG synthesis inhibition reduced the afferent renal nerve activity and reflex pressor responses to reduction in renal blood flow.[11,80]

Stretching the renal pelvic wall leads to activation of protein kinase C (PKC) via activation of bradykinin 2 (B2) receptors (*vide infra*) and induction of cyclooxygenase-2 (COX-2) mRNA in the renal pelvic wall, with a resultant increase in renal pelvic release of PGE_2[146,147,154,162] (Figure 16.18). PGE receptors have been classified into four general subtypes, EP1, EP2, EP3, and EP4, based on cloning and pharmacological interventions.[20] Immunohistochemical studies together with functional studies have provided evidence for a role of EP4 receptors in the activation of renal pelvic mechanosensory nerves.[147] It is well-established that PGE_2 activates the cAMP-protein kinase A (PKA) transduction cascade in DRG neurons, leading to depolarization of the cell membrane and a release of substance P and CGRP.[73,209,245] Using various activators and inhibitors of cAMP and PKA it was shown that PGE_2 increased the release of substance P and stimulated renal mechanosensory nerves by activating the cAMP/PKA transduction cascade in renal pelvic tissue.[154]

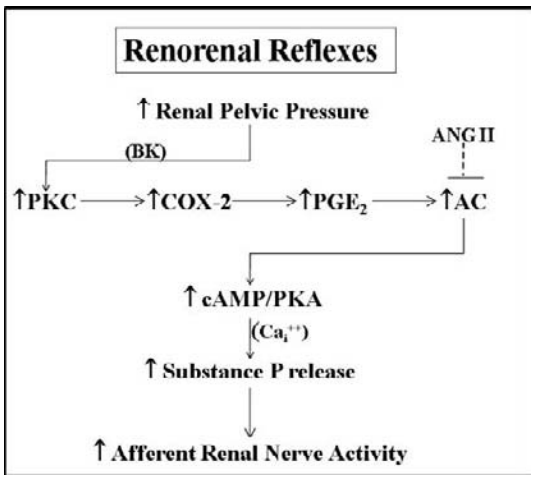

FIGURE 16.18 **Mechanisms involved in the activation of renal mechanosensory nerves. Stretching the renal pelvic wall by increasing renal pelvic pressure activates bradykinin (BK) 2 receptors, leading to activation of protein kinase C (PKC) and induction of cycloxygenase-2 (COX-2) with a resultant increase in renal pelvic release of PGE_2.** PGE_2 activates EP4 receptors on/close to the renal sensory nerves which leads to activation of adenylyl cyclase (AC)/cAMP/protein kinase A (PKA) transduction pathway, resulting in a calcium-dependent release of substance P and increases in afferent renal nerve activity. In conditions of increased endogenous angiotensin (ANG) II activity, e.g., low-sodium diet, the responsiveness of the renal mechanosensory nerves is suppressed due to ANG II reducing the PGE_2-mediated activation of AC by a pertussis toxin sensitive mechanism. *(Data derived from references [146,147,151,154,162].)*

ANGIOTENSIN II

In normal rats, low-sodium diet reduces the responsiveness of renal mechanosensory nerves,[151] i.e., similar to the well-known reduced responsiveness of carotid baroreceptors in healthy low-sodium diet rats.[57,117] The reduced afferent renal nerve activity response to increased renal pelvic pressure in low-sodium diet rats was associated with impaired PGE_2-mediated release of substance P from the isolated renal pelvic wall preparation. These data suggested that the reduced responsiveness of the renal sensory nerves was, at least in part, due to a mechanism at the peripheral sensory nerve endings.

A low-sodium diet is characterized by increased activity of the renin–angiotensin system.[56–58] Angiotensin II present in the renal pelvic wall is modulated by dietary sodium.[149] Renal pelvic administration of angiotensin II reduces, and renal pelvic administration of the AT1 receptor antagonist losartan enhances, the PGE_2-mediated release of substance P and activation of renal mechanosensory nerves.[151] Because the effects of losartan on the PGE_2-mediated release of substance P were observed in response to acute administration of losartan to an isolated renal pelvic wall preparation, these data suggest that endogenous angiotensin II exerts its inhibitory effect on renal mechanosensory nerves by a mechanism at the peripheral renal sensory nerve endings. Further studies showed that endogenous angiotensin II in the renal pelvic tissue reduces the responsiveness of the renal sensory nerves by suppressing the PGE_2-mediated activation of cAMP by a pertussis toxin sensitive mechanism[149] (Figure 16.18).

ALPHA-ADRENOCEPTORS

The increases in afferent renal nerve activity produced by reflex increases in efferent renal sympathetic nerve activity are reduced by renal pelvic administration of prazosin, an α_1-adrenoceptor antagonist, and enhanced by rauwolscine, an α_2-adrenoceptor antagonist[157] in rats fed normal-sodium diet, demonstrating that changes in

efferent renal sympathetic nerve activity modulate afferent renal nerve activity by the release of norepinephrine (Figure 16.17). The presence of α_1-adrenoceptors on the renal sensory nerves modulating their activation was demonstrated in an isolated renal pelvic wall preparation. These studies showed that norepinephrine resulted in a release of substance P that was blocked by prazosin and dependent on intact renal PG synthesis. Prazosin reduced the norepinephrine-induced release of PGE_2. Taken together these findings suggest that increases in efferent renal sympathetic nerve activity increases the release of norepinephrine which activates α_1-adrenoceptors on or close to the renal sensory nerves, resulting in increases in PGE_2 synthesis leading to release of substance P and increases in afferent renal nerve activity.

Similar to the responsiveness of the renal mechanosensory nerves being modulated by dietary sodium, the interaction between efferent renal sympathetic nerve activity and afferent renal nerve activity is also modulated by dietary sodium. Examining the mechanisms involved in the reduced responsiveness of the renal sensory nerves to increases in efferent renal sympathetic nerve activity in rats fed low-sodium diet it became clear that renal pelvic administration of losartan alone failed to enhance the efferent renal sympathetic nerve activity-induced increase in afferent renal nerve activity or the norepinephrine-induced increase in substance P. These findings suggested that the impaired responsiveness of the renal sensory nerves to increases in efferent renal sympathetic nerve activity may involve additional mechanisms upstream of PGE_2. Because activation of renal pelvic α_2-adrenoceptors reduces the activation of renal sensory nerves in rats fed normal-sodium diet,[157] one of the mechanisms contributing to the suppressed responsiveness of the renal sensory nerves in low-sodium diet rats likely involved increased activation of renal α_2-adrenoceptors. The involvement of α_2-adrenoceptors in the central nervous system in the cardiovascular regulation has long been known.[224,226] Of the three subtypes of α_2-adrenoceptors, the $\alpha^2{}_A$- and $\alpha^2{}_C$-adrenoceptors are expressed on primary afferent neurons in the spinal cord and DRG.[237,238] Whether α_{2B}-adrenoceptors are also expressed on DRG is not clear.[34,91,238] In the kidney, α_{2A}- and α_{2C}-adrenoceptors are localized on or close to sensory nerve fibers in the renal pelvic wall[158] (Figure 16.19). A role for increased activation of these receptors in the suppressed responsiveness of the renal sensory nerves to increases in efferent renal sympathetic nerve activity was subsequently shown by studies which showed that a combination of losartan plus rauwolscine enhanced the responsiveness of the renal sensory nerves to norepinephrine towards that seen in high-sodium diet rats.[158] Importantly, rauwolscine has no effect in rats fed a high-sodium diet.

Taken together in low-sodium dietary conditions, increased activation of α_2-adrenoceptors together with increased endogenous angiotensin II activity suppress the norepinephrine-mediated activation of the renal sensory nerves. The consequence is decreased PG synthesis and reduced PGE_2-mediated activation of the adenylyl cyclase/cAMP/PKA transduction pathway, leading to little or no increase in substance P release, and afferent renal nerve activity, and thereby no inhibition of efferent renal sympathetic nerve activity. In high-sodium dietary conditions, the enhanced norepinephrine-mediated activation of renal sensory nerves is due, at least in part, to little or no activation of renal α_2-adrenoceptors and very low endogenous angiotensin II opposing the norepinephrine-mediated increase in afferent renal nerve activity which will eventually lead to renorenal reflex decreases in efferent renal sympathetic nerve activity (Figure 16.20).

BRADYKININ

Among the various mechanisms involved in the release of substance P and activation of renal mechanosensory nerves is bradykinin (*vide supra*). Bradykinin is a well-known activator of sensory nerve fibers.[89] Bradykinin receptors have been localized on sensory nerve fibers[250] and in the lamina propria of the tissue lining the pelvis.[193] Bradykinin increases afferent renal nerve activity when administered into the renal pelvis in association with an increased renal pelvic release of PGE_2 and substance P, and a contralateral natriuresis. B2 receptor antagonists block the renorenal reflex responses to either bradykinin *per se* or increases in renal pelvic pressure.[161,162] Interestingly, the responses to bradykinin are dependent on the route of administration. In contrast to the inhibitory reflex response elicited by renal pelvic administration of bradykinin,[161,162] administration of bradykinin into the renal artery (i.r.a.) elicits an excitatory reflex which includes activation of neurosecretory vasopressin cells in the supraoptic nucleus,[47] increases in plasma ADH concentration, and increased arterial pressure and vascular resistance in most circulatory beds.[246] The sympatho-excitatory effects of i.r.a. bradykinin were due to activation of afferent renal nerves since they were abolished by denervation of the infused kidney. This reflex has been suggested to be of importance during renal ischemia, which is likely to be associated with increased release of bradykinin.

These findings suggest that bradykinin activates different reflex pathways, one excitatory and one inhibitory, when administered into the renal artery and pelvis, respectively. The physiological or pathophysiological significance of these different reflexes is currently not known.

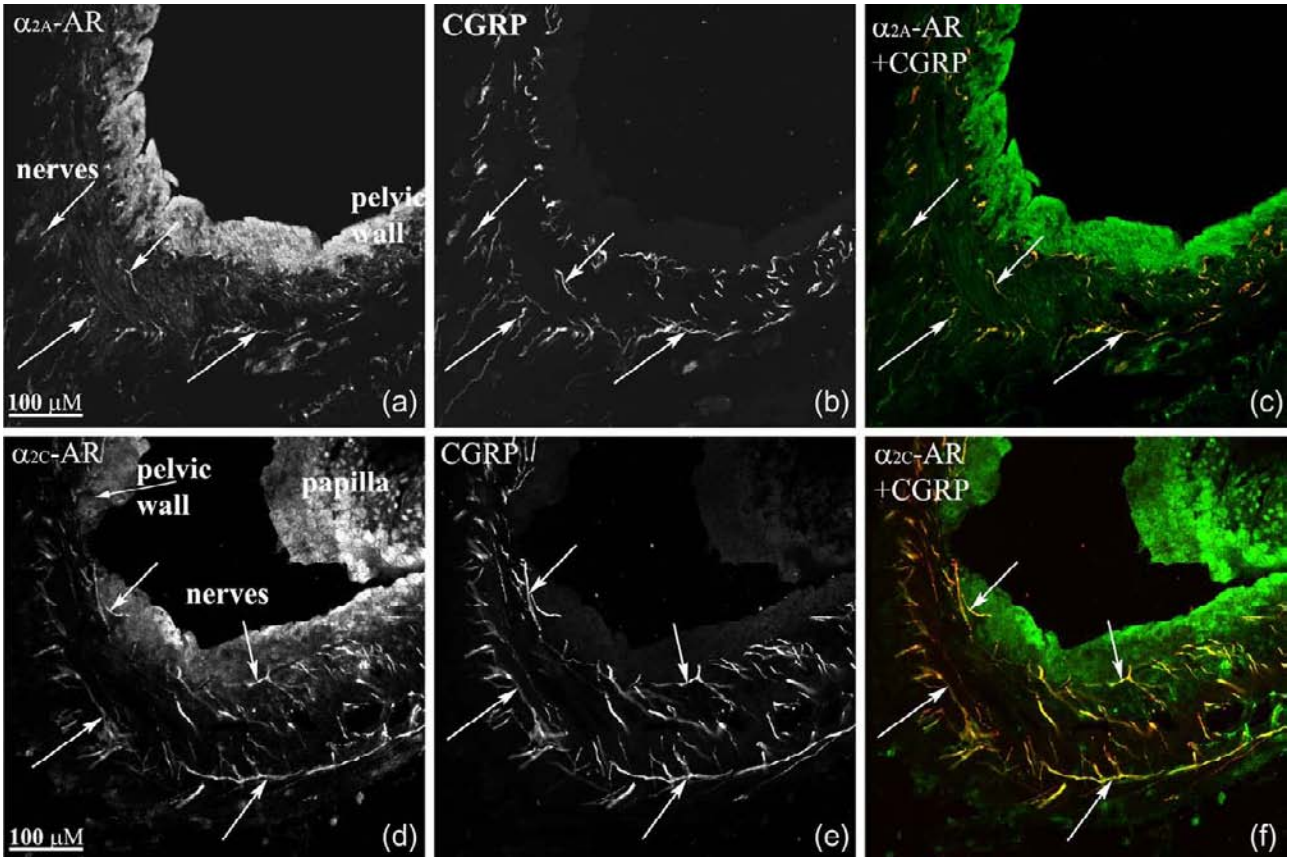

FIGURE 16.19 **Applying antibodies against α_{2A}-adrenoceptors (AR) (a) and α_{2C}-(AR) (d) labels nerve fibers (arrows) in the renal pelvic wall that are also labeled with an antibody against CGRP, a marker for sensory nerve fibers (b,e) as shown by the color yellow in (c) and (f).** *(Reference [158].)*

ENDOTHELIN

Endothelin is abundantly expressed throughout the body, including the brain and the kidney.[106] Endothelin exerts its effects by activating two G-protein coupled receptors, endothelin-A (ETA) and endothelin-B (ETB) receptors.[230] Both ETA and ETB receptors are localized in the renal pelvic wall, the ETA receptors on smooth muscle cells and the ETB receptors on or close to the afferent renal sensory nerves,[163] suggesting a role for endothelin in modulating the activation of afferent renal sensory nerves. Studies examining the role of endothelin in the activation of afferent renal sensory nerves by increased renal pelvic pressure or reflex increases in efferent renal sympathetic nerve activity suggested an important role for endothelin in modulating the responsiveness of the renal sensory nerves. The nature of the endothelin-induced activation of the afferent renal sensory nerves is dependent on dietary sodium intake.[163] In low-sodium dietary conditions, activation of ETA-receptors contributes to the suppressed responsiveness of the renal sensory nerves, whereas in high-sodium dietary conditions activation of ETB-receptors plays a major role in the enhanced responsiveness of the renal sensory nerves. These findings are of interest in view of the well-documented hypertension in ETB-receptor deficient rats and mice fed high-sodium diets.[87,227] Together, these studies may suggest that impairment of the inhibitory renorenal reflexes contributes to the salt-sensitive hypertension in conditions of renal ETB-receptor deficiency. Further support for this hypothesis is derived from studies in rats treated neonatally with capsaicin to destroy all sensory nerves.[274] These rats develop salt-sensitive hypertension which is reduced by ETA receptor antagonists in a similar fashion to that seen in ETB receptor deficient rats.[87,227]

The similar effects of an ETA-receptor antagonist and an AT1-receptor antagonist in low-sodium diet rats to restore the suppressed activation of renal sensory nerves towards that seen in rats fed normal-sodium diet[151,163] suggested an interaction between angiotensin II and endothelin. Comparing the effects of inhibitors of ETA-receptors and AT-1 receptors on the responses to activation of the renal mechanosensory nerves showed that ETA receptors play an important contributory role to the angiotensin II-induced

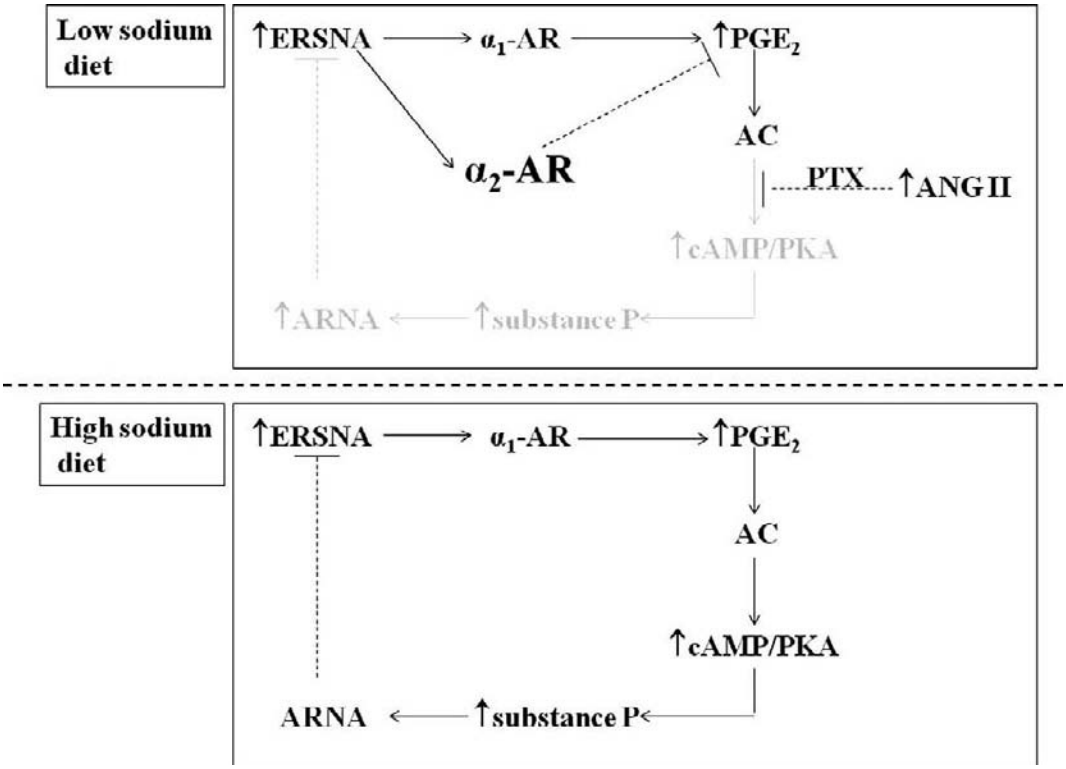

FIGURE 16.20 **In low-sodium dietary conditions, increased activation of α_2-adrenoceptor (AR) together with increased endogenous angiotensin (ANG) II activity suppresses the norepinephrine-mediated activation of the renal sensory nerves by decreasing PG synthesis, leading to reduced PGE_2-mediated activation of adenylyl/cAMP/PKA transduction pathway resulting in little or no increase in substance P release and increase in afferent renal nerve activity, and thereby no inhibition of efferent renal sympathetic nerve activity (ERSNA).** In high-sodium dietary conditions, the enhanced norepinephrine-mediated activation of renal sensory nerves is due, at least in part, to little or no activation of renal α_2-AR and very low endogenous ANG II activity opposing the norepinephrine-mediated increase in PGE_2 synthesis, substance P release, and increase in afferent renal nerve activity, leading to renorenal reflex decreases in ERSNA. Modulation of the interaction between efferent and afferent renal nerve activity is an appropriate physiological response to changes in dietary sodium intake in the overall goal of maintaining water and sodium balance.

suppression of the responsiveness of the afferent renal mechanosensory nerves[148] in low-sodium diet rats. These findings are supported by the considerable evidence showing that angiotensin II increases the expression of preproendothelin-1 mRNA in various tissues, including the kidney and urinary bladder,[123] increases endothelin-1 protein expression and secretion in vascular smooth muscle cells, cardiomyocytes and mesangial cells,[125,140,271] and increases ETA expression in cardiomyocytes.[125]

Activation of Renal Mechanosensory Nerves: Pathohysiological Conditions

Impairment of the Inhibitory Renorenal Reflexes in Various Diseases

Activation of the renal mechanosensory nerves is impaired in various pathological conditions of increased efferent renal sympathetic nerve activity and sodium retention, including congestive heart failure, spontaneous hypertension, diabetes type I, ischemia-induced acute renal failure, obstructive nephropathy, cirrhosis, and chronic hypoxia.[32,33,145,152,153,159,168,185–187] Impairment of the inhibitory renorenal reflexes in pathological conditions would aggravate and/or contribute to further increases in efferent renal sympathetic nerve activity and sodium retention. Many of these pathological conditions are characterized by increased angiotensin II activity. Importantly, renal pelvic administration of an AT-1 receptor antagonist has been shown to markedly improve the responsiveness of the renal mechanosensory nerves in rats with congestive heart failure, hypertension, and diabetes type I.[145,153,159] The marked enhancement of the renorenal reflex mechanism produced by AT1 receptor antagonists may contribute to the well-known beneficial effects of inhibiting the renin–angiotensin system in heart failure and hypertension.

In addition to the impaired responsiveness of the renal mechanosensory nerves in spontaneous hypertensive rats, the interaction between efferent renal sympathetic nerve activity and afferent renal nerve

activity is also impaired. The impaired interaction between efferent renal sympathetic nerve activity and afferent renal nerve activity is related to increased activation of renal pelvic α_2-adrenoceptors, in addition to increased activation of AT-1 receptors,[152] i.e., similar mechanisms as those contributing to the suppressed responsiveness of the renal sensory nerves in low-sodium diet rats.

Excitatory Reflexes Originating in Injured/Diseased Kidneys

The depressor effects of (T_9–L_1)DRX observed in rats with one-kidney, one-clip hypertension,[137] 5/6 nephrectomy,[28] and in rats exposed to i.v. infusion of cyclosporine[184] would appear to contradict the notion of the afferent renal nerves exerting a tonic inhibitory effect on efferent renal sympathetic nerve activity. However, it is likely that different mechanisms are involved in the activation of renal sensory nerves in normal and diseased kidneys. Whereas in normal kidneys activation of renal sensory nerves elicits inhibitory renorenal reflexes (*vide supra*), in diseased kidneys when the inhibitory renorenal reflexes are impaired, activation of renal sensory nerves may result in excitatory reflexes. Studies in 2-kidney 1-clip rats would support this notion. The responsiveness of the renal mechanosensory nerves in the clipped ischemic kidney is impaired.[144] Interestingly, renal denervation of the clipped kidney increased urinary sodium excretion from both the clipped and the contralateral non-clipped kidney, which is in contrast to the findings in normal healthy rats in which unilateral renal denervation decreases contralateral urinary sodium excretion.[39,60] In 2-kidney 1-clip rats, the contralateral natriuretic response was associated with decreases in contralateral efferent renal sympathetic nerve activity, suggesting that the balance between inhibitory and excitatory reflexes originating in the kidney was shifted from mainly being of an inhibitory nature to being of an excitatory nature in ischemic kidneys.[144] Thus, these data suggest that the afferent renal nerves in the ischemic kidney exert an excitatory influence on the sympathetic nervous system, in contrast to the inhibitory reflexes originating from normal healthy kidneys.[39,60] Further support for excitatory reflexes originating in an ischemic kidney derives from long-term blood pressure recordings in conscious rats following the onset of hypertension in 2-kidney 1-clip hypertension rats. Whereas renal denervation of the clipped kidney (six weeks after renal artery clipping) reduced arterial pressure almost to the same level as removing the clip from the renal artery, denervation of the contralateral non-clipped kidney had no effect on arterial pressure.[136] Further studies suggested an important role for adenosine in the excitatory reflexes originating in the ischemic kidneys. Intrarenal administration of adenosine deaminase reduced arterial pressure in 1-kidney 1-clip hypertensive rats, but had no effect in healthy normal rats.[134] Also, administration of adenosine into one renal artery resulted in increases in contralateral efferent renal sympathetic nerve activity and arterial pressure which were abolished by renal denervation of the infused kidney in healthy dogs.[135] Taken together, these studies suggest that excitatory reflexes originating in ischemic kidneys involve adenosine activating chemosensitive afferent renal nerves.

Further evidence for excitatory reflexes originating in diseased/injured kidneys is derived from studies in humans and rats with renal failure. Comparing arterial blood pressure and muscle sympathetic nerve activity in hemodialysis patients with and without their native diseased kidneys intact showed markedly reduced arterial pressure and muscle sympathetic nerve activity in patients with bilateral nephrectomy compared with patients who had their kidneys intact.[40] These findings were subsequently confirmed and extended in studies comparing arterial pressure and muscle sympathetic nerve activity in patients with kidney transplants, with and without their native kidneys intact.[104] None of the patients were uremic, thus they all had well-functioning renal grafts. However, muscle sympathetic nerve activity was increased in all patients versus healthy controls, except in the patients in which bilateral nephrectomy had been performed. In a subgroup of transplant patients, muscle sympathetic nerve activity was measured before and after the second kidney was removed, and was found to be reduced following removal of the second diseased kidney. Thus, these studies provide strong evidence for the diseased kidneys exerting an excitatory effect on sympathetic nerve activity. Studies in rats with chronic renal failure would support the notion that excitatory effects exerted by the diseased kidneys are related to activation of the afferent renal nerves in the diseased/injured kidney.[28] These rat studies showed that chronic renal failure increased arterial pressure and norepinephrine turnover in posterior hypothalamus and locus coeruleus. Importantly, prior dorsal rhizotomy to remove the afferent renal innervation prevented the increases in arterial pressure and norepinephrine turnover in the various brain regions.

Thus, local renal injury may result in sympathoexcitatory reflexes involving afferent renal nerves, central cardiovascular regulatory areas, and efferent systemic and renal sympathetic nerve activity, eventually leading to hypertension.

The notion of excitatory reflexes originating in diseased/injured kidney may provide an explanation to the marked prolonged decrease in arterial pressure in drug-resistant hypertensive patients following the one-time renal denervation procedure.[53,77,173] The reduction in arterial pressure following renal denervation is

associated with reduction in whole body norepinephrine spillover and reduction in muscle sympathetic nerve activity, indicative of removal of excitatory reflexes originating in the kidneys.

SUMMARY

The efferent renal sympathetic and afferent renal nerves constitute a significant control system for the physiological regulation of renal function. Efferent renal sympathetic nerve activity is governed by a centrally-based reflex control system which responds to diverse peripheral and central afferent inputs. The kidney is densely innervated by sympathetic nerves, including the renal vasculature, the nephron, the juxtaglomerular cells, and the renal pelvic wall, enabling the renal nerves to contribute to one of the major tasks of the kidney, the homeostatic regulation of body fluid volume.

Activation of the afferent renal nerves located in the renal pelvic wall leads to decreases in efferent renal sympathetic nerve activity and increases in urinary sodium excretion, a renorenal reflex response. Changes in efferent renal sympathetic nerve activity modulate the responsiveness of the renal sensory nerves. Increases in efferent renal sympathetic nerve activity increase afferent renal nerve activity. The increased afferent renal nerve activity will, in turn, decrease efferent renal sympathetic nerve activity via activation of the renorenal reflexes, a negative feedback mechanism, to maintain low-level efferent renal sympathetic nerve activity. Thus, there is an interaction between efferent renal sympathetic nerve activity and afferent renal nerve activity in the renal neural control of body fluid and sodium homeostasis wherein activation of the afferent renal nerves buffers the antinatriuretic effects of increases in efferent renal sympathetic nerve activity. This is most clearly evident in conditions of high-sodium dietary intake, when the afferent renal nerves are tonically active to suppress efferent renal sympathetic nerve activity to minimize sodium retention. Conversely, in low-sodium dietary conditions when increased efferent renal sympathetic nerve activity is essential for maintaining sodium balance, the activity of the afferent renal nerves are suppressed.

In pathophysiological sodium-retaining states, efferent renal sympathetic nerve activity is inappropriately increased in the presence of sodium retention. It has long been known that impairment of the aortic and arterial baroreflexes contributes to the inappropriately increased efferent renal sympathetic nerve activity in these pathological conditions. What has previously been overlooked is an impairment of reflexes originating in the kidneys, *per se*. However, there is now convincing evidence that impairment of the inhibitory renorenal reflexes contributes to the increased efferent renal sympathetic nerve activity and sodium retention prevalent in hypertension and various disease models of sodium retention. In conditions of renal injury/disease, available data would suggest that there is a shift from inhibitory to excitatory renorenal reflexes which would contribute to the increased efferent renal sympathetic nerve activity, leading to increased sodium retention and arterial pressure prevalent in these pathophysiological conditions.

CHAPTER

17

Eicosanoids and Renal Function

Matthew D. Breyer[1], *Raymond C Harris*[2] *and Richard M. Breyer*[2]

[1]Biotechnology Discovery Research Eli Lilly and Company Indianapolis, IN, USA

[2]Division of Nephrology, Department of Medicine, Vanderbilt University, Nashville, TN, USA

Perhaps nothing underscores the special relationship between the kidney and the eicosanoids better than the profound clinical effects non-steroidal anti-inflammatory drugs (NSAIDS) have on kidney function. NSAIDs are widely used to treat pain and inflammatory diseases, and work by blocking the enzymatic synthesis of prostaglandins, a type of eicosanoid, from arachidonic acid. However, chronic NSAID use is often complicated by major side effects, including renal sodium retention, resulting in edema, hypertension, and congestive heart failure.[1,2] Conversely, in the sodium depleted state, NSAIDs can reduce renal blood flow, glomerular filtration rate, and cause acute renal failure.[3–5] These observations underscore the critical role cyclooxygenase-derived arachidonic acid metabolites play in maintaining normal kidney function – particularly in the setting of physiological stress.

CELLULAR ORIGIN OF EICOSANOIDS

Eicosanoids are a family of biologically active, oxygenated metabolites derived from arachidonic acid (AA). AA is comprised of 20 carbon atoms configured as a polyunsaturated fatty acid chain with four double bonds (C20:4). Mammals lack the enzymatic machinery to synthesize AA *de novo*, instead it must be formed from dietary linoleic acid (C18:2) by addition of two carbons and further desaturation.[6,7] Essential fatty acid (EFA) deficiency occurs in the absence of dietary linoleic and other fatty acid AA precursors, depleting the hormone-responsive pool of AA metabolite products.[8,9] Of the approximate 10 gm of linoleic acid ingested per day, only about 1 mg/day is eliminated as end products of AA metabolism.[10–12] Following its formation, AA is esterified into cell membrane phospholipids, principally at the 2 position of the phosphatidylinositol fraction (i.e., sn-2 esterified AA). This source comprises the major hormone-sensitive pool of AA that is susceptible to release by phospholipases.

Phospholipase-Mediated Arachidonic Acid Release

Multiple stimuli lead to release of membrane-phospholipid esterified AA via activation of cellular phospholipases, principally phospholipase A2s (PLA_2).[13,14] This cleavage step is rate-limiting in the production of arachidonate metabolites. Activation of phospholipase C or PLD, on the other hand, releases AA via the sequential action of the phospholipase C-mediated production of diacylglycerol (DAG), with subsequent release of AA from DAG by DAG lipase.[15] The physiological significance of AA release by these other phospholipases remains uncertain since, at least in the setting of inflammation, phospholipase A_2 action appears to be essential for the generation of biologically active AA metabolites.[16] Cellular levels of free arachidonic acid available for eicosanoid production are primarily controlled by phospholipase A2 (PLA2).[16–18] So far, more than 30 enzymes with PLA_2 activity have been identified, and have been classified into four groups: secretory PLA_2 (sPLA2); cytosolic PLA2 (cPLA2); calcium-independent PLA2 (iPLA2); and PAF acetylhydrolases (PAF-AH).[14,19] The activity of cPLA2 is regulated by diverse cell membrane receptors, including the EGF receptor, and transmembrane guanine-nucleotide protein coupled (GPCRs) including adrenergic receptors, angiotensin II receptors, and purinergic receptors.[20–25] These receptors activate guanine nucleotide-binding (G) proteins, leading to PLA_2-mediated release of AA from membrane phospholipids.[20,26,27] Alternatively, these receptors may

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00017-3

activate cPLA$_2$ via mitogen-activated protein kinases (MAPK), protein kinase C (PKC), and Ca^{2+}-calmodulin-dependent kinases.

Ambient physical conditions in the kidney including hypoxia, oxidative stress, and mechanical stretch can also activate PLA$_2$ activity.[28–32] Dysregulated renal PLA$_2$ activity with attendant change in AA release results in altered substrate availability for the production of downstream metabolic products. This activation is believed to contribute to pathologic processes including acute kidney injury, diabetic nephropathy, and inflammatory glomerulonephritis.[33–35] Some snake and bee venoms are imbued with high levels of secretory PLA$_2$ activity and, in part through this activity, can induce acute renal failure[36,37]. A role for secretory PLA$_2$ in the pathogenesis of acute ischemic-reperfusion renal injury has also been supported by studies showing that sPLA$_2$ neutralizing antibodies protect rats from this form of injury.[36,38]

Phospholipase A2 Receptors

Recently, an important role for a transmembrane cell surface secretory PLA$_2$ receptor (PLA$_2$R) has been recognized in the pathogenesis of human idiopathic membranous nephropathy.[39] Auto-antibodies to PLA$_2$R are detected in ~70% of cases of human idiopathic membranous nephropathy.[39] The antigen appears to be selectively expressed in podocytes[39]; however, the mechanism by which the auto-antibodies induce proteinuria and how these auto-antibodies arise remains to be determined. PLA$_2$R is a type I transmembrane receptor and one of four mammalian members of the mannose-receptor family.[40] PLA$_2$R was initially identified as a binding protein for secreted phospholipase A$_2$ (PLA$_2$) that now has been expanded to a PLA$_2$R family that exhibit different affinities for the secreted PLA$_2$.[41] New studies suggest these receptors could play additional transmembrane signaling roles, and may promote terminal cell differentiation and mitotic arrest.[42]

Arachidonic Acid Metabolism

Following its release from membrane phospholipids, AA is usually rapidly re-esterified into the membrane or avidly bound by intracellular proteins, becoming unavailable for further metabolism. Should AA escape re-esterification and protein binding, it may be metabolized through one of three major enzymatic transformations, the common result of which is the incorporation of oxygen atoms at various sites of the fatty acid backbone, with accompanying changes in its molecular structure (such as ring formation). This results in the formation of biologically active molecules, collectively referred to as "eicosanoids." The specific nature of the products generated is a function of the initial stimuli for AA release, as well as the metabolic enzymes available, as determined by the cell type involved.[43,44]

Enyzmes capable of mediating AA metabolism through all three known pathways are present in the kidney, including cyclooxygenases 1 and 2, lipoxygenases, and cytochrome P450s (Figure 17.1). Cyclooxygenase (COX, also called Prostaglandin H2 synthase or PGHS)-mediated AA metabolism comprises the first committed step in the formation of prostaglandins (PGs), prostacyclin, and thromboxane.[45] The lipoxygenase pathway mediates the formation of mono-, di-, and trihydroxyeicosatetraenoic acids (HETEs), leukotrienes (LTs), and lipoxins (LXs),[46,47] and the cytochrome P450-dependent oxygenation of AA mediates the formation of epoxyeicosatrienoic acids (EETs), their corresponding diols, HETEs, and monooxygenated AA derivatives.[48–50] Fish oil diets, rich in *n-3* polyunsaturated fatty acids (*n-3* fatty acids are those in which the double bond is three carbons from the terminal, i.e., *n* carbon, that is furthest from the carboxy-group atom, AA is thus an n-6 fatty acid) interfere with metabolism via all three pathways by competing with AA oxygenation, resulting in the formation of biologically inactive end-products.[51,52] Interference with the production of pro-inflammatory lipids has been hypothesized to underlie the beneficial effects of fish-oil in IgA nephropathy, membranous nephropathy, and other cardiovascular diseases.[7,53,54]

CYCLOOXYGENASE DERIVED PROSTANOIDS

Prostanoids, including the prostaglandins PGE$_2$, PGF$_{2\alpha}$, and PGD$_2$, as well as the non-prostaglandin molecules thromboxane A$_2$ (TxA2) and prostacyclin (PGI$_2$), are derived from arachidonic acid via its dioxygenation by cyclooxygenases 1 and 2 (COX1 and COX2).[52] Cyclooxygenases exist as homodimers that are physically associated with, but do not pass through, the intracellular endoplasmic reticular membrane.[55–57] Cyclooxygenases mediate a two-step reaction, initially converting free arachidonic acid to the unstable intermediate PGG$_2$ via a *bis*-oxygenase activity. PGG$_2$ is converted to PGH$_2$ via the peroxidase activity of COX.[52,58–63] PGH$_2$ is subsequently metabolized to more stable primary biologically active prostanoids PGE$_2$, PGF$_{2\alpha}$, PGD$_2$, PGI$_2$, and TxA$_2$ by distinct enzymatic prostanoid synthases. These prostanoids exit the cell through uncharacterized mechanisms, where they exert paracrine or autocrine activity on specific and distinct cell surface G-protein coupled receptor(s).[64,65] There is also less definitive evidence that prostanoids may provide physiologically relevant

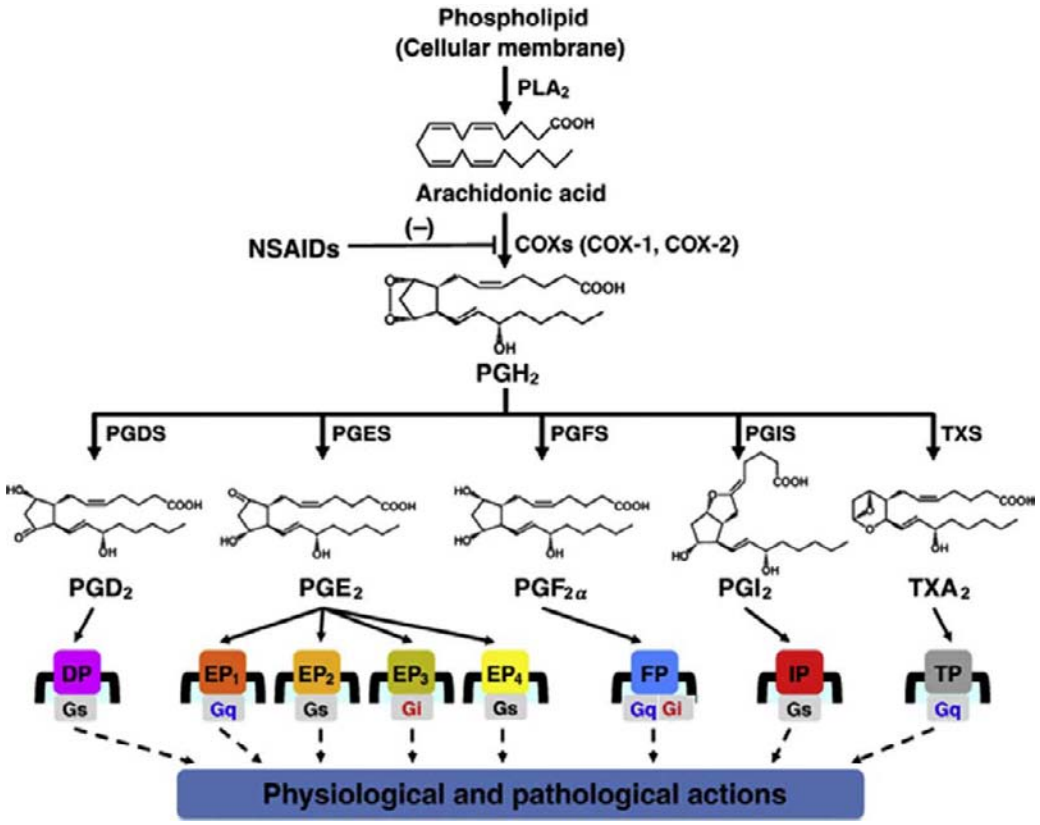

FIGURE 17.1 **Prostaglandin synthesis and the family of G-protein coupled receptors that mediate their functional effects.** *(With permission from Yuhki et al. [348].)*

ligands for nuclear hormone receptors, including peroxisome proliferator activated receptors.[66–68]

Two isoforms of COX have been identified, designated COX1 and COX2.[69–71] Based on transcriptional elements in its 5′ upstream sequence, COX1 is believed to serve a constitutive housekeeping role, responsible for maintaining basic physiological function such as cytoprotection of the gastric mucosa, and control of platelet aggregation.[72,73] Conversely, COX2 upstream promoter region has NF-κB, NFAT, and its expression is potently induced by inflammatory mediators and mitogens, consistent with its role in pathophysiologic processes including angiogenesis, inflammation, and tumorigenesis.[74–77]

The major phenotype of COX2 knockout mice is renal dysgenesis,[78–80] underscoring the special role COX2 plays in the kidney. This defect is characterized by a structurally normal medulla, but hypotrophic renal cortical development with small glomerular size,[79] due to a defect occurring relatively late in parturition.[79] The mechanism is undetermined, but may be related to the particular expression pattern of COX2 in the kidney since normally it is focally expressed adjacent to the glomerulus in the macula densa and the surrounding thick ascending limb cells.[81–83] As in other organs, the housekeeping gene is COX1, which is also constitutively expressed at high levels in the kidney but in cellular compartments distinct from COX2, especially in the collecting duct and glomerular parietal epithelium.[84,85] Low levels of COX1 are also detected in medullary interstitial cells,[81,86,87] but these cells are also uniquely characterized by high endogenous levels of COX2.[81,88,89]

Clinical pharmacologic studies are also consistent with a critical role of COX2 for maintaining cardiovascular homeostasis and normal renal function.[90–92] Indeed, most of the clinically observed side effects associated with the use of non-selective NSAIDs, including edema, hypertension, increased congestive heart failure, hyperkalemia, and acute renal failure, have also been observed with COX2 selective inhibitors.[3] COX2-dependent PGE_2 production is inversely related to luminal chloride concentration delivered to the macula densa,[93] so that in volume depleted states high PGE_2 production rates may exert a vasodilator effect on the afferent arteriole, contributing to maintenance of glomerular blood flow. Impairment of renal function is presumed due to loss of specific prostanoids, derived from the metabolism of the common cyclooxygenase product PGH_2.

Prostanoid Function

Once formed, the COX-derived arachidonate metabolite PGH_2 is further metabolized by prostanoid synthases into at least five primary biologically active prostanoids. Prostanoid synthases include PGE_2 synthase (PGES), prostacyclin synthase (PGIS), PGD synthase (PGDS), PGF synthase (PGFS), and thromboxane synthase, responsible for PGE2, PGI2, PGD2, PGF2α, and TxA2 biosynthesis respectively.[77,94,95]

Most prostanoids are short lived, being highly susceptible to enzymatic inactivation, thereby limiting their effect to the immediate vicinity of their synthesis. The paracrine and autocrine biologic effects of COX-derived prostanoids are diverse and complex, depending on which prostanoid is produced and which receptor is available.[96,97] Thus, the effects of prostanoids on kidney function rely on distinct enzymatic machinery that couples phospholipase and COX to specific prostanoid synthase in specific cells, yielding a specific prostanoid which acts locally through specific G-protein coupled receptors, exerting its particular effect.[96]

At steady-state PGE_2 is the most abundant prostanoid in the mouse kidney, followed by PGI_2, $PGF_{2\alpha}$, and TxA_2.[98] Under basal conditions, both COX1 and COX2 pathways are responsible for the biosynthesis of these prostanoids.[98] Similarly, PGE2 is the most abundant prostanoid in human urine, and under basal, non-stressed conditions is produced by both COX1 and COX.[99,100] In contrast, COX2 primarily contributes to angiotensin II-induced PGE_2 and PGI2 generation in the kidney,[98] and under conditions of low-sodium diet in humans.[101] The intrarenal cellular sites where COX1 and COX2 prostanoids are synthesized remain to be fully defined.

Following their synthesis, these prostanoids become available to exert their biological effects via a diverse family of membrane spanning G-protein coupled prostanoid receptors. These include the DP, EP, FP, IP, and TP receptors, each of which is selectively activated by a specific ligand – PGD_2, PGE_2, $PGF_{2\alpha}$, PGI_2 or TXA_2, respectively.[97,102] PGE2 receptors, designated EP receptors, are unique in that they are encoded by four distinct genes encoding the proteins for EP1, EP2, EP3, and EP4 receptors.[102,103] Each prostanoid receptor activates a distinct G-protein coupled signaling pathway. The IP, DP1, EP2, and EP4 receptors are coupled to the stimulatory G-protein (Gs) and signal by increasing intracellular cAMP levels, whereas the TP, FP, and EP1 receptors induce calcium mobilization.[96,97] The FP, DP2, and EP3 receptors can couple to an inhibitory G-protein (Gi) and reduce cAMP synthesis.[97,102,104]

Restricted cellular expression of prostanoid receptors provides an important mechanism by which a COX-derived prostanoid can exert differential actions in physiological and pathophysiological processes. In the kidney the EP receptors map to distinct segments of the nephron.[96,105] Similarly, all four EP receptors have been described in major inflammatory cells including T-lymphocytes, B-lymphocytes, macrophage, and mast cells[106]; however, whether these receptors are simultaneously expressed in individual cells is uncertain. It has been proposed that activation of different receptors on different cells at different stages of inflammation may account for the pro- or anti-inflammatory action of PGE_2.[107,108]

Prostaglandin E2

PGE_2 is synthesized by at least three forms of PGE synthases, including microsomal PGE synthase 1 (mPGES1), microsomal PGE synthase 2 (mPGES2), and cytosolic PGE synthase (cPGES1).[109–111] The two membrane associated PGE_2 synthases are 33 kDa and 16 kDa enzymes designated mPGES1 and mPGES2, respectively. Microsomal PGES1 displays a higher catalytic activity relative to other PGE synthases and, like COX2, its expression can be induced by cytokines and inflammatory stimuli.[109] In contrast, the expression of cPGES and mPGES2 do not seem to be inducible and may play housekeeping functions.

Genetic disruption confirms that mPGES1$^{-/-}$ mice exhibit a marked reduction in inflammatory responses compared with mPGES1$^{+/+}$ mice,[112] and indicates that mPGES1 is critical for the induction of inflammatory fever.[113] It has been proposed that mPGES1 couples primarily to the inducible COX2 in inflammatory cells.[114] In contrast, intrarenal expression of mPGES1 maps to cells of the collecting duct that primarily express COX1 with lower expression in medullary interstitial cells and macula densa that express COX2[84,115–117] (Figure 17.2). Thus, in the kidney mPGE1 co-localizes with both cyclooxygenase 1 and 2.

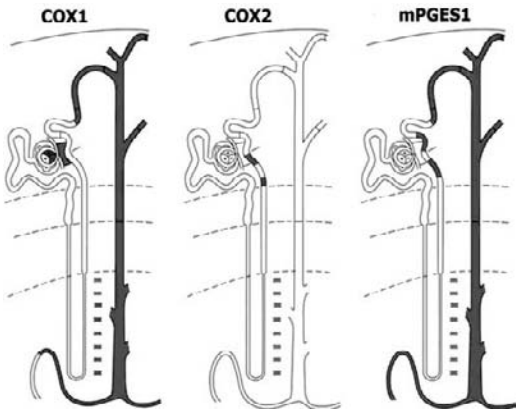

FIGURE 17.2 **Expression of COX1, COX2, and microsomal prostaglandin E synthase 1 in the kidney.** *(With permission from ref. [84].)*

The renal phenotype of the mPGE1 knockout mouse is relatively subtle, and is characterized by increased blood pressure sensitivity to high-sodium diet and mineralocorticoids, as well as increased vascular reactivity to angiotensin-II,[118,119] although not all investigators have seen these effects.[120] These results are consistent with a role for mPGES1-derived PGE_2 in buffering physiologic stresses that tend to increase blood pressure. Notably, the kidneys of mPGES1$^{-/-}$ mice are normal and do not exhibit the renal dysgenesis observed in COX2$^{-/-}$ mice.[78,80] Nor do these mice exhibit perinatal death from patent ductus arteriosus observed with the prostaglandin EP4 receptor knockout mouse,[121] suggesting other sources of PGE2 production are sufficient to provide adequate receptor activation. These sources could include cPGES and mPGES2.[122] Both cPGES and mPGES2 are expressed in the kidney[123]; however, their intrarenal role(s) have not yet been elucidated. In addition, several cytosolic glutathione-S-transferases have the capacity to convert PGH_2 to PGE_2; however, their physiologic role in this process remains uncertain.[122]

E-Prostanoid Receptors

All four E-Prostanoid receptors (EP receptors) are expressed in the kidney (Figure 17.3). Each exhibits a distinct mRNA expression profile along the nephron. The EP4 receptor predominates in the glomerulus, while the EP3 and EP1 receptors are primarily detected in the thick limb and collecting duct.[105,124] The EP2 receptor is expressed at lower levels in the renal vaculature and stroma.[125,126] Each receptor plays a distinct role in these regions, mediating many of the well-defined physiologic actions of PGE_2 that have been identified over the past several decades.

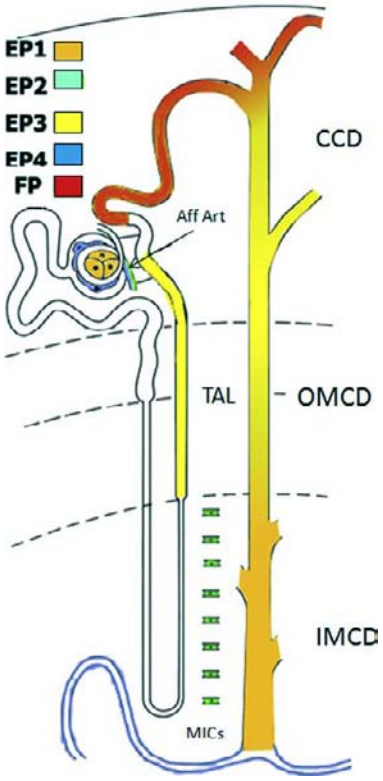

FIGURE 17.3 **Distribution of EP1, 2, 3, 4, and FP receptors in the kidney.**

EP_1 Receptor

The EP1 receptor was originally identified pharmacologically via its smooth muscle constrictor activity in guinea pig ileum, and its unique profile of response to a series of prostanoid analogs.[127–130] The EP1 receptor cDNA has been cloned from numerous species, including human, dog, mouse, rat, and rabbit.[131–135] The human EP1 receptor cDNA encodes a 402 amino acid polypeptide with a predicted molecular mass of 41,858 kDa.[131] This receptor signals via a mechanism linked to increased cell Ca^{2+}, and is accompanied by modest increases in IP_3 generation.

Studies of EP1 receptors have taken advantage of several relatively selective antagonists that block their activation, including SC-19220, SC-53122,[136,137] and ONO-8130.[138–141] A significant impetus behind the development of clinically active EP1 receptor antagonists derives from evidence that the EP_1 receptor plays an important role in prostaglandin-mediated pain,[140,142,143] and that EP1 receptor antagonists have EP1 properties.[136,137,139,144,145] These antagonists provide useful tools to study EP_1 receptor physiology *in vivo*.

The EP1 receptor is highly expressed in the kidney, where it primarily localizes to the collecting duct with an increasing mRNA expression gradient from the cortical to the medullary collecting duct.[105,132,146] In the collecting duct, activation of the EP1 receptor inhibits Na^+ and water reabsorption via a Ca^{2+}-coupled mechanism.[132] These results suggest that renal EP_1 receptor activation contributes to PGE_2-dependent natriuresis by inhibiting Na^+ transport in the collecting duct. Despite this *in vitro* demonstration, these natriuretic effects have been difficult to demonstrate *in vivo*.[132,143]

Genetic disruption of the EP1 receptor does not lead to a significant impairment of sodium excretion; however, EP1 knockout mice do exhibit increased renin and aldosterone levels, consistent with maintenance of normotension at the expense of activation of the renin–angiotensin system.[132,143] EP1 receptor knockout mice not only exhibit reduced blood pressure on normal chow, but also impaired pressor response to angiotensin II.[145] These studies identified EP1 mRNA expression in small resistance vessels of mice including the afferent arterioles of the glomerulus, and are

consistent with more recent studies suggesting Ang II-stimulated vasoconstriction may in part be mediated by activation of vascular EP1 receptors.[147] EP1 receptors have also been identified in glomerular mesangial cells, where they may contribute to mesangial contraction. Inhibition of the EP1 receptor slows the progression of mesangial expansion in experimental models of diabetic nephropathy.[139] EP1 receptor knockout mice are resistant to the pressor effects of angiotensin II, and EP1 receptor antagonists can also block the Ang II pressor activity.[145,147–149] It is instructive to consider the role of PGE_2 as a vasoconstrictor through its actions on the EP1 receptor, as opposed to its classically characterized role as a vasodilator/vasodepressor. This underscores the capacity of PGE_2 to serve as a physiological buffer of blood pressure, either in support or reduction of blood pressure (see below).

EP_2 Receptors

In contrast to the smooth muscle constrictor activity of the EP1 receptor, the EP2 receptor was originally defined by its relaxant activity in smooth muscle.[128] The human EP_2 receptor cDNA encodes a 358 amino acid polypeptide, which signals through increased cAMP and is selectively activated by butaprost.[150] The EP_2 receptor may be distinguished from the EP_4 receptor, the other major cAMP stimulating and vasorelaxant EP receptor, by its selective activation by butaprost and relative insensitivity to the EP_4 agonist PGE_1-OH.[150] Literature prior to 1995 may be confusing regarding the EP_2receptor, because before the human EP_2 receptor was cloned, the previously cloned EP_4 receptor was classified as the EP_2 receptor.[150,151]

The physiological processes mediated by the EP2 receptor include important roles in reproduction and blood pressure regulation. The precise tissue distribution of the EP_2 receptor has only been characterized by Northern blot analysis of mRNA distribution. This reveals a major mRNA species of ~3.1 kb that is most abundant in the uterus, lung, and spleen, exhibiting only low levels of expression in the kidney.[135,150,152] EP2 knockout mice exhibit a fertility defect and the development of hypertension on a high NaCl diet (these latter effects are significantly influenced by the genetic background of the mouse strain).[153,154] In the kidney, despite incomplete histological characterization, a preponderance of functional and mRNA expression evidence suggests the EP2 receptor is expressed in stromal cells of the kidney, including renal medullary interstitial cells,[125] vascular pericytes along the vasa recta,[126,155,156] and glomerular arterioles where it contributes to afferent arteriolar dilation (Figure 17.4).[126,157] Evidence suggests that deletion of the EP2 receptor in renal medullary interstitial cells,[158] combined with the absence of its systemic vasodilator activity, contributes to salt-sensitive hypertension in the EP2 knockout mouse.

EP_3 Receptor

In smooth muscle the EP_3 receptor generally acts as a constrictor.[159,160] This receptor is unique, in that at least seven alternatively spliced variants defined by unique COOH-terminal cytoplasmic tails exist in humans alone, and over 22 unique variants have been observed in rats, rabbits, mice, cows, and humans.[161–164] These splice variants encode proteins of a predicted molecular mass between 40 and 45 kDa.[161–164] All the EP_3 splice variants bind PGE_2 and the EP_3 specific prostanoid analogs with similar affinity, and inhibit cAMP generation via a pertussis toxin-sensitive G_i-coupled mechanism; however, additional signaling mechanisms may be differentially activated by the different COOH-terminal tails.[165]

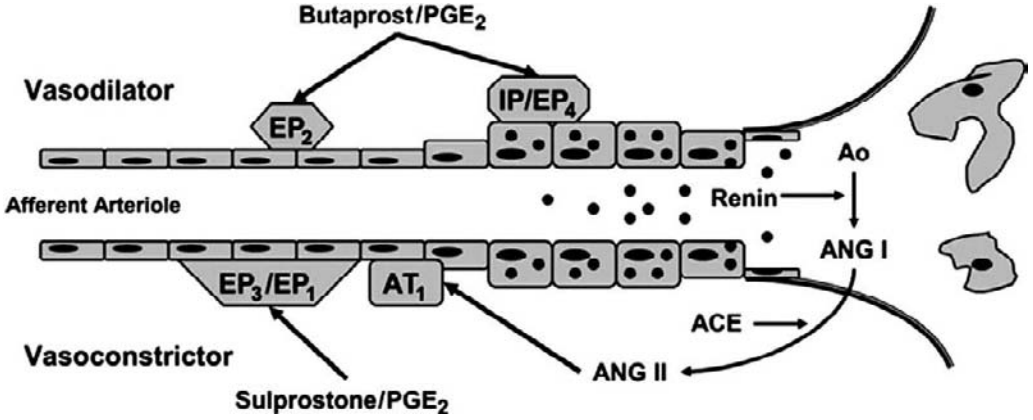

FIGURE 17.4 **Schematic of prostanoid receptor action at the afferent arteriole including EP1, EP2, EP3, EP4, and IP receptors.** *(From ref. [157], with permission from Am J. Physiol.)*

Mice with targeted deletion of the EP_3 receptor exhibit an impaired febrile response to lipopolysaccaride and PGE_2, suggesting that the EP_3 receptor antagonists could be effective antipyretic agents.[166] In the kidney the EP_3 receptor is highly expressed in the cortical and outer medullary collecting duct, where it antagonizes vasopressin-stimulated water absorption via pertussis toxin-sensitive inhibition of cAMP generation.[167,168] Despite relatively high levels of EP_3 receptor in the kidney collecting duct, mice with targeted disruption of this receptor only display a subtle alteration with altered urinary concentrating ability in mice treated with NSAIDs.[169] These findings raise the possibility that prostaglandin receptors other than the EP_3 receptor exert overlapping effects that also (such as the EP1 and FP receptor) modulate the urinary concentration and dilution by this segment of the nephron.

EP_4 Receptor

The EP_4 receptor can be distinguished from the EP_1 and EP_3 receptors by its insensitivity to sulprostone, and from EP_2 receptors by its insensitivity to butaprost and relatively selective activation by PGE_1-OH.[129,150,170,171] The human EP_4 receptor cDNA encodes a 488 amino acid polypeptide with a predicted molecular mass of ~53 kDa.[171] Like the EP_2 receptor, EP_4 signals through increased cAMP, but may also engage other signaling mechanisms including PI3K activation.[172,173] EP_4 receptor mRNA is relatively highly expressed compared with the EP_2 receptor and widely distributed, with a major species of ~3.8 kb detected by Northern analysis in thymus, ileum, lung, spleen, adrenal gland, and kidney.[133,174,175] In contrast to other EP receptor knockouts, EP4 receptor knockout mice exhibit a profound perinatal lethal phenotype due to impaired closure of the ductus arteriosus,[121,176] consistent with its robust expression in this vessel.

In the kidney, EP4 receptor mRNA is predominantly expressed in the glomerulus[105,124,126] where it modulates glomerular hemodynamics through opposing direct vasodilator activity,[157,177] and an indirect vasoconstrictor activity via stimulation of renin release (Figure 17.4).[178] The ability of PGE_2 to increase renin release is well-established[178–181] and of clinical relevance, since NSAID blockade of prostaglandin synthesis can be associated with hyporeninemic hypoaldosteronism,[182] and COX2 inhibitors can block the hyper-reninemia associated with volume depletion or Bartter's syndrome.[101,183,184] Accumulating evidence supports a role for COX2-mediated PGE_2 production, and subsequent activation of juxtaglomerular EP4 receptor in mediating renin release.[93,181] As mPGES-specific inhibitors and EP4 receptor antagonists become increasingly available it will be important to determine the relative contribution of PGE2-dependent renin release versus prostacyclin-dependent effects (see below).

In volume depletion,[185] congestive heart failure,[186] and shock, intrarenal PGE_2 production helps maintain glomerular perfusion via afferent arteriolar vasodilator EP2 receptors[157] (Figure 17.4), while simultaneously maintaining systemic blood pressure by stimulating renin release through EP4 receptors.[187,188] Genetic deletion of the EP4 receptor or EP4 inhibitors impairs renin release in mice following furosemide-induced volume depletion.[181] Inhibition of PGE_2 synthesis using NSAIDs or COX2 inhibition in these settings can actually drop blood pressure by inhibiting renin release,[189] and lead to acute renal failure due to decreased glomerular perfusion.[190–192]

The EP4 receptor is also abundant in glomerular podocytes.[124,193,194] In podocytes EP4 receptor activation may impair their ability to withstand mechanical stress, since podocyte selective overexpression of EP4 receptors accelerates renal injury in a mouse renal ablation model of kidney disease.[195]

Other roles for the EP4 receptor in controlling blood pressure have been suggested, including the ability to stimulate aldosterone release from zona glomerulosa cells.[196] It remains to be determined whether the adrenal EP4 receptor plays any role in hyperkalemia and hyporeninemic hypoaldosteronism associated with NSAID blockade of prostaglandin synthesis[182,197,198] or whether this is primarily due to hyporeninemia.[199] Important vasodilator effects of EP_4 receptor activation in venous and arterial beds have been described.[130,200] Roles for EP4 receptors in immune cell activation and osteoblast function have also been reported.[201–203]

Prostaglandin F Synthesis

$PGF_{2\alpha}$ may derive either directly from PGH_2 via a PGF synthase[204] or via a NADPH-dependent 9 ketoreductase, which converts PGE_2 into $PGF_{2\alpha}$. This enzymatic activity is typically cytosolic,[204] and may be detected in homogenates from renal cortex, medulla or papilla.[204,205] Another more obscure pathway for PGF formation is by the action of a PGD_2 ketoreductase, yielding a stereoisomer of $PGF_{2\alpha}$, 9α,11ß-PGF_2 (11epi-$PGF_{2\alpha}$).[204] This reaction, and conversion of PGD_2 into the biologically active metabolite (9α,11β-$PGF_{2\alpha}$) has been documented *in vivo*.[206] This $PGF_{2\alpha}$ isomer can also ligate and activate the FP receptor.[207] The physiologically relevant enzymes responsible for $PGF_{2\alpha}$ formation in the kidney remain incompletely characterized.

Prostaglandin 9-Ketoreductase (PG9KR) and $PGF_{2\alpha}$ Synthesis

Prostaglandin F synthase activity may be mediated via several distinct, and incompletely defined, enzymes. One major synthetic pathway appears to occur via a member of the aldo-ketoreductase 1C family.[208] Renal PGE_2 9-ketoreductase also exhibits 20α-hydroxyl-steroid reductase activity that may be involved in steroid metabolism.[204] PG9KR activity appears to be particularly robust in suspensions from the thick ascending limb of Henle (TALH).

Interestingly, some studies suggest activity of a 9-ketoreductase may be modulated by salt intake and the angiotensin AT2 receptor.[209] This activity may play a role in the development of salt-sensitive hypertension.[210] AT2 receptor knockout mice exhibit salt-sensitive hypertension associated with increased PGE_2 production and reduced production of $PGF_{2\alpha}$,[209] consistent with decreased 9-ketoreductase activity. Other studies suggest increased dietary potassium intake may also enhance the activity of conversion from PGE_2 to $PGF_{2\alpha}$.[211] The intrarenal sites of expression of this enzymatic activity remain to be characterized.

F-Prostanoid Receptors

Once formed, $PGF_{2\alpha}$ is available to interact with the intrarenal FP receptors. The human FP receptor mRNA is predicted to encode 359 amino acid residues with a molecular mass of ~40 kDa.[212] In fibroblasts and smooth muscle the FP receptor signals through increased cellular calcium, and its activation is associated with muscle contraction.[213–215] The FP receptor is highly expressed in the ovarian corpus luteum, and mice lacking the FP receptor exhibit a major reproductive defect due to failure of partuition because of impaired reduction of progesterone at term.[216] FP receptor antagonists have been developed, and their use proposed as a means of delaying pre-term delivery.[217,218] The FP receptor is highly expressed in the ocular ciliary body and FP selective agonists including travaprost, latanoprost, and bimatoprost are in use for clinical treatment of glaucoma d.[214,219] In the kidney, the FP receptor is highly expressed in the distal convoluted tubule, connecting tubule, and cortical collecting duct, where it inhibits vasopressin-stimulated renal water transport[104,220] consistent with recent studies that the FP receptor knockout mice exhibit mild polyuria and polydipsia.[221] Interestingly, in the rabbit cortical collecting duct epithelium the FP receptor appears to signal through a pertussis toxin-sensitive G_i-coupled mechanism, rather than the classical Ca^{2+}-coupled signaling mechanism observed in smooth muscle cells.[104] Vascular expression of FP receptor in pre-glomerular arterioles and other resistance vessels has also been demonstrated, and studies in FP receptor knockout mice show they are relatively hypotensive.[221] These studies also provide evidence that renal JGA FP receptor activation directly stimulates renin release.[221]

Prostaglandin D_2 is derived from PGH_2 via the action of specific enzymes designated PGD synthases. Two major enzymes are capable of transforming PGH_2 to PGD_2 – a lipocalin type PGD synthase and a hematopoietic type PGDS.[222,223] RT-PCR showed that L-PGDS is strongly expressed in kidney cortex and outer medulla, including in nearly all segments of the nephron,[224] while H-PGDS mRNA is only detected in microdissected outer medullary collecting duct.[224]

Lipocalin PGD synthase (L-PGDS) is a multifunctional molecule, and on addition to prostaglandin H2 it binds a variety of small lipophilic molecules including bilirubin and biliverdin.[225] Mice lacking the lipocalin D synthase gene exhibit pain sensation.[226] LPGDS-mediated PGD2 synthesis also appears to play an important role in the sleep/wake cycle,[225] but its role in renal PGD2 synthesis has not been studied. Urinary levels of L-PGDS, also known as beta-trace protein, have been increasingly studied as a biomarker of acute and chronic renal injury.[227–230] LPDGS knockout mice appear to be more susceptible to diabetic nephropathy.[231]

PGD_2 is the major prostanoid released from mast cells following challenge with IgE, and this synthesis appears to be mediated by the hematopoietic form of PGDS.[223,232,233] The precise role of hematopoietic PGDS in the kidney remains uncertain, as does the significance of its reported localization in the outer medullary collecting duct.[224]

D-Prostanoid Receptors

Once synthesized, PGD_2 is available to interact with either the DP1 or DP2 (originally identified as CRTH2) receptors or undergo further metabolism to a PGF_2-like compound that can interact with the FP receptor (see above). The human DP1 receptor is a cAMP-coupled GPCR with a predicted molecular mass similar to other prostanoid receptors (~40 kDa).[234,235] It exhibits a relatively selective tissue distribution, with particularly high expression in retina and small intestine, where it appears to be highly expressed in mucus secreting goblet cells.[235] The DP2 receptor is a GPCR that is also activated by PGD2, but it is unrelated in sequence to the classic prostanoid receptor family, being more closely related to members of the *N*-formyl peptide receptor (FPR) subfamily.[236,237] DP2 is selectively expressed in Th2 cells, cytotoxic T-cells,

eosinophils, and basophils. DP and DP2 receptors are intimately involved in the immune allergic response.[236,238] Neither DP1 receptors nor DP2 receptors appear to be highly expressed in the kidney, and while infusion of a DP1 selective agonist lowers blood pressure these effects appear to be primarily due to peripheral vasodilation and not by directly affecting renal blood flow.[239]

Prostacyclin (PGI_2)

The biological effects of prostacyclin are numerous and include nocioception, anti-thrombosis, and vasodilator actions, which have been targeted therapeutically to treat pulmonary hypertension.[240] Prostacyclin (PGI_2) is derived from the enzymatic conversion of PGH_2 via prostacyclin synthase (PGIS) to PGI_2. The PGIS cDNA is comprised of a 1500 bp open reading frame that encodes a 500 amino acid protein of approximately 56 kDa.[241] Northern blot analysis shows prostacyclin synthase mRNA is widely expressed in human tissues and is particularly abundant in ovary, heart, skeletal muscle, lung, and prostate. PGI synthase expression exhibits segmental expression in the kidney, especially in kidney inner medulla tubules and interstitial cells.[224,242]

PGI_2 synthase-null mice exhibit a profound renal phenotype with nephrosclerosis and areas of renal infarction.[243] PGI_2 levels in the plasma, kidneys, and lungs were reduced, documenting the role of this enzyme as an *in vivo* source of PGI_2. Blood pressure and blood urea nitrogen and creatinine in the PGIS knockout mice were significantly increased, and renal pathological findings included surface irregularity, fibrosis, cysts, arterial sclerosis, and hypertrophy of vessel walls. Thickening of the thoracic aortic media and adventitia were observed in aged PGIS-null mice.[243] Interestingly, this is a phenotype different from that reported for the IP receptor knockout mouse,[244] which failed to exhibit abnormal kidney morphology. These differences suggests the presence of additional IP receptor independent PGI_2 activated signaling pathways – possibly through nuclear receptors such as PPARdelta.[245,246] Regardless, these findings demonstrate the importance of PGI_2 in the maintenance of blood vessels and to the kidney.

IP Receptor

The IP receptor mRNA is highly expressed in the afferent arteriole, where it may combine with the effects of EP2 and EP4 receptors to dilate renal arterioles and stimulate renin release.[247,248] IP receptor deficient mice exhibit reduced renin and are resistant to the development of hypertension following unilateral renal artery stenosis, consistent with an impaired IP receptor-mediated renin release.[249] COX2-derived prostacyclin from the endothelium also appears to serve an atheroprotective role in mice, and its loss could contribute to the cardiovascular risks associated with the use of COX2 inhibitors.[250] Conversely, thromboxane receptors may counteract the effects of these protective effects of prostacyclin and accelerate atherosclerotic lesions, as well as increasing vascular resistance.

Thromboxane A2

Thromboxane A_2 (TxA_2) is produced from PGH_2 by thromboxane synthase (TxAS), a microsomal protein of 533 amino acids with a predicted molecular weight of ~60 kDa. The human gene is located on chromosome 7q, and the enzyme exhibits homology to the cytochrome P450s and is now classified as CYP5A1.[251] TxAS mRNA is highly expressed in hematopoietic cells, including platelets, macrophages, and leukocytes, as well as thymus, kidney, lung, spleen, prostate, and placenta.[252,253] Immunolocalization of TxA synthase demonstrates high expression in the dendritic cells of the interstitium, with lower expression in glomerular podocytes of human kidney.[254] In the kidney, thromboxane synthase is mainly detected in the glomeruli.[224] TxA_2 synthase expression is regulated by dietary salt intake.[255] Furthermore, experimental use of ridogrel, a specific thromboxane synthase inhibitor, reduced blood pressure in spontaneously hypertensive rats.[256] The clinical use of TxA_2 synthase inhibitors is complicated by the fact that its endoperoxide precursors (PGG_2/PGH_2) are also capable of activating its downstream target, the TP receptor,[257] so thromboxane receptor antagonists would be expected to more definitively interfere with this pathway.

TP Receptor

The thromboxane receptor (TP) was the first member of the prostanoid receptor family cloned.[258] This GPCR has a predicted molecular mass ~37.5 kDa, and is highly expressed in platelets and vascular tissue where its activation increases intracellular calcium.[258] In the kidney TP receptor mRNA is predominantly expressed in the glomerulus and vascular tissue,[224,259] where it contributes to vasoconstrictor activity following Ang II infusion[260] and following renal injury.[261–263]

Prostaglandin Transport

One of the major areas of uncertainty in eicosanoid research is precisely how prostanoids, synthesized inside the cell, transit the cell membrane to become available to interact with cell surface receptors.

Recent studies have identified several transmembrane proteins capable of facilitated transport of prostaglandins across cell membranes.[264] Schuster's group identified a lactate/PGE_2 exchanger they designated prostaglandin transporter or PGT.[265] The importance of PGT in mediating the *in vivo* effects of PGE_2 has been substantially bolstered by studies showing genetic disruption of the PGT gene is associated with perinatal death due to persistence of a patent ductus arteriosus[266] recapitulating the phenotype of the EP4 receptor knockout.[121,176] Although this prostaglandin transporter appears poised primarily to provide a PGE2 re-uptake mechanism, it is notable that the transporter is expressed in renal cells that are major sites of prostaglandin synthesis,[267] rather than those renal cells involved in PGE_2 inactivation.[264] These findings are consistent with the possibility that PGT plays an important role in directing vectorial PGE_2 release. Nevertheless, it seems unlikely that this protein comprises the pathway mediating PGE_2 release. More recent evidence supports a role for the multi-drug resistance protein 4 (MRP4) as a potential PGE_2 efflux mechanism.[268] MRP4 knockout mice exhibit low levels of circulating PGE_2 and reduced inflammatory pain,[269] consistent with a role in PGE2 extrusion.

Prostaglandins and the Pathogenesis of Kidney Disease

Renal Inflammation

Increased glomerular COX1 or COX2 expression has been reported in patients with nephritis, and in animal models of nephritis.[270,271] Glomerular expression of COX2 is upregulated in patients with active lupus nephritis and in lupus nephritis animal models.[270,272] COX2 inhibition has shown beneficial effects on passive Heymann nephritis (PHN), a model of membranous nephropathy.[273] Cell culture studies show that thromboxane A2 contributes to complement-induced cytotoxicity of glomerular epithelial cells.[273] In contrast, in anti-Thy1.1 glomerulonephritis model, an animal model of mesangioproliferative glomerulonephritis (MPGN) that is characterized by endothelial injury, COX2 inhibition is associated with increased mesangiolysis, albuminuria, and delayed recovery from glomerular injury.[274] Further studies suggest that healing of injured glomerular capillary endothelium in this model may depend on COX2-derived prostanoids, and COX2 inhibition may lead to impaired capillary endothelium healing.[274] The role of COX-derived prostanoids in autoimmune and inflammatory disease has been well-documented.[275,276] COX2 expression and prostanoid biosynthesis can be induced in macrophages and dendritic cells by inflammatory agents, such as LPS, IL-1ß, and interferon.[74,75] PGDS expression or activity has been described in dendritic cells, macrophage, eosinophil, neutrophil, and mast cells.[106] Prostanoids, particularly PGE2 and PGI2, have been shown to enhance inflammatory reactions.[106] Conversely prostanoids also exert anti-inflammatory effects. The pro- or anti-inflammatory effect of prostanoids is dependent on specific prostanoid, receptor subtype, cell population, and context of activation.[106] Additional studies are required to define the precise roles of prostanoids in different forms of glomerulonephritis.

Renal COX-Derived Prostanoids and Diabetic Nephropathy

Diabetic nephropathy is characterized by microalbuminuria, glomerular hypertrophy, mesangial expansion with glomerular basement membrane thickening, arteriolar hyalinosis, and global glomerular sclerosis, which ultimately lead to the progression to proteinuria and renal failure.[277,278] Supra-normal GFR (hyperfiltration) typifies the early stages of diabetic nephropathy.[279–282] Studies in diabetic humans and streptozotocin (STZ)-induced type I diabetic rats show increased renal PGE2, PGI2, and TxB2 levels.[282–285] COX2 expression is increased in the thick ascending limb and macula densa in diabetic humans and rodents.[286–288] Selective COX2 inhibition reduces glomerular hyperfiltration in streptozotocin-induced diabetic rats, consistent with COX2-derived prostanoids increasing renal blood flow in the diabetic kidney.[288] The identity of the specific COX2-derived prostanoids and their cognate receptors involved in pathogenesis of diabetic hyperfiltration has not been completely characterized. EP1 receptor antagonist treatment ameliorates renal and glomerular hypertrophy, and decreases mesangial expansion.[139] A thromboxane receptor (TP) antagonist has also been reported to attenuate proteinuria and ameliorate histological changes of diabetic nephropathy in diabetic apolipoprotein E-deficient mice.[289] It has not been determined whether similar beneficial effects might be observed in human diabetic nephropathy.

Prostaglandins and Progression of Kidney Disease

COX-derived prostanoids may also modify renal function and glomerular damage in non-diabetic chronic renal disease.[290,291] After subtotal renal ablation, renal cortical COX2 expression is increased, predominantly in the macula densa and surrounding cTAL.[291,292] Selective COX2 inhibition decreases proteinuria and inhibits the development of glomerular

sclerosis.[291,292] These studies are consistent with a role of COX2-derived prostanoids in the pathogenesis of structural and functional deterioration of kidney in chronic kidney disease.

LIPOXYGENASE DERIVED EICOSANOIDS: 5-, 12-, AND 15-HETES AND LEUKOTRIENES

Arachidonic acid may be metabolized to form leukotrienes and hydroxyeicosatetraenoic acids (HETEs) by a family of enzymes designated lipoxygenases[293,294] (Figure 17.5). Leukotriene arachidonic acid metabolites play a major role in inflammatory disease, especially asthma and other inflammatory pulmonary diseases where cysteinyl leukotriene receptor antagonists have found a place as a standard of care.[295,296] In contrast to the prostaglandins, it has been difficult to demonstrate a major role for leukotrienes in the normal kidney.

Lipoxygenases (LOX) are comprised of non-heme iron containing enzymes that insert molecular oxygen into polyunsaturated fatty acids such as arachidonic acid and linoleic acid.[294,297] Six functional human lipoxygenases have been cloned: 5-lipoxygenase (gene name: ALOX5); platelet-type 12-lipoxygenase (gene name: ALOX12); 12/15-lipoxygenase (leukocyte-type 12-LO for mice, 15-LO type 1 for human, gene name: ALOX15); epidermal-type 12-lipoxgenase (gene name: ALOXE3); 12(R)-lipoxygenase (gene name: ALOX12B); and 15-lipoxygenase type 2 (gene name: ALOX15B, 8-lipoxygenase in mice).[293,297]

5-Lipoxygenase is the key enzyme in leukotriene biosynthesis.[293,296,297] In the presence of 5-LO-activating protein (FLAP)[298] 5-lipoxygenase catalyzes the generation of leukotriene A4 (LTA4). LTA4, in turn, is converted by LTA4 hydrolase to LTB4, capable of activating LTB4 receptors. LTB4 is a potent chemotactic substance, and increases polymorphonuclear leukocytes (PMN) aggregation and adhesion to the endothelium.[299,300] Alternatively, LTA4 can be converted to cysteinyl (cys) leukotrienes (LTC4, LTD4, and LTE4) through leukotriene C4 synthase.[297] LTC4 and LTD4 contract vascular smooth muscle cells and increase vascular permeability.[301–304] These leukotrienes are usually released locally by leukocytes. Mice with 5-LO gene disruption exhibit a reduced inflammatory reaction,[305–307] supporting the pro-inflammatory action of 5-LO-derived metabolites. Recently, increased expression of leukotriene C4 synthase and formation of cysteinyl-leukotrienes have been reported in human abdominal aortic aneurysm.[308]

As might be predicted from its expression in inflammatory cells, 5-LO-derived products appear to play an important role in glomerular immune injury.[309–311] 5-LO mRNA and 5-LOX-activating protein (FLAP) mRNA are detected in the glomeruli and vasa recta.[312] Both leukotriene receptor B4 and the cysteinyl leukotriene receptor type 1 are selectively expressed in the

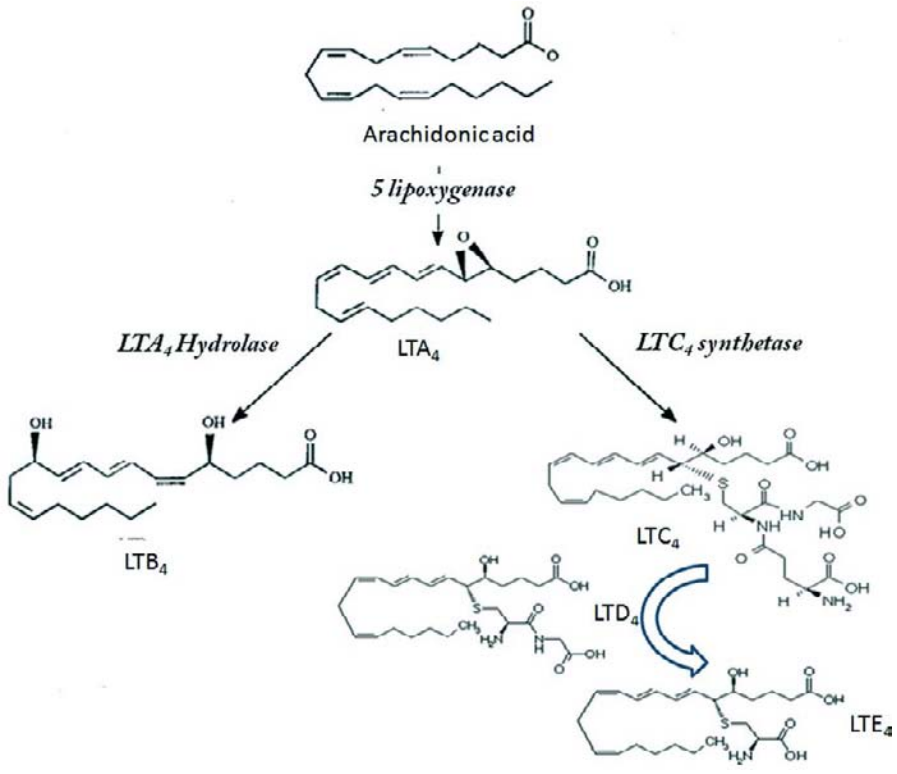

FIGURE 17.5 **Leukotriene synthetic pathway.**

glomerulus,[312] suggesting 5-LO products are involved in glomerular function. Glomerular synthesis of LTB4 and LTC4/LTD4 is markedly enhanced in both human disease and experimental glomerular immune injury.[313–315] LTD4 may contribute to the reduction of GFR in the acute phase of injury by virtue of its potent vasoconstrictor action and contraction of mesangial cells.[314] LTD4 may also increase intraglomerular pressure, contributing to proteinuria.[315] LTB4, a potent promoter of PMN attraction, participates in glomerular damage by amplifying PMN-dependent mechanisms of injury.[314]

The biological functions of the other members of the lipoxygenase family are more obscure. The 12-LO, catalyzes the formation of oxidized lipids 12(S)-hydroxyeicosatetraenoic acid [12(S)-HETE]. Human 15-LO type 1 shares high homology with rodent leukocyte-type 12-LO; both can mediate the formation of 12(S)-HETE and 15(S)-HETE from arachidonic acid, and are thus classified as 12/15-LO.[293,297,316] Some evidence suggests that 12(S)-HETE and 15(S)-HETE play important roles in systemic homeostasis and renal–cardiovascular pathology[317,318]; however, specific receptors for these products have not yet been identified. A recent study implicates ALOX15 as playing a role in bone mineralization.[319] 12/15-Lipoxygenase products also appear to be involved in the pathogenesis of atherosclerosis.[320]

12/15-Lipoxygenase-derived products may contribute to the pathogenesis of diabetic complications, including diabetic nephropathy.[321,322] 12/15-LO is detected in renal microvessels, glomeruli, and mesangial cells.[312,323,324] 12/15-LO levels are increased in the glomeruli of experimental diabetic animals.[321,325] The 12/15 LO pathway has been shown to be a critical mediator of TGFβ and angiotensin II (ANG II)-induced mesangial cell hypertrophy and extracellular matrix accumulation.[322,326,327] These studies also suggest that ANG II-induced mesangial cell hypertrophy and extracellular matrix synthesis in cultured rat mesangial cells can be blocked by an LO inhibitor or targeted 12/15 LO gene deletion.

CYTOCHROME P450 MONOOXYGENASE-DERIVED EICOSANOIDS: 20-HETE AND EETS

Free arachidonic acid can also be metabolized by the cytochrome P450 monooxygenases (CYP450) to produce hydroxy- and epoxy-arachidonic acid derivatives.[328,329] The major CYP450-catalyzed reactions in most tissues are mediated by epoxygenase and ω-hydroxylase activities of the CYP450 family, which are responsible for biosynthesis of epoxyeicosatrienoic acids (EETs) and 20-hydroxyeicosatetraenoic acid (20-HETE), respectively[328,329](Figure 17.6). These metabolites have been shown to possess biological activity, but the mechanisms mediating these biological effects remain obscure since specific receptors have not been identified.[48,330,331]

Members of the P450 *CYP2C*, and *2J* subfamilies have been identified as functionally relevant epoxygenases, while members of 4A and 4F are ω-hydroxylases, respectively.[48,331–333] 20-HETE is a potent vasoconstrictor.[334–336] EETs are produced in the vascular endothelium, and are potent vasodilators.[337,338] EETs are also produced in tubules, including the proximal tubule and collecting ducts in the rodent kidney.[335,339] EETs have been shown to inhibit ENaC activity,[339,340] which may contribute to their natriuretic effect. EETs have also been shown to mediate the natriuretic effect of angiotensin II.[339,341] Studies of knockout mice have supported a role for CYP450 metabolism in the regulation of blood pressure, but the mechanisms of these effects remain incompletely understood. Genetic disruption of CYP2J8 was associated with hypertension in females, but it is uncertain whether this effect is related to its arachidonate epoxygenase activity in mice or an effect on estrogen metabolism.[342] Genetic disruption of cyp4a10 and 4a14 are also associated with hypertension,[343,344] adding to uncertainty regarding the distinct roles of epoxygenase and ω-hydroxylase activity of arachidonic acid in regulating vascular tone and blood pressure.

Role of Renal CYP450-Derived Arachidonate Metabolites in Renal Damage

Increased EET formation has been reported in the kidney of rats with liver cirrhosis. While it is well-documented that renal vasoconstriction leading to impaired renal function occurs during cirrhosis, this result suggests increased EET synthesis may be a homeostatic response to help preserve renal perfusion.[345] Reduced CYP arachidonate hydroxyglase activity and 20-HETE levels have been reported in the kidney following ischemia and reperfusion. Reduced CYP4A protein expression and enzyme activity in ischemia/reperfusion was suggested as an adaptive mechanism to preserve renal vasculature from excessive vasoconstriction.[346] Other studies suggest that the CYP hydroxylase-derived product 20-HETE plays an important role in the maintenance of the glomerular protein permeability barrier.[347] An *in vitro* glomerular albumin permeability study using isolated rat glomeruli shows that puromycin aminonucleoside (PAN) significantly increases glomerular albumin permeability.[347] 20-HETE treatment blocks PAN-induced increase in albumin permeability.[347]

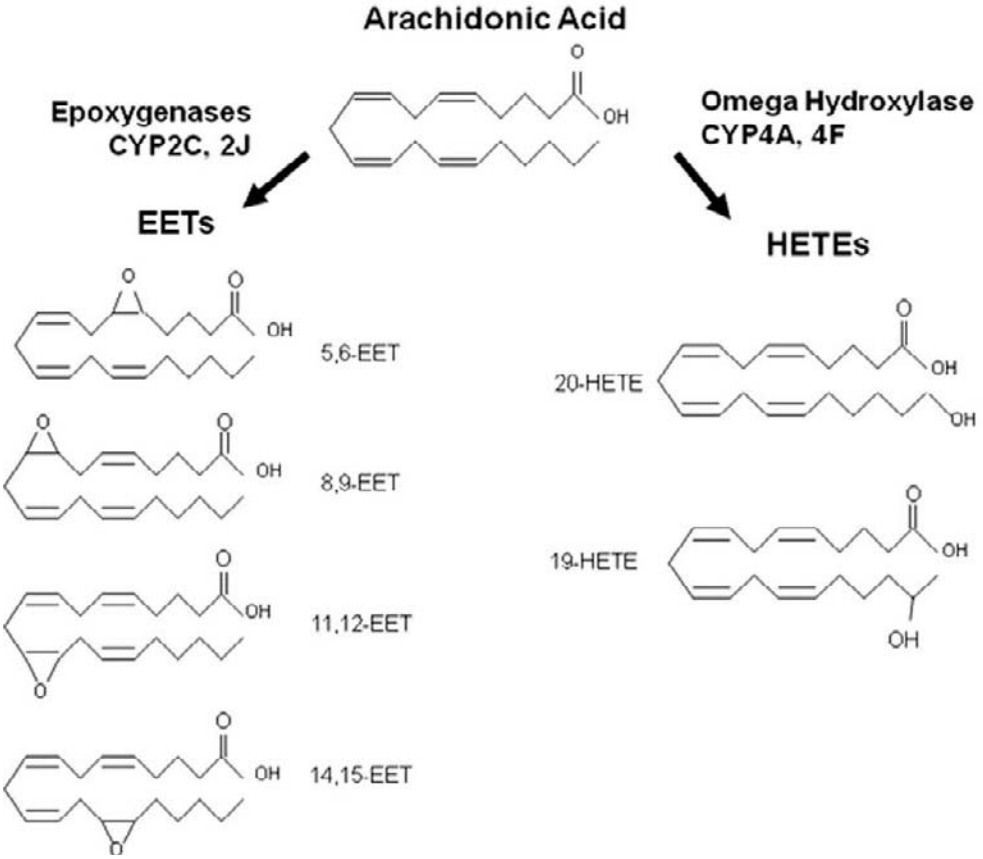

FIGURE 17.6 **Products of cytochrome P450-mediated metabolism of arachidonic acid.**

SUMMARY

Eicosanoids exert diverse and sometimes self-opposing functions. The specific effect of each eicosanoid depends on sequential enzymatic machinery in a specific cell, yielding a specific eicosanoid, exerting its distinct function. The biosynthesis of each eicosanoid is regulated at multiple levels from phospholipase A2 that catalyzes the release of arachidonic acid to specific enzymes that catalyze the formation of bioactive eicosanoids. Arachidonate-derived eicosanoids including prostanoids, leukotrienes, 12/15-HETEs, EETs, and HETEs, and sphingomyelin-derived ceramide play important roles in maintaining normal renal function. They are also involved in the pathophysiology of diabetic nephropathy, and inflammatory or toxic glomerular injury. Those signaling pathways should provide a fruitful area to identify targets for intervention in the pharmacologic treatment of renal disease.

Historically, the control of renal vascular and tubular function has been attributed solely to neural and endocrine regulation. However, in addition to these extrinsic factors, it is now recognized that several complex humoral control systems exist *within* the kidney that act in an autocrine and/or paracrine manner. One of these is the extracellular nucleotide/P2 receptor system.

Although physiological actions of extracellular adenine nucleotides were reported as long ago as 1929,[34] it was not until many years later (1972) that the importance of ATP as a transmitter for non-adrenergic, non-cholinergic neurones of the autonomic nervous system was proposed by Geoffrey Burnstock.[13] Since then it has become apparent that the function of extracellular nucleotides is not confined to neurones: rather, they are ubiquitous autocrine/paracrine agents regulating diverse physiological processes in almost every tissue in the body. Information on their roles in the kidneys has only really begun to emerge in the last decade.

P2 RECEPTORS

Extracellular nucleotides exert their effects by binding to and activating cell surface located receptors; P2 receptors. These are subdivided into P2X receptors, of which seven mammalian subunits have been cloned ($P2X_{1-7}$), and P2Y receptors, of which eight mammalian subtypes are currently recognized, $P2Y_{1,\ 2,\ 4,\ 6,}$ and $P2Y_{11-14}$.[14]

P2X Receptors

P2X receptor subunits are proteins with two transmembrane-spanning regions, the N- and C-termini being within the cell.[114] Three P2X subunits assemble to form a P2X receptor ion channel that, when activated, is permeable to small cations (Na^+, K^+, Ca^{2+}). Each of the seven P2X subunits can make homomeric ion channels, and can also form heteromeric assemblies involving more than one type of subunit. Until recently it had been thought that $P2X_7$ subunits could only make homomeric assemblies, but a $P2X_{4/7}$ heteromer has now been described.[51] As well as a non-selective ion channel, the $P2X_7$ receptor can form a larger membrane pore, and initiate cell death by necrosis or apoptosis.

The principal natural ligand for all P2X subunits is ATP. The $P2X_1$ subunit is the most sensitive (requiring sub-micromolar concentrations of ATP); $P2X_{2-6}$ subunits require micromolar concentrations, while the $P2X_7$ subunit is easily the least sensitive, requiring almost millimolar concentrations.

P2Y Receptors

P2Y receptors are G-protein-coupled receptors with seven transmembrane-spanning regions; the C-terminus is inside the cell and the N-terminus extracellular. In rodents, ATP is probably the principal natural ligand for $P2Y_{2,\ 4,}$ and $P2Y_{11}$ subtypes and, at sufficiently high dose and/or receptor density, can activate $P2Y_{1,\ 12,}$ and $P2Y_{13}$

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00018-5

subtypes. However, the natural ligand for $P2Y_{1,\ 12,}$ and $P2Y_{13}$ subtypes is ADP. Although $P2Y_6$ receptors can also be activated by ADP, UDP is much more potent. In rodents, UTP activates $P2Y_2$ and $P2Y_4$ subtypes with similar potency to ATP, an observation often used in physiological studies as an initial pointer to receptor identity. Human $P2Y_4$ receptors, however, are activated primarily by UTP (50-fold more potent than ATP[178]). This is a particularly striking example of species differences, serving to highlight the need for caution before extrapolating from findings in one species to another. The $P2Y_{14}$ receptor is exceptional in that its natural ligand is UDP-glucose; although originally believed to be unaffected by unglycosylated purine- or pyrimidine-based nucleotides, it is now known that UDP is also a full agonist at rat and human $P2Y_{14}$ receptors.[55]

P2Y receptors are coupled to either G_q or G_i signaling proteins. $P2Y_{1,\ 2,\ 4,\ 6,}$ and $P2Y_{11}$ subtypes are coupled to G_q/G_{11}, resulting in PLC-β activation and increased $[Ca^{2+}]_i$, while $P2Y_{12-14}$ are coupled to G_i/G_o, resulting in adenylyl cyclase inhibition and reduced cAMP levels. The $P2Y_{11}$ subtype is unusual, in that it can couple to both G_q and G_s, resulting in both PLC-β and adenylyl cyclase activation, causing increased cAMP levels.[172]

Heterodimeric Receptors and Dinucleotide Receptors

A further layer of complexity has been added to the picture with the finding that adenosine A1 receptors can be co-expressed with $P2Y_1$ or $P2Y_2$ receptors (and possibly other P2Y subtypes) as a discrete receptor type, at least in non-renal cells. The chimeric nature of such receptors is reflected in their mixed pharmacological and signaling properties.[200,201] The possible functional significance of these heterodimeric P1/P2Y receptors with regard to the kidneys is currently unknown.

Finally, a number of dinucleotides, in which the 5′-carbon positions of two nucleosides are linked by a polyphosphate chain, occur naturally in the body. These dinucleotides can be symmetrical (e.g., Ap_4A, where two adenosine moieties are linked by a chain of four phosphates) or asymmetrical (e.g., Up_4A, where a uridine moiety and an adenosine moiety are similarly linked). Dinucleotides can have both vascular and tubular effects within the kidneys (*vide infra*), but the receptors responsible are unknown; evidence for dinucleotide-specific receptors has been provided in other tissues, but several P2Y receptors ($P2Y_{1,\ 2,\ 4,}$ and $P2Y_6$) and P2X receptors ($P2X_{1-5}$) are known to be dinucleotide-sensitive.[81,143]

It is likely that both adenine-based and uracil-based nucleotides are released from most cells in the body (including renal cells); moreover, ecto-enzymes that metabolize nucleotides, either inactivating them or converting them to molecular forms that can stimulate different P2 receptor subtypes, are ubiquitous (*vide infra*). Figure 18.1 shows the molecular structures of some of the principal nucleotides involved, and Figure 18.2 provides a simplified overview of nucleotide release, degradation, and purinoceptor (i.e., P1 (adenosine) receptor and P2 receptor) activation.

Synthetic Agonists and Antagonists of P2 Receptors

Agonists

An ever-increasing range of synthetic nucleotide analogs and non-nucleotide agonists is being developed in an attempt to find agents that, unlike naturally occurring nucleotides, are not subject to degradation by ectonucleotidases, and can act as selective agonists for given receptor subtypes. Such exclusivity is rarely achieved, although substantial progress is now being made. Unfortunately, many of the initial observations on P2 receptor stimulation and renal function were made at a time when information on the selectivity of agonists was incomplete, and the agonists used were often more promiscuous than was appreciated, giving rise to misleading interpretations. Thus, although 2 meSADP, for example, has been used as an agonist for $P2Y_1$ receptors, it also activates $P2Y_{12}$ and $P2Y_{13}$ subtypes; the same applies to 2 meSATP which, additionally, can stimulate a number of P2X receptors, while ATPγS, originally used as a $P2Y_2$ and/or $P2Y_4$ agonist, is now known as a broad-spectrum agonist, being effective in a range of P2Y and P2X receptors. Another ATP analog, 2′3′-*O*-(4-benzoylbenzoyl)ATP (BzATP), has often been used as a "selective" $P2X_7$ agonist, given that it is more potent than ATP at this receptor subunit, but it is also effective at $P2X_{1,\ 3}$ and $P2Y_5$ subunits, so it is in reality only a non-selective P2X agonist. Furthermore, BzATP has been shown to act as an antagonist at $P2Y_4$ receptors.[185]

As our knowledge of truly selective P2 agonists expands, future investigations should provide more precise information about the purinoceptor subtype(s) involved in a given physiological response. That knowledge, however, is still limited. The *N*-methanocarba-ADP derivative MRS2365 is selective for $P2Y_1$ receptors; MRS2698 and INS365 (Up_4U or "diquafosol") are selective $P2Y_2$ agonists; and UDPβS, INS48823, and MRS2693 are selective $P2Y_6$ agonists.[14,72,178] At the time of writing, a selective agonist for $P2Y_4$ receptors has not been identified. Similarly, a truly selective agonist for any of the P2X subunits is still lacking.

Antagonists

As with agonists, nucleotide receptor-selective antagonists are something of a rarity. Probably the compound

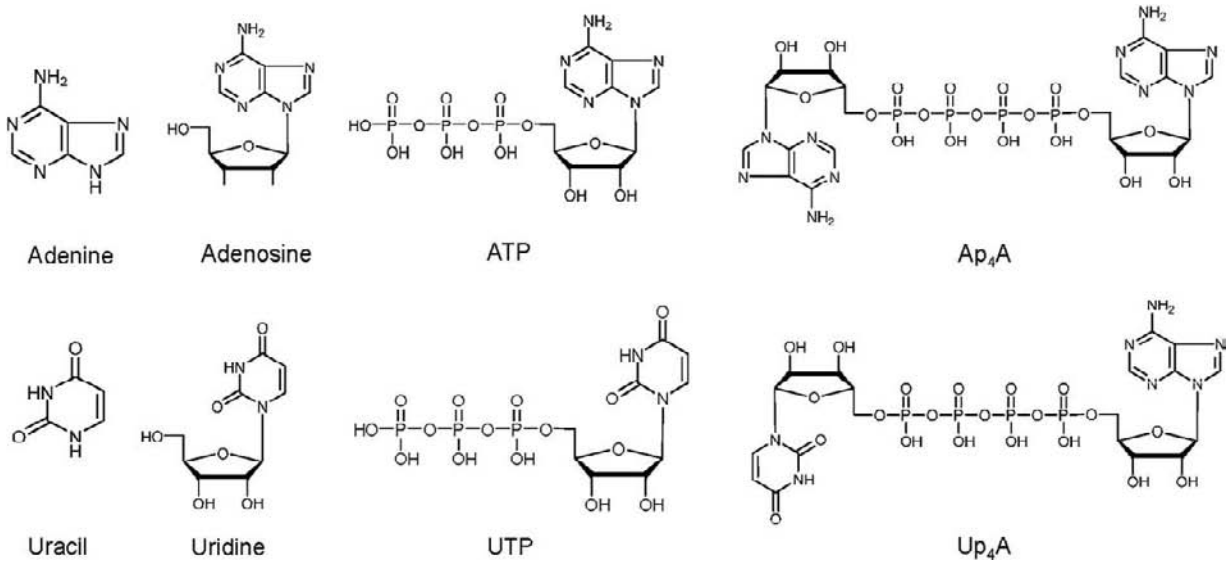

FIGURE 18.1 **Molecular structures of some of the principal nucleotides and their parent nucleosides and purine/pyrimidine bases.**

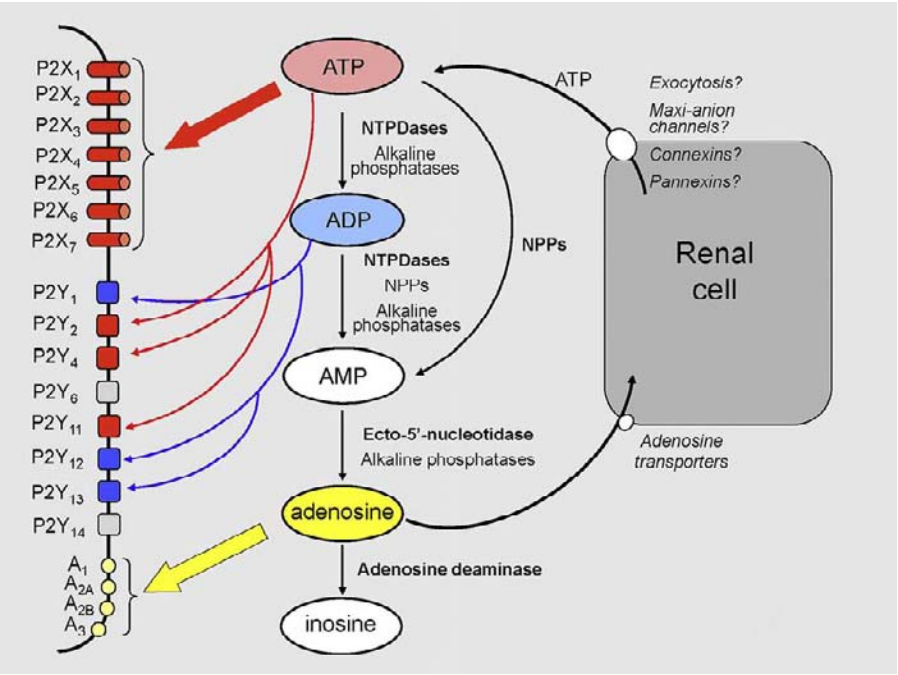

FIGURE 18.2 **The renal purinoceptor system and its modulation by the major renal ectonucleotidases.** The mechanism of ATP release from renal cells is still a matter of debate (see text for details). It is important to note that nucleotides derived from other bases are also likely to be secreted and are also hydrolyzed/synthesized by ectonucleotidases, but have been omitted for clarity. Uracil-based nucleotides are particularly significant: UTP is a potent agonist of $P2Y_2$ and $P2Y_4$ subtypes, and its derivative UDP is the major naturally occurring agonist of the $P2Y_6$ subtype.

most commonly used to inhibit P2 receptors is suramin, although it also affects a variety of other cellular processes. In sufficient concentration, suramin antagonizes practically every P2 receptor subtype, be it P2Y or P2X. The same comment applies to PPADS (pyridoxal-5-phosphate-6-azophenyl 2′,4′-disulphonic acid) and, to a lesser extent, reactive blue 2 (RB-2). However, a clutch of selective and potent antagonists is now available. Thus, the ADP derivatives MRS2179, MRS2279, and MRS2500 are selective $P2Y_1$ antagonists; AR-C126313 and AR-C118925 are selective $P2Y_2$ antagonists; MRS2578 is a selective $P2Y_6$ antagonist; INS49266, INS50589, and AZD6140 are selective $P2Y_{12}$ antagonists; and MRS2211 is a selective $P2Y_{13}$ antagonist.[14,72,178]

For P2X subunits, the list is shorter. Ip_5I is a selective $P2X_1$ antagonist,[14] and A-740003 and A-438079 are selective $P2X_7$ antagonists.[33] Trinitrophenyl-ATP (TNP-ATP) "selectively" antagonizes $P2X_{1-5}$ subunits without affecting P2Y receptors.

Assignment of Physiological Responses to Specific P2 Receptor Subtypes

The plasma membranes of any renal cell, be it vascular or tubular, can contain a variety of P2 receptor subtypes. Moreover, epithelial cells can have different (as well as the same) subtypes on their apical and basolateral membranes. This raises the question of how to attribute a given functional response to a particular subtype. A number of approaches can be used. First, it is useful to identify immunologically the subtypes present in the region of interest (although this, of course, depends on the availability of suitable antibodies) and, if possible, to localize the receptor to apical and/or basolateral membrane. In some cases, instead of the immunohistochemical approach, determination of mRNA has been used, although this obviously does not guarantee the presence of the receptor protein itself. Second, it is possible to try to mimic the effect of the naturally occurring nucleotide using "selective" agonists and antagonists. However, as indicated above, only a few of these are truly selective (although the situation is improving). Consequently, it is usually necessary to compare the individual responses to a variety of agonists (both natural and synthetic) to provide a pharmacological profile from which tentative conclusions can be drawn, but even then their effects will depend not only on agonist/antagonist concentration, but also on the number and distribution of receptor subtypes. Moreover, naturally occurring agonists are degraded by ectonucleotidases, making it difficult to control their absolute concentrations at the receptor site. A further limitation is the use of intracellular Ca^{2+} transients to assess responses to direct application of agonists, since these are not invariably associated with recognizable functional changes.

A completely different, and superficially more attractive, approach is to use "knockout" mice in which the gene encoding the receptor of interest has been deleted. However, this is not without its own potential problems. Life-long, global deletion of a receptor subtype that performs a vital function is likely to lead to compensatory changes in several organ systems. The P2 receptor profile within the kidney may then change in order to restore overall excretion rates, which could then lead to misleading conclusions about the role of the receptor. The *Cre-loxP* system adds a degree of refinement to the gene-targeting approach, permitting tissue- or cell-type-specific deletion. Nevertheless, compensatory changes in up- or downstream nephron segments cannot be excluded, and this approach is further complicated by incomplete (knockdown rather than knockout) and off-target deletion. Furthermore, genetically-engineered deletions have so far been restricted to mice, where $P2Y_2$ receptors seem to predominate in the renal tubule. There are important differences in the distributions of receptor subtypes between mice and rats – and presumably between mice and other species. Thus, for the foreseeable future it seems that we will need to continue to rely on a combination of approaches; as yet, there is no "silver bullet" when it comes to defining P2 receptor function.

Finally, to obviate the need for working with complex renal tubules, many investigators have made use of simpler systems: immortalized cell lines originally derived from renal-like tissue (e.g., Madin–Darby canine kidney (MDCK) cells). Unfortunately, these cell lines often express membrane proteins that differ from those found in native tissue. Consequently, in this chapter we will avoid deductions based solely on observations concerning P2 receptors in non-native renal tissue.

P2 RECEPTORS AND RENAL FUNCTION

The Renal Vasculature

Figure 18.3 summarizes current knowledge about the distribution of P2 receptors in renal vascular and tubular structures. P2 receptors are expressed widely in the renal vasculature, in the glomerulus, and in the extraglomerular mesangium. Immunohistochemical and Western analyses indicate that $P2X_1$ receptors are present in the vascular smooth muscle of the rat renal artery, arcuate and interlobular arteries, and the afferent arteriole, but not in the efferent arteriole.[19,171] Functional approaches have confirmed the expression of a $P2X_1$-like receptor in the afferent arteriole.[70] $P2X_2$ subunits have been immunolocalized in the smooth muscle of larger arteries and veins within the kidney,[66,171] and molecular evidence has recently been provided for $P2X_4$ subunits, at least in arcuate and interlobular arteries.[56] Of the P2Y receptors, $P2Y_1$ has an extensive distribution, being expressed in the endothelium of the large arteries, and both afferent and efferent arterioles.[171]

Most information concerning P2 receptor expression in the glomerulus comes from cell culture systems. On the basis of mRNA detection and/or agonist profiling, $P2Y_{1,2,4,}$ and $P2Y_6$ subtypes and $P2X_{2,3,4,5,}$ and $P2Y_7$ subunits have been identified in glomerular mesangial cells[53,65,132,151]; $P2Y_{1,2}$ and $P2Y_6$ subtypes in podocytes[41]; and $P2Y_1$ and $P2Y_2$ subtypes in glomerular endothelial cells.[12] Studies performed on RNA extracted from pools of intact glomeruli from rats found messages encoding $P2Y_{1,2,4}$ and $P2Y_6$

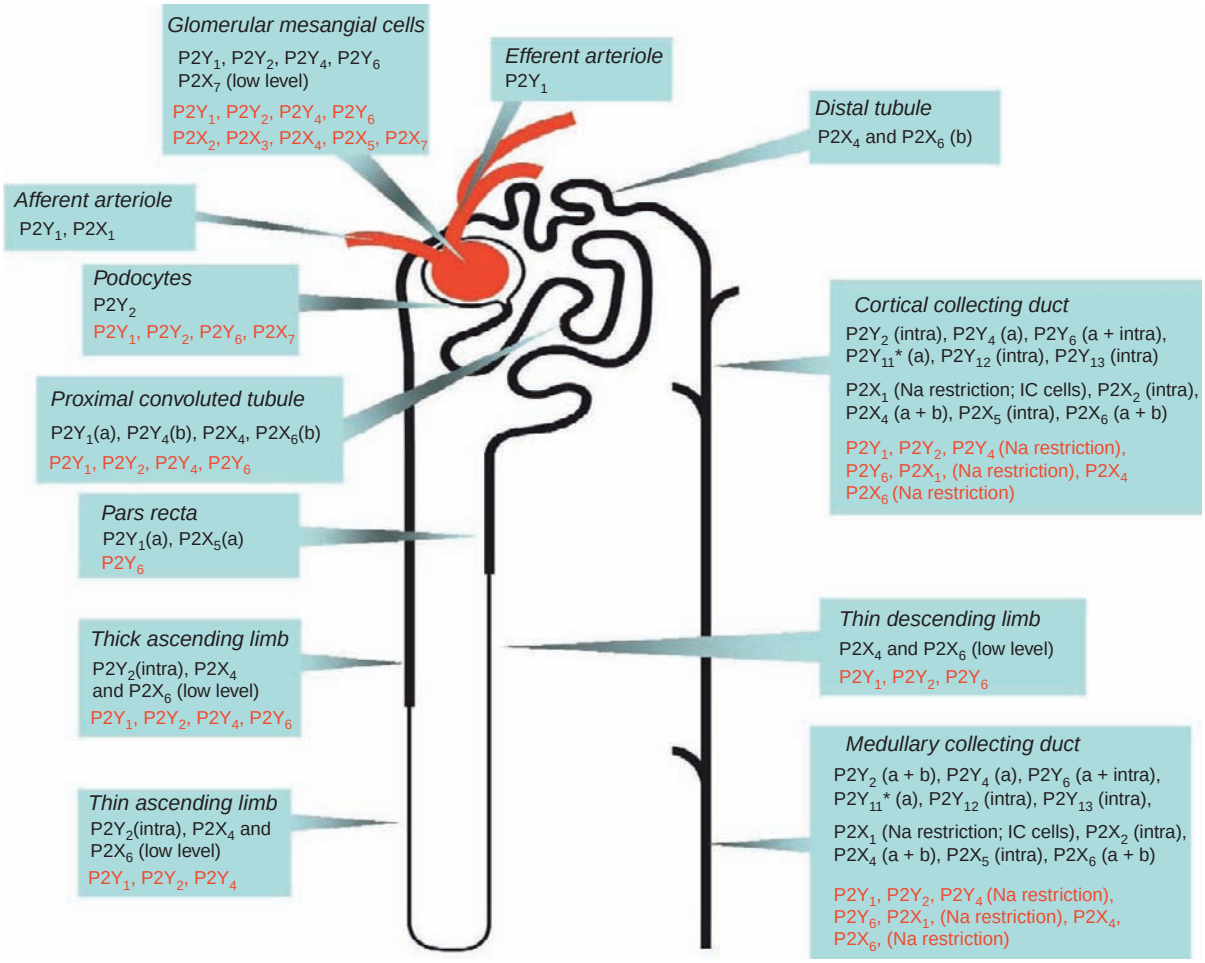

FIGURE 18.3 **P2 receptors in the vasculature and tubules of the rat kidney.** Those receptors in the rat kidney for which firm evidence from immunohistochemical studies and/or Western blotting has been obtained are shown in black. Those receptors for which expression of mRNA has been documented are shown in red. Where possible, apical (a), basolateral (b) or intracellular (intra) location is indicated. *The antibody used to detect $P2Y_{11}$ was raised against an epitope of human, not rat, $P2Y_{11}$ receptors. Information is taken from ref. 4–7,19,41,53,83,132,151,171,187,203

subtypes[7]; the expression of other P2Y receptors was not assessed. Immunohistochemical analysis and measurements of agonist-induced phosphoinositide production confirmed the presence $P2Y_1$ and $P2Y_2$ subtypes in the rat glomerulus. On the basis of co-localization with cell-specific markers, $P2Y_1$ receptors were localized in mesangial cells and $P2Y_2$ receptors in podocytes[7,171]; expression of $P2Y_4$ and $P2Y_6$ receptor protein could not be confirmed, either functionally or immunologically. Of the P2X subtypes, only a low and variable expression of $P2X_7$ immunoreactivity was found in the rat glomerulus.[171]

Physiological Responses

Infusion of ATP into the renal artery has long been known to alter renal vascular resistance, although the nature and magnitude of the response are dependent upon species, basal vascular tone, and to some extent the experimental approach.[67] The larger renal arteries serve principally as conductance vessels,[202] and renal vascular resistance (and therefore renal blood flow) is regulated primarily through pressure-dependent vasoactivity of the preglomerular arterioles[153] and, to a lesser extent, the small interlobular arteries.[58] The responsiveness to ATP of the arcuate and interlobular arteries and the glomerular arterioles has been evaluated in rats using the isolated perfused kidney preparation.[70] The preglomerular arteries were relatively insensitive to ATP, with micromolar concentrations evoking transient vasoconstriction (Figure 18.4). In contrast, the afferent arteriole underwent sustained contraction at concentrations in the submicromolar range, whereas the efferent arteriole was unresponsive to extracellular ATP. Thus, in the isolated perfused rat kidney, intrarenal administration of ATP is normally vasoconstrictive. This vasoconstriction can be potentiated by inhibition of nitric oxide (NO) synthesis.[37] However, when baseline renal vascular resistance is

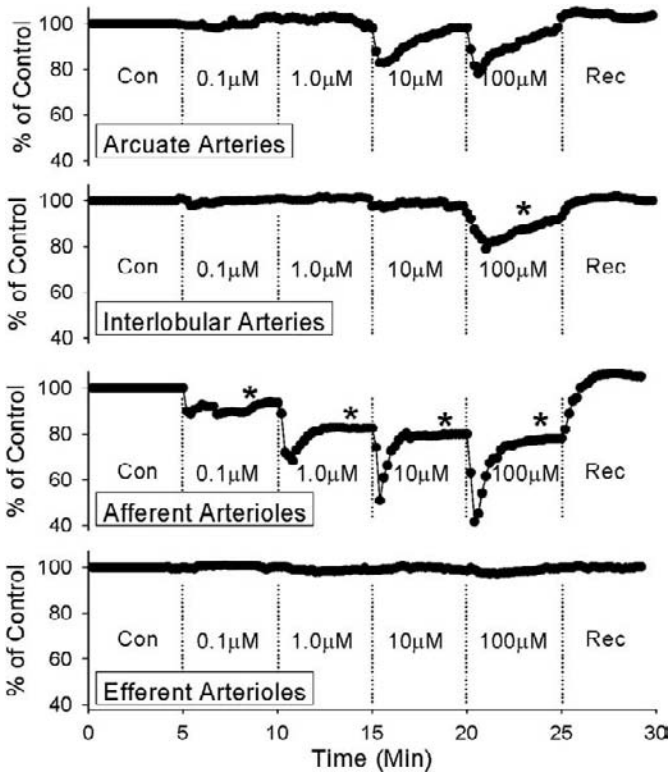

FIGURE 18.4 **ATP concentration–response relationships for pre- and post-glomerular vasculature.** The figure shows average segmental diameter responses evoked by ATP applied to the adventitial surface of arcuate arteries, interlobular arteries, afferent arterioles, and efferent arterioles of rat juxtamedullary vascular segments. After the control period (Con), increasing concentrations of ATP were applied at 5 min intervals; each protocol ended with a 5 min recovery period (Rec). Each data point is normalized as a percentage of the control diameter *(from ref. [67]).*

high, ATP induces *vasodilatation*, due to P2Y-mediated production of NO.[40] Thus, P2 receptor "tone" can influence renal vascular resistance, with P2Y/NO-mediated vasodilatation exerting a counterbalancing influence on $P2X_1$-mediated vasoconstriction. The dominant receptor pool, as well as the source and local concentration of extracellular nucleotide, will therefore influence the net physiological response to extracellular nucleotides. ATP released from renal nerve terminals, for example, will act directly on the vascular smooth muscle, promoting $P2X_1$-mediated vasoconstriction.[139,162] Conversely, release of ATP in the vicinity of the endothelial P2Y receptors would be expected to promote NO synthesis and vasodilatation.

Renal Autoregulation

The majority of vascular beds stabilize blood flow in the face of fluctuating blood pressure. This autoregulation of blood flow is an intrinsic property of the vasculature, and in the kidney it is highly efficient: over the physiological range, renal blood flow can be effectively independent of blood pressure.[26] Whole-kidney autoregulation is governed through the combined influence of at least two mechanisms, tubuloglomerular feedback (TGF) and the intrinsic myogenic response of the vascular smooth muscle; these regulatory systems have different, but overlapping, operational frequencies. Computational analysis of the dynamic frequencies of the two systems indicates a degree of interaction; constriction of the terminal afferent arteriole by TGF increases pressure in the upstream vasculature and the myogenic response is enhanced.[180]

Myogenic Responses to Altered Perfusion Pressure

Of the two major components, only the intrinsic myogenic response to altered perfusion pressure is both necessary and sufficient for full, whole kidney autoregulation.[26] The myogenic response operates along the preglomerular vascular tree, reacting to increased transmural pressure by channel-mediated calcium influx and reflex vasoconstriction of the vascular smooth muscle. The exact signaling mechanisms are not defined, but local release of ATP is implicated. In the afferent arteriole, pressure-mediated vasoconstriction is markedly blunted by PPADS or suramin, or by the saturation and subsequent desensitization of the P2 receptor system.[69] The central role of the P2 system is further underscored by experiments in $P2X_1$-deficient mice, in which pressure-induced reductions in afferent arteriole diameter are abolished[68] (Figure 18.5). Similarly, pharmacological[119] or pathological[50] maneuvers that impair $P2X_1$ receptor signaling significantly attenuate whole kidney autoregulation of blood flow both *in vivo* and *in vitro*. Furthermore, mice with a targeted deletion of the ectonucleotidase NTPDase1 (thereby prolonging the half-life of extracellular ATP – *vide infra*) exhibit enhanced pressure-induced vasocontriction in the mesenteric artery,[78] consistent with a key role for local nucleotide signaling in the general myogenic response.

Tubuloglomerular Feedback and the Juxtaglomerular Apparatus

Tubuloglomerular feedback (TGF) is a dynamic process whereby changes in the concentration of NaCl in the fluid emerging from the loop of Henle elicit inverse changes in the glomerular filtration rate of the nephron of origin. TGF is mediated by the juxtaglomerular apparatus (JGA), which includes a sensor, the macula densa, and an effector, the granulated cells of the afferent arteriole; other components of the JGA (e.g., mesangial cells) also play a role.

Bell and colleagues demonstrated the release of ATP across the basolateral membrane of the macula

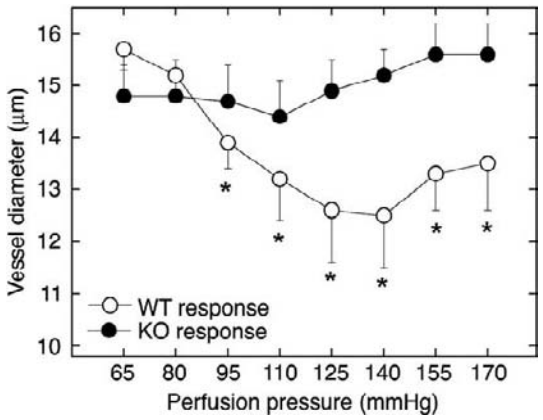

FIGURE 18.5 **Autoregulatory responses in P2X1 knockout (KO) mice versus wild-type (WT) mice.** The normal autoregulatory vasoconstrictor response to increases in perfusion pressure is absent in the KO mice. *(from ref. [68]).*

densa plaque in response to altered luminal NaCl concentration within the physiological range,[11,87] and the concentration of ATP in the cortical interstitium was shown to respond appropriately to inhibition or activation of TGF *in vivo*.[112] This compelling evidence suggests that ATP is the primary signaling molecule for TGF, the effects of which might well be modulated by other paracrine agents produced in the macula densa cell, such as nNOS- (NOS1-) derived NO and COX2-derived prostaglandin E_2.[10] Gene-targeting experiments, however, suggest that ATP may not be the ultimate signal through which TGF causes constriction of the afferent arteriole; hydrolysis of ATP to adenosine appears to be critical. *In vivo* TGF responses are attenuated in mice lacking either adenosine A_1 receptors[157] or ecto-5′-nucleotidase, the enzyme catalyzing the final stage of the degradation of ATP to adenosine.[15] This proposition is supported by a recent *in vivo* study in which the TGF response in mice (as assessed by changes in stop-flow pressure in the proximal tubule) was unaffected during intravenous infusion of PPADS or suramin.[136]

It would be rash, however, to conclude that the P2 receptor system has no role in TGF. Desensitization of this system inhibits TGF in rats,[113] and it is notable that *in vivo* manipulations of TGF affect the interstitial concentration of ATP, but not of adenosine.[67] Furthermore, an anatomical consideration argues strongly for involvement of the P2 receptor system in the TGF response: the ATP released from macula densa cells cannot directly activate P2 receptors in the afferent arteriole, being physically separated in most species by the extraglomerular mesangium. An intact mesangium is required for TGF responses,[129] and Peti-Peterdi has demonstrated that TGF activation causes a wave of increased cytosolic calcium to pass through the mesangium, to the granulated cells of the afferent arteriole and into the glomerular podocytes.[121] Propagation of this calcium wave was abolished by suramin, but not by adenosine receptor antagonism. The P2 receptor response was later shown to be dependent on gap junctional coupling, being inhibited by specific antagonists against connexins 37 and 40[159] (*vide infra* for discussion of connexins).

The basolateral membrane of macula densa cells expresses a $P2Y_2$-like receptor, the function of which is not yet known.[10] It is possible that this provides a negative feedback loop for TGF signaling or a mechanism through which ATP release can be coupled to production.

Glomerular and Medullary Microcirculation

Infusions of nucleotide analogs into the renal artery exert powerful effects on regional blood flow, which can be measured by laser-Doppler flow probes inserted into specific regions of the kidney. In the rabbit, ATP evokes a biphasic response, with vasoconstriction of the medullary blood flow being followed by hyperemia.[39] On the basis of relative agonist potency, the vasoconstriction was attributed to $P2X_1$ receptors; the secondary vasodilatation, which was independent of NO, was partially mediated by adenosine receptors. In the rat, the net effect of ATP is influenced by sodium status. In sodium-restricted rats, ATP increased medullary blood flow in a nitric oxide-dependent manner.[32] In rats fed a high-salt diet, ATP caused vasoconstriction in the outer medulla, without affecting inner medullary flow. The authors' speculated that the inner medullary vasodilatation reflected an effect of nucleotides on vasa recta pericytes. However, preliminary data from Peppiatt-Wildman's laboratory, obtained in slices of rat kidney, suggest that P2 receptor activation promotes vasoconstriction in this setting.[79]

Renin Release

The renin–angiotensin system is influenced by many factors, the final pathways of which converge at the level of altered $[Ca^{2+}]_i$ in the granular cell; renin secretion is inversely related to $[Ca^{2+}]_i$. The combined use of receptor-selective agonists and antagonists has demonstrated that A_1 receptors exert a tonic inhibitory effect on renin secretion at the level of the granular cell.[110] However, the adenosine receptor system is not vital for the control of renin secretion, since A_1 receptor knockout mice are able to raise their secretion appropriately in response to a low-salt diet,[140] a regimen that increases two-fold the sensitivity to luminal NaCl of ATP release by the macula densa.[87]

The role of the P2 receptor system in the regulation of renin release is not entirely clear, and is to some extent contradictory. Purinoceptor signaling is a prerequisite for synchronization of the intercellular calcium wave that controls renin secretion in the JGA,[198] and infusion of ATP into the isolated perfused rat kidney causes profound inhibition of renin secretion.[198] On the other hand, activation of an ADP-selective receptor, thought to be $P2Y_1$, was shown to stimulate renin secretion in rat renal cortical slices via a nitric oxide-dependent mechanism.[21] Resolution of this issue awaits further investigation.

Proximal Tubule

Immunohistochemical studies have identified apical expression of $P2Y_1$ and $P2X_5$ receptors in the S3 segment of the rat pars recta, and basolateral expression of $P2Y_4$ and $P2X_6$ receptors in the proximal convoluted tubule (PCT); low-level expression of $P2X_4$ protein was also seen in the PCT, although the membrane domain was not identified.[171] Western blot analysis has additionally shown the presence of $P2Y_1$ receptors in brush-border membrane vesicles from the S2 segment of rat PCT[6] (see Figure 18.3). Messenger RNA expression has been assessed for only four P2 receptor subtypes: $P2Y_{1,\ 2,\ 4}$ and $P2Y_6$ are all present in rat proximal tubule.[4,5] In terms of Ca^{2+} transients following application of P2 receptor agonists of varying selectivity, supportive evidence has been provided for apical $P2Y_1$-like receptors in an immortalized cell line with a proximal phenotype,[76] and for basolateral $P2Y_1$ receptors in native rat PCT[4,17]; Bailey and colleagues[5] also reported that basolateral UDP was effective in increasing $[Ca^{2+}]_i$, corroborating the presence of $P2Y_6$ receptors. Finally, ATP and UTP were equally effective in stimulating Ca^{2+} transients when applied to rat or rabbit basolateral membranes,[4,196] implying mediation by $P2Y_2$ or $P2Y_4$ receptors; the immunohistochemical evidence in rats favors $P2Y_4$ receptors.[171]

Using a stationary microperfusion technique in rat PCT *in vivo*, Bailey[2] showed that addition of adenosine nucleotides to the lumen inhibited bicarbonate reabsorption. ADP was more effective than ATP, implicating $P2Y_1$ receptors; this was supported by the observation that the $P2Y_1$ agonist 2 meSADP also had a potent inhibitory effect, which was blocked by the $P2Y_1$-selective antagonist MRS2179. (When the tubule was perfused with MRS2179 alone, a small increase in bicarbonate reabsorption was seen, suggesting a tonic inhibitory effect of endogenous nucleotides acting via $P2Y_1$ receptors.) The $P2Y_1$-mediated effect on bicarbonate reabsorption involved inhibition of the Na^+/H^+ exchanger NHE3, since it was not additive to that of EIPA. The effect was blocked by either U73122 or H89, indicating involvement of phospholipase C and protein kinase A. In apparent contrast to these findings from intraluminal perfusions, Diaz-Silvester et al.[31] found that addition of ATP to peritubular capillaries perfused *in vivo* caused an *increase* in transepithelial bicarbonate reabsorption in rat PCT. Conceivably, given the presence of ectonucleotidases in peritubular capillaries and the peritubular space (*vide infra*), degradation of ATP through to the nucleoside adenosine (which stimulates proximal tubular bicarbonate reabsorption[29]) could not be ruled out. However, increasing the viscosity of the peritubular perfusate also stimulated bicarbonate reabsorption, and this effect was blocked by peritubular suramin, suggesting P2 receptor mediation. (Shear stress was proposed as the activating factor.) Interestingly, the increase in bicarbonate reabsorption induced by ATP or by raised viscosity could be blocked by a nitric oxide synthase inhibitor.

In a preliminary study of membrane transporters in the tubules of $P2Y_2$ receptor knockout mice, Listhrop et al.[99] reported increased expression of NaPT2 protein in the proximal tubule (but no change in NHE3 abundance). In line with this, ATP has been shown to inhibit phosphate uptake (and mRNA for NaPT2) in primary cultures of rabbit PCTs.[94] Interestingly, in the same preparation, ATP *stimulates* sodium-glucose co-transport by increasing both SGLT1 and SGLT2 protein expression.[93]

A renal clearance study in rats, using lithium clearance as an index of end-proximal tubular fluid delivery,[165] reported remarkable effects of the naturally occurring diadenosine polyphosphate Ap_4A. When infused intravenously, Ap_4A increased lithium clearance almost two-fold, despite a fall in GFR, indicating a profound reduction in fractional proximal tubular reabsorption.[154] Although a fascinating observation, it is debatable whether intravenous infusion of relatively high-dose exogenous nucleotide provides physiologically useful information about normal autocrine/paracrine control by endogenous agents. It is also difficult to know which P2 receptor(s) is/are involved, since Ap_4A can stimulate a number of subtypes, including $P2Y_1$ and $P2Y_4$ receptors,[143,185] which are both expressed in the rat proximal tubule ($P2Y_1$ apically, $P2Y_4$ basolaterally); intravenous delivery of the agonist does not allow differentiation between these possibilities.

In addition to effects on proximal tubular transport, both adenine-based and uracil-based nucleotides can stimulate gluconeogenesis, an important metabolic function of this nephron segment.[16,109] Diadenosine polyphosphates also have this effect.[35] As these experiments were performed using tubule suspensions or isolated tubules, the agonists will presumably have gained access to both apical and basolateral membranes; moreover, ectonucleotidase-mediated

metabolism of the nucleotides is a possibility, hindering identification of the receptor subtype(s) responsible. However, ATP and UTP were equipotent in stimulating gluconeogenesis, implicating $P2Y_2$ or $P2Y_4$ receptors.[109] Although these authors plumped for $P2Y_2$ mediation, the fact that $P2Y_2$ receptors have not been found in rat proximal tubules, whereas $P2Y_4$ receptors have (*vide supra*), makes a basolateral $P2Y_4$-mediated effect more likely.

Loop of Henle

The pars recta (also called the thick descending limb of Henle), has been dealt with in the preceding section. In the rat thin descending limb there is some immunohistochemical evidence for $P2X_4$ and $P2X_6$ receptors (membrane domain not stated[171]), and indications, from measurements of $[Ca^{2+}]_i$ transients during superfusion of isolated segments with various agonists, of a basolateral pyrimidine receptor,[4] although no $P2Y_2$ or $P2Y_4$ protein has yet been identified. Messenger RNA is expressed for $P2Y_1$ and $P2Y_6$,[4,5] but again immunohistochemical evidence of receptor protein is lacking. In the rat thin ascending limb, similar evidence for a basolateral pyrimidine receptor[4] is in this case accompanied by immunohistochemical confirmation of (intracellular) $P2Y_2$ receptor protein; low-level $P2X_4$ and $P2X_6$ protein expression has also been reported.[171] Hardly surprisingly, given the paucity of information regarding normal transport processes in these nephron segments, the functional significance of P2 receptors in the thin limbs is unknown.

Consideration of P2 receptors in the thick ascending limb (TAL) of the loop of Henle must take account of species differences between rat and mouse. In the rat TAL, binding sites for ATPγS are present on the basolateral membrane[3]; this agonist stimulates several P2Y and most P2X subtypes. Immunohistochemistry has identified $P2Y_2$ (intracellularly), $P2X_4$, and $P2X_6$ (membrane domain not stated) receptor proteins.[171] In addition, mRNA is expressed for $P2Y_{1,2,4,}$ and $P2Y_6$ subtypes.[4,5,83] It has been reported that rat TAL segments are poorly responsive to basolateral application of nucleotides, at least in terms of Ca^{2+} transients,[4,5] which is in marked contrast to the situation in mice, where basolateral ATP and UTP were each found to evoke large Ca^{2+} transients, consistent with activation of $P2Y_2$ receptors.[3,120] A major role for $P2Y_2$ receptors in mice was supported by Jensen et al.[75] who showed, in mouse medullary TAL (mTAL) perfused *in vitro*, that luminal application of ATP or UTP caused almost identical increases in $Ca^{2+}{}_i$ and, importantly, that these increases were absent in $P2Y_2$ knockout mice. In the same study, however, significantly different results were obtained when the nucleotides were applied basolaterally: both ATP and UTP caused an initial peak in $[Ca^{2+}]_i$ followed by a sustained plateau, but whereas both phases were virtually abolished in mTAL from $P2Y_2$ knockout mice treated with UTP, the plateau phase in mTAL from $P2Y_2$ knockout mice treated with ATP persisted, suggesting the presence of an additional basolateral P2 receptor. Since the plateau phase was dependent on extracellular Ca^{2+}, the authors proposed a Ca^{2+}-permeable P2X receptor.[75]

Some information, albeit circumstantial, on the effects of $P2Y_2$ receptors on transport processes in the TAL has come from a comprehensive study of the renal phenotype of $P2Y_2$ knockout mice by Vallon's group. These animals were shown to exhibit increased expression of the apical $Na^+K^+2Cl^-$ co-transporter (NKCC-2) in mTAL, associated with an increased natriuretic response to furosemide.[130] The obvious implication is that nucleotide activation of $P2Y_2$ receptors inhibits NaCl transport in mouse TAL.

During the last decade, in a series of meticulously controlled experiments using cell suspensions or nephron segments perfused *in vitro*, Garvin's group has begun to piece together evidence for a functional role of ATP on TAL function in the rat. Using suspensions of rat mTAL, Silva et al.[146] showed that ATP increased intracellular NO production in a concentration-dependent manner, and that the response was significantly inhibited by suramin. Although the EC_{50} value for the NO response to ATP was high, at 37 μM, prevention of ATP hydrolysis by administration of the ectonucleotidase inhibitor ARL67156 reduced the EC_{50} to 0.8 μM. On the basis that the ATP analog βγmeATP caused an increase in NO production, it was argued that the response was mediated primarily by P2X receptors, although it was noted that UTP also had a weak effect. A recent study from the same group[148] has provided some insight into the signaling cascade involved in ATP-stimulated NO production. Confirmation that endothelial nitric oxide synthase (eNOS; or NOS3) is the enzyme responsible came from the finding that ATP was unable to stimulate NO production in TAL cells from NOS3 knockout mice, whereas a normal response was seen in wild-type mice given NOS1- or NOS2-selective inhibitors. The PI_3 kinase inhibitor LY294002 caused a major reduction in the response to ATP, and a similar reduction was seen in the presence of an Akt-selective inhibitor. This finding, together with the observation that ATP stimulated Akt1 (serine threonine kinase; also called protein kinase B) phosphorylation, whereas phosphorylation of Akt2 and Akt3 was either unchanged or reduced, led the authors to conclude that ATP increases NOS3-derived NO via activation of Akt1. A possible functional link between the recently observed effect of increased flow on nucleotide release in the TAL[75]; (*vide infra*) and the production of NO can be drawn from an earlier study by

Ortiz et al.,[118] in which increasing flow (in the physiological range) in isolated perfused TALs from rat caused markedly increased NO production (which was all but blocked by the NOS inhibitor L-NAME). Notably, increasing luminal flow caused a redistribution of NOS3 within the TAL cells, with translocation towards the apical membrane. It was already known that NO (and presumably therefore ATP) can reduce TAL transport by inhibiting NKCC-2 activity[117] and (to a lesser extent) Na^+/H^+ exchange,[45] but a recent study from this group explored the possibility that ATP might have a primary effect in reducing basolateral Na^+K^+-ATPase activity, and thereby Na^+ extrusion from the TAL cell.[149] Using rat mTAL suspensions, it was found that ATP reduced oxygen consumption in a dose-dependent manner and that this was blocked by suramin, but not by the adenosine receptor antagonist theophylline; it was also blocked by the NOS inhibitor L-NAME. The "2P2X-selective" agonist βγmeATP also reduced oxygen consumption concentration-dependently, while the "P2X-selective" antagonist NF023 blocked ATPs action. (However, as with nucleotide-stimulated NO production, it was found that UTP had a (weak) inhibitory effect on oxygen consumption, suggesting some P2Y involvement.) When NKCC-2 and Na^+/H^+ exchange were blocked with a combination of furosemide and dimethyl amiloride, oxygen consumption fell, and was no longer affected by ATP; while the Na^+ ionophore nystatin increased oxygen consumption to a similar extent in TALs treated with ATP or vehicle alone. These experiments provide powerful confirmatory evidence that ATP, by increasing NO production, can inhibit Na^+ transport in the rat TAL, not by inhibiting basolateral Na^+K^+-ATPase activity, but principally by reducing apical Na^+ entry, particularly via the $Na^+K^+2Cl^-$ co-transporter. Whilst this series of *in vitro* findings is strongly suggestive of a physiological role for nucleotides in autocrine/paracrine control of TAL function (a putative schema is shown in Figure 18.6), a full assessment awaits a comprehensive investigation of electrolyte transport in the loop of Henle *in vivo*.

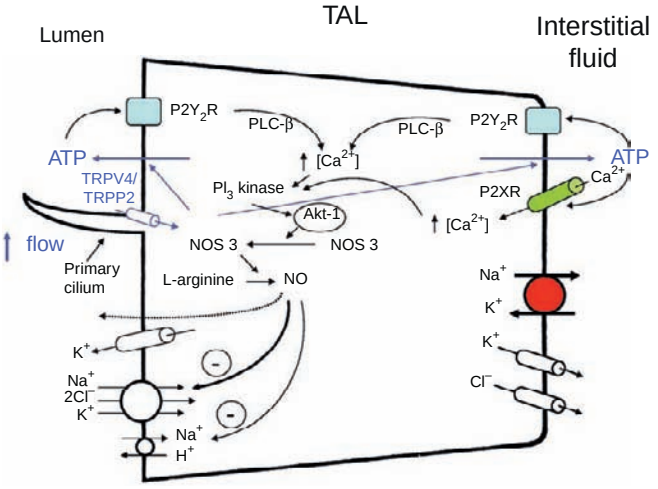

FIGURE 18.6 **Putative effects of flow-induced stimulation of ATP release in thick ascending limb of Henle (TAL).** According to this hypothesis, an increase in tubular flow is most likely detected by the primary cilium, and the consequent increase in Ca^{2+} influx stimulates ATP release. ATP, acting on apical and basolateral P2 receptors, stimulates (via intracellular 2nd messengers) PI_3 kinase which, in turn, phosphorylates Akt1. This kinase phosphorylates NOS3 (which itself may be translocated towards the apical membrane); thus activated, the enzyme stimulates the production of nitric oxide, which inhibits apical sodium entry into the cell via the $Na^+K^+2Cl^-$ co-transporter and the Na^+/H^+ exchanger, thereby inhibiting net Na^+ reabsorption. Information compiled from references [44,45,64,75,118,127,146,148,149]. $P2Y_2R$, $P2Y_2$ receptor; P2XR, P2X receptor; NO, nitric oxide; NOS3, nitric oxide synthase 3.

Distal Tubule

Little is known about P2 receptor distribution in this nephron segment (which, here, we arbitrarily define as distal convoluted tubule (DCT) plus connecting tubule (CNT); the final segment of the properly defined distal tubule – the initial collecting tubule – will be included under "Cortical Collecting Duct"). Immunohistochemical studies have identified $P2X_4$ and $P2X_6$ receptors on the basolateral membrane in rat distal tubule[171] (although it is not clear which region of the distal tubule was involved, as no markers of cell types were used in this study), and basolateral application of ATP to microdissected rat DCTs resulted in (weak) Ca^{2+} transients,[4] but no corresponding investigations have been made in other species or in CNT. Furthermore, no direct studies of distal tubular transport function have been made in native tissue, either *in vitro* or *in vivo*; the only information we have from whole-animal studies is that thiazide-sensitive sodium excretion is unaffected in $P2Y_2$ knockout mice, corresponding with a lack of change in Na^+-Cl^- co-transporter (NCC) abundance.[99,130] Consequently, our knowledge of the role of P2 receptors in these nephron segments is fragmentary and largely restricted to findings from studies of primary cultures of native cells or immortalized distal or "distal-like" cell lines.

Considerable evidence exists for the expression of a number of P2 receptor subtypes and for a range of P2-mediated actions in *Xenopus* A6 cells and Madin–Darby canine kidney (MDCK) cells, both widely used as "distal-like" cell lines. However, as indicated above, for reasons of physiological relevance it will not be considered here, as such cell lines often express membrane proteins different from those found in native tissue. Similar considerations may apply to immortalized cell lines derived from DCT: activation of apical receptors, characterized pharmacologically as $P2Y_2$ subtype, in immortalized rabbit DCT was shown to increase apical chloride

conductance[134]; while activation of receptors (membrane domain not stated) characterized pharmacologically as P2X, rather than P2Y, in immortalized mouse DCT was shown to inhibit magnesium reabsorption.[27] Finally, cultured cells from rabbit CNTs responded to extracellular ATP with an increase in $[Ca^{2+}]_i$ and inhibition of sodium and calcium absorption, although these inhibitory effects were not dependent on the Ca^{2+} transient.[88,173] Either apical or basolateral application of ATP was effective and, when ATP was added to both compartments, the inhibitory effects were additive. On the basis of pharmacological profiling, $P2Y_2$ receptors were implicated.[88]

It is difficult to build a coherent picture from these disparate findings. As with the loop of Henle, a comprehensive *in vivo* assessment of distal tubular function is required.

Collecting Duct

A large array of P2 receptor subtypes has been reported in rat collecting duct (CD) (Figure 18.3). Immunohistochemistry has indicated the expression of $P2Y_2$, $P2Y_4$, $P2Y_6$, $P2Y_{11}$, $P2Y_{12}$, and $P2Y_{13}$ subtypes, and $P2X_1$ (sodium-restricted rats only, intercalated cells only), $P2X_2$, $P2X_4$, $P2X_5$, and $P2X_6$ subunits[83,171,187] with, in some cases, differential expression in the different subsegments of the CD. With respect to membrane localization in principal cells, $P2Y_{4,6,}$ and $P2Y_{11}$ were reported to be exclusive to the apical membrane, whereas $P2Y_2$ and $P2X_4$ and $P2X_6$ were found in both apical and basolateral membranes; staining for $P2Y_{12}$ and $P2Y_{13}$ subtypes and $P2X_2$ and $P2X_5$ subunits was designated "intracellular".[187] In the mouse, immunohistochemistry has localized $P2X_1$ and $P2X_4$ subunits to the apical membrane of medullary CD cells.[97]

Expression of P2 receptor mRNA in the rat kidney broadly agrees with the immunohistochemical findings – at least in the one study in which both methodologies were used.[187] Messenger RNA has been identified for $P2Y_{1,2,4,}$ and $P2Y_6$ subtypes, and $P2X_4$ subunits in cortical (CCD) and outer medullary CD (OMCD),[4,5,187] and for $P2Y_{1,2,4}$ and $P2Y_6$ subtypes in inner medullary CD (IMCD).[83,203] Additionally, mRNA for $P2X_1$ and $P2X_6$ receptors has been reported in CCD and OMCD following dietary sodium restriction.[187] Messenger RNA levels for $P2Y_{11,12,13,}$ and $P2Y_{14}$ receptors have not yet been investigated. Studies using mice have so far focused on P2X receptors, and have identified mRNA for $P2X_{1,4,5,6,}$ and $P2X_7$ subunits in CCD and OMCD,[46,97] suggesting a species difference. As far as the human kidney is concerned, the only published information we have comes from a heroic study by Charbardès-Garonne and coworkers, in which the transcriptome from human kidneys was characterized using serial analysis of gene expression (SAGE). They found that, of tags for 258 genes conferring transport properties, the only P2X receptor detected in significant amounts in the CD was $P2X_4$.[18]

A complex picture is beginning to emerge concerning the role of P2 receptors in the CD. A combination of approaches has demonstrated that extracellular nucleotides, acting from both apical and basolateral sides, can have significant effects on water and electrolyte handling in this important nephron segment – the final site of regulation of urinary output.

Water

In the mid-1990s it was shown that activation of basolateral P2 receptors in rabbit CCD and rat IMCD, perfused *in vitro*, reversibly inhibited vasopressin-stimulated osmotic water permeability.[82,133] On the basis that UTP and ATP were equipotent, whereas other nucleotides were without effect, the inhibition found in the rat was attributed to basolateral $P2Y_2$ receptors[82]; this P2 receptor-mediated inhibition has been found to be PKC-dependent, and to result from decreased intracellular cAMP and increased PGE_2 levels.[181] The inhibitory action (at least in IMCD) appeared to be mediated only by basolateral receptors, since luminal application of ATP was without effect in this nephron segment.[36] Enhanced expression of $P2Y_2$ mRNA, and of the receptor protein itself, in the inner medulla of hydrated versus dehydrated rats, has provided additional evidence for a regulatory role for $P2Y_2$ receptors in modulating CD water reabsorption,[85] and this view is supported by the observation that chronic vasopressin V_2 receptor stimulation with dDAVP reduces inner medullary $P2Y_2$ mRNA and protein expression.[158] Gene deletion studies further substantiate a role for the $P2Y_2$ receptor in ATP-evoked inhibition of AVP-stimulated osmotic water permeability in the CD. Under basal conditions, $P2Y_2^{-/-}$ mice concentrated their urine to a greater degree, and their renal medullary aquaporin-2 (AQP2) abundance was significantly higher, compared with values in wild-type mice, despite almost identical plasma vasopressin levels,[130,205] and following chronic dDAVP treatment, inner medullary AQP2 expression was increased to a markedly greater extent in the $P2Y_2$ knockout animals.[205] In summary, the overall picture is that $P2Y_2$ receptor activation inhibits vasopressin-stimulated, AQP2-mediated water transport in the CD, and this results from decreased intracellular cAMP and increased intracellular PGE_2; the latter, in turn, can reduce cAMP levels and effect the retrieval of AQP2 from the apical membrane.[86]

A recent study from our laboratory, albeit in a cultured, immortalized mouse CCD cell line (mpkCCDc14), has provided additional evidence that P2 receptor activation may exert its inhibitory effect on water transport via altered AQP2 trafficking. Application of dDAVP to the basolateral membrane for four days resulted in marked AQP2

immunofluorescence in the apical membrane, but when ATP or ATPγS was then added to the medium, either apically or basolaterally, the AQP2 was internalized.[186] Treatment with dDAVP induced gene expression of $P2X_1$ in the apical domain, and led to translocation of $P2X_2$ and $P2Y_2$ to the apical and basolateral membranes, respectively. When these three subtypes were co-expressed with AQP2 in *Xenopus* oocytes, their activation reduced cell membrane AQP2 abundance and consequently reduced water permeability.[186] These findings suggest that: (1) in addition to basolateral $P2Y_2$ receptors, apically located P2 receptors can contribute to the downregulation of AQP2-stimulated water transport; (2) altered trafficking of AQP2 is involved; and (3) vasopressin itself can increase membrane abundance of P2 receptors (c.f. [158]). However, it must be stressed that the observations were confined to *in vitro* systems using a mouse CD-derived cell line and *Xenopus* oocytes. As such, they must be viewed with caution.

Potassium

Although early studies in MDCK cells reported that ATP activates K^+ channels,[42] evidence in native CD suggests that K^+ secretion by principal cells is *inhibited* by nucleotides. A patch-clamp investigation of split-open mouse CCDs (allowing access to the apical membrane) demonstrated that ATP reversibly inhibits the activity of the small-conductance K^+ (SK; also called ROMK) channels, which are believed to mediate most potassium secretion in the distal nephron.[104] On the basis of equipotency of ATP and UTP, and the absence of effect of αβmeATP and 2 meSATP, it was concluded that apical $P2Y_2$ receptors were responsible. That $P2Y_2$ knockout mice maintain a robust potassium excretion despite mild hypokalemia is consistent with this hypothesis.[130] It is worth noting that the inhibitory effect of ATP on SK channel activity observed by Lu and colleagues[104] could be blocked by the NOS inhibitor L-NAME, which implies that the NO-dependency of nucleotide-induced physiological actions may not be confined to the TAL (*vide supra*).

K^+ secretion in the distal nephron is generally enhanced when tubular flow rates are increased. This flow-induced increase in K^+ secretion is now thought to be mediated not by SK channels, but by large-conductance, maxi-K (big K; BK) channels.[191] Activation of BK channels is through increased $[Ca^{2+}]_i$,[100] and there is good evidence for a causal link between increased tubular flow rate, increased tubular nucleotide secretion, and increased $[Ca^{2+}]_i$ (*vide infra*). Although highly speculative at this stage, one implication of these various observations is that nucleotides may have conflicting effects on SK and BK channels.

Sodium

Studies into the effects of extracellular nucleotides on CD Na^+ transport have generally used sensitivity to amiloride as a basis for identifying ENaC-mediated transport; although occasionally sensitivity to benzamil – a more selective inhibitor of ENaC – has been employed. Koster and colleagues were the first to report that benzamil-sensitive transcellular Na^+ transport is inhibited by nucleotide activation of P2 receptors.[88] Using primary cultures of rabbit CD (and CNT) cells grown to confluence, they demonstrated that apically or basolaterally applied ATP inhibited benzamil-sensitive short circuit current (SCC; used as an index of Na^+ transport) across cell monolayers; the mechanism involved activation of PKC and/or PLC. The P2 receptor responsible for this inhibition was equally sensitive to ATP and UTP, but was insensitive to ADP. On this basis, the inhibition of ENaC was attributed to activation of $P2Y_2$ receptors. Subsequent studies using the mouse M1 cell line reported similar findings, except that the mechanism did not involve PKC.[25,164] Another CD cell model, the mouse mIMCD-K2, responded similarly to apical (but not basolateral) nucleotides, although in this case, on the basis of pharmacological profiling and mRNA expression, P2X receptors ($P2X_3$ and $P2X_4$) as well as P2Y receptors ($P2Y_1$ and $P2Y_2$) were thought to be responsible.[107] A more recent study, using the mouse IMCD-3 cell line, provided an exception to the "rule" of nucleotide-induced inhibition of CD transport: apical application of ATP induced an *increase* in SSC,[97] although sensitivity to amiloride or benzamil was not tested. Since this effect could be reproduced by the P2X agonist BzATP, it was inferred that the receptors responsible were $P2X_1$ and/or $P2X_4$, as located in native medullary collecting duct (*vide supra*), although UTP was able to increase SCC to some extent, implying a contribution from P2Y receptors.

Investigations of nucleotide effects on CD sodium transport are not limited to cell cultures: nucleotide-induced inhibition of Na^+ reabsorption in the CD has also been reported in native tissue. In mouse CCD perfused *in vitro*, ATP and UTP, applied either luminally or basolaterally, caused an increase in $[Ca^{2+}]_i$ (and subsequent activation of PKC), and inhibition of amiloride-sensitive SCC, an effect attributed to $P2Y_2$ receptor activation.[28,95] Subsequent single-channel patch-clamp experiments, using both rat and mouse CCD, showed that activation of apical P2 receptors with ATP decreased ENaC open probability (P_o), via PLC-dependent breakdown of PIP_2.[123] Although not tested in rats, it was found that in mice UTP was able to reduce P_o to the same extent as ATP. Further pharmacological profiling led to the conclusion that $P2Y_2$ receptors were responsible (at least in mice). The fact

that in $P2Y_2^{-/-}$ mice the effect of ATP on ENaC P_o was severely blunted provided strong support for this conclusion,[123] although a residual effect was still evident, suggesting partial involvement of other P2 receptors. A follow-up study from the same laboratory showed that increased dietary sodium causes a lowering of ENaC P_o in wild-type mice, but not in $P2Y_2$ knockout mice, implying a central role for $P2Y_2$ receptors in the CD response to changes in sodium intake.[124] More recently, the same group has extended this conclusion to implicate $P2Y_2$ receptors in the phenomenon of aldosterone escape – the restoration of normal sodium excretion rates in the face of chronically raised mineralocorticoid levels. Hitherto, aldosterone escape had been thought to rely on compensatory changes in more proximal segments of the nephron delivering an increased sodium load to the aldosterone-sensitive sites. However, Stockand and colleagues found that whereas wild-type mice on a high-sodium diet excreted appropriately high levels of sodium in the face of three days of deoxycorticosterone acetate treatment, owing partly to reduced ENaC activity, in $P2Y_2^{-/-}$ mice the reduction in ENaC activity was much less pronounced, and the natriuresis correspondingly compromised.[155]

At the time of writing, only one study of the effect of nucleotides on CD Na^+ reabsorption *in vivo* has been published.[144] Late distal tubules of rats were microperfused with artificial tubular fluid containing ^{22}Na, the urinary recovery of which was recorded. In animals fed a low-sodium diet (to upregulate ENaC activity), addition of ATPγS to the luminal perfusate was found to inhibit CD ^{22}Na reabsorption. Despite firm evidence from *in vitro* studies in mice for $P2Y_2$ mediation, "selective" $P2Y_2/P2Y_4$ agonists were ineffective *in vivo* in rats, and a P2X heteromer-mediated effect was suggested.[144] A recent patch-clamp investigation of split-open rat CCD (allowing access to the apical membrane) has provided evidence that both apical P2X and P2Y receptors can affect ENaC activity.[187] Activation of P2Y receptors, molecularly and pharmacologically characterized as $P2Y_2$ and/or $P2Y_4$ subtypes, inhibited ENaC activity by a PLC-dependent mechanism. Notably, activation of P2X receptors, characterized as $P2X_4$ and/or $P2X_{4/6}$ receptors, either inhibited or potentiated ENaC activity, depending on the luminal concentration of sodium. When luminal sodium was 145 mM (which is the concentration typically used in this type of *in vitro* experiment), $P2X_4$ and/or $P2X_{4/6}$ activation with 2 meSATP inhibited ENaC activity, whereas when luminal sodium concentration was 50 mM (which mimics the normal sodium concentration of fluid entering the CD *in vivo*), $P2X_4$ and/or $P2X_{4/6}$ activation with 2 meSATP potentiated ENaC activity (Figure 18.7). These findings led us to propose that $P2X_4$ and/or $P2X_{4/6}$ receptors might act as apically expressed sodium sensors for the local regulation of ENaC activity in the rat CD.[187] The situation is almost certainly more complex, since preliminary data from our laboratory, using the same electrophysiological techniques, have demonstrated that $P2X_4$ and $P2X_{4/6}$, and $P2Y_2$ and $P2Y_4$ receptor-mediated regulation of ENaC is also dependent on nucleotide concentration, duration of exposure to nucleotide, and tubular pH: higher nucleotide concentrations and prolonged exposure favor P2Y-mediated inhibition, while reducing tubular fluid acidity favors P2X-mediated increases in ENaC activity.[183] Staying with the $P2X_4$ theme, a causal link has been established between P2X activation, the apical insertion of ENaC, and enhancement of sodium transport, albeit in a "distal-like" cell line; activation of a basolateral $P2X_4$-like receptor in *Xenopus* A6 cells alters cell shape by a rearrangement of the cytoskeleton, which results in increased Na^+ transport[204] brought about by the unruffling of the apical membrane and insertion of ENaC.[49]

Gene deletion studies have so far concentrated on murine $P2Y_2$ knockout models, although studies using the $P2X_4^{-/-}$ mouse (which, like the $P2Y_2$ knockout, is hypertensive[197]) are afoot. Unsurprisingly (on the basis of the studies cited above), $P2Y_2$ gene deletion was found to result in facilitated Na^+ reabsorption in the kidney but, unexpectedly, this appeared to stem from increased expression of the $Na^+K^+2Cl^-$ co-transporter in the TAL (*vide supra*); expression of α-ENaC was *reduced*, while no overall change in amiloride-sensitive sodium transport was seen.[130] Subsequent studies using the $P2Y_2^{-/-}$ mouse have proposed that the $P2Y_2$ receptor tonically regulates ENaC activity by reducing ENaC P_o.[124] It has been suggested that in $P2Y_2$ knockout mice, the increase in ENaC P_o is compensated for in the longer-term by suppression of the renin–angiotensin–aldosterone system, resulting in downregulation of ENaC expression.[172]

In summary, a variety of approaches leaves little room for doubt that apical and basolateral nucleotides can alter ENaC-mediated Na^+ reabsorption in the CD, and more than likely play a role in blood pressure regulation. In simplistic terms, it appears that activation of $P2Y_2$ receptors inhibits ENaC activity, and activation of $P2X_4$ receptors stimulates ENaC activity. In reality, however, P2 receptor and ENaC interactions in the CD are complex, with an interplay between P2X and P2Y receptors dependent on a variety of factors yet to be unraveled.

Secretion of Nucleotides

As indicated earlier, it is thought that virtually all cells are able to release nucleotides,[127] renal vascular and epithelial cells included. Initial support for the

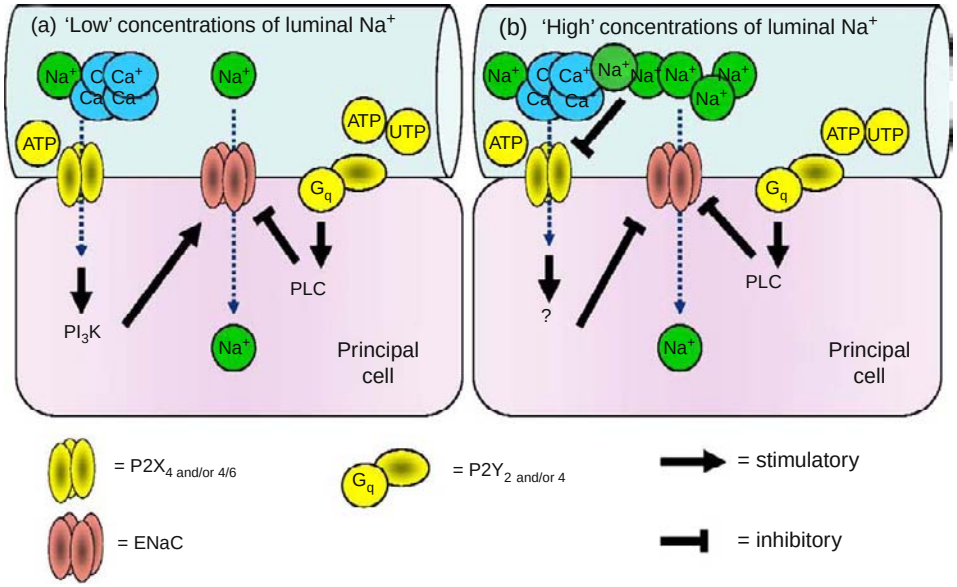

FIGURE 18.7 **Proposed regulation of ENaC activity by P2 receptors in principal cells of rat CD.** The hypothesis is that ENaC activity in the rat CD is differentially regulated by $P2X_4$ and/or $P2X_{4/6}$ receptors, depending on the concentration of luminal Na^+; i.e., that $P2X_4$ and/or $P2X_{4/6}$ receptors act as Na^+ sensors. Real time-PCR and immunohistochemistry suggest that levels of $P2Y_4$ and $P2X_4$ and/or $P2X_{4/6}$ are increased when ENaC is expressed. (a) When the concentration of luminal Na^+ is low (i.e., at 50 mM in our experiments), activation of apically expressed $P2X_4$ and/or $P2X_{4/6}$ receptors (which are highly permeable to Ca^{2+} and to a lesser extent to Na^+) increases ENaC activity through the activation of PI3K. In contrast, activation of apically expressed $P2Y_2$ and/or $P2Y_4$ receptors inhibits ENaC activity through the activation of PLC. N.B.The overall effect of P2 receptor activation (i.e., both P2X and P2Y, by using ATP) is a small degree of ENaC inhibition. (b) When the concentration of luminal Na^+ is high (i.e., at 145 mM in our experiments), activation of $P2X_4$ and/or $P2X_{4/6}$ receptors results in inhibition of ENaC activity by an unidentified mechanism, possibly involving an influx of Na^+. As before, activation of apically expressed $P2Y_2$ and/or $P2Y_4$ receptors inhibits ENaC activity through activation of PLC. The overall effect of P2 receptor activation (i.e., both P2X and P2Y, by using ATP) is a much larger degree of ENaC inhibition. *(from ref. [187]).*

latter came from studies using epithelial cultures and cell lines,[141,142,174] but clear evidence now exists that native renal tubules are also able to secrete ATP. (Cellular secretion of UTP and diadenosine polyphosphates also occurs,[74,199] but has not yet been firmly established in renal tubules.) The question of whether nucleotide release from renal tubular epithelia is constitutive (raising the concept of "purinergic tone"[127]) or is triggered by mechanical or agonist-induced stimuli, now appears to be resolved: both are likely.

Vekaria et al.[176] reported intraluminal ATP concentrations in rat PCTs *in vivo* of 200–300 nmol/l; these concentrations were markedly higher than those in the glomerular filtrate, suggesting secretion of ATP by PCT cells. Intraluminal concentrations in distal tubules were only ~30 nmol/l; the possibility that this ATP was merely flushed downstream, rather than secreted by distal tubular cells, could not be discounted. Using mouse medullary thick ascending limbs (mTALs) perfused *in vitro*, Leipziger's group demonstrated spontaneous oscillatory increases in $[Ca^{2+}]_i$ that appeared to require tubular nucleotide release.[47] An increase in intraluminal pressure from 10 to 80 cm H_2O also resulted in elevations in $[Ca^{2+}]_i$.[75] Convincing evidence was provided that this flow-induced Ca^{2+} transient was itself dependent on nucleotide release, being prevented by luminal or basolateral application of either apyrase (an ATP scavenger) or the P2 receptor blocker suramin. Moreover, both the oscillatory and flow-induced increases in $[Ca^{2+}]_i$ were greatly reduced in $P2Y_2$ receptor knockout mice. In an elegant follow-up study, the same group assessed agonist-induced, rather than flow-induced, nucleotide release in mouse mTAL, and made use of 132-1N1 astrocyte cells transfected with human $P2Y_2$ receptors, positioned at the outflow of perfused mTAL to act as biosensors for ATP[116]; these transfected cells respond dose-dependently to extracellular ATP by increasing their $[Ca^{2+}]_i$. Using this preparation, spontaneous nucleotide secretion was documented, while intraluminal vasopressin or dDAVP (10 nM) triggered $[Ca^{2+}]_i$ bursts. Since the 132-1N1 cells' response was mediated by $P2Y_2$ receptors, it was impossible to distinguish between ATP and UTP as the nucleotide in question, but calibration of the response to vasopressin revealed peak intraluminal nucleotide concentrations of 200–300 nmol/l, remarkably similar to *in vivo* ATP concentrations in the PCT.[176] In the same study, Odgaard et al.[116] found that vasopressin also triggered nucleotide secretion from mouse CCD perfused *in vitro*; intraluminal ATP/UTP

concentrations again reached values approaching 300 nmol/l. Unfortunately, no parallel studies in $P2Y_2$ knockout mice were reported.

It is open to debate whether the nucleotide concentrations measured intraluminally in the above studies reflect those in the vicinity of the P2 receptors in the cell membrane. Membrane-bound and soluble ectonucleotidases (*vide infra*) will rapidly metabolize secreted nucleotides, and it has been estimated that bulk-phase measurements could underestimate concentrations at the cell membrane by more than 20-fold, at least in astrocytes.[77]

Role of Primary Cilium in Flow-Induced Nucleotide Release

A discussion of nucleotide secretion in the tubule would be incomplete without reference to the possible role of the primary cilium. Most renal cells possess a primary cilium protruding from the centriole into the lumen; in the absence of fluid flow it is perpendicular to the cell membrane, but flow causes the cilium to bend, with a consequent increase in $[Ca^{2+}]_i$ in the relevant cell.[128] The question is whether this increase in $[Ca^{2+}]_i$ is triggered by nucleotide release. *In vitro* studies using a cell line (MDCK cells) provided support for nucleotide involvement, as ciliated cells released ATP (detected by biosensor cells downstream) in response to an increase in flow, whereas cells deciliated by means of chloral hydrate did not; apical apyrase or suramin also abolished the response.[127] It is thought that the link between the bending of the cilium and the release of ATP involves a member of the transient receptor potential vanilloid (TRPV) channels – TRPV4 – which is expressed along the TAL and all subsequent nephron segments.[166] Silva and Garvin[147] provided strong evidence that secretion of ATP by cell suspensions of mTAL in response to reduced tonicity depends on activation of TRPV4 channels: the response was reduced by ~75% after blockade of TRPV4 with ruthenium red, while treatment with siRNA against TRPV4 had a similar inhibitory effect. In MDCK cells, ruthenium red also inhibited flow-stimulated Ca^{2+} transients,[89] and it was noted that in these cells TRPV4 co-localizes in cilia with TRPP2 (polycystin 2), an ion channel that is required for cilia-mediated Ca^{2+} transients, but has no mechanosensitive properties. When these two channels were co-expressed in *Xenopus* oocytes, hypotonicity-induced cell swelling was found to cause a bigger increase in membrane currents than that seen when TRPV4 was expressed alone (no currents were sustained by TRPP2 alone).[89] The implication is that TRPV4 and TRPP2 form a sensory channel complex in the primary cilium, which mediates Ca^{2+} influx when the cilium is bent, thereby triggering the release of nucleotides into the surrounding extracellular space which, in turn, activate P2 receptors and cause a more general increase in $[Ca^{2+}]_i$.[127]

Further support for a role of the primary cilium came from a study of collecting duct principal cells derived from the Oak Ridge polycystic kidney (*orpk*) mouse model. These cells lack a well-formed apical cilium; however, they can be genetically rescued with the wild-type *orpk* gene. Constitutive ATP release under basal conditions was not different in mutant versus rescued monolayers of cells, but hypotonicity or increased flow rate induced markedly greater responses from the rescued cells than from those lacking primary cilia.[64]

The evidence thus far, then, favors a crucial role for the primary cilium, but the key question is whether it is equally important in native tissue. In this connection, Woda et al.[192] found comparable flow-induced increases in $[Ca^{2+}]_i$ in principal and intercalated cells of rabbit CCD, despite the fact that intercalated cells in rabbit CCDs do not have cilia.[101] However, the increases in $[Ca^{2+}]_i$ did not appear to depend on nucleotide secretion, since they were unaffected by suramin. It might be, therefore, that rabbits are a special case.

Mechanism of Nucleotide Release

The mechanism of secretion of nucleotides from renal tubular cells is not yet resolved. A large intracellular pool of ATP is available, but the exit route for the nucleotide is controversial, and it may well differ from segment to segment. In neurones and neuroendocrine cells, exocytosis of vesicles containing ATP is well-established, and circumstantial evidence has been provided for a similar mechanism in a proximal tubular cell line,[174] but confirmation is lacking. A variety of channels/transporters has been implicated in nucleotide release. A notable example is the ATP transport across the basolateral membrane of macula densa cells in response to increased NaCl delivery to this nephron site, which is mediated by maxi-anion channels (*vide supra*[10]). Speculation that CFTR channels can also mediate ATP release in the kidney[152] has not received firm support.[126]

In recent years, attention has focused on the possible role of connexin hemichannels in ATP release from renal cells. Connexins (Cxs) are a family of transmembrane proteins comprising approximately 20 members. Messenger RNA and immunohistochemistry studies indicate that several members of the connexin family are expressed in the renal vasculature and tubules.[52] When six connexins assemble, either as homomers or heteromers, they form a connexon. When

two connexons from neighboring cells dock, they form a gap junction; a channel with a central pore. Undocked connexons ("hemichannels") can also function independently as transmembrane channels. Although their functional role, if any, in the tubule remains to be clarified, it has been shown that dietary sodium intake can influence Cx30 and Cx37 expression in tubular cells,[108,156] and evidence is beginning to accumulate for involvement of connexin hemichannels in tubular ATP secretion, as has already been established in other cell types.[24] Evidence for such a role in the distal nephron has come from a recent study using Cx30 knockout mice.[150] Partially split-open CCDs were microperfused *in vitro* and PC12 cells (expressing $P2X_2$ receptors and used as ATP biosensors) were placed in direct contact with the apical membranes of principal cells and intercalated cells. In wild-type mice, increases in tubular flow or reductions in osmolality of the bathing solution evoked increases in $[Ca^{2+}]_i$ in the PC12 cells. Interestingly, these increases were much greater in PC12 cells placed in the vicinity of intercalated cells than in those placed in the vicinity of principal cells, which correlates with the observation that in the mouse distal nephron, immunohistochemical labeling for Cx30 is restricted to the apical membrane of intercalated cells.[108] Also notable was the calculated ATP concentration of 10–50 μmol/l, far in excess of concentrations measured in the bulk phase,[116] thus corroborating the view that bulk-phase measurements may be wide of the physiological mark. Responses were abolished by preincubation of the PC12 cells with suramin, and were almost absent in Cx30 knockout mice. These observations in themselves were striking enough, but the same study went on to assess their physiological significance by comparing pressure–natriuresis curves in wild-type and Cx30 knockout mice. While both groups responded to an imposed increase in renal perfusion pressure (to ~150 mmHg) by a natriuresis, the response in knockout mice was significantly blunted, despite almost identical GFRs in the two groups.[150]

There can be little doubt that these findings provide powerful evidence not only for a crucial role of Cx30 in ATP release in the CCD, but also for an important autocrine/paracrine function of nucleotides in the tubular response to elevations in blood pressure, at least under the conditions of the study. However, a cautionary note should be sounded concerning the physiological significance of the observations: the perfusion rates employed *in vitro* (2–20 nl/min) were far in excess of those found in mouse CCD *in vivo*, and it is clear that the authors used tubular flow rates in the rat, rather than in the mouse, as their reference point. Furthermore, connexin hemichannels appear to open only under non-physiological conditions, such as removal of extracellular divalent cations or major membrane depolarization.[127] In contrast, another group of proteins – the pannexins, which are structurally homologous to connexins and can also form hemichannels[8,135] – is permeable to ATP and can be activated by membrane depolarizations in the physiological range.[102] Further studies will be needed to determine their physiological or pathophysiological role in the kidney.

Ectonucleotidases

As indicated above, the nucleotides that are released from the renal vasculature and from apical and basolateral membranes of renal epithelial cells elicit a variety of autocrine/paracrine actions via P2 receptors. However, these nucleotides are rapidly degraded by surface-located and soluble enzymes (ectonucleotidases) to other nucleotides or nucleosides. Four families of ectonucleotidases, with differing but partly overlapping properties, exist: ectonucleoside triphosphate diphosphohydrolases (NTPDases); ectonucleotide pyrophosphatase phosphodiesterases (NPPs); ecto-5′-nucleotidase; and alkaline phosphatases. Members of all four families have been identified in the kidney,[145] where they will have a profound influence on the stimulation of purinoceptors, not only because the availability of nucleotide agonists is regulated by their hydrolysis, but also because the generation of other nucleotides (e.g., ADP) preferentially targets different P2 receptor subtypes, while the nucleoside derivative adenosine targets P1 (adenosine) receptors (Figure 18.2).

In addition to enzymes that break down nucleotides, two families of phosphorylating enzymes exist: nucleoside diphosphate kinases, which catalyze the transfer of the terminal phosphate of nucleoside 5′-triphosphates to nucleoside 5′-diphosphates (e.g., $ATP + GDP \rightleftharpoons ADP + GTP$), and adenylate kinases, which catalyze the production of ADP from ATP and AMP or *vice versa*, depending on the concentrations of the respective nucleotides ($ATP + AMP \rightleftharpoons 2ADP$). Although initially believed to be restricted to the cell cytosol, there is evidence that nucleoside diphosphate kinases are also present in the cell membrane[199]; mRNA and protein for these enzymes have been identified in rat kidney,[80] but their distribution is unknown. Adenylate kinases are also largely intracellular but, again, ecto-adenylate kinase activity has also been identified.[199] Adenylate kinase enzyme action has been documented along the nephron,[22] although the relative contributions of intracellular and extracellular activity could not be differentiated.

The principal catalytic activities of the ectonucleotidases and phosphorylating enzymes expressed in the kidney are summarized in Table 18.1. Since no

TABLE 18.1 Catalytic Activities of the Ectonucleotidases and Phosphorylating Enzymes Expressed in the Kidney

Enzyme	Hydrolysis Pathways
NTPDases	
NTPDase1	$ATP \rightarrow ADP + Pi \rightarrow AMP + 2P_i$
	$ADP \rightarrow AMP + P_i$
NTPDase2	$ATP \rightarrow ADP + P_i$
	$ADP \rightarrow AMP + P_i$
NTPDase3	$ATP \rightarrow ADP + P_i$
NTPDase8	$ADP \rightarrow AMP + P_i$
NPPs	
NPP1	$ATP \rightarrow AMP + PP_i$
NPP3	$ADP \rightarrow AMP + P_i$
	3′,5′-cAMP → AMP
	$Ap_nA \rightarrow AMP + Ap_{n-1}$
NPP2	$ATP \rightarrow AMP + PP_i$
	$ADP \rightarrow AMP + P_i$
	3′,5′-cAMP → AMP
	$Ap_nA \rightarrow AMP + Ap_{n-1}$
Ecto-5′-nucleotidase	$AMP \rightarrow adenosine + P_i$
Alkaline phosphatases	$ATP \rightarrow ADP + P_i$
	$ADP \rightarrow AMP + P_i$
	$AMP \rightarrow adenosine + P_i$
Nucleotide diphosphate kinases	$ADP + NTP \rightleftharpoons ATP + NDP$
Adenylate kinases	$ATP + AMP \rightleftharpoons 2ADP$

(Adapted from ref. [145].)
Major pathways are shown in black, others in gray. NB: In many cases, nucleotides derived from other bases (UTP, GTP, TTP, CTP, UDP, GDP, TDP, and CDP) can also act as substrates (NDP: nucleoside diphosphate; NTP: nucleoside triphosphate).

information is yet available on the possible functional relevance of the phosphorylating enzymes, in the account below we will restrict ourselves to ectonucleotidases. More detailed information can be found in recent reviews.[145,199]

Although the NTPDase family comprises eight members, only four of these (NTPDases 1, 2, 3, and 8) hydrolyze extracellular nucleotides. NTPDase1 hydrolyzes ATP and ADP with almost equal preference, whereas NTPDase2 has a much greater preference for ATP, therefore causing accumulation of ADP; NTPDases 3 and 8 are intermediate in their preference.[145] The possible functional consequence is that if NTPDase1 is present, P2 receptor stimulation will be abruptly terminated, whereas if NTPDase2 (and to some extent NTPDases 3 and 8) is expressed in the absence of NTPDase1 (or of NPPs), local production and accumulation of ADP would be expected to stimulate $P2Y_1$ (and $P2Y_{12}$ and $P2Y_{13}$) receptors.[172] In rats and mice, NTPDase1 is prominent throughout most of the renal vasculature (interlobular arteries, afferent arterioles, glomeruli, mesangial cells, peritubular capillaries) and is also present in the thin ascending limb of Henle and medullary CD.[84,175] NTPDase2 has been immunolocalized to Bowman's capsules and to most nephron segments beyond the proximal tubule[84,175]; the intrarenal expression of NTPDase3 has been investigated only in the rat where, like NTPDase2, it was found in TAL, distal tubule and CD.[175] Information on NTPDase8 is confined to porcine kidney and is incomplete.

The NPP family comprises seven members, but only NPPs 1–3 are able to hydrolyze nucleotides. NPPs can hydrolyze not only ATP and ADP to AMP, but also dinucleoside polyphosphates (again to AMP; see Table 18.1). Information on the intrarenal distribution of NPPs is limited. Staining for NPP1 protein has been identified in mouse proximal tubules and (more strongly) in basolateral membranes of distal tubules,[54] while prominent staining for NPP3 has been found in rat glomeruli and in the apical membrane of the pars recta, but not in more distal segments.[175]

Ecto-5′-nucleotidase catalyzes the final stage of nucleotide hydrolysis to nucleoside (e.g., AMP → adenosine + P_i). It has a high level of expression in the kidney; it is found in apical membranes of rat PCT and in intercalated cells throughout the distal nephron, as well as the peritubular space.[43,92,175]

An alkaline phosphatase has been identified in the apical membrane of PCT and pars recta of rat kidney.[9] Although alkaline phosphatases have broad substrate specificity, capable of breaking down ATP right through to adenosine, the K_m values for adenine nucleotides are in the low millimolar range, raising questions about the physiological significance of this enzyme, at least in relation to nucleotide degradation.

A summary of existing knowledge of the distribution of ectonucleotidases in the kidney is shown in Figure 18.8.

Given that our knowledge of ectonucleotidase location is incomplete, we can only make a limited number of speculations concerning their possible function in the kidney. The NTPDase1 located in the renal vasculature seems likely to fulfill an important function of that found elsewhere in the body: termination of the platelet aggregation response to extracellular ADP.[38] This enzyme may also terminate the vasoconstrictive action of locally produced ATP on $P2X_1$ receptors in afferent arterioles (*vide supra*) and, along with glomerular NPP3, may modulate the action of ATP on mesangial cells,[73] thereby influencing the ultrafiltration

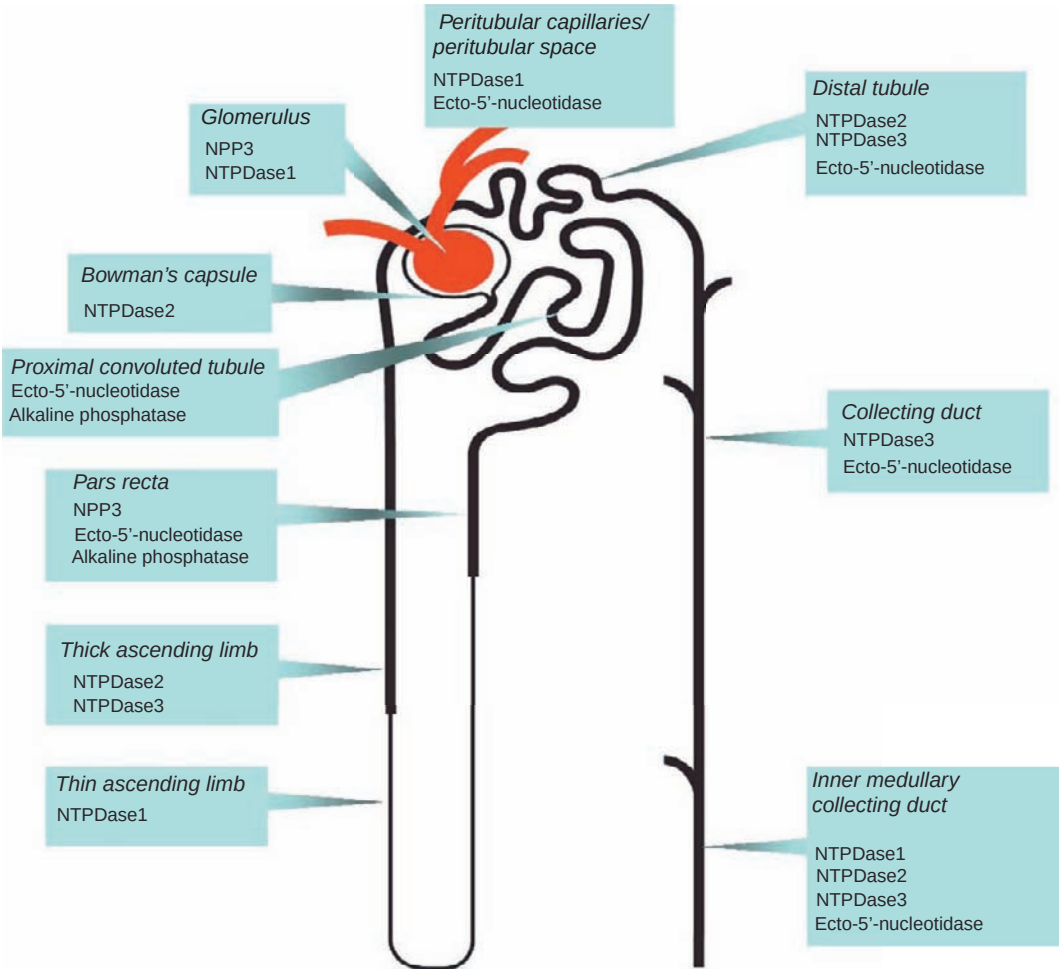

FIGURE 18.8 **Distribution of ectonucleotidases along the rat nephron.** Information compiled from [22,43,84,92,175]. N.B. No information is yet available concerning NPPs 1 and 2 in the rat. *(Adapted from ref. [145]).*

coefficient. The possible roles of ATP and adenosine in mediating TGF have already been discussed. In this context, NTPDase1, expressed in the peritubular space, and/or NPP1, present in basolateral membranes of mouse distal tubule, together with ecto-5′-nucleotidase, also expressed in the peritubular space, are available for the conversion of ATP to adenosine.

As yet, no enzymes that initiate the degradation of ATP have been identified in the PCT (although it should be noted that no suitable antibodies to rat NPP1 or NPP2 are available) and, as already indicated, it is unlikely that proximal tubular alkaline phosphatase could effect ATP degradation at the normal physiological concentrations of the nucleotide. However, it is worth noting that ATPase and ADPase activities have been described in porcine PCT apical membranes.[96] Any AMP produced in the proximal tubule will be converted rapidly to adenosine by the apical ecto-5′-nucleotidase present throughout this part of the nephron. The adenosine could then either activate adenosine A_1 receptors, increasing proximal tubular fluid reabsorption,[182] be converted to inosine or be transported into proximal tubular cells for reuse.[106] Finally, given the effects of extracellular nucleotides on solute and water transport in the distal nephron (*vide supra*), and the inhibitory effect of A_1 receptor activation on sodium reabsorption in the medullary collecting duct,[195] the NTPDases and ecto-5′-nucleotidase present throughout the distal nephron are likely to be of considerable functional significance.

In conclusion, although our knowledge of the intrarenal location of ectonucleotidases is still incomplete, it seems clear that their distribution varies along the nephron, and this provides scope for the rapid termination of the actions of locally produced ATP and/or initiation of ADP-mediated or adenosine-mediated effects.

Role of P2 Receptors in Renal Pathophysiology

The well-documented release of ATP from injured and dying cells at sites of injury and inflammation, and

from red cells and platelets during thrombus formation, suggests that the P2 receptor system could be involved in the pathophysiology of renal disease.[20] As well as producing changes in vascular tone and in fluid and electrolyte reabsorption or secretion (*vide supra*), stimulation of P2 receptors can influence renal cell growth[53,71,138] and – especially in the case of the $P2X_7$ receptor – can also result in cell death and promote inflammation.[59,137]

The published work supporting a pathophysiological role for P2 receptors in the kidney is still limited and remains somewhat speculative. Two disease models have been the main focus of interest: (1) renal cystic disease; and (2) glomerular injury and inflammation. The first stems from work on P2 receptors in secretory epithelia,[91] in particular the airway epithelium in cystic fibrosis,[115] and has been extrapolated to a potential role for these receptors in renal cyst growth in polycystic kidney disease.[142] The second concerns the broadly pro-proliferative effect of stimulating various P2Y receptor subtypes,[132] and the pro-apoptotic effect of activating the $P2X_7$ receptor, particularly when expressed by renal glomerular cells,[179] inflammatory macrophages,[167] and interstitial fibroblasts.[125]

Polycystic Kidney Disease

Mutations in polycystin 1, a membrane receptor, or polycystin 2, a putative Ca^{2+} channel (*vide supra*), give rise to polycystic kidney disease (PKD), a condition associated with uncontrolled proliferation of renal epithelial cells and disordered fluid transport, leading to tubular dilatation and formation and expansion of fluid-filled cysts, which eventually compress and destroy adjacent normal tissue.[189] Cyst-lining cells are thought to exhibit: (1) disordered regulation of proliferation and apoptosis; (2) abnormal secretion of fluid and electrolytes; and (3) disturbed polarity of membrane transport proteins and receptors, which is also believed to relate to a defect in mechanosensation (including detection of the flow of tubular fluid) due to mislocalization and dysfunction of the epithelial cell primary cilium.[193]

In culture, human PKD cells have been shown to release more ATP than normal proximal tubular cells, predominantly from their apical surface.[190] The cysts themselves accumulate and concentrate ATP (0.5–10 μM) and their ecto-ATPase activity appears to be diminished.[142] This extracellular ATP, acting on P2Y (and possibly P2X) receptors on cyst-lining cells, may not only promote cell growth and fluid secretion, but also, by activating the $P2X_7$ receptor, increase cell loss by apoptosis as part of the remodeling necessary for progressive cyst expansion (Figure 18.9); in this regard it is worth noting that inhibition of caspase-mediated apoptosis slows PKD progression.[161] However, much of the evidence in support of this appealing hypothesis is indirect and circumstantial. Schwiebert and

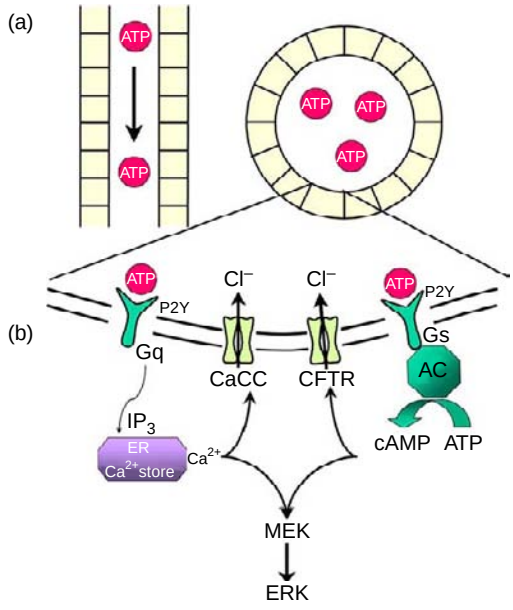

FIGURE 18.9 **Proposed role of P2 receptor signaling in cyst growth.** (a) Remodeling of the normal renal tubule (top left) into an enclosed cyst (top right) allows ATP to accumulate. Reduced nucleotidase activity, coupled with the large representation of P2 receptor subtypes likely to be present in these cyst lining epithelial cells, would allow an amplifying loop of autocrine signaling to occur that might promote osmotically driven fluid accumulation and cellular proliferation. (b) Exploded view of the apical cell membrane lining a hypothetical renal cyst. G-protein-coupled P2Y receptor activation triggers release of Ca^{2+} from the endoplasmic reticulum or production of cAMP via adenylyl cyclase (AC) and subsequent activation of calcium-sensitive chloride channels (CaCC) or CFTR, respectively. The facilitated transcellular transport of Cl^- creates a solute gradient that promotes the osmotic flow of water into the cyst lumen. The increase in $[Ca^{2+}]_i$ and cAMP can modulate the ERK pathway and consequently cellular proliferation. *(from ref. [167]).*

colleagues performed an *in vitro* analysis of P2 receptor signaling in cyst-derived epithelial cells. They confirmed ATP release and P2 receptor-mediated stimulation of SCC (Cl^- secretion), and they also documented mRNA expression for several P2Y and P2X receptor subtypes.[142] At the same time Hillman and co-workers demonstrated expression of the $P2X_7$ receptor (at mRNA and protein levels) in the cystic epithelium of the *cpk/cpk* mouse model of autosomal recessive PKD.[60] Using cells isolated from the *cpk/cpk* mouse, a three-dimensional (3D) suspension model of cyst development was used to study the effects of $P2X_7$ receptor activation on cyst development. The widely used P2X receptor agonist BzATP *reduced* cyst number, but not cyst size, in this model[61] (although BzATP is not selective for $P2X_7$ and can act as an antagonist at some P2Y receptors). In another 3D model of cyst formation using MDCK cells, cyst expansion was inhibited by BzATP; however, this appeared to depend on P2Y,

rather than P2X, stimulation.[168] In a rat model (Han-SPRD) of autosomal dominant PKD, although the $P2X_7$ subtype was detected in cyst-lining cells and its mRNA level increased, other P2X and P2Y receptors were also detected, with particular increases in $P2Y_{2,4}$, and $P2Y_6$ subtypes.[169] All this suggests a complex interplay of P2 receptor subtypes in PKD, with perhaps differing effects on cyst number and cyst size.

More mechanistically, expression of a C-terminal polycystin 1 construct, fused to a membrane expression cassette in a mouse CD cell line (M1), upregulated ATP-stimulated Cl^- secretion, which was associated with a rise in $[Ca^{2+}]_i$ due to an increase in Ca^{2+} entry.[63,184] However, more recent studies of cultured human PKD cells have described a loss of flow-mediated ATP release and the flow-dependent rise in $[Ca^{2+}]_i$, and this was attributed to reduced $P2X_7$ expression and function.[193,194] In this same model, expression of the ectonucleotidase NTPDase1 was also reduced, which would be expected to lead to an increase in local ATP levels. These human PKD cells have also been shown to have defective cilia, which are presumed to be the sensors for flow-activated cell signaling; in ciliated airway epithelia, cilial motion is increased by ATP and these cilia express a P2X receptor that is probably a heteromer of $P2X_{4/7}$,[105] P2X subtypes that are also found in PKD cells. However, although tantalizing, these findings provide more questions than answers, and the exact role of P2 receptors in PKD pathogenesis is still unclear.

The $P2X_7$ Receptor and Renal Inflammation

As already indicated, $P2X_7$ receptor expression is barely detectable in normal healthy kidney. However, its expression is increased in rodent models of glomerular injury, diabetes mellitus, and renin-dependent hypertension.[179] As well as the ability to form a non-selective cation channel or a larger membrane pore leading to cell death by necrosis or apoptosis, the $P2X_7$ receptor can mediate an inflammatory response by causing release of interleukin (IL)-1β (Figure 18.10).[30] Factors that determine whether $P2X_7$ receptor stimulation will cause cell necrosis or apoptosis, and/or inflammatory cytokine release, include the cell type, the concentration of ATP and duration of exposure to the nucleotide, as well as the level of $P2X_7$ receptor surface expression. In cultured human embryonic kidney cells expressing P2X7 receptors, membrane blebbing and microvesiculation are seen within seconds-to-minutes of receptor stimulation, which is associated with cell death by apoptosis.[188] More prolonged receptor stimulation leads to formation of a large membrane pore that permits leakage of vital intracellular components (including ATP) and loss of membrane potential, ultimately leading to cell death and necrosis[114]; somewhat paradoxically, lower concentrations of ATP (and perhaps tonic stimulation of P2X7) in at least some cell types seem to be able to enhance cell proliferation, rather than cause cell death.[1]

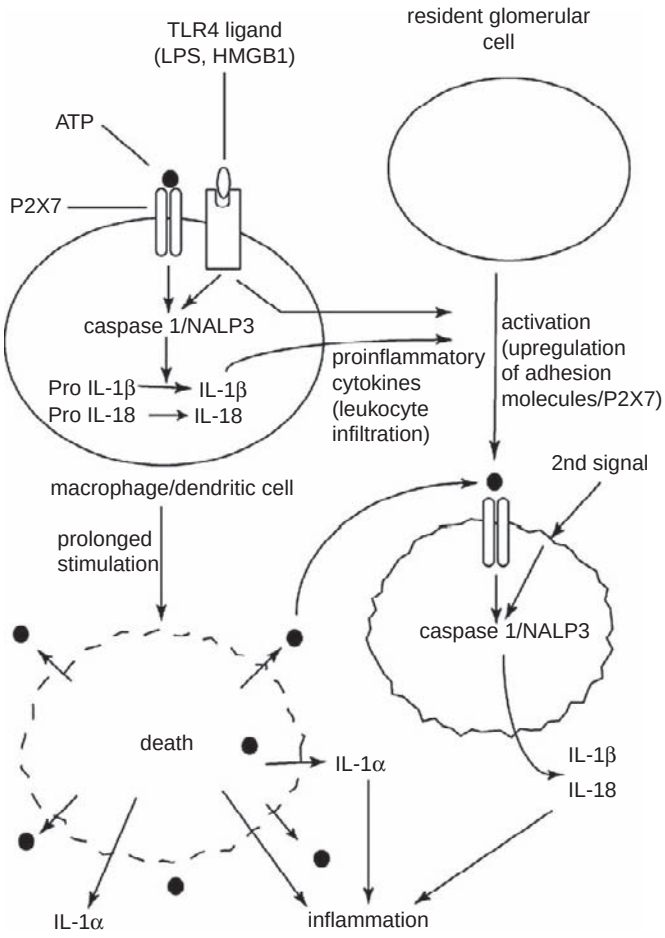

FIGURE 18.10 **Putative role of the P2X7 receptor in inflammatory glomerular disease.** Following initial injury to the kidney, ATP released from damaged cells, possibly together with endogenous Toll-like receptor 4 (TLR4) ligands such as High Mobility Group Box 1 (HMGB1) and lipopolysaccharide (LPS), stimulates the NALP3 inflammasome. Inflammasome activation leads to the maturation of caspase 1, which in turn promotes cleavage, maturation, and release of IL-1β and IL-18 from resident macrophages. Released cytokines promote leukocyte influx and stimulate upregulation of $P2X_7$ on intrinsic renal cells. Prolonged $P2X_7$ stimulation results in cell death with release of intracellular pro-inflammatory mediators such as ATP, IL-1α, and HMGB1, resulting in further rounds of $P2X_7$ stimulation. *(from ref. [167]).*

Activation of the $P2X_7$ receptor promotes release of mature IL-1β, IL-6, and IL-18 from activated macrophages, and both interferon-γ and tumor necrosis factor-α (TNF-α) can increase expression of $P2X_7$ receptors,[53,90,98,177] suggesting that this receptor can both regulate, and is regulated by, inflammatory cytokine processing and release. Moreover, we have observed a marked increase in glomerular expression of $P2X_7$ receptors in a rodent model of proliferative

glomerulonephritis, reaching a peak that coincides with the onset of proteinuria.[170] Macrophage infiltration and release of inflammatory cytokines are characteristic features of glomerular damage in many forms of glomerulonephritis.[160] $P2X_7$ receptor gene knockout or treatment with a $P2X_7$ receptor antagonist significantly reduced the severity of proliferative glomerulonephritis in mouse and rat models, respectively, as shown by reduced renal expression of CC chemokine ligand 2 (CCL2; monocyte chemoattractant-1 (MCP-1)), reductions in glomerular macrophage infiltration, glomerular capillary thrombosis and proteinuria, and a smaller rise in serum creatinine concentration.[163] In the rat diabetic model, both glomerular epithelial (podocytes) and mesangial cells express $P2X_7$ receptors[179]; damaged podocytes have been shown to release IL-13[111]; and both IL-13 and TNF-α are increased in diabetic glomeruli.[57] Thus, ATP, acting via the $P2X_7$ receptor, could interact with, and control, the inflammatory response, eventually leading to cell death, perhaps as a mechanism for deleting damaged cells without dispersal of their potentially toxic contents. Two auto-inflammatory rheumatic diseases, SAPHO and Schnitzler's syndrome, involve an enhanced interaction and dysregulation of the $P2X_7$ receptor with the inflammasome, leading to excessive IL-1β production and release,[23,122] which suggests a wider and more fundamental role for this receptor in tissue inflammation.

Fibrosis often follows inflammation, and it has always been a major goal to determine which factors during inflammation determine its resolution and repair, and which ones lead to chronicity and progressive fibrosis. The potential role of the $P2X_7$ receptor in renal fibrosis has been investigated in a mouse model of unilateral ureteric obstruction. Transient expression of $P2X_7$ receptors was detected in tubular epithelial cells following ureteric obstruction, and the severity of tubulo-interstitial macrophage infiltration, and expression of TGF-β and fibrosis, were reduced in $P2X_7$ receptor knockout mice.[48] In the kidney, interstitial fibroblasts are important in normal repair, and their $P2X_7$-mediated loss might contribute to post-injury fibrosis and scarring in this model.[125] A similar protective effect of $P2X_7$ gene deletion has been reported recently in a model of lung fibrosis.[131]

In another model of proliferative glomerulonephritis, the $P2Y_1$ receptor has been implicated.[62] Interestingly, the acute injury was similar in $P2Y_1$ knockout and wild-type mice (cf. $P2X_7$), but there was less glomerular capillary loss and fibrosis in the $P2Y_1$ knockouts at later time points (10 and 28 days). It would clearly be useful to explore the relationship and possible interaction between $P2Y_1$ and $P2X_7$ receptors in this and related models of acute glomerulonephritis, and whether there might be synergy in targeting therapeutically both receptors.

Finally, P2 receptor activation has also been implicated in the renal injury resulting from ischaemia-reperfusion (IR), a major cause of clinical acute renal failure. Such injury can result from a wide variety of insults, including transplantation, and a common unifying mechanism is therefore difficult to define. Nevertheless, the broad-spectrum P2 inhibitor suramin was found to attenuate the renal infiltration of leukocytes and tubular cell apopotosis that usually follows IR injury.[206] Furthermore, gene deletion of ecto-5′-nucleotidase also ameliorated IR-induced apoptotic and histological renal damage, while deletion of NTPDase1 aggravated it.[103]

CONCLUDING REMARKS

For extracellular nucleotides to be effective autocrine/paracrine agents, there are three fundamental requirements: release of nucleotides from cells; controlled degradation of the nucleotides once released; and the presence of specific nucleotide receptors that can initiate transduction of the signal to a functional response. In the fourth edition of this textbook it was established that these conditions were met, both in the vasculature and the tubule. Since then, significant advances have been made in all three areas, and the many and varied functions of nucleotides in the kidneys have received increased attention. Consequently, in some areas the situation is becoming clearer. For example, nucleotide-induced NO synthesis can account for an inhibitory effect on transport in the TALH; and, given NOs putative actions in the proximal tubule and CD, this might provide a unifying hypothesis to explain nucleotide-induced effects in these segments. On the other hand, several areas continue to defy understanding – for example, the mechanism(s) of release of nucleotides and the apparently differential effects of P2Y and P2X receptors on ENaC activity. As more and more sophisticated techniques are brought to bear, it is to be hoped that ongoing research will solve even the most intransigent problems. Furthermore, although much of the work on renal pathophysiology remains at a descriptive stage, altered P2 receptor signaling is strongly implicated, and the potential for novel therapeutic targets is high.

HISTORICAL PERSPECTIVE

Classical transmitter ligands evolved about 1000 million years ago.[1] The role of dopamine as a neurotransmitter has evolved with time. In primordial and plant cells, dopamine is present, even though catecholamine signaling is not used. In invertebrate neural systems, dopamine is the pre-eminent catecholamine. In vertebrates, the catecholamine pathway terminates in norepinephrine and epinephrine.[2] Endogenous dopamine was mainly recognized as a precursor to norepinephrine and epinephrine[3] until the late 1950s, when Carlsson demonstrated that dopamine itself had a transmitter role.[4] This finding, for which he was awarded the Nobel Prize in Physiology or Medicine 2000, was revolutionary for the understanding of various central functions of the brain, including memory, learning, drug abuse, cognition, and attention; it has also enlightened us regarding the pathogenesis and treatment of various psychiatric and neurological disorders.

Since 1910, dopamine has been known to be a vasoconstrictor, but less potent than norepinephrine and epinephrine. However, in 1942 Holtz et al. reported that dopamine, via its oxidized form, decreases blood pressure in the guinea pig and rabbit.[5] In 1958, Hornykiewicz reported that the vasodepressor effect of dopamine is due to dopamine *per se*.[6] Goldberg et al. confirmed the depressor effect of low doses of dopamine in 1959, and demonstrated a direct negative effect of dopamine on vascular resistance in 1962.[7,8] The same group reported that dopamine increased renal blood flow, glomerular filtration rate, and sodium excretion in dogs and humans. In 1977, Lokhandwala and Buckley subsequently reported that presynaptic dopamine receptors may be responsible for the dopaminergic inhibition of renal neurogenic vasoconstriction.[10] In 1981, Morgunov and Baines demonstrated a positive relationship between renal sodium and dopamine excretion that was independent of renal nerves,[11] indicating that the kidney can synthesize dopamine. Dopamine had been shown to increase cAMP production in the canine renal artery in 1973,[12] and in renal particulate preparations containing tubules, glomeruli, and blood vessels in 1977.[13] In 1980 Nakajima and Kuruma reported that renal particulate preparations had two binding sites to a radio-labeled dopamine receptor antagonist, indicating two types of dopamine receptors.[14] In 1984, Felder et al. reported that renal tubules and glomeruli express D_1-like and D_2-like receptors, respectively.[15] That dopamine can directly inhibit sodium transport in the renal proximal tubule was demonstrated by Bello-Reuss et al. in 1982[16]; Aperia et al. in 1987[17] showed that this occurs, in part, by inhibition of Na^+,K^+-ATPase activity. Subsequently, renal endogenous dopamine was shown to be important in the regulation of renal sodium excretion[18–20] in normotensive rats, but not in spontaneously hypertensive rats (SHRs).[21] In mice, deletion of any of the dopamine receptor gene subtypes produces hypertension, the mechanism of which is specific to the particular dopamine receptor subtype deleted.[22–27]

OVERVIEW

Pharmacological doses of dopamine, such as those administered intravenously to increase blood pressure, achieve concentrations that stimulate other G-protein-coupled receptors (GPCRs) (e.g., α- and β-adrenergic receptors) in addition to dopamine receptors. In this dose range, the vasoconstrictor action of α-adrenergic receptors completely overcomes any vasodilatory effect of dopamine. Normal circulating concentrations of dopamine (picomolar range) are not sufficiently high to activate vascular dopamine receptors, but high nanomolar to low micromolar concentrations can be attained in dopamine-producing tissues.[10,28–32] The Ki of dopamine for its receptors may be as low as 5 nM[33] and as high as 2.5 μM.[34]

Dopamine is important in the regulation of water and electrolyte balance, and blood pressure,[29–31] partly by regulation of the secretion/release of hormones and humoral agents that affect water and electrolyte balance. Dopamine also modulates water and electrolyte intake via the "appetite" centers in the brain,[35] and regulates ion and water transport in the kidney[29–31] and gastrointestinal tract.[32] Physiological concentrations of locally produced dopamine, acting in an autocrine or paracrine manner, inhibit ion transporter/channel/pump activity directly by actions on enzyme or channel kinetics, and indirectly by regulating their protein expression and cellular distribution. The physiological effects of dopamine occur by occupation of its specific receptors, as well as via synergistic interaction with natriuretic agents/receptors such as atrial natriuretic peptide (ANP)/ANPA,[36] eicosanoids,[37,38] endothelin/ETBR,[39] nitric oxide,[40] prolactin,[41] urodilatin,[36] angiotensin III/AT_2R,[42] and negative interaction with antinatriuretic agents/receptors such as insulin,[43] renin,[44] angiotensin II/AT_1R,[45,46] and aldosterone.[37,47,48] In general, under normal conditions and especially when extracellular fluid volume is moderately expanded, dopamine impedes ion and water transport and facilitates their excretion. During normal or moderately increased NaCl intake, inhibition of D_1-like receptors decreases sodium chloride excretion by about 60%.[18–22,29–31,49] Dopamine, however, is not important in natriuresis with marked volume expansion with isotonic saline[20,49] or even moderate volume expansion with albumin[50] or hypotonic saline.[51] With volume deficit renal dopamine production decreases[52–54]; this may allow sodium retaining mechanisms to work more effectively. The decrease in renal dopamine production during volume depletion has been related to a decrease in angiotensin II-mediated renal tubular uptake of dopamine,[55] and an increase in renal MAO activity and dopamine turnover, without altering COMT activity.[52,55] Indeed, during volume deficit, exogenous dopamine may actually decrease sodium excretion, apparently caused by an increase in sodium reabsorption in the distal nephron.[56]

RENAL DOPAMINE PRODUCTION

Plasma dopamine is freely filtered through the glomerulus, but the concentration of free dopamine in the plasma is normally too low (below 1 nmol/L)[57] to account for any significant contribution to urinary dopamine, which is in the high nanomolar to low micromolar range.[23,32,58–63] Renal deconjugation of circulating conjugated dopamine probably does not occur and, therefore, cannot account for the free dopamine in the urine.[64] Intact afferent vagal pathways have been shown to mediate the increase in renal dopamine production during acute volume expansion with isotonic saline.[65] However, renal dopaminergic nerves[66] contribute less than 30% of renal dopamine production.[11,30,31] Moreover, renal denervation does not prevent the dopaminergic-mediated increase in sodium excretion associated with volume expansion with isotonic saline.[67]

The synthesis of dopamine differs between renal tubular and neural cells. Neural cells express tyrosine hydroxylase (TH), which converts tyrosine to L-3,4-dihydroxyphenylalanine (L-DOPA) that is subsequently decarboxylated to dopamine by aromatic acid decarboxylase (AADC). Non-neural tissues, such as the renal tubules (Figure 19.1), do not express TH,[68] and therefore cannot synthesize L-DOPA. Rather, L-DOPA is taken up intracellularly by renal tubule cells and converted to dopamine by AADC, which is expressed in many non-neuronal tissues, such as immune cells,[69] kidney,[68,70,71] liver,[72] adrenal,[72] spleen,[72] pancreas,[73] and thyroid,[74] among others. There is sexual dimorphism in the levels of AADC in mice; AADC protein expression and activity are higher in the kidneys of females than in males, while the converse is true in the intestines.[71]

Renal dopamine production is regulated by several factors, including the availability and renal tubular uptake of L-DOPA, activity of AADC, transport of dopamine from inside the proximal tubule cell into the tubular lumen and perivascular space, and metabolism of dopamine. However, sodium intake and intracellular sodium are probably the major stimuli in the renal tubular synthesis/release of dopamine in normal adults.[23,54,63,75]

Sources of L-DOPA

As previously mentioned, the major source of renal dopamine production is the renal tubular

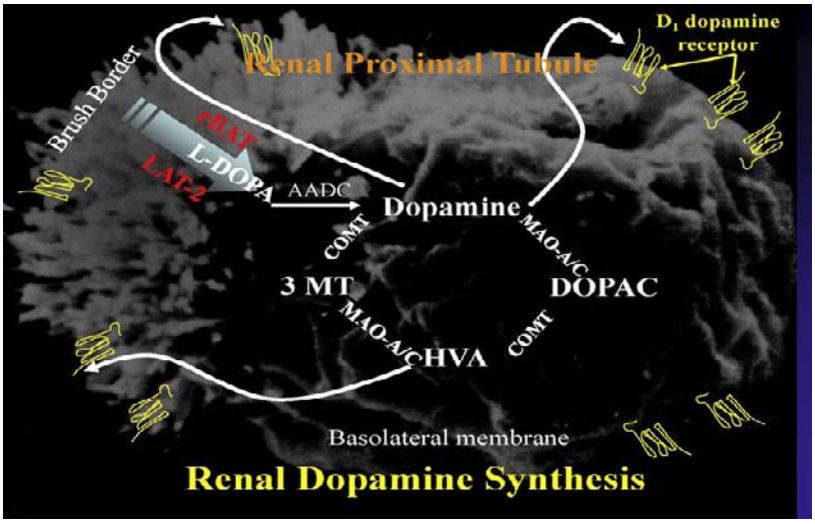

FIGURE 19.1 **Dopamine synthesis inside a renal proximal tubule cell (scanning electron microscopy).** The principal source of renal dopamine is from circulating L-dihydroxyphenylalanine (L-DOPA) which is found in the general circulation and is freely filtered by the glomerulus. Dopamine is produced in renal tubules following uptake by a sodium-independent and pH-sensitive L-type amino acid transporter (LAT2) and rBAT (related to Bo amino acid transporter and other transporters, including ASCT2, B0AT1, among others.), which is rate-limiting of the renal tubular dopamine synthesis. Renal proximal tubules convert L-DOPA to dopamine, via L-aromatic amino acid decarboxylase (AADC). In renal tubules, dopamine is produced from tyrosine and not converted to norepinephrine, because unlike neural tissue renal tubules do not express tyrosine hydroxylase or dopamine β-hydroxylase (COMT: catechol-*O*-methyl transferase; MAO: monoamine oxidase; 3MT: 3 methoxytyramine; HVA: homovanillic acid; DOPAC: 3,4 dihydroxymandelic acid).

decarboxylation of L-DOPA taken up by renal tubule cells from the glomerular filtrate and circulation.[76] Plasma L-DOPA, which is about 2 μM, reflects catecholamine turnover from sympathetically innervated tissues, such as skeletal muscle, heart, adrenal gland, and gut.[75,76] There are non-neuronal sources of plasma L-DOPA, because patients with pure autonomic failure have normal plasma levels of L-DOPA.[77] Indeed, L-DOPA is produced by non-neuronal cells that express TH in mesenteric organs (gastrointestinal tract, spleen, and pancreas[78]). Plasma L-DOPA sulfate levels increase after meals, possibly related to the amount of DOPA in the food.[79–83] Inhibition of the decarboxylation of L-DOPA during a protein meal doubles its plasma levels, indicating that normally a protein meal-induced increase in plasma L-DOPA is immediately decarboxylated.[82] Tyrosinase activation,[83] decreased degradation of L-DOPA, and renal demethylation of 3-O-methyl DOPA may be additional sources of urinary dopamine.[84–86]

Renal Tubular Uptake of L-DOPA

As already indicated, the rate-limiting step in the synthesis of dopamine by the kidney is the uptake of L-DOPA by renal tubule cells from the circulation and glomerular filtrate.[76,87] The conversion of L-DOPA to dopamine[66,88,89] occurs mainly in the proximal tubule, since AADC activity is highest in this nephron segment,[68,90] although AADC is also present in more distal nephron segments.[90–92] L-DOPA is taken up by the renal tubules via organic cation transporters[87,93] located at both apical and basolateral membranes.[94] These include sodium-dependent amino acid transporters, L-amino acid transporter-2 (LAT-2), and related to b0,+ amino acid transporter (rBAT), sodium-dependent L-amino acid transporters, ASCT2 and B0AT1, and as yet unidentified transporters.[95,96] rBAT is predominantly expressed at the apical membrane, while LAT-2 is expressed at both apical and basolateral membranes. In normotensive rats, LAT-2 and rBAT may account for more than 50% of the L-DOPA uptake in renal proximal tubules, while ASCT2 and B0AT1 may account for the rest.[95,96] In contrast in SHRs, 50% of L-DOPA uptake occurs via LAT-1, 25% via LAT-2, and 25% via ASCT2 and B0AT1.[95,97] Aging is associated with a decreased tubular uptake of L-DOPA resulting in a decrease in urinary dopamine production, the mechanism of which has not been determined.[98]

Aromatic Amino Acid Decarboxylase (AADC) Activity

Renal AADC activity is dependent on L-DOPA concentration and not on its Km. However, the increase in urinary dopamine in sodium-replete states may be caused, in part, by increased AADC activity.[89,99,100]

Patients with AADC deficiency have normal or increased levels of urinary dopamine that may be explained, in part, via tyramine hydroxylation by renal CYP2D6.[101] Hypertonic saline can increase the expression of AADC, that is mediated, in part, by TonEBP.

Dopamine Transporters

The accumulation of monoamines from the cytoplasm to storage organelles and their secretion are dependent on vesicular monoamine transporters 1 and 2 (VMAT-1, VMAT-2). VMAT-2 is expressed in neurons and certain neuroendocrine cells, while VMAT-1 is expressed in endocrine and rat renal proximal tubule cells.[60] VMAT-1 may participate in the dopaminergic regulation of renal ion transport, because renal tubular VMAT-1 mRNA and protein expression are increased by a high sodium diet.[60] However, dopamine synthesized in renal tubules is not stored, but is transported both to the basolateral membrane and into the tubular lumen, where it acts on its receptors locally.[31] Dopamine is secreted into the basolateral space via organic acid cationic transporters,[102] while dopamine probably diffuses into the lumen where it is concentrated, reaching high nanomolar to low micromolar concentrations (see above), as a result of water reabsorption and can stimulate its receptors in more distal nephron segments.[28–31]

Dopamine Metabolism

Dopamine that is synthesized in the renal tubule cells is probably not converted to norepinephrine or epinephrine. Dopamine β-hydroxylase (DBH) mRNA is not expressed in bovine or rat kidneys.[103] However, DBH is expressed in adrenergic nerves supplying the kidney, and inhibition of DBH increases renal dopamine concentration three-fold.[104] In tissues expressing phenylethanolamine-*N*-methyl transferase (PNMT) (e.g., adrenal medulla, heart, and some areas of the brain) norepinephrine is converted to epinephrine (Figure 19.1). PNMT is also not expressed in human renal proximal tubules, but is expressed in glomeruli, renal distal tubules, and endothelial cells.[105] Non-specific NMT, which is expressed in non-neuronal tissues including the kidney, enables the synthesis of epinephrine even after denervation.[106] More recent studies have also shown that TH and DBH are expressed in mesangial and renal proximal tubule cells in culture, in a pig renal tubular cell line (LLCPK) with proximal tubule and distal tubule characteristics,[107] in a canine distal tubular cell line, MDCK, and mouse inner medullary collecting duct cells.[91] Because TH is not expressed in renal proximal tubules,[68] the presence of TH in LLCPK could be indicative of its distal tubular characteristics.[107] Although dopamine may have access to non-specific NMT,[106] the increase in urinary dopamine with salt loading is not accompanied by an increase in urinary norepinephrine or epinephrine.[23,25,51,58]

In renal tubules, dopamine is degraded both by deamination via monoamine oxidase (MAO) to 3,4-dihydroxyphenylacetic acid (DOPAC), and by methylation via COMT to 3-methoxytyramine. Newly formed dopamine is metabolized predominantly by MAO-A rather than MAO-B, especially in the proximal tubule.[108] In contrast, dopamine is metabolized by COMT in more distal nephron segments.[109,110] A novel flavin adenine dinucleotide-dependent amine oxidase named renalase or MAO-C has been identified in the kidney, but its role in the intrarenal metabolism of renal dopamine is unknown.[111] Acute inhibition of COMT activity may be more important than MAO in the short-term,[112] while the converse is true for chronic inhibition.[110] The inhibition of dopamine degrading enzymes can increase its concentration. However, the increase in urinary dopamine with high salt intake is probably not related to any decrease in dopamine degradation.[62,99]

Dietary Influence Including Salt Intake

Feeding increases urinary dopamine that have been related to the amount of sodium in the diet. Most studies have shown that a low sodium intake is associated with low urinary dopamine, while the converse occurs with a high sodium diet.[31,50,53,58,62–65,92,113–117] This could be due to an increased spillover of L-DOPA into the arterial blood,[53,61] as ingestion of food/protein which contains sodium causes an increase in circulating L-DOPA.[80–84] However, plasma L-DOPA levels may not be increased by a high sodium diet.[32] Even if circulating L-DOPA is not increased by salt intake, the increase in urinary dopamine with salt loading is associated with an increase in urinary excretion of L-DOPA.[61] Therefore, the increase in urinary excretion of dopamine appears to be secondary to an increase in the uptake of L-DOPA by renal proximal tubules, presumably from the glomerular filtrate and circulation.[61,88,93–99,118–120] There may also be a mechanism by which L-DOPA is delivered to the kidney independent of circulating L-DOPA (e.g., via the adrenal gland).[121,122]

Chloride may be more important than sodium in the regulation of renal dopamine production, because an increase in the intake of chloride without sodium increases urinary dopamine, while sodium bicarbonate does not.[115] An increase in the intake of phosphate[112] or calcium[115,123] also increases renal dopamine production. Blockade of N-type, but not L-type, calcium channels can decrease urinary dopamine excretion.[124,125]

An important factor in the increase in urinary dopamine caused by sodium loading is the preferential egress of dopamine into the renal tubular lumen, rather than into the interstitium.[62,126] In LLC-PK1 cells dopamine egresses at the apical surface by a non-saturable process, while its egress at the basolateral surface is saturable, with the latter 5–7-fold higher than the former.[94] The egress of dopamine in LLC-PK1 is probably not related to VMAT-1, because the egress of dopamine is not inhibited by dopamine transporter inhibitors.[94] However, chronic sodium loading increases the expression of the VMAT-1 in the renal proximal tubule, which may contribute to the modification of the polarity of dopamine secretion during sodium loading.[60] Inhibition of sodium hydrogen exchanger (NHE) activity decreases efflux of dopamine into the peritubular space, which presumably favors luminal outflow. Thus, dopamine, by inhibiting proximal tubular luminal NHE activity,[127–133] may facilitate its own egress into the tubular lumen. The preferential luminal efflux and tubular fluid reabsorption result in high nanomolar to low micromolar concentrations[31,134] of dopamine in the tubular lumen, concentrations that approach the EC_{50} of dopamine and D_1-like receptor agonists to stimulate adenylyl cyclase and phospholipase C activity.[127,131,135–143] This mechanism, and the fact that dopamine can also be synthesized in more distal nephron segments, albeit to a lower extent relative to the proximal tubule, enables dopamine to stimulate its receptors in more distal nephron segments.

There may not always be a relationship among dietary sodium, urinary dopamine, and sodium excretion.[143–153] Mühlbauer and colleagues have claimed that food intake rather than sodium is responsible for the increase in urinary dopamine.[145–147] However, all the acute saline loading studies were performed in rats in which food, but not water, was withheld for 24 hours.[20,21,49,117] Differences in the amount[49,117] and duration[116,148–150] of the sodium load in the food, as well as differences in the strains of rats studied (see below) are possible explanations. In humans, increasing sodium intake from 20 to >200 mmol/day increases renal dopamine production that peaks by the second day, followed by a gradual decline to 50% of the peak value by the 5th day.[116] In rats, sodium chloride loading maximally increases dopamine excretion on the first few days, with the excretion decreasing close to control levels at 1 week, only to gradually increase again from 2 to 4 weeks.[148,149] Renal dopamine concentrations are not higher in non-salt loaded rats than in rats loaded with salt for 6 weeks.[150] There may also be an interaction between sodium and other substances in food, e.g., protein. Ingestion of food with very low sodium content (<0.02% sodium) is not associated with an increase in sodium excretion (unpublished data).

The renal production of dopamine is strain-dependent in rodents. Urine dopamine is lower in Sprague-Dawley than in Dahl salt-sensitive or -resistant rats[61] or in WKY and SHRs.[151] A strain of WKY rat increases urinary dopamine after 24 hours of salt loading at 4 weeks, but not at 12 weeks of age.[61] Uninephrectomy increases urinary dopamine in Wistar-Han from Harlan, but not from Charles-Rivers or WKY rats from Harlan.[97,152] The increase in urinary dopamine with chronic sodium chloride loading is less in the salt-sensitive C57BL/6 than the salt-resistant SJL mice from Jackson Laboratory.[153]

The renal production of dopamine is also age-dependent. Renal dopamine synthesis increases with development.[92] However, in contrast to the stimulatory effect of sodium intake on dopamine excretion in normal adult humans,[53,58,113,115,116] in pre-term infants sodium supplementation prevents, while sodium restriction increases, urinary dopamine[154]; the significance of this in terms of sodium balance remains to be determined. The stimulatory effect of increased dietary sodium on renal dopamine production and ability to excrete salt load are diminished with aging.[98,100,155–157] Urinary dopamine excretion is also decreased in patients with chronic renal failure, but due to loss of nephron number rather than an inability to synthesize dopamine.[158]

Gender may influence the urinary dopaminergic response to a sodium load. For example, sodium loading has been reported to increase urinary dopamine excretion in Chinese females, but not Chinese males.[159] Ethnic differences in the relationship between urine dopamine and sodium have been reported.[160–162] The blunted increase in urinary dopamine in response to acute volume expansion in blacks may be caused by reduced decarboxylation of L-DOPA.[125]

Patients with type 1 or type 2 diabetes have decreased basal urinary dopamine,[163,164] as well as a deficient response to high sodium chloride diet[165] or infusion.[166] Decreased dopamine production in human adults[164,167] and children[168] with type 2 diabetes[169] may affect the ability to excrete a sodium load. Rats with type 1 diabetes also have decreased renal dopamine production.[170]

Patients with salt-sensitive, low renin or non-modulating hypertension, and some with normal renin hypertension[161,171–174] have a blunted increase in urinary dopamine in response to salt loading, despite higher rates of L-DOPA excretion.[173] Protein intake[171] or high dietary sodium intake may not increase urinary dopamine in essential hypertensive patients or even normotensive subjects with a family history of hypertension.[159,165,172,175–177] However, salt-sensitive[173] and normal renin essential hypertensives[178] have normal basal urinary dopamine. Mild exercise has been reported to increase renal dopamine production in Stage 1 hypertensive subjects.[179] Borderline and young

hypertensives[180,181] have higher basal urinary dopamine than control subjects or stable hypertensive patients,[181,182] suggesting that the renal dopaminergic system may act as an early defense against hypertension that fails during its progression.[183]

There are also abnormalities in renal dopamine production in animal models of genetic hypertension. Renal dopamine production may be decreased in adult spontaneously hypertensive and Dahl salt-sensitive rats relative to their normotensive controls, the WKY and Dahl salt-resistant rat, respectively.[63,184] However, urinary free dopamine and renal tissue dopamine are actually increased in young SHRs in comparison with WKY rats,[184,185] but the difference disappears at age 16 weeks. In the young Dahl salt-sensitive rat, urinary dopamine is normal and increases with salt intake, as in Dahl salt-resistant rats,[63,186] although kidney levels of dopamine are lower in Dahl salt-sensitive than in salt-resistant rats on a high salt diet.[186] In adult Dahl salt-sensitive rats, the urinary excretion of dopamine is not increased or may even be decreased in response to acute volume expansion or salt loading.[185,187] Mice deficient of D_2 dopamine receptors have salt-sensitive hypertension and decreased renal dopamine production.[23,24]

Dopamine Receptor Subtypes

Dopamine receptors probably evolved from a common ancient ancestor over 750 million years ago, before the divergence of vertebrates and invertebrates.[188] Dopamine receptors belong to the α group of the rhodopsin-like family of GPCRs,[29–31,189–193] characterized by seven transmembrane domains. Based on their ability to stimulate or inhibit adenylyl cyclase, dopamine receptors have been classified into two families (Table 19.1): D_1-like receptors stimulate adenylyl cyclases, while D_2-like receptors inhibit adenylyl cyclases.[29–31,189–193] There are two D_1-like receptors in eutherian mammals, D_{1A} and D_{1B}, also known as D_1 and D_5 in humans; archosaurs have four D_1-like receptors, D_{1A}, D_{1B}, D_{1C}, and D_{1D}; all other jawed vertebrates have three D1-like receptors, D_{1A}, D_{1B}, and D_{1C}.[194] The D_2-like receptors include D_2 (D_2R), D_3 (D_3R), and D_4 (D_4R).[29–31,189–193] The rank order affinity of dopamine to its receptors is: $D_3R \geq D_4R > D_5R \geq D_2R > D_1R$.[195]

Based on site-directed mutagenesis and protein modeling of some GPCRs, including D_2R, the binding of their respective agonist has been suggested to occur at the hydrophobic transmembrane domains, i.e., aspartate residues in transmembrane domains II and III, two serine residues in transmembrane V, and a phenylalanine residue in transmembrane VI.[190] Dopamine receptors have not been crystallized, but studies of the crystallized β2-adrenergic receptor suggest that agonist binding occurs at the extracellular ends of helices III, IV, V, and VII, with the cytosolic ends mediating G-protein activation.[196] Nuclear magnetic resonance spectroscopy has revealed three distinct conformations of the β_2AR: unliganded receptor or neutral antagonist, inverse agonist, and agonist.[197] The binding pocket of the A_{2A} adenosine receptor is slightly different, with the binding pocket closer to helices VI and VII, suggesting GPCR specificity.[198]

Dopamine Receptor Signaling

Receptor activation, at least for rhodopsin, occurs by a disruption of the Arg135/Glu134 ionic bond in transmembrane VI resulting in the formation of a new Arg135/Tyr223 interaction in transmembrane V261. This causes the GPCR to function as a guanine nucleotide exchange factor promoting the exchange of GDP with GTP on the Gα-subunit, resulting in the dissociation and release of the Gα-subunit from the Gβγ-subunit.[189,199] The dissociated G-protein-subunits then initiate the activation or inhibition of downstream effectors. Hydrolysis of GTP by the intrinsic GTPase activity of Gα promotes the reassociation of the G-protein-subunits. RGS (regulators of G-protein signaling) acting as a GTPase-activating protein (GAP), stimulate the hydrolysis of GTP and, therefore, the reassociation of the G-protein-subunits. RGS act as a GAP for GαS, Gαi and Gαq. While a primary function of RGS is to suppress G-protein signaling via GAP activity, RGS have non GAP actions such as direct antagonism of Gα and binding of Gβ/γ. Specific RGS have been reported to regulate dopamine receptors. For example, RGS7 with Gβ5 can regulate dopamine receptor signaling[200] and RGS9-2, but not RGS4, inhibits D_2R internalization,[201] while RGS19 inhibits D_2R signaling.[202] RGS4 may be involved in D_1R signaling.[203] In contrast, RGS2 may be regulated by both D_1R and D_2R.[204]

In some instances, agonist specific ligand binding does not cause dissociation of the protein subunits, but rather a conformational change.[205] Heterotrimeric G-proteins can also interact with proteins other than GPCRs to regulate physiological processes.[206] These include activators of G-protein signaling (AGS) which promote guanine nucleotide exchange independent of GPCRs and activate or inhibit adenylyl cyclase or phospholipase C. Dopamine receptors have been reported to decrease AGS1 expression.[207] In addition, GPCR signaling can be independent of G-protein-subunits.[208] For example, the inotropic effect of angiotensin II with occupation of $AT_{1a}R$ in cardiomyocytes occurs via a Gαq/PKC-independent, but GRK6/β-arrestin 2-dependent, mechanism.[209]

Both D_1-like receptors, D_1R and D_5R couple to $G\alpha_S$[29–31,189–193] and Gαq.[135,136,138–142] There are also

differences in G-protein linkage between D_1R and D_5R. For example, the D_1R, but not D_5R, also couples to Go[210] and $G\alpha_{Olf}$,[211] which is expressed in renal tubules and macula densa.[212] In contrast, D_5R, but not D_1R, couples to Gz and $G\alpha_{12/13}$.[211,213] $G\alpha_{12/13}$ proteins may have functions different from those ascribed to GPCR activation, including cell movement, actin cytoskeleton, and protein phosphatase 2A activity.[214] Because the recycling of D_1R is partly under the control of protein phosphatase 2A or a protein phosphatase 2-like enzyme,[215,216] this may be a mechanism for D_5R and D_1R cross-talk.

The linkage of G-protein-subunits to the specific D_1-like receptor may be tissue-specific. This apparently discordant linkage of D_1-like receptors to G-protein-subunits can be explained by recent observations that a specific ligand acting on the same receptor recruits specific signaling proteins that elicit a specific phenotype.[217] For example, most D_1-like receptor agonists stimulate both adenylyl cyclase and phospholipase C. However, there are exceptions; SKF83822 stimulates adenylyl cyclase but not phospholipase C,[218] whereas SKF83959 stimulates phospholipase C but actually inhibits adenylyl cyclase.[219]

Adenylyl Cyclase and Protein Kinase A (PKA)

As indicated above, D_1-like receptors are linked to stimulation of adenylyl cyclase which leads to the formation of cAMP. There are at least 10 isoforms of adenylyl cyclase (adenylyl cyclases I-IX and adenylyl cyclase short). In the neostriatum, the D_1R is linked to adenylyl cyclase V.[191] However, adenylyl cyclase V is not expressed in the rat renal proximal tubules[220] (but may be expressed in humans, unpublished observations). In kidney tubule cells, D_1R is linked to adenylyl cyclase VI, while D_5R is linked to adenylyl cyclase IV.[221] cAMP binds to the regulatory subunits of PKA resulting in the activation (disinhibition) of its catalytic subunits. There are two PKA isoforms, but D_1-like receptors, specifically D_1R, may utilize PKA II rather than PKA I.[222,223] There are several PKA substrates, among which are dopamine and cAMP-regulated 32 kDa phosphoprotein (DARPP-32) which inhibits protein phosphatase 1.[224] In contrast to the stimulatory effect of the D_1R/PKA pathway on DARPP-32, the D_1R/phospholipase C pathway inhibits DARPP-32.[225] The roles of PKA, DARPP-32, and protein-phosphatases in renal sodium transport are discussed below.

Phospholipase C

Phospholipase C catalyzes the formation of diacylglycerol and inositol phosphates. D_1-like receptors are linked to phospholipase C, via $G\alpha q$, independent of adenylyl cyclase, a phenomenon that was initially described in renal cortical tubules.[135,136,138–142] There are several isoforms of phospholipase C; the D_1R directly stimulates phospholipase $C\beta1$ in renal cortical[140] but not in medullary membranes, and indirectly stimulates phospholipase $C\gamma$ via PKA and PKC, in fibroblasts.[139]

In neuroblastoma cells, the D_1R is not linked to G_q[210] and in neurons, D_1R-mediated stimulation of phospholipase C may require the presence of D_2R[226] while D_5R, by itself, can increase phospholipase C-mediated calcium mobilization that is inhibited by D_2R.[227] However, in a pituitary adenoma rat cell line (GH4C1) transfected with the D_5R, the D_5R activation actually decreases inositol phosphate production.[228] The report that D_1-like receptor-stimulated phospholipase C persists in $D_1^{-/-}$ mice[229] has been taken to indicate that there is a D_1-like receptor other than D_1R that can stimulate phospholipase C. This is indeed the case, as the D_5R is also linked to phospholipase C activation in neural tissue (hippocampus, cortex, and striatum).[230]

Phospholipase D

Phospholipase D (PLD) hydrolyzes phospholipids, such as phosphatidylcholine, to form phosphatidic acid and the free polar head group of the phospholipid substrate. Phosphatidic acid can be cleaved by phosphatidic acid phosphohydrolase to produce diacylglycerol; both are important second messengers in the "late" response of cells to certain stimuli.[231] The two mammalian isoforms of PLD (PLD1 and PLD2) have ~50% identity, and are distributed widely in mammalian tissues and cells. They are believed to play an important role in the regulation of cell function and cell fate by a variety of extracellular signals.[231] D_5R inhibits PLD2 activity in renal proximal tubule cells,[232] while both D_1R and D_5R can inhibit phospholipase D activity in vascular smooth muscle cells.[233] These actions lead to inhibition of the production of reactive oxygen species (ROS).[232–234] The D_3R heterologously expressed in HEK293 cells has been reported to activate PLD, via Rho and independent of Gi/Go.[235] The relationship between PLD and endogenously expressed D_3R remains to be determined.

Protein Kinase C

Protein kinase C (PKC) isoforms are classified into three groups: (1) conventional PKCs (cPKC-α, -βI, -βII, and -γ); (2) novel PKCs (nPKC-δ, -ε, -θ, and -η/G); and (3) atypical PKCs (aPKC-$\lambda(\iota)$ and -ξ) and PKCμ, also called PKD which consists of PKD1, PKD2, and

PKD3.[236] In renal tubule cells, D_1-like receptors can stimulate PKCθ[237] and PKCξ,[237,238] and inhibit PKCδ.[237] The D_1R increases the phosphorylation of $PKC\theta^{S676}$ in human embryonic kidney (HEK293) cells.[239] D_1-like receptors can also translocate specific PKC isoforms. Thus, D_1-like receptors translocate conventional (α, β) and novel (ε) PKCs from renal tubule cytosol into membranes,[240,241] and the novel PKC-δ from membranes to cytosol.[240] Some studies have shown that the stimulation of PKC by dopamine may be secondary to PKA activation.[139,242]

While PKA and PKC mediate the actions of D_1R, both can also regulate D_1R signaling. PKC activation can produce differential D_1R and D_5R signaling. PKC can increase the membrane expression of D_1R in vascular smooth muscle cells.[243] In HEK293 cells, novel PKC isoforms stimulate D_1R signaling, but inhibit D_5R signaling.[244] However, in HEK293T cells, PKCα, β1, γ, δ, and ε constitutively phosphorylate and dampen D_1R signaling.[245] Ethanol enhances D_1R signaling by inhibiting PKCγ and PKCδ.[246] PKA and PKC have been reported to phosphorylate D_1R, modulating the rate of agonist-induced D_1R desensitization and intracellular trafficking.[243–248] RanBP9 and RanBP10 interact with both PKCδ/γ to increase the phosphorylation and desensitization of D_1R in neural and renal proximal tubule cells.[248] RanBP9 and RanBP10 may function as scaffolding proteins to regulate the spatial and temporal organization of D_1R and PKC. In renal proximal tubule cells, NHERF-1 is necessary for the D_1R-mediated stimulation of cAMP accumulation and PKC activity.[249]

D_2-Like Receptors

The D_2-like receptors couple to G-proteins $G\alpha_i$ and G_o, and inhibit adenylyl cyclases.[29–31,189–193]

There are two isoforms of D_2R; postsynaptic D_2R effects are mediated by the long isoform, $D_{2L}R$, while the presynaptic D_2R effects are mediated by the short isoform, $D_{2S}R$.[192,250] The $D_{2S}R$ is localized at the plasma membrane, while the $D_{2L}R$ is localized in the perinuclear region in several cell lines heterologously expressing $D_{2S}R$ and $D_{2L}R$.[251] However, in renal proximal tubule cells that express the $D_{2L}R$ rather than the $D_{2S}R$, the $D_{2L}R$ is expressed mainly at the plasma membrane.[252] The particular G-protein-subunit that interacts specifically with either D_2R isoform is not clear.[253] The D_2R can couple to the same extent to Gαi (Gαi2 and Gαi3) and Gz,[253] but Gαo may be the major G-protein that is activated by $D_{2S}R$ and $D_{2L}R$[254]; neither $D_{2S}R$ nor $D_{2L}R$ subtype is linked to Gq11 or $G\alpha_{12/13}$. A splice variant of Gαi2, $sG\alpha_{i2}$, is important in the intracellular localization of D_2R, and its dissociation from D_2R following D_2R agonist stimulation increases cell surface D_2R expression.[254]

The D_4R, like the D_2R, couples to Gαi ($G\alpha_{i2}$ and $G\alpha_{i3}$), Gαo, Gz, and Gαt2.[191,255] Different numbers of 16 amino acid repeats in the third cytoplasmic loop cause several human D_4R isoforms (e.g., D4-2, D4-4, and D4-7).[256] The role of these D_4R isoforms in cell function remains to be determined. However, the D_4R long (at least one 7 to 10 repeat) has been reported to be associated with higher diastolic and systolic blood pressure.[257]

The D_3R linkage to $G\alpha_i$ is not robust, in contrast to that observed for D_2R and D_4R.[258] In rat renal proximal tubule cells the D_3R stimulation of phospholipase C is via $G\alpha_{i3}$.[259] The signaling of D_3R, like the D_2R and D_4R, may be mediated by Gαo.[191] The utilization of G-proteins in D_2R and D_3R-mediated stimulation of extracellular signal-regulated kinase differs, D_2R utilizes $G\alpha_i$ while D_3R utilizes Gα/o and the βγ-subunit of G_i.[260] The D_3R also couples to Gz and, in the presence of pertussis toxin, the D_3R can also couple to Gαs.[253] The D_3R can also couple to Gq11.[259] The linkage of the D_3R to other effectors, such as inhibition of K^+ and Ca^{2+}, may be more sensitive than its weak linkage to G-proteins.[258] The D_3R is also insensitive to GTP, relative to the other dopamine receptor subtypes.[191] There could be seven distinct alternatively spliced D_3R variants.[261] The full-length D_3R and a shorter receptor isoform, the D_3S, bind to dopamine. The five other alternatively spliced D_3R variants do not bind dopamine, but one of them, D_3Rnf, regulates receptor dimerization.

Adenylyl Cyclase

Although D_2-like receptors inhibit adenylyl cyclase activity, in many cell lines heterologously expressing the D_3R, its linkage to $G\alpha_i$ is not robust.[258] However, the D_3R robustly inhibits adenylyl cyclase isoform V,[258] but because this adenylyl cyclase isoform is not expressed in the rat renal proximal tubule,[220] it is expressed in human renal proximal tubule cells (unpublished data). D_3R action in this rat nephron segment is not due to $G\alpha_i$ signaling. Because D_3R can couple to Gαs in the presence of pertussis toxin,[253] the D_3R could increase adenylyl cyclase activity in this nephron segment in the rat. This has not been directly tested, but D_1R and D_3R dimerization increases the ability of dopamine to stimulate adenylyl cyclase activity.[262] In contrast, the co-expression of D_2R with D_3R increases the ability of D_2-like agonists to inhibit adenylyl cyclase activity.[263] This becomes a conundrum in cells expressing these dopamine receptor subtypes, but at least in renal proximal tubules there is no evidence

of D_1R and D_2R or D_2R and D_3R heterodimerization (unpublished data). However, in the kidney and vascular smooth muscle D_1R and D_3R do interact, and this interaction probably predominates over the other possible D_1-like and D_2-like interactions.[264–266] While D_2R, by itself, stimulates Na^+K^+-ATPase activity,[267] simultaneous stimulation of D_1-like and other D_2-like receptors inhibits Na^+K^+-ATPase activity.[268] Furthermore, $D_{2L}R$ and $D_{4.4}R$ can potentiate PKC-stimulated adenylyl cyclase II activity through the release of β/γ-subunits,[269] and $D_{2L}R$ can sensitize adenylyl cyclase VI.[270] Although these adenylyl cyclase isoforms are expressed in renal proximal tubule cells, this interaction probably does not occur in renal proximal tubule cells because quinpirole, a D_2-like receptor agonist with preference for the D_3R and D_4R over the D_2R, does not stimulate adenylyl cyclase activity (unpublished studies). As stated above, there are species differences because adenylyl cyclase V is expressed in the human (unpublished data) but not in the rat renal proximal tubule.[220]

Phospholipase C

In neural cells, D_2R, via $G\beta/\gamma$, stimulates phospholipase C[191] and specifically phospholipase Cβ4 in the intermediate lobe of the pituitary gland[271]. D_1R and D_2R can interact to stimulate phospholipase C in neural cells,[226] but as stated above there is no evidence for D_2R and D_3R interaction in renal proximal tubule cells. D_2R and D_5R can also heterodimerize to stimulate phospholipase C in neural tissue and HEK-293 cells.[227] The $D_{2S}R$ can also stimulate phospholipase D,[272] but the latter enzyme is inhibited by D_5R.[232] These effects need not be counter-regulatory, because as previously mentioned the $D_{2S}R$ is presynaptic, while the D_5R inhibition of phospholipase D is postsynaptic in renal proximal tubule cells (in particular). In addition, presynaptic inhibition of adrenergic neurotransmitters by $D_{2S}R$ facilitates the inhibitory effects of dopamine on ion transport.

Dopamine Regulation of Ion Channels

D_1-like receptors inhibit voltage-gated K^+ channels and G-protein-regulated inward rectifying channels, but stimulate L-type Ca^{2+} channels.[191] D_1-like receptors inhibit G-protein-dependent inward rectifier K-like channels in medial prefrontal cortex via PKC.[273] In contrast, D_2-like receptors stimulate voltage-gated K^+ channels and G-protein-regulated inward rectifying channels, but inhibit L-type Ca^{2+} channels. Both D_1-like and D_2-like receptors inhibit N-, P-, and Q-type Ca^{2+} channels and transient sodium channels, but stimulate persistent P sodium channels.[191] We have reported that the D_3R-mediated vasorelaxation of rat mesenteric arteries is due to stimulation of small- and/or large-Ca^{2+}-activated K^+ channels.[264] In human coronary vascular smooth muscle cells, D_5R stimulates Ca^{2+}-activated big K^+ channel,[274] via cAMP-mediated stimulation of PKG.

Dopamine Regulation of Mitogen-Activated Protein (MAP) Kinase and other Kinases

D_1-like receptors may activate MAP kinases, including p38MAP kinase, and c-jun amino-terminal kinase.[191] In the brain, D_1-like receptors can also activate ERK,[275] but ERK1/2 is actually inhibited by D_5R but not by D_1R in human renal proximal tubule cells.[276] D_2-like receptors can also activate MAP kinase via $G\beta/\gamma$.[277] D_2-like receptor-mediated stimulation of Na^+ K^+-ATPase in the kidney is linked to the p44/42 MAP kinase pathway.[278] Aberrant D_1R activation of ERK1/2/MAP kinase has been reported in D_1R supersensitivity.[279] However, in the kidney, MAP kinase reduces D_1R affinity and G-protein coupling.[280]

Dopamine inhibits DNA synthesis of cultured human mesangial cells.[281] In rat vascular smooth muscle cells, D_1R or D_3R does not affect vascular smooth muscle cell proliferation, but inhibits the proliferative effect of insulin and norepinephrine.[282,283] D_2R, via inhibition of MAP kinase, inhibits angiotensin II-induced hypertrophy of cultured neonatal rat ventricular myocytes.[284] However, dopamine increases the phosphorylation of and activates p44/42 MAP kinases in rabbit renal proximal tubule cells in primary culture.[285] In human renal proximal tubule cells and Chinese hamster ovary cells, the D_3R promotes mitogenesis or cell proliferation through the activation of MAP kinases.[191,286,287] The variable effects of dopamine on MAP kinase in smooth muscle and epithelial cells may be related to tissue- or cell-specificity.

DARPP-32

As stated above, DARPP-32 was identified initially as a major target for dopamine-activated adenylyl cyclase in striatum.[224] Since the mid-1980s, DARPP-32 has been acknowledged as a crucial mediator of the biochemical, electrophysiological, transcriptional, and behavioral effects of dopamine.[288] The state of DARPP-32 phosphorylation has been shown to provide a mechanism for integrating information arriving at dopaminoceptive neurons, in multiple brain regions, via a variety of neurotransmitters, neuromodulators, neuropeptides, and steroid hormones. Activation of PKA or PKG stimulates DARPP-32

phosphorylation at Thr,[34] and thereby converts DARPP-32 into a potent inhibitor of protein phosphatase-1 (PP1). Protein phosphatase-2B (PP2B) is the most effective protein phosphatase in dephosphorylating DARPP-32 at Thr.[34] Thus, DARPP-32 acts as an amplifier of PKA and PKG-mediated signaling when it is phosphorylated on Thr,[34] which converts it into an inhibitor of PP1. The role of DARPP-32 in signaling has turned out to be very complex. Under basal conditions, DARPP-32 is phosphorylated at Thr[75] and inhibits PKA. Thus, DARPP-32 has the unique property of acting either as an inhibitor of PP1 or an inhibitor of PKA. However, under hyperdopaminergic conditions, the phosphorylated state of Thr[75] is reduced, allowing increased phosphorylation at Thr.[34] This positive feedback loop acts as a switch to potentiate dopaminergic signaling. Cdk5, a cyclin-dependent kinase family member, also phosphorylates DARPP-32 at Thr.[75] Furthermore, protein phosphatase 2A dephosphorylates DARPP-32 both at Thr[34] and Thr,[75] and the state of phosphorylation of DARPP-32 at Thr[34] depends on the phosphorylation state of two serine residues, Ser[102] and Ser.[137] DARPP-32 has been demonstrated with biochemical, immunohistochemical, and *in situ* hybridization techniques to have an anatomical distribution similar to that of dopaminoceptive cells possessing D_1Rs in the central nervous system.[289–291] DARPP-32 is also expressed in several peripheral tissues, including brown fat cells, parathyroid, retina, and renal tissue.[289,291–293] The ability of D_1R to stimulate protein phosphatase 2A[215,294] may serve as a negative feedback in the D_1R and DARPP-32 relationship, and prevent the inhibitory effect of DARPP-32 on PKA.

Regulation of Dopamine Receptor Function

Effect of Sodium on Dopamine Receptor Expression

While acute sodium loading generally increases renal dopamine production,[31,50,53,58,62–65,92,99,113,114,119] it may decrease brain[295] and renal D_1-like and D_2-like receptor density.[296,297] However, the decrease in renal D_1-like receptor expression occurs after 7–28 days of increased sodium intake during peak renal dopamine production.[148,149] In C57BL/6 mice, increasing NaCl diet to 6% for 5–7 days decreases renal D_1R expression, but increases renal D_3R expression without affecting the renal expression of D_2R, D_4R or D_5R (unpublished observations).

Dopamine Receptor Recycling

As with other GPCRs, dopamine receptor signal transduction is precisely regulated.[189–193,195,298,299] In the basal state, in human renal tubules, human D_1Rs exist as homooligomers in lipid raft microdomains.[300] Occupation of D_1Rs increases the amount of D_1R monomers associated with a transient increase in D_1R function, as a result of the recruitment of D_1R from an intracellular pool of D_1R to the lipid rafts of plasma membranes.[215,300–304] Following the transduction of the GPCR signals, there is a transient loss of receptor responsiveness (desensitization). This mechanism dampens short-term agonist effects following repeated agonist exposure. At least three families of regulatory molecules contribute to GPCR desensitization: second messenger-dependent protein kinase; G-protein-coupled receptor kinases (GRKs); and arrestins.[141,189–191,195,280,286,298,299,305–308] Homologous desensitization, in response to agonist stimulation, occurs via action of a member(s) of the GRK family. Heterologous desensitization, mediated by second messenger-dependent kinases, occurs when a decrease in receptor responsiveness is induced by a ligand other than its own specific ligand. The phosphorylation of GPCRs, including the D_1R, leads to the binding of a member(s) of the arrestin family, uncoupling of the receptor from its G-protein complex, and a decrease in its functional response. Desensitization of GPCRs involves phosphorylation, sequestration/internalization, and degradation of receptors. The D_1R (but not D_5R), expressed endogenously in renal proximal tubule cells,[288,299–307] is regulated to a lesser extent by GRK2 and to a greater extent by GRK4 in human kidneys,[299] but the converse may be true in rat kidneys.[305] Moreover, GRK4 may constitutively phosphorylate D_1R.[307] GRK3 regulates rat D_1R overexpressed in HEK293 cells.[308] It is not clear whether or not GRK5 regulates the rat D_1R.[308] GRK6 is not important in the regulation of D_1R in the kidney (unpublished), but it is important in the desensitization of the D_1R in intestinal crypt cells,[309] emphasizing the importance of cell type in D_1R regulation. The desensitization of D_5R, in contrast, does not involve GRKs, but rather sorting nexin 1.[310] Similarly, GRK is not involved in the first 20 minutes of D_1R desensitization in human renal proximal tubule cells,[299] but could be related to sorting nexins (unpublished data). It has also been suggested that GRK2 may negatively regulate D_2R signaling by a phosphorylation-independent mechanism.[311]

Heterologously expressed D_1Rs, after ligand stimulation, rapidly (but not completely) internalize (5–12 minutes) in cell lines (HEK-293 and Neuro2A neuroblastoma cells).[307] In HEK-293 cells heterologously expressing rat D_1R, 15 minutes of agonist stimulation does not completely desensitize D_1R.[307] Presumably, the internalized D_1R continues to function until it is completely desensitized.[312] Phosphorylation, desensitization, and internalization cannot be directly equated.[216,298,299] GPCR desensitization cannot be completely explained by phosphorylation; ubiquitination may also play a role.[46,313] AT_1R,[46] D_1R, and D_5R (unpublished data) are

ubiquitinated within the first 15 minutes following ligand stimulation; AT_1R and D_5R,[46] but not D_1R, are targeted for degradation following ligand occupation. Thus, desensitization may also occur at the plasma membrane.[216] Cell membrane invagination and endocytosis are important in D_1R trafficking; prevention of endocytosis with hypertonic sucrose abrogates ligand-induced D_1R desensitization in human renal proximal tubule cells.[314] The phosphorylated GPCR/β-arrestin complex undergoes endocytosis/internalization via clathrin-coated pits into a series of endosomal units, where it is dephosphorylated and recycled back to the plasma membrane or degraded. Dopamine receptors belong to Class A receptors that are rapidly recycled to the plasma membrane. In contrast, AT_1R receptors belong to Class B receptors that are slowly recycled to the plasma membrane, and some are actually degraded.[315] Protein phosphatases are involved in the resensitization of GPCRs in endosomes[316] and at the plasma membrane.[216] Protein phosphatases, including protein phosphatase 2A (PP2A),[215,294,317,318] a GPCR phosphatase,[216] and PP2B (calcineurin)[319] have been reported to resensitize D_1R, but PP2A is probably the major protein phosphatase involved in D_1R function and/or resensitization in renal tubule cells.[215,294,317]

The D_2R, like some GPCRs, is not desensitized by phosphorylation but rather by association with β-arrestin, but phosphorylation is required for its recycling.[256,311,320] The GRK regulating D_2R in renal tubule cells is not known, but D_2R in other cells is regulated by GRK2, GRK3, GRK5, and GRK6,[256,287,311,320] and constitutively desensitized by GRK2. GRK2 and GRK3 preferentially sequester $D_{2S}R$ over $D_{2L}R$, while β-arrestin 2 has the converse effect.[256] GRK2 or GRK3, but not GRK5 or GRK6, is involved in the desensitization of the calcium signal mediated by the interaction of D_1R/D_2R heterologously expressed in HEK293TSA cells.[321] The desensitization of D_3R is weakly regulated by GRK2 and GRK3,[322] but robustly by GRK4 (GRK4γ > GRK4α); GRK4 and D_3R colocalize and interact in human renal proximal tubule cells.[286] D_4R, like some GPCRs, e.g., AT_2R and β_1R, may not undergo internalization and is resistant to desensitization.[256,323] The GRK regulating D_4R is not clear, but does not seem to involve either GRK2 or GRK3. The GRK regulating D_5R is also not clear, but does not seem to involve GRK4.

Membrane Microdomains

Cholesterol rich domains in membranes are called lipid rafts and the rest are called non-lipid rafts.[324,325] Lipid rafts serve as signaling platforms for several signaling molecules such as G-protein-subunits, enzymes, and adaptor proteins. Lipid rafts can affect the function of GPCRs by inducing a conformational change and/or alteration of the physical properties of the membrane in which the GPCR is embedded. We have reported that angiotensin II does not affect the differential expression of AT_1R in lipid and non-lipid rafts in renal proximal tubule cells from normotensive rats, but increases the amount of glycosylated AT_1R in lipid rafts in renal proximal tubule cells from SHRs; this may lead to an increased ability of angiotensin II to stimulate the Cl^-/HCO_3^- exchanger.[326] D_1-like receptors also regulate NADPH oxidase activity and subunit expression in lipid microdomains of renal proximal tubule cells.[327] The D_2-like receptor antagonist, haloperidol, has been reported to disrupt lipid rafts.[328] Interestingly, high doses of simvastatin, a cholesterol depleting reagent, increase dopamine receptor expression in the rat prefrontal cortex.[329] In human renal tubule cells, heterologously or endogenously expressed D_1R exists as homo-oligomers; agonist stimulation increases the amount of D_1R monomers[300,330,331] consistent with other GPCRs.[332–334] D_1R oligomers exist in caveolae-like microdomains; decreasing caveolin expression or depleting cholesterol impairs D_1R-mediated generation of cAMP and oligomer formation.[300] Renal inhibition of caveolin-1 expression, an important component of lipid rafts, via caveolin-1 siRNA in the kidney impairs D_1-like receptor-mediated natriuresis in salt-loaded rats and produces hypertension.[335] Thus, the function of GPCRs, including dopamine receptors, can be regulated by cholesterol membrane microdomains.

Regulation of GPCR Membrane Expression

Plasma membrane expression of GPCRs requires proper folding that is aided by chaperones.[336] Homodimerization has been suggested to help in GPCR folding. Indeed, folding efficiency has been suggested to regulate the expression of D_4R.[337] A proper amount of calnexin, an endoplasmic reticulum chaperone, is important in the proper trafficking of both D_1R and D_2R to the plasma membrane.[338]

D_1R

Dopamine receptor interacting protein 78 (DRiP78) is an endoplasmic reticulum protein that regulates the transport of D_1R and other GPCRs, including AT_1R, and the assembly of G-protein β- and γ-subunits.[339] Increased expression of DRiP78 impairs the transport of D_1R from the endoplasmic reticulum to the plasma membrane.[340] In contrast, DRiP78 increases the plasma membrane expression of AT_1R,[341] another example of how certain proteins have contrasting effects on AT_1R, and dopamine receptor trafficking and expression.[45,46,342,343] Neurofilament-M specifically decreases the cell surface membrane expression of D_1R (not with D_2-like receptors and weakly with D_5R).[344] Calcyon is another D_1R interacting protein that may be important

in D_1R-calcium-mediated signaling in neural tissue.[345] Whether these proteins regulate D_1R endogenously expressed in renal tissue remains to be determined. However, RanBP9/10 which colocalizes with D_1R in renal and neural tissues, phosphorylates and impairs D_1R function.[248]

D_2R

Cbl-interacting protein of 85 kDa (CIN85) may be important in the trafficking of D_2R, at least in striatal tissue.[346] Absence of striatal CIN85 is associated with decreased endocytosis of D_2R and implicated in the hyperactivity of CIN85-deficient mice. A Ca^{2+}-binding protein, S100B, increases the ability of D_2R to inhibit adenylyl cyclase and stimulate ERK activity.[347] Two D_2R interacting proteins decrease the expression and/or function of D_2R, including neuronal calcium sensor 1[348] and protein kinase Cξ-interacting protein.[349] In neural cells, a spliced variant of the Gαi2 may also be important in the plasma membrane expression of the D_2R[350] and protein 4.1N for both D_2R and D_3R.[351]

D_3R

The D_3R has been reported to interact with proteins that affect plasma membrane localization. Filamin-A interacts with D_2R and D_3R, linking them to the cytoskeleton and increasing their plasma membrane localization.[322,352] In contrast, paralemmin specifically interacts with the D_3R decreasing its localization to the plasma membrane.[353] The role of these interacting proteins on D_3R function in renal proximal tubules or blood vessels remains to be determined.

D_4R

KLHL12, which can act as a ubiquitin ligase, interacts with the D_4R, but its ubiquitination does not result in its degradation.[354] Indeed, the D_4R is resistant to agonist-induced internalization and degradation.[323]

D_5R

The D_5R, but not the D_1R, requires N-glycosylation for membrane localization in transfected HEK-293 cells. However, it does not contribute to the radioligand-binding properties of D_5R.[355]

Renal Distribution of Dopamine Receptors

The expression of the dopamine receptors in the kidney (Table 19.1) of several mammals has been reported.

Tubular Distribution

The dopamine receptor subtypes are differentially expressed along the mammalian nephron.[213,252,356–365] However, their expression in the medulla is species-dependent. In the rat, the D_2R and D_4R are expressed in the inner medulla[357,365] (Table 19.1). The mouse kidney has no dopamine receptors in the inner medulla[360] (unpublished observations). High concentration of dopamine (100 μM) stimulates prostaglandin E2 production in the inner medulla and thin limb of Henle.[358] The dopamine receptor subtype expressed in the thin limb of Henle is not known, although dopamine (100 μM) stimulates prostaglandin E2 production in rat thin ascending limb cells[366.]

Immunohistochemical studies in human and rodent kidneys have shown expression of D_1R in the apical and basolateral membranes, as well as in the cytoplasm of proximal tubules (mouse:S3 > S1 = S2), distal convoluted tubules, medullary thick ascending limb (mTAL) of Henle, macula densa, and cortical collecting duct.[356,361,364,365] The presence of D_1R in the rat outer or inner medulla has not been shown consistently using immunohistochemistry[356,361,362,365] or *in situ* mRNA amplification,[367] and dopamine does not stimulate cAMP production via dopamine receptors,[368,369] in this nephron segment. Moreover, there is no D_1-like receptor radioligand-binding in the rat inner or outer medulla.[370,371] The human[372] and mouse kidney[360] (unpublished observations), do not express dopamine receptors in the inner medulla.

$D_{2L}R$ mRNA is expressed in the rat cortex, and outer and inner medulla.[252] Immunoreactive D_2R is present in rat[357] and human (unpublished observations) proximal tubule (mouse:S2 > S1/S3), distal convoluted tubule, and cortical and outer medullary collecting duct. The D_2R is expressed in the intercalated cells of the medullary collecting duct in the rat,[357] but not in the mouse (unpublished data). D_2R protein is also expressed in the OK cell, an opossum proximal tubule cell line that also exhibits distal tubular cell characteristics.[373]

D_3R mRNA is expressed in the rat cortex, and outer medulla and inner medulla.[252] Immunoreactive D_3R is expressed in rat apical and subapical areas, but not in the basolateral membrane of proximal tubules (S1 >> S2/S3) in three reports[357,373,375]; one study also showed immunoreactive D_3R in the distal convoluted tubule,[375] and two studies showed D_3R protein in the cortical collecting duct.[357,375] One[357] of three reports[374,375] found D_3R immunostaining in the inner medulla. Immunoreactive D_3R is present in mouse proximal tubule, thick ascending limb of Henle, and distal convoluted tubule, but not in the cortical collecting or outer and inner medullary collecting ducts (Table 19.1).

D_4R is present in the rat proximal tubule (S1 > S2 > S3), distal convoluted tubule, and especially in the cortical[357,376] and outer and inner medullary

collecting ducts, where it is more abundant at the luminal than at the basolateral areas.[365] In the mouse, D_4R is present in the proximal convoluted tubule (but not proximal straight tubule), thick ascending limb of Henle, and cortical and outer medullary collecting duct (unpublished observations). D_4R mRNA is expressed in the human kidney, but its expression along the nephron has not been reported.[377]

D_5R is expressed in the rat and mouse proximal tubule (S1 > S2/S3), thick ascending limb, and distal convoluted tubule and cortical and outer medullary collecting duct.[213,360,364] The expression of D_5R protein has not been reported in human kidney, but is expressed in human renal proximal tubule cells in culture,[46,276] and D_5R may be expressed preferentially over the D_1R in the thick ascending limb of Henle and the cortical collecting duct, while the D_1R is preferentially expressed in the proximal tubule[378](unpublished data).

VASCULAR RECEPTORS

D_1-Like Receptors

The D_5R may have chemo- and mechano sensory roles in primary cilia of mouse vascular endothelial cells.[379] D_1Rs, and to a greater extent D_5Rs, are expressed in the tunica media of rat mesenteric, pial, and renal arteries.[361,380,381] They are mainly located postjunctionally, which has been confirmed by insensitivity to chemical sympathectomy.[381] In the rat kidney, D_1R mRNA is also found in smooth muscle cells of large and small arteries, and afferent and efferent arterioles.[367] In humans D_1R protein is also present in vascular smooth muscle cells in the large intrarenal arteries, but not in renal veins.[372]

D_2-Like Receptors

The D_2-like receptors are expressed in the adventitia and adventitia–media border of arteries. D_2R and D_4R, but not D_3R, are expressed in rat mesenteric and pial arteries. Rat renal arterial branches express D_2R and D_3R.[380] Although renal arteries and arterioles in Wistar rats were not found to express D_4R,[380] a subsequent study in Sprague-Dawley rats showed expression of D_4R in large segmental, arcuate, interlobar, interlobular, and afferent and efferent arterioles.[376] Bilateral superior cervical ganglionectomy and renal denervation confirmed the prejunctional localization of the D_2-like receptors, and the location of D_2-like receptors in the renal artery suggest their prejunctional localization.[376,380] However, we have reported that D_3R stimulation relaxes mesenteric arterial rings, independent of the endothelium.[264] The failure of the endothelium to influence the vasorelaxant effect of D_3R stimulation is in agreement with the absence of D_2-like receptor expression in the intima.[380] One study could not find D_3R expression in renal vessels,[374] although another study found D_3R immunostaining in medial and adventitial layers of renal arteries[378] in agreement with the report of D_3R mRNA in renal microvessels.[252]

GLOMERULAR RECEPTORS

Radioligand binding and autoradiographic studies using D_1-like receptor ligands that recognize both D_1R and D_5R have failed to detect specific binding in rat and human glomeruli.[370,371,381,382] D_1R mRNA studied by *in situ* mRNA amplification is not detected in rat renal glomeruli[367] (Table 19.1). Immunoreactive D_1R[361,372] or D_5R[360,364] has not been demonstrated in rat or human glomeruli. In rat glomeruli isolated by sieving, two[383,384] of three[15] studies showed that dopamine, via an uncharacterized dopamine receptor, increased cAMP production. Dopamine increases cGMP, but not cAMP production in isolated dog glomeruli, also obtained by sieving.[385] However, because afferent and efferent arterioles express D_1R and D_5R (Table 19.1) it is possible that glomerular preparations that contain arterial vessels may confound the results. Nevertheless, rat glomerular mesangial cells[386] and mouse glomerular podocytes,[387] in culture, express D_1-like receptors, assessed by an increase in cAMP production in response to dopamine or D_1-like receptor agonist. Rat glomerular epithelial cells in culture do not increase cAMP production in response to dopamine.[386]

D_2-like receptors, $D_{2L}R$, D_3R, and D_4R, are present in rat glomeruli[252,357,375,381,388] (Table 19.1). Specifically, immunoreactive D_2R and D_3R have been reported in rat mesangial cells in one study[357] and in podocytes in another study.[375] However, there are three reports of the absence of D_4R receptors in rat glomeruli.[357,365,376] D_2-like receptor stimulation decreases cAMP production in rat glomeruli.[15] Dopamine attenuates the contractile response to angiotensin II in rat isolated glomeruli, but the receptor mediating this effect is not known.[389]

Receptors in Juxtaglomerular Apparatus

Rat[361,390] and mouse (unpublished observations) but not human[372] juxtaglomerular cells, *in situ*, and rat juxtaglomerular cells in culture[390] express D_1R (Table 19.1). Rat[361] and mouse (unpublished studies) but not human[372] macula densa cells express D_1R. Rat[364] but not mouse[360] juxtaglomerular or macula cells express

D_5R. Rat[361] but not mouse (unpublished studies) macula densa cells express D_1R. D_5R expression in human juxtaglomerular or macula cells has not been reported.

Rat, mouse, and human (unpublished studies) juxtaglomerular cells, *in situ*, do not express D_2R. Mouse juxtaglomerular cells, *in situ*, express D_3R (Table 19.1). In contrast, rat juxtaglomerular cells, *in situ*, also do not express D_3R[374,375] or D_4R,[365,376] but express D_3R and D_4R in culture.[391] Rat macula densa cells were found to express D_3R in one[375] of two reports.[374] Mouse macula densa cells express D_3R and D_4R (unpublished studies). D_2R is not expressed in human or mouse macula densa cells, but is expressed in rat macula densa (unpublished studies; Table 19.1); D_3R and D_4R expression has not been studied in human macula densa.

DOPAMINE AND RENAL HEMODYNAMICS

D_1-Like Receptors

Dopamine, administered in low doses intravenously or directly into the renal artery, increases renal blood flow and decreases renal vascular resistance.[9,392,393] The renal vasodilatory effect of dopamine is mimicked by D_1-like receptor agonists and blocked by the D_1-like receptor antagonists.[394–397] The contribution of D_1R and D_5R in this action remains to be determined. Dopamine and D_1-like receptor agonists dilate afferent and efferent arterioles to the same extent.[398,399] However, afferent arterioles are preferentially dilated in the hydronephrotic kidney.[400] Dopamine induces a greater vasodilatory effect in the renal artery than in the coronary artery,[401] mesenteric,[402] in agreement with the receptor density data.[403]

cAMP/PKA[12,404–406] is the primary signaling pathway of the renal vasodilatory effect of dopamine via D_1-like receptors. However, a dopamine-mediated stimulation of PKC is associated with increased expression of D_1-like receptors that enhances cAMP production in renal vascular smooth muscle cells.[243] However, as stated earlier in HEK293 cells, novel PKC isoforms stimulate D_1R[244] but inhibit D_5R signaling, while conventional PKCs and two of the novel PKCs (δ and ε) impair D_1R signaling.[245] In coronary arteries, the vasorelaxant effect of D_1-like receptors has also been attributed to PKA/PKG-dependent activation of K^+-ATP, calcium-, and voltage-activated K^+ channels.[274] Prostacyclins may also contribute to dopamine- and D_1-like receptor-mediated renal vasodilation.[407]

The effect of D_1-like receptors in the rat aorta and tail artery is complex. Dopamine has been reported to decrease both sodium influx and efflux by inhibition of NHE and Na^+/K^+-ATPase activity, respectively, in part via PKA, in rat aorta smooth muscle cells.[408] A predominant inhibitory effect on NHE activity would result in a decrease in intracellular sodium and a decrease in vessel tone, while a predominant inhibitory effect on Na^+/K^+-ATPase activity would result in an increase in intracellular sodium and an increase in vascular tone. The latter situation may explain the apparent vasoconstrictor action of a D_1-like receptor agonist in the rat tail artery.[409] In the rat tail artery, dopamine and SKF 38393, a D_1-like receptor agonist, inhibited Na^+/K^+-ATPase and increased vascular tone, an effect that was associated with activation of phospholipase C.[409] Since the effects were abolished by pertussis toxin, the D_1-like receptor in the rat tail artery is must be different from the D_1-like receptor in renal proximal tubules, because in this tissue phospholipase C is pertussis-toxin resistant and linked to Gq.[142,410] When phospholipase Cβ1 is not expressed, D_1-like agonists can be indirectly linked to phospholipase Cγ1 via PKA.[139] The effect of dopamine in resistance vessels may not be the same as that in conduit vessels (e.g., aorta) and in the rat tail artery, which may subserve a thermoregulatory function.

D_2-Like Receptors

Both the $D_{2S}R$ and $D_{2L}R$ may act as autoreceptors in certain nerves (GABA transmission), while the $D_{2S}R$ but not the $D_{2L}R$ regulates glutamate release.[411] However, the $D_{2S}R$ but not the $D_{2L}R$ is involved in presynaptic dopamine transmission, while postsynaptic dopamine transmission is via the $D_{2L}R$.[412] The D_3R[413] but not the D_4R[414] can also function as an autoreceptor (presumably located in prejunctional areas) and inhibit catecholamine release. Prejunctional D_2-like receptors in the kidney inhibit norepinephrine release.[415,416] This effect may explain the ability of bromocriptine (D_2R and D_3R agonist), but also with D_1-like antagonistic properties, to increase renal blood flow in the anesthetized rat,[417,418] and the renal vasodilatory effect of endogenous dopamine in humans on a low-sodium diet.[419]

The effect of postjunctional D_2-like receptors on the renal vasculature is inconsistent. When both α- and β-adrenergic receptors are blocked in the dog kidney, the renal vasodilatory effect of dopamine is antagonized by D_1-like but not by D_2-like receptor blockade.[395] However, in a similar preparation, bromocriptine has been reported to decrease renal blood flow.[420] In the conscious, chronically instrumented dog on a moderate sodium intake (40 mmol/day), low (picomolar) concentrations of quinpirole, a D_2-like receptor agonist with selectivity for the D_3R and D_4R over the D_2R, also produces vasoconstriction.[421] This result agrees with the report that D_3R stimulation constricts renal vessels in

volume-loaded rats.[422] In humans, D_2-like receptor blockade with L-sulpiride does not affect renal plasma flow but potentiates the renal vasoconstrictor effect of NO inhibition with L-NAME.[423] D_4R stimulation also enhances the contractile response of guinea pig vas deferens.[424]

In contrast to the above observations that D_2-like receptors induce vasoconstriction, in the preconstricted isolated perfused rat kidney bromocriptine (D_2R/D_3R agonist) induces vasodilation via postjunctional D_2-like receptors.[425] In the norepinephrine- or high-potassium-preconstricted rat mesenteric arterial rings, D_3R stimulation induces vasorelaxation.[264,426] The vasodilatory effect of D_3R is caused by activation of potassium channels (small- and/or large-conductance calcium-activated potassium channels).[264,426] Although the D_3R is present in the intima, the vasodilatory effects of the D_1R and D_3R agonists are endothelium independent; D_1R is not expressed in the intima.[264,426] In humans, the renal vasodilatory effect of D_2-like receptors is reduced during sodium loading and increased during sodium restriction.[419] This is in contrast to the lack of effect of sodium loading on the renal vasodilatory effect of D_1-like receptors.[427]

The D_3R can augment the vasodilatory effect of the D_1R by mechanisms independent of signal transduction. In embryonic thoracic aortic smooth muscle cells and coronary artery smooth muscle cells, stimulation of the D_1R increases D_1R and D_3R expression.[264,426] However, the additive vasorelaxant effects of D_1R and D_3R could not be explained by the increased expression of those two receptors, because the vasorelaxant effect occurs within minutes following agonist stimulation. Rather, the D_1R and D_3R may acutely and physically interact with each other; D_1R and D_3R co-immunoprecipitate within minutes after agonist stimulation, consistent with the timeframe of the additive vasodilation effect of D_1R and D_3R.[264]

The published studies show that D_1-like receptors cause renal vasodilation. Stimulation of pre-junctional D_2-like receptors should cause vasorelaxation, while stimulation of post-junctional D_2-like receptors can result in either vasodilation or vasoconstriction. With chronic sodium chloride loading, basal reactivity of renal vessels may be enhanced by an increase in levels of endogenous Na^+/K^+-ATPase inhibitor, e.g., ouabain, and an increase in intracellular sodium and calcium.[428] Ouabain, *per se*, can decrease renal D_1R expression and function.[429] Under these conditions, dopamine can further increase intracellular sodium by stimulating NHE1 activity via D_2-like receptors.[430] The increase in intracellular sodium increases sodium calcium exchanger activity. The increase in intracellular calcium increases vascular reactivity and, thus, dopamine, via D_2-like receptors which can then elicit vasoconstriction. When renal nerve activity is increased, as seen in renal nerve stimulation, low-sodium diet, hypovolemia or during anesthesia, the vasodilator effect of dopamine occurs via prejunctional D_2-like receptors,[415,416] presumably of the D_3R subtype.[264,426] In addition, when renal vascular resistance is increased, the D_2-like receptor effect at postjunctional sites would be that of vasodilation, since D_2-like receptors inhibit Ca^{2+} channels and stimulate K^+ channels, both of which can lead to vasorelaxation. Under these conditions, a synergistic effect between D_1- and D_2-like receptors may become evident.[264,394,398,426] The effect of dopamine on vascular tone may differ between conduit (e.g., aorta) and resistance (e.g., mesenteric and renal arterioles) vessels. The increase in vascular tone produced by D_1-like receptor agonists in conduit vessels may serve to increase perfusion in downstream vessels dilated by D_1-like receptors.

Glomerular Filtration

Although low concentrations (nM) of dopamine consistently increase renal blood flow, this is not the case for glomerular filtration rate.[427,431,432] Normally, low concentrations of dopamine dilate afferent and efferent arterioles to the same degree, and therefore transglomerular pressure remains unchanged.[368] However, dopamine can ameliorate the reduced glomerular filtration rate caused by amphotericin B,[433] radiocontrast material, and hypovolemic states.[434] This could be a direct effect on glomerular cells, since dopamine can attenuate the contractile effect of angiotensin II in isolated glomeruli.[389] This effect is probably exerted via D_2-like receptors, because D_1-like receptors are not expressed in glomerular mesangial cells, *in situ*.[15,360,361,364,367,370–372,381,382] It is only after culture that glomeruli express D_1-like receptors and their stimulation increases cAMP production.[383,384,386,387] In isolated dog glomeruli, dopamine increases cGMP formation[385] and in isolated rat glomeruli, dopamine decreases adenylyl activity,[15] in keeping with the presence of D_2-like receptors[252,357,376,381,388] (Table 19.1). *In vivo*, D_2-like receptors can decrease or increase glomerular filtration rate, depending upon the state of renal vascular D_2-like receptor activation. When the interaction of D_1- and D_2-like receptors results in a greater vasodilatory effect on afferent than efferent arterioles, glomerular filtration rate can increase.[435] D_2-like receptors are involved in the increase in glomerular filtration rate associated with amino acid infusion, an effect that is mediated by renal nerves.[436] The D_2-like receptor-mediated decrease in renal blood flow is associated with greater constriction of afferent than efferent arterioles, resulting in a greater decrease in glomerular

filtration rate than renal blood flow and, therefore, a fall in filtration fraction.[421,437]

Tubuloglomerular Feedback

Tubuloglomerular feedback describes a mechanism by which changes in distal tubular sodium chloride delivery induce changes in afferent glomerular arteriolar resistance mediated by the adenosine A_1 receptor.[438–441] Tubuloglomerular feedback is initiated by transport of sodium via sodium potassium 2 chloride transporters type A (NKCC2A) and type B (NKCC2B) at the macula densa.[441] Because dopamine stimulates NKCC2 activity,[442] it would be expected that dopamine should promote the tubuloglomerular feedback. However, dopamine inhibits tubuloglomerular feedback[443] by occupation of luminal D_1R but not D_2R on macula densa cells that may be more evident during sodium surfeit.[444] How can this be done when D_1R stimulates NKCC2?[442] There are several possible explanations. D_1-like receptors counteract the effect of adenosine A_1 receptors on the tubuloglomerular feedback.[134] The heterodimerization of the D_1R and adenosine A_1 receptor[445] and D_2-like and adenosine A_{2A} receptors[446] inhibit dopamine receptor function (see adenosine and dopamine receptor interaction). Adenosine A_{2A} receptors counteract the effect of adenosine A_1 receptors on tubuloglomerular feedback[447] and dopamine (probably via D_2-like receptors) counters the effects of adenosine A_{2A} receptors.[446] Superoxide anion activates 5′-nucleotidase, thereby increasing adenosine generation in the kidney. Dopamine also induces ecto-5′nucleotidase in glomeruli[448] and because ecto-5′-nucleotidase catalyzes the formation of adenosine, dopamine should enhance tubuloglomerular feedback.[438,440] However, the ability of dopamine receptors to inhibit ROS production[449] may also play a role, because ROS is also involved in tubuloglomerular feedback.[439] These counteracting effects of dopamine on adenosine formation, adenosine receptor action, NKCC2, and ROS may explain the variable effect of dopamine on tubuloglomerular feedback.

RENIN, ANGIOTENSINOGEN, AND ALDOSTERONE SECRETION

Dopamine can increase, decrease or have no effect on renin secretion, *in vivo*.[44] Dopamine can alter renin secretion directly or indirectly by effects on blood pressure and renal tubular ion transport. As indicated above, rat and mouse juxtaglomerular cells express the D_1R[361,367,390] (Table 19.1). The D_1R stimulates secretion of renin in rat primary cultured cells.[390,450] In pithed rats and anesthetized dogs, dopamine and D_1-like receptor agonists increase renin release.[451,452] However, in non-pithed rats, dopamine or a D_1-like receptor agonist inhibits renin secretion on a low or normal salt diet, by inhibiting cyclooxygenase 2 expression.[44] However, when cyclooxygenase 2 expression[44] is already inhibited, as is the case with salt-loading, D_1-like receptor stimulation increases renin secretion.[44] In humans on low or high sodium (300 mmol/day) intake D_1-like receptor stimulation does not affect renin secretion,[427] in agreement with the absence of D_1R in human juxtaglomerular cells.[372] D_1-like receptor stimulation also does not affect plasma renin activity in subjects with mild essential hypertension on an unmonitored sodium intake,[453] but increases it in hypertensive humans on a high (150 mmol Na)[454] or normal sodium intake.[455] The role of D_5R on renin secretion in the rat remains to be determined; D_5R is expressed in rat[364] but not in mouse[360] juxtaglomerular cells and deletion of *Drd5* does not affect plasma or renal renin levels.[360]

In salt replete humans, D_2-like receptor blockade with metoclopramide does not affect plasma renin activity[456] but another D_2-like receptor antagonist, domperidone, inhibits the fall in plasma renin activity induced by intravenous γ-L-glutamyl-L-dopa in humans on an unmonitored salt intake.[457] Disruption of the *Drd3* in mice leads to increased renin release and renin-dependent hypertension.[25] In contrast, deletion of *Drd4* does not affect plasma or renal renin levels.[26] D_2R also probably do not play a role in renin secretion, because they are not expressed in the juxtaglomerular cell in rat,[357] mouse or human kidney (unpublished observations). Whether or not the reported effects of dopamine and D_1-like and D_2-like receptors on renin secretion are exerted at the macula densa remains to be confirmed, but all the dopamine receptor subtypes have been found in macula densa cells, albeit with species variability (Table 19.1). These studies would suggest that in humans, the predominant effect of dopamine receptors on renin secretion is inhibitory, via D_2-like receptors. A stimulatory effect could occur in hypertensive humans (see above), similar to that suggested in Sprague-Dawley rats[44], which are salt-sensitive.

D_1R is expressed in the zona glomerulosa of rat adrenal glands[458] and increases aldosterone secretion in isolated and cultured rat adrenal glomerulosa cells.[459] In humans, dopamine does not affect aldosterone secretion in the salt-replete state[460] but dopamine[461] inhibits angiotensin II-induced aldosterone secretion. This would be in keeping with the attenuation of angiotensin II-induced aldosterone secretion by bromocriptine (D_2R/D_3R agonist) in human adrenal cortical and adenocarcinoma cells.[462] These observations are confounded by the report that stimulation of D_4R enhances[463] angiotensin II-stimulated aldosterone

[i] *In culture.*

The renal expression of dopamine receptor subtypes is species dependent. In the rat, all the dopamine receptors except the D_5R are expressed in the outer and inner medulla[213,252,356-365]. The mouse kidney has no dopamine receptors in the inner medulla[360] (unpublished observations).

Abbreviations: Glom: glomerulus; MC: mesangial cell; PCT: proximal convoluted tubule; PST: proximal straight tubule; TDL: thin descending limb; ATL: ascending thin limb; TAL: thick ascending limb; DCT: distal convoluted tubule, CCD: cortical collecting duct, OMCD: outer medullary collecting duct; IMCD: inner medullary collecting duct; JGC: Juxtaglomerular cell; MD: Macula densa.

secretion in the same human adrenal cortical and adenocarcinoma cells. However, in hypertensive subjects, the D_2-like receptor agonist bromocriptine (D_2R/D_3R agonist) decreased renin and aldosterone secretion which was reversed by metoclopramide, a non-selective D_2-like receptor antagonist.[464] Metoclopramide did not affect aldosterone levels in saline-loaded normal and heart failure subjects.[465] Because saline loading normally decreases aldosterone levels, this study suggests that dopamine does not normally stimulate aldosterone secretion.[465] However, the inhibitory effect of D_2R on aldosterone secretion is consistent with the increase in urinary aldosterone in $D_2^{-/-}$ mice.[47] In contrast, urinary aldosterone is not different between $D_4^{-/-}$ and $D_4^{+/+}$ mice, $D_3^{-/-}$ and $D_3^{+/+}$ mice (unpublished studies) or $D_5^{-/-}$ and $D_5^{+/+}$ mice.[360] Thus, dopamine probably normally is inhibitory of aldosterone secretion, mainly via the D_2R.

Autocrine/Paracrine Regulation of Renal Function by Dopamine

The autocrine/paracrine regulation of renal tubular sodium transport, via D_1-like receptors, is mediated by tubular and not by hemodynamic mechanisms[18–21,371,466,467] (also see below). Systemically administered dopaminergic drugs may not mimic the autocrine/paracrine function of dopamine. The quantitative contribution of each dopamine receptor subtype on renal sodium transport remains to be determined. However, the D_1R is responsible for ≈80% of D_1-like receptor activity in renal proximal tubule cells[468]; D_5R may be more important in the distal nephron,[360] while the D_3R may regulate glomerular dynamics.[422] Each of the dopamine receptor subtypes, alone or via interaction with the other dopamine receptor subtypes or other GPCRs, regulates sodium transport in a unique fashion.[30] Indeed, disruption of any of the dopamine receptor genes results in hypertension, the pathogenesis of which is specific for each subtype.[22–27]

REGULATION OF ION AND WATER TRANSPORT

Ion Transport

Euvolemia and Moderate Volume Expansion

Dopamine and its receptors are important in the regulation of ion transport during euvolemia or moderate volume expansion, but have a minor role under marked volume expansion.[49,117] Inhibition of renal dopamine production by pharmacological inhibition of DOPA decarboxylase activity[469] or silencing of *Ddc* in mouse proximal tubule[470] impairs the ability to excrete a sodium load. In contrast, inhibition of the breakdown of renal tubular dopamine by inhibition of COMT but not MAO activity increases sodium excretion.[471] Deletion of *Comt* in mice, however, decreases the natriuretic response to an acute sodium load, apparently because in these mice, basal renal dopamine production is increased and is not futher increased by saline loading.[472] The increase in ion excretion caused by dopamine or D_1-like receptor agonists cannot be entirely ascribed to its ability to increase renal blood flow or glomerular filtration rate.[21,371,427,431,432,466,467,473] Reduction in renal blood flow to control values decreases but does not abolish the natriuretic effect of the D_1-like receptor agonist fenoldopam administered into the renal artery.[396] Rather, dopamine can directly inhibit renal tubular ion transport by inhibition of ion transporters, sodium channels, and sodium pump activity.[18–21,28–31] The short-term inhibition of ion transport by dopamine involves alteration in enzyme kinetics[89,474] and internalization of ion transporters/pump.[132,242,249,301,302,475–482] The long-term inhibition of sodium transport by dopamine may involve regulation of protein expression by decreasing gene transcription and translation, and increasing their degradation.[360]

The inhibitory effect of dopamine on ion transport is not simply a direct effect, but is modulated by its regulation of the release or secretion of other hormones/humoral substances. Hormones which directly inhibit ion transport interact with dopamine to increase (e.g., angiotensin III/AT_2R,[43] ANP/ANPA,[36,483–485] eicosanoids,[37,38,358,486] nitric oxide,[41,423,487,488] prolactin,[42,489] and urodilatin[36]) their inhibition of ion and water transport. In addition, dopamine negatively interacts with hormones that increase ion transport (e.g., angiotensin II,[45,46,490–494] insulin,[495,496] renin,[44] angiotensin II/AT_1R,[45,46] and aldosterone[37,47,48,461,463]) and water transport (e.g., vasopressin[51,365,497–499]). The natriuretic effect of D_1-like receptor stimulation persists even after renal denervation.[67]

The inhibitory effects of dopamine, via D_1-like receptors, on renal ion transport *in vivo* is well-established (*vide infra*). In contrast, the effect of D_2-like receptor agonists on ion transport *in vivo* has not been consistent; reports have found no effect,[395,418] a decrease[421,437,500] or an increase in sodium excretion.[24,419,501,502] The effect of blockade of D_2-like receptors may not become evident unless the nitric oxide mechanism is impaired.[423] The D_2R and D_2-like receptors have been reported to stimulate Na^+K^+-ATPase.[267,278,503,504] The D_2R/D_3R agonist, bromocriptine, transiently increases basolateral chloride transport in the isolated mTAL.[505] However, D_2-like receptor stimulation inhibits the stimulatory effect of angiotensin II on Na^+K^+-ATPase.[493]

Stimulation of D_3R also inhibits NHE3 activity.[506] The apparent discrepancies in these studies may be

related, in part, to the status of the extracellular fluid volume.[24,419] For example, a two-day administration of quinpirole, a D_2R/D_3R agonist, increased while a D_2R antagonist decreased sodium excretion in $D_2^{+/+}$ mice fed high but not normal sodium diet.[24] Because D_1-like receptor effect is increased with moderate sodium loading,[18–22,29–31,49,466,507] this would indicate the need of D_1-like receptors for D_2-like receptors to inhibit Na^+ transport.[268,473,508,509] A selective D_3R agonist, 7-OH-DPAT, increases sodium excretion in rats on a normal and high salt diet.[501] The natriuresis in rats with streptozotocin-induced diabetes is decreased by D_3R antagonist.[502] However, the natriuretic effect of another D_3R agonist, pramipexole, is blocked by a D_1-like receptor antagonist.[266] The natriuretic effect of dopamine has also been shown to depend on the activation of both D_1-like and D_2-like receptors.[508] Therefore, the inhibitory effect of D_2-like receptors on sodium transport may not be observed, unless the animals are salt-loaded, a state that enhances the natriuretic effect of D_1-like receptors.

In hypovolemic or euvolemic states where vasopressin levels are elevated, the ability of D_2-like receptor agonists, probably acting via the D_4R, to inhibit the effects of vasopressin[498,510] may obscure any stimulatory effect of D_2-like receptors, probably via the D_2R, on water and ion transport in more proximal parts of the nephron. However, preliminary studies suggest that D_4R stimulation inhibits NCC activity in mouse renal distal convoluted tubule cells.[511]

Dopamine inhibits ion and water transport in the proximal and distal nephron,[427,512–514] as estimated from lithium clearance studies. It must be noted that the renal tubular site of action of endogenous dopamine and its agonists on ion transport may not always match that given exogenously. Most of the renal dopamine is produced in the proximal tubule, and so its effects in the distal nephron could be limited while exogenously administered dopamine would reach all nephron segments equally.

Luminal Membrane

Proximal Tubule

As stated earlier, all the dopamine receptor subtypes are expressed in the proximal tubule. The stimulation of D_1-like receptors decreases the activity of several ion transporters, including the sodium hydrogen exchanger 3 (NHE3, SLC9A3),[22,127–133,515] sodium phosphate co-transporter (NaPi-IIa/SLC34A1 and NaPi-IIc/SLC34A3)[242,476,482,516–519] and Cl^-/HCO_3^- exchanger (SLC26A6)[520] at the luminal membrane. G-protein-dependent, cAMP/PKA-, PKC-, NHERF-1-, and phosphatase-dependent and -independent mechanisms are involved in the dopamine or D_1-like receptor inhibition of NHE3, $Na^+/Pi2$, Na^+/HCO_3, and Cl^-/HCO_3^- exchanger activity, including their translocation out of the brush border membranes into the cytosol.[127,130–133,249,476–482,515,518] The signaling pathways by which D_1-like receptors inhibit NHE3 activity may be species-specific, involving PKA only in rat and human renal proximal tubule cells (Figure 19.2), but involving both PKA and PKC in renal opossum kidney cells.[521] Specific PDZ domains of Pals-associated tight junction protein (PDZ 2, 4 or 5) or NHERF-1 (PDZ 2) may be important in organizing the signaling pathways by which dopamine inhibits sodium transporter/pump activity.[249,477–480,518,522] In contrast, NHERF3/4 regulates the internalization of NaPiIIa.[482]

The D_3R[506] and D_4R may also regulate NHE3 (Table 19.2) because its expression is increased in $D_3^{-/-}$ and $D_4^{-/-}$ mice on normal salt intake.[523] However, the inhibitory effect of the D_3R on NHE3 activity in renal proximal tubules is not linked to $G\alpha s$ because pretreatment of the cells with cholera toxin did not prevent the D_3R effect. Rather, the D_3R-mediated inhibition of NHE3 activity in renal proximal tubules is related to $G\alpha_{i3}$, stimulation of PKC, and modulation of intracellular calcium.[259] The effect of the D_3R, in the rat, is probably independent of changes in intracellular cAMP because renal proximal tubules do not express adenylyl cyclase V.[220] In mesenteric arteries, D_3R causes vasodilation that is mediated by inhibition of Ca^{2+} channels and modulation of K^+ channels,[264] in agreement with the suggestion that the linkage of the D_3R to other effectors, such as inhibition of K^+ and Ca^{2+} may be more sensitive than the weak linkage to G-proteins.[258]

Loop of Henle

The mTAL expresses the D_1R, D_3R (in the mouse but not in the rat), D_4R, and D_5R. D_1-like and D_2-like receptor agonists administered to the apical membrane of the rat mTAL do not affect chloride transport. However, their application to the basolateral membrane decreases chloride transport via D_1-like receptors[505] that is unrelated to PKA or PKC, but rather to PLA2-mediated formation of 20-HETE.[524] Incubation of mTAL suspensions with dopamine increases sodium potassium 2 chloride co-transporter (NKCC2, SLC12A1) activity.[442] Indeed, NKCC2 activity is stimulated by PKA and PKC, but inhibited by 20-HETE.[525] The PKA-mediated stimulation of Na^+/K^+-ATPase activity is observed only under oxygenated conditions, but is overridden by PLA2 inhibitory pathways under hypoxic conditions.[526] Therefore, overall ion transport is inhibited, probably because of inhibition of basolateral chloride[505] transport and Na^+/K^+-ATPase activity.[442,527] The D_1-like receptor-mediated stimulation of

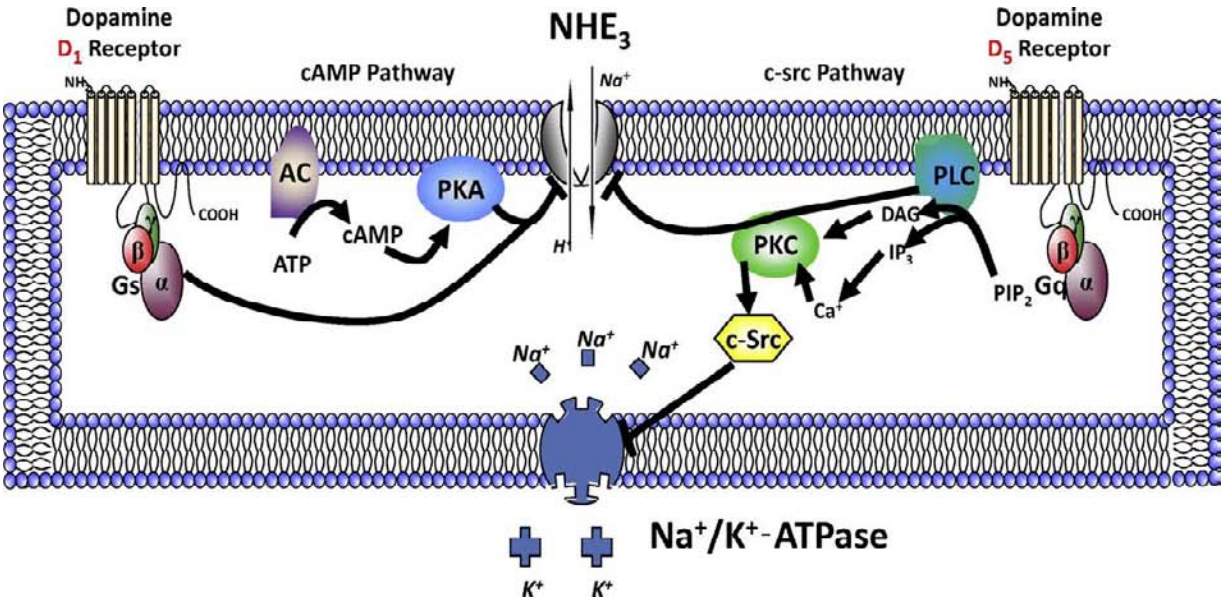

FIGURE 19.2 **Schematic model of the intracellular 2nd messenger pathways known for the dopamine-1 and dopamine-5 receptors (D_1R, D_5R) in the human renal proximal tubule cell.** The D_1R is coupled through Gas to stimulate adenylyl cyclase activity which converts ATP to cAMP. cAMP dependent protein kinase A (PKA) then inhibits the sodium hydrogen exchanger type 3 (NHE_3); GaS can also directly inhibit NHE_3. The D_5R interacts with Gaq to stimulate phospholipase C (PLC)[230] which converts phosphatidylinositol 4,5-bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3) (The co-activation of D_1R and D_2R can also increase PLC activity.[226]) DAG and IP_3, through its release of intracellular calcium (Ca^{2+}), stimulate protein kinase C (PKC). Na^+/K^+-ATPase is then inhibited via a c-Src-mediated pathway. The inhibitory effect of D_1-like receptors on Na^+/K^+-ATPase also involves PKA in the distal convoluted tubule and cortical collecting duct, while eicosanoids are involved in all nephron segments, including the mTAL[241,522,530,539,540–544]; PKC may also be involved in the inhibition of Na^+/K^+-ATPase in the mTAL.[527] *(The authors acknowledge Robby Van Sciver for producing this diagram.)*

NKCC2 may be important in K^+ recycling in the mTAL.[442] Bromocriptine (D_2R/D_3R agonist) increases chloride transport, albeit transiently,[505] reminiscent of the ability of this agonist to increase Na^+/K^+-ATPase activity in renal proximal tubules.[267] However, the D_4R and D_5R may negatively regulate NKCC2 expression because its expression is increased in $D_4^{-/-}$ (unpublished) and $D_5^{-/-}$ mice.[360] NKCC2 expression is not altered in $D_2^{-/-}$ and $D_3^{-/-}$ mice and has not been reported in $D_1^{-/-}$ mice (Table 19.2).

Distal Convoluted Tubule

The distal convoluted tubule expresses all the dopamine receptor subtypes, but their effect on ion transport in this nephron segment has not been reported, except for D_4R which inhibits NCC.[511] However, the D_2R, D_3R, D_4R, and D_5R may regulate NCC because its expression is increased in $D_2^{-/-}$, $D_3^{-/-}$, $D_4^{-/-}$ and $D_5^{-/-}$ mice[360,528] (unpublished data). NCC expression has not been reported in $D_1^{-/-}$ mice (Table 19.2).

Cortical Collecting Duct

D_1-like receptor stimulation of the rabbit cortical collecting duct depolarizes the luminal membrane and increases cAMP production.[363,530] D_5R may regulate ENaC because α- and γ-subunit expressions are increased in $D_5^{-/-}$ mice[360]; sodium transporters in $D_1^{-/-}$ mice have not yet been quantified. Dopamine, via D_4R, at the basolateral membrane decreases sodium transport in the rabbit cortical collecting duct.[529] The D_4R may also inhibit the increase in sodium transport mediated by vasopressin, via a decrease in cAMP.[365,498] αENaC is increased in $D_4^{-/-}$ mice but only following a high salt diet (unpublished observations). ENaC expression is not altered in $D_2^{-/-}$ and $D_3^{-/-}$ mice. ENaC expression has not been reported in $D_1^{-/-}$ mice (Table 19.2).

Medullary Collecting Duct

The D_1R is expressed in the collecting duct or in the outer but probably not in the inner medulla, while the D_5R is also expressed in the outer but not in the inner medullary collecting duct in the mouse kidney.[360,528] Indeed, dopamine does not stimulate cAMP production in the rat inner medullary collecting duct.[369] D_2-like receptors are expressed in the medullary collecting duct; the D_2R is expressed in the intercalated cells,[357] while D_3R and D_4R are not differentially expressed between intercalated and principal cells.[357,528] A D_2-like

receptor has been shown to stimulate PGE2 production in rat inner medullary collecting duct cells.[358,359] The specific D_2-like receptor involved is not known, but only the D_4R is expressed in the inner medullary collecting duct; the expression of the D_2R has not been consistently shown (Table 19.2).[528] It is not clear if dopamine regulates ion transport in the medullary collecting duct. Indeed, the inhibitory effect of dopamine on vasopressin-induced water permeability and cAMP accumulation in the rat inner medullary collecting duct is mediated by the α_2 adrenergic receptor.[368]

Basolateral Membrane

D_1-like receptors inhibit the electrogenic Na^+/HCO_3^- co-transporter (NBCe1A, SLC4A4) expressed in the basolateral membrane of the proximal tubule[481] and Na^+/K^+-ATPase expressed at the basolateral membrane in all nephron segments studied (proximal tubule, thick ascending limb of Henle, cortical collecting duct).[17,38,89,268,293,301,304,318,319,477–480,495,522,526–543] Although stimulation of D_2-like receptors may increase Na^+/K^+-ATPase activity,[267,373,503] the inhibitory effect of dopamine on Na^+/K^+-ATPase activity may require simultaneous stimulation of D_1-like and D_2-like receptors,[268] and could result in a potentially greater inhibition of the sodium pump caused by D_1-like receptors. For example, in the rat proximal tubule (but not in the mTAL or cortical collecting duct) D_2-like receptors act in conjunction with D_1-like receptors to inhibit Na^+/K^+-ATPase activity and decrease sodium transport, similar to that proposed for NaPiII[545] and NHE3.[546] Under normal circumstances, dopamine receptors probably do not regulate the expression of the α-subunit of Na^+/K^+ATPase, because its expression is not altered in $D_2^{-/-}$, $D_3^{-/-}$, $D_4^{-/-}$, and $D_5^{-/-}$ mice on a normal salt intake[360,523,528] although this has not been studied in $D_1^{-/-}$ mice.

The inhibitory effect of D_1-like receptors on Na^+/K^+-ATPase is mediated by cAMP/PKA, certain PKC isoforms, and 20-HETE. The overall consequence of D_1-like receptor stimulation is internalization of $Na^+/$

TABLE 19.2 Characteristics of Mice With Knockout of Dopamine Receptor Subtype Gene (Normal Sodium Intake Unless Indicated)

Variable	$D_1^{-/-}$	$D_2^{-/-}$	$D_3^{-/-}$	$D_4^{-/-}$	$D_5^{-/-}$
Blood Pressure	High[22]	High[23,47]	High[25], Normal[560*]	High[26]	High[27,232,234]
Salt Sensitivity (chronic NaCl load)	Yes#	BP increased only with sodium load[24]	Yes#, No[560*]	Yes#	Yes[234,360]
Increased Na^+ transporter/exchanger, channel	ND	NHE3, NCC#	NHE3, NCC#	NHE3, NKCC2, NCC#	NKCC2, NCC, α & β ENaC subunits[360]
Na^+K^+ATPase, a subunit	ND	Low activity[23] and protein#	Normal#	High#	Normal[360]
GPCR (kidney)	ND	Normal AT_1R#, normal response to ARB, increased ETBR[23]	High AT_1R[342],	High AT_1R[26]	High AT_1R[a,46, 360]
Renin-Angiotensin	ND	ND	High[25]	Normal[26]	Normal[360]
Aldosterone	ND	High[47]	Normal#	Normal#	Normal[360]
Reactive Oxygen Species	ND	High[47]	Normal#	Normal#	High[a, 234]
Inflammation	ND	High#	Normal	Normal#	ND
Body Weight	Low [22,561]	Normal[23,24,47], Low[b]	Normal[25,560], Fat load increases body weight in males; increased body fat in males and females[c]	Normal[26]	Normal[360]

ND = not determined, # unpublished, *chronic administration of D_3R antagonist causes salt-dependent hypertension in rats.[501] Please read text for important details.

K^+-ATPase subunits.[301,477–480,533–536,540] The inhibitory effect of D_1-like receptors on Na^+/K^+-ATPase involves PKC in the proximal convoluted tubule (Figure 19.2) and PKA in the distal convoluted tubule and cortical collecting duct, while the eicosanoids are involved in all nephron segments, including the mTAL,[241,522,530,539,540,544] PKC may also be involved in the inhibition of Na^+/K^+-ATPase in the mTAL.[527] 20-HETE is important in the ability of dopamine to inhibit Na^+/K^+-ATPase activity in rat renal cortex, because it overrides the stimulatory effect of PKA.[38,544] In the renal medulla, but not in the renal cortex, PKA[544] and phosphatase inhibition also contribute to the inhibition of Na^+,K^+-ATPase activity that may be related to DARPP-32 inhibition of PP-1,[293,317,543] in the case of dopamine.

The effect of dopamine on Na^+/K^+-ATPase is tissue-specific. As stated above, dopamine inhibits Na^+/K^+-ATPase activity in renal cortical and medullary tubules.[17,38,89,268,293,301,304,318,319,477–480,495,522,526–543] However, the regulation of the phosphorylation of Na^+/K^+-ATPase at Ser-23 is different between the proximal convoluted tubule and thick ascending limb of Henle; PKC phosphorylates Na^+/K^+-ATPase at Ser-23 in the proximal tubule but not in the mTAL.[527] D_1-like receptors may actually stimulate Na^+/K^+-ATPase activity in human ciliary nonpigmented epithelial[547] and pulmonary alveolar cells.[548] $D_{2L}R$ also stimulates Na^+/K^+-ATPase in murine fibroblasts.[503] D_1R and D_2R, on the one hand, and Na^+/K^+-ATPase, on the other, can also negatively regulate each other in HEK293T cell by direct protein–protein interaction.[549] While the inhibition of Na^+/K^+-ATPase in the kidney by dopamine under conditions of sodium chloride excess is beneficial, inhibition of Na^+/K^+-ATPase activity in neuronal cells by high concentrations of dopamine can lead to cell death.[550] Inhibition of Na^+/K^+-ATPase activity in vascular smooth muscle cells would increase vascular resistance, as has been reported in the rat tail.[409] Low concentrations of dopamine, however, decrease systemic vascular resistance probably by mechanisms other than via regulation of sodium transporter or pump activity,[264,551,552] e.g., opening of potassium channels[274,553–555] (*vide supra*, "Dopamine and Renal Hemodynamics").

Water Transport

Dopamine may also regulate water transport.[497] Dopamine inhibits arginine vasopressin-mediated increase in water transport,[510] via the D_4R in the rat cortical collecting duct.[498] Dopamine has been reported also to inhibit vasopressin-stimulated increase in water permeability in inner medullary collecting duct cells.[368] Although it has been claimed to be exerted at a_2-adrenergic receptors, the effect could be[498] inhibited by clozapine, a D_4R antagonist. The dopamine-mediated reversal of vasopressin-mediated increase in water transport has been related to a decrease in expression, and increase in phosphorylation, of aquaporin 2 at the apical plasma membrane.[499] In addition, dopamine, via D_4R, increases the ubiquitin-mediated degradation of aquaporin 2 in lysosomes and decreases the aquaporin 2 transcription by decreasing vasopressin-induced increase in cAMP production.[497] D_1-like receptors probably do not play a role in the vasopressin-mediated transport, at least in the rat inner medullary collecting duct, because dopamine does not increase cAMP levels in this nephron segment.[369] Aquaporin 4-mediated increase in basolateral permeability is also impaired by dopamine, via a yet to be determined receptor subtype that is linked to PKC.[556] The D_2R can regulate aquaporin 4 in glial cells,[557] but is probably not the dopamine receptor involved in the medullary collecting duct because the D_2R is not expressed in principal cells of this nephron segment.[357] The diuresis associated with hypotonic saline loading has been related to the ability of D_1-like receptor antagonist to decrease vasopressin release.[51] However, dopamine is known to increase vasopressin secretion from the hypophysis.[558] This discrepancy could be taken to indicate that the dopamine-mediated release of vasopressin may be influenced by the state of volume expansion.

Hypovolemia

In contrast to the natriuretic effect of endogenous renal dopamine in euvolemic and in moderately volume-expanded states, in sodium-depleted states the D_1-like agonist, fenoldopam, does not affect sodium excretion,[427] while dopamine actually decreases sodium excretion.[56] A limited number of studies have assessed the dopamine receptor subtype that may increase renal sodium reabsorption in hypovolemic states. In conscious, chronically instrumented dogs on a sodium intake of 40 mmol/day, quinpirole (D_3R and D_4R agonist) decreased sodium excretion as a consequence of both a decrease in renal blood flow and an increase in tubular sodium reabsorption.[421] Dopamine has also been reported to stimulate NHE3 and Na^+/K^+-ATPase activity in rabbit renal proximal tubule cells[559] and NKCC2 in mTAL[442]; bromocriptine (D_2R/D_3R agonist) stimulates Na^+/K^+-ATPase activity in rat renal proximal tubule cells[267] and increases chloride transport in the mTAL.[505] Stimulation of the $D_{2S}R$ or $D_{2L}R$ heterologously expressed in murine LTK-cells increased Na^+/K^+-ATPase[503] and NHE1[430] activity. These may be the mechanisms by which dopamine increases sodium transport during hypovolemia.[56]

Dopamine Receptor Subtype Mutant Mice

The deletion of dopamine receptor subtype in mice has helped to determine the role of each dopamine receptor subtype in the regulation of renal function and blood pressure.[22–27,30,232,234,360,511,523,528,560] Each dopamine receptor subtype participates in the regulation of blood pressure by mechanisms specific for the subtype. As described above, some receptors influence epithelial transport. Others, as described below, regulate blood pressure by influencing the central and/or peripheral nervous system and regulating the secretion and receptors of several humoral agents (Table 19.2).

D_1R Mutant Mice

$D_1^{-/-}$ mice are growth retarded without obvious neurological defects, but exhibit a decrease in rearing behavior.[561] The low survival after weaning is caused by decreased feeding ability. $D_1^{-/-}$ mice and $D_1^{-/+}$ mice (C57BL/6 background) on a normal NaCl diet have higher systolic and diastolic blood pressures than D_1R wild-type ($D_1^{+/+}$) mice.[22] Homozygous $D_1^{-/-}$ mice do not increase renal tubular cAMP accumulation in response to dopamine stimulation, but the response to parathyroid hormone is intact. These data indicate D_1R specificity in the increased blood pressure in mice.[22] However, it is not clear why the other D_1-like receptor, D_5R, is unable to compensate for the lack of D_1R; D_5R expression is not altered in $D_1^{-/-}$ mice[193,229] and D_1R expression is not altered in $D_5^{-/-}$ mice.[27] The hypertension of $D_1^{-/-}$ mice is aggravated by an increase in salt intake (Table 19.2). The hypertension of $D_1^{-/-}$ mice is aggravated by an increase in salt intake (Table 19.2).

D_2R Mutant Mice

$D_2^{-/-}$ mice in C57BL/6J background have decreased motor activity but rotarod performance is not impaired.[192] D_1-like receptor binding may be decreased, while D_3R is transiently increased after birth in $D_2^{-/-}$ mice.[192] $D_2^{-/-}$ and $D_2^{-/+}$ mice (C57BL/6J) on a normal NaCl diet have higher systolic and diastolic blood pressures than D_2 wild-type ($D_2^{+/+}$) mice.[23] α-Adrenergic blockade decreases blood pressure to a greater extent in $D_2^{-/-}$ mice than in $D_2^{+/+}$ mice, but acute adrenalectomy decreases blood pressure to a similar level in $D_2^{-/-}$ and $D_2^{+/+}$ mice. ETB receptor expression is greater in $D_2^{-/-}$ mice than in $D_2^{+/+}$ mice, and ETB receptor blocker decreases blood pressure in $D_2^{-/-}$ mice but not $D_2^{+/+}$ mice. $D_2^{-/-}$ mice also have increased production of ROS; increasing antioxidant activity with hemin normalizes the increased blood pressure.[47] These data indicate that $D_2^{-/-}$ mice may have enhanced vascular reactivity caused by increased sympathetic and ETB receptor activities, and oxidative stress.[47] The $D_2^{-/-}$ mice also have increased production of aldosterone, and treatment with a mineralocorticoid receptor blocker normalizes blood pressure but not the increased oxidative stress in these mice,[47] indicating that the increased mineralocorticoid activity is distal to the increased oxidative stress. In an unspecified strain of $D_2^{-/-}$ mice, blood pressure is increased only when the mice are fed a high-salt diet; this is associated with a decrease in renal AADC activity and renal dopamine production. Sympathetic activity is not increased in these $D_2^{-/-}$ mice.[24] The differences between the two strains of $D_2^{-/-}$ mice could be related to differences in the genetic background,[153] similar to the differences in behavior of $D_2^{-/-}$ mice from different genetic backgrounds.[192,193]

D_3R Mutant Mice

The locomotor phenotype of $D_3^{-/-}$ mice does not resemble that of $D_2^{-/-}$ mice. $D_3^{-/-}$ mice may show a transient locomotor hyperactivity in a novel environment.[562] The D_3R may be involved in seeking behavior for natural reinforcers such as food in rodent models of obesity[563]; $D_3^{-/-}$ mice fed a high fat diet become obese.[564] $D_3^{-/-}$ and $D_3^{-/+}$ mice (C57BL/6J) on a normal NaCl diet have both higher systolic and diastolic blood pressure than their wild-type ($D_3^{+/+}$) littermates.[25] These $D_3^{-/-}$ and $D_3^{-/+}$ mice have increased renal renin production, but sustained decrease in blood pressure with AT_1R blockade is observed in the $D_3^{-/-}$ but not $D_3^{-/+}$ or $D_3^{+/+}$ mice.[25] An unspecified strain of $D_3^{-/-}$ mice has normal blood pressure regardless of salt intake.[560] Nevertheless, these two strains (C57BL/6 and an unspecified strain) of $D_3^{-/-}$ mice have decreased sodium excretion after an acute or chronic sodium chloride load. Differences in phenotypes can occur depending on the genetic background, and even the same mouse strain from different commercial sources. For example, the blood pressure of C57BL/6 from Jackson Laboratories is salt-sensitive while the blood pressure of C57BL/6 mice from Taconic is salt-resistant.[153] The salt-sensitive hypertensive phenotype of human G-protein-coupled receptor kinase type 4 (GRK4) 486V transgenic mice is dependent on the percentage of genetic background from salt-resistant SJL mice.[565]

D_4R Mutant Mice

D_4R deficient ($D_4^{-/-}$) mice have impaired photoreceptor response, reduced response to novelty, but attenuated locomotor response to amphetamine, but not to methylphenidate or cocaine.[192] Congenic $D_4^{-/-}$[26] but not $D_4^{-/+}$ (Table 19.2) mice have increased systolic and diastolic blood pressures. The blood pressure is increased further with increased sodium intake in

$D_4^{-/-}$ mice (Table 19.2) but the effect of sodium intake on blood pressure in $D_4^{-/+}$ has not been tested. $D_4^{-/-}$ mice do not have altered circulating or renal renin or aldosterone levels.[26] Renal and brain, but not cardiac, AT_1R expression is increased in $D_4^{-/-}$ mice. The hypotensive effect of a bolus intravenous injection of the angiotensin type 1 receptor blocker, losartan, persists longer in $D_4^{-/-}$ than in $D_4^{+/+}$ mice. Thus, the hypertension brought about by the absence of the D_4R is mediated, in part, by increased AT_1R expression , similar seen in $D_3^{-/-}$ and $D_5^{-/-}$ (*vide infra*).[26]

D_5R Mutant Mice

$D_5^{-/-}$ mice have no impairment in learning and memory.[27,192] $D_5^{-/-}$ mice have normal expression of the other dopamine receptors, including the D_1R, a feature found in the other dopamine receptor subtype knockout mice except for the $D_2^{-/-}$ mice.[192] $D_5^{-/-}$[27] and $D_5^{-/+}$ mice are hypertensive. As with the $D_4^{-/-}$ mice (Table 19.2), the blood pressure is increased further with increased sodium intake in $D_5^{-/-}$ mice.[360] Epinephrine/norepinephrine ratio and the hypotensive response to the acute administration of an α-adrenergic blocker are greater in $D_5^{-/-}$ mice than their $D_5^{+/+}$ littermates, indicating that increased sympathetic activity plays a role in the elevated blood pressure observed with deletion of the *Drd5* gene.[27] Central nervous system pathways involving glutaminergic, oxytocin, vasopressin, and adrenergic receptors are important in the pathogenesis of hypertension in $D_5^{-/-}$ mice.[27] Besides these central nervous system mechanisms, renal AT_1R[46,567] and increased production of ROS are also involved[232,234] in the hypertension of $D_5^{-/-}$ mice.

DOPAMINE RECEPTOR INTERACTIONS

Interaction among the Dopamine Receptors and with Other GPCRs in the Regulation of Renal Function and Blood Pressure

Dopamine Receptor Subtype Interaction

D_1-like and D_2-like receptors[266,473,508,509] interact to enhance the natriuretic effect of dopamine in sodium-replete states. In sodium-replete states, the synergistic interaction between D_1-like and D_2-like receptors to increase sodium excretion occurs by inhibiting NHE3[546] and Na^+/K^+-ATPase[38,268,362] activity, as stated above.

D_1R and D_3R

D_1R and D_3R synergistically interact to decrease sodium transport in renal proximal tubule cells[265,266,426] and to relax vascular smooth muscle cells.[264,283] D_1R and D_3R reciprocally regulate each other's function and trafficking in HEK293 cells heterologously expresses tagged D_1R and D_3R, but not D_5R.[262] This has to be reconciled to the fact that $G\alpha_S$, which by itself decreases NHE3 activity independently of PKA,[130] is linked to both D_1R[30,183–193,687] and D_3R.[253] Gαq/11, involved in the D_1-like receptor inhibition of Na^+/K^+-ATPase,[410] can also be linked to D_3R.[568] The natriuretic action of the D_3R agonist pramipexole is partially blocked by a D_1-like receptor antagonist.[266] The D_3R co-localizes with D_1R in renal proximal tubule cells of WKY rats and in these cells, stimulation of D_3R increases both the co-immunoprecipitation of D_1R with D_3R, and the protein expression of D_1R.[265] The individual inhibitory effect of either D_1-like receptors or the D_3R on transporters is not 100%, not always on the same transporter or in the same nephron segment, and thus, additive or even synergistic effects are possible with co-stimulation. In mouse brain, the ALG-2 interacting protein 1 may be important in the interaction between D_1R and D_3R.[569] Whether or not this protein is also important in D_1R and D_2R interaction in the kidney remains to be determined.

The D_3R promotes natriuresis, in the short-term, alone[388,501,502] and by interacting with the D_1R.[266] In the long-term, the D_3R increases the expression of D_1R.[426] The interaction between D_1R and D_3R receptors is absent or impaired in hypertension, and results in defective inhibition of sodium transport and relaxation of vascular smooth muscles and ultimately in the development or maintenance of high blood pressure.[264,265,283,426]

D_2R and D_3R

In HEK293 cells, activation of heterologous D_2R inhibits both adenylyl cyclases V and VI, while activation of D_3R inhibits only adenylyl cyclase V and does not affect the activity of adenylyl cyclase VI.[258] However, when D_2R and D_3R are co-expressed in a monkey kidney cell line, lower concentrations of a D_2-like receptor agonist are needed to induce inhibition of adenylyl cyclase VI than those needed in cells expressing only the D_2R.[263] This suggests that the D_2R/D_3R heterodimer may enable the G-protein coupling of the D_3R to adenylyl cyclase VI. The D_3R, however, cannot inhibit adenylyl cyclase V in the rat renal proximal tubule, because this isoform is not expressed in this rat nephron segment.[220]

D_1R, D_5R, and D_2R

D_1R and D_2R heterodimerize in expression systems[570] and neural tissues,[571] and the degree of receptor protein–protein interaction is significantly enhanced by concomitant addition of D_1R and D_2R receptor subtype-specific agonists.[570] The physical

interaction between D_1R and D_2R is increased by the chaperone, calnexin.[338] The co-activation of D_1R and D_2R increases phospholipase C products[571] and eicosanoids[572] which inhibit sodium transport. In the brain striatum, the D_1R and D_2R complex activates calcium−calmodulin-dependent protein kinase 2α.[573] The D_1R can inhibit the cellular sequestration of D_2R and could explain the synergy between these two dopamine receptor subtypes.[256] The D_2R also hetero-oligomerizes with D_5R, which causes a decrease in D_5R-mediated increase in intracellular calcium levels.[227] However, there is no evidence of a D_1R and D_2R or D_5R and D_2R heterodimerization in renal tubule cells. It remains to be determined whether or not D_1R and D_5R interact to regulate renal ion.

D_4R and Other Dopamine Receptor Subtypes

A direct interaction between D_4R and the other dopamine receptor subtypes has not been reported. However, the dopaminergic regulation of glutamate N-methyl-D-aspartate receptor activity in the amygdala may be due to a functional interaction between D_1R and D_4R.[574] Gene−gene interaction between D_2R and D_4R is associated with the development of conduct disorder and adult antisocial behavior in males.[575]

Dopamine Interaction with Other GPCRs

The dopamine receptor subtypes interact with several GPCRs, e.g., D_1R and μ opioid receptor,[576] and N-methyl-D-aspartic acid glutamate receptor.[577−579] Only those receptors that have been shown to be involved or have the potential to be involved in the regulation of renal function are included in this review.

Adenosine Receptors

Stimulation of renal adenosine receptors lowers glomerular filtration rate by constricting afferent arterioles, and exerts differential effects on NaCl transport along the nephron, depending upon the adenosine receptor subtype; the adenosine type 2 receptor decreases (adenosine A_{2b} promotes chloride secretion), while the adenosine A_1 receptor increases sodium transport. Adenosine antagonizes some effects of dopamine. The dopamine-mediated inhibition of tubuloglomerular feedback is antagonized by adenosine via the regulation of adenylyl cyclase activity in the macula densa.[134] In opossum kidney cells, low concentrations of an adenosine analog, via the adenosine A_1 receptor, stimulate NHE3 activity and attenuate dopamine-mediated inhibition of NHE3.[580] Adenosine A_1 receptor modulates D_1R; co-administration of adenosine A_1R receptor and D_1R agonists in HEK293 cells stably expressing both receptors potentiate the D_1R-mediated desensitization of D_1R.[581] Interestingly, adenosine A_1 receptor and D_1R have been shown to physically interact in the central nervous system, with the formation of a heteromeric complex that leads to the uncoupling of the D_1R from its Gs-like protein complex.[445,581] However, in COS-7 cells and fibroblasts heterologously expressing adenosine A_1 receptor, D_1R, and D_5R, activation of adenosine A_1 receptor blocks the desensitization of D_1R but not D_5R,[582] another instance of cell-specific effects or related gene overexpression. In contrast, in HEK293 cells heterologously expressing adenosine A_1 receptor, D_1R, activation of adenosine A_1 receptor desensitizes the D_1R.[581] These studies illustrate the importance of studying receptor function in cells where such GPCRs are endogenously expressed.

The adenosine A_2 receptor isoform, A_{2A} receptor, heterodimerizes with D_2R in striatal membranes and reduces the high affinity state of D_2Rs, especially the high-affinity agonists.[583] The heterodimerization of adenosine A_{2A} receptor and D_3R or D_4R also results in an impairment of D_3R and D_4R function.[584]

Adrenergic Receptors

β-Adrenergic receptor agonists interact with dopamine in the regulation of Na^+/K^+-ATPase activity in the rat kidney. Activation of β-receptors with isoproterenol increases D_1R translocation from the cytosol to the membranes and D_1R-mediated inhibition of Na^+/K^+-ATPase activity in renal proximal tubule cells.[585] However, as stated above, stimulation of β_2Rs reduces the uptake of L-DOPA and the production of dopamine.[586] Thus, endogenous renal β-adrenergic receptors may not always enhance the dopaminergic inhibition of sodium transport.

Dopamine receptors may counter-regulate the actions of α-adrenergic receptors on renal sodium transport (unpublished data) and vascular proliferation. Stimulation of α_1Rs increases proliferation of vascular smooth muscle cells. However, in the presence of D_1-like or D_3R agonists, the proliferative effect of norepinephrine, via α_1Rs, is inhibited, although D_1-like or D_3R agonists have no effect by themselves. Moreover, co-stimulation of D_1-like or D_3R has an additive inhibitory effect on norepinephrine-mediated vascular smooth muscle cell contraction and proliferation.[264] The failure of dopamine to induce natriuresis in sodium-depleted states may be a consequence of increased sympathomimetic activity.[56]

Angiotensin II and Angiotensin Receptors

AT_1R and Dopamine Receptors

There are several areas of interaction between the dopamine and the renin−angiotensin system (RAS).

The D_3R, D_4, and D_5R D_4R and D_5R or D_2R (Table 19.2), but not D_1R, decrease AT_1R expression in the kidney.[26,46,276] In contrast, the D_2R may negatively regulate the expression of AT_1R,[587] and angiotensin II may increase D_2R expression in neural cells.[588]

Angiotensin II inhibits the uptake of dopamine by rat renal tubule cells[589] and the intravenous infusion of angiotensin II in humans reduces urinary dopamine.[590] Angiotensin II, via AT_1R, causes renal vasoconstriction while at low concentrations of dopamine, D_1-like receptors cause vasodilation.[405,591] Activation of the RAS may cause the development of tolerance to the hypotensive action of D_1-like receptor agonists.[592] In the rat, dopamine attenuates the glomerular mesangial contractile response to angiotensin II independently of eicosanoids.[389] D_1-like receptor agonists block angiotensin II-induced afferent and efferent arteriolar constriction.[399,591] Blockade of AT_1R normalizes the impaired renal vasodilator effect of D_1-like receptor stimulation in the SHR.[492] The increased vasodilatory effect of a D_3R/D_4R agonist (quinpirole) after renal denervation may also depend on decreased activity of the RAS).[593]

Activation of the RAS has been suggested to cause attenuation of the natriuretic effect of the D_1-like receptor agonist, fenoldopam, in sodium-deplete states.[427] When angiotensin II generation is inhibited or AT_1Rs are blocked, the natriuretic effect of dopaminergic drugs is enhanced.[490,491,492] In humans, this effect is seen mainly in subjects on a low salt diet (Natarajan et al., unpublished studies). D_1- and D_2-like receptor agonists also antagonize the stimulatory effect of angiotensin II, acting on AT_1R, on renal proximal tubule sodium transport.[45,397,493,494,589] These counterbalancing effects of dopamine and angiotensin II on sodium transport occur by the regulation of sodium transporter/channel/pump activity in the short-term, and the regulation of receptor expression in the long-term.[477,534,528] The short-term counteracting actions may occur by differential cell membrane trafficking. Thus, angiotensin II, via the AT_1R, in renal proximal tubule cells, induces recruitment of Na^+/K^+-ATPase to the plasma membrane. At an intracellular concentration of sodium of 9 mM, angiotensin II increases Na^+/K^+-ATPase activity[534]; dopamine is without effect. Increasing intracellular sodium to 19 mM is associated with an increasing inhibition of Na^+/K^+-ATPase activity by dopamine and blunting of the stimulatory effect of angiotensin II. This is associated with the recruitment of D_1R to the plasma membrane and a reduction in plasma membrane AT_1R.[534]

The mechanism by which dopamine receptors interact with the angiotensin receptors is receptor subtype-specific. The D_1R[45,343] and the D_3R[342] inhibit angiotensin II effects via physical interaction (heterodimerization) with the AT_1R. In contrast, the D_5R and AT_1R can also heterodimerize but negatively regulate each other's expression. In renal proximal tubule cells, the D_5R (not the D_1R) decreases AT_1R expression and AT_1R-mediated extracellular signal-regulated kinase phosphorylation. The D_1-like receptor-induced decrease in AT_1R expression is reversed by tyrosine-kinase inhibition and proteasome inhibitor, demonstrating that the D_5R-mediated decrease in total cell AT_1R expression is a result of a c-Src- and proteasome-dependent process.[45,46,276,567] Dopamine has also been reported to decrease AT_1R mRNA expression in renal proximal tubules.[594] The D_4R also negatively regulates AT_1R expression, but the mechanism remains to be determined.[26]

AT_2R and Dopamine Receptors

In the rat striatum, AT_2R stimulation decreases dopamine synthesis.[595] However, stimulation of D_1-like receptors induces an AT_2R-dependent natriuresis.[596] Selective intrarenal activation of D_1-like receptors induces sustained natriuresis and diuresis in sodium-loaded Sprague-Dawley rats that is abolished by intrarenal AT_2R inhibition. D_1-like receptor-mediated natriuresis is accompanied by recruitment of both D_1Rs and AT_2Rs to the plasma membrane of renal proximal tubular cells. These observations suggest that D_1-like receptor-induced natriuresis and diuresis are modulated by functional AT_2Rs that are translocated from intracellular compartments to the plasma membrane of renal proximal tubule cells in response to D_1-like receptor activation, and that dopamine-induced natriuresis requires AT_2R activation.[596] Therefore, in the normotensive state, dopaminergic stimulation favors natriuresis not only via specific dopamine receptor subtype mechanisms, but also by enhancing AT_2R function[596]; D_1R increases AT_2R expression. In addition, dopamine impairs AT_1R function by decreasing AT_1R expression via D_3R,[342] D_4R,[27] and D_5R,[46,276,567] and a negative interaction of AT_1R with D_1R,[45,343] D_3R, and D_5R.[46,276,567]

Atrial Natriuretic Peptide (ANP)

The inhibition of dopamine synthesis or uptake impairs the ability of ANP to inhibit renal tubular Na^+K^+-ATPase activity.[597] The inhibitory effect of ANP on NHE3 activity becomes manifest in the presence of dopamine.[598] However, the ability of carbidopa to affect sodium excretion or the natriuretic effect of ANP in humans has not been consistent.[599–603] This could be related to the state of hydration.[599–603] The renal dopaminergic system is not responsible for the natriuresis caused by marked volume expansion,[49,117] and dopamine does not affect sodium excretion in subjects fed a low salt diet[427] and may actually decrease sodium excretion during hypovolemia.[56] The natriuretic effects of dopamine

and ANP are additive in humans.[604] Carbidopa or dopamine receptor blockade, especially by D_1-like receptor blocker, attenuates the natriuretic effect of ANP in rats[605–608] and the natriuretic effect of ANP is abolished in mice lacking *Ppp1r1b*, which is also involved in D_1R signaling.[224,225,288–293] The potentiation of the natriuretic effect of dopamine by ANP may be due to its ability to recruit D_1R to the plasma membrane.[609] The conflicting effects of carbidopa on the natriuretic effect of ANP may also be related to the fact that ANP can increase or decrease renal tubular dopamine synthesis.[597,610]

Cholecystokinin Receptors

There are two cholecystokinin receptors, namely, cholecystokinin type A receptor (CCKAR) and cholecystokinin type B receptor (CCKBR). Cholecystokinin modulates dopamine release in the nucleus accumbens through CCKAR. Cholecystokinin may also modulate D_2R expression in the nucleus accumbens; D_2R expression is higher in $CCKAR^{-/-}$ and lower in $CCKBR^{-/-}$ mice than in wild-type controls.[611] Also, activation of CCKBR reduces the affinity of the D_2R in the brain.[612,613] Cholecystokinin at low concentrations activates Na^+/K^+-ATPase activity via the CCKAR.[614] CCKBR is expressed in the kidney, and the postprandial increase in sodium excretion may be mediated by an increase in serum gastrin acting at CCKBR in the kidney to decrease Na^+/K^+-ATPase activity.[615]

Endothelin Receptors

There are two endothelin receptors, endothelin A receptor (ETAR) and endothelin B receptor (ETBR).[616] In the brain striatum, stimulation of the ETBR increases dopamine release, but dopamine does not increase endothelin-1 levels.[617] The ETB and dopamine receptors can interact to regulate renal function and blood pressure. Stimulation of the D_3R increases ETBR protein expression and D_3R/ETB receptor co-immunoprecipitation and co-localization in renal proximal tubules.[39,618] The interaction between D_3R and ETBR has physiological significance, because pretreatment with a D_3R agonist increases the ETBR-mediated inhibitory effect on Na^+/K^+-ATPase activity in renal proximal tubule cells from WKY rats.[39,618] Conversely, stimulation of ETBR increases D_3R expression and function in renal proximal tubule cells from WKY rats (unpublished data). The natriuretic effect of D_3R may be, in part, mediated by ETBR, because the natriuretic effect is attenuated in WKY rats when the renal ETBR is blocked.[39,618] In renal proximal tubule cells, the ability of D_3R to stimulate ETB expression is blocked by an L-type calcium channel blocker.[39]

The D_2R may also regulate ETB receptor expression. $D_2R^{-/-}$ mice have increased ETBR expression and an ETBR blocker normalized blood pressure in these mice, but did not affect blood pressure of D_2R wild-type littermates.[23] GPR37, a parkin-associated endothelin-like receptor, can associate with D_2R in HEK-293 cells.[619] In rat lactotrophs, D_2-like receptor stimulation antagonizes the ETAR-mediated activation of large-conductance K^+ channels.[620] The functional consequences of D_2R and ETBR interaction on renal ion transport remain to be determined.

Insulin and Insulin Receptors

Insulin and dopamine have opposite effects on Na^+/K^+-ATPase activity in renal proximal tubule cells, and may counter-regulate each other. Chronic exposure of renal proximal tubule cells to insulin causes a reduction in D_1R abundance and uncoupling from G-proteins, resulting in impairment of the inhibitory effect of dopamine on Na^+/K^+-ATPase.[621] This suggests a direct role of insulin in D_1R regulation.[495,622] Insulin causes renal D_1R desensitization via GRK2-mediated receptor phosphorylation (*vide infra*) involving PI3 kinase and PKC.[305] Hyperinsulinemic animals and patients with type 2 diabetes have a defective renal dopaminergic system.[623] In obese Zucker rats, a model of type 2 diabetes or in insulin-induced hypertension, renal D_1Rs are downregulated and dopamine fails to produce diuresis and natriuresis.[621] Treatment with an insulin sensitizer, rosiglitazone, decreases plasma insulin levels and restores D_1R function in obese Zucker rats.[622,624] Insulin has also been shown to increase the expression of the D_5R in renal proximal tubular cells from WKY rats, probably a compensatory response. In HEK293 cells heterologously expressing the D_5R, pretreatment with insulin increases the D_5R-mediated inhibition of Na^+/K^+-ATPase.[496] Both PKC and PI3 kinase are involved in the signaling pathway leading to increased D_5R expression.

Dopaminergic activity may influence insulin secretion, and *vice versa*. Insulin has been reported to increase renal proximal tubule uptake of L-DOPA, which should increase dopamine synthesis,[625] but this could be an attempt to compensate for the ability of insulin to decrease and uncouple D_1R.[621] The D_1-like receptor agonist fenoldopam improves peripheral insulin sensitivity and renal function in streptozotocin-induced type 2 diabetes in rats.[626] Normalizing blood sugar levels with insulin also normalizes renal D_1R expression and function in rats with sreptozotocin-induced diabetes.[627] D_2-like receptors in pancreatic β-cells inhibit[628] or stimulate glucose-stimulated insulin secretion, depending on dopamine concentration; an

inhibitory effect occurs at higher dopamine concentration (10^{-7}–10^{-4} M), while the effect is stimulatory at lower dopamine concentrations ($<10^{-8}$ M).[629] Bromocriptine (D_2R/D_3R agonist) decreases insulin levels and ameliorates several metabolic features in obese women.[630] The counter-regulatory actions of the insulin and dopamine receptors extend to their effects on vascular proliferation. Bromocriptine (D_2R/D_3R agonist) inhibits the insulin-like growth factor-mediated proliferation in rat vascular smooth muscle cells (A7r5) and human aortic smooth muscle cells.[631] Stimulation of D_1-like receptors or D_3R inhibits insulin receptor expression and insulin-mediated proliferative effects in vascular smooth muscle cells, showing an interaction between dopamine (D_1-like and D_3R) and insulin receptors.[40,632] A D_3R antagonist was found to be protective of renal injury in hypertensive type II diabetic SHR/Ncp rats.[633] In these rats, a D_3R antagonist ameliorated glomerulosclerosis and prevented mesangial cell proliferation. These apparent contradictory interactions between D_3R and insulin may be related to the biphasic effect of dopamine on insulin secretion.

Dopamine and Mineralocorticoid Receptor

Aldosterone increases catecholamine production in a pheochromocytoma cell line.[634] In the rabbit cortical collecting duct D_2-like, but not D_1-like, receptor stimulation at the basolateral surface depolarizes transepithelial voltage and decreases sodium transport.[529] It is possible that this effect is related to D_4-like negative interaction with the non-genomic effects of aldosterone.[48]

Dopamine and Prolactin

D_2R inhibits prolactin secretion by the pituitary gland.[189,193] However, prolactin is also expressed in the renal cortex and induces a natriuresis that requires an intact renal dopaminergic system. Prolactin recruits D_1Rs to the plasma membrane in renal proximal tubules which inhibits Na^+K^+-ATPase activity that involves activation of PKA, PKC, and PI-3 kinase.[42]

Dopamine and Prostaglandins

Earlier studies have suggested that the renal vasodilatory effect of dopamine is independent of prostaglandins because indomethacin, an inhibitor of prostaglandin synthase, did not affect the renal vasodilatory effect of dopamine or the D_1-like receptor agonist fenoldopam in the dog, rat[635] or humans.[636] The intrarenal arterial infusion of the D_1-like receptor agonist fenoldopam is also not associated with an increase in urinary prostaglandin E2 (PGE2) and $F_2\alpha$ in the dog.[396] Subsequent studies in normotensive humans revealed that the renal vasodilatory effect of dopamine was also not associated with an increase in urinary excretion of PGE2, but rather with 6-keto-PGF1α, a stable metabolite of prostacyclin. The effect of dopamine was blocked by metoclopramide or domperidone, D_2-like receptor antagonists, and two cyclooxygenase inhibitors.[407] These studies suggest that the dopamine and prostaglandin communication is via the D_2-like rather than D_1-like receptors. D_2-like but not D_1-like receptors may also regulate PGE2 synthesis in rat inner medullary collecting cells.[358] Dopamine stimulates medullary prostaglandin production, and may be involved in the attenuation of deoxycorticosterone acetate/high salt-induced increase in blood pressure.[37] Eicosanoids may act synergistically with D_1-like receptors to inhibit Na^+/K^+-ATPase activity in the proximal tubule, mTAL, and cortical collecting duct.[38,524,530,539,541] Moreover, the renal cortical expression of COX-2 is tonically suppressed by the renal D_1-like receptors secondary to inhibition of proximal tubular reabsorption.[44,637]

Regulation of Reactive Oxygen Species (ROS)

Dopamine regulates ROS production, stimulating production at high concentrations ($\geq 10\ \mu M$) but physiological concentrations of dopamine decrease ROS production via D_1-like receptors.[233,638,639] All the dopamine receptor subtypes are capable of decreasing ROS production. However, deletion of *Drd2* or *Drd5* but not *Drd3* or *Drd4* in mice is associated with increased ROS production. The D_1R inhibits NADPH oxidase activity via PKA and PKC cross-talk[239]; the D_5R inhibits NADPH oxidase directly and also indirectly, by inhibiting phospholipase D activity and independent of cAMP.[232,234] The D_5R may also positively regulate antioxidants such as heme oxygenase 1 (HO-1).[640] Plasma thiobarbituric acid-reactive substances (TBARS), an index of systemic oxidative stress, and PLD and NADPH oxidase subunit expression and activity are higher in $D_5R^{-/-}$ mice than in $D_5R^{+/+}$ mice[232,234] (Table 19.2). Chronic administration of apocynin, an NADPH inhibitor, normalizes blood pressure, plasma TBARs, and NADPH oxidase activity in the brain and kidney of $D_5R^{-/-}$ mice, suggesting that the D_5R keeps blood pressure in the normal range by preventing excessive ROS production.[234] The redox status of the $D_1R^{-/-}$ mice remains to be determined. ROS impair the function of renal D_1-like receptor. Rat renal proximal tubules treated with hydrogen peroxide, and those from streptozotocin-treated or old rats,

have increased oxidative stress and impaired D_1-like receptor function.[449,641–643] Oxidative stress causes the nuclear translocation of NFκB and subsequent activation of PKC and GRK2, which in turn increases D_1R phosphorylation, impairing its activity.[641,642]

The D_2R has also antioxidant activity. The neuroprotective effect of D_2R may be related to its ability to decrease ROS production by the mitochondria.[644] D_2R, similar to the D_1-like receptors, decreases oxidative stress by inhibition of NADPH oxidase and stimulation of HO-2,[47] $D_2^{-/-}$ mice are hypertensive and have increased urinary excretion of 8-isoprostane, a parameter of oxidative stress, as well as increased activity and expression of NADPH oxidase and decreased expression of the antioxidant enzyme HO-2 in the kidney. Apocynin (an NADPH inhibitor) or hemin (an inducer of HO) normalizes blood pressure in $D_2^{-/-}$ mice. Spironolactone normalizes the blood pressure in $D_2^{-/-}$ mice, but does not normalize the renal expression of NADPH oxidase, indicating that the increased ROS production is proximal to the increased aldosterone secretion in $D_2^{-/-}$ mice.[47]

The effect of D_3R receptors on ROS production is controversial. The D_3R has been reported to increase a dopamine autotrophic factor that has an antioxidant action, and thus the D_3R has antioxidant effect, albeit indirectly.[645] The selective D_3R agonist pramipexole inhibits lipid peroxidation,[646] increases the activity of antioxidant enzymes (glutathione peroxidase and catalase), and inhibits the production of ROS by the mitochondria, but this effect is not related to its dopamine agonist properties.[647] Moreover, the D_3R has been reported to stimulate PLD activity in HEK293 cells heterologously expressing the human D_3R.[235] The D_3R and D_4R may also have neuroprotective effects by inhibition of ROS production.[648,649]

Regulation of Inflammation

Lymphocytes can synthesize catecholamines, including dopamine.[650] All the dopamine receptor subtypes are expressed in normal human leukocytes, with the highest expression in B-lymphocytes and natural killer cells, followed by neutrophils and eosinophils, with least expression in T-lymphocytes and monocytes.[650–653] Dopamine, D_1- and D_2-like receptor subtype agonists can regulate the immune response and inhibit the inflammatory reaction,[654–657] the extent of their involvement is tissue-dependent. Dopamine inhibits the release of pro-inflammatory cytokines (e.g., interleukin-2 (IL-2), interferon (IFN)γ, IL-4,[657] but stimulates the production of the anti-inflammatory IL-10 in immune cells.[658] The D_1-like receptors and D_3R but not D_2R or D_4R can also stimulate TNFα secretion.[658] Indeed, the D_2R may actually decrease lipopolysaccharide-induced release of TNFα.[659] Dopamine or bromocriptine (D_2R/D_3R agonist), inhibits lymphocyte proliferation,[660] decreases the antigen-induced macrophage activation and the secretion of IL-2, IL-4 and IFNγ.[661]

Renal tubule cells produce pro-inflammatory cytokines and chemokines (e.g., IL-1, TNFα, IL-6, IL-8, IL-12, and macrophage chemoattractant protein (MCP)-1), as well as anti-inflammatory cytokines (e.g., IL-10).[662–664] Both pro-inflammatory and anti-inflammatory cytokines are secreted by tubular cells across their apical or basolateral membranes.[664] The pro-inflammatory cytokines contribute to the development and progression of glomerular and tubular injury.[662–664] Lipopolysaccharide causes dysfunction of renal D_1R and salt-sensitive hypertension,[665] but the D_2R may protect the kidney from the adverse effects of inflammation.[666] Silencing the D_2R in renal proximal tubule cells increases the expression of TNFα and MCP-1; expression of TNFα, MCP- 1, IL-6, and IL-10 are increased in the renal cortex of $D_2^{-/-}$ mice. These mice show renal injury and increased urinary albumin, suggesting that impaired D_2R function results in renal inflammation and injury.[666] The role of the other dopamine receptor subtypes in inflammation remains to be determined.

Dopamine and Essential Hypertension

About 50% of human essential hypertension is thought to be heritable, but the genetic causes of essential hypertension have been difficult to identify.[667] More than one gene is undoubtedly involved, because Mendelian dominant and recessive traits are not readily discernible in hypertensive subjects, except in those with monogenic forms of hypertension. Indeed, recent genome-wide association studies (GWAS) have been able to identify 2% of genetic factors believed to influence blood pressure.[668–674] However, the GWAS were not designed to identify predisposing genes engaged in a complex network of gene–gene and gene/environment interactions.[675] One example is salt sensitivity, a dietary sodium-induced increase in blood pressure that may or may not produce elevation in the hypertensive range. Several criteria have been suggested to link gene (s) to complex diseases such as hypertension and salt sensitivity, but the definitive evidence is swapping one phenotype for another (i.e., transgenic studies).[676] Many genes have been proposed to be causal of hypertension; however, their gene variants, including those identified in the GWAS, have not been shown to produce hypertension in mice. Many gene overexpression and deletion studies are performed in mice without

taking into account the salt sensitivity of the strain. C57BL/6 mice from Jackson Laboratories have an impaired ability to excrete a salt (NaCl) load with a resultant increase in blood pressure, while others are salt-resistant (e.g., SJL mice).[153]

GRK4 regulates renal D_1R[298] and D_3R.[286] Renal D_1-like receptor function is impaired in C57BL/6 Jackson mice, and is associated with increased expression of GRK4 upon salt loading.[153] Deletion of the *Grk4* gene in C57BL/6 mice prevents the development of salt-sensitive hypertension.[677] Renal cortical silencing of *Grk4* attenuates the increase in blood pressure with age in SHRs, but not in normotensive WKY rats.[306] Aging and obesity are associated with decreased D_1-like receptor dysfunction.[100,532,542] In obese rats, the D_1-like receptor dysfunction is acquired and has been related to increased GRK4 expression and membrane translocation of GRK2 due to insulin resistance.[624]

The GRK4 locus on human chromosome 4p16.3 is linked with hypertension.[678,679] Interestingly, adolescents with GRK4 65L, 142V, and A486 haplotype have a greater increase in blood pressure with age than those with the wild-type GRK4 haplotype.[680] GRK4 gene variants (65L, 142V, and 486V) are associated with essential hypertension in several ethnic groups: Caucasians, Chinese, Ghanaians, and Japanese.[681–686] In salt-sensitive hypertensive Japanese, the presence of three GRK4 variants impaired the natriuretic effect of a dopaminergic drug and predicted salt-sensitive hypertension correctly in 94% of cases.[683] In Ghanaians, the combination of angiotensin-converting enzyme insertion/deletion polymorphism and GRK4 65L has an estimated predictive accuracy for hypertension of 70%.[685,686] A meta-analysis revealed a significant association of GRK4 486V with hypertension with an odds ratio of 1.5 (95% CI: 1.2 to 1.9).[687] A re-analysis of a negative study in Han Chinese[688] found an association of GRK4 486V and other genes (GNB3A-350G) with essential hypertension.[682] One study, however, did not find an association of GRK4 486V with the top fifth percentile of diastolic blood pressure of subjects with white European ancestry; however, the authors did not test the association of GRK4 gene variants with hypertension.[689] Another study did not find an association between GRK4 142V and hypertension, but did find an association between variants of the promoter region of D_1R and hypertension.[690] The discordance of this report in European Caucasians[690] with other populations may be the influence of ethnicity in the phenotypic expression of a quantitative trait such as essential hypertension. Interestingly, low-renin hypertension is less frequent in Caucasians (15–20%)[708] than in other ethic groups (e.g., 40–60% in Japanese).[709] In the Japanese, the single best genetic model for low-renin hypertension included only GRK4 A142V, by itself, or GRK4 A142V and aldosterone synthase gene, CYP11B2, with an estimated predictive accuracy of 78%.[683] Ethnicity may also explain some of the discordances. GRK4 65L and GRK4 142V are less frequent, while GRK4 486V is more frequent in Asians than in African-Americans. GRK4 486V is also more frequent in Hispanic and non-Hispanic whites than in African-Americans.[710] The recent GWAS did not identify GRK4 as associated with hypertension.[669–673] This is probably because salt sensitivity was not taken into account and because previous studies have shown that it was critical to assess the role of GRK4 in conjunction with other single nucleotide polymorphisms and genes, e.g., ACE with GRK4 65L,[685,686] and *ADRB2* and *TH* with *GRK4 486V*.[682] While GRK4γ142V transgenic mice are hypertensive even on a normal salt diet,[298,691] GRK4γ486V transgenic mice develop hypertension only when stressed by a high salt diet.[692] Depending upon the genetic background of the mouse, overexpression of human GRK4γ wild-type converts a salt-sensitive phenotype to a salt-resistant phenotype, while overexpression of human GRK4γ486V converts a salt-resistant phenotype to a salt-sensitive phenotype.[692]

Polymorphisms in the non-coding region of the human D_1R gene are associated with decreased[690,693] and increased blood pressure.[694] However, D_1R and D_3R expression is not always decreased in hypertension.[29,30,141,298,343,426,695] Polymorphisms in the coding region of D_1R and D_3R genes[690,694,696] have also not been associated with essential hypertension. A D_2R variant may be associated with salt-sensitive human essential hypertension (unpublished studies). The D_4R long (at least one 7 to 10 repeat) has been reported to be associated with higher diastolic and systolic blood pressure.[697] There are inactivating mutations of D_5R,[698] but their association with hypertension has not been studied. D_1-like and D_2-like receptor functions are impaired in other rodent models of human essential hypertension, such as in the spontaneously hypertensive rat (SHR) and the Dahl salt-sensitive rat (DSS). As indicated earlier, deletion of any of the dopamine receptor genes causes hypertension,[22–27] and dopamine receptor dysfunction is found in several animal models of hypertension.[29,30]

Dopamine and Blood Pressure Regulation: Peripheral versus Central Nervous System

The effect of dopamine in the regulation of blood pressure differs in the kidney from that in the central nervous system. Overactivity of the dopaminergic system in the brain, e.g., the amygdala, is associated with

hypertension.[699] Hypertension induced in rats by decreasing blood flow to one kidney is also associated with increased levels of dopamine and dopamine metabolites in the brain striatum.[700] However, monkeys made hypertensive by constricting the aorta have decreased D_1-like receptor binding in the pre-frontal cortex,[701] and decreased post-synaptic dopaminergic and cholinergic functions in the ventrolateral striatum of SHR,[702] reinforcing the similarities and differences in the regulation of blood pressure between the dopaminergic system inside and outside the central nervous system.

Dopamine Pharmacogenetics and Hypertension

Current treatment of essential hypertension is empirical. It is not based on the molecular mechanisms of essential hypertension. Theoretically, drugs prescribed based on one's genetic make-up would be more effective, with fewer and lesser side-effects than empirical treatment. In African-American men with early hypertensive nephrosclerosis, GRK4 65L and 142V are associated with a poor response to β-adrenergic blockers, while GRK4 142V is associated with a good response to a β-adrenergic blocker.[703] In another study in two cohorts, GRK4 142V, but not GRK4 486V, was also associated with a blood pressure response to a β-adrenergic blocker.[704] There are at least two mechanisms by which β-adrenergic blockers may be beneficial in hypertensive subjects with GRK4 142V polymorphisms. The activity of GRK4, which decreases plasma membrane β-adrenergic receptor expression, can be blocked by β-adrenergic receptor antagonists.[705] As indicated above, normally the D_3R may be important in the negative regulation of renin secretion, at least in mice,[25] and because GRK4 142V can impair D_3R function, this may provide an explanation for the good response of subjects to β-adrenergic blockers. In an African hypertensive population, GRK4 142V is associated with a poor response to reduction in sodium intake,[706] in agreement with the report that human GRK4142V transgenic mice develop hypertension even on a normal salt intake.[298,691] In a Japanese population with essential hypertension ($n = 881$, unpublished data), carriers of the GRK4 142V allele had a larger drop in systolic blood pressure than non-carriers in response to angiotensin receptor blockade.[707] The addition of a diuretic to the non-responders ($n = 94$) decreased blood pressure which was associated with GRK4A486V,[707] in agreement with the reports that human GRK4γ 486V transgenic mice develop salt sensitivity that is dependent on genetic background.[692] Japanese with at least three GRK4 polymorphisms have salt-sensitive hypertension.[683]

CONCLUSION

Dopamine, one of the oldest hormones in phylogeny, serves not only as a precursor to norepinephrine and epinephrine, but also as a neurotransmitter. However, in non-neural cells, dopamine acts independently of the other catecholamines. Dopamine controls water and electrolyte balance and blood pressure by regulating the secretion/release of hormones and humoral agents that affect water and electrolyte balance, salt "appetite" centers in the brain, and ion and water transport in the kidney and gastrointestinal tract. Independent of innervation, the kidney and intestines synthesize dopamine from circulating or filtered L-DOPA (kidney only) that is not metabolized to norepinephrine or epinephrine. Sodium intake and intracellular sodium are probably the major determinants of the renal tubular synthesis/release of dopamine. In mammals, the actions of dopamine occur by occupation of two families of cell surface receptors, D_1-like receptors (D_1R and D_5R), and D_2-like receptors (D_2R, D_3R, and D_4R). The dopamine receptor subtypes interact among themselves, resulting in new signaling pathways. They also interact extensively with other GPCR, hormones, and humoral agents. D_1-like receptors are linked to vasodilation, while the effect of D_2-like receptors on the renal vasculature is probably dependent upon the state of renal nerve activity. The dopamine-induced increase in renal blood flow is not consistently associated with an increase in glomerular filtration rate. The autocrine/paracrine regulation of renal tubular sodium transport, mainly via D_1-like receptors, is mediated by tubular and not by hemodynamic mechanisms. The dopamine receptor subtypes are differentially expressed along the nephron and species-specific; all the five dopamine receptor subtypes are expressed in the proximal tubule, mTAL distal convoluted tubule, and cortical collecting duct, and only D_4R in the cortical TAL, D_1R, D_2R, D_4R, and D_5R in the outer medullary collecting duct, and only the D_2-like receptors, D_2R, D_3R, and D_4R in the inner medullary collecting duct. Dopamine inhibits ion transport in the proximal and distal nephron. D_1-like receptors inhibit NHE3, NaPi2 co-transporter, Cl^-/HCO_3^- exchanger, and ENaC at the apical membrane, and the electrogenic Na^+/HCO_3^- co-transporter and Na^+/K^+-ATPase at the basolateral membrane. Dopamine may also inhibit NCC but stimulates NKCC2, the latter effect for K^+ recycling. The inhibitory effects of dopamine and its receptors on ion transport are important under conditions of euvolemia and moderate volume expansion, but play a minor role under marked volume expansion. D_2-like receptors also participate in the inhibition of ion transport during conditions of

euvolemia and moderate volume expansion, but may increase ion transport in hypovolemic states. Dopamine also controls sodium transport and blood pressure by regulating the production of ROS and the inflammatory response. Aging, obesity, metabolic syndrome, and essential hypertension are associated with abnormalities in dopamine production, and receptor number, post-translational modification, and function.

CHAPTER

20

Structural Organization of the Mammalian Kidney

Wilhelm Kriz[1] *and Brigitte Kaissling*[2]

[1]Department of Anatomy and Developmental Biology, Medical Faculty Mannheim, University of Heidelberg, Mannheim, Germany

[2]Institute for Anatomy, University of Zürich, Switzerland

KIDNEY TYPES AND RENAL PELVIS

The mammalian kidney is multiform. The basic architecture is best understood in the unipapillary kidney, which is common in all small species. A coronal section of this kidney shows the main structural parts (Figure 20.1a). The renal cortex, as a whole, is cup-shaped with inverted margins, and surrounds the renal medulla. The medulla can be roughly compared to a pyramid; its top portion, the papilla, projects into the renal pelvis. The pelvis is located within the renal sinus, which opens through the renal hilum to the medial surface of the kidney.

The cortical parenchyma is divided into the cortical labyrinth and the medullary rays. The uppermost part of the cortex, a continuous layer that covers the tops of the medullary rays, is called the cortex corticis. The medulla is divided into an outer medulla (subdivided into outer and inner stripes) and an inner medulla. The innermost part of the inner medulla generally forms the papilla.

The unipapillary kidney is the most simple kidney type; in comparative anatomy, such a kidney as a whole corresponds to a renculus. All other kidney types may be regarded as adaptations to larger body sizes. The crest kidney and the kidney with tubi maximi are magnifications of a one-reniculus unit. The multipapillary kidney (Figure 20.2) and the reniculus kidney multiply this unit.[1,2,3] The human kidney is a multipapillary kidney; however, it is particular because a variable number of papillae are generally fused, forming compound papillae.[4]

The renal pelvis (Figures 20.1a and b) or the renal calyces (Figure 20.2) are anchored to the renal parenchyma by connective and smooth-muscle tissues that follow the intrarenal arteries. The cavity of the pelvis and calyx surrounds the renal papilla (or its equivalent in other kidney types). In many species the pelvic cavity forms different kinds of pelvic extensions (Figure 20.1b).[5,6] Leaf-like extensions called "specialized fornices" accompany the large vessels for some distance along their entry into the renal parenchyma. Secondary pouches protrude toward the hilus, communicating with the primary pelvic cavity only above the free semilunar borders of the pelvic septa. These extensions increase the contact area between the pelvic cavity and the renal medulla, especially the outer medulla.[7]

RENAL VASCULATURE

Close to the renal hilum and afterwards within the renal sinus the renal artery undergoes several divisions, finally establishing the interlobar arteries which then enter the renal tissue at the border between the cortex and medulla (Figures 20.1a and 20.2). From there they follow an arc-like course and are therefore called arcuate arteries. They give rise to the cortical radial arteries, which ascend radially within the cortical labyrinth. The cortex is very densely penetrated by arteries; in contrast, no arteries enter the medulla. The renal veins (cortical radial (interlobular) veins, arcuate veins) accompany the corresponding arteries. In some species (cat, dog, man) the venous blood from the outer

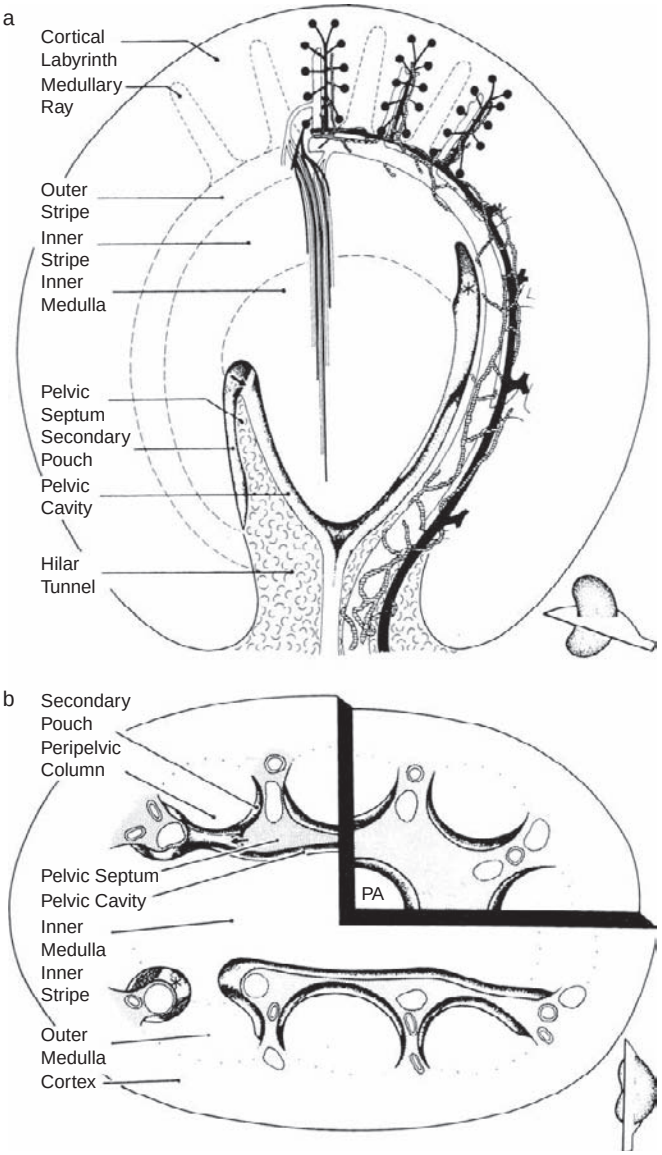

FIGURE 20.1 **Schematics of a coronal and two transverse (b) sections through the rabbit kidney.** The inset in the right lower corner indicates the section plane. The general architecture of the kidney and the renal pelvis is demonstrated. (a) Arterial vessels, including glomeruli and descending vasa recta, are shown in black, venous vessels are gray, and lymphatics are hatched. (b) The section plane of the main drawing runs through the middle part of the inner medulla; a deeper section through the papilla (PA) is shown in the upper right quarter. The cross-sectioned pelvic septa are stippled. The leaf-like extensions of the pelvic cavity are marked by a star, the free semilunar edges of the main pelvic septa by an arrow (in a and b). *(Adapted from Kaissling, B., and Kriz, W. (1979). Structured analysis of the rabbit kidney. Adv. Anat. Embryol. Cell Biol.* ***56****, 1–123, with permission.)*

cortex drains into veins on the renal surface (in man called "stellate veins") which are connected by additional cortical radial veins (interlobular veins) to arcuate veins. Such additional veins are not accompanied by arteries.[8]

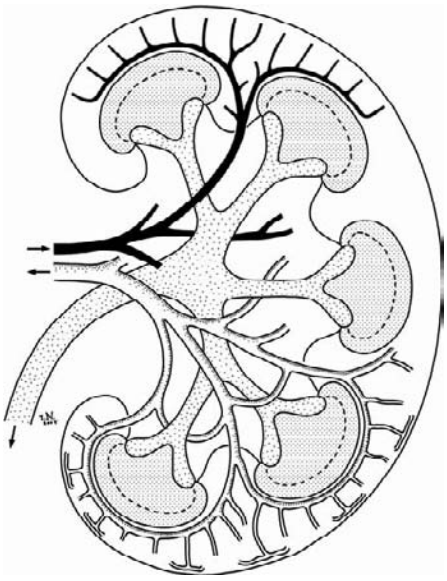

FIGURE 20.2 **Schematic illustration of a compound multipapillary kidney (coronal section) similar to the human kidney.** The renal cortex as a whole encloses several papillae; fused papillae typical for the human kidney are not shown. The central region, the renal sinus, contains the calyces and the pelvis (stippled), the pattern of branching arteries (black), and joining veins (white). The arcuate arteries, running at the cortico-medullary border, do not form true arches, but rather represent end-arteries. In contrast, the veins do form anastomoses at the level of the arcuate and interlobar veins. In the human kidney there are two types of cortical radial veins (interlobular veins); one group starting as stellate veins drains the most superficial cortex, the second group starts at deeper levels in the cortex; both drain into arcuate veins.

The microvasculature pattern of the kidney appears to be very similar among mamma*lian species; a basic pattern can be described (Figures 20.3 and 20.4a).[9–11] The afferent arterioles arise from the cortical radial arteries (a minor portion from the arcuate arteries) and supply the glomerular tufts of the renal corpuscles. The efferent arterioles drain the glomeruli. Several types of efferent arterioles have been described.[11,12] Basically, a distinction between superficial, midcortical, and juxtamedullary renal corpuscles is essential (Figures 20.3 and 20.5). The efferent arterioles of juxtamedullary glomeruli turn toward the medulla; they supply the medulla. Juxtamedullary glomeruli are best defined by this type of efferent arteriole. The superficial efferent arterioles extend to the kidney surface before dividing. Again, superficial glomeruli are best defined because of the typical pattern of their efferent arterioles. The efferent arterioles of midcortical nephrons (defined by exclusion) vary in length between those that branch abruptly near the glomerulus and others that extend to a medullary ray before splitting off into capillaries. All the efferent arterioles together (superficial, midcortical, and also small

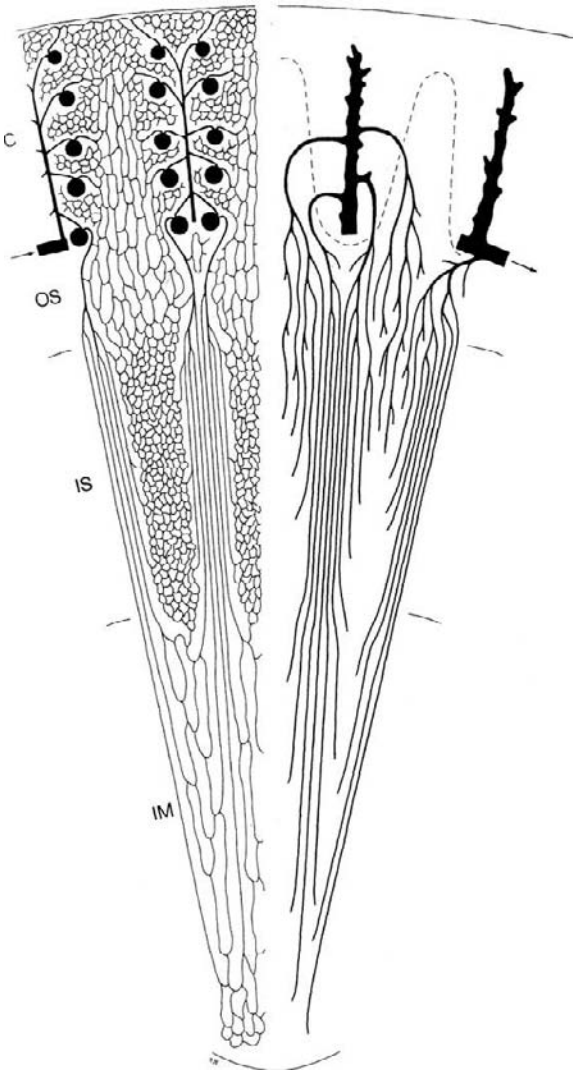

FIGURE 20.3 **Schematic of the microvasculature of the rat kidney** (C: cortex; OS: outer stripe; IS: inner stripe; IM: inner medulla). The left panel shows the arterial vessels and capillaries. An arcuate artery (arrow) gives rise to a cortical radial (interlobular) artery, from which afferent arterioles originate to supply the glomeruli. The efferent arterioles of the juxtamedullary glomeruli descend into the medulla and divide into the descending vasa recta, which, together with ascending vasa recta, form the vascular bundles of the renal medulla. At intervals, descending vasa recta leave the bundles to feed the adjacent capillaries. The right panel shows the venous vessels. The interlobular veins start in the superficial cortex. In the inner cortex they, together with the arcuate veins, receive the ascending vasa recta from the medulla. The vasa recta ascending from the inner medulla all traverse the inner stripe within the vascular bundles, whereas most of the vasa recta from the inner stripe ascend outside the bundles. Both of these types of ascending vasa recta traverse the outer stripe as wide, tortuous channels. *(Adapted from Kriz, W., and Lever, A. F. (1969). Renal countercurrent mechanisms: Structure and function. Am. Heart J.* ***78****(1), 101–118 and Rollhaeuser, H., and Kriz, W. (1964). The vascular system of the rat kidney. Z. Zellforsch. Mikrosk. Anat.* ***64****, 381–403, with permission.)*

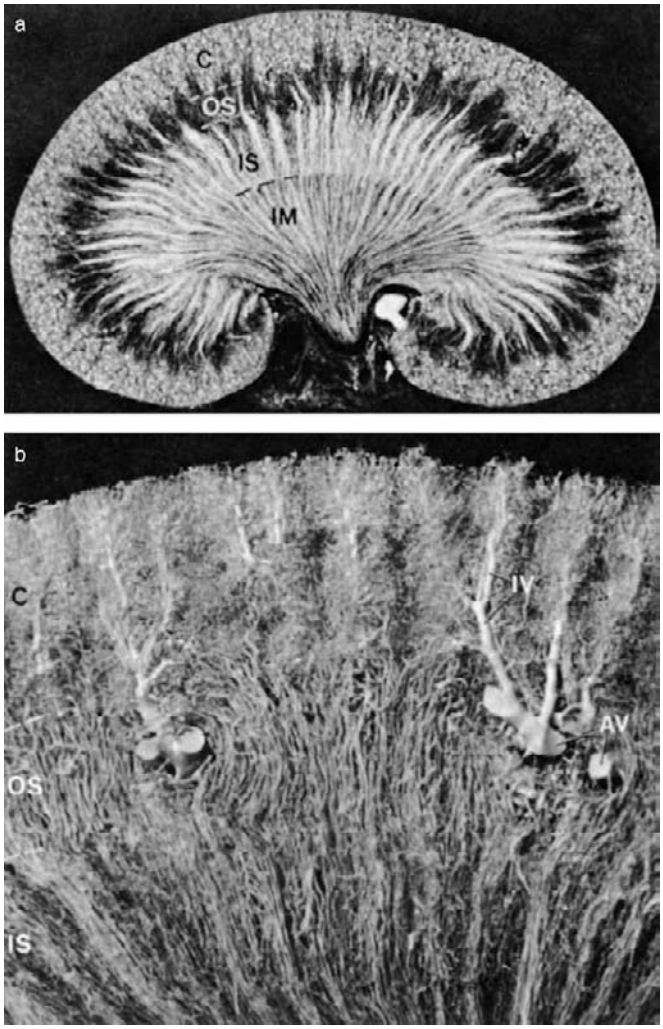

FIGURE 20.4 **Microvasculature.** (a) Rat kidney; silicon rubber (Microfil) filling of the arterial vessels. Cortex (C), outer stripe (OS), inner stripe (IS), and inner medulla (IM) are clearly distinguishable by their vessel patterns. The vascular bundles take shape along the OS and are best developed within the IS. Only a minor part of the descending vasa recta of each bundle enter the IM, where they gradually decrease in number toward the papilla. Note the scantiness of capillaries in the OS (×8). (b) Rabbit kidney; silicon rubber filling of the venous vessels. The interlobular veins (IV) accept the cortical capillaries and a major part of the ascending vasa recta. Note the density of ascending vasa recta within the OS. In the IS, ascending vasa recta are found within the bundles (mostly originating from the IM) and between the vascular bundles (draining the interbundle regions of the IS) (AV: arcuate vein; ×14). *(In cooperation with L. Bankir.)*

branches of the juxtamedullary efferent arterioles) supply the cortical peritubular capillaries. Direct aglomerular arterial supplies to the peritubular capillaries or to the medulla are sparse[13] and have frequently been shown to be the result of degeneration of the corresponding glomeruli.[14]

Within the capillary network of the cortex (Figures 20.3 and 20.4), a differentiation between two parts is necessary: namely, the dense, round-meshed

FIGURE 20.5 **Arterial vessels after filling with silicone rubber; rabbit kidney.** The broken lines show the renal surface and the corticomedullary border. Arcuate arteries (AA) give rise to cortical radial arteries which split into the afferent arterioles. The efferent arterioles of superficial glomeruli (arrow) ascend unbranched to the kidney surface before splitting into capillaries. The efferent arterioles of juxtamedullary nephrons (arrowheads) descend into the outer stripe and devide into the descending vasa recta (×80). *(From ref. [5].)*

capillary plexus of the cortical labyrinth (including the cortex corticis); and the less dense, long-meshed plexus of the medullary rays, both associated with the course of the tubules. Functionally these two plexuses are different with respect to their drainage. The blood from the medullary ray plexus has to pass the plexus of the cortical labyrinth to gain access to the interlobular veins. Therefore, the blood that has perfused the straight tubules within the medullary rays mixes with the blood that perfuses the convoluted tubules of the cortical labyrinth.

The medulla (Figures 20.3, 20.4, and 20.5) is exclusively supplied by the efferent arterioles of the juxtamedullary glomeruli.[5,8,10,11,15,16] These efferent arterioles descend through the outer stripe and divide into the descending vasa recta. In addition, the efferent arteriole and its first divisions give rise to small side branches that supply the sparse capillary plexus of the outer stripe of the outer medulla. This plexus is continuous with the cortical capillary plexus above and the capillary plexus of the inner stripe below. The descending vasa recta then penetrate the inner stripe of the outer medulla in cone-shaped vascular bundles. At intervals, descending vasa recta leave the bundles to join the capillary plexus at the adjacent medullary level, most leaving the bundle within the inner stripe. Only a small portion of the descending vasa recta penetrate the inner medulla, and even fewer reach the tip of the papilla.

The capillary plexuses of the renal medulla (Figures 20.3 and 20.4a) differ in the three regions. That of the outer stripe is sparse. In contrast, the capillary plexus of the inner stripe is very dense and characteristically round-meshed in appearance. In the inner medulla the capillary plexus is less dense and long-meshed.

The ascending vasa recta are the draining vessels of the renal medulla (Figures 20.3 and 20.4b). In the inner medulla they arise at every level and ascend as unbranched vessels to the border between the inner and outer medulla. At this point, they join the vascular bundles and traverse the inner stripe of the outer medulla within the vascular bundles. The ascending vasa recta, which drain the inner stripe, behave differently. Those of the lowermost part of the inner stripe (and therefore probably a minor portion) join the bundles as they pass through this region. Those from the middle and upper part (and thus probably the majority) do not join the bundles, but ascend directly within the interbundle regions to the outer stripe. There are, however, interspecies differences; in the sand rat (*Psammomys obesus*), all ascending vasa recta that drain the inner stripe ascend directly to the outer stripe without joining the bundles.[17]

Within the outer stripe, the vasa recta ascending within the bundles spread out and, together with the directly ascending vasa recta, traverse the outer stripe as individual tortuous channels with wide lumina (Figure 20.4b). They contact the tubules like true capillaries, and because the true capillaries which are derived from direct branches of efferent arterioles are few in the outer stripe (Figure 20.3a), they mainly affect the blood supply to the tubules in this region. At the corticomedullary border, the ascending venous vessels of the medulla empty into the arcuate veins or into the basal parts of interlobular veins. In some species, such as rat, guinea pig, and especially the sand rat (*Psammomys obesus*) some of the venous medullary vessels continue to ascend within the medullary rays of the cortex and finally empty into middle or even upper parts of interlobular veins.

Wall Structure of Intrarenal Vessels

The intrarenal arteries and the proximal portions of the afferent arterioles appear to be similar to arteries and arterioles of the same size elsewhere in the body. The terminal portions of the afferent arterioles are unique because of the occurrence of granular cells (renin producing cells) which replace ordinary smooth muscle cells in their wall.[18] It is generally agreed that granular cells are modified smooth muscle cells. Compared to proper smooth muscle cells, granular cells contain less myofilaments; thus, the contractile capacity of the very last portion of the afferent arteriole appears to be considerably decreased.[19] The endocrine function of granular cells will be considered later in the context of the juxtaglomerular apparatus. The glomerular capillaries will be described together with the glomerulus.

Efferent arterioles are already established inside the glomerular tuft. Thus, in contrast to afferent arterioles, efferent arterioles have an intraglomerular segment which passes through the glomerular stalk[20,21] (Figure 20.6a). After this, efferent arterioles have a segment which is narrowly associated with the extraglomerular mesangium (details will be given later in the context of the glomerulus). Thereafter, the efferent arterioles are established as arterioles with a proper media made up of smooth muscle cells.

Efferent arterioles from juxtamedullary glomeruli differ considerably from those of cortical (midcortical and superficial) glomeruli (compare Figures 20.6b and 20.6c). Juxtamedullary efferent arterioles are larger in diameter than cortical efferent arterioles; their size even exceeds that of their corresponding afferent arterioles. In the rabbit, the diameters of afferent arterioles throughout the cortex average approximately 20 μm; juxtamedullary efferent arterioles average 28 μm, and cortical efferent arterioles average only 12 μm.[22] Similar differences have been found in dog,[12] rat,[23] and human[24] kidneys.

Cortical efferent arterioles (Figure 20.6b) are only sparsely equipped with smooth muscle cells (generally not more than one layer). A striking feature of efferent arterioles (including those from juxtamedullary glomeruli) is the thick, irregular basement membrane. In contrast to the usual appearance of a basement membrane, basement membrane-like material fills the wide and irregular spaces between the endothelium and the muscle layer. The juxtamedullary efferent arterioles (Figure 20.6c) are surrounded by two to four layers of smooth muscle cells. Their endothelium is composed of a strikingly large number of longitudinally arranged cells; up to 30 individual cells may be found in cross-sections.[23,25]

In the descending vasa recta (Figure 20.6d) the smooth muscle cells are gradually replaced by

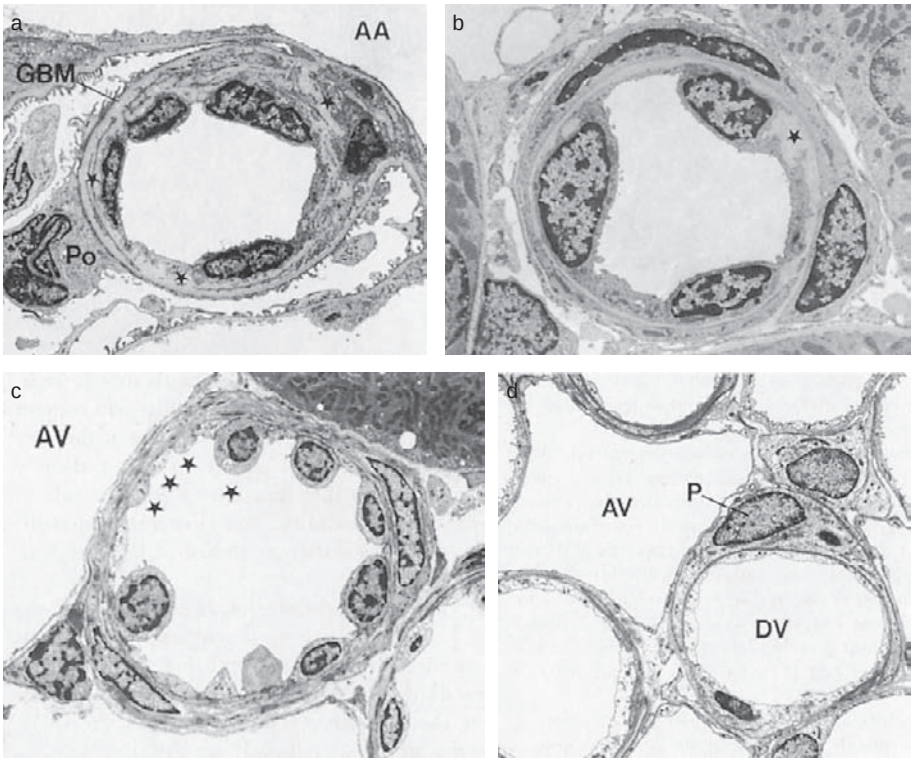

FIGURE 20.6 **Efferent arteriole.** (a) Intraglomerular segment of the efferent arteriole. Between the basement membrane (GBM) and the endothelium a mesangial layer is interposed. Note the intimate relationships of the afferent arteriole (AA) to the mesangium. PO: podocyte (Rat; TEM ×~4600). **(b)** Efferent arteriole of a superficial glomerulus. Note the irregular basement membrane-like material beneath the endothelium **(*)**. One to two layers of smooth muscle cells (SM) are encountered (Rabbit; TEM ×~3400). **(c)** Efferent arteriole of a juxtamedullary glomerulus. Note the many profiles of endothelial cells **(*)**; the tight junctions between them are shallow (Rat; TEM ×~2450). **(d)** Descending (DV) and ascending (AV) vasa recta of a vascular bundle are shown. The continuous endothelium of the descending vas rectum is surrounded by a pericyte (P). The endothelium of the ascending vas rectum is highly fenestrated **(**arrows**)** (Rabbit; TEM ×~2400).

pericytes, which form an incomplete layer around the vessel trunk. Pericytes should be regarded as contractile cells. The pattern of these cells, which encircle the endothelial tube-like hoops, and their dense assemblys of microfilaments strongly imply that they have a contractile function. In contrast to smooth muscle cells, they are not contacted by nerve terminals. The descending vasa recta finally lose their pericytes, and the concurrent appearance of endothelial fenestrations marks their gradual transformation into medullary capillaries.

The ultrastructure of the capillaries in the kidney is similar in both the cortex and the medulla (with the exception of glomerular capillaries; *vide infra*). The capillaries of the kidney are of the fenestrated type (Figure 20.7). The capillary wall consists of an extremely flat endothelium surrounded by a thin basement membrane. In non-nuclear regions the endothelial cells contain densely and regularly arranged fenestrations that (in contrast to the glomerular capillaries) are bridged by a thin diaphragm. An estimated 50% of the capillary circumference is composed of these fenestration-bearing areas.[23] The fenestrations themselves are of rather complex structure. In normal TEM sections the diaphragm appears as a very thin (5–6 nm) single-layered proteinaceous membrane provided with a central knob. Deep-etch freezing techniques have revealed a composition of radial fibrils converging to the central knob.[26] So far only one protein, PV1, a caveolar transmembrane protein, has been attributed to the diaphragm.[27] The diaphragm is considered to be permeable to water and small water-soluble substances.

FIGURE 20.7 **Freeze-fracture electron micrograph demonstrating the dense arrangement of fenestrations within the wall of a peritubular capillary (rabbit).** Pinocytotic vesicles (arrows) are found within areas of thicker cytoplasm, which connect the perikaryon and the more voluminous areas along the cell borders (not shown) (×7600). *(In cooperation with A. Schiller and R. Taugner.)*

The wall structure of the ascending vasa recta (Figure 20.6d) is similar to that of the capillaries. These draining vessels, with wide lumina, are bound for their entire length by an extremely flat endothelium with extensive fenestrations. The same structure is found in the large veins of the cortex and at the corticomedullary border (Figures 20.8 and 20.15). The interlobular and arcuate veins are not veins in the classic sense, but they have a wall structure fundamentally the same as that of the renal capillaries.[9,23] This wall consists solely of an extremely flattened, partly fenestrated endothelium that rests on a basement membrane.

NEPHRONS AND COLLECTING DUCT SYSTEM

The specific structural units of the kidney are the nephrons. In the rat, each kidney contains 30,000 to 35,000 nephrons[28]; each human kidney has an estimated 1 million,[29] but great interindividual differences exist.[30,31]

The nephron consists of a renal corpuscle connected to a complicated and twisted tube that finally drains into a collecting duct. Based on the location of the renal corpuscles within the cortex, three types of nephrons are distinguished: superficial; midcortical; and juxtamedullary nephrons. Exact definitions of these types, grounded on more than arbitrary decisions, can be based on the different patterns of the efferent arterioles (*vide supra*).

The tubular part of the nephron consists of a proximal and a distal portion connected by a loop of Henle. For details of subdivisions, see Figures 20.9 and 20.10.

According to the lengths of the loops of Henle, two types of nephrons are distinguished (Figure 20.9): those with long loops and those with short loops (including those with cortical loops). Short loops turn back in the outer medulla. In many species (rat, rabbit), the bends of the short loops are all located roughly at the same level of the inner stripe, namely, near the junction to the inner medulla. In other species (pig and human), short loops may form their bends at any level of the outer medulla, and even in the cortex (cortical loops).

The long loops turn back at successive levels of the inner medulla, many at its start; others reach intermediate levels, and only a few reach the tip of the papilla. Thus, the number of loops is successively reduced along the inner medulla toward the papilla. This decrease is paralleled by a decrease in collecting ducts

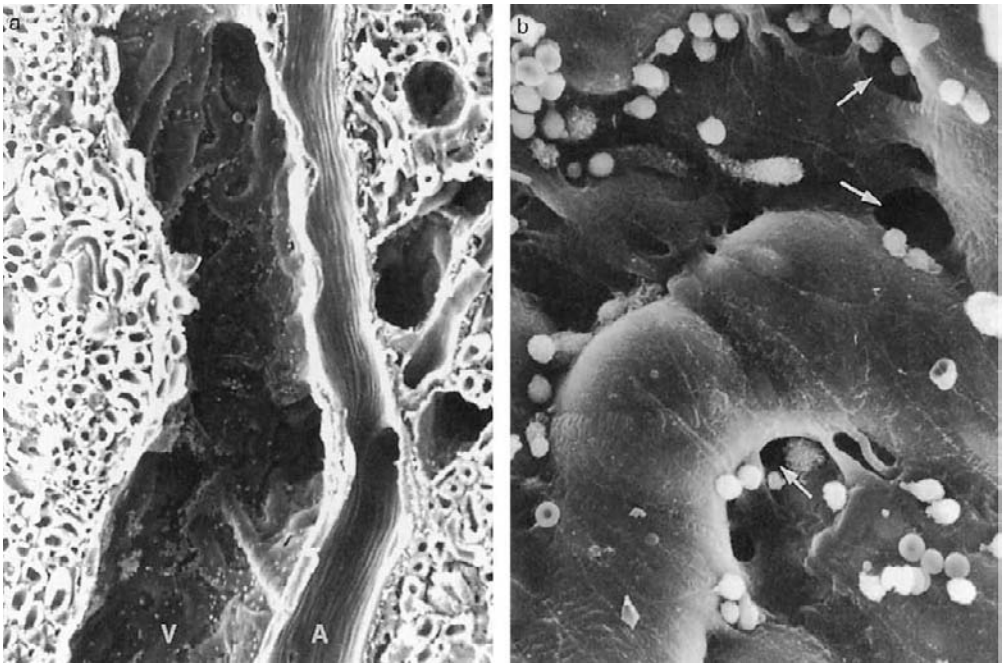

FIGURE 20.8 **Scanning electron micrographs of the inner surface of an arcuate artery and vein (Rat).** (a) The tubules underneath the venous wall are clearly discernible through the endothelium, which covers the tubules as a thin coat. (b) Higher magnification of the venous endothelium. The openings in the endothelial wall (arrows) mark the positions where venous vasa recta and capillaries empty into the vein. (a) ×~120; (b) ×~1900. *(From Frank, M., and Kriz, W. (1988). The luminal aspect of intrarenal arteries and veins in the rat as revealed by scanning electron microscopy. Anat. Embryol. (Berl) **177**(4), 371–376, with permission.)*

and vasa recta, leading to the characteristic form of the inner medulla, which in all species tapers from a broad basis to a papilla (or crest).

The division of nephrons according to the position of their corpuscles in the cortex does not coincide with the division based on the length of their loops. Among species, all three types of renal corpuscles may be attached to both short and long loops. However, within a given species (with short and long loops), the long loops always belong to the deeper renal corpuscles (i.e., juxtamedullary and deep midcortical) and the short loops to the more superficially situated corpuscles.

The number of short and long loops varies among species. Some species have only short loops (mountain beaver, muskrat), and consequently lack an inner medulla, which results in a poor ability to concentrate urine.[6] Only two species, cat and dog, are known to have just long loops. In comparison with other species, their urine concentrating ability is considered to be average. In the cat, however, many long loops penetrate into the inner medulla for a very short distance (less than 0.5 μm. Defining a loop by ultrastructural criteria (*vide infra*), a feline kidney does contain many loops resembling the short loops in other species. The formerly held presumption that rodent species with the most powerful ability to concentrate urine, like *Psammomys* or *Meriones*, have only long loops has been proved incorrect.[32] Most species have short and long loops whose ratio varies from species to species. A correlation between the ratio of short and long loops and urine concentrating ability is not obvious. Most rodent species that have a high urine concentrating ability (rat, mouse, golden hamster, *Psammomys*, *Meriones*) have more short loops than long loops.[32–34]

The collecting ducts are formed in the renal cortex by the joining of several nephrons (Figures 20.9 and 20.10). The location of the exact border between a nephron and a collecting duct is disputed. According to cytological criteria, a connecting tubule is interposed between a nephron and a cortical collecting duct. Whether this connecting tubule derives from the nephrogenic blastema, and therefore must be considered as a part of the nephron, or from the ureteral bud, and therefore is part of the collecting ducts, remains an open question.

Microanatomically, the connecting tubules of deep and superficial nephrons differ (Figure 20.9). The connecting tubules of deep nephrons generally join to form an arcade before draining into a collecting duct; superficial nephrons drain via an individual connecting tubule. The numerical ratio between nephrons draining through an arcade and those draining individually varies greatly among species. In rat, rabbit, and pig, the majority of nephrons drain via arcades; as Sperber[3] observed, some arcades probably exist in all mammalian kidneys. An arcade ascends within the cortical labyrinth before

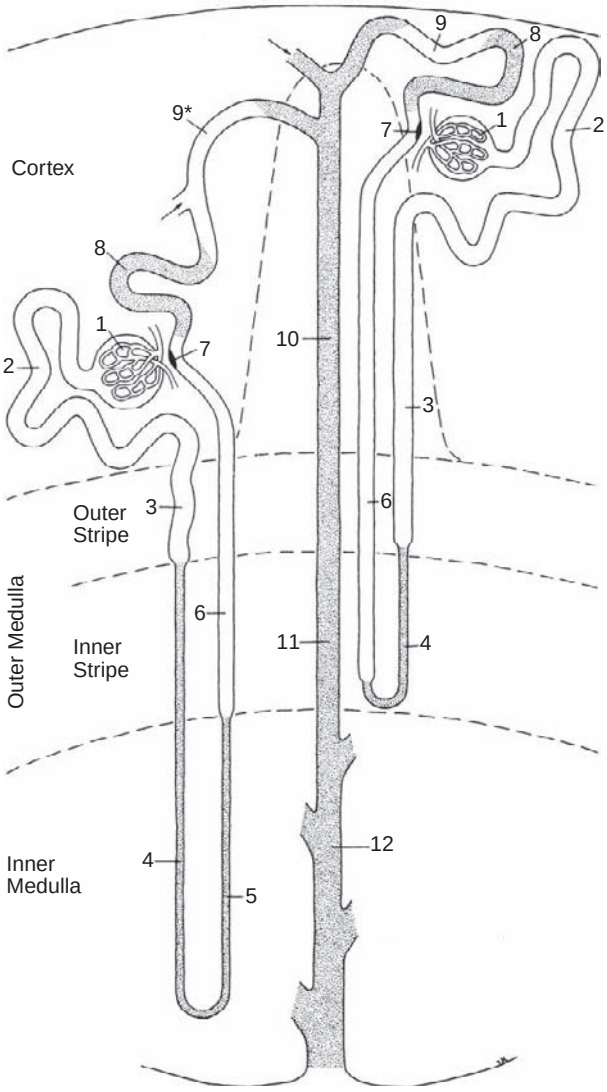

FIGURE 20.9 **Schematic of nephrons and collecting duct.** This scheme depicts a short-looped and a long-looped nephron, together with the collecting system. Not drawn to scale. Within the cortex a medullary ray is delineated by a dashed line. (*From Kriz, W., and Bankir, L. (1988). A standard nomenclature for structures of the kidney. The Renal Commission of the International Union of Physiological Sciences (IUPS). Kidney Int, 33, 1–7, with permission.*) 1: Renal corpuscle including Bowman's capsule and the glomerulus (glomerular tuft); 2: Proximal convoluted tubule; 3: Proximal straight tubule; 4: Descending thin limb; 5: Ascending thin limb; 6: Distal straight tubule (thick ascending limb); 7: Macula densa located within the final portion of the thick ascending limb; 8: Distal convoluted tubule; 9: Connecting tubule; 9*: Connecting tubule of the juxtamedullary nephron that forms an arcade; 10: Cortical collecting duct; 11: Outer medullary collecting duct; 12: Inner medullary collecting duct.

draining into a cortical collecting duct (Figure 20.9). Functionally, an arcade appears to serve as a device that prevents the addition of dilute distal urine to collecting ducts at the corticomedullary junction.[35]

The cortical collecting ducts descend within the medullary rays of the cortex and then, as unbranched tubes, traverse the outer medulla (outer medullary collecting ducts). On entering the inner medulla (inner medullary collecting ducts), they fuse successively. In the human kidney, an average of eight fusions has been found,[36] a number that may also be a good approximation for other species.[37] Because a cortical collecting duct in the human kidney accepts 11 nephrons on average, it can be calculated that a papillary duct (opening into the renal pelvis) drains a total of 2750 nephrons. In the rabbit kidney, which has only 6 nephron tributaries to a cortical collecting duct,[5] approximately 1000 nephrons are drained by a terminal collecting duct. It must be emphasized that an inner medullary collecting duct is not a single unbranched tube, but rather is a system of tubules that fuse successively.

INTERSTITIUM

Definition, Volume Fraction

The space between the basement membranes of the renal epithelia and the peritubular capillaries (Figure 20.11) is called the "*interstitial space*." Cells and extracellular matrix within this space constitute the "*interstitium*." The fractional volume of the interstitium in the cortex in healthy kidneys has been estimated between 4 to 9%,[38–41] in the outer stripe of the outer medulla and in the vascular bundle compartment ~3–5%. In the interbundle compartment of the inner stripe the fractional volume amounts to 10% in rat,[42,41] and in the inner zone the relative interstitial volume continuously increases from the base (10–15% fractional volume in rat, 20–25% in rabbit) to the tip of the papilla (~30% in rat; more than 40% in rabbit[42,43]). Reabsorption and secretion of fluid and solutes, as well as the transport for many regulatory substances from their site of production to their target site, implies a transit across the interstitial compartment.[44] In the cortex only about 26%[39] or 42%[40] of the total outer tubular surfaces are directly apposed to capillaries.

Cellular Constituents

The majority of cells in the interstitium of healthy kidneys are *interstitial fibroblasts* and *dendritic cells* (Figure 20.12). Other cell types (*macrophages* and *lymphocytes*) are scarce in healthy kidneys,[45] but they invade the interstitial spaces under inflammatory conditions.[46]

Interstitial Fibroblasts

Interstitial fibroblasts provide the scaffolding of the tissue, take part in the modeling of the extracellular matrix, and play a role in the production of regulatory

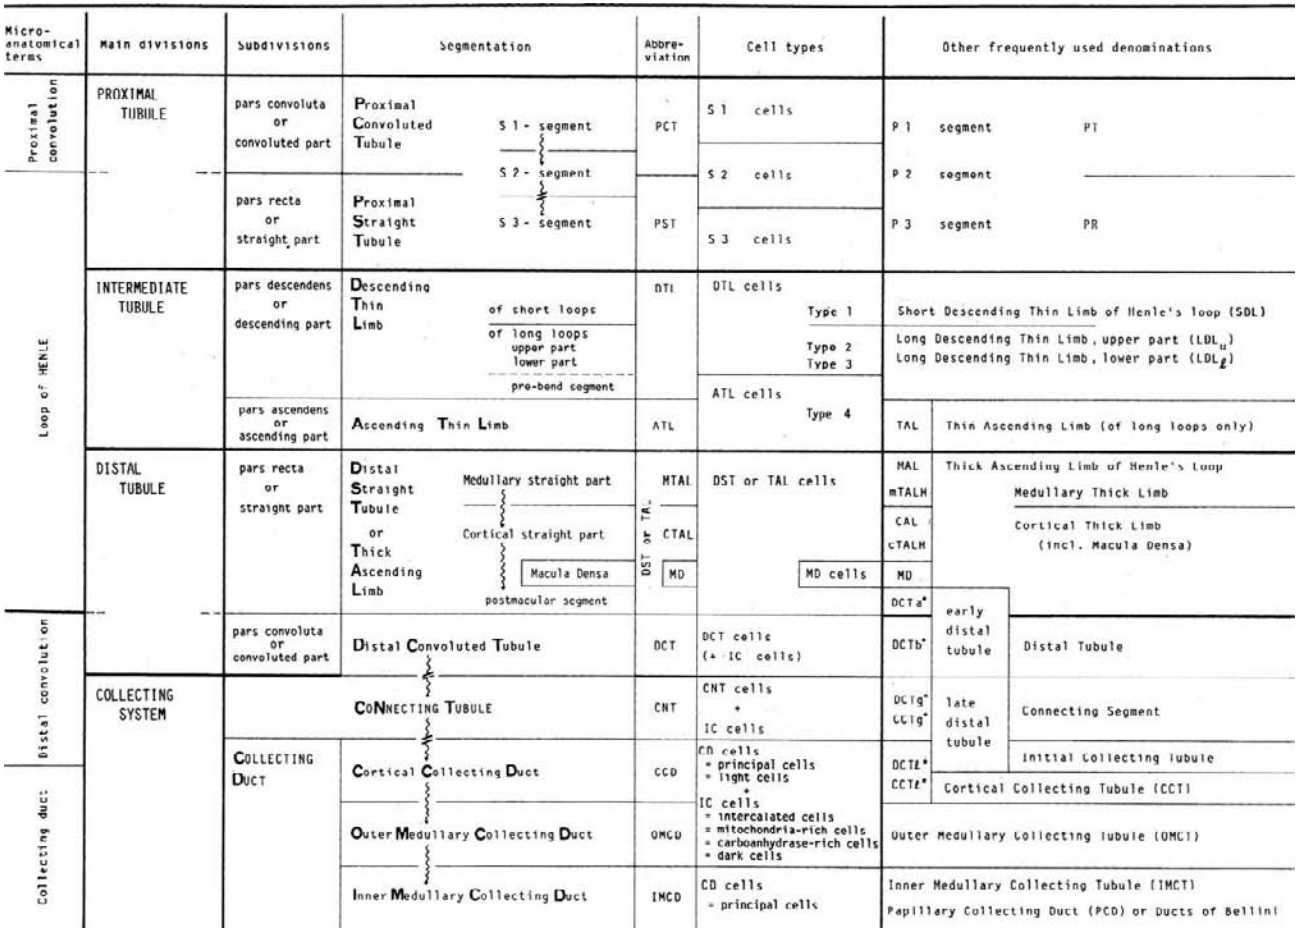

FIGURE 20.10 **Segmentation of the renal tubule.** This table summarizes the nomenclature of segments and cells of the renal tubule. A continuous serpentine arrow means that the transition between the two structures is gradual. An interrupted serpentine arrow means that the transition is gradual in some species, abrupt in others. *Abbreviations marked by a star were introduced by Morel and co-workers: Functional segmentation of the rabbit distal tubule by microdetermination of hormone-dependent adenylate cyclase activity. Kidney Int. 1976; **9**, 264–277* (DCTa: Distal convoluted tubule, initial portion; DCTb: Distal convoluted tubule, bright portion; DCTg: Distal convoluted tubule, granular portion; DCTl: Distal convoluted tubule, light portion; CCTg: Cortical collecting tubule, granular portion; CCTl: Cortical collecting tubule, light portion). *(From ref. [542].)*

(b) Fibroblast (F) in focal peritubular inflammation, caused by a lesion in a distal tubule; the fibroblast bridges the space between a healthy proximal tubule (PT), and a diseased distal tubule (DT), extends with thin processes closely along the basement membrane of the DT, partially encloses a profile of a peritubular capillary (C), and has close contact to migrating cells of the immune system (L: lymphocyte; D: dendritic cell; Insert: Higher magnification of the contact ("kiss") of the extension of the dendritic cell and a lymphocyte; TEM ×~6000; Insert ×~23,000).

substances. Interstitial fibroblasts bridge the interstitial space (Figures 20.12, 20.13 and 20.14). They are physically affixed to the basement membranes of tubules, renal corpuscles, and peritubular capillaries, they are interconnected by adhering junctions[44,45,47–49] (Figures 20.12 and 20.14), and narrowly contact all types of migrating cells within the interstitial space (Figures 20.12 and 20.13).

Cortical Interstitial Fibroblasts

In transmission electron microscopic (TEM) images (Figure 20.14), cortical interstitial fibroblasts display a heterochromatin-rich angular nucleus which is surrounded by a narrow organelle-free cytoplasmic rim. Filiform and leaf-like, perforated and filiform processes spread from the cell body, traverse the interstitial space and are affixed to the basement membranes of tubules, enveloping glomerular arterioles and cells of the immune system.[50] Characteristic for fibroblasts is the dense layer of f-actin filaments immediately under the plasmalemma (Figures 20.12 and 20.14). In the filiform processes and the pedicle- or spine-like attachments to the basement membranes, the f-actin is markedly dense[48] (Figures 20.12 and 20.14).

The anchorage of fibroblasts to tubular and capillary basement membranes and their interconnections suggests the possibility that each configurational change of tubules or capillaries (e.g., related with tubular/capillary growth, tubular/capillary dilatation or collapse) exerts mechanical forces on the f-actin frame of the fibroblasts and induces signaling pathways.[51,52] In concert with chemokines and other factors[53] the mechanical forces might be essential components in the cross-talk between fibroblasts and epi- or endothelia,

The production of *extracellular matrix* is another distinguishing characteristic of fibroblasts. The morphological correlate for matrix production is the prominent apparatus for protein synthesis, i.e., abundant large profiles of rough endoplasmic reticulum filled with flocculent, rather electron-dense material, as well as several sets of Golgi-fields. These organelles, including mitochondria, are predominantly located in the peripheral thicker parts of the leaf-like processes, close to the sites of release of matrix and collagen fibrils into the interstitial space (Figure 20.14).[47,48]

The *extracellular matrix* of the interstitium is composed of a network of fibers, proteoglycans, glycoproteins, and interstitial fluid.[44,54] Several types of fibers are found, among them typical interstitial collagen fibers (type 1, type 3, and type 6).[55] Microfibrils (collagen type 1) are found throughout the renal interstitium. Type 3 fibers correspond to the reticular fibers which form a network enveloping individual tubules. Proteoglycans are an important component of the interstitial matrix in the kidney.[56] As elsewhere in the body, various glycoproteins (fibronectin, laminin, and others) are found associated with tubular basement membranes, as well as with fibrillar structures. All these substances contribute to the scaffolding function of the interstitium. Furthermore, they are important substrates for migrating immune cells in the interstitial space.

Fibroblasts can accumulate *lipid droplets*. These are not common in cortical fibroblasts (in contrast to medullary fibroblasts, see below) of healthy kidneys; yet, they may also appear in cortical fibroblasts under specific functional conditions (e.g., anemia[38]). Lysosomal bodies are rarely observed under control conditions.

Cortical interstitial fibroblasts play important roles in the adaptive response to local and systemic hypoxia.

The cleavage of AMP by ecto-5′-nucleotidase (5′NT) on the plasmalemma of cortical fibroblasts generates *extracellular adenosine* (*ADO*) in the cortical interstitium.[57] ADO has been widely implicated in adaptive responses to local hypoxia[58] and in regulating local hemodynamics.[59] The particularly narrow sheathing of glomerular arterioles by 5′NT-positive fibroblasts[48,60] suggests a role of ADO in the regulation of glomerular blood flow and glomerular filtration rate. Indeed, purinergic receptors in afferent and efferent glomerular arterioles are implicated in the regulation of renal functions and hypertension.[61] Studies on 5′NT-deficient mice have confirmed that ADO mediates the vascular response elicited by changes in NaCl concentration at the macula densa.[62] Cortical fibroblasts also exhibit soluble guanylyl cyclase (sGC),[63] and a *b*-type cytochrome 558.[64]

Interstitial fibroblasts in the deep cortex are the source of renal erythropoietin.[65–67] The hypoxia-inducible factor (HIF Hif-2), which has also been located to 5′NT-positve fibroblasts,[68,69] mediates regulation of transcription of erythropoietin following changes in oxygen supply.[70] In conditions of anemia[38] and hypoxia, cortical interstitial fibroblasts from all cortical regions are rapidly recruited for EPO-synthesis.[71]

Extensive phenotypical modulations of cortical peritubular fibroblasts *in vivo* occur under the concerted action of inflammatory cytokines and growth factors.[72–74] Under these conditions, the interstitial fibroblasts proliferate and transform into *myofibroblasts*.[75] Morphologically myofibroblasts differ from interstitial fibroblasts of the healthy renal interstitium, having rounded, euchromatin-rich nuclei and large irregularly-shaped cellular extensions containing dramatically expanded cisterns of rER,[75] and by increased junctional coupling.[76] Differing from healthy interstitial fibroblasts, myofibroblasts express αSMA and vimentin, and 5′NT is internalized from the plasma membrane into the cytoplasm. Functionally, myofibroblasts have an increased capacity for quantitatively and qualitatively different matrix production,[72–74] and a reduced potential for erythropoietin gene expression.[70]

Medullary Interstitial Fibroblasts

The phenotype of fibroblasts in the medulla is basically the same as in the cortex, yet their three-dimensional configuration[50] changes in correlation with the change in tubular arrangement, from convolutions in the cortex to the strictly parallel course of tubules and vessels in the inner zone. The longitudinal axis of the pericaryon of inner medullary fibroblasts is oriented perpendicularly to the longitudinal axis of tubules and vessels (Figure 20.15), and in two-dimensional microscopic images they appear like "rungs of a ladder".[44]

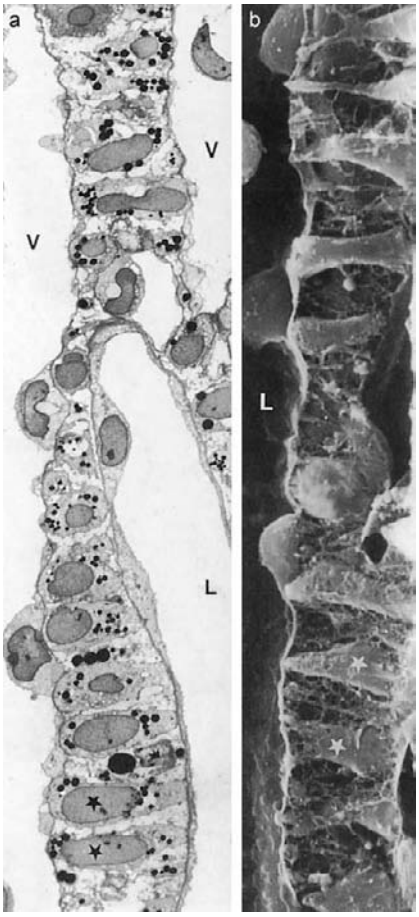

FIGURE 20.15 **Interstitial fibroblasts of the inner medulla, demonstrated in longitudinal sections.** The fibroblasts (asterisks) are arranged like the rungs of a ladder between parallel running tubules or vessels. The fibroblasts contain numerous lipid granules (black) of different sizes (visible in a). (L: loop limb; V: vessel; (a) *Psammomys*; TEM ×~1350; (b) Rat; SEM ×~3400). *(In cooperation with J. M. Barrett.)*

One noticeable change in the ultrastructure of medullary fibroblasts is the progressive increase in cytoskeletal elements towards the deep inner zone; actin filaments form a very prominent layer under the plasma membrane of the pericaryon (Figure 20.16) and the processes. The latter may be interconnected by a composite type of intercellular junction.[49] The increase in cytoskeletal elements in the cells in the inner zone most probably contributes to withstanding the increasing osmotic pressure towards the papillary tip. Furthermore, the occurrence of lipid granules increases progressively from the outer medulla towards the inner medulla where they may be so prominent that the cells were designated as "lipid-laden cells." However, inner medullary fibroblasts may also lack lipid droplets.[44] *In vitro* studies have revealed that the

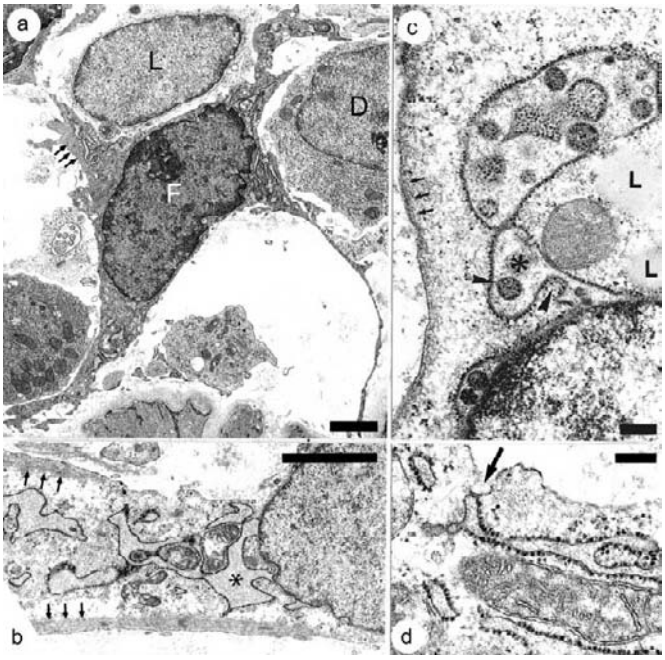

FIGURE 20.16 **Medullary fibroblasts, (a, b, d) human fibroblasts from a renal biopsy; (c) fibroblast from a perfusion-fixed rat kidney.** (a) Human fibroblast at the cortico-medullary border; stellate pericaryon and microfilament-rich cell processes (small arrows), extending between immune cells. (b) Part of a human fibroblast in the inner stripe of the outer medulla; the cisterns of the rough endoplasmic reticulum are widened and filled with flocculent material (Asterisk: Dilated perinuclear cistern; Small arrows: Accumulations of microfilaments along the plasma membrane). (c) Rat fibroblast from the inner medulla showing dilated perinuclear and endoplasmic reticulum cisterns (asterisk); infoldings of the ER into the cistern (arrow head) (L: Lipid droplets). (d) Fibroblast in the outer stripe of the outer medulla; a profile of rough endoplasmic reticulum in direct contact with the plasma membrane (arrow) (TEM (a): ×~4760; (b): ×~8500; (c) ×~37,400; (d) ×~33,150; Bars: (a,b): ~2 mm; (c,d): ~0.2 mm). *(From ref. [47].)*

occurrence and amount of lipid droplets in the inner medullary fibroblasts depends on the specific environment of the cells, conditioned by the presence of inner medullary collecting duct cells, and that inner medullary fibroblasts can transform to myofibroblasts with upregulation of alpha smooth muscle actin and desmin.[77] In medullary fibroblasts the cisterns of rough endoplasmic reticulum, including the perinuclear cistern, are often strikingly enlarged and they may narrowly enclose mitochondria (Figure 20.16). Occasionally the rER membranes are in direct contact with the plasma membrane (Figure 20.16). The functional interpretation of these particular features, only rarely observed in cortical fibroblasts, is still to be resolved.

The medullary fibroblasts do not display 5′NT or mRNA for EPO. A role of medullary interstitial cells has been proposed in the regulation of urinary osmolarity. *Glycosaminoglycans* are particularly abundant in the inner medullary interstitium,[78] and condensed hyaluronate-proteoglycan aggregates are associated with basement membranes, with collagen fibers, as well as with diffuse reticular structures.

The inner medulla has the greatest capacity for *renal prostaglandin* (PG) synthesis.[79,80] *Cyclooxygenase* (COX) isoforms, rate-limiting enzymes in PG biosynthesis, are expressed at substantially higher levels in the inner medulla than in the renal cortex.[81–84] COX-2 is found predominantly in inner medullary interstitial fibroblasts, and its expression increases under chronic salt loading.[84]

Dendritic Cells

Dendritic cells (DC) belong to the mononuclear phagocyte system and constitute the major antigen-presenting cell population in the healthy kidney.[85] Interstitial DCs continually probe the surrounding environment through dendrite extensions, and readily respond to insults to the parenchyma.[86–88] DCs have been recognized by their expression of MHC class II (Figures 20.12 and 20.13) and CD11c. In the healthy kidney DCs are present in their immature phenotype with comparatively low levels of MHC class II and of co-stimulatory proteins,[89] but with a high capacity for uptake of antigens.[86]

Similar to fibroblasts, DCs form an organ-spanning network,[88] located in very close contact with fibroblasts (Figures 20.12, 20.13 and 20.14).[45,47] DCs are constantly moving. Unlike fibroblasts, the pericaryon of DCs is large and confines the often rounded or elongated nucleus together with most cell organelles. The rER profiles of dendritic cells are narrow and less abundant than in fibroblasts. The intermediate filament protein vimentin is regularly present in the pericaryon of DCs, whereas it is absent in fibroblasts in the healthy renal cortex. Dendritic cells have, in comparison to macrophages and lymphocytes, more mitochondria, more rER, and a large Golgi apparatus. Lysosomes are less apparent than in macrophages. The so-called Birbeck granules, which are characteristic for dendritic cells, are a special formation of the endocytotic compartment serving as a loading compartment and/or reservoir of antigens before DC maturation.[90]

The ramified "veil-like" and perforated cellular extensions (Figure 20.12) lack the prominent stuffing with f-actin filaments, and are largely devoid of cell organelles, in marked contrast to fibroblasts. The long filiform processes of DCs have approximately the same diameter as the filiform fibroblast processes, but due to the lack of f-actin filaments are much less electron-dense (Figure 20.14). In contrast to fibroblasts, DCs

have no junctional connections among each other or with tubules or vessels. However, frequently the plasma membranes of dendritic cells and of fibroblasts or dendritic cells and lymphocytes form points of membrane adhesion, so-called "kisses" (Figure 20.14). Parts of dendritic cells are often nestled into the hollows of the pericaryon or the processes of fibroblasts. The narrow intermingling of both cell types (Figures 20.12, 20.13 and 20.14) suggests the possibility of extensive cross-talk between them.

Dendritic cells are abundant in the inner stripe in the outer medulla and, as in the cortex, are narrowly associated with fibroblasts. Accumulations of dendritic cells are particularly striking around collecting ducts and thick ascending limbs.

In the inner medulla the pericaryon of dendritic cells is often situated in the spaces between the "ladder rungs" formed by the fibroblasts, and their processes may extend over several "ladder rungs." In the lower two-thirds of the inner medulla bone marrow-derived cells are not detected in the healthy kidney.[45,47]

Macrophages and Lymphocytes

Macrophages and lymphocytes are rarely found in the healthy renal interstitium, but they massively invade the interstitial spaces under inflammatory conditions.[46] A large proportion of the invading mononuclear cells display the established "marker proteins" (CD 45, CD3, CD4, CD 8; ED1, ED2, CD44, etc.) and the protein S100A4.[35,91] Neutrophil granulocytes are found occasionally, basophil and eosinophil granulocytes and plasma cells are rare in the healthy cortical renal interstitium.

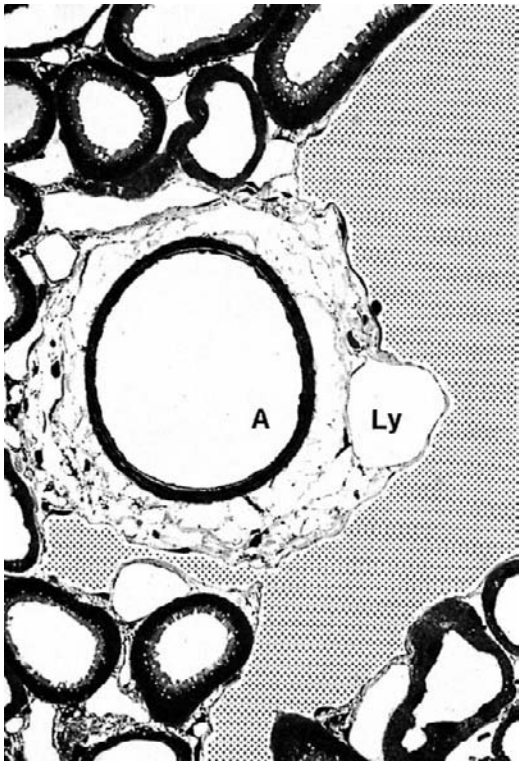

FIGURE 20.17 **Cross-section through the deep cortex (rat).** The cortical radial artery (A) is surrounded by a layer of loose connective tissue that contains the lymphatics (L_Y). The cortical radial vein is only partly shown; its lumen and those of direct tributaries have been highlighted by a dotted pattern. Note the intimate relationships of the artery, vein, and lymphatic, mediated by the periarterial loose connective tisue (TEM: $\times \sim 360$).

PERIARTERIAL CONNECTIVE TISSUE AND LYMPHATICS

The periarterial tissue is a sheath of loose connective tissue, surrounding the intrarenal arteries (arcuate arteries, cortical radial arteries). The considerable thickness of the periarterial sheath is apparent in quick-frozen specimens,[92] and in perfusion fixed tissue. It attenuates towards the end of the cortical radial arteries and terminates along the afferent arteriole at the vascular pole of the glomerulus (Figures 20.17, 20.18 and 20.19). The periarterial sheath is continuous with the peritubular interstitium and with the connective tissue underlying the epithelium of the renal pelvis and ureter at all sites. The renal veins are apposed to the periarterial sheath.[92]

The periarterial sheath constitutes wide meshes of the extremely attenuated processes of 5′NT-negative, but weakly alpha-smooth muscle actin- and vimentin-positive fibroblasts.[47] The meshes are filled with thick bundles of collageneous fibers and interstitial fluid and regularly confine some macrophages and dendritic cells.

The periarterial connective tissue sheath provides the path for renal nerves (see below) and for *renal lymphatics*.[92] Lymphatics start in the vicinity of the glomerular vascular pole[25] or at a more proximal level of the afferent arteriole, depending on the species, and travel along the branches of the renal arteries towards the renal hilum (Figures 20.17 and 20.18). Their recognition and distinction from blood capillaries at light microscopic levels is facilitated by their specific expression of podoplanin.[93] Also, 5′NT labels in rat and mice lymphatics, but not in blood vessels. Lymphatic endothelial cells secrete chemokines that attract dendritic cells. An increase in lymphatic microvessels has been observed, e.g., in tubulointerstitial fibrosis and progression to end-stage renal failure in remnant kidney.[93]

Regulatory substances that are released into the peritubular interstitium might access the systemic blood circulation via the lymphatics in the periarterial sheath. This suggestion has been made for renin,[92] and it may

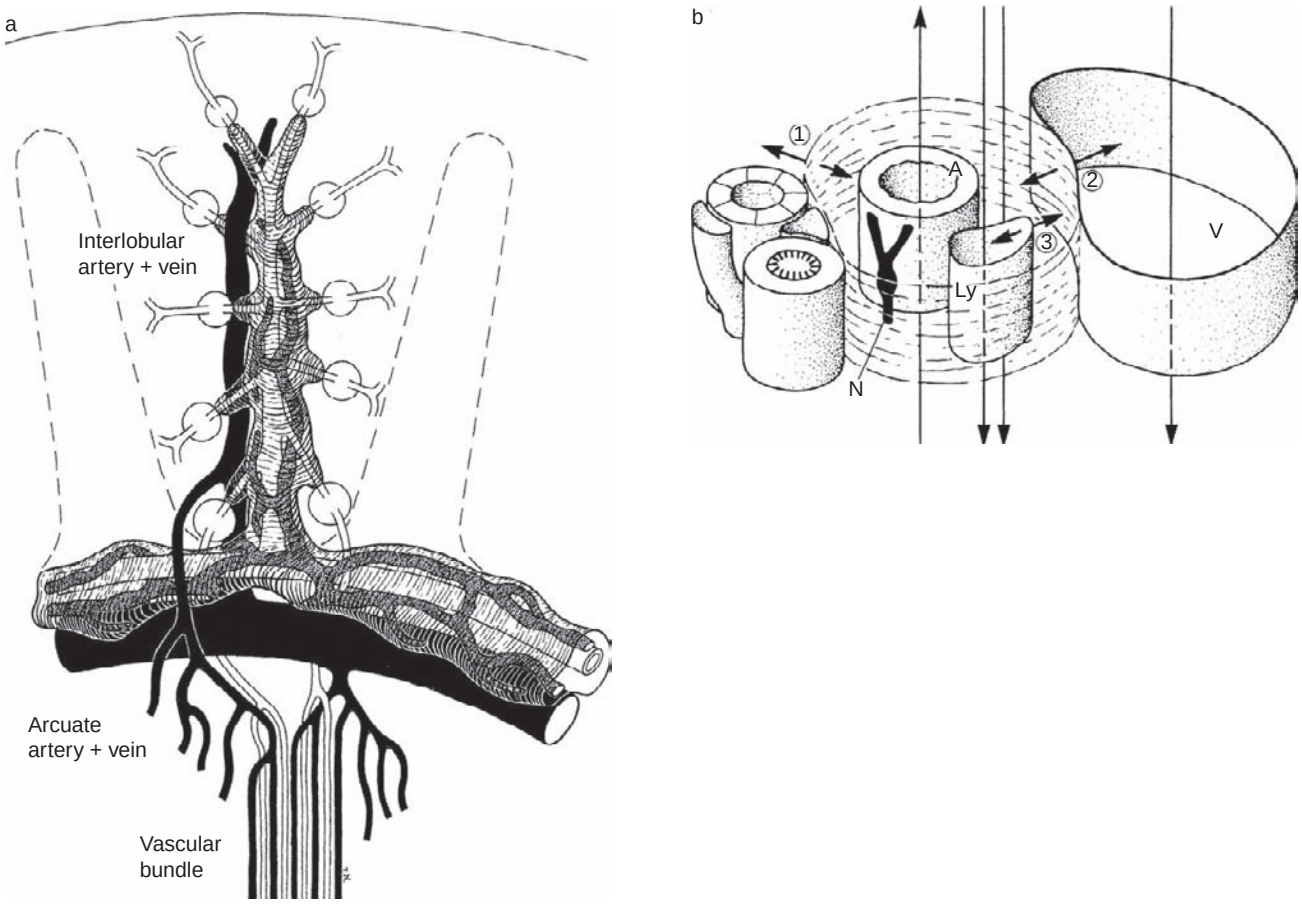

FIGURE 20.18 **Schematics to show (a) the distribution, and (b) the topographical relationships of the periarterial connective tissue sheath.** Not drawn to scale. (a) The periarterial sheath is schematically indicated as a wide "stocking" drawn over the intrarenal arteries and lymphatics. In reality this stocking has no limiting tissue that separates the interior from the surroundings. An arcuate artery transforms into a cortical radial artery, which gives rise to afferent arterioles. These segments are surrounded by the periarterial connective tissue sheath. The efferent arterioles, as well as the veins (drawn in black), are not included. The lymphatics (stippled) originate and travel within the periarterial sheath. Note there are no lymphatics coming up from the medulla. Within the cortex, medullary rays are indicated by a broken line. In (b) a transverse section through an cortical radial artery (A) shows the relationships of the periarterial sheath and the possibilities for functional exchanges (double-headed arrows) with surrounding structures: (1) with the peritubular interstitium; (2) with the accompanying vein (V); and (3) with lymphatics (Ly). The single-headed arrows indicate the flow of the respective fluid. Note the nerves (N) traveling through the periarterial tissue. In addition, two neighboring tubules, including an arcade and a proximal tubule, together with peritubular capillaries, are drawn. *(From ref. [92], with permission.)*

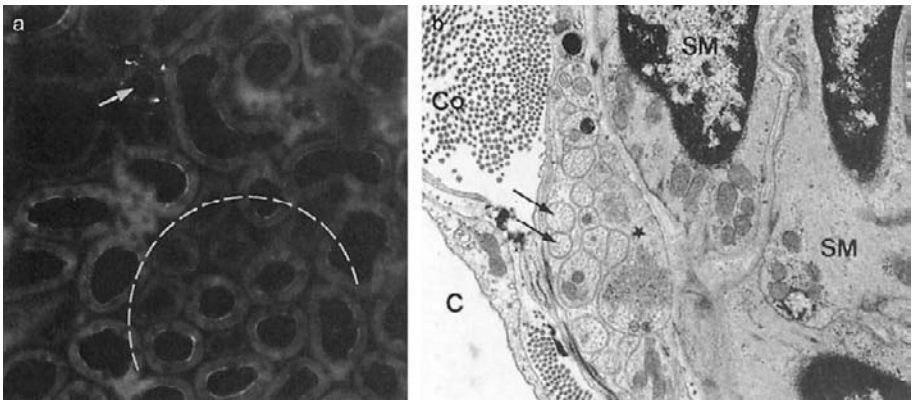

FIGURE 20.19 **The renal nerves accompany (a) the intrarenal arteries.** A cortical radial artery (arrow) is seen which is associated with three nerve bundles, identified by staining with a monoclonal antibody against protein gene product 9.5 (PGP 9.5) which is a universal marker for vertebrate neurons. Among the tubules no nerves are found. A medullary ray is delineated by a hatched line (Rat; LM $\times\sim$240). (*In cooperation with M. Siry, W. Kummer and S. Bachmann*). (b) A large terminal nerve accompanying an afferent arteriole. Several axons (arrows) and a varicosity (star) with synaptic vesicles are seen (SM: Smooth muscle cell; CO: Collagen; C: Capillary; Rabbit kidney: TEM $\times\sim$12,000).

apply to other protein hormones such as erythropoietin. The periarterial tissue sheaths have been interpreted as a mixing chamber for a variety of vasoactive substances, ultimately determining the contractile status of the renal resistance vessels. In addition to the lymphatics, the periarterial tissue itself constitutes a pathway for interstitial fluid drainage. Indeed, a tracer injected under the renal capsule can be followed within the periarterial tissue, as well as within the lymphatics.

While a fraction of cortical interstitial fluid gains access to the periarterial tissue, and eventually to lymphatics, there is no direct pathway for regulatory substances released in the cortical interstitium to reach medullary targets. It has been proposed that the intimate relationships between cortical radial arteries and veins permits countercurrent exchange of O_2, being responsible – at least in part – for the low partial pressure of O_2 in the superficial cortex.[94,95]

NERVES

The efferent nerves of the kidney are composed of sympathetic nerves and terminal axons, which accompany the intrarenal arteries, and the afferent and efferent arterioles (Figures 20.18 and 20.19).[96] The nerve fibers are monoaminergic. Norepinephrine[97–99] and dopamine have been identified.[100] In addition, several neuropeptides are co-localized with norepinephrine in renal nerves.[101] The presence of acetylcholinesterase in renal nerves cannot be taken to indicate cholinergic nerves, but rather that monoaminergic nerves obviously possess acetylcholinesterase activity.[97]

The nerve fibers run in the loose connective tissue around the arteries and arterioles. The descending vasa recta within the medulla are also innervated by adrenergic nerve terminals as far as they are enveloped by smooth muscle cells.[102,103] A dense assembly of nerves and terminal axons is found around the juxtaglomerular apparatus[99] which is described in more detail along with the JGA.

Tubules have direct relationships to terminal axons only when they are located around the arteries or arterioles.[96,99] Tubules adjacent to the juxtaglomerular apparatus (terminal portion of the cortical thick ascending limb) are more frequently touched by terminal axons than at other sites.[99] The density of nerve contacts to convoluted proximal tubules (located in the cortical labyrinth) is low[104]; nerve contacts to straight proximal tubules (located in the medullary rays and the outer stripe) have never been encountered. The overwhelming majority of tubular portions have no direct relationships to nerve terminals.

Consequently, morphologists are left with the question of how the neuronal influence on tubular function[105] is mediated. In addition to a systemic distribution of catecholamines, a more specific, but also indirect, mode seems possible for certain tubular segments.[5] Because nerve fibers do pass along the vascular pole of each glomerulus from afferent to efferent arterioles, the distribution of nerves in the renal cortex is dense. Catecholamines (and other transmitters) released from nerve terminals at the vascular poles and at the efferent arterioles may gain access to peritubular capillaries, and in this way may perfuse the convoluted tubules of the cortical labyrinth. Tubules arranged around the cortical radial arteries would be reached most easily by transmitters released from periarterially located nerve terminals. This may be of relevance with respect to arcades (connecting tubules), which have been shown to be sensitive to isoproterenol.[106] Exposure of the straight tubules within the medullary rays of the cortex to neural transmitters reaching them directly by diffusion from nerve terminal is improbable.

Tubules in the outer medulla may only be reached by neurotransmitters if they are either situated adjacent to vascular bundles (a minority of tubules) or secondarily, by a capillary distribution of the transmitters from nerve terminals accompanying the vascular bundles. The tubules of the inner medulla cannot be reached by neurotransmitters directly delivered from nerve terminals in the medulla.

Little is known about the afferent nerves of the kidney; they are commonly believed to be sparse, but the issue remains unresolved.[102,105,107–110]

TOPOGRAPHICAL RELATIONSHIPS

Cortex

The architectural pattern of the renal cortex is best understood when viewing a cross-section through the midcortex (Figures 20.20 and 20.21). Two portions within the cortical parenchyma, the labyrinth and the medullary rays, are distinguishable. Within the cortical labyrinth, the vascular axes, which consist of the cortical radial (interlobular) artery, vein, and a lymphatic, are regularly distributed. The renal corpuscles and the corresponding convoluted tubules (proximal and distal) are situated around each vascular axis. Barriers separating the population of renal corpuscles and convoluted tubules belonging to another vascular axis are not discernible. Thus, the cortical labyrinth is a continuous parenchymal layer that contains the vascular axes of the cortex and the medullary rays in a regular pattern. The straight tubules (proximal and distal), together with the collecting ducts, are located within the medullary rays. Because the number of straight tubules increases

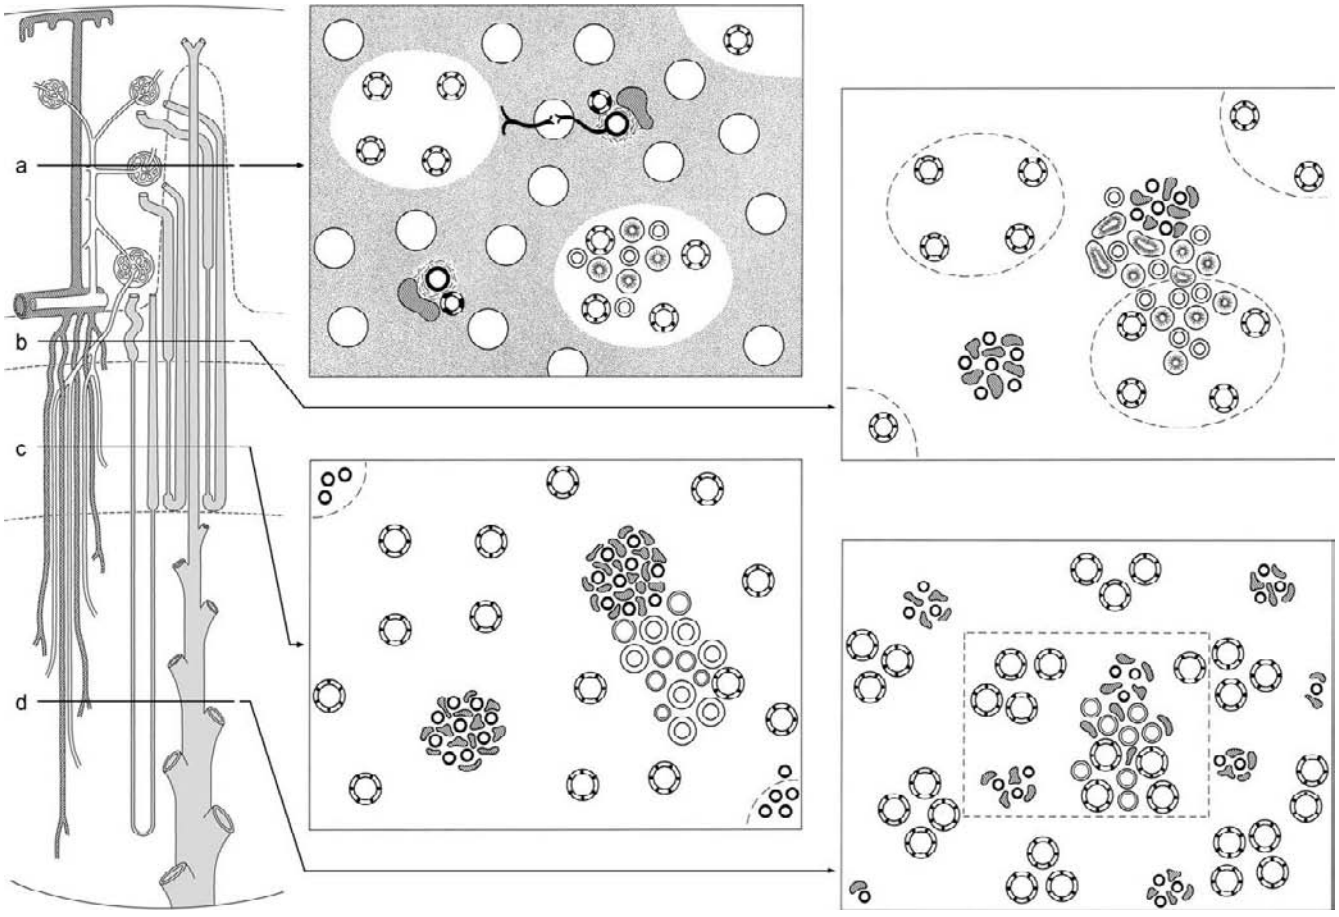

FIGURE 20.20 **Schematics of histotopography.** Histotopography of the kidney as revealed by four successive cross-sections through: (a) cortex; (b) outer stripe; (c) inner stripe; and (d) inner medulla. The simple type of the medulla (rabbit, man) is shown. (*From Koushanpour, E., and Kriz, W. (1986). In "Renal Physiology. Principles, Structure and Function." Springer-Verlag, New York, with permission.*) In the cortex the cortical labyrinth (shaded area) and the medullary rays (white) are shown. The labyrinth contains the cortical radial (interlobular) blood vessels, glomeruli, and the convoluted tubular portions (the latter are not shown). The arcades accompany the interlobular vessels. The medullary rays contain the collecting ducts and the straight proximal and distal tubules. Note the typical grouping of collecting ducts within a medullary ray. In the outer stripe, vascular bundles replace the interlobular vessel axis of the cortex. The continuations of the medullary rays are surrounded by hatched lines. Within these areas the collecting ducts and the loop limbs of superficial and midcortical nephrons are found. The loop limbs of juxtamedullary nephrons are situated around the vascular bundles. In the inner stripe, the vascular bundles are fully developed. Like in the outer stripe, the loop limbs of juxtamedullary nephrons are situated near the bundles, and those from superficial and midcortical nephrons together with the collecting ducts are located distant from the bundles. Note the heterogeneity of the thin limbs: Those of juxtamedullary nephrons lie near the bundles and are thicker in diameter, whereas those of the superficial nephrons lie distant from the bundles. Inner medulla. The area defined by the dashed rectangle corresponds to the entire area shown in section (c). This reduction in size is because short loops and many vasa recta have turned back in the inner stripe. Note the grouping of collecting ducts reflecting their medullary ray arrangement in the cortex. Thin limbs (both descending and ascending) are associated with vasa recta or collecting ducts.

toward the corticomedullary border, the medullary rays increase in width toward the outer stripe.

A regular pattern of the convoluted tubules within the labyrinth is not apparent. Proximal and distal convoluted tubules (the latter constitute only a minor portion of profiles in comparison with proximal tubules) are equally embedded in the dense capillary plexus of this region. A strikingly constant position is occupied by the arcades (if they are present). They ascend within the cortical labyrinth and are grouped immediately around the vascular axes. The topographical relationships within the juxtaglomerular apparatus will be described later.

Within the medullary rays the straight tubules of superficial nephrons (proximal and distal) generally occupy a central position, and those of midcortical nephrons occupy a peripheral position. The collecting ducts are situated between the two groups, and therefore are situated neither in the center nor at the very border of a medullary ray. Efferent arterioles do not enter the medullary rays, but frequently break off into capillaries just at the border between the labyrinth and

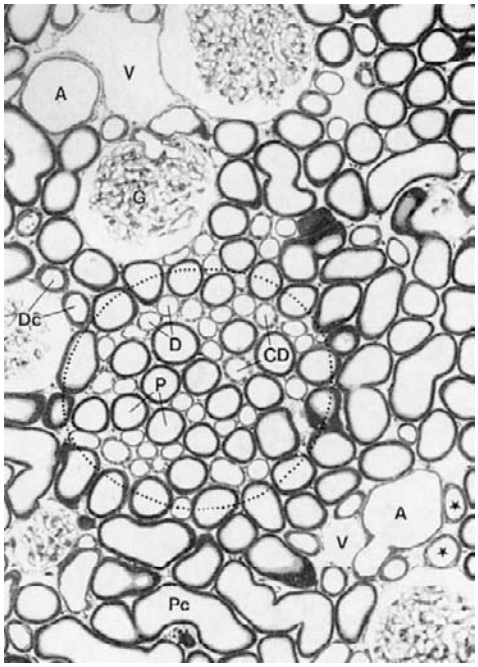

FIGURE 20.21 **Renal cortex of the rat; 1 μm cross-section.** The architectural pattern of the cortex is demonstrated. A medullary ray is delineated by a dashed line. It contains the straight proximal tubules (P), the straight distal tubules (thick ascending limb; asterisks), and the collecting ducts (C). The cortical radial vessels (A: Artery; V: Vein), glomeruli (G), and convoluted proximal (Pc) and distal (D) tubules establish the cortical labyrinth. Arcades (stars) ascend close to the cortical radial vessels (×∼200).

the medullary rays. As a result, the blood supply of the medullary ray tubules is as direct as that of the tubules within the cortical labyrinth. However, blood that perfuses the straight tubules of the medullary rays mixes afterwards with the blood that perfuses the convoluted tubules (*vide supra*).

Medulla

The three regions of the medulla contain different populations of nephron segments. The outer stripe contains straight parts of the proximal tubule (S_3 segments), straight parts of the distal tubule (thick ascending limbs), and collecting ducts. The inner stripe is composed of descending thin limbs, ascending thick limbs (distal straight tubules), and collecting ducts. The inner medulla contains thin descending and ascending limbs, and collecting ducts.

The architectural organization of the medulla can best be described by considering the vascular bundles as central axes and studying how the tubules are arranged around them.[33,112] A "simple" and a "complex" type of renal medulla are distinguished (Figure 20.22); the differences between both are mainly found in the inner stripe.

The vascular bundles develop in the outer stripe (Figures 20.20 and 20.23). At the very beginning of the bundles the straight proximal and distal tubules of juxtamedullary nephrons are grouped immediately around the bundles. In the continuation of the medullary rays, the tubules of superficial and midcortical nephrons, together with the collecting ducts, fill the spaces between the bundles and their adjacent juxtamedullary tubules. In the outer stripe straight proximal tubules and straight distal tubules (thick ascending limbs) should theoretically be present in equal numbers; however, a cross-section through the outer stripe shows that proximal tubular profiles are much more numerous than distal tubules. In the rat, proximal tubules occupy roughly 68% of the space in the outer stripe, in contrast to approximately 13% by the thick ascending limbs, and 5% by the collecting ducts.[41] The dominance of the proximal tubules is rooted in the fact that the straight proximal tubules of juxtamedullary nephrons are not straight (as their name indicates), but rather take a tortuous course when descending through the outer stripe; this holds true for the mouse kidney.[113] In addition, straight proximal tubules are much thicker in diameter than the straight distal tubules, and proximal tubules of juxtamedullary nephrons are even thicker than those of the midcortical and superficial nephrons.[5]

The tubules of the outer stripe are perfused by a specific "capillary" plexus. "True" capillaries, derived from direct branches of efferent arterioles, are few; the dominating "capillary" vessels in the outer stripe are the ascending vasa recta (Figures 20.3 and 20.4b). They traverse the outer stripe as wide tortuous channels closely contacting the tubules like proper capillaries. Because these vessels carry the entire venous blood from the medulla, the outer stripe tubules are mainly supplied by venous blood from deeper parts of the medulla.

The outer stripe varies considerably in thickness among species; in the rat[33] and mouse,[34] it is very well-developed and constitutes approximately one-third of the outer medulla. In contrast, in *Psammomys*,[32] cat,[37] dog,[114] and humans,[37] the outer stripe is very thin.

The inner stripe (Figures 20.20 and 20.24) of the outer medulla is the most constant part of the renal medulla, consisting of the regularly distributed vascular bundles (VB) leaving between them the interbundle region (IBR). Two types of vascular bundles can be distinguished, which form the basis for the discrimination of a "simple" and a "complex" type of medulla.

In most species[5,115] vascular bundles of the simple type are present, which exclusively contain descending and ascending vasa recta. The tubules are found in the IBR and are arranged around the bundles in a pattern similar to that found in the outer stripe. The loops of

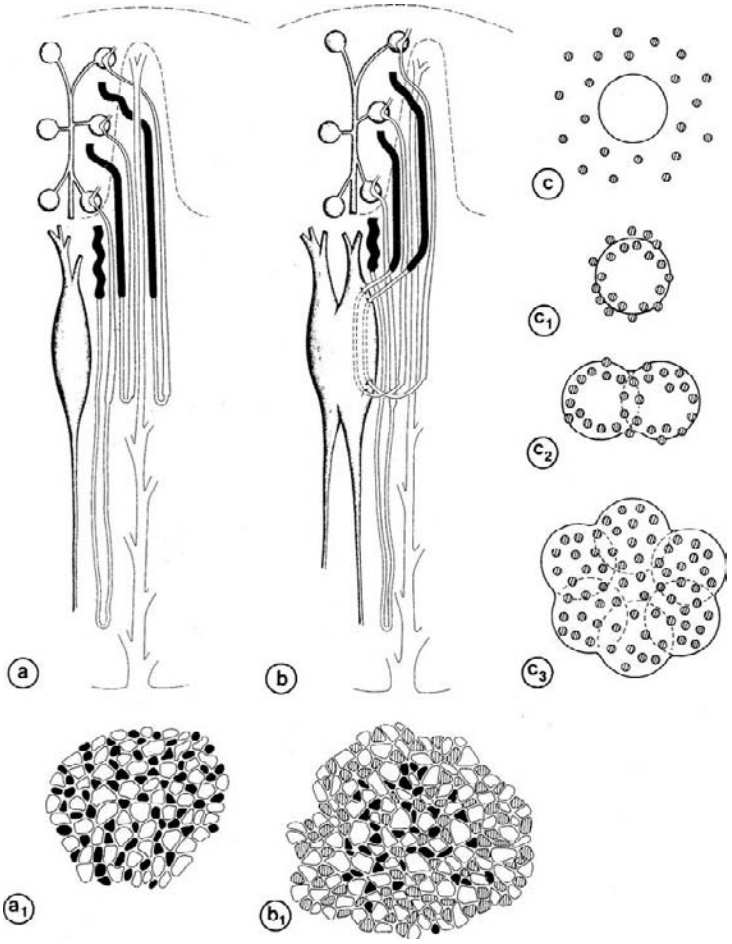

FIGURE 20.22 **Schematic to demonstrate the difference between the simple (a and a_1) and complex (b and b_1) types of medulla.** In the simple medulla (a), loops of Henle surround the vascular bundle according to the pattern established in the cortex. The long loops lie nearest to the bundle, the short loops of superficial nephrons farthest away. The collecting ducts are situated at a distance from the bundle. The bundle itself (a_1) contains only descending (black) and ascending (white) vasa recta. In the complex medulla (b), the descending thin limbs of short loops descend within the vascular bundles. The complex bundle (b_1) contains, in addition to descending (black) and ascending (white) vasa recta, the descending thin limbs of short loops (hatched). *(From ref. [133], with permission.)* (c−c_3): Schematics of cross-sections through vascular bundles to show different degrees of bundle fusing and loop integration in the complex type of renal medulla (c1−c_3) compared with the simple type (c) (Large circle: Vascular bundle; Small hatched circles: Descending thin limbs of short loops). In the simple type of medulla (c), the descending thin limbs of short loops are all located outside the bundle. Complex bundles (c_1−c_3) may be established in different degrees. In rat (c_1), descending thin limbs of short loops are arranged in the periphery of the bundles; bundles generally do not fuse. In mouse (c_2), bundles frequently fuse; descending thin limbs of short loops have penetrated deeper into the bundle. In *Psammomys* or *Meriones* (c_3), bundle fusing has produced giant bundles; descending thin limbs of short loops are distributed over the entire bundle area. *(From ref. [115], with permission.)*

Henle, originating from juxtamedullary nephrons (generally the longest long loops), lie nearest to the bundles, whereas the loops derived from superficial and midcortical nephrons (in most species, short loops) lie distant from the bundles. The collecting ducts are generally arranged in distant rings around the bundles, and are intermingled with loops derived from superficial and midcortical nephrons. Altogether, they are perfused by the dense capillary plexus of the IBR.

The complex type of vascular bundle (Figure 20.25) is present in several rodent species with a high urine concentrating ability, including rat,[33] mouse,[16,34] *Meriones*,[116] and *Psammomys*.[32] It differs from the simple type in that the descending thin limbs of short loops (only of short loops!) descend within the vascular bundle (Figure 20.26). Consequently, the bundles within the inner stripe change from the classic countercurrent arrangement of a rete mirabile, consisting of DVRs and AVRs, to a system in which one ascending tube (AVRs) is closely packed together with two descending tubes (DVRs and SDTLs). In addition, the vascular bundles in the complex type of medulla tend to fuse and to form larger bundles, up to giant bundles (*Psammomys*). These complex bundles are developed at the transition from the outer stripe to the inner stripe, and are maintained only throughout the inner stripe.

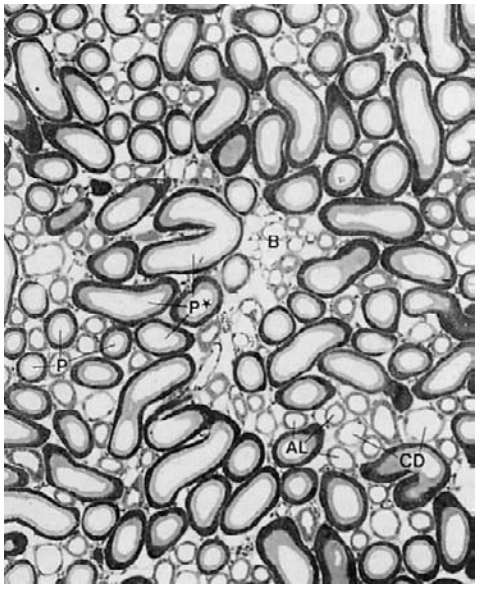

FIGURE 20.23 **Outer stripe of rat kidney; 1 μm cross-section.** The vascular bundle (VB) is surrounded by the straight proximal tubules of juxtamedullary nephrons (asterisk), which are larger in diameter than those of superficial and midcortical nephrons (P), which lie distant from the bundles (Asterisks: thick ascending limb; C: collecting duct). Interstitial spaces are sparsely developed (×∼220).

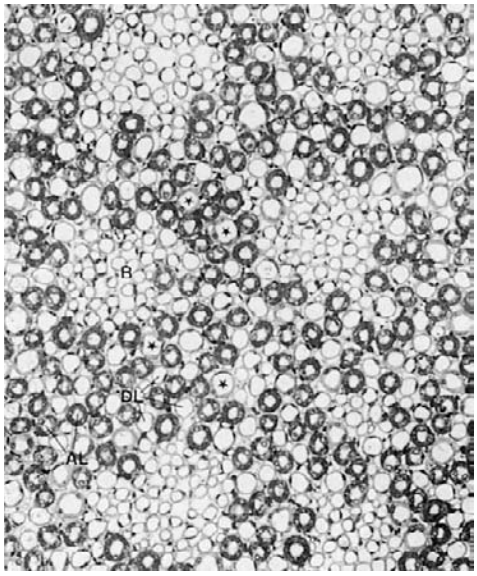

FIGURE 20.24 **Inner stripe of rabbit kidney (simple medulla); 1 μm cross-section.** The vascular bundles (VB) are regularly distributed. The collecting ducts (C) lie distant from the bundles. Descending thin limbs (asterisks) and thick ascending limbs (stars) are situated within the interbundle regions (×∼200).

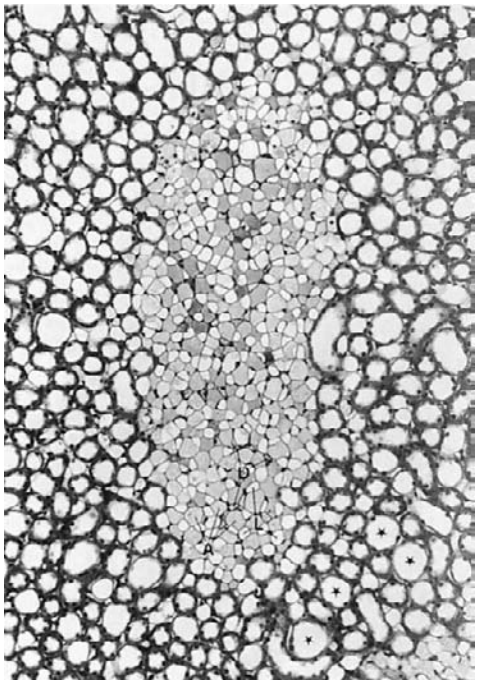

FIGURE 20.25 **Inner stripe of *Meriones shawii* kidney (complex medulla); paraffin cross-section.** The large vascular bundle originates by fusing of primary bundles. In addition to descending (D) and ascending (A) vasa recta, complex vascular bundles contain descending thin limbs of short loops (L). Collecting ducts (some are marked by asterisks) are situated distant from the bundles (×∼190).

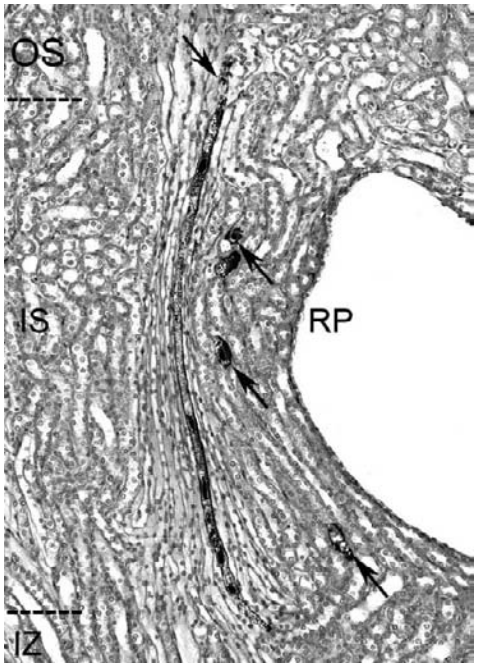

FIGURE 20.26 **Longitudinal section through a vascular bundle in the inner stripe of a gerbil kidney (complex medulla); paraffin section.** One superficial nephron has been injected with microfill; at the transition from the outer (OS) to the inner stripe (IS) the proximal tubule transforms to the intermediate tubule (thin descending limb; left arrow) which descends within the vascular bundle; the tubule leaves the bundle at the border between the inner stripe and the inner zone (IZ), and ascends as thick ascending limb (right arrows) within the interbundle region (RP: Extension of the renal pelvis; ×∼200).

At the border to the inner medulla, the SDTLs leave the bundles, and the fused bundles split into the original number of bundles. The characteristics of the complex type are developed to different degrees in the species so far investigated. A somewhat "gradual" transition from the rat, via the mouse, to *Meriones* and *Psammomys* is observed.

The tubular pattern around these complex bundles is different from that of the simple type. At the border between the outer stripe and inner stripe, the SDTLs leave their position distant from the bundles, then turn toward a bundle and descend within the bundle. Their TALs maintain a position distant from the bundles and near to a collecting duct throughout the outer medulla. As observed in the simple type, the tubules of the interbundle regions are embedded in the dense capillary plexus of the IBR. In contrast to what is observed in the simple type, it is worthwhile to stress the fact that in the complex type only the LDTLs, scattered among the TALs of short and long loops, traverse IBR. Specific variations of this pattern in mice[117] and *Psammomys*[17,32] are described elsewhere.

To understand the possible functional implications of the inner stripe architecture, as well as the differences between the simple type and the complex type, we have to consider precisely the composition of the vascular bundles. The vascular bundles of the simple type contain all descending and all ascending vasa recta servicing the inner medulla. Furthermore, they contain most of the descending vasa recta, which service the inner stripe, but only few of the ascending vasa recta, which drain the inner stripe. The numerical relationship between descending and ascending vasa recta is about 1 to 1 (at the level of the inner stripe). Thus, in the simple type of vascular bundle, the venous blood from the inner medulla contacts the arterial blood that supplies both the inner medulla and the inner stripe of the outer medulla in a countercurrent arrangement. Therefore, inner medullary venous blood may exchange not only with the arterial blood that is predetermined for the inner medulla, but also with blood predetermined for the inner stripe. Substances originating from the inner medulla could be trapped by countercurrent exchange to the inner medulla, but could also be shifted to the inner stripe capillary plexus, and thereby be offered to inner stripe tubules (see below).

In the complex type of medulla, the vascular bundles incorporate the descending thin limbs of short loops. In *Psammomys*, at the level of the inner stripe, the bundles consist of approximately 10% descending vasa recta, 45% ascending vasa recta, and 45% descending thin limbs,[32] with the descending thin limbs being completely surrounded by ascending vasa recta. The difference between the simple and the complex types of bundles is even more pronounced when it is realized that the bundles in *Psammomys* no longer contain any vasa recta servicing the inner stripe. All vasa recta present in the giant bundles of *Psammomys* either descend to the inner medulla or ascend from the inner medulla. The vasa recta servicing the inner stripe in *Psammomys* descend or ascend, respectively, independent of the bundles. Thus, the giant bundles of the inner stripe in *Psammomys* appear to form a countercurrent trap for the inner medullary blood that is located in the inner stripe. In other species with complex bundles (rat, mouse), vasa recta servicing the inner stripe are not as strictly excluded from the bundles as in *Psammomys*; even in these species the vascular bundles appear to be a countercurrent trap for mainly the inner medullary circulation.

The inner medulla develops very differently among species. Species with only short loops of Henle[6] do not have an inner medulla; their urine concentrating ability is poor. All species with high urine concentrating ability have a well-developed inner medulla.[3,118] It is characteristic for the inner medulla to taper from a broad basis to a papilla (or crest). The mass of the inner medulla is therefore unevenly distributed along the longitudinal axis. A study in the rat[2,119] has shown that the decrease in the mass of the inner medulla along the longitudinal axis follows an exponential function. The upper half of the inner medulla accounts for roughly 80% of the total inner medullary volume, and consequently only 20% are left for the papillary half.

With regard to the ratio between Henle's loops and collecting ducts along the inner medulla, considerable differences are found when comparing the base with the tip of the inner medulla, as well as notable interspecies differences.[42] In the rat, the ratio is about 2.5 (2.5 loops per one collecting duct) at the beginning of the inner medulla; this ratio rapidly decreases to about 1 toward the papilla. In the rabbit, the ratio increases from 3 at the beginning of the inner medulla to 9 within the papilla, then later decreases to 5 in the papillary tip. These data all await functional interpretation, thus indicating the limitation of our knowledge concerning structure–function correlations in the inner medulla.

An architectural pattern within the inner medulla is less apparent than in the outer medulla.[5,34,120] Constant histotopographical relationships between certain structures or spatial separations of others do not seem to be as important to the function of the inner medulla compared to the outer medulla. When entering the inner medulla, the vascular bundles already contain a drastically decreased number of vasa recta. Towards the papilla, this number continues to decrease; finally single descending vasa recta enter the tip of the papilla. Ascending vasa recta in the inner medulla generally ascend independent of the bundles, which they finally

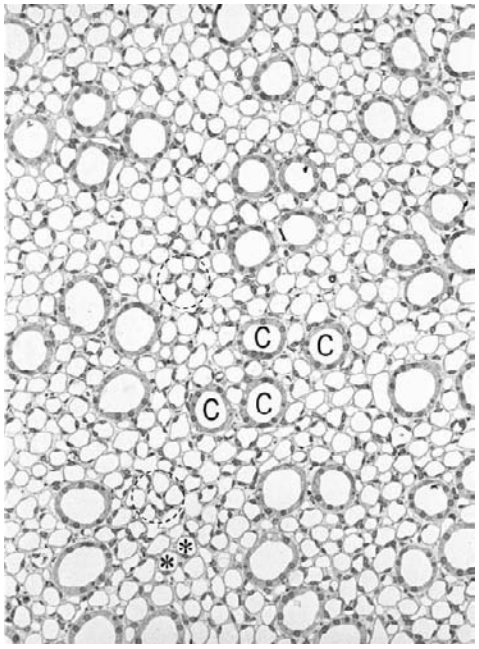

FIGURE 20.27 **Inner medulla of the rabbit kidney; 1 μm cross-section through the upper part.** The collecting ducts are still arranged in groups, reflecting the pattern in the medullary rays of the cortex. Vascular bundles (dashed circles) are poorly delineated. Thin loop limbs (asterisks) lie near collecting ducts (C), as well as near vasa recta of the vascular bundles (× ~240).

join at the border of the inner stripe. Thus, in the inner medulla, the vasa recta are never as closely packed to bundles as they are in the inner stripe.

As far as vascular bundles are discernible, the collecting ducts are generally distanced from them. At the very beginning of the inner medulla, collecting ducts are still arranged in groups that reflect their grouping within the medullary rays of the cortex (Figure 20.27). Joining of collecting ducts first occurs among the ducts of one group. Descending and ascending thin loop limbs, together with individually running vasa recta and capillaries, fill the spaces between the bundle centers and the collecting ducts. DTLs in general tend to be more distant from CDs, whereas ATLs tend to be positioned more closely to CDs[120,121]; a thin limb of Henle, regardless of whether descending or ascending, may be associated with both collecting ducts and/or vasa recta. Obviously, the interactions of the structures in the inner medulla are mediated through the wide interstitial spaces.

With regard to the functional connections of the inner medulla with the outer medulla, it is notable that all descending vasa recta servicing the inner medulla have already been established as individual vessels in the outer stripe and traverse the inner stripe within the bundles. All ascending vasa recta from the inner medulla traverse the inner stripe within the bundles without joining with ascending vasa recta from the inner stripe. The blood flow of the inner stripe and that of the inner medulla are apparently distinct from each other. In the outer stripe, however, venous vasa recta coming up from the inner medulla and those from the inner stripe finally take a similar route. Both traverse the outer stripe as wide capillary channels representing the major capillary supply of the outer stripe tubules.

GLOMERULUS (RENAL CORPUSCLE)

The renal corpuscle consists of a tuft of specialized capillaries that protrudes into Bowman's space (urinary space) surrounded by Bowman's capsule (BC). The tuft consists of specialized capillaries held together by the mesangium and covered – as a whole – by the glomerular basement membrane (GBM), followed by a layer of unique epithelial cells, the podocytes. Traditionally, this layer is called the visceral epithelium of BC, which – at the vascular pole of the glomerular tuft – reflects into the parietal epithelium of BC. Nowadays, the term Bowman's capsule is generally used only for this parietal cell layer which – together with its basement membrane (parietal, BM, PBM) – forms the outer wall of a glomerulus. At the urinary pole, BC transforms into the proximal tubule epithelium, Bowman's space opens into the tubular lumen (Figures 20.28 and 20.29).

The diameters of the – more or less – spherical renal corpuscles in different species range from approximately 100 μm (mouse) up to 300 μm (elephant), in humans they are approximately 200 μm, in rat 120 μm, and in rabbit 150 μm.[29,36,37] In many species (rodents) the diameter of juxtamedullary renal corpuscles may exceed that of midcortical and superficial nephrons by up to 50[22,29,34,37]; this does not hold true for the human kidney.[122]

Architecture of the Glomerulus

The reflection of the parietal epithelium of Bowman's capsule into the visceral epithelium creates an oval opening in the glomerulus, which is called the glomerular hilum. Actually, it is the reflection of the GBM into the PBM (i.e., the basement membrane of the parietal epithelium of Bowman's capsule) that borders the opening. Through it the glomerular arterioles, together with the glomerular mesangium, enter the inner space of the GBM, which forms a complex folded sack. Inside this sack the glomerular capillaries pursue a tortuous course around centrally located mesangial axes. Together, capillaries and mesangium totally fill the labyrinthine spaces inside the GBM. The outer

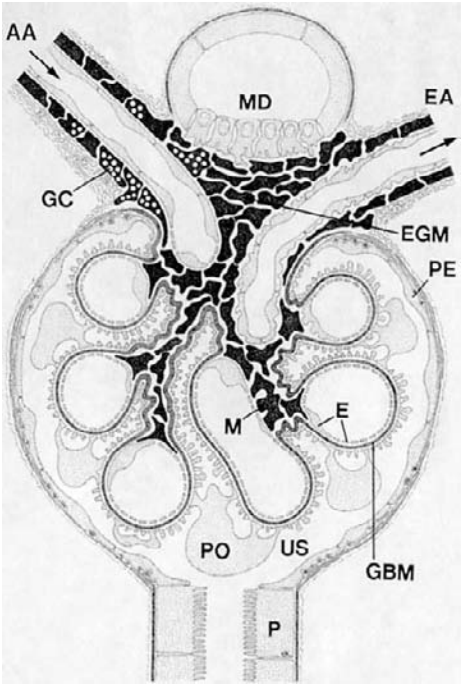

FIGURE 20.28 **Diagram of a longitudinal section through a glomerulus and its juxtaglomerular apparatus (JGA).** The capillary tuft consists of a network of specialized capillaries, which are outlined by a fenestrated endothelium. *(From Cunningham, R. et al. (2005). Am. J. Physiol. Renal Physiol. **289**(4), F933–938.)* Defective PTH regulation of sodium-dependent phosphate transport in NHERF1$^{-/-}$ renal proximal tubule cells and wild-type cells adapted to low-phosphate media. At the vascular pole, the afferent arteriole (AA) branches into capillaries immediately after its entrance; the efferent arteriole (EA) is established inside the tuft and passes through the glomerular stalk before leaving at the vascular pole. The capillary network, together with the mesangium, is enclosed in a common compartment bounded by the glomerular basement membrane (GBM). Note that there is no basement membrane at the interface between the capillary endothelium and the mesangium. The glomerular visceral epithelium consists of highly-branched podocytes (PO) which, in a typical interdigitating pattern, cover the outer aspect of the GBM. At the vascular pole, the visceral epithelium and the GBM are reflected into the parietal epithelium (PE) of Bowman's capsule, which passes over into the epithelium of the proximal tubule (PT) at the urinary pole. At the vascular pole, the glomerular mesangium is continuous with the extraglomerular mesangium (EGM) consisting of extraglomerular mesangial cells and an extraglomerular mesangial matrix. The extraglomerular mesangium, together with the granular cells (G) of the afferent arteriole and the macula densa (MD), establish the JGA. All cells which are suggested to be of smooth muscle origin are shown in black (F: foot processes; N: sympathetic nerve terminals; US: urinary space). *(Adapted from Kriz, W., and Sakai, T. et al. (1988). Morphological aspects of glomerular function.* In *"Nephrology," A. M. Davison, Vol. 1, Proceedings of the X International Congress of Nephrology," 3–23. Bailliere Tindall, London.)*

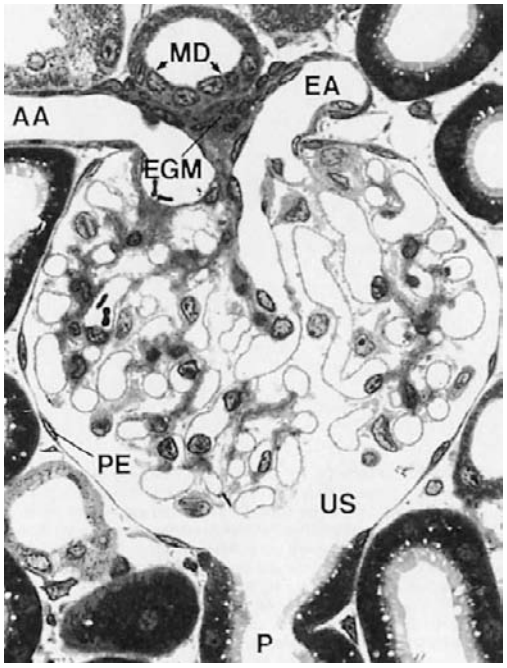

FIGURE 20.29 **Longitudinal section through a glomerulus (rat).** At the vascular pole the afferent arteriole (AA), the efferent arteriole (EA), the extraglomerular mesangium (EGM), and the macula densa (MD) are seen. At the urinary pole the beginning of the proximal tubule is seen (P) (PE: Parietal epithelial of Bowman's capsule; US: Urinary space; LM ×~490).

aspect of the GBM is covered by the visceral epithelium, i.e., by the podocytes. The glomerular tuft therefore consists of the glomerular capillaries and the mesangium inside the sack of the GBM (frequently called the "endocapillary compartment"), and the podocytes covering this sack from outside ("exocapillary compartment").

The glomerular capillaries are derived from the afferent arteriole which – strictly at the entrance level – divides into several (two to five) primary capillary branches.[20,123] Each of these branches gives rise to an anastomosing capillary network which runs toward the urinary pole and then turns back, running toward the vascular pole. Thereby, the glomerular tuft is subdivided into several (2–5) lobules, each of which contains an afferent and efferent capillary portion. The lobules are not strictly separated from each other; some anastomoses between lobules occur. The efferent portions of all lobules together establish the efferent domain of the capillary network out of which the efferent arteriole develops.

In contrast to the afferent arteriole, the efferent arteriole is already established inside the glomerular tuft; thus, the efferent arteriole has a significant intraglomerular segment which runs through the glomerular stalk (Figures 20.30, 20.31 and 20.32).[20] At this site, the efferent arteriole has close spatial relationships to the first branching of the afferent arteriole. After leaving the tuft, the efferent arteriole has a segment which is narrowly associated with the extraglomerular mesangium (see below). The intraglomerular segment is

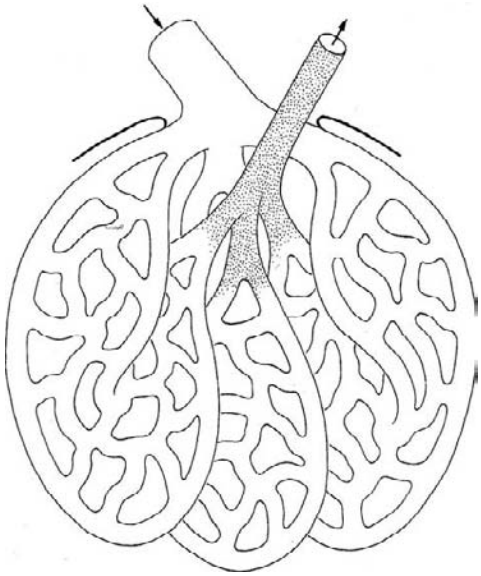

FIGURE 20.30 **Schematic to show the branching pattern of the glomerular tuft.** Immediately after its entrance into the tuft, the afferent arteriole splits into large superficially located capillaries which are the supplying vessels of glomerular lobules (three are shown). The capillaries run toward the urinary pole. After turning back they unite to establish the efferent arteriole still inside the glomerular tuft. Thus, in contrast to the afferent arteriole, the efferent arteriole has an intraglomerular segment (stippled). An afferent and an efferent capillary domain are distinguished. The efferent capillary domain occupies roughly a quarter sector of the tuft; it is partly covered by the afferent domain. *(From Winkler, D., and Elger, M. et al. (1991). Branching and confluence pattern of glomerular arterioles in the rat. Kidney Int. Suppl 32, S2–8, with permission.)*

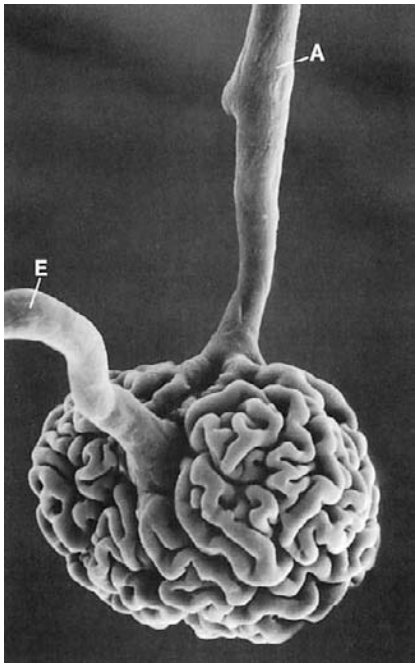

FIGURE 20.31 **Scanning electron micrograph of a vascular cast of a dog glomerulus with afferent (A) and efferent (E) arterioles.** Note the superficially located branching pattern of the afferent arteriole, out of which the afferent capillary domain is supplied. The efferent arteriole emerges from inside of the glomerular tuft.

made up by a continuous endothelium which is fully separated from the GBM by a "mesangial layer" consisting of mesangial cell processes and matrix. Thus, this initial segment of the EA is fully embedded into the mesangium. Along the course through the extraglomerular mesangium, the mesangial and/or extraglomerular mesangial cells in its wall are gradually replaced by smooth muscle cells.[20] Thereafter, the efferent vessel is established as a proper arteriole.

Glomerular capillaries are a specific type of blood vessel whose wall is made up of an endothelial tube only. A small strip of the outer circumference of this tube is in contact with the mesangium, the major part bulges toward the urinary space and is covered by the GBM, followed by the layer of podocyte foot processes. Taken together, these peripheral portions of the capillary wall represent the filtration area. The small juxtamesangial portion of the capillary wall is not underlain by a basement membrane, but directly abuts the mesangium.[124] The glomerular mesangium constitutes the axis of a glomerular lobule, to which the glomerular capillaries are attached by their juxtamesangial portion. Apart from this attachment site, the mesangium is bounded by the perimesangial part of the GBM. Like the peripheral GBM, it is covered at its outer aspect by podocyte processes. At the turning points of the GBM the opposing parts of the GBM are interconnected by podocyte processes that are strongly armed with actin filaments.

The Glomerular Basement Membrane (GBM)

The glomerular basement membrane represents the skeletal backbone of the glomerular tuft. Topographically, the GBM consists of a peripheral (pericapillary) and a perimesangial part. At the border between both parts, the GBM changes from a convex pericapillary into a concave perimesangial course; the turning points are called mesangial angles.[124]

During development, the GBM originates from the fusion of an endothelial and a podocytic basement membrane. In the adult, the collagen component of the GBM is solely derived from podocytes, whereas the laminin component originates from both podocytes and endothelial cells.[125] The GBM is a remarkably stable structure; the *in vivo* loss of protein radioactivity suggests a half-life of more than 100 days.[126] Nevertheless, a continuous turnover occurs,[127,128] but few details are known about where and how new

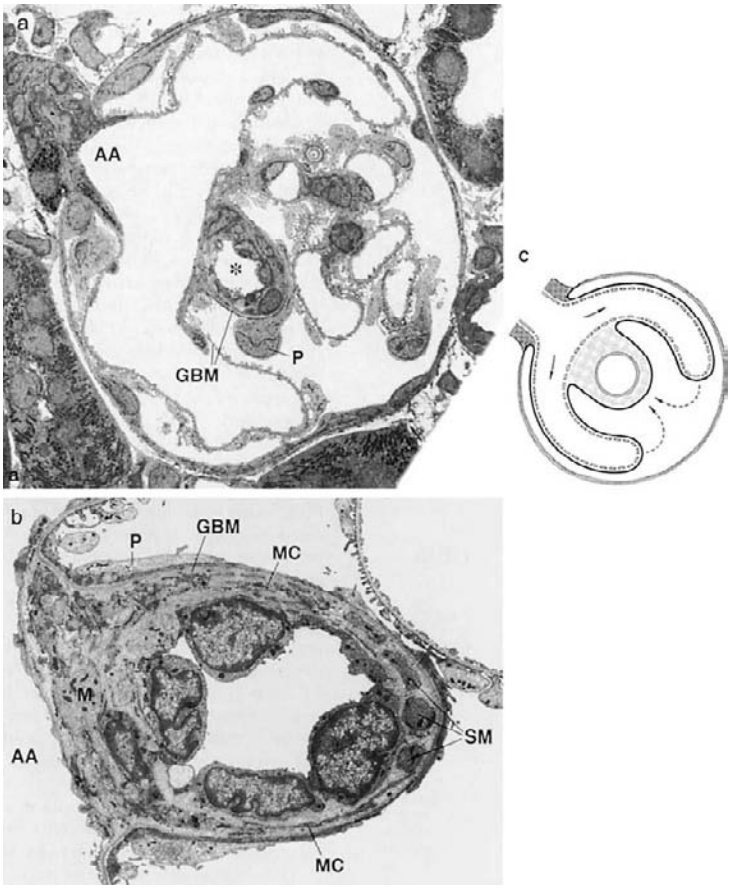

FIGURE 20.32 (a) Narrow association between the afferent arteriole (AA) and the intraglomerular segment of the efferent arteriole (*, EA) as seen in a section approximately 15 μm inside a glomerulus. The afferent arteriole (AA) splits into primary branches. The branching point of the AA has a narrow spatial relationship to the inraglomerular segment of the EA (asterisk), which is located in the center of the tuft. The intraglomerular segment of the EA is enclosed – together with the AA – in a common compartment bordered by the GBM. (b) Higher magnification of the intraglomerular segment in a subsequent section with several conspicuous features: the lumen is narrow; the continuous endothelium consists of four cell bodies that bulge into the lumen; the endothelium is surrounded by a mesangial envelope made up of mesangial cells (MC) and matrix; a few smooth muscle cell processes (*SM*) are interspersed. AA and EA are separated only by mesangial tissue (*M*); there is no basement membrane separating the AA and EA. *P*, cell body of a podocyte attached to the GBM surrounding the EA. (c) Schematic of a cross-section through the glomerular vascular pole, showing the spatial relationships of the AA and EA within the glomerular stalk corresponding to the situation in (a). Immediately after its entry into the glomerulus, the AA splits into wide capillary branches with open endothelial pores. The branching point of the AA has a narrow spatial association with the outflow segment of the EA. The outflow segment is enclosed, together with the AA, in a common compartment bordered by the GBM. The EA is completely surrounded by a layer of mesangial tissue (shown in gray), and is separated from the AA only by this layer; there is no basement membrane between AA and EA. Broken arrows represent blood flow from afferent branches through the capillary network to the outflow segment (TEMs: (a) ×~1500; (b) ×~4300). *(From ref. [20], with permission.)*

components are added, and others removed and degraded. Several extracellular matrix degrading enzymes have been found to be produced by podocytes and mesangial cells[129–131]; however, the relevance of these enzymes to the turnover of the GBM remains to be established.

The GBM varies in width among species. In humans the thickness ranges between 240 and 370 nm, in rat and other experimental animals it is between 110 and 190 nm. In electron micrographs of traditionally fixed tissue the GBM appears as a trilaminar structure made up of a lamina densa bounded by two less dense layers – the lamina rara interna and externa. Recent studies using freeze techniques reveal only one dense layer directly attached to the bases of the epithelium and endothelium.[132]

The major components of the mature GBM include type IV collagen, type II laminin (= laminin 521), heparan sulphate proteoglycans (agrin, perlecan), and the glycoproteins entactin/nidogen[133,134]; type V and VI collagen have also been demonstrated.[135]

The mature GBM is established during the development of a glomerulus from the S-shaped body to the capillary loop stage. During this transition, the collagen

IV α_1 and α_2 chains are replaced by α_3, α_4, and α_5 chains, and the laminin α_1 and β_1 chains are replaced by α_5 and β_2 chains, the γ_1 chain remains preserved, together forming laminin 521.[136,137] The components of the mature GBM are all synthesized by the podocytes. The functional importance of this specific composition of the GBM compared to basement membranes elsewhere in the body becomes evident when looking at their involvement in glomerular diseases: the various forms of Alport syndrome are caused by mutations in the genes encoding the α_3, α_4, and α_5 chains of collagen type IV; Goodpasture syndrome is mediated by antibodies against the α_3 collagen IV chain.[138]

Current models depict the basic structure of the basement membrane as a three-dimensional network of collagen type IV.[139] Monomers of type IV collagen consist of a triple helix of α_3, α_4, and α_5 chains measuring 400 nm in length which, at its carboxy-terminal end, has a large non-collagenous globular domain, called NC1. At the amino-terminus the helix possesses a triple helical rod 60 nm in length, the 7S domain. Interactions between the 7S domains of two triple helices or the NC1 domains of four triple helices allow collagen type IV monomers to form dimers and tetramers. In addition, triple helical strands interconnect by lateral associations via binding of NC1 domains to sites along the collagenous region.

Fibronectin, laminin, and entactin are the glycoproteins of the GBM[140]; the major one is laminin 521. Laminin forms a second network that is superimposed onto the collagenous network. Laminin is a noncollagenous glycoprotein consisting of three polypeptide chains, two of which are glycolylated and cross-linked by disulfide bridges.[137] Laminin, via entactin, binds to specific sites on the polymerized network of type IV collagen, as well as to integrin and dystroglycan surface receptors of the podocytes and endothelial cells (see later). This combined network of type IV collagen and laminin is considered to provide mechanical strength to the basement membrane, and to serve as a scaffold for alignment of other matrix components.

The proteoglycans of the GBM consist of core proteins and covalently bound glycosaminoclycans which are concentrated in the laminae rarae internae and externae. The electronegative charge of the GBM is mainly due to these polyanionic proteoglycans.[141] The major proteoglycans of the GBM are heparan sulfate proteoglycans; most prominent is agrin but perlecan is also present.[142,143] Proteoglycan molecules aggregate to form a meshwork that is kept highly hydrated by water molecules trapped in the interstices of the matrix. Within the GBM heparan sulfate proteoglycans may act as an anticlogging agent to prevent hydrogen bonding and adsorption of anionic plasma proteins and maintain an efficient flow of water through the membrane.

The Cells of the Glomerular Tuft

Within the glomerular tuft three cell types (Figure 20.33) are found which all contact the GBM: (1) mesangial cells; (2) endothelial cells; and (3) podocytes (visceral epithelial cells).

Mesangial cells, together with the mesangial matrix, establish the glomerular mesangium (Figure 20.34). Mesangial cells are quite irregular in shape, with many processes extending from the cell body towards the GBM.[144,145] In these processes (to a lesser extent also in cell bodies) dense assemblies of microfilaments are found which have been shown to contain actin, myosin, and α-actinin.[146]

The processes of mesangial cells run towards the GBM, to which they are attached either directly or mediated by the interposition of microfibrils (see below). The GBM represents the effector structure of mesangial contractility.[124,147] Mesangial−cell−GBM connections are

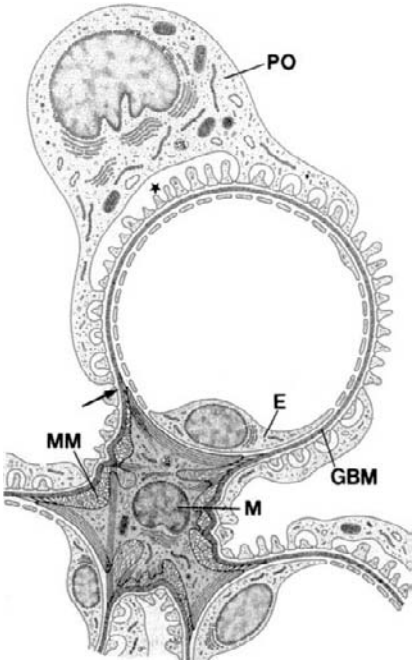

FIGURE 20.33 **Schematic to show the arrangement of the structures in the glomerular tuft.** Part of a glomerular lobule is shown with three glomerular capillaries (two are only partly shown) attached to a mesangial center. The glomerular capillary is made up of a fenestrated endothelium. The peripheral part of the endothelial tube is surrounded by the GBM which, at the mesangial angles (arrow), deviates from a pericapillary course and covers the mesangium. The interdigitated pattern of the podocyte (PO) foot processes form the external layer of the filtration barrier. Note the subcell body space (star). Podocyte foot processes are also found covering the paramesangial GBM. In the center a mesangial cell (M) is shown. Its many processes contain microfilament bundles and run towards the GBM, to which they are connected. The mesangial matrix (MM) contains an interwoven network of microfilaments. *(From Venkatachalam, M. A., and Kriz, W. (1992).* In *"Anatomy of the Kidney. Pathology of the Kidney," 1–92, Heptinstall, R. Little, Brown and Company, Boston, with permission.)*

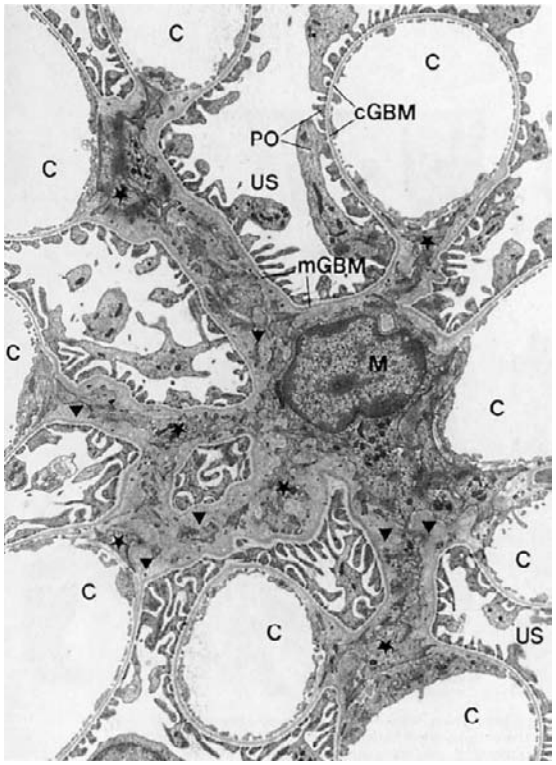

FIGURE 20.34 **Section through a glomerular lobule (rat).** The relationships of glomerular capillaries to the mesangium in the lobule center are seen. Glomerular capillaries (C) and the glomerular mesangium occupy a common compartment enclosed by the glomerular basement membrane (GBM). The mesangial cell body (M) gives rise to several processes (some are marked by stars) which extend toward the peripherally located capillaries. Note the abundant mesangial matrix **(**triangles**)**. The layer of podocytes (PO) covers the outer aspect of the GBM. Thus, neither the GBM, nor the podocyte layer encircle the capillaries completely; both together form a common surface cover around the entire lobule. Therefore, two subdomains of the GBM (as well as of the podocyte layer) can be delineated: the pericapillary (peripheral) GBM (cGBM; faced by podocytes and the endothelium); and the perimesangial GBM (mGBM) bordered by podocytes and the mesangium. The peripheral part of the capillary wall establishes the filtration barrier. Note the mesangial cell body (M) giving rise to many cell processes (some are marked by stars) which are embedded in the mesangial matrix (triangles**)** **(**US: Urinary space; TEM: $\times \sim 5500$).

especially prominent alongside the capillaries. At these sites mesangial cell processes (densely stuffed with microfilament bundles) extend underneath the capillary endothelium towards the mesangial angles of the GBM where they are anchored. Generally, these processes interconnect the GBM from two opposing mesangial angles (Figure 20.35b). Functionally, the microfilament bundles bridge the entire distance between both mesangial angles. In the axial mesangial region as well, numerous microfilament bundles extending through mesangial cell bodies and processes bridge opposing parts of the GBM. The connection of mesangial cell processes to the GBM is mediated by the integrin $\alpha 3\beta 1$ and the Lutheran glycoprotein, which both adhere to the laminin $\alpha 5$ chain.[148]

The mesangial matrix fills the highly irregular spaces between the mesangial cells and the perimesangial GBM (for review see [147,149]). A large number of common extracellular matrix proteins have been demonstrated within the mesangial matrix, including several types of collagen (III, IV, V, and VI), heparin sulfate proteoglycans (including the small proteoglycans biglycan and decorin),[150] fibronectin, laminin, and entactin, as well as fibrillin 1 and other specific elastic fiber proteins.[140,151–153] Among these components, fibronectin is the most abundant, and has been shown to be associated with microfibrils.[151,154]

The basic ultrastructural organization of the matrix is a network of microfibrils. In specimens prepared for TEM by routine methods a fine filamentous network is seen, which possibly corresponds to collagenous filaments. In specimens prepared by a technique that avoids osmium tetroxide and uses tannic acid for staining, the mesangial matrix is seen to contain abundant elastic microfibrils.[124,155] Microfibrils are unbranched, noncollagenous tubular structures that have an indefinite length and are about 15 nm in diameter. They form a dense three-dimensional network establishing a functionally continuous medium anchoring the mesangial cells to the GBM.[147,153] Distinct bundles of microfibrils may be regarded as "microtendons" that allow the transmission of contractile force of mesangial cells to specific sites of the GBM, predominantly to the mesangial angles.[124,155] α-8 integrin serves as a specific matrix receptor in the mesangium.[156]

Glomerular endothelial cells (Figures 20.33, 20.34 and 20.35) are large flat cells consisting of a cell body (which contains all the usual cell organelles) and densely perforated peripheral parts. These regions are extremely attenuated and characterized by round to oval pores varying in diameter between 50 and 100 nm. Unlike fenestrae (unfortunately, these pores are frequently also called "fenestrae"), the pores of glomerular endothelial cells lack a diaphragm, they are virtually open[26]; (Figures 20.36b and 20.37b). Fenestrae bridged by diaphragms in glomerular capillaries are only found along the intraglomerular segment of the efferent arteriole and its tributaries.[20] In rat, about 60% of the capillary surface is covered by the porous regions; the total area of pores occupies about 13% of the capillary surface.[157] Micropinocytotic vesicles are very rare in glomerular endothelial cells, corroborating the fact that the open pores make transcytotic processes unnecessary.

Glomerular endothelial cells contain the usual inventory of cytoplasmic organelles, generally located within the cell body cytoplasm. The endothelial skeleton comprises intermediate filaments and microtubules; individual pores are lined by clusters of microfilaments.[158]

The luminal membrane of endothelial cells is highly negatively charged, due to a cell coat that also fills the

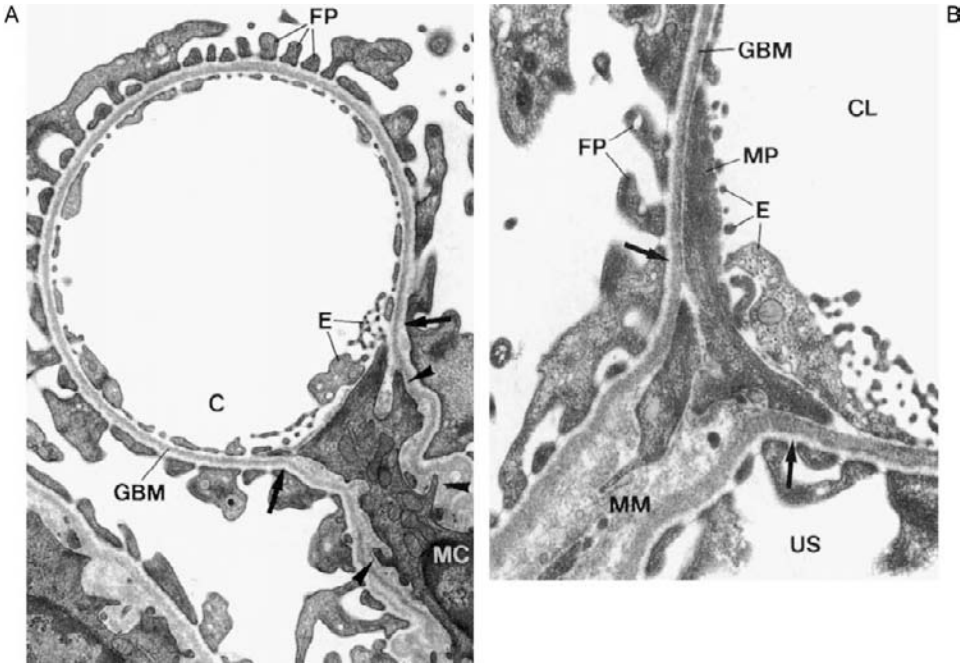

FIGURE 20.35 **(a) Overview of a glomerular capillary (mouse).** Within the mesangium, a mesangial cell (MC) is seen whose processes extend toward the peripherally located capillary (C). Microprojections (arrowheads) originating from the primary process extend toward the GBM. Note that the GBM (as well as the podocyte layer) deviates from its pericapillary course at the two mesangial angles (marked by arrows), continuing as a cover of the mesangium. Thus, the juxtamesangial part of the glomerular capillary lacks a basement membrane; at this site the endothelium is directly exposed to the mesangium. The capillary endothelium is thin and fenestrated. The podocyte layer consists of interdigitating foot processes (FP) which abut the GBM on its outside surface (TEM: ×~13,500). **(b) Capillary–mesangium interface (rat).** At this site a basement membrane is not developed. Beneath the endothelium, tongue-like mesangial cell processes (MP) are found which run toward both opposing mesangial angles. They contain microfilament bundles, which obviously interconnect the GBM of both mesangial angles (marked by arrows) (CL: capillary lumen; US: urinary space; MM: mesangial matrix; FP: foot processes; TEM: ×~23,000).

pores like "sieve plugs".[159] It consists of several polyanionic glycoproteins including a sialoprotein called podocalyxin, which is considered as the major surface polyanion of glomerular endothelial as well as epithelial cells.[160] Endothelial cells are active participants in the processes controlling coagulation, inflammation and immune processes. Glomerular endothelial cells synthesize and release endothelin-1, endothelium-derived relaxing factor (EDRF),[161] and PDGF B.[162] Glomerular endothelial cells have receptors for VEGF A and angiopoetin that are produced by podocytes.[163,164] The continuous stimulation of glomerular endothelial cells by podocyte-derived VEGF A has major relevance for the maintenance of glomerular capillaries and the formation of pores instead of fenestrae.[165]

Within the conspicuously narrow portion of the efferent arteriole (outflow segment) the endothelial cells are arranged in an eye-catching pattern: their cell bodies bulge into the lumen being longitudinally stretched, suggesting a specific shear stress receptor of glomerular capillaries.[20,166]

Mature podocytes are highly-differentiated cells. In the developing glomerulus at the S-shaped body stage, podocytes are a simple polygonal shape connected by apical tight junctions. At the transition to the capillary loop stage the mitotic activity of the cells is completed, the interdigitating foot process pattern with basally located slit membranes instead of apical tight junctions is established, and the final number of podocytes is determined. In rat this point is reached soon after birth, in man it is established during prenatal life. Differentiated podocytes are unavailable for regenerative cell replication[167]; thus in the adult, lost podocytes cannot be replaced by division of the remaining cells. The only way to replace the function of lost podocytes is the hypertrophy of the remaining podocytes.

Podocytes have a voluminous smooth surfaced cell body (Figures 20.36a and 20.37a), which floats within the urinary space; it appears to adapt in shape to the surrounding flow conditions created by the filtrate. The cells give rise to long primary processes (frequently branching another time) that extend towards the capillaries, finally splitting apart into terminal processes, called foot processes, which affix to the GBM (Figures 20.36 and 20.37a). The foot processes of neighbouring podocytes regularly interdigitate with each other, leaving meandering slits (filtration slits) between them, which are bridged by an extracellular structure,

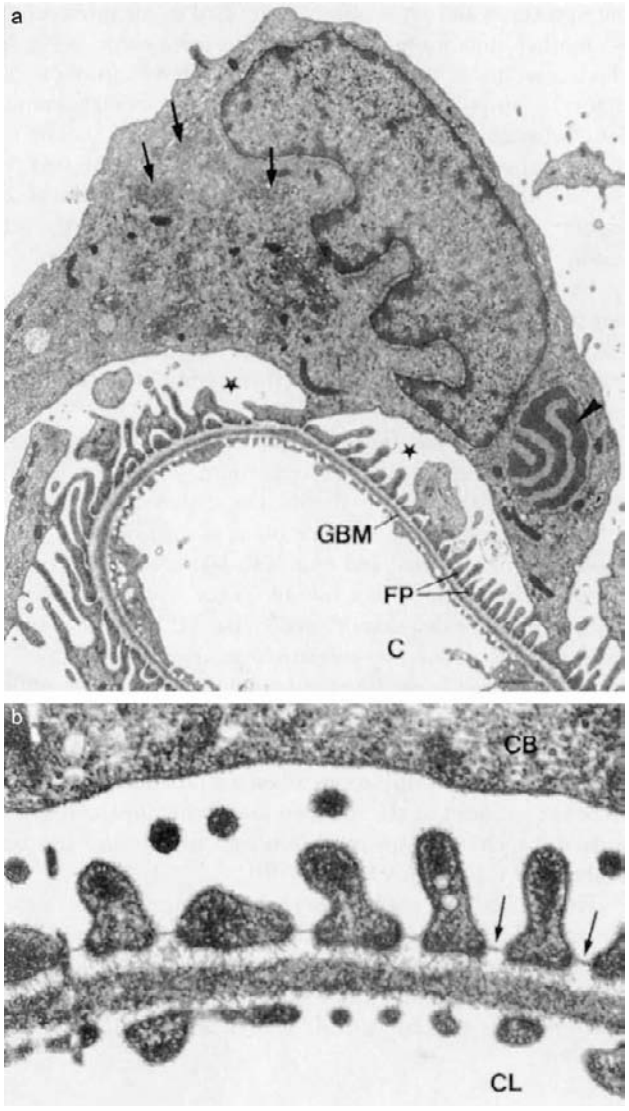

FIGURE 20.36 **(a) Podocyte (rat)**. The cell body contains a large nucleus with indentations. The cytoplasm contains a well-developed Golgi apparatus (arrows), and a conspicuous lamellated inclusion body (arrowhead). The cell processes run toward the GBM forming the interdigitating pattern of foot processes (FP) there. Note the subcellbody space (stars) (C: capillary; TEM: × ~7600). **(b) Filtration barrier (rat)**. The peripheral part of the glomerular capillary wall comprises three layers: the endothelium with large open pores; the basement membrane (GBM); and the layer of interdigitating podocyte foot processes. The GBM consists of a lamina densa, a lamina rara interna toward the endothelium, and a lamina rara externa toward the epithelium. Note the slit diaphrams bridging the floor of the filtrations slits (arrows) (CL: capillary lumen; CB: cell body of a podocyte; TEM: ×~57,000).

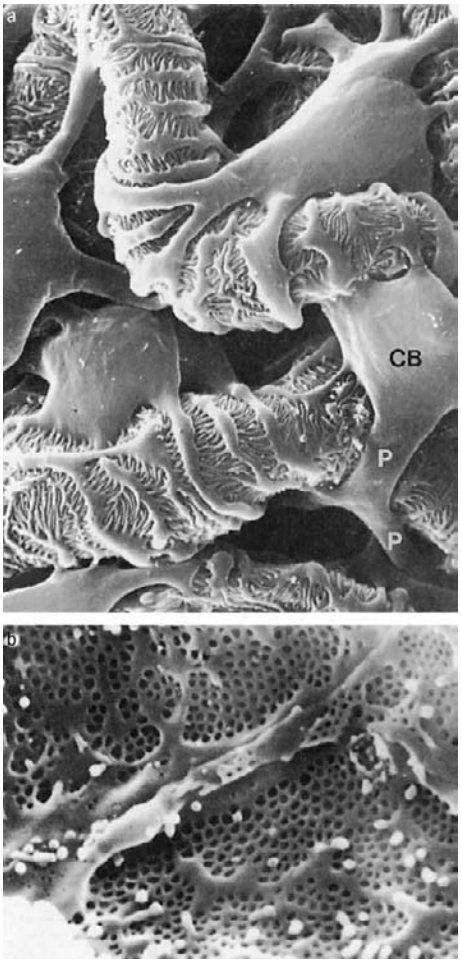

FIGURE 20.37 **(a) Outer surface of glomerular capillaries (rat).** Processes (P) of podocytes run from the cellbody (CB) toward the capillaries where they ultimately split into foot processes. By interdigitation, foot processes from neighbouring cells create the filtration slits (SEM: ×~3400). **(b) Inner surface of a glomerular capillary (rat).** The open fenestrations (not bridged by a diaphragm) are shown (SEM: ×~16,000).

the so-called slit diaphragm. Podocytes are polarized epithelial cells with a luminal and a basal cell membrane domain; the latter corresponds to the sole plates of the foot processes which are embedded into the GBM to a depth of 40 to 60 nm. The border between basal and luminal membrane is represented by the insertion of the slit diaphragm.[167]

The cell body contains a prominent nucleus, a well-developed Golgi system (Figure 20.36a), abundant rough and smooth endoplasmic reticulum, prominent lysosomes (including abundant multivesicular bodies), and many mitochondria. In contrast to the cell body, the cell processes contain only a few organelles (except from multivesicular bodies). The density of organelles in the cell body indicates a high level of anabolic, as well as catabolic, activity. In addition to the work necessary to sustain the structural integrity of these specialized cells, all components of the GBM are synthesized by podocytes.[133,143]

A well-developed cytoskeleton accounts for the complex shape of the cells. In the cell body and the primary processes, microtubules and intermediate filaments (vimentin, desmin) dominate, whereas

microfilaments are densely accumulated in the foot processes. In addition, in the cell body and the primary processes, microfilaments are seen as a thin layer underlying the cell membrane.[168,169]

The prominent bundles of microtubules in the large processes are associated with microtubule-associated proteins, including MAP3/MAP4 and tau.[170] Moreover, like in neuronal dendrites, the microtubules of the podocyte foot processes are non-uniformly arranged with peripheral plus- and minus-end microtubules associated with the specific protein CHO1/MKLP1.[171] In addition, the large processes contain the intermediate type filament protein vimentin.[168]

In the foot processes a complete microfilament-based contractile apparatus is present. The microfilaments form loop-shaped bundles, with their limbs running in the longitudinal axis of the foot processes. The bends of these loops are located centrally at the transition to the primary processes, and are probably connected to the microtubules by "tau" which is concentrated at those sites.[172] Tau is known from other places to mediate connections between microtubules and microfilaments.[173] The microfilament bundles contain actin, myosin II, α-actinin, and synaptopodin[168,174,175]; synaptopodin, a novel podocyte-specific actin-associated protein interacts with α-actinin inducing the formation of long unbranched parallel bundles of microfilaments.[176] Peripherally, the actin bundles anchor in the dense cytoplasm associated with the basal cell membrane of podocytes, i.e., the sole plates of foot processes.[167]

Anchoring of the sole plates to the GBM is achieved by specific transmembrane receptors; two systems are so far known (Figure 20.38). First, a specific integrin heterodimer, consisting of $\alpha_3\beta_1$ integrins, which bind within the GBM to collagen type IV, fibronectin, and laminin 521.[177–179] Second, a dystroglycan complex connects the intracellular molecule utrophin to laminin 521, agrin, and perlecan in the GBM.[180,181] Both integrins and dystroglycans are coupled via adapter molecules (paxillin, vinculin, α-actinin) to the podocyte cytoskeleton, allowing outside-in and inside-out signaling, as well as transmission of mechanical force in both directions. A major role in this issue is played by the integrin-linked kinase.[182]

A huge body of data has been accumulated in recent years concerning the inventory of receptors and signaling processes starting from podocytes. cGMP signaling

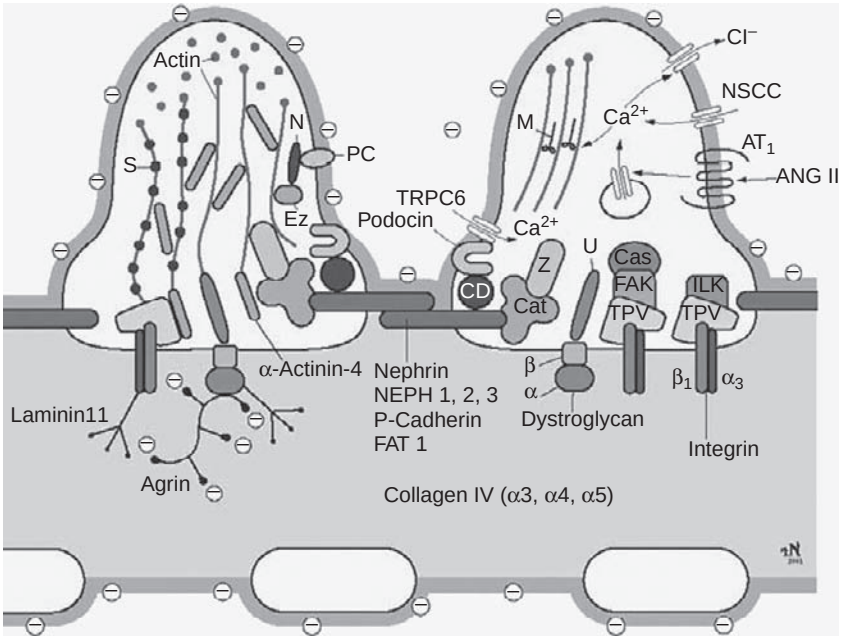

FIGURE 20.38 **Glomerular filtration barrier.** (*Modified from Endlich, K. H., Kriz, W., and Witzgall, R. (2001). Update in podocyte biology. Curr. Opin. Nephrol. Hypertens.* ***10****, 331–340.*) Two podocyte foot processes bridged by the slit membrane, the GBM, and the porous capillary endothelium are shown. The surfaces of podocytes and of the endothelium are covered by a negatively-charged glycocalyx containing the sialoprotein podocalyxin (PC). The GBM is mainly composed of collagen IV (α_3, α_4, and α_5), of laminin 11 (α_5, β_2, and γ_1 chains) and the heparan sulphate proteoglycan agrin. The slit membrane represents a porous proteinaceous membrane composed of (as far as is known) Nephrin, Neph1, 2, and 3, P-cadherin, and FAT1. The actin-based cytoskeleton of the foot processes connects to both the GBM and the slit membrane. With regard to the GBM, β_1/α_3 integrin dimers specifically interconnect the TVP complex (talin, paxillin, vinculin) to laminin 11; the β and α dystroglycans interconnect utrophin to agrin. The slit membrane proteins are joined to the cytoskeleton via various adaptor proteins, including Podocin, Zonula occludens protein 1 (ZO-1; Z), CD2-associated protein (CD), and catenins (Cat). TRPC6 associates with podocin (and nephrin; not shown) at the slit membrane. Among the many surface receptors only the angiotensin II (ANG II) type 1 receptor (AT1) is shown (Additional abbreviations: Cas: P130Cas; Ez: ezrin; FAK: focal adhesion kinase; ILK: integrin-linked kinase; M: myosin; N: NHERF2 (Na^+-H^+ exchanger regulatory factor); NSCC: Non-selelctive cation channel; S: Synaptopodin).

(stimulated by ANP, BNP, and CNP, as well as by NO), cAMP signaling (stimulated by prostaglandin E_2, dopamine, isoproterenol, PTH/PTHrP), and Ca^{2+} signaling (stimulated by a huge number of ligands including angiotensin II, acetylcholine, PGF_2, AVP, ATP, endothelin, histamine) have been identified. Among the cation channels, TRPC6, a nonselective Ca^{2+} channel, has recently received attention, since mutations in the respective gene lead to hereditary FSGS.[183,184] The major target of this signaling orchestra is the cytoskeleton, the concrete effects, however, are poorly-understood. Other receptors, such as for C3b,[185] TGFß,[186,187] FGF2,[188] and various other cytokines and chemokines have been shown to be involved in the development of podocyte diseases (for details see [189]). Megalin, a multi-ligand endocytotic receptor, is associated with coated bits[190–192]; it represents the major antigen of rat Heymann nephritis.[193]

The filtration slits are the site of convective fluid flow through the visceral epithelium. They have a width of 30 to 40 nm and are bridged by the slit membrane. The structure and molecular composition of this proteinaceous membrane is insufficiently understood. Chemically fixed and tannic acid treated tissue reveals a zipper-like structure with a row of "pores" approximately 4 × 14 nm on either side of a central bar.[194] According to its dimension and its components (as far as is known) the slit diaphragm may be considered as a specific adherens-like intercellular junction. Intensive research in recent years has uncovered several transmembrane proteins that participate in the formation of the slit membrane, including nephrin,[195] Neph1,[196] P-cadherin,[197] and FAT[198] (Figure 20.38). Other molecules, such as ZO1,[199] Podocin,[200] CD2AP,[201] and catenins mediate the connection to the actin cytoskeleton (see below). Nephrin is a member of the immunoglobin superfamily (IgCAM); its gene NPHS1 has been identified as the gene whose mutations cause congenital nephritic syndrome of the Finnish type.[195] In addition to its role as a structural component, nephrin acts as a signaling molecule that can activate MAP kinase cascades.[202] Neph1 is considered as a ligand for nephrin. Podocin belongs to the raft associated stomatin family, whose gene NPHS2 is mutated in a subgroup of patients with autosomol-recessive stereoid-resistent nephrotic syndrome.[200] These patients show disease onset in early childhood and rapid progression to end-stage renal failure. Podocin interacts with nephrin and CD2AP.[203] FAT is a novel member of the cadherin superfamily, with 34 tandem cadherin-like extracellular repeats and a molecular weight of 516 kDa.[204] Because FAT has a huge extracellular domain, it is speculated that it dominates the molecular structure of the slit membrane[198]; the FAT mutant mouse fails to develop a slit membrane.[205] P-cadherin[197] is thought to mediate the linkage to ß- and γ-catenin with its intracellular domain, a complex which then connects to the actin cytoskeleton via α-catenin and α-actinin. Taken together, many components of the slit membrane are known, but an integrative model of its substructure including all components is so far lacking.

The luminal membrane and the slit diaphragm are covered by a thick surface coat which is rich in sialoglycoproteins (including podocalyxin, podoendin, and others) that are responsible for the high negative surface charge of the podocytes.[206,207] Podocalyxin is anchored to the actin cytoskeleton beneath the cell membrane via the linker protein NHERF 2 (Na^+/H^+ exchanger regulatory factor 2) and ezrin.[208,209] The surface charge of podocytes contributes to the maintenance of the interdigitating pattern of the foot processes. In response to neutralization of the surface charge by cationic substances (e.g., protamine sulfate), the foot processes retract, resulting in what is called "foot process effacement".[210]

Filtration Barrier

The walls of glomerular capillaries represent a specific barrier which is very permeable to water, and yet able to prevent all but very minute losses of serum albumin and other major plasma proteins from the circulation. The glomerular capillary wall consists of three distinct layers (Figures 20.36b and 20.37). Starting at the capillary lumen, there is the porous endothelium, followed by the GBM, and the layer of interdigitating foot processes with the filtration slits in between.

The high hydraulic permeability of this barrier suggests that the filtrate pathway is entirely extracellular, passing through the endothelial fenestrae, across the GBM, and through the slit diaphragms of the filtration slits. According to a calculation by Drumond and Deen,[211] the hydraulic resistance of the endothelium is negligible. The GBM and the filtration slits each make up roughly one half of the total hydraulic resistance of the filtration barrier.

Charge, size, and shape determine the specific permeability of a macromolecule. It is now generally accepted that the charge barrier plays an important part in preventing polyanionic macromolecules such as albumin from passing through the glomerular filter. All components of the glomerular filter are heavily laden with negative charges.[212] Recent investigation[213,214] suggests that the negative residues of the endothelium play the major role in establishing a negative charge field which considerably decreases the entry of polyanionic macromolecules, i.e., albumin, into the filter.

With regard to the size selectivity, direct experimental findings,[211,215,216] as well as recent findings about the molecular composition of the slit membrane (see above) and the consequences of genetic mutations in these components, suggest that it is for the major part the slit membrane which is responsible for the size selectivity; it appears to be the main barrier for uncharged large molecules.

There is another major unresolved problem in glomerular physiology, namely the regulation of the ultrafiltration coefficient Kf. Kf is the product of the local hydraulic permeability and the filtration area. There has been a widespread belief that Kf is regulated through changes in the filtration area due to an action of the mesangium.[217] However, the structural arrangement of the mesangium,[124] as well as several morphometric studies,[218,219] do not support such an assumption. Dimensional changes in just the slit membrane area have also been regarded as a reasonable and, theoretically, very effective site to change Kf.[220] In pathological conditions, e.g., in membranous nephropathy,[221] the decrease in Kf correlates perfectly with the decrease in total slit length. With respect to acute regulatory mechanisms under physiological conditions, however, no convincing morphometric data have been published showing that changes in Kf are correlated with corresponding dimensional changes in the slit membrane. Thus, the question of where and how Kf is regulated remains an open problem.

Stability of the Glomerular Tuft

The glomerular tuft is constantly exposed to comparably high intraglomerular pressures within glomerular capillaries and mesangium. The high intraglomerular pressures challenge not only the glomerular capillaries themselves, but also the folding pattern of the glomerular tuft. Increased pressures lead to loss of the folding pattern, and to dilation of the glomerular capillaries. Therefore, we have to ask what are the specific structures and mechanisms that counteract the expansile forces in the glomerular tuft. To answer this question we have to distinguish between the structures and mechanisms maintaining: (1) the folding pattern of the glomerular tuft; and those maintaining (2) the width of glomerular capillaries (Figure 20.39).

The folding pattern of the glomerular tuft is primarily sustained by the mesangium.[124,147,222] Mesangial cells are connected to the GBM by their contractile processes (see above); by centripetal contractions they maintain the infoldings of the GBM, thereby allowing the capillaries to arrange in the peripheral expansion of the GBM. This supporting role of mesangial cells is best illustrated under circumstances with loss of mesangial cells, such as Thy-1 nephritis.[223] Under those circumstances the folding pattern of the GBM is progressively lost, finally resulting in mesangial aneurysms. Podocytes clearly contribute to the maintenance of the folding pattern by specific cell processes that interconnect opposing parts of the GBM from outside within the niches of the infoldings. This function is again clearly illustrated in Thy-1 nephritis under circumstances with loss of mesangial support: podocytes are capable of maintaining a high degree of the GBM folding pattern for 2–4 days, after which they fail and mesangial aneurysms become prominent.[223]

The width of glomerular capillaries, in the long run, is probably controlled by growth processes accounting for different-sized capillaries. The width of a given capillary, in an acute situation being exposed to changes in blood pressure, appears to be stabilized by the GBM which is a strong elastic structure[224] and, together with the mesangial cell bridges (see above), is capable of developing wall tension.[147,225] In addition, the tensile strength of the GBM is reinforced by podocytes. Podocytes are a kind of pericyte; their foot processes represent a unique type of pericyte process which, like elsewhere in the body, counteract the dilation of the vessel. Podocyte processes are firmly attached to the underlying GBM (see above); their cytoskeletal tonus counteracts the elastic extension of the GBM. Podocytes cannot be replaced by any other cell; failure in this function will lead to capillary dilation.

Parietal Epithelium of Bowman's Capsule

The parietal layer of Bowman's capsule consists of squamous epithelial cells resting on a basement

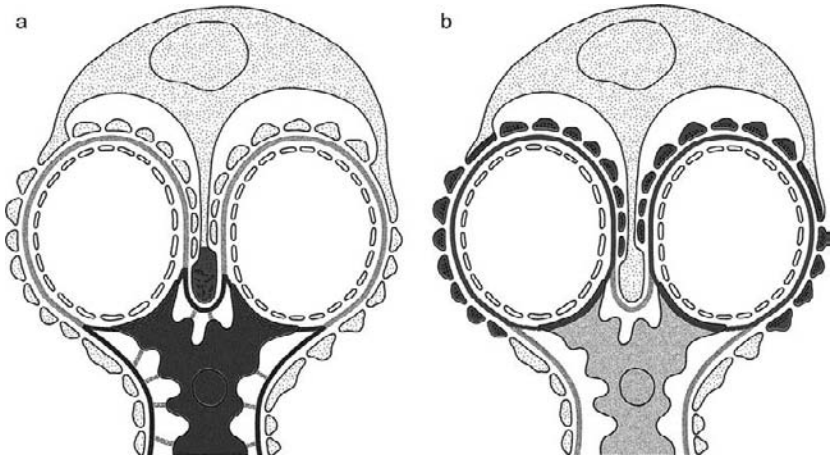

FIGURE 20.39 **Schematic to show the mechanisms that stabilize the glomerular tuft against expansion (relevant structures are highlighted in dark gray).** The folding pattern of the GBM is thus stained by mesangial cells from inside, and by specific podocyte processes located in the depth between two capillaries from outside. The width of capillaries against transmural pressure gradients is maintained by wall tension, which is generated by the rigidity of the GBM, by the mesangial cell processes that interconnect opposing turning points of the GBM, and by the tonus of podocyte foot processes.

membrane (Figure 20.29). The cells are of polygonal shape and contain prominent bundles of actin filaments running in all directions. Microfilament bundles are especially prominent in the parietal cells surrounding the vascular pole, where they are located within cytoplasmic ridges that run in a circular fashion around the glomerular entrance.[20]

The basement membrane of the parietal epithelium (PBM) is, at variance with the GBM, composed of several dense layers which are separated by translucent layers and contain bundles of fibrils.[226] Recent studies suggest a role of type XIV collagen in the organization of the multilayered PBM.[227] In contrast to the GBM, the predominant proteoglycan of the PBM is a chondroitin sulfate proteoglycan.[149] The transition from the GBM to the PBM borders the glomerular entrance. This transitional region is mechanically connected to the smooth muscle cells of the afferent and efferent arterioles as well as to extraglomerular mesangial cells.

At the urinary pole, the flat parietal cells transform into proximal tubule cells. In some cases the flat cells may continue for a certain distance as a so-called neck segment of the tubule (rabbit)[228] or the typical proximal tubule epithelium generally starts within the glomerular capsule. This is the case in the mouse,[824] most pronounced in males.

In rare cases, parietal epithelial cells may be replaced by podocytes ("parietal podocytes") which display a process pattern identical to that of podocyte proper of the tuft.[229] At such sites, the PBM is similar to the GBM and capillaries may attach from outside. As shown recently, parietal podocytes are regularly found when ß-catenin is deleted in renal epithelial cells during development at the S-shaped body stage.[230] Recent observations suggest that a niche of glomerular epithelial stem cells resides within the parietal epithelium at the transition to the proximal tubule.[231,232]

It is an intriguing hypothesis that proliferating stem cells from this locus may transform into podocytes and may reach the tuft via the transitions of the epithelia at the glomerular vascular pole. Migration of parietal cells via the vascular pole and subsequent transition into podocytes has been shown to occur in the new-born mouse.[233] However, evidence that such a process may be of any relevance in the adult has so far not been presented.[233]

STRUCTURAL ORGANIZATION OF RENAL ELECTROLYTE TRANSPORTING EPITHELIA

General Overview of Renal Epithelial Organization

The renal tubular epithelia function as selective barriers between the tubular fluid in the luminal compartment and the interstitial compartment that communicates with the blood compartment. The epithelium consists of a single layer of cells, resting on a basement membrane composed of extracellular matrix. The cells are interconnected by *junctional complexes* that encircle each individual cell like a belt. The *tight junction* (zonula occludens) separates the luminal compartment from the lateral intercellular space and is the boundary between the apical plasma membrane domain, facing the tubular fluid, and the basolateral membrane domain, which lines the intercellular compartments and is in contact with the basement membrane. The *intermediate junctions* (zonula adherens), and the patches of *desmosomes* (maculae adherentes) provide mechanical adherence. Gap junctions that provide intercellular communication exist exclusively in the proximal tubule.

This basic organization of the epithelium (Figure 20.40) implies two *transepithelial transport pathways* for solutes and macromolecules: (1) the paracellular pathway across the tight junctions and the lateral intercellular spaces (the passage of solutes through the paracellular pathway is driven by the transepithelial electrochemical and oncotic gradients); (2) the transcellular pathway across the luminal membrane domain, the cellular cytoplasm and the basolateral membrane domain, and *vice versa* (the passage of solutes via the transcellular pathway occurs mostly against electrochemical gradients and is energy-dependent).

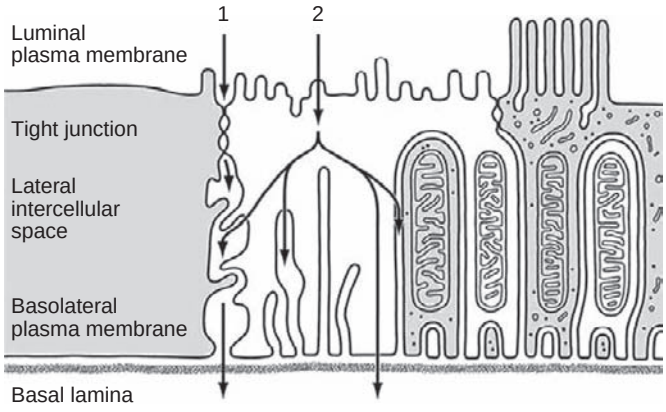

FIGURE 20.40 **Schematic drawing, demonstrating the essential structural features of renal transporting epithelia.** (1) Paracellular route through the tight junction and the lateral intercellular spaces; (2) Transcellular route, across the apical plasma membrane, which may be augmented by short microvilli, microfolds (not shown) or long microvilli of uniform length, called " brush border," across the cytoplasm, and across the basolateral plasma membrane; the latter may be augmented by infoldings of the basal plasma membrane or by basolateral processes of the cells, which narrowly interdigitate with each other. The lateral interdigitating processes contain large mitochondria.

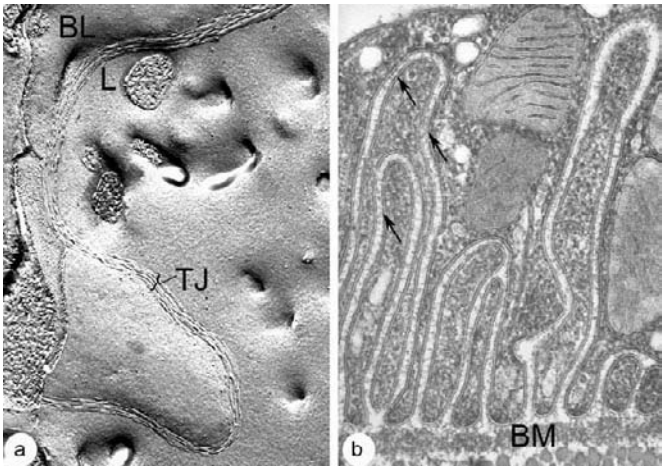

FIGURE 20.41 **Tight junction and intercellular space.** (a) Freeze-fracture electron micrograph of thick ascending limb cells. (b) The tight junction (TJ) consists of several densely arranged parallel strands (BL: basolateral membrane; L: luminal membrane; Rabbit: ×~45,000). (Cooperation with A.Schiller and R.Taugner).

Paracellular Pathway

As seen in freeze-fracture replicas, tight junctions are composed of globular particles, arranged in one or several roughly parallel strands or in a net-like pattern[234] (Figure 20.41a). The more-or-less densely packed particles in the strands presumably represent the transmembrane proteins that participate in the junction's formation.

The tight junctions function as barriers between the luminal compartment and the lateral intercellular spaces. At the same time they allow a selective, regulated paracellular flow of small inorganic cations,[235,236] and the passage of some large organic cations and of some uncharged molecules.[234,237] The selectivity of tight junctions for different solutes varies among the different tubular epithelia.[238,239] Claudins, a large family of integral membrane proteins, make up the bulk of tight junctional strands,[240–243] and play a key role in determining and regulating the paracellular permeability for small inorganic cations.[244] They act as size-, charge-, ion concentration- and pH-dependent channels or pores in the intercellular space,[245–247] and seem to be targets of the serine-threonine kinases WNK1 and WNK4.[248–251] The dynamic regulation of paracellular flux does not seem to involve structural changes of the tight junctional complexes. Mutations in claudin members[252,253] or defects in the WNK-signaling cascades may have major implications on volume homeostasis.[250,251,254–257] Occludin, another integral membrane protein, is interspersed with claudins in the tight junctional strands. The cytoplasmic domain of occludin is associated with ZO1, thereby providing a linkage for the membrane to its scaffolding actin cytoskeleton.[234,244] The interaction of occludins with the actin skeleton may be important in regulating the paracellular passage for larger molecules, and for "macropermeation" across the epithelium, as well as in the transduction of signals from apoptotic cells.[258] Further, ZO1 seems to be associated with the "fence" function of tight junctions,[258] i.e., the ability of the tight junction to prevent diffusion of lipids from the apical to the basolateral membrane domain. Via transcription factor zonula occludens 1 (ZO-1)-associated nucleic acid binding protein (ZONAB), it can also be involved in controlling cell proliferation.[259]

Cell adhesion proteins at the extracellular face of the basolateral surface of renal tubular cells maintain a basal level of cell–cell adhesion, in addition to strong cellular adhesion provided by the junctional complexes and/or desmosomes. The cell adhesion proteins in the intercellular spaces can be made visible by electron-microscopy with specific fixation procedures.[260] The "classical" cell adhesion proteins N- and E-cadherin,[261–264] as well as the "atypical" kidney-specific (ksp) cadherin 16[265,266] have been located by immunostainings on the basolateral membranes all along the tubular system. The classical cell adhesion molecules are linked to the scaffolding actin skeleton, as well as to β-catenin, at the cytoplasmic face of the basolateral cell membranes.[267] This connection provides a pathway for coupling extracellular signals (among others, binding of a hormone to its receptor, mechanical stresses) to intracellular signaling cascades that control various cellular responses, such as endocytosis, ubiquitination of proteins, transcription, proliferation or apotosis.[267]

Transcellular Pathway

The prerequisite for transcellular vectorial transport of solutes across epithelia is the asymmetric or polarized allocation of co-transporters, exchangers, channels, and enzymes, to the luminal and basolateral plasma membrane

LUMINAL MEMBRANE DOMAIN

The uptake of most solutes into the cell is coupled to passage of sodium via solute-specific co-transporters, via channels or via exchange against protons (H^+) in the luminal plasma membrane. The given assembly of transport proteins in the luminal membrane of the cells of a segment determines the segment-specific solute transport pattern. Enzymes (e.g., phosphatases, peptidases) in the luminal membrane hydrolyze poorly permeable organic compounds to readily permeable ones, and various receptor proteins (e.g., megalin, cubilin etc.[268]) mediate the uptake of their ligands into the cell.

Many of the apical transport proteins are linked to the actin-based cytoskeleton under the plasma

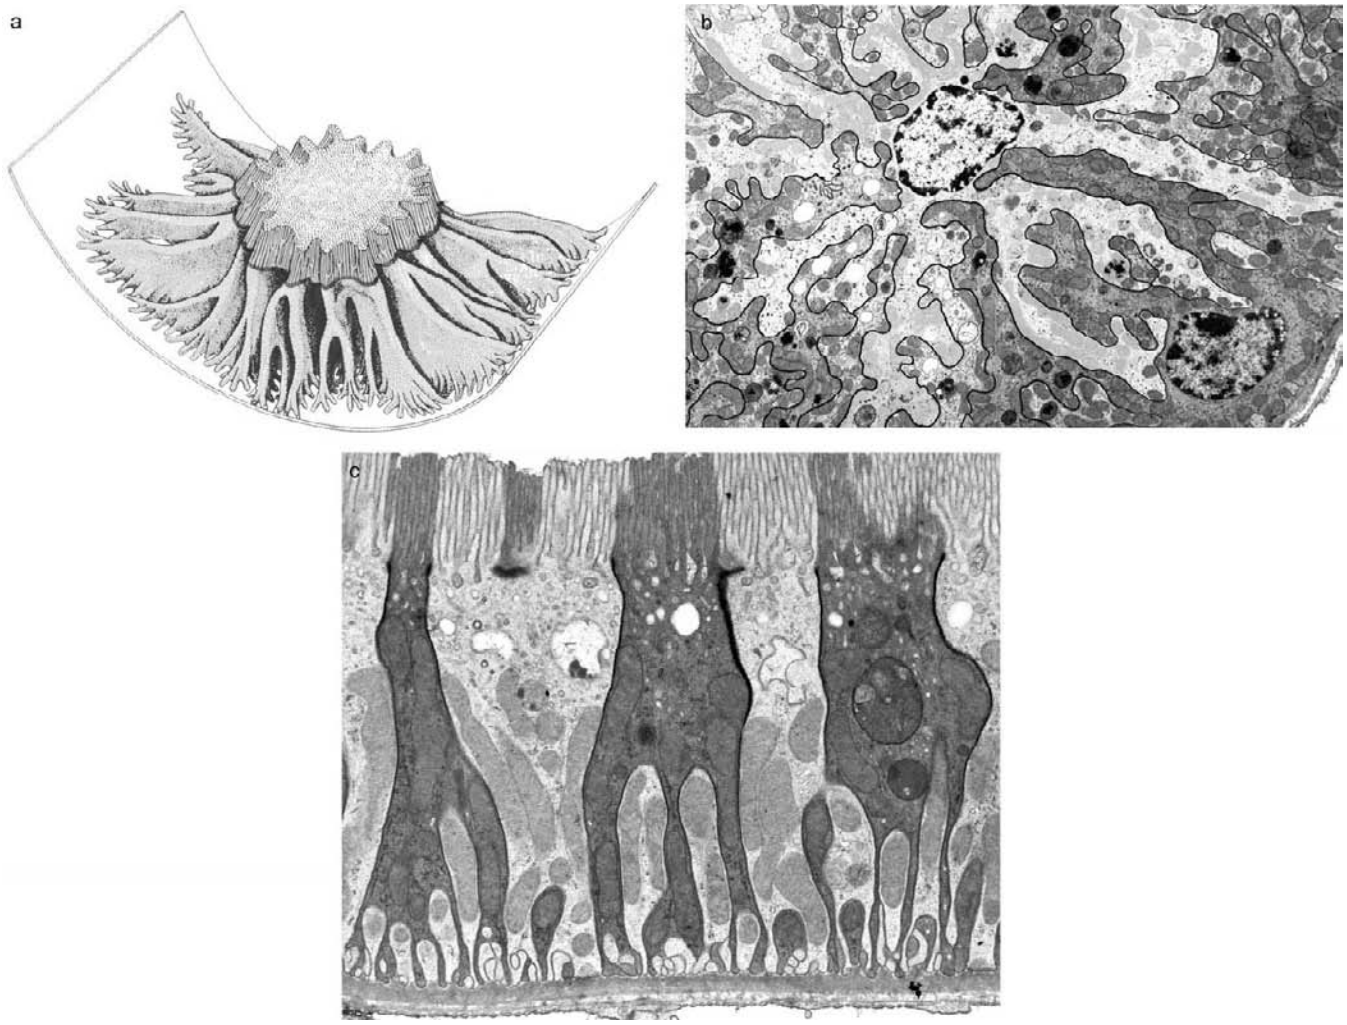

FIGURE 20.42 **Augmentation of apical and basolateral plasma membrane surfaces by microvilli and interdigitating lateral cell processes.** (a) Three-dimensional model of a rabbit proximal tubule cell. *(From Welling, L. W., and Welling, D. J. (1975). Surface areas of brush border and lateral cell walls in the rabbit proximal nephron. Kidney Int. 8(6), 343–348 ,with permission.)* The dark line indicates the position of the tight junctional belt between the apical and basolateral membrane domains; the apical membrane domain is amplified by microvilli, which form a brush border; the basolateral membrane domain is augmented by interdigitating lateral cell processes that split in an apico–basal direction to primary and secondary processes and basal plicae; the latter are anchored in the basement membrane. (b) and (c): Sections through S1 proximal tubule (*Psammomys obesus*); the dark contrast of the intercellular spaces (black lines), and the differential contrast of adjacent cells result from fixation with reduced osmium; (b) the section, cut approximately in parallel to the basement membrane through the center of the cell reveals the complex interdigitation of the lateral cell processes; (c) in the section in an apico–basal direction apical interdigitation by lateral processes is revealed by the different contrast in the brush border; the lateral interdigitating processes increasingly split up towards the cell base; the larger ones are filled out with mitochondria (TEM: $\times \sim 9000$).

membrane via adaptor proteins containing PDZ interactive domains,[269–273] namely NHERF1, 2, 3, and are thereby maintained in the specific cell membrane areas.[274]

The given assembly of transport proteins in the apical plasma membrane of a segment confers the *specificity* for transported solutes. The *rate* of solute permeation across the membrane critically depends on type (co-transporter, exchanger, channels) and *quantity of active transport systems* in the apical cell membrane domain. The latter is ultimately related to the available *surface area*. Thus, in many epithelia with high transport rates the apical membrane area is much larger than the area of a virtual plane at the level of the tight junctional belt.

Three modes of amplification of apical plasma membrane surface are distinguished (Figure 20.40): (1) densely arranged finger-like microvilli, all of similar dimensions, evenly distributed over the entire cell surface, forming the so-called "brush border" (Figures 20.42 and 20.44). The microvilli have an axial cytoskeleton of actin filaments, arranged in a 6 + 1

pattern, associated with villin and fimbrin in the microvillar core.[275] The actin filaments extend into the terminal web, located in the subapical cytoplasm immediately beneath the base of the microvilli. Brush border formation characterizes the proximal tubule: (2) short microvilli, found on all other tubular cells; their density and distribution on the cell surface varies considerably; (3) microfolds, found on cells in which regulation of the permeation rates for given solutes is associated with rapid transient modulation of the luminal cell surface area (subtypes of intercalated cells and occasionally also in collecting duct cells; see below).

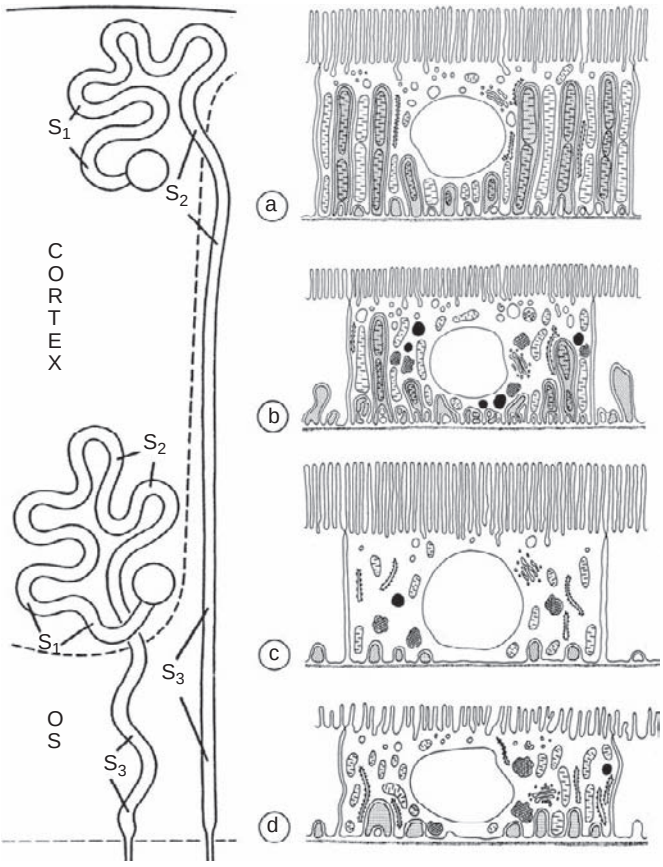

FIGURE 20.43 **Survey on location and ultrastructure of proximal tubule segments.** (a) S1 segments start at the urinary pole of the renal corpuscle in the cortex, and transform gradually to S2 segments within the labyrinth, S2 segments give way to S3 at different levels (depending on the nephron generation) within the medullary rays; S3 terminates at the border (dashed line) of the outer stripe (OS) and the inner stripe. (b) Salient features of S1, S2, and S3 proximal tubule cells; neighbouring cells are shaded in order to reveal the interdigitation by lateral cell processes; the vacuolar apparatus in the subapical cytoplasm, mitochondria, ER, Golgi apparatus, lysosomes (black spots), and peroxisomes (cross-hatched) are indicated; in rat S3 segments (c) the brush border micovilli are the highest, in rabbit (d) and most other species they are the shortest. *(Adapted from ref. [5], with permission).*

BASOLATERAL MEMBRANE DOMAIN

The entry of sodium-coupled solutes across the luminal membrane is driven by the enzymatic splitting of ATP by the Na-K-ATPase, the so-called sodium pump.[276] In renal epithelia ATP is mainly made available by mitochondria. The Na-K-ATPase is inserted in the basolateral membrane domain of all tubular cells, and is firmly linked to the actin cytoskeleton by interacting proteins, such as ankyrin, spectrin/fodrin, and NHERF.[277]

Segment-specific differences in Na-K-ATPase activity/protein[278,279] per unit tubular length rely on cell type-specific differences in the density of the enzyme molecules per area basolateral membrane, and on the available surface area of basolateral membrane per unit tubular length.[280,281] Basically two modes of increases of the basolateral membrane surface per unit tubular length are distinguished in renal epithelia:

1. *Lateral folding and interdigitation* (*basolateral interdigitations*): this mode increases the lateral membrane area[282] and implies an increase of the lateral intercellular space, the common compartment of para- and transcellular transport routes.[40] The width of the lateral intercellular spaces (about 20–50 nm) varies little with function.
   In interdigitated epithelia the tight junctions are composed of one or several parallel strands with more-or-less high particle density. The tall lateral plasma membrane folds, equipped with Na-K-ATPase, narrowly enclose large mitochondria. The folds split into complex basal ridges with densely packed actin filaments (but no Na-K-ATPase[283,284]), arranged in a circular manner,[285–287] which provide attachment to the underlying basememt membrane. This arrangement prevails in proximal (Figures 20.42, 20.43 and 20.44) and distal tubules (Figures 20.52, 20.53, 20.54, 20.56 and 20.57), and causes the characteristic basal striation of these segments in histological sections.
2. *Infoldings of the basal plasma membrane* into the cell body; the spaces between the infolded (Na-K-ATPase carrying) membranes open via so-called basal slits directly towards the underlying basement membrane, and have no continuity with the lateral intercellular spaces. Consequently, trans- and paracellular solute transport pathways are largely separated. The tight junctional belt consists of networks of anastomosing strands with high particle density. The width of the intercellular spaces can be narrow or dilated, depending on the functional conditions. The lateral membranes carry small finger-like villi or folds, and are often interconnected by small desmosomes, These might help to maintain mechanical cohesion under

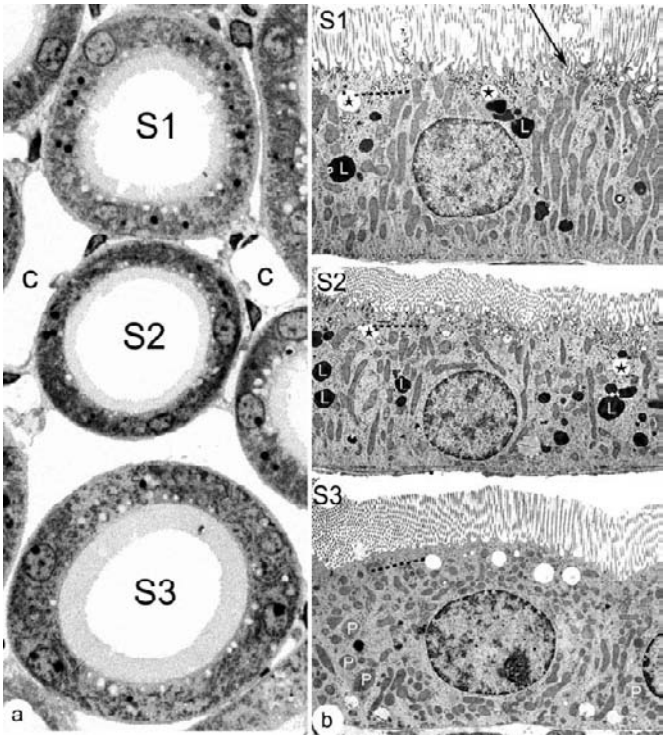

FIGURE 20.44 **Proximal tubule (rat).** (a) Profiles of S1, S2, and S3 segments of juxtamedullary proximal tubules; note the differences in brush border length, in cell height, cytoplasmic density, and outer diameter (c: Peritubular capillaries; Rat: 1 mm Epon section; ×~1000). (b) Ultrastructure of S1, S2, and S3 proximal tubule cells (Rat). The mitochondria in S1 and S2 are located in lateral cell processes, in S3 they are mainly scattered throughout the cytoplasm; the endocytotic apparatus in the subapical cytoplasm (roughly delimited by broken lines) is most prominent in S1 and early S2; endosomes (stars) and lysosomes (L) are located deeper in the cytoplasm; in S3 the vacuolar apparatus and lysosomes are virtually absent, whereas peroxisomes (P) are more frequent than in S1 and S2; interdigitation by lateral folds is almost lacking (TEM: ×~5400).

functionally-induced dilation of the intercellular space. This epithelial organization characterizes the collecting duct system. Increases in membrane area by lateral interdigitating folds and basal infoldings may well be found in the same cell (e.g., connecting tubule cells; Figures 20.56 and 20.58).

Correlation Between Structure and Transport

In defined nephron segments rather constant ratios have been found between Na-transport rates, Na-K-ATPase activity, basolateral plasma membrane surface area, and mitochondrial density.[276,279–281,288–294]

Acute changes in flow rates for a given solute across the luminal cell membrane may be sensed by local purinergic signaling and responded to by rapid adjustment in transport rates.[295,296] They depend on the availability of active transport systems in the cell, and can be effected by several mechanisms, e.g., by gating of transport channels (e.g., ENaC in collecting duct cells), that are present in the luminal plasma membrane,[277] by redistribution of the given protein between microdomains in the apical membrane (e.g., NHE3 in the brush border of proximal tubuli,[297,298] by cycling of luminal and vesicular membrane domains containing the respective transport proteins (e.g., AQP2 in collecting duct cells; H^+ATPase in intercalated cells) between the cell surface and intracellular vesicles[299] or by exocytotic insertion and endocytotic retraction of specific transport proteins into and from, respectively, the luminal membrane (e.g., ENaC[300]; NaPiIIa[301,302]).

Prolonged duration of increased transcellular flow rates stimulates, in addition to the acute responses, the transcription rates for the given transport proteins,[303] and finally results in cellular and epithelial hypertrophy, including cell proliferation.[304,305] Inversely, chronic decreases in Na-transport rates may result in epithelial hypotrophy, including a reduction of cell mass by apoptosis.[293,305–307] On this background it is tempting to interpret the internephron heterogeneity as a reflection of their different filtration and transport rates. In rats the juxtamedullary nephrons with the largest glomeruli and highest filtration rates[308] display the largest tubular diameter, the largest basolateral membrane area, Na-K-ATPase activity, and mitochondrial volume density.[41] The superficial nephrons have the smallest glomeruli, filtration rates, and tubular dimensions.

Primary Single Cilia

All renal cell types, except the intercalated cells, carry a central single primary cilium on their luminal surface. Primary cilia are regarded as mechanosensors that sense changes in luminal flow rate and circumferential stretch.[309–312] The extracellular mechanical stimulus caused by the urinary flow is transduced via the transmembrane proteins Polycystin 1 (PC-1) and Polycystin 2 (PC-2),[313] located in the membrane of the cilium.[314,315] Both together form a complex required for flow-mediated calcium entry in response to the deflection of the axoneme.[316] This subsequently results in release of calcium stores from the endoplasmic reticulum, possibly mediated by Polycystin 2.[309,311] On the one hand, this might induce local purinergic signaling and modulate renal tubular transport[317]; on the other hand, the primary cilia may be involved in the functional differentiation of polarized cells,[318] in the maintenance of normal tubular architecture,[309] in regulation of tissue morphogenesis,[319] and in gene transcription.[320] Cilia seem also to help to regulate and control mTOR and temper the response of this pathway to growth factors.[321] Loss-of-

function mutations in the genes for PC-1 or PC-2 cause ciliary abnormalities[322] and the autosomal dominant form of polycystic kidney disease (ADPKD).[315,323]

PROXIMAL TUBULE

The proximal tubule takes up the glomerular filtrate and recovers the major fraction of water, sodium, and solutes by reabsorption from the tubular lumen back to the blood compartment, and it clears the blood of various organic compounds by uptake from the blood compartment and secretion into the tubular lumen.[324,325] Furthermore, the epithelium removes almost completely filtered proteins from the tubular fluid by endocytosis.

The proximal tubule begins at the urinary pole of the renal corpuscle, and ends at the transition to the descending thin limb of Henle's loop which defines the border between the outer and the inner stripes. It has a convoluted part, situated in the cortical labyrinth, and a straight part (pars recta: the thick descending limb of Henle's loop), located in the cortical medullary rays and in the outer stripe (Figure 20.43). The volume fraction of proximal tubules is about 48% in the rat cortex and about 54% in the outer stripe.[41] From the collected tubular volume in the cortical labyrinth of an adult rat the convoluted proximal tubule takes a fraction of 80 to 85%.[38]

Morphology of Proximal Tubular Epithelium

The proximal tubule is lined by cells with complex, interdigitating folding of the basolateral plasma membrane and characteristic formation of a brush border at the apical pole. The largely amplified apical and basolateral plama membrane surfaces correspond to the high transcellular solute transport rates (see "Organization of Electrolyte Transporting Epithelia"). The lateral foldings narrowly ensheath large mitochondria. At the base the foldings are split into numerous basal ridges, which are densely filled with circular running f-actin filaments, and provide the anchoring of the cell to the underlying extracellular basement membrane. The tight junctions are shallow, mostly consisting of a single strand with low particle density,[275] in agreement with the low-resistance shunt pathway in parallel with a high-resistance pathway across the limiting cell membranes.[326,327] The proximal tubule cells are electrically coupled by gap junctions.

The subapical cytoplasm immediately under the base of the brush border microvilli is a membrane-rich region, called the "vacuolar apparatus".[268] It is the structural correlate of the early endocytotic apparatus (Figure 20.45a) and contains intermicrovillar more or less deep infoldings ("clefts") into the cytoplasm, small clathrin-coated vesicles, uncoated "dense apical tubules" (DAT) 70−90 nm in diameter, and large uncoated vesicles. The dimensions of the vacuolar apparatus are very variable, and depend on the rate of endocytosis (see below). The more or less abundant lysosomes, present in the center of the cells, are functionally related with the degradation of proteins. The nucleus is encircled in its equatorial plane by well-developed Golgi apparatus. Cisterns of rough ER are preferentially extended in parallel with the lateral cell membranes; ribosomes are abundant throughout the cytoplasm. Fenestrated cisterns of smooth ER are particularly abundant. In the terminal portions of the proximal tubule the cisterns of smooth ER contain xenobiotc-metabolizing enzymes[328] which contribute to detoxification processes. The cisterns of the smooth ER often extend along the lateral membranes and narrowly enwrap mitochondria and peroxisomes.[329] The latter are generally situated in the basal portions of the cells.[330] The amount of lysosomes, peroxisomes, and lipid droplets in proximal tubule cells strongly varies with the functional stage of the animal, food intake, and sex hormones.[331−333]

The proximal tubule is subdivided into three segments, S1, S2 and S3.[334,335] The subdivision is based on more-or-less gradually occurring quantitative changes along the proximal tubule. S1 cells line the initial half of the convoluted portion, and have the largest basolateral plasma membrane surface, Na-K-ATPase activity per unit membrane area, and mitochondrial density. They transform to S2 cells within the second half of the convoluted portion. All proximal tubule segments touching the renal capsule are S2 cella,[336] and S2 cells also form the beginning of the straight part in the medullary rays. In rats and rabbits the microvilli in S2 are markedly shorter than in S1 (in rat S1: ∼4.5 to 4.0 μm; S2: ∼4.0 to 1.5 μm). S2 cells usually have very prominent lysosomes. The basolateral surface area, Na-K-ATPase activity per unit membrane area, and mitochondrial density decrease from S1 to S3. S3 cells supersede S2 cells at various levels (depending on the nephron generation) in the medullary rays[34,113,268,336] and line the terminal portion of the proximal tubule. In rabbits, dog, and human the height of microvilli further decreases along S3.[5,114,334,335] In mice differences in the length of the brushborder microvilli among the three segments are little apparent,[113] whereas in rats the brush border microvilli of S3 are the longest from the three proximal tubule subsegments (Figure 20.44a). Lateral folding of the plasma membrane is lacking, and the S3 cells usually have a polygonal outline and a comparably small basolateral plasma membrane surface and

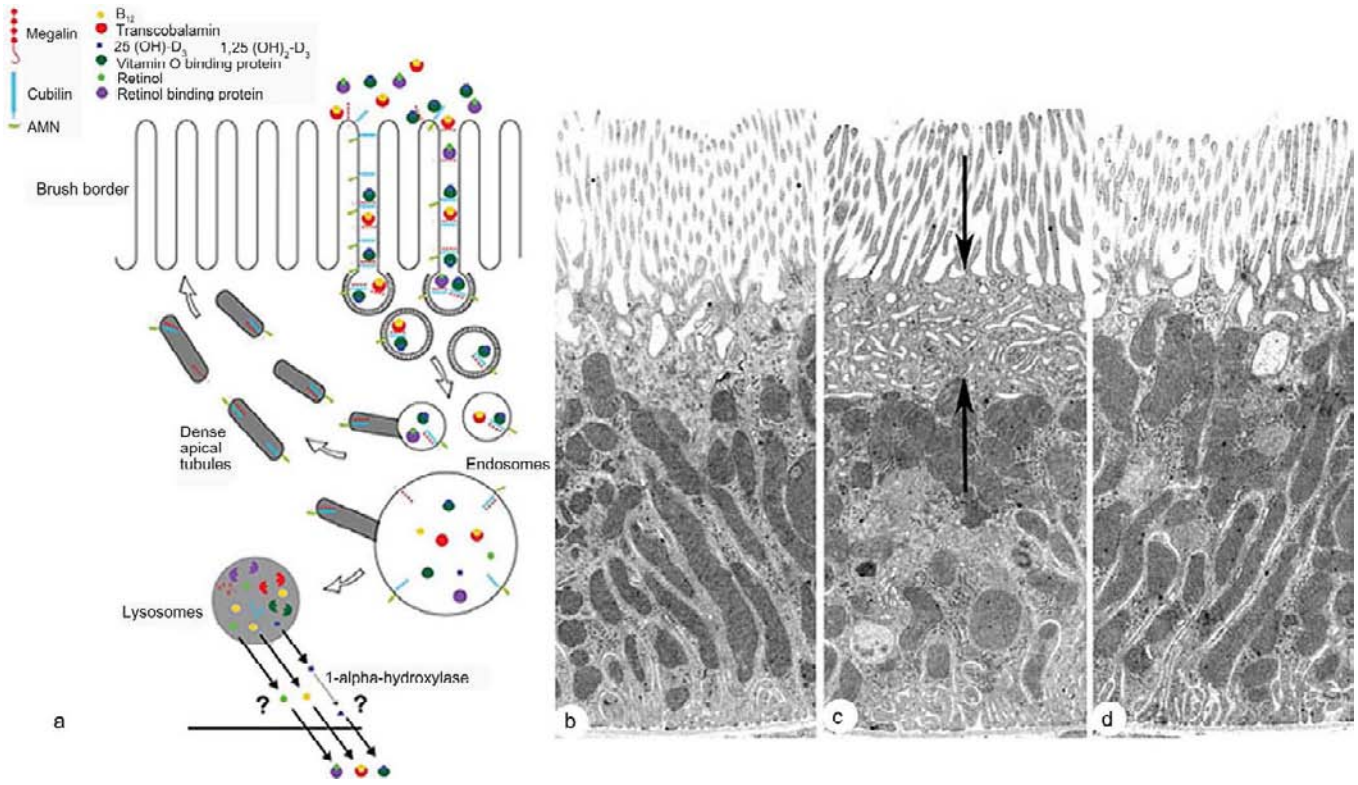

FIGURE 20.45 (a) Schematic representation of receptor-mediated endocytosis in the proximal tubule, exemplified for the megalin- and cubilin-mediated uptake of three vitamin carrier protein complexes: DBP-vitamin D3, TC-vitamin B12, and RBP-retinol in renal proximal tubule. Likewise, the cubilin chaperone protein amnionless, AMN, is indicated. Following receptor-mediated endocytosis via apical coated pits, the complexes accumulate in lysosomes for degradation of the proteins, while the receptors recycle to the apical plasma membrane via dense apical tubules. Megalin mediates the uptake of cubilin and its ligands. The mechanisms for the cellular release of the vitamins remain to be clarified. *(From ref. [346].)* (b)–(d) Transmission electron micrographs of S1 cells of the proximal tubule of rats; (b) control; (c) 15 min and (d) 60 min after a single PTH-injection; PTH induces rapid downregulation of the sodium phosphate co-transporter NaPi-IIa in the brush border membrane by endocytotic mechanisms, associated with a transient expansion of the vacuolar apparatus (between arrows) in the subapical vesicular compartment (TEM ~10,000). *(Modified from ref. [356].)*

Na-K-ATPase activity. Yet, the volume density of mitochondria in S3 of rat and mice is rather high. The mitochondria are scattered throughout the cytoplasm. Structural correlates for endocytosis and lysosomes are almost absent in S3, whereas amount and size of peroxisomes increases from S2 towards S3.

Functional Aspects

Structural Correlate for Receptor-Mediated Endocytosis

Receptor-mediated endocytosis (Figure 20.45a) is the most efficient mechanism for cellular uptake of filtered proteins[268,337,338] and plays an important role in the acute downregulation of transport rates by selective retraction of transport proteins from the microvillous membrane rapid (e.g., NaPiIIa, Figures 20.45b,c,d; see below). By multiphoton microscopy the passage of proteins across the different endocytotic compartments has been directly observed *in vivo*.[339,340]

The first requirement for cellular uptake of a protein by endocytosis is binding of a ligand to a receptor protein on the surface of the tubular cell. The multireceptors megalin, cubilin, and amnionless[341,342] have all been located in the proximal tubule, mainly on the base of the microvillous plasma membrane, in the intermicrovillar membrane invaginations ("clefts"), and in subapical clathrin-coated pits. Megalin belongs to the LDL-receptor family, and is bound with its cytoplasmic tail to cytoplasmic adaptor proteins.[343,344] It forms a tandem with the peripheral protein cubilin which is associated with the membrane by amnionless.[345,346] Megalin is responsible for the internalization of its own ligands and of cubilin with its ligands.[338] The receptor–ligand complexes are gathered in the clathrin-coated membrane pits, and are directed by clathrin-coated vesicles to larger, uncoated early and late

endosomes, located slightly deeper in the cytoplasm. In the endosomes the receptors are cleaved from the ligands and travel back to the luminal membrane via uncoated "dense apical tubules" (DAT).[347–350] The DAT form an elaborate, moving dynamic network of anastomosing tubules,[348,351] which are transiently connected to the larger endosomes, and which display at their other end small clathrin-coated domains.[352–354] From the endosomes the ligands are sorted either for degradation to lysosomes or for ubiquitination via the proteasome pathway.

The trafficking of internalized material from the vacuolar apparatus to lysosomes critically depends on the microtubular system.[355] Microtubules normally form a loose network across the proximal tubule cells, and become highly oriented in the apico–basal direction during vesicular transport of endocytosed cargo to lysosomes.[356] The dimensions of the vacuolar apparatus and the abundance of megalin in proximal tubule cells are correlated with the rate of endocytosis. If endocytosis does not take place, either due to paucity of ligands in the tubular fluid (e.g., normally in S3) or due to lack or low levels of the endocytosis receptor,[338,357,358] the vacuolar apparatus is barely developed.

The processing of material in the vesicular compartments of the endocytotic pathway relies on acidification. NHE3, the proton-ATPase, and the chloride channel ClC-5 (for a review see [359]), are all highly expressed and co-localized in the intermicrovillous clefts and in the vesicular membranes of the early endocytotic pathway.[360–362] Dysfunction of one or several of these acidifying proteins may cause primary defects in endocytosis. Knockout of the ClC-5 channel, for instance, impairs the clearance of PTH from the tubular fluid, bringing about hyperphosphaturia and hypercalciuria.[361,362] This mechanism can explain the high incidence of kidney stones in Dent's disease, with functionally impaired ClC-5 channels.[363–367]

The role of basolateral endocytosis is interesting, since the basolateral cell membrane is the site of different hormone receptors,[368] e.g., the insulin receptor. After binding to the receptors peptide hormones seem to be, at least in part, taken up by the cells and are transported to the lysosomes.[369]

Sodium Proton Exchange

Apical Na^+-H^+ exchange in the proximal tubule and the reabsorption of the bulk of filtered sodium is mediated by the sodium/hydrogen exchanger NHE3 in the microvillous plasma membrane[361,370–372] and in the plasma membrane of the intermicrovillous invaginations.[297] The sodium/hydrogen exchanger is enriched in the intermicrovillar microdomain,[370] where it interacts with the scavenger receptor megalin (see above, [298]). Changes in Na/H exchange activity correlate with changes in cell surface expression of NHE-3, mediated by sgk2.[373] Rapid and reversible redistribution of NHE3 between the two microdomains in the microvillous plasma membrane domain and the intervillous plasma membrane invaginations ("clefts") may also alter the surface expression of NHE3 and activity of Na/H exchange.[298,374–377]

Reabsorption of Water and Solutes

The plasma membrane of the microvilli is covered by a glycocalyx containing hydrolases (phosphatases, peptidases, nucleotidases) which cleave their substrates in the tubular fluid (ecto-enzymes). The microvillous membrane holds a large variety of transport proteins for uptake of water and solutes from the tubular fluid. The density of a given transport protein in the microvillous membrane can be dissimilar along the segments of the proximal tubule and among nephron generations. Many of the transport proteins are anchored by adaptor proteins, such as PDZ-proteins and NHERF1/2, to the underlying apical scaffold.[372,373,378,379]

Transcellular water reabsorption in the proximal tubule is mediated by the constitutive water channel, aquaporin 1 (AQP1) located in the microvillous- and basolateral plasma membrane domains.[380–384] Orthogonal arrays of intramembrane particles in the basolateral membranes of S3 of mice[385] are associated with another water channel, AQP4, AQP7, which is probably involved in the reabsorption of glycerol (see review in [386]) and is expressed in the brush border, especially of S3 in rats and mice, as shown by immunocytochemistry.[387,388]

Sodium-coupled solute uptake from the lumen into the cells is mediated by co-transport proteins located in the plasma membrane of the microvilli. The proximal tubule usually recovers all filtered glucose. The sodium–glucose co-transporter SGLT2 is found primarily in S1, and is responsible for 90% of glucose reabsorption. SLGT*1* is located in S3, and is responsible for only 10% of reabsorption (reviewed by Hediger and Rhoads[389,390]). SGLT*1* is more highly expressed in females than in males.[391] The exit of glucose across the basolateral plasma membrane occurs by the glucose transporters GLUT2 (low affinity in S1) and GLUT1(high affinity in S3).[392]

Inorganic phosphate (Pi) transport is mediated by at least three different brush border Na^+/P(i) co-transporter proteins, the electrogenic transporter NaPi IIa, Pit-2, and the electroneutral transporter NaPi Iic.[393,394] Their expressions and activities appear to be tightly regulated.

Low dietary intake of Pi increases mRNA and brush border expression of NaPi IIa.[395] High dietary Pi intake, parathyroid hormone (PTH) and activation of dopamine receptors[358] rapidly downregulate NaPiIIa-mRNA[395] and NaPiIIa in the brush border,[396–398] and induce phosphaturia. Downregulation of NaPiIIa in

the brush border involves receptor-mediated endocytosis (see above) and subsequent lysosomal degradation.[355,356,358,399,400]

The passage of NaPi-IIa across the successive endocytotic compartments namely, the megalin-containing clefts, the clathrin-coated-vesicle compartment,[401] through the early and late endosomal compartment, and finally its disposal in lysosomes, where NaPi-IIa is degraded, has been tracked by immunofluorescence.[301] The shifting of the protein through the early endocytotic compartments goes along with a dramatic, rapidly transient expansion and remodeling of the vacuolar apparatus in the subapical compartment[356] (Figure 20.45). PTH also reduces Pit-2 expression and activity, whereas NaPi-IIc is inhibited and internalized with a delay of several hours after PTH application.[394]

Recently Klotho has been recognized as a phosphatonin, and an important regulator of phosphate homeostasis. In partnership with the FGF-R, Klotho functions as an obligate co-receptor for FGF23.[402] Secreted soluble Klotho inhibits Pi transport by altering the trafficking of the proximal tubule Na-coupled phosphate transporter.[402]

Neutral amino acids, which represent about 80% of circulating amino acids, are transported by the low affinity Na^+-co-transporter B(0)AT1, located in the early proximal tubule. The high affinity transporter B(0)AT3 is located in the late proximal tubule, at least in mice. In addition, there are several other apical and basolateral amino acid transporters (for a recent review see [403]). Similarly the short-chain peptide, di-, and tripeptide carriers PEPT1, high capacity, low affinity, and PEPT2 low capacity, high affinity are located in mainly S1 and S3, respectively.[404,405]

Secretion of organic amphiphilic electrolytes from the blood into the tubular fluid is a pathway for clearance and detoxification of xenobiotics and drugs, including diuretics.[325,406–410] The uptake into the proximal tubule epithelium proceeds via multispecific organic anion transporters (OAT) and organic cation transporters (OCT) in the basolateral membrane domain. The majority of members of the OAT- and OCT-family have been immunolocalized to the basolateral cell membrane of S3 proximal tubule,[411–413] yet OAT 1 has been detected mainly in S2,[414] a few also in S1. The expression of the OATs and OCTs is strongly regulated by sex hormones.[415–420]

The export into the tubular lumen of both conjugated and unconjugated lipophilic anionic substrates involves various OATs and primarily active transporters with ATP-binding casette motifs, belonging to the MRP-family,[421] and located in the brush border membrane of S1, S2, and S3 proximal tubule segments.[421,422]

The role of basolateral endocytosis is interesting, since the basolateral cell membrane is the site of different hormone receptors,[368] e.g., the insulin receptor. After binding to the receptors peptide hormones seem to be, at least in part, taken up by the cells and are transported to the lysosomes.[369]

THIN LIMBS OF HENLE'S LOOP (INTERMEDIATE TUBULE)

The intermediate tubule comprises the thin tubular portions, interposed between the proximal and the distal tubules (Figure 20.46). Ultrastructurally, the intermediate tubule has four structurally different segments: (1) the descending thin limbs of short loops (SDTL); (2) the upper part; (3) the lower part of descending thin limbs of long loops (LDTLup and LDTL lp); and (4) the ascending thin limbs (ATL). This pattern has been observed in various species, including rat,[423,424] mouse,[34,425] golden hamster,[426] rabbit,[5,427] *Perognathus*,[428] *Octodon degus*,[429] *Meriones shawii*,[116] and *Psammomys obesus*.[430–432] An additional subsegment of thin limbs has been identified in Chinchilla.[433] The thin limbs in human have so far not been studied in comparable completeness.[434–436]

Surprisingly, by lightmicroscopy these simple-looking epithelia are strikingly different from each other with respect to ultrastructure and function, not only the ascending from the descending limbs but, most remarkably, the descending limbs of short from those of long loops. Furthermore, within the descending segments (SDTL, LDTLup, LDTLlp) the proximal portion, although structurally no different from the distal portion, displays considerable functional differences. In the IM a high percentage of thin limbs was found that consisted of a patchwork of descending and ascending type epithelia.[437,438] Beyond all these heterogeneities, there are prominent differences among species. This complex situation appears to account for the persistent discussion about the integrated function of thin limbs in the urine concentrating process.

The type I epithelium (Figure 20.47), which is characteristic for descending thin limbs of short loops (SDTL), has a simple and uniform organization. It is composed of flat, non-interdigitating cells reposing on a thin basement membrane. The luminal cell membrane bears only a few short microvilli that are mainly found along the cell borders. The tight junction consists of several anastomosing junctional strands; desmosomes are frequently encountered. The SDTLs in the rat have, among all other thin limb segments, a particularly prominent cytoskeleton with a high content of cytokeratins and desmoplakins.[439] Cell organelles, such as mitochondria, profiles of rough and smooth

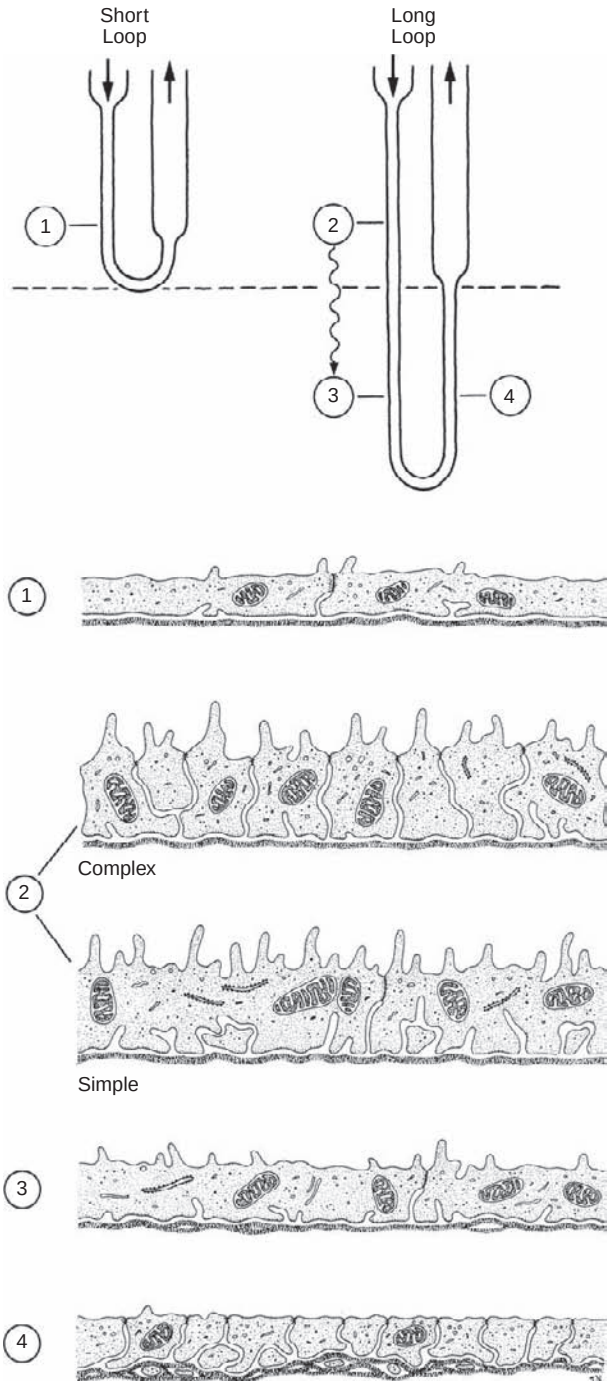

FIGURE 20.46 **Survey of thin limb ultrastructure.** Four thin limb segments are discernible: (1) Descending thin limb of short loops. (2) Descending thin limbs of long loops, upper part. This segment is differently developed among species: a complex type (upper panel) found e.g., in rat, mouse, and *Psammomys* is distinguished from a simple type (lower panel) found e.g., in rabbit and guinea pig. (3) Descending thin limb of long loops, lower part. The transition between upper and lower parts is gradual. (4) Ascending thin limb. *(Adapted from Kriz, W., and Schiller, A. et al. (1980). endoplasmic reticulum, etc., are exceedingly sparse in type I epithelium.

Apart from an initial stretch of maximally 400 μm in about 10% of SDTLs in mouse, these nephron segments do not show any labeling for aquaporin 1 (AQP1), thus they are rather impermeable to water.[440] The lower parts of SDTLs contain the urea transporter UT-A2 in its cell membranes.[382,441,442] In species with complex vascular bundles (e.g., rat, mouse), the short descending limbs lie within the vascular bundles[115]; in these surroundings, the thin limbs are in an ideal position to recycle urea from the ascending vasa recta into the short loop nephrons (see below).

This simple type I epithelium is also found in many descending loop profiles in the inner stripe of feline and canine kidneys which, by microanatomical definition, possess only "long" loops. Consequently, it may be assumed that these simple profiles belong to those long loops that descend into the inner medulla for only very short distances, frequently less than 500 μm.[443] The epithelial characteristics of these loops may be more important than their short descent into the inner zone for determining their functional role. From this point of view, "short loops" are also present in the cat kidney. The short descending thin limbs of cortical loops – studied in the minipig[444] and guinea pig (unpublished results from our laboratory) – are also established by the simple type 1 epithelium.

The descending thin limbs of long loops are generally much larger in diameter, and have a thicker epithelium than those of short loops. Moreover, the LDTLs are heterogeneous; obviously, those of the "longest" long loops begin in the inner stripe as a much thicker tubule than those of "shorter" long loops. The character of the epithelium gradually changes as the limbs descend toward and into the inner medulla. The subdivision of these thin limbs into an upper part (type 2 epithelium) (Figure 20.48a) and a lower part (type 3 epithelium) (Figure 20.48b) is an approximation, and reflects the gradual change to a more and more structurally simplified epithelium. Moreover, this process of epithelial simplification appears to be individually related to the length of each loop. It occurs earlier and more quickly in "short" long loops and is delayed in the longest of the long loops.[34,260,424,432,445] This explains the heterogeneity among descending thin limb profiles in a given cross-section through the medulla: profiles lined with the lower-part epithelium (type 3) may already be found at the end of the inner stripe. Even deep in the inner medulla, profiles with the upper part epithelium (type 2; in reduced elaboration) are still present.

Furthermore, considerable interspecies differences, concerning in particular the upper parts of LDTLs, complicate understanding of the long descending thin limbs. Two patterns may be distinguished[260]; in one group of species (mouse, rat, golden hamster, *Perognathus*, *Psammomys*, *O. degus*, cat), the epithelium (type 2) of the LDTLup is characterized by an extremely high degree of cellular interdigitation. In a single cross-section, more than 100 cell processes may be encountered (Figures 20.48a and 20.49a,b). The tight junctions are extremely shallow, usually consisting of one junctional strand. Thus, the most characteristic features of this epithelium are the prominent paracellular pathways. The junctions are "leaky," and the amount of junctional area available per unit area of epithelial surface is increased several-fold by the tortuosity of the junction due to cellular interdigitation. The lateral cellular spaces form an elaborate "labyrinth," bordered by correspondingly amplified basolateral membranes. Additional structural characteristics of the epithelium are numerous apical microvilli, considerable numbers of mitochondria, and a strikingly high density of uniform intramembranous particles in the luminal and basolateral membrane. In addition, cytochemical and immunohistochemical studies have revealed that the LDTLup exhibits a sodium–potassium ATPase in both membranes,[446,447] suggesting active salt secretion. In addition, salt transport may occur through the tight

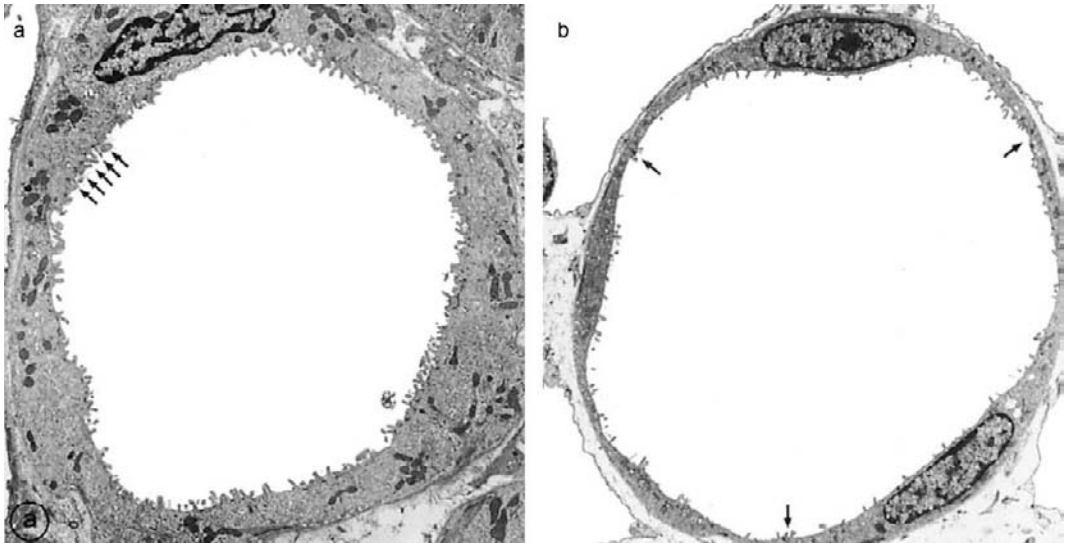

FIGURE 20.48 **Descending thin limbs of long loops, upper part.** (a) Complex type; note the many tight junctions (arrows) (*Psammomys*: TEM: ×~3000). (b) Simple type; only three junctions are encountered (arrows) (rabbit: TEM: ×~3000).

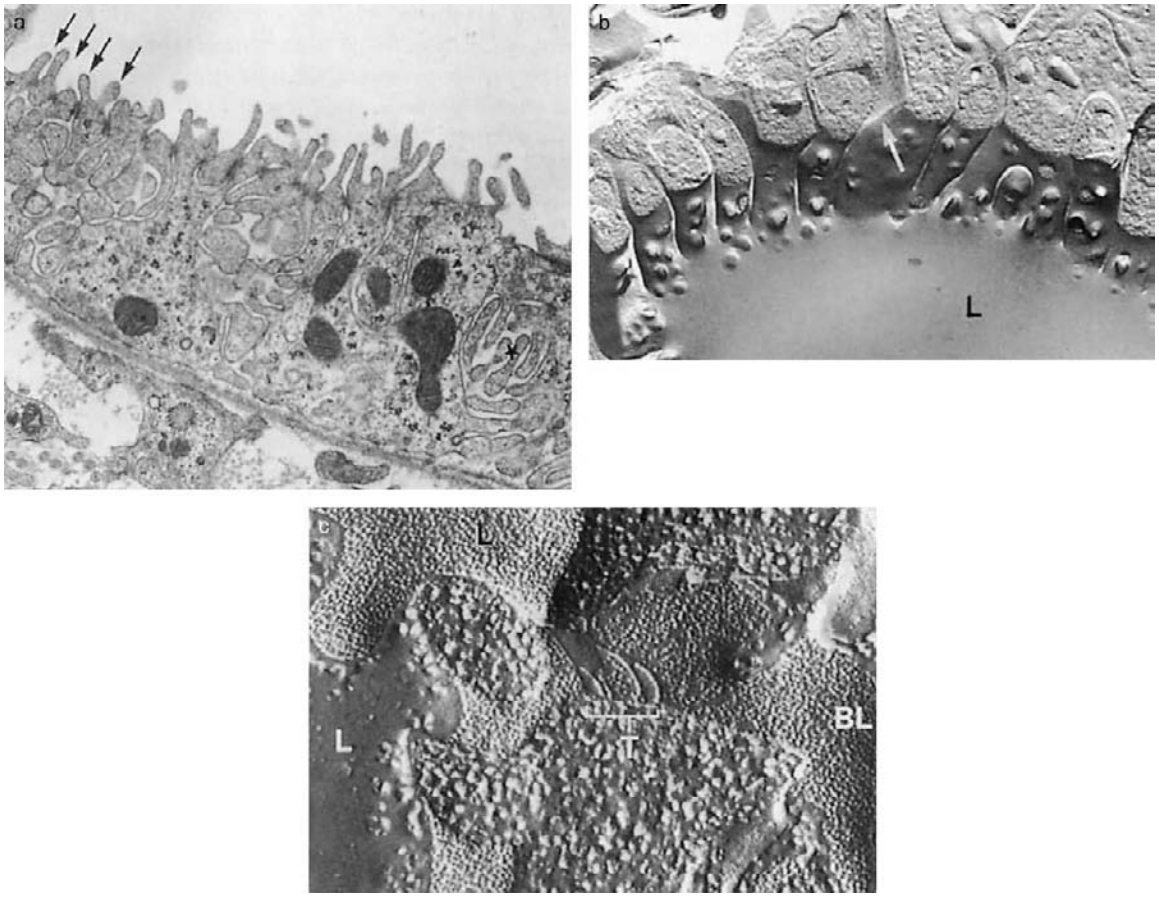

FIGURE 20.49 **Descending thin limbs of long loops, upper part.** (a) The complex epithelium is characterized by numerous tight junctions (arrows) indicating the extensive intercellular digitation. Academic Press, London, with permission.)* (c) Freeze-fracture electron micrograph of the simple type epithelium. The tight junction (T) consists of several junctional strands. Note the dense pattern of intramembrane particles on the P face of luminal (L) and basolateral (BL) membranes (an equally dense particle pattern is also found in the complex type) (L: Tubular lumen; Rabbit: × ∼66,000). *(From Schiller, A., and Taugner, R. et al. (1980). The thin limbs of Henle's loop in the rabbit. A freeze fracture study. Cell Tissue Res.* ***207****(2), 249–265, with permission.)*

junctions, which contain claudin 2.[261,448] LDTLups are highly permeable to water due to the abundancy of the constitutive water channel aquaporin 1 (AQD1) in both membranes,[449] probably correlating with the high density of intramembrane particles. Carbonic anhydrase activity was found in both short and long descending thin limbs.[450]

In a second group of species that includes rabbit,[427,451] minipig[444] and guinea pig (unpublished data from our laboratory), the upper parts of LDTLs are more simply organized. The prominent paracellular pathway typical of the first group is lacking. The epithelial cells in this group do not interdigitate, and are joined by much deeper tight junctions consisting of several anastomosing junctional strands (Figures 20.48b and 20.49c). In other respects, however, the epithelia are similar in the two groups. Numerous luminal microvilli, many mitochondria, and the dense assembly of intramembrane particles in luminal and basolateral membranes are present in type 2 epithelium also in this group. The high density of intramembrane particles may be partially due to the high density of aquaporin 1 (AQP1) channels in both membranes; corresponding to the decrease of particle density along its descending course the density of AQP1 channels decreases.[452–454]

The epithelium of the lower part of LDTL (type 3 epithelium) is comparably simple (Figure 20.50); interspecies differences are no longer prominent. The epithelium consists of relatively flat, noninterdigitating

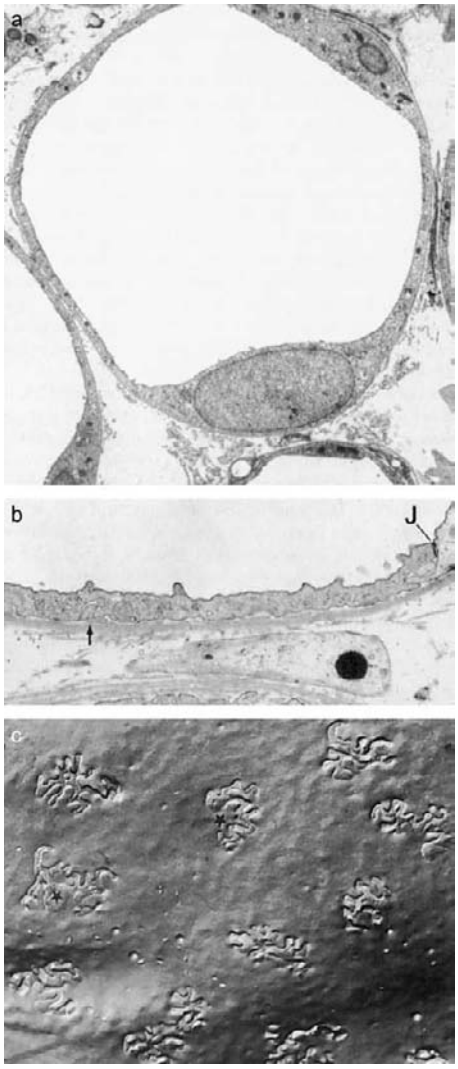

FIGURE 20.50 **Descending thin limbs of long loops, lower part.** (a) Cross-sectional profile (rat: TEM: ×~3800). (b) The epithelium is simply organized; basal infoldings (arrow) are regularly encountered (J: Junctional complex; Rabbit: TEM: ×~10,200). (c) Freeze-fracture electron micrograph demonstrating the regular pattern of basal infoldings within the basal cell membrane (*) (*Psammomys*: ×~12,800). *(In cooperation with A. Schiller and R. Taugner.)*

cells bearing some sparse microvilli; in the rat it is covered by an unusually thick surface coat.[424] The tight junctions are of an intermediate apicobasal depth, composed of several junctional strand (in rabbit: 138 ±37 nm and 3.5 ±0.7 strands; in *Psammomys*, 51 ± 28 nm).[260] The basolateral membrane regularly forms basal infoldings, similar to those found in the simple type of LDTLup.[260] The fluid spaces between the infoldings are not continuous with the lateral intercellular spaces, and thus they are not part of a paracellular pathway route. The pattern and density of intramembrane particles in the luminal and basolateral membranes are inconspicuous; the dense packing, typical for the upper parts, has disappeared. This appears to correlate with the decrease in density of AQP1 channels that, in the terminal portions of this segment, may completely disappear. Thus, the water permeability probably decreases toward the loop bend[452,453]; the terminal segment may accordingly be thought to have a very low water permeability. Regarding the permeability to urea and the distribution of the urea transporter UT-A, conflicting data are published, especially when comparing data from different species.[438,442,452,455–457] In the mouse in antidiuretic conditions, the UTA2 urea transporter is upregulated in LDTLep.[458] Also, claudin 8 has been found in this segment.[240]

With respect to the descending thin limbs of the human kidney, the published data do not allow a final conclusion. In an older TEM investigation[459] a thin limb profile is shown with a heavily interdigitated epithelium corresponding to the thin limb epithelium described above as the complex type in other species. However, in the text the descending thin limbs in the human kidney are described as being outlined by a simply structured epithelium. In 1967, when this paper was published, it was not yet known that there were four different thin limb epithelia.

The axial, the internephron, as well as the interspecies differences in descending thin limb epithelia, is surprisingly prominent compared to all other nephron segments. Differences among thin limb segments were also found with respect to the cholesterol content of their cell membranes.[460] Binding studies with various lectins have revealed distinct labeling patterns in the descending, as well as the ascending, thin limbs in rat and rabbit.[461–463]

The ascending thin limb is present only in long loop nephrons, and is uniformly organized among mammals (Figure 20.51). Generally, the transition from the type 3 epithelium of the descending limb to the type 4 epithelium of the ascending limb occurs a short, but fairly constant, distance before the bend ("pre-bend segment[34,120,121,431]). Therefore, functionally, the entire bend should be regarded as part of the ascending thin limb. The type 4 epithelium is characterized by very flat but heavily interdigitating cells joined by shallow tight junctions, consisting of only one prominent junctional strand. This leaky organization of the paracellular pathways corresponds with functional studies,[464,465] which all demonstrate that the ascending thin limbs are highly permeable for ions.

The change from the type 3 epithelium to the type 4 epithelium coincides with the disappearance of the urea transporter UT-A 2, and the abrupt beginning of the expression of the chloride channel ClC-K1[437,452,466]; aquaporins are completely lacking. Thus, the ascending thin limb is water- and urea-impermeable, but highly

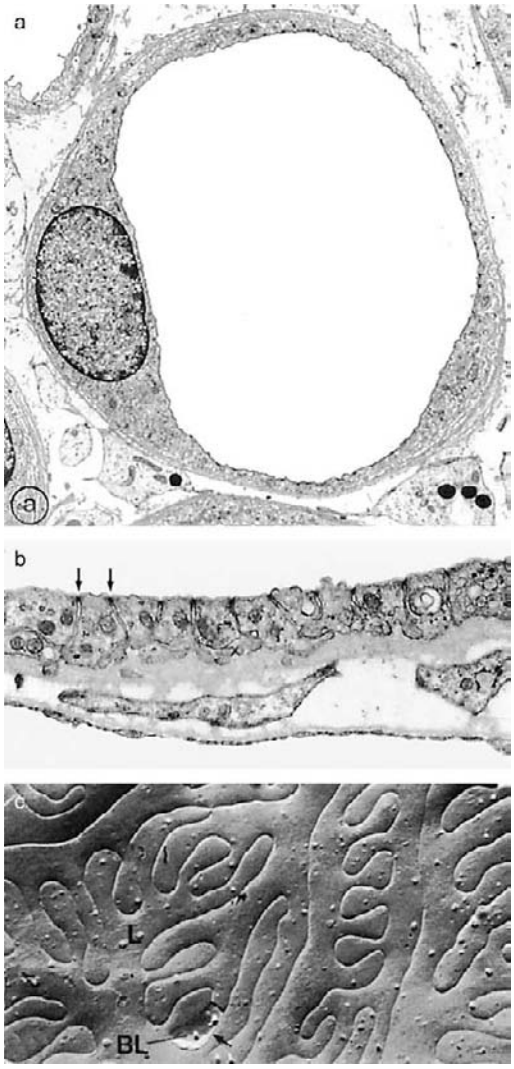

FIGURE 20.51 **Ascending thin limbs.** (a) Cross-sectional profile; note the many junctions (arrows) (*Psammomys*: TEM: ×~3500). (1981). Freeze-fracture studies on the thin limbs of Henle's loop in Psammomys obesus. Am. J. Anat.* ***162****(1), 23–33, with permission.)*

permeable for Cl^- and also Na^+. The relevance of the expression of claudin 4[261] is poorly-understood. Surprisingly, in mouse, rat, and rabbit a high fraction of "mixed" thin limbs was found consisting of alternating stretches of descending and ascending type epithelia.

In most species the transition from the ascending thin limb to the thick ascending limb (distal straight tubule) is abrupt over the length of one cell. The level of this transition defines the border between the inner medulla and the inner stripe of the outer medulla. In the canine[467] and human kidney,[459] a gradual transition between the thin and thick ascending parts of the limb has been observed.

THICK ASCENDING LIMB OF HENLE'S LOOP

The **T**hick **A**scending **L**imb (TAL = distal straight tubule – DST) absorbs NaCl in excess of water.[468] The subtraction of salt from the tubular fluid contributes to rendering the surrounding interstitium hypertonic, a crucial prerequisite for the urinary concentration process. The tubular fluid delivered by the segment into the cortex becomes progressively diluted. In addition, the TAL plays a prominent role in acid–base homeostasis, and recovers important fractions of filtered Mg^{2+} and Ca^{2+} via the paracellular transport route.

The beginning and end of the TAL epithelium are sharply demarcated from the preceding thin limb epithelium, and the successive DCT epithelium. The TAL of nephrons with long loops begins at the border between inner and outer medulla, and that of nephrons with short loops at various levels within the inner stripe of the outer medulla (in cortical loops even in the medullary rays in the cortex). It ascends through the outer medulla and the cortical medullary rays, enters the cortical labyrinth for a short distance, and contacts with the "macula densa," the vascular pole of its parent glomerulus (Figure 20.52). After a short "post-macula" segment the TAL transforms to the **d**istal **c**onvoluted **t**ubule (DCT). The length of the post-macula segment varies not only among species (< 500 μm in rabbits), but also among nephrons within the same kidney.[5,37,260] An association of its length with nephron types has not been established.

Long-looped nephrons have a thinner epithelium than nephrons with short loops.[5,308,469] The thickness of the epithelium decreases gradually, although considerably in the flow direction along the segment (Figures 20.52 and 20.53).[308]

The organization of the TAL-epithelium is exemplary for electrolyte transporting epithelia (see above: "Organization of Electrolyte Transporting Epithelia") (Figure 20.52). The cells display prominent lateral membrane foldings (Figure 20.22a)[5,470] which narrowly interdigitate with adjacent cells and enclose plate-like large mitochondria, and occasionally a few cisterns of rough endoplasmic reticulum (rER)[470] (Figure 20.53). Except in the deep inner stripe the lateral folding extends over the entire cell height. Hence, the luminal outline and tight junctional belt are much longer in upstream portions than in the deep inner stripe,[471] evident by the very frequent hits of the tortuous tight junctional belt in sections of cortical TAL

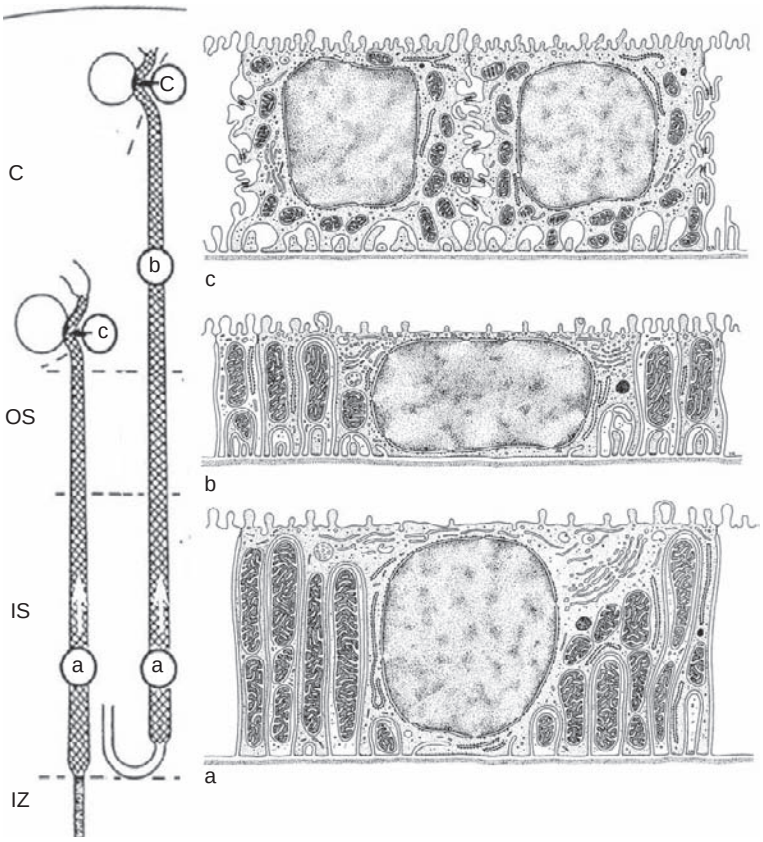

FIGURE 20.52 **Survey on location and ultrastructure of the thick ascending limb of Henle's loop.** (TAL: distal straight tubule, including macula densa; C: cortex; IS: inner stripe; OS: outer stripe; IZ: inner zone.) The direction of the urinary flow is indicated by white arrows, interdigitated cells with large mitochondria, enclosed in the lateral processes; (a) medullary part; (b) cortical part; (c) macula densa; note the difference in the organization of the lateral intercellular spaces between macula densa cells and other TAL cells. *(Adapted from Kaissling, B., and Kriz, W. (1979). Structural analysis of the rabbit kidney. Adv. Anat. Embryol. Cell Biol.* ***56****, 1–123, and Kaissling, B., and Kriz, W. (1992). Oxford University Press, New York, with permission).*

epithelium (Figure 20.53b). The tight junction is organized by a few strands, arranged in parallel, and with a high particle density (Figure 20.41a).

The large nucleus usually (except in the deep inner stripe) spans the entire cell height. The cytoplasm in the nuclear region displays small, round mitochondrial profiles, a particularly extensive Golgi apparatus,[308] polyribosomes, and some short cisterns of rER. The varying amounts of narrow tubular profiles and smooth vesicles in the subapical cytoplasm might be related with trafficking of apical transport proteins (see below). The apical membrane of the cells carries short stubby microvilli,[114,472] which usually border the tight junctional belt[471] and are less abundant in the center of the cell and in the vicinity of the single cilium. Scanning electron microscopy revealed that "rough" cells with numerous microvilli may be present side-by-side with rather smooth cells with only a few microvilli.[469] The latter cells display strong immunoreactivity for EGF, which seems to play a role in the regulation of growth and differentiation of cells in the loop of Henle.[473]

Role of the TAL in NaCl Reabsorption

The major fraction of salt reabsorption by the TAL (including the macula densa cells) proceeds via the Na^+,K^+,$2Cl^-$ (NKCC2) symporter[468] in the luminal membrane[474–476] which is specifically inhibited by loop diuretics, such as bumetanide and furosemide.[477] The apical entry of Na^+,K^+ and $2Cl^-$ is driven by the Na-K-ATPase in the basolateral plasma membrane. The density of Na-K-ATPase in the TAL exceeds by far that of more proximal tubular sites.[278,279]

The inwardly rectifying renal outer medullary K channel, ROMK, which recycles the K^+ ions entering the cell via NKCC2 over the apical membrane, is particularly abundant in the apical plasma membrane of TAL cells.[365,478–483] The basolateral extrusion of Cl^- occurs passively through ClC-K and ClC-Kb channels.[479,484]

Role in Bicarbonate Reabsorption

In addition to its role in salt reabsorption, the TAL has also an important function in maintaining acid–base homeostasis. It reabsorbs about 15–20% of the filtered bicarbonate[485–488] via the sodium/hydrogen exchangers NHE3 and NHE2 in the luminal plasma membrane of the TAL cells[370,489–491] and the NEM-sensitive vacuolar H^+-ATPase.[492] The apical Na/H exchange is tightly coupled with the basolateral Cl^-/HCO_3^- exchange that proceeds by the Cl^-/HCO_3^-

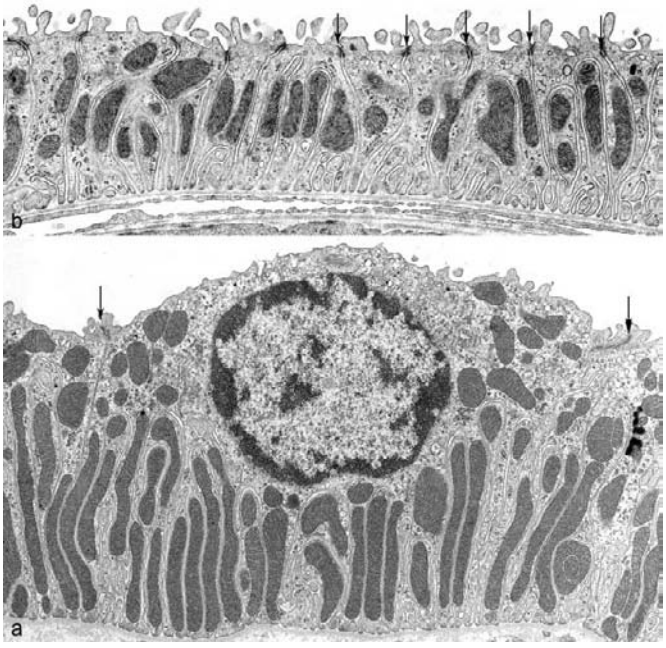

FIGURE 20.53 **Thick ascending limb cells.** (a) Deep level of the inner stripe; the lateral interdigitated foldings contain large mitochondria and do not reach up to the lumen; (b) Cortical part; in the much lower cells the lateral interdigitated foldings reach up to the lumen, causing a folded course of the tight junctions (arrows) (rat: TEM: × ~14,500). *(Adapted from and Kaissling, B., and Kriz, W. (1992). In "Morphology of the Loop of Henle, Distal Tubule and Collecting Duct. Handbook of Physiology: Section on Renal Physiology," 109–167, Windhager, E. E. Oxford University Press, New York, with permission).*

exchanger AE2.[493,494] The abundance of the NHE3 protein in the apical plasma membrane of the TAL has been shown to increase with functional adaptation to reduced renal mass,[487] under metabolic acidosis,[495] and with high levels of glucocorticoids.[496]

Role in Mg^{2+} and Ca^{2+} Recovery

Although virtually impermeable to water, the junctions in the TAL display a selective permeability for Mg^{2+} and Ca^{2+}. 40–70% of the filtered Mg^{2+} is recovered by the TAL in a passive paracellular manner facilitated by tight junction proteins claudin-16 and claudin-19 protein.[252,497]The much greater length of the tight junctional belt in the CTAL than in the MTAL might explain the higher paracellular movement of Mg^{2+} and Ca^{2+} in the CTAL than in the MTAL.[497,498] Impaired function of paracellin 1 (claudin 16) leads to urinary losses, specifically of magnesium and calcium.[499–506]

Regulation of salt transport rates in the TAL involves peptide hormones, among them vasopressin and glucagons, which bind to receptors on the basolateral plasma membranes. Via the cAMP messenger system they increase the abundance of the NKCC2 co-transporter and the K-channel in the luminal membrane.[106,117,474,468,507–512]

The acute response to decreases or increases of cAMP seem to involve endocytotic and exocytotic, respectively, membrane translocation.[513] The various amounts of NKCC2-displaying vesicular and tubular structures in the apical cytoplasm of TAL cells[270,510,514] might well be part of the membrane pool, available for translocation. Similar to the proximal tubule, endocytosis requires NHE3-mediated acidification, and needs the chloride channel CLC5. NHE3 and ClC5 are both located in the apical cytoplasm of TAL cells.[480,515] The basolateral extrusion of Cl occurs passively through ClC-K and ClC-Kb channels.[479] The trafficking of ClC-K to the basolateral membrane depends on the protein barttin.[479]

Cyclooxygenase 2 (COX2) has been located in the TAL cells, including the macula densa cells, and contributes through local production of prostaglandins[479,516–518] to the handling of ions by the TAL.

All maneuvers that chronically affect the salt transport rates by the TAL finally result in structural hyper- or hypotrophy of the TAL epithelium. The plasticity of the TAL epithelium in response to variations in plasma levels of vasopressin (ADH) or cAMP had been revealed by studies on Brattleboro rats, which genetically lack ADH and suffer from diabetes insipidus (DI).[519] In these rats the medullary and cortical portion of the TAL are equally thin.[520] In healthy rats with chronic low plasma levels of ADH due to chronic high water intake the structural appearance of the TAL resembles that seen in DI-rats.[521] Several weeks of substitution of ADH in DI rats or of endogeneously increased ADH-levels, associated with chronic water restriction, restore the normal axial heterogeneity.[522,523]

The transport rates by the TAL epithelium are correlated with the DNA synthesis rate of TAL cells. Specific inhibition of NaCl reabsorption in the TAL of rats by furosemide transiently reduces the incidence of TAL cells showing DNA synthesis (assessed by nuclear detection of the proliferating cell nuclear antigen, PCNA, and incorporation of the thymidine analog bromodesoxyuridine) from about 1%, the basal rate in the rat TAL epithelium, to zero.[305]

With the given background it is likely that the structural heterogeneity regarding cell height, mitochondrial density, and basolateral plasma membrane surface along the TAL represents the physiologically lower tubular salt load, and ensuing lower transport rates in the cortical than in the medullary portions.[468] In rabbits the overall reduction of the cell height, membrane area and mitochondrial volume (per unit tubular

length) along the TAL is much more pronounced than in rats and mice.

Disruption of genes coding for NKCC2 (SLC12A1) or for one or several proteins and/or channels associated with the NaCl-transport via NKCC2 (e.g., chloride channels ClCKA, ClCkB or the Barttin subunit, CLC5, NHE3), involved in regulation of its surface expression, or of the respective signaling cascades causes more or less severe renal salt-wasting, characteristic of "Bartter" syndrome. Symptoms of the Bartter syndrome are, e.g., lowered blood pressure, hypokalemic metabolic alkalosis, and hypercalciuria, with variable risk of kidney stones.[479,483–484,524–527]

The Tamm-Horsfall glycoprotein (THP), the most abundant urinary protein in mammals, is synthesized exclusively by the renal TAL epithelium. It is located in high density on the apical plasma membrane, in low density also on the basolateral plasma membrane.[528,529] Uromodulin has been linked to water–electrolyte balance and to kidney innate immunity.[530] THP is thought to be relevant in the pathogenesis of cast nephropathy and urolithiasis. By its property to compete efficiently with urothelial cell receptors, such as uroplakins, in adhering to type I fimbriated *Escherichia coli*, it may play a role in defense against urinary tract infection.[531] Mutations in the gene encoding uromodulin lead to rare autosomal dominant diseases, collectively referred to as uromodulin-associated kidney diseases.[532] Recently, it has been shown that THP-deficient ($THP^{-/-}$) mice showed moderately impaired urinary concentrating abilityuromodulin plays a permissive role in TAL reabsorptive fu/uromodulin plays a permissive role in TAL reabsorptive function.[533]

SEGMENTS DOWNSTREAM OF THE TAL: DISTAL CONVOLUTED TUBULE, CONNECTING TUBULE, AND COLLECTING DUCT

Electrolyte transports by the tubular epithelia distal of the loop of Henle provide the fine tuning of urinary electrolyte- and water-excretion. Located downstream of the macula densa, their transepithelial solute transport rates are no more directly submitted to tubuloglomerular feedback control but, rather, they are regulated by systemic hormones and a multitude of local factors.[296,317]

The structural subdivision of these portions in the cortex into the distal convoluted tubule (DCT), the connecting tubule (CNT), and the cortical collecting duct (CCD) goes back to light microscopic observations made in sections and microdissected tubules from kidneys of rabbits, human, mouse, sheep, cat, pig, beef, and dolphin by Karl Peter early in the 20th century.[37] More than half-a-century later, microdissection studies of nephrons from rabbits and mice by the group of Morel[534] revealed that the distribution of sensitivities for several peptide hormones was bound to the morphological segmentation. Detailed electron microscopic investigations of the distal tubular portions in rabbits,[5] rats,[291,535,536] *Psammomys obesus*,[35] and mice[537,538] further confirmed and extended the earlier findings. The few studies on the human nephron[459,539–541] agree with the data obtained from experimental animals.

In contrast to the preceding tubular portions, the epithelial lining of each of the segments following the TAL display at least two distinct cell types: one cell type is segment-specific and called accordingly DCT cell, CNT cell, and CD cell; the other one, the intercalated cell (IC cell), is interspersed in differing amounts among the specific cells of each segment.[542] The transition from one segment to the next may be sharp and unequivocally definable, e.g., as in rabbits[5,268] or they may develop gradually, involving more-or-less long transitional portions with a mixture of cells from the successive segments or with cells showing features intermediate between the segment-specific cell types of the given segments.[535] The presence of a rather long transitional portion between the definite DCT and CNT in rats,[543,544] in mice,[537,538] and in humans[539] claimed a subdivision of the DCT in these species into the "early" DCT and the "transitional portion"[538,545] or the DCT 1 and the DCT 2,[537] respectively. Taken the morphological data of the various species (except rabbits!) together it is obvious that the segmentation of the cortical tubular portion distal of Henle's loop is a matter of definition.[544] The nowadays conventionally-used segment definitions for the DCT, the CNT and the CCD (Figure 20.55) take into account the structural data and the distribution of the major apical salt and water transport proteins (Figure 20.55). The uptake by the cell type-specific transport proteins in the luminal plasma membrane into the cell and the movement across and out of the cell is facilitated by a bunch of "auxiliary" cytoplasmic and/or basolateral membrane proteins (e.g., Na-K-ATPase, Ca-binding proteins, K-channels, hormone receptors, etc.). These "auxiliary" proteins are not restricted to the given cell type and thus, are not segment-specific. The inventory of gene expressions (*in situ* hybridization of mouse kidney sections with annotations) in given segments can be looked up in the "Euregene Expression Database." "The Kidney Atlas" (http://www.euregene.org/portal/pages/index.html).

The segmentation of the CD into cortical (CCD), outer medullary (OMCD), and inner medullary CD (IMCD) is based mainly on the location in the given zones. The structural differences between the CCD and

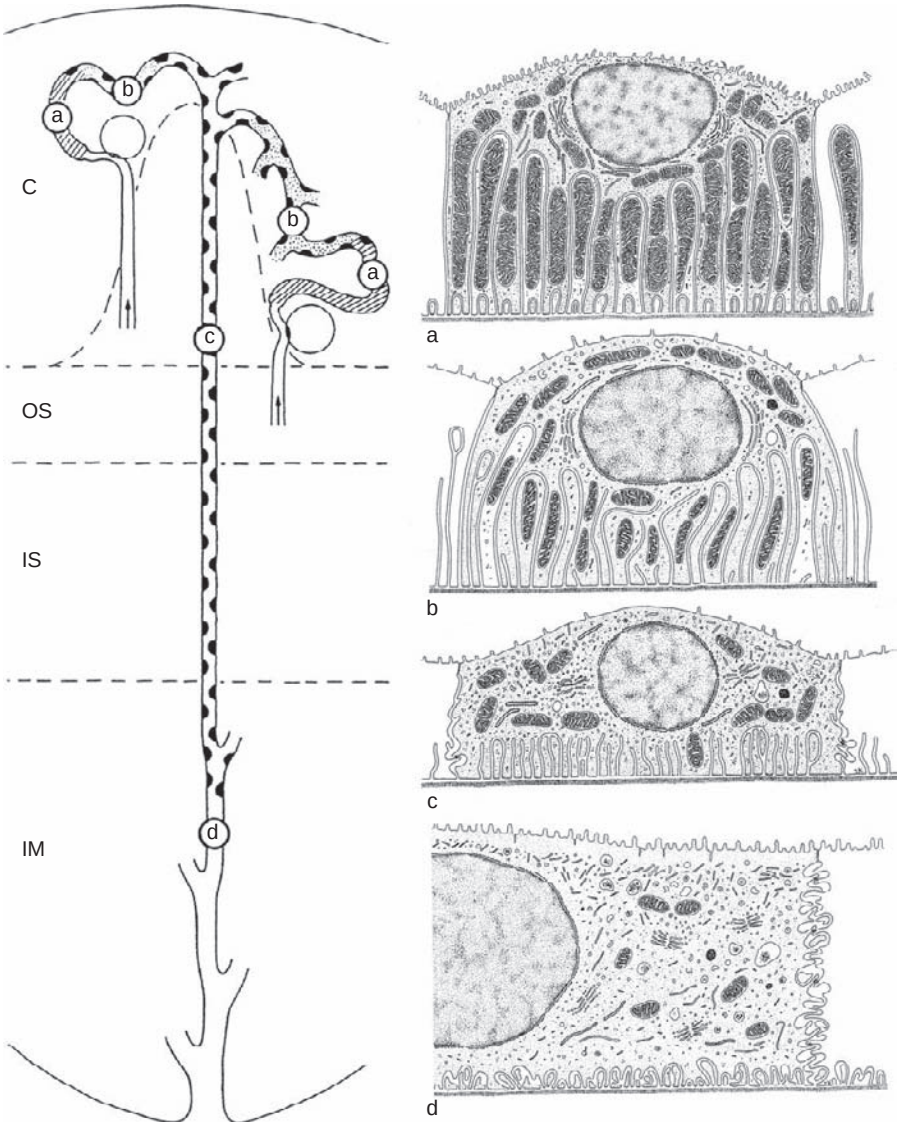

FIGURE 20.54 **Survey on organization of the cortical distal segments and collecting ducts (left panel) and on ultrastructure of the segment-specific cells (right panel).** (C: cortex; OS: outer stripe; IS: inner stripe of the outer medulla; IM: inner medulla; Dashed line: delimits the medullary ray; (a): distal convoluted tubule (DCT) and DCT-cell; (b): connecting tubule (CNT) and CNT-cell; (c): CCD and CCD cell; (d): inner medulla (IM) and IMCD cell; Black semicircles indicate the occurrence of intercalated (IC) cells.) Each DCT opens into one CNT. In superficial nephrons the CNT opens directly into a CCD; connecting tubules of deeper nephrons join to form an arcades which ascend in the cortical labyrinth, before they open into a CCD. The collecting ducts descend in the medullary rays and through the outer and inner stripes of the outer medulla; the lower two-thirds of the collecting duct are lined by IMCD cells exclusively; the IMCD open as papillary ducts on the renal papilla. *(Adapted from and Kaissling, B., and Kriz, W. (1992). In "Morphology of the Loop of Henle, Distal Tubule and Collecting Duct. Handbook of Physiology: Section on Renal Physiology," 109–167, Windhager, E. E. Oxford University Press, New York, with permission).*

OMCD cells are quantitative rather than qualitative. Usually, the IMCD does not display any more IC cells in its two lower thirds and the lining cells (IMCD cells) are regarded as a separate cell type[546] (Figure 20.54).

Distal Convoluted Tubule (DCT)

The DCT reabsorbs 5–10% of the filtered Na-load[547] and determines the final urinary Mg^{2+} concentration through active transcellular transport.[548] In addition, the transitional portion (DCT2) participates (together with the subsequent CNT; see below) in regulation of calcium excretion by transcellular calcium reabsorption.[538,549] The DCT epithelium is water-impermeable, similar as the preceding TAL.

The abrupt increase in epithelial height (Figure 20.56)[550,544] marks the beginning of the DCT. This prominent feature in the tubular epithelium has been observed in all mammalian species investigated so far, and it coincides exactly with the replacement in the luminal membrane of the NKCC2, characterizing the TAL cells, by the thiazide-inhibitable sodium chloride co-transporter, NCC, characterizing the DCT cells.[547] The NCC characterizes all DCT cells (DCT1 and DCT2). The breaking off of NCC expression defines the end of the DCT.[537] It is sharp in rabbits,[551] but it drops off over a more or less long distance in mice and rat.[538]

The DCT epithelium is organized by laterally interdigitating cells (Figures 20.57 and 20.58a) similar to the TAL, yet the lateral folding excludes the apical cell portion in DCT cells. The amount of Na-K-ATPase,[279] the

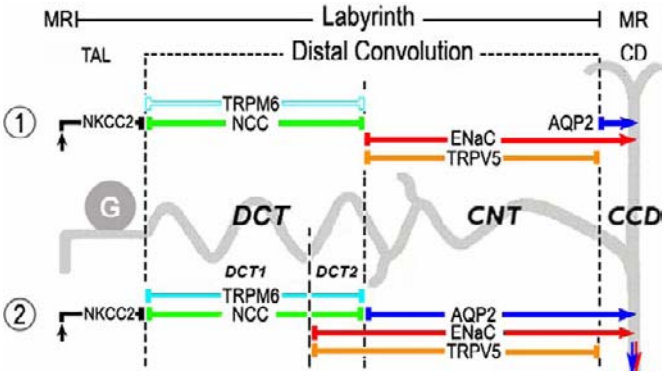

FIGURE 20.55 **Schematic distribution of the major apical transport proteins (NKCC2, NCC, TRPM6, TRPV5, ENaC, and AQP2) along the cortical distal segments.** (1) In rabbit; and (2) in rat, mouse, and human (MR: medullary ray; TAL: thick ascending limb; G: renal corpuscle; DCT: distal convoluted tubule; CNT: connecting tubule; CCD: cortical collecting duct). Sharp beginning and stop of a transporter along the cortical nephron is indicated by vertical bars, the continuation along the CD by arrows.

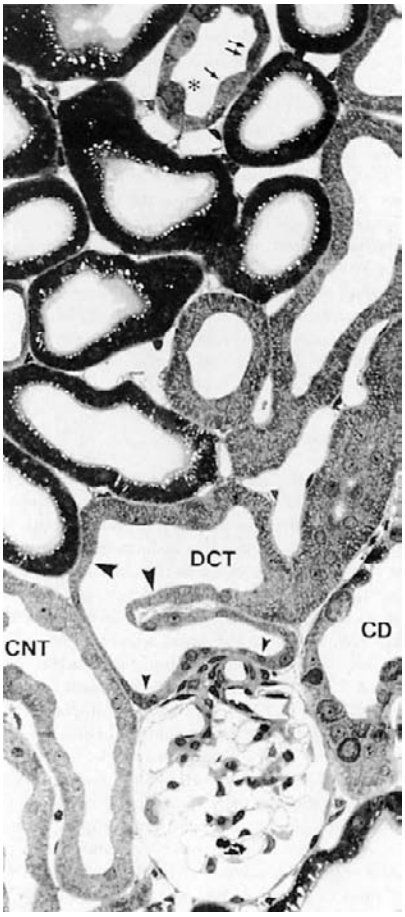

FIGURE 20.56 **Distal tubular segments beyond the macula densa.** Small arrowheads delimit the macula densa, large arrowheads point to the transition from the epithelium of the thick ascending limb to the distal convoluted tubule (DCT) (CNT: connecting tubule; CD: cortical collecting duct). surface area of basolateral membranes and the volume density of mitochondria[280] are the highest of all tubular cells[41] (Figure 20.26). The large lamella-like mitochondria are narrowly enveloped by the lateral interdigitating plasma membrane foldings, all other cell organelles are situated in the apical cytoplasm: the nucleus; the distinct Golgi apparatus; numerous small mitochondrial profiles; short cisterns of rough endoplasmic reticulum; and abundant smooth small, invaginated vesicles closely beneath the apical plasma membrane.[260,552] Lysosomes are less frequently observed in DCT cells. The microtubular system in DCT cells is much more prominent than in proximal tubule cells. The tight junctional belt has a similar organization as in the TAL, but is shorter since the apical portions of the DCT cells have a polygonal outline.The intercellular space has a regular width of about 50 nm and is bridged by an intercellular skeleton.[553] The apical plasma membrane carries numerous stubby microvilli. Single cilia are present on the center of all DCT cells.

In the transitional portion (DCT-2) the lateral folding is progressively superseded by infoldings of the basal plasmalemma which may extend into the apical cell pole. The infolded membranes carry a few caveolae on their cytoplasmic face.[260] This structural observation is confirmed by the finding of caveolin in late DCT cells.[554,555] Size and volume density of mitochondria slightly decrease along the DCT2.

In rats, mice, and humans the appearance of basal plasmalemma infoldings of the DCT cells coincides with the most upstream appearance of intercalated cells. In rabbits, a species that lacks a transitional segment (DCT2), infoldings of the basal plasmalemma and the most upstream appearance of IC cells mark the beginning of the CNT.

Functional Data

Sodium chloride reabsorption by the DCT proceeds via the electro-neutral Na^+-Cl^- co-transporter (NCC) in the apical plasma membrane of DCT cells. NCC is specifically inhibitable by thiazide diuretics,[547,556] which are frequently used in the treatment of hypertension.[547] The driving force for influx of NaCl via NCC is generated by the Na-K-ATPase activity in the basolateral membrane of DCT cells. The basolateral chloride channel, subunit b (ClC-Kb),[479,556,557] extrudes Cl^- ions at the basolateral side of DCT cells. Potassium handling, associated with NCC-mediated transport,

(a) DCT cell, interdigitating, lateral cell processes (arrows) narrowly enclose large mitochondria; (b) CNT cell, displaying a few interdigitating lateral cell processes and abundant infoldings of the basal plasma membrane (arrows), extending up into the apical cell half; most mitochondria are aligned between the infolded membranes; (c) non-interdigitating CCD cell; all infoldings of the basal plasma membrane are restricted to the basal cell portion; the location of mitochondria above the basal rim of infolded membranes is characteristic for CD cells (TEM: ×~10 000).

involves ROMK, detectable by immunomethods in the cytoplasm of DCT1,[481,558] and in the apical membrane of DCT2 cells, and BK channels.[558,559]

The NaCl transport rates by the DCT epithelium are linked with NCC surface expression. It is regulated (among others) by the luminal NaCl-load,[560] dietary salt,[561] by angiotensin II,[562–564] and by sex hormones.[565] Although mineralocorticoid receptors have been detected in the DCT,[547] aldosterone has no effect on NCC-mediated transport since beta hydroxysteroid-dehydrogenase, which confers mineralocorticoid specificity to the receptor, is lacking in DCT1.[562]

Changes in NCC surface expression are effected by trafficking of the co-transporter from the subapical vesicular compartment into[564] and removal by endocytosis[566] from, respectively, the apical plasmalemma, and by altering the NCC degradation rate through the lysosomal pathway.[567,568]

Kinases, such as the serum- and glucocorticoid-inducible kinase, SGK1, with-no-lysine kinases WNK1 and WNK4, both themselves controlled by NaCl intake, play an important role in this regulation.[559,561,569–571] WNKs promote NCC-targeting to the lysosome for degradation.[572] WNK signaling is implicated in the coordination of transcellular and paracellular flux to achieve NaCl and K^+ homeostasis.[250]

Recent data obtained in genetically vasopressin-deficient Brattleboro rats suggest that vasopressin and the vasopressin-V2 receptor-NCC signaling cascade might play a role in the short-term regulation of NCC in the apical plasmalemma of DCT cells.[573,574]Vasopressin-dependent increases in cAMP had not been recorded in the DCT of rats and other species.[534,575]

Chronic increases in the NaCl-transport rates in the DCT, induced in rabbits by high dietary Na-intake combined with low K-intake[280,281] or in rats by rises in NaCl-delivery due to impaired NaCl-reabsorption in the preceding TAL, provoke extensive structural compensatory hypertrophy in the DCT,[290,292,304,576,577] including substantial increases in the DNA synthesis rate in DCT cells.[305,578] These changes occur in the presence, but also in the absence, of increased plasma levels of mineralocorticoids,[578] and are mediated most probably by angiotensin II.[562]

In line with these earlier structural observations are recent studies in a ROMK-deficient mice model for Bartter's syndrome with loss of TAL function. The ROMK-deficient mice reveal hypertrophy of the DCT epithelium, with compensatory upregulation of NaCl reabsorption via the thiazide-sensitive NCC co-transporter.[579,580]

The renal abundance and the NCC-labeling in DCT were found to be profoundly and selectively decreased in aldosterone-escape rats, suggesting that the thiazide-sensitive NaCl co-transporter may be the chief molecular target for regulatory processes responsible for mineralocorticoid escape via a post-transcriptional mechanism.[581]

The DCT determines the final urinary Mg^{2+} concentration through active transcellular transport.[504,548,582,583] The transient receptor potential channel melastatin subtype 6 (TRPM6),[548,584] co-localizes with NCC, at least in the early DCT (DCT1), and is regarded as a likely candidate for influx of Mg^{2+} across the luminal membrane. This influx apparently requires the presence of the gamma subunit of the renal Na-K-APTase in the basolateral membrane of the

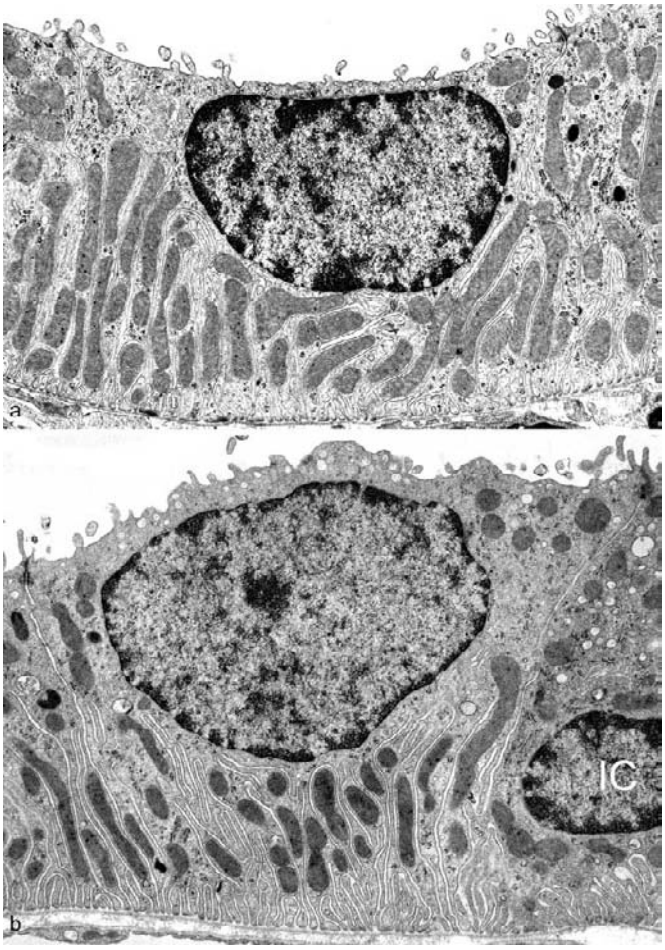

FIGURE 20.58 **Ultrastructure of distal convoluted tubule cells (rat kidney).** (a) Cell in the early and (b) late portion of the DCT; in (a) characteristic apical position of the nucleus and location of the mitochondria in basolateral interdigitating cell processes; the volume density of mitochondria is high; in (b) the amount of basal plasma membrane infoldings is higher than in (a), the amount of mitochondria is lower; the most upstream appearance of intercalated cells (IC) is in the late DCT (TEM: ×~5400).

DCT cells.[276,585] Transcription factor HNF1B (hepatocyte nuclear factor 1 homeobox B) is proposed to regulate the expression of the g-subunit of the Na^+/K^+-ATPase.[586] In addition to the Na-K-ATPase, the DCT cells weakly display the plasma membrane $Ca^{2+}(Mg^{2+})$-ATPase (PMCA)[307,587] and the sodium–calcium exchanger (NCX).[544]

The epidermal growth factor (EGF) expressed by the DCT epithelium[473,588,589] seems to be involved in TRPM6-mediated regulation of active Mg^{2+} reabsorption. Transcellular magnesium reabsorption via TRPM6 seems to critically depend on low levels of free intracellular magnesium, putatively kept low by the cytoplasmic calcium-binding protein parvalbumin (PV). PV has a several-fold higher binding capacity for magnesium than the calcium-binding protein calbindinD28k, and is prominent in the early part of the DCT of mice.[537,538] PV seems also to play a role in the endogeneous NCC expression in DCT cells by modulating intracellular Ca^{2+} signaling in response to ATP.[590]

The key players for paracellular Mg^{2+}-transport, Claudin 16 (paracellin1) and Claudin 19, are both detected in the DCT tight junction,[497] and may enable paracellular Mg^{2+}-movement across the DCT epithelium in addition to the transcellular Mg^{2+}-transport. The tight junction protein Claudin 7 has been found to be highly expressed in the distal convoluted tubules (and collecting ducts) of the mature kidney, suggesting that it may play a role in paracellular NaCl and K handling.[240,591,592]

DCT 2

This transitional segment expresses, in addition to NCC, the amiloride-sensitive epithelial sodium channel, ENaC. The onset of ENaC in the apical plasma membrane coincides with the most upstream appearance of intercalated cells (see below), apical immunoexpression of ROMK. The eyecatching beginning of prominent cytoplasmic immunostaining for Vitamin D-dependent calbindin-D28k, and the marked increase in immunostaining for PMCA and NCX in the basolateral plasma membrane go along with the onset in the luminal membrane of the epithelial calcium channel, TRPV5,[538] the gatekeeper for renal epithelial Ca^{2+} transport.[593] ENaC and TRPV5 are coexpressed in the CNT and will be discussed there.

Rabbits have no DCT2; in this species the transition from the DCT to the CNT is sharp and marked by an abrupt change in cell structure,[280] coinciding with the abrupt onset of ENaC[538] in the apical membrane, as well as the onset of the TRPV5[594] (Figure 20.55), and also the appearance of IC cells.

Dysfunctions of NaCl Reabsorption in the DCT

Inhibition of NCC in rats treated for three to four days with thiazide diuretics induces massive rates of apoptotic cell death of DCT cells in the early part of the DCT, while the late part of the segment with the additional sodium entry pathway ENaC remains intact.[307] If the transport activity of the early DCT cells is inhibited for only a few days, the epithelium rapidly and fully recovers within a few days after removal of the drug.

In loss-of-function mutations of the NCC gene in mice,[595] permanent, dramatic atrophy of the early DCT portion is seen.[545] These data highlight the eminent importance of the transport activity in maintaining and modeling the tubular epithelium. Loss-of-function mutations in the NCC-gene in humans cause "Gitelman's syndrome." This syndrome is characterized by mild

renal sodium-wasting, hypocalciuria, hypomagnesaemia, hypokaliemic alkalosis, and reduced blood pressure in humans.[596–599]

Mutations in the NCC-regulating WNK1 and WNK4 increase NCC activity, and cause Gordon's Syndrome (Pseudohypoaldosteronism type II - PAH II). The symptoms of this disease comprise arterial hypertension, hyperkaliaemia, hypercalciuria and hypermagnesaemia, and mirror Gitelman's disease.[251,567,600] Loss-of-function mutations of one or several of the genes involved in Mg^{2+} reabsorption are associated with hypomagnesemia,[601] characteristic for Gordon's syndrome.[602]

Connecting Tubule (CNT)

In all species the epithelium of the CNT is lined by two distinct cell types (Figure 20.59): the segment-specific CNT cells; and the intercalated cells (IC cells) (see below). The segment-specific CNT cells display the calcium channel TRPV5 and the amiloride-sensitive epithelial sodium channel (ENaC) in their apical plasma membrane. In rats, mice, and humans they display, in addition, the vasopressin-regulated water channel, aquaporin-2 (AQP2) (Figure 20.55). In these species the emergence of AQP2 in the apical plasmalemma in the epithelial lining defines the beginning of the CNT, since TRPV5 and ENaC already appear in the transitional region (DCT2) (see Figure 20.55). Contrastingly, in rabbits vasopressin-regulated water channels are lacking in the CNT. In rabbits the beginning of the CNT is defined by a distinct change in epithelial structure, expression of TRPV5 and ENaC, and the first incidence of intercalated cells[544] (Figure 20.55). Evidently, the CNT shares cytological and functional features ascribed to both the nephron (derived from the metanephrogenic blastema) and the collecting duct (derived from the ureteric bud). The assignment of the CNT to either the nephron or the collecting ducts is disputed.[36,37,603,604]

CNT Cell Organization

The organization of CNT cells (Figures 20.54b, 20.57b, and 20.59b) is similar to that of DCT2 cells, i.e., intermediate between the DCT cells with basolateral membrane surface augmentation by interdigitating lateral folds and the non-interdigitating epithelia (CD cells) with basal plasma membrane infoldings.

The apical and the basal outlines of CNT cells approach a polygonal shape, and the cells are smoothly apposed to each other. The basolateral plasma membrane area is increased predominantly by folding of the basal plasma membrane into the cell. The infolded plasma membranes may extend into the most apical

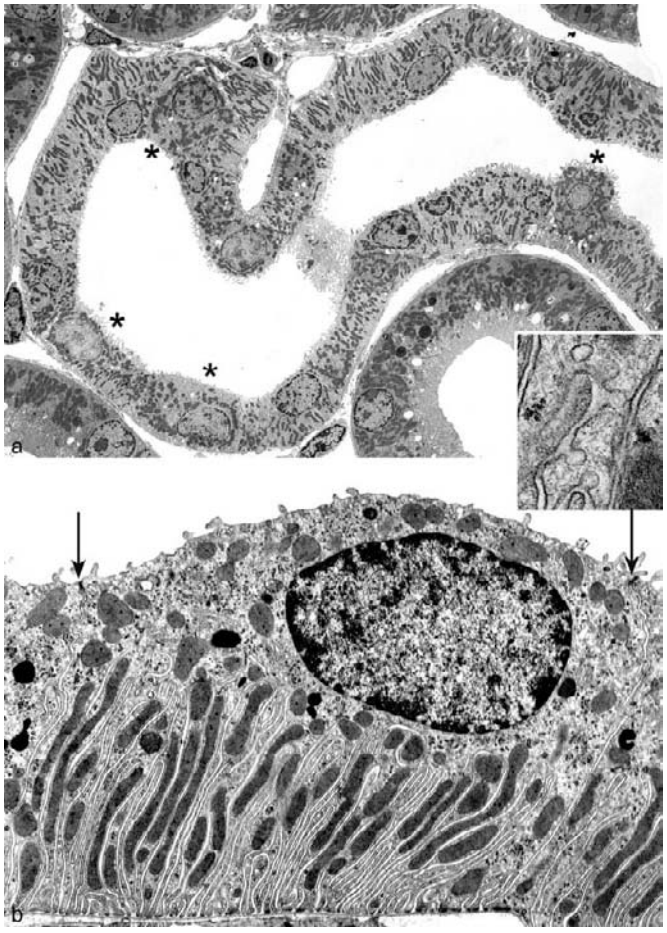

FIGURE 20.59 **Connecting tubule (rat kidney).** (a) The epithelium is composed of CNT cells and IC cells, (asterisks). (b) Characteristic CNT cell with abundant infoldings of the basal cell membrane; the arrows point to the tight junction. Insert: The infolded plasma membranes reveal numerous caveolae (TEM (a): ×~1400; (b): ×~6100).

cell portion, and are endowed with abundant caveolae on their cytoplasmic face[260,554] (Figure 20.59). The extracellular spaces between the basal plasma membrane foldings and the lateral intercellular spaces have no direct continuity and are usually narrow.[260] The apical plasma membrane with short slender microvilli is delimited from the lateral plasma membrane by rather deep tight junctions, composed of several anastomosing strands.[427] The nucleus, the Golgi apparatus, polyribosomes, very short profiles of rER, and elongated and small round mitochondrial profiles are located in the cytoplasm between or above the infolded membranes. Smooth vesicles are particularly abundant in the apical half of CNT cells. In contrast to DCT cells, small lysosomes are frequent in CNT cells.

From the beginning to the end of the segment, the height of the CNT cells, the extent of basal plasma membrane, and their volume density of mitochondria decrease. The steepness of the axial changes is more pronounced in rabbits[280] and mice than in rats, and varies with the functional conditions.[605,606]

Functional Aspects

Calcium Reabsorption

Microperfusion[607] and micropuncture studies had located active Ca^{2+} reabsorption to the distal convolution, including the DCT and CNT (for review see [608]) a long time before the specific Ca^{2+}-channel in the distal segments, TRPV5, was known.. The localization of TRPV5[609] in the apical plasmalemma of the late distal tubule (DCT2 cells and CNT cells[538]) (Figure 20.55) unequivocally identified these segments as sites for active transcellular Ca^{2+} reabsorption in the kidney. The paracellular pathway in these segments is impermeable for Ca^{2+}.

The cytoplasmic calcium-binding protein, calbindin D28k, the sodium calcium exchanger, NCX, and the plasma membrane calcium-Mg ATPase, PMCA, located in the basolateral plasma membrane, are auxiliary proteins necessary for TRPV5-mediated transcellular calcium movement. All three reveal very heavy immunostaining in DCT2 and CNT cells.[537,538] Upon its entry into the cell via TRPV5, calbindinD28k buffers Ca^{2+} and the basolateral Ca^{2+} transporters NCX and PMCA extrude Ca^{2+} into the interstitial compartment.[593] Interestingly, in tubular flow direction immunostaining for TRPV5 progressively shifts from the apical plasma membrane into the cytoplasm,[538] associated with parallel decreases of immuno-traceability for cytoplasmic calbindinD28k, for basolateral PMCA and for NCX. These changes most probably indicate respective changes of transcellular calcium transport rates.

Regulation of transcellular Ca^{2+} transport rates involves changes in the apical channel abundance and direct TRPV5 channel activation.[610] Via binding to its receptor (PTH/PTHrP) in the basolateral plasma membrane of CNT cells,[611–613] parathyroid hormone (PTH) increases the protein expression of TRPV5[593,614] and via a cAMP-PKA signaling pathway PTH increases the channel opening probability.[615] Transcription of the Ca^{2+} channel is regulated by the active form of vitamin D_3, 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$).[594,616] The male and female sex hormones, estrogens and androgens, also play a role in renal Ca^{2+} handling.[617]

Urinary klotho stimulates TRPV5 channel activity at the apical membrane, whereas intracellular klotho enhances basolateral Na-K-ATPase surface expression that activates NCX-mediated Ca^{2+} efflux.[593] Urinary tissue kallikrein (TK) activates a bradykinin receptor (BK2) in the apical membrane of segment-specific CNT cells,[618] and thereby stimulates TRPV5-mediated Ca^{2+} influx.[615,619–621] The sites of TK synthesis in the kidney are approximately congruent with the sites of calcium reabsorption, i.e, the late DCT and CNT.[618] These findings suggest that TK may be a physiologic regulator of renal tubular calcium transport.[622,623] Kallikrein synthesis in the CNT and its subsequent release into the urine are stimulated by aldosterone,[624] dietary Na^+ restriction,[618] and in particular by dietary K^+ loading.[625,626] TK knockout mice display a somewhat delayed kaliuretic response to potassium loading.[623,627]

Sodium Reabsorption

The amiloride-sensitive sodium channel, ENaC, is the key player in the final sodium recovery by the kidney.[628,629] ENaC is a heteromultimeric channel composed of three homologous subunits (α, β, γ).[630] Full activity of ENaC requires the co-expression of all three subunits in the luminal membrane.

The activity of amiloride-sensitive transport is under the tight control of aldosterone.[631] Therefore, all segments with ENaC-mediated sodium reabsorption – DCT2, CNT, and CD – are collectively designated as "aldosterone-sensitive distal nephron" (ASDN[632]). While the mineralocorticoid receptor (MR) is expressed in all distal segments,[633] only the renal ENaC-expressing portions display the enzyme 11-β-hydroxysteroid dehydrogenase type 2 (11βHSD2),[605,606,634–639] which confers mineralocorticoid specificity to the MR. The rate-limiting factor for transepithelial Na^+ transport in the ASDN is the activity and abundance of ENaC in the luminal membrane of the ENaC-expressing cells.

Under control conditions[605,606] all three EnaC subunits are well detectable by immunostainings in the apical plasma membrane of the DCT2- and CNT-cells.[605,606] Along the course of the CNT and CD-segments all three subunits become undetectable in the apical plasmalemma, but heavily accumulate in the cytoplasm.[605,606,639] The decline in available channels in the luminal membrane is paralleled by reduction of basal infoldings and of mitochondria, most evident along the CNT epithelium and by a respective progressive decline of Na^+ transport activity along the axis of the ASDN (CNT > CCD).[604,640] The physiological relevance of ENaC-mediated Na^+ transport in the CNT is highlighted by the observation that the collecting duct-specific deletion of the alpha ENaC gene in mice[604] is fully compensated by the residual activity of ENaC in the upstream located CNT (and in the DCT2).[604]

In fact, recent data on the three-dimensional reconstruction of the mouse nephron show that five to seven nephrons are connected via a CNT to a single CCD.[34] Thus, the collected luminal surface for ENaC-mediated sodium reabsorption in the late DCTs and the CNT,[37,641] is several-fold greater than that available in the CCD itself.

All factors involved in regulation of sodium transport rates in the ASDN (hormones, proteases, intra-, and extracellular ion concentrations, tubular flow rate, as well as kinases and interacting proteins (for review see [562,642–644]), ultimately target the ENaC channel activity or abundance in the apical plasma membrane. Changes in ENaC abundance in the luminal plasma membrane involve channel synthesis, exocytotic delivery of subunits to the cell surface, and endocytotic retrieval of channels from the luminal membrane and their degradation.[300,562,628,644,645]

Endogeneous increases in plasma aldosterone levels rapidly induce (within hours) activation and redistribution of ENaC subunits from intracellular compartments to the apical plasma membrane[605,631,639,646] and a decrease of internalization of ENaC through the synthesis of SGK1.[647–649] Prolonged changes in EnaC-mediated sodium transport promote respective changes in cell height, abundance of basolateral plasma membrane infoldings, and the density of mitochondria,[280,290,292,293] which all together reflect the changes in Na^+ transport rates.

ENaC channel activity and abundance in the apical plasma membrane of the ASDN is also target of other hormones. The co-expression of ENaC with vasopressin receptors (V1 and V2) and vasopressin-sensitive water channels AQP2 in rat-, mice-, and human-segment-specific CNT (not in rabbit CNT cells) suggests the mutual interaction of sodium and water transport.[650,651] Indeed, vasopressin facilitates the translocation of ENaC to the apical membrane[652] and on removal of a V2R agonist ENaC is endocytosed from the membrane surface and reorganized into recycling vesicles, with a mechanism similar to that described for AQP2 regulation.[653] The delivery of somewhat water-depleted tubular fluid from the CNTs to the cortical collecting duct might enhance the urinary concentration process in the CD. Interestingly, in rabbits, in which the CNT lacks vasopressin-sensitive water channels, the arcades open at a much higher cortical level into the cortical collecting duct than in rats, mice or humans.[37]

Insulin and insulin-like growth factor,[610] angiotensin II[654–656] kinases, interacting proteins, intra-, and extracellular ion concentrations, osmolarity (for review see [645]), locally released nucleotides, and tubular flow rate (for review see [657]) have also been shown to modulate ENaC-mediated Na-transport activity.

Potassium Transport

In all ENaC-displaying cells renal outer medulla potassium channel ROMK is strongly expressed in the luminal membrane, where it co-localizes with PDZ proteins (NHERF2).[272] ENaC-mediated sodium reabsorption is coupled in a fixed ratio with K secretion via the ROMK. K^+ enters the cell by the activity of the Na-K-ATPase in the basolateral membrane, and exits into the tubular fluid via ROMK. The ratio of sodium-reabsorption and K-secretion by the segment-specific (CNT; CD cells)[658] can be modulated by intercalated cells which are bound to ENaC-displaying epithelia. The proton secretion by IC cells via a H-K-ATPase can apparently be coupled with K reabsorption.[659] Therefore, the ASDN is also the tubular site for net renal potassium (K^+) excretion.[482,660] The main factors regulating K^+ secretion are dietary K^+ intake and aldosterone (for review see [562]).

Mutations in the genes coding for ENaC subunits,[628,629] and for proteins involved in ENaC-associated K-secretion (ROMK),[661] as well as the correct targeting into or removal from the membrane (e.g., SGK1, Nedd4-2; for review see [645]) are associated with severe disturbances of blood pressure regulation.[662]

Transition From CNT tO CCD

In rodents and humans no marked structural change indicates the transition from the CNT to the CCD. Morphologically, the CCD can be defined by its location in the medullary ray. In difference, in rabbits the clear-cut onset of vasopressin-regulated water permeability marks the beginning of the CCD. It is associated with the appearance of dilated intercellular spaces in the epithelium[5,280] and the change of segment-specific cells, i.e., from CNT- to CD-cells.

By immunostaining, the beginning of the CCD is defined in rodents and rabbits by the break-off of TRPV5 (Figure 20.55) and related proteins (NCX, calbindin D28k[538,544]). In humans, NCX and calbindin D28k have also been detected in the CCD.[539]

Collecting Ducts

The CCD, the OMCD, and the upper part of the IMCD are composed of segment-specific cells (CD cells) and intercalated cells (IC cells; see subsequent sections) (Figure 20.54). The CD cells (Figures 20.54, 20.57, 20.60 and 20.61) have simple polygonal basal and apical outlines. Their most characteristic feature is the narrowly arranged basal plasmalemma infoldings of uniform height (Figures 20.54, 20.57, and 20.60) at the base of the cells, easily recognizable in light- and electron-microscopy as a basal light rim. All major cell organelles – the nucleus, small

mitochondria, numerous small Golgi-fields, abundant profiles of smooth ER, and a few of rough ER, lysosomes, multivesicular bodies, and occasional glycogen accumulations – are located in the zone above the infolded membranes. The subapical zone often reveals small round or elongated vesicles, oriented either perpendicularly or at an oblique angle to the luminal membrane (Figure 20.61c). These vesicles contain aggregates of AQP2, and are called aggrephores. Many of the aggrephores carry spherical clathrin-coated heads. The tight junctional belt is deep and consists of anastomosing strands with high particle density.[663] The apical plasma membrane generally bears only a few short slender microvilli or microfolds. The prominent central single cilia on the collecting duct-specific cells (Figure 20.62a) have been proposed as the key structural element in the Ca^{2+} response to fluid shear stress.[312,664] Short microvilli or folds of the lateral plasma membrane project into the intercellular space, and are connected by small desmosomes with those of adjacent cells (Figure 20.62b). In marked contrast to the water-impermeable epithelia of the TAL and the DCT, the width of the intercellular spaces between CD cells as well as the space between the infolded basal plasma membranes may be largely dilated or narrow, correlating with bulk water flow across the epithelium (see below).

The cytoskeleton is particularly prominent in CD cells. Actin filaments and microtubules form a dense meshwork along the apical and lateral plasma membrane. The cytoskeleton is essential for the shuttling of AQP2 to and from the plasmalemma (see below). Furthermore, the prominent cytoskeleton may be one mean, among others, to withstand the varying osmotic pressure in the collecting duct.

The CD cell undergoes gradual, although considerable, changes from the deep cortex (CCD) downstream to the upper third of the inner zone (IMCD) (Figure 20.61). The extent of basal plasma membrane foldings and the volume density of mitochondria decrease from the cortex towards the inner zone, whereas the volume density of lysosomes and the density of cytoskeletal proteins increase. The degree of changes along the CD differs among species.[5,260,540]

The CD cells in the lower two-thirds of the inner medulla are distinguished as inner medullary collecting duct cells (IMCD cells).[552] In rabbit[5] and guinea pig, IMCD cells increase in height toward the papilla up to 20-fold. A substantial, albeit less dramatic, increase occurs in rhesus monkey[665] and in human kidney.[540] In other species (e.g., rat, mouse, *Psammomys*, and dog[260]) the epithelium near the tip of the papilla is cuboidal or low columnar. The luminal membrane of IMCD cells is covered by numerous stubby microvilli, and generally lacks the central cilium.[546] The lateral intercellular spaces are conspicuous by their dense assembly of microvilli and microfolds, projecting from the lateral cell membranes. In the beginning of the inner medullary collecting duct (IMCD) the tight junctions are complex and consist of several anastomosing strands.[260] Toward the papillary tip in rat and rabbit, there is a considerable decrease in the number of strands, and in the apico–basal depth of the junction.[260]

Sodium Reabsorption in the Collecting Duct

Together with the vasopressin-regulated water-channel AQP2, the CD cells consistently express the amiloride-sensitive Na-channel ENaC (see CNT)[666] (Figure 20.55) and ROMK. The coexistence of the differentially regulated pathways for water- and Na-reabsorption in the same cell suggest the possibility for mutual interactions.[650,666,667]

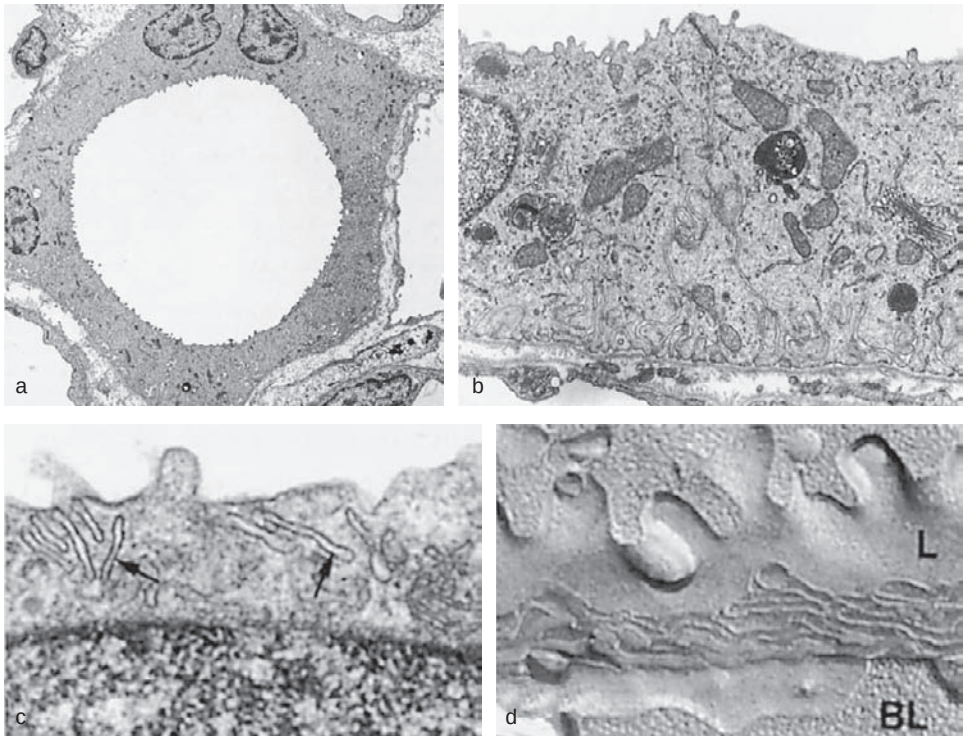

FIGURE 20.61 **Inner medullary collecting duct.** (a) Tubular profile showing the homogenous epithelium (rat: TEM: ×~3400). (b) Epithelium of the middle portion of an IMCD. Within the epithelium three zones are seen: a basal zone with basal infoldings, a middle zone containing Golgi fields, mitochondria and lysosomal elements, and a thin apical zone with tubular and vesicular profiles. Note the deep tight junction (rat: TEM: ×~17,000). (c) Apical zone of a CD cell with many elongated tubular profiles (arrows) which are believed to represent agrophores (rat: TEM: ×~38,000). (d) Freeze-fracture electron micrograph to show the multistranded tight junction of the collecting duct epithelium (L: luminal membrane; BL: basolateral membrane; Rabbit: ×~34,000).

Recently, a second pathway for electroneutral NaCl absorption has been revealed in the collecting duct epithelium, This pathway is located in the intercalated cells (see below) and is insensitive to amiloride but inhibited by thiazides, and couples 2 anion exchangers, pendrin and Na-driven chloride/bicarbonate exchanger (NDCBE)[668,669] (see "Intercalated Cells").

Paracrine and autocrine regulation by the purinergic system[296,657,670,671] mediates flow-and metabolic rate-dependent changes of Na^+ and water transport in the collecting duct.

Vasopressin-Regulated Water and Urea Reabsorption in the Collecting Duct

Collecting ducts are the canonical targets for vasopressin-sensitive water and urea reabsorption.[672] They display receptors for vasopressin (V_1 and V_2) in the basolateral plasma membrane of the segment-specific cells, the CD cells,[519] and vasopressin-sensitive water channels AQP2. Water permeability of the luminal membrane is achieved by exocytotic insertion of the vasopressin-regulated water-channel AQP2 from subapical vesicles (aggrephores) into the apical cell membrane. The exocytosis is triggered by binding of vasopressin (ADH) to the V2-receptor at the basolateral membrane of CD cells and the subsequent signal transduction cascade. The aggregates of AQP2 in the aggrephores are colocalized with dynein and dynactin.[673] Many of the aggrephores carry spherical clathrin-coated heads. With low levels of vasopressin, the AQP2-containing membrane portions recycle back into the subapical cytoplasm.[299,674–676] The movement of aggrephores critically depends on microtubules and actin filaments in the apical cytoplasm.

High levels of vasopressin-independent AQP2 surface expression have been observed under long-term[677] and acute[678] exposure of rats and mice to statins. Applied chronically, statins decrease membrane cholesterol[679] and clathrin-mediated endocytosis of AQP2. Acutely, the statins seem to decrease endocytosis of AQP2 and vesicle trafficking by modulating Rho-GTPase,[678] which is involved in regulation of the cytoskeleton, endocytosis, and vesicle trafficking.[680,681] The water channels AQP3 and AQP4 are both located in the basolateral membrane of CD cells.[682] AQP3 is permeable to glycerol, urea, and water; AQP4 is associated with orthogonal arrays of intramembrane particles, as

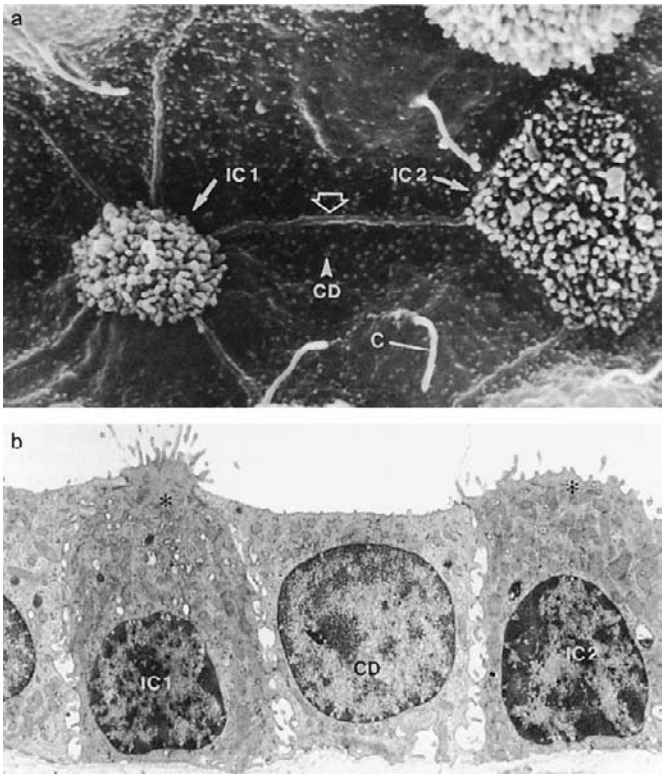

FIGURE 20.62 **Intercalated cells from the rabbit.** (a) Scanning electron micrograph of a cortical collecting duct with collecting duct-specific CD cells (CD) and intercalated cells (IC). The CD cells carry single cilia (C) and short microvilli (arrowhead). The straight ridges (open arrow) represent the cell borders between CD cells. From the IC cells one (IC 1) has a narrow, constricted apical cell pole, the other one (IC 2) a large apical cell pole, both adorned with numerous long microvilli (TEM: ×~13,000). (b) Section across corresponding cells. Note the position and accumulation of flat vesicles (asterisk) in the apical cell pole of the IC cells (TEM: ×~7500).

revealed by freeze-fracture studies in the outer medullary collecting duct.[683,684]

The IMCD cells co-express, in addition to vasopressin-regulated AQP2, the vasopressin-regulated urea transporters UT-A1/3 and possibly UT-A4 (for review see [148]). The abundance of UT-A1/3 in the apical membrane is rate-limiting for transepithelial, vasopressin-dependent urea reabsorption.[571,685] The basolateral membranes of the IMCD cells display the water channel AQP3. The abundance of UT-A1/3 in the apical membrane is rate-limiting for transepithelial, vasopressin-dependent urea reabsorption.[571,685] In the basolateral membranes of the IMCD cells the water channels AQP3,[682] permeability to glycerol, urea and water,[686] and AQP4[683,687] with an apparently low urea permeability have been demonstrated.

The genes coding for proteins, which are involved in cellular accumulation of organic osmolytes, such as the vasopressin-regulated urea transporter UT-A and heat shock protein 70,[688] are target genes of the tonicity-response enhancer binding protein (TonEBP), a transcriptional activator of the REL-family. During kidney development, expression of TonEBP precedes that of the urea transporter. It is first detected in the renal medulla of mice at the fetal age of 16 days and increases up to postnatal day 21, when the medulla is fully developed and the urinary concentrating ability is achieved.[689]

Intercalated Cells (IC Cells)

Intercalated cells (IC cells) are interspersed as single cells among the epithelium of the ASDN (i.e., among ENaC-displaying epithelia, the late DCT (DCT2), the CNT (Figure 20.59a), and the CD (Figure 20.60a). IC cells play a decisive role in the final regulation by the collecting system of acid−base excretion, in potassium reabsorption and secretion, in ammonia excretion and, as discovered recently, intercalated cells participate together with the segment-specific cells in electroneutral sodium reabsorption.

Consistent Structural Features of Intercalated Cells

Intercalated cells reveal conspicuous structural heterogeneity (Figure 20.61). IC cells usually do not form a continous epithelial layer, but at least their luminal poles are entirely surrounded by the segment-specific cells. The luminal outline of IC cells is in most cases rather circular (Figure 20.62a),[291,540,690−692] IC cells generally reveal a specific surface pattern of microprojections (Figure 20.62a) and lack, at least in the cortex, the central cilium which is apparent on other cells (Figure 20.62b). Among the most consistent distinguishing intracellular features is the distribution pattern of mitochondria: the often rounded mitochondrial profiles lack the systematic association to basolateral cell membranes[35,693,694] evident in other tubular cells. The generally small, more or less round vesicles often reveal an invagination bordered by a thin smooth membrane ("invaginated vesicles"[5]); they participate in endocytosis[695−697]; the elongated slender profiles − "tubules" − probably represent sections through flat saccules or collapsed large spherical vesicles ("flat vesicles").[5] Occasionally they are found to be continuous with the luminal membrane, and are often in close juxtaposition with mitochondria.[5] Transitional forms between the two vesicle types can be seen; the presence of specific particles in one or several membrane domains (luminal, basolateral, and/or tubulo-vesicular) have been observed. In TEM preparations the membranes reveal a coat of densely arranged, approximately rectangular large particles, so-called "studs," on their cytoplasmic face. The "studs" are 10 nm spherical

structures (Figure 20.65a,c,d), which represent the H^+-ATPase.[698,699] In freeze-fracture preparations dense arrays of intramembrane particles, so-called "rod-shaped" particles appear on the P-face of the membranes (Figure 20.65b).[543,700] The presence of "studs" and of "rod-shaped" particles on the cytoplasmic membrane faces often coincides. Clathrin-coated pits on either the luminal or the basal cell membrane and clathrin heads on the "studded" vesicles are regularly found. The nucleus generally reveals more heterochromatin condensations and looks darker than that of the adjacent CNT or CD cells.

Proteins Related to Intercalated Cell Functions

All intercalated cells display high levels of cabonic anhydrase II in the cytoplasm.[450,472,701–704] All IC cells express the electrogenic V-type proton-ATPase, the proton pump[698] in at least one of their membrane domains, and all express an anion exchanger, either anion exchanger 1 (AE1, gene Slc4A1; band 3[705]) or Pendrin (Slc 26A4[706]) in one membrane domain. Pendrin is an aldosterone-sensitive Na^+-independent Cl^-/HCO_3^- exchanger that mediates Cl^- absorption and HCO_3^- secretion in the cortical collecting duct (CCD).[669] Furthermore, studies on isolated CCDs suggested that the parallel action of the Na^+-driven Cl^-/HCO_3^- exchanger (NDCBE/SLC4A8) and the Na^+-independent Cl^-/HCO_3^- exchanger (pendrin/SLC26A4) account for the electroneutral thiazide-sensitive sodium transport in the CCD (where the thiazide sensitive electroneutral NaCl co-transporter NCC is not expressed), a finding that challenges the current concept of a functional separation between principal cells for the regulation of sodium and potassium balance, and intercalated cells for acid–base regulation.[668]

All IC cells express the Rhesus glycoproteins, Rh B Glycoprotein (Rhbg[707]) and Rh C Glycoprotein (Rhcg[708]). These proteins are recently recognized ammonia transporters in the distal tubule and collecting duct. Rhcg is present in both the apical and basolateral plasma membrane, is expressed in parallel with renal ammonia excretion, and mediates a critical role in renal ammonia excretion and collecting duct ammonia transport. Rhbg is expressed specifically in the basolateral plasma membrane.[709]

Subtypes of Intercalated Cells

By morphological criteria and distribution patterns of specific transport proteins (Table 20.1) three different manifestation of IC cells have been described, type A cells, type B cells,[694] and type nonA-nonB cells.[710]

TYPE A IC CELLS

Morphologically, the type A IC cells usually have a broad protruding apical cell pole, which is adorned with numerous slender microfolds and/or finger-like microvilli giving rise to a very complex surface pattern[5,691,694](Figures 20.63a and 20.64a). The cytoplasmic membrane face of the microprojections and of the esicles in the apical cell pole are "studded"[594] (Figure 20.65a). "Rod-shaped" particles (Figure 20.64b) have also been demonstrated.[700] The mitochondria are particularly numerous, and are accumulated in the apical cell pole above the large round nucleus (Figure 20.64a). They are often found very closely adjacent to the luminal cell membrane. They possess narrower cristae, and their matrix appears more electron-dense than in other cell types. The Golgi apparatus and other cell organelles are only slightly apparent among the numerous mitochondria. Polyribosomes may be exceedingly frequent. Some profiles of RER are

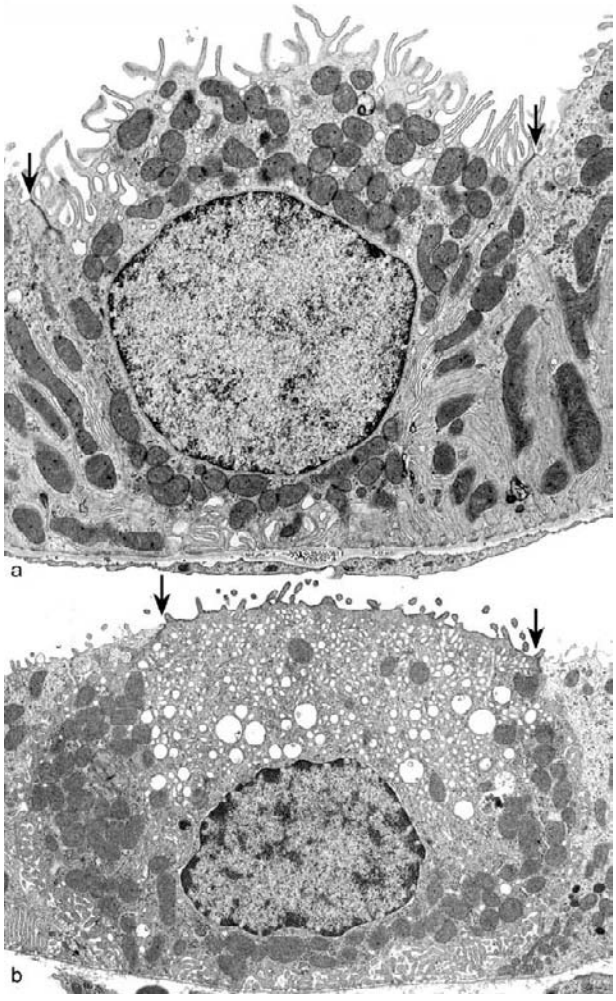

FIGURE 20.64 **Intercalated cells (rat).** (a) Type A cell with many luminal microfolds and abundant mitochondria in the apical cell pole. (b) Type B cell with a rather narrow apical cell pole, a narrow rim of dense cytoplasm with no vesicles under the apical plasma membrane, abundant smooth-surfaced vesicles in the apical cytoplasm, and a huge Golgi complex (G), with abundant mitochondria along the basolateral plasma membrane (Arrows: Tight junction; TEM: ×∼7000).

generally found in basal cell portions. Basal infoldings can be extensive in the rat,[694,711] yet in the rabbit they are virtually absent.[712]

Some structural variation within type A cells exist among and even within individuals. They concern essentially the extent of studded membrane projections on the luminal cell surface, and the abundance of studded tubulo-vesicular profiles in the apical cell pole. The membrane surface area of the microfolds seems to be inversely related that of the tubular-vesicular profiles; both vary with functional conditions. For instance, under acute metabolic and respiratory acidosis[711] and/or potassium depletion the vesicular pool decreases and the apical membrane increases. Mitochondria with rather short profiles and narrowly arranged cristae are amassed in the apical cell pole, in particularly close vicinity to the apical cell membrane. Many microtubules and clathrin-coated vesicles are apparent between the tubulo-vesicular profiles and the mitochondria. The nucleus is shifted to the basal cell portion (Figures 20.63a and 20.64a) (for review see [492,698,713]).

IC cells in the outer medulla and the initial part of the inner medullary CD (rats) appear slightly different from the cortical type A cells. In rats, the apical cell pole is often narrower than the basal cell pole.[268] The mitochondrial profiles are fewer and smaller than in cortical type A, the Golgi apparatus and the SER are less apparent than in cortical type A cells, the basal infoldings are less extensive compared to cortical type A cells and the nucleus has a characteristic elongated flattened profile. Among the "studded" vesicles in the apical cell pole very large round profiles and

particularly long flat vesicles often predominate over other cell organelles.

Type A IC cells are considered as the proton-secreting cells. Their apical membrane domain possesses various subunits of H^+-ATPase, among them the B1- and d-subunits which possess a high selectivity for intercalated cells.[698,699,715–719] The proton-ATPase functions in series with a bicarbonate/Cl (HCO_3^- /Cl^-) exchanger located in the basolateral membrane domain (for review see [492]). In type A IC cells the HCO_3^- /Cl^- exchanger is the anion exchanger AE1 (SLC4A1, band 3), a splice variant product of the erythrocyte band 3 gene.[705,720] The presence of AE1 in the basolateral membrane is decisive for diagnosis of type A IC cells.[705,721]

In addition to the V-type proton-ATPase type A IC cells – at least in the outer stripe – also display a P-type (gastric-type) K-H-ATPase, shown so far in rat and rabbit.[578,659,722–726] This K-reabsorbing ATPase seems to be associated with clusters of rod-shaped particles, revealed by freeze-fracture studies on the P-face of cell membranes in rabbit IC cells.[700] Thus, the type A IC cells could be involved in recovering potassium, secreted via ROMK, in association with EnaC-mediated Na-reabsorption by the segment-specific cells. Type A cells also express the chloride channel ClC 5.[727] The secretory isoform of the Na-K-Cl-co-transporter, NKCC 1, has been detected in the basolateral membrane of type A cells in the outer stripe.[728]

The type A IC cells express apically and basolaterally non-erythroid Rh-associated glycoproteins Rhcg and basolaterally Rhbg,[492,494,709,729–731] which mediate transport of ammonia/ammonium (NH_4^+/NH_3)[494,732] when expressed in *Xenopus laevis* oocytes.[733]

In chronic metabolic acidosis and prolonged high proton secretion the type A IC cells hypertrophy (for review see [492]), and IC cells in the OMCD and IMCD show increased RhCG expression.[734] However, genetic ablation of the RhBG gene is not a critical determinant of NH_4^+ excretion by the kidney under acidic or under control conditions.[729] Under chronic acidosis the type A IC cells proliferate, as evidenced by upregulation of cell cycle proteins, by incorporation of the thymidine analog bromo-deoxyuridine (BrdU) and mitotic figures.[735]

TYPE B IC CELLS

Morphologically, Type B IC cells reveal a relatively small, occasionally slightly polygonal luminal outline and protrude only slightly into the lumen (Figures 20.60a, 20.63b, and 20.64b[711]). The cells seem to be partly covered by the adjacent CD cells, and their sectional profiles often appear almost elliptical (Figures 20.63b and 20.64b). The luminal membrane, with only a few short microprojections, lacks "studs".[736] In contrast, "studs" may be apparent on

fragments or even along the entire lateral and often extensive formation of infoldings of the basal plasma membrane (Figure 20.65d). The small short mitochondria are accumulated in the basal cell portion and along the lateral cell faces (Figures 20.63b and 20.64b), but they are never found immediately beneath the luminal membrane. The cytoplasm above the plane of the tight junctional belt may be completely devoid of any cell organelles. The nucleus often reveals some basal indentations,[711] and is often situated eccentrically. The center of the cell is occupied by a conspicously developed Golgi apparatus, a few short profiles of RER, polyribosomes, and microtubules, as well as lysosomes of varying dimensions, and autophagosomes containing frequently recognizable remnants of mitochondria or membranes. A striking feature of these cells is the high abundance of narrow-meshed profiles of smooth ER, often with clathrin-coated heads.[329] The SER is intermingled with a great amount of small, generally "unstudded" invaginated vesicles, which are preferentially found in the apical cell portion, but may be accumulated also in the direct vicinity of the basal cell membrane. "Studded" vesicles are sparse or lacking.

The type B cells also display different manifestations. Between cells which are densely stuffed with SER and display very few mitochondria and very few "studded" membrane domains, and cells which contain large amounts of mitochondria, of "studded" vesicles, and which may be even densely covered with short microvilli, all intermediates can be found. Another configuration of possibly type B cells is found in the cortex of rabbits. These cells appear "constricted" at the level of the tight junctional belt where a prominent web of microfilaments is evident. Some elongated profiles of "studded" vesicles are found within and beneath this web. The narrow, apical cell pole is adorned with a tuft of long microvilli.[260]

Type B IC cells mediate secretion of HCO_3^- through apical Cl^-/ HCO_3^- exchange, which functions in series with H^+-ATPase-mediated H^+ efflux across the basolateral plasma membrane.[737] They are characterized by apical pendrin (Slc4A1)[738–740] and basolateral H^+-ATPase. Type B cells reveal less carbonic anhydric activity than type A cells,[702] and they express the chloride channel ClC 3[727] in the apical cell pole.

Metabolic alkalosis is compensated in the kidney by reducing bicarbonate reabsorption and increased bicarbonate secretion by type B IC cells. Type B IC cells adapt under chronic metabolic alkalosis with cellular hypertrophy.[741] DNA synthesis and mitoses of type B cells have been recorded under this situation.[742] Adaptive downregulation of pendrin in metabolic acidosis indicates the important role of this exchanger in acid–base regulation in the CCD.[741] The type B intercalated cell does not express either Rhbg or Rhcg detectable by immunohistochemistry.

NON A-NON B CELLS

A third type of IC cells without evident polarity with respect to proton-APTase, and so far with undefined function, are called "non A-non B" cells.[738] These cells are often much larger and protrude much more into the lumen than type A or B.[709] In contrast to type A and B IC cells, neither the luminal nor the basolatreal plasma membranes reveal "studs," at best "studs" are found on membranes of vesicular profiles in the cytoplasm. In mice this latter population of intercalated cells is more frequent than in rats.[743] It decreases in either pronounced chronic metabolic acidosis or pronounced chronic metabolic alkalosis.[492,711,744]

On their apical plasma membrane they display, similar to type B IC cells, the anion exchanger pendrin (Slc4A1) and diffusely distributed H^+-ATPase, occasionally also in the apical membrane. They express apical, but not basolateral, Rhcg and basolateral Rhbg.[709]

The observations on non A-non B cells, the striking structural diversity[713,745] and the apparent plasticity of IC cells raised the question whether one, two or more distinct cell types are subsumed in the IC cell population or whether the different appearances are manifestations of different functional stages of the same cell type. Based on studies in collecting ducts *in vitro* from adult rabbits and IC cells cultured *in vitro*,[746–749] (IC cells with the morphology of type B were identified by apical binding to peanut lectin),[750] it was speculated that the IC cells might reverse their polarity in response to specific functional environmental conditions. Type A would present the terminal differentiation of IC cells. This hypothesis received support from studies *in vitro* showing that the matrix protein hensin could reverse the functional phenotype of cultured intercalated cells (for review see [492]), and induce the type A IC cells. The non A-non B cells might represent intermediate stages. The diminution of this latter population under chronic acidotic or alkalotic conditions would agree with this hypothesis.

Another view was that the non A-non B cells could be precursors for either A or B cells or only of B cells (for review see [492]). This hypothesis would also be supported by the finding of a diminution of non A-non-B cells under chronic acidosis or alkalosis. The observations on mitosis in fully-differentiated type A,[735,751] as well as in type B IC cells[742] do not agree with the hypothesis on reversal of polarity, nor with the hypothesis claiming a common precursor cell of type A and B.

Most IC cells also display on at least one membrane domain (more often on the luminal and vesicular than on the basolateral) the AMP-degrading phosphatidyl-inositol-anchored ecto-enzyme 5′nucleotidase

(5′NT)[57,60,740,752,753] and the protein Connexin 30, that might function as plasma membrane ATP channel.[754] It has been shown that increased flow in the distal nephron induces K secretion through the large-conductance, calcium-activated K channel (BK), which is primarily expressed in intercalated cells (IC). High distal flows and shear stress induce BK-dependent K efflux and ATP release from IC cells.[295] These mechanisms might play a role in the purinergic autocrine and/or paracrine regulation of salt and water reabsorption.[317]

The intergral membrane proteins syntaxin 3[755] and synaptotagmin VIII demonstrated in the basolateral membrane of IC cells,[756] are possibly involved in the targeting of acid−base transporters and may participate in the basolateral membrane remodeling of IC cells in response to systemic acid−base perturbations.

Interestingly, it had been reported that IC cells lack significant levels of Na-K-ATPase in the basolateral membranes.[283] However, more recently, weak to moderate Na-K-ATPase was revealed in cortical and outer medullary IC cells, whereas IC cells in the upper part of the inner medullary collecting duct showed a staining intensity that was similar or even stronger to that in adjacent IMCD cells.[757]

Distribution of IC Cells

The ratio of intercalated cells to other tubular cell types varies among and within species, and along the distal segments (DCT, CNT, upper and lower half of cortical collecting duct, outer and inner stripe collecting duct). Possibly, it may be altered by some functional conditions.[744] Discrepancies in reported data for a given species may be rooted in poor definition of the investigated kidney region, and also in the criteria used for the recognition of cells. The relative number of intercalated cells (all forms) in the various segments is roughly ∼25−30% in the CNT, ∼40% in the CCD and OMCD, and ∼10% in the initial IMCD.[699,718,743,758] IC cells are absent in deeper levels of the inner medulla in most species.

In the rat, taking the morphological, cyto-, and immunochemical data together, it can be deduced that among the IC cells in the CNT the type A cells prevail. Type B cells are in the minority among the IC cells in the CNT in rat, but not in mouse. Type B IC cells constitute the majority of IC cells in the CCD, of which a varying proportion may present proton-ATPase in the basolateral cell membrane. Based on the different distribution of the proton-ATPase in non-type A intercalated cells, it has been suggested type B IC cells with only basolateral proton-ATPase staining and non-A/non-B IC cells with bipolar or luminal proton-ATPase staining should be distinguished.[743] However, both subpopulations carry pendrin staining, and may represent different states of activity.

In the CCD type A cells are in the minority, and often appear in their apparently functionally less active form, with less microprojections, but more intracellular "studded" vesicles than type A cells in the CNT.[759] Accordingly, they display a slightly weaker luminal, but often a diffuse cytoplasmic, staining for the proton-ATPase. Apparently only one type of IC cells exists in the OMCD of rats, mice, and humans. It resembles the type A cells in the cortex.

Disruption of IC Cell Characteristic Genes

Inheritable forms of distal renal tubular acidosis (dRTA) most often affect the physiology of type A IC cells.[760] Disruption of one of the IC cell characteristic genes leads to profound structural alterations of IC cell types. In mice with functional deletion of carbonic anhydrase II, the frequency of IC cells is drastically reduced.[701]

The genetic disruption of pendrin (Slc26a4) leads to marked reduction of type B cell size, with reduced H^+/OH^- transporter expressions.[506,738] In mice with disruption of the Foxi1 gene, upstream of several anion transporters, proton pumps, and anion exchange proteins expressed by intercalated cells, and of the collecting ducts cells, the normal collecting duct epithelium with its two major cell populations − collecting ducts cells (principal) and intercalated cells − has been replaced by a single cell type positive for both principal and intercalated cell markers.[761]

ARCHITECTURAL−FUNCTIONAL RELATIONSHIPS

So far we have always emphasized the relationships between structure and function. However, we have neglected the important relationships between architecture and function − i.e., arrangements through which the close relationships between certain nephron and vascular portions permit the carrying out and coordination of complex regulatory functions. The two most obvious examples in this respect are the juxtaglomerular apparatus (JGA), regulating glomerular perfusion and renin secretion, and the renal medulla permitting the production of urine, varying in dilution and concentration.

Juxtaglomerular Apparatus

The juxtaglomerular apparatus (JGA) is a composite assembly of specialized structures at the vascular pole of the glomerulus (Figures 20.28 and 20.29). The thick ascending limb of Henle's loop (TAL) returns to its parent glomerulus and extends through the angle

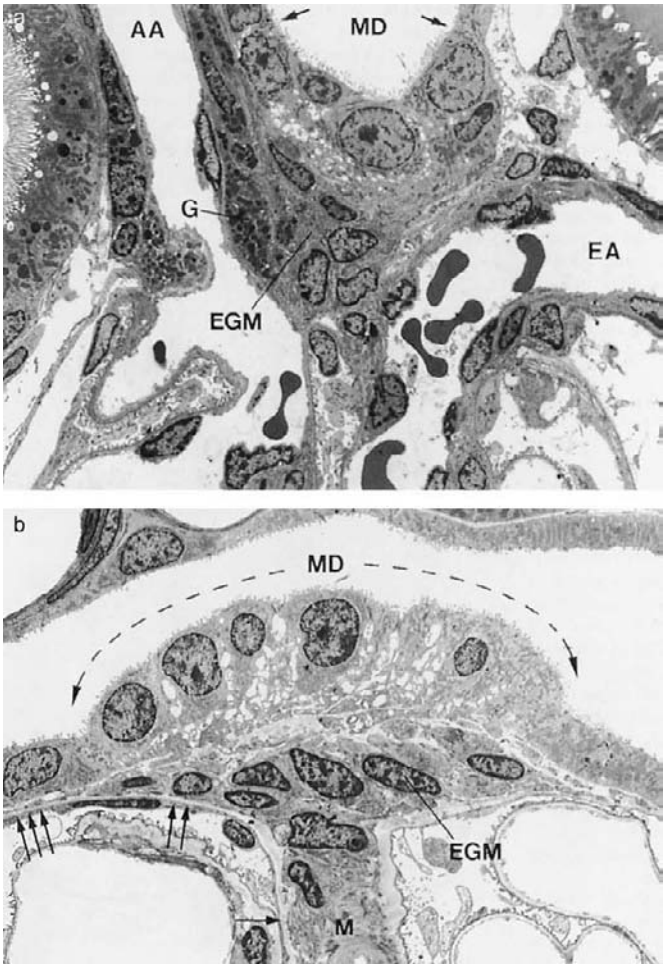

FIGURE 20.66 **Juxtaglomerular apparatus.** (a) Meridional section through a glomerulus which runs through both glomerular arterioles (rat). The macula densa (MD) is attached to the extraglomerular mesangium (EGM), which fills the angle between the afferent (AA) and efferent (EA) arteriole. Within the wall of the afferent arteriole granular cells (G) are seen. Note the intraglomerular segment of the efferent arteriole (TEM: ×~1850). (b) Meridional section through a glomerulus running in between both arterioles (rabbit). The macula densa (MD) is a prominent cell plaque within the thick ascending limb. It covers the extraglomerular mesangium (EGM). Within the glomerular stalk the EGM continues into the mesangium (M). The EGM interconnects opposing parts of the GBM (one arrow) to the basement membrane of Bowman's capsule (BCBM) (two arrows), as well as the first parts of the BCBM (three arrows). Note the dilated intercellular spaces between macula densa cells (TEM: ×~8100).

between afferent and efferent arterioles, where it is firmly attached to the extraglomerular mesangium (Figure 20.66a). At the attachment point, the TAL changes its character: a plaque of specialized cells, known as the macula densa (MD), represents the contact site of the tubule. Around this attachment, other specialized structures are developed which, together with the macula densa, comprise the JGA. These are: the terminal portion of the afferent arteriole housing the renin producing granular cells; the initial portion of the efferent arteriole; and the extraglomerular mesangium (EGM). The latter is in continuity with the intraglomerular mesangium, and has intimate relationships with the parietal epithelium of Bowman's capsule.[20] The JGA, more precisely the granular cells and the smooth muscle cells of afferent and efferent arterioles, are richly innervated by sympathetic nerves.

Macula Densa

Shortly before its end, the TAL passes between the afferent and efferent arterioles of its original glomerulus. At this site the basal face of the tubule is affixed to the extracellular matrix, enveloping the cells of the extraglomerular mesangium (EGM), tying together both arterioles. The TAL cells in contact with the EGM are transformed into the "macula densa" (MD). The MD is a cell plaque comprising some 20 to 30 specialized epithelial cells (in juxtamedullary nephrons more than in superficial nephrons). The MD completely and consistently overlaps the EGM, and may extend over variable portions of the afferent and efferent arterioles.[429,762] The specific histo-topographical relationship of the epithelial tubular cells and the other components of the JGA at the glomerular vascular pole are established already during nephron formation. The prospective MD cells are affixed to the mesenchymal cells accompanying the capillary loops that invade the distal cleft of the S-shaped body of the nephron-anlage to form the glomerular tuft.[763] This occurs before the epithelial cells of the prospective loop of Henle have elongated into a tubule.

The cells of the MD (Figure 20.66) differ from the surrounding cells of the thick ascending limb in several aspects. The most eye-catching feature of the MD are the closely packed nuclei, usually located in the apical cell pole.[5,764] This feature, well recognizable even in light microscopic preparations at low magnification, conferred the name "macula densa" to the cell plaque.

Most importantly, and in marked contrast to the cells of the thick ascending limb, MD cells do not interdigitate with each other by large lateral folding; rather, the lateral cell membranes of MD cells run in a fairly straight fashion from the tight junction toward the base of the epithelium.[5,764] They possess slender microplicae or microvilli that protrude into the lateral intercellular spaces, and contact (frequently by desmosomes) corresponding protrusions from opposite cells. At the very base the cells ramify into slender processes. They are fixed to the basement membrane of the MD cells which is fused with the basement membrane-like material

surrounding the extraglomerular mesangial cells. The tight junctions are morphologically similar as in the TAL, but they may be slightly deeper (e.g., in rabbit). Like all other TAL cells, MD cells do not display gap junctions.

The cytoplasm of MD cells is relatively sparse and displays the usual organelles comprising some small mitochondria. The Golgi apparatus is large, smooth endoplasmic reticulum and free ribosomes are abundant, but rough endoplasmic reticulum is infrequent.

The luminal cell membrane is densely studded by short stubby microvilli and displays, like the other tubular cells, single cilia. In some species (e.g., rabbit[5]) the MD cells are distinctly taller than the surrounding TAL cells, so that the entire plaque of the MD protrudes into the tubule lumen.

The inventory of transport proteins in MD cells is essentially the same as in the other TAL cells, i.e., they display the bumetanide-sensitive NKCC2 co-transporter,[537,765,766] ROMK,[767,768] and NHE3[769] in the apical plasma membrane, and express cyclooxygenase-1.[516] They specifically express cyclooxygenase-2[516] and nitric oxide synthetase 1.[770,771] In contrast to the TAL, MD cells lack the Tamm-Horsfall protein.[528]

Recent findings[772] detected by RT-PCR and by immunohistochemistry demonstrated olfactory-related adenylate cyclase 3 (AC3) and the olfactory G-protein limited to the distal convoluted tubule and especially the MD.[772] These findings suggest a role of the olfactory machinery in the regulation of renin secretion and glomerular filtration rate.[772]

In contrast to all other TAL cells, the lateral intercellular spaces in the MD epithelium have been found to be dilated under most physiological conditions, usually regarded as "normal" conditions.[754,764,773–776] In agreement with the suggestion that water flow through the MD-epithelium is secondary to active sodium reabsorption, compounds that block sodium transport by MD cells (e.g., furosemide), as well as high osmolalities of impermeable solutes in the tubular fluid (e.g., mannitol), are associated with narrow intercellular spaces.[764,773] These observations suggested that the MD epithelium might be a water-permeable cell plaque within the water-impermeable TAL epithelium,[764] but so far direct evidence for this suggestion is missing. The lack of immunoreactivity for TRPV4, a nonselective cation channel of the transient receptor potential (TRP) family, gated by hypotonicity, had been interpreted as indirect support for this assumption.[777]

The granular cells (often termed juxtaglomerular cells) (Figure 20.67)[778] are assembled in clusters (up to 15 cells, but generally not more than 4 or 5) within the wall of the terminal portion of the afferent arteriole, replacing ordinary smooth muscle cells. Occasionally, they are also found within the wall of the efferent arteriole, again occupying the space where one would otherwise expect to find an ordinary smooth muscle cell. In rare cases, extraglomerular mesangial cells may also be replaced by granular cells. The name "granular" cell points to the specific cytoplasmic granules which may densely fill the cell body cytoplasm. They are electron-dense, membrane-bound, and irregular in size and

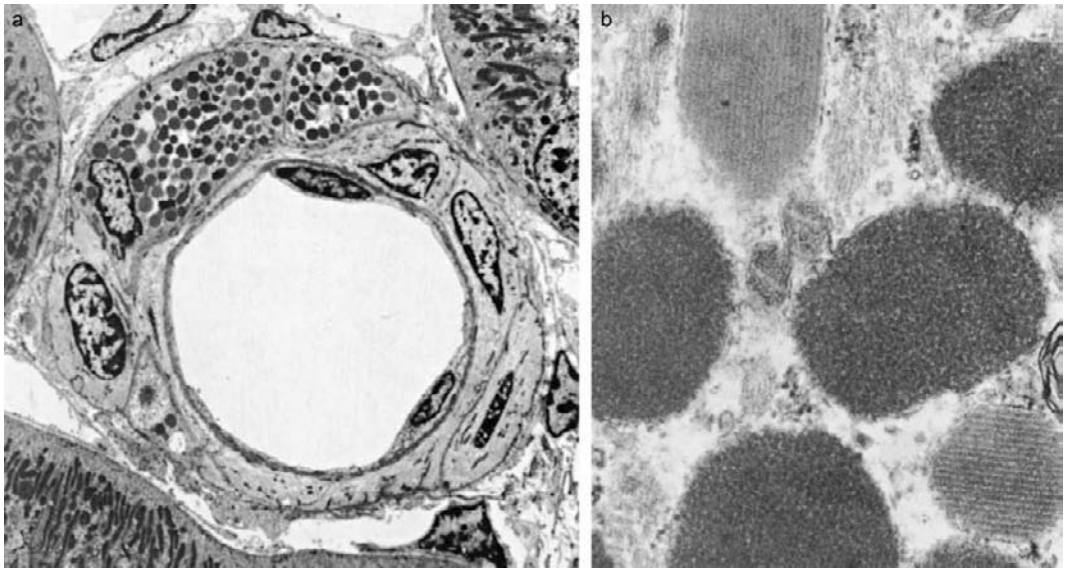

FIGURE 20.67 (a) Juxtaglomerular portion of an afferent arteriole. Smooth muscle cells are replaced by two granular cells (rabbit: TEM: ×~2700). (b) Granular cell. Renin granules are membrane-bound. Granules with a crystalline substructure are considered as "protogranules" which will develop into mature amorphous granules (rat: TEM: ×~48,000).

shape. Small granules with crystalline substructure represent protogranules, which are developed within the prominent Golgi apparatus and are then transformed into the major amorphous granules. Immunocytochemical studies with two antibodies against the renin prosegment and against mature renin have shown that only protogranules are prosegment-positive, whereas a signal of mature renin was found in mature as well as protogranules. These findings show that the cleavage of the prosegment, i.e., the maturation of renin, takes place in the juvenile granules; mature renin is then stored in the electron-dense granules. However, it is suggested that a major fraction of pro-renin never matures to renin, but is constitutively secreted as pro-renin – together with an unknown fraction of renin. Mature renin is segregated into storage granules for regulated release. The release mode of renin is not fully-understood. In addition to classic exocytosis, other mechanisms may also be involved.[18] It is important to know that renin release occurs into the surrounding interstitium, not into the lumen of the afferent arteriole, as has been frequently suggested.

Granular cells are modified smooth muscle cells. Within the peripheral parts of the cytoplasm, especially within the many cell processes, granular cells contain myofibrils. In situations that require enhanced renin synthesis (e.g., volume depletion or stenosis of the renal artery) additional smooth muscle cells located upstream in the wall of the afferent arteriole transform into granular cells.[19]

Granular cells have processes of manifold shapes.[99] Because of them, granular cells have extensive membrane contacts to all surrounding cells, e.g., other granular cells, smooth muscle cells, and extraglomerular mesangial cells. At these contacts, gap junctions are frequently encountered.[19] Like ordinary smooth muscle cells, granular cells also have membrane contacts to endothelial cells, in the manner that foot-like processes of endothelial cells penetrate the basement membrane and come into contact with granular cells; gap junctions are found at these contact sites.[99]

Peripolar cells have first been described in sheep, where they are regularly found[779]; in most other species, including man, they are rare.[780] Peripolar cells are parietal cells of Bowman's capsule which are located around the glomerular hilum (i.e., at the vascular pole, therefore: peripolar), and which contain numerous cytoplasmic membrane-bound granules filled homogeneously with electron-dense fibrillogranular material.[779] Subsequent studies have shown that these granules contain a neuron-specific enolase-like protein[781] and transthyretin[782]; their function is unknown. The number of cells and the number of granules per cell vary greatly among species and, furthermore, are dependent on age.[780] In the rat kidney, granulated peripolar cells have only rarely been found.[780]

Extraglomerular mesangial cells (EGM-cells, Goormaghtigh cells, lacis cells) together with the surrounding matrix establish the extraglomerular mesangium (polar cushion). The EGM represents a solid cell complex that is not penetrated by blood vessels or lymphatic capillaries. Nerves pass on both sides of it from the afferent to the efferent arteriole, but do not enter the cell complex.[99]

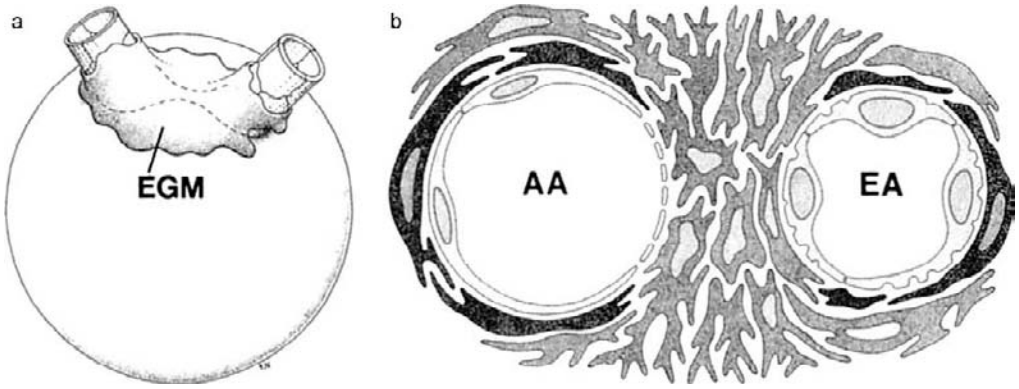

FIGURE 20.68 (a) Schematic of the extraglomerular mesangium (*EGM*). The glomerulus is shown as a globe. Its outer aspect is represented by the parietal basement membrane of Bowman's capsule (*PBM*). The EGM lies between the two arterioles above the opening of Bowman's capsule (broken line). It is attached to the PBM and has extensive contacts with the two arterioles. The macula densa and the smooth muscle layers of the arterioles are not shown. (b) Schematic cross-section through the vascular pole just above Bowman's capsule. Afferent and efferent arterioles (*AA*, *EA*) are cut transversely. Extraglomerular mesangial cells (*EGM*) are shown in moderate gray, smooth muscle cells in dark gray, and endothelial cells in light gray. Note differences in the walls of AA and EA; the AA already displays endothelial fenestration on the side facing the EGM. Conversely, the EA has a continuous endothelium with many cell bodies. In both AA and EA the smooth muscle layer (*SM*) is not complete; towards the center of the EGM the SM cells are replaced by EGM cells. *(Elger, M., and Sakai, T. et al. (1998). The vascular pole of the renal glomerulus of rat. Adv. Anat. Embryol. Cell Biol.**139**, 1–98, with permission).*

The EGM is located within the triangular space bordered by the two glomerular arterioles and the macula densa (Figures 20.66 and 20.68).[778] Reconstruction studies have shown that EGM-cells are flat and elongated, separating into two bunches of long cell processes at their poles.[783] They are arranged in several layers parallel to the base of the macula densa. The cells nearest to the glomerular stalk, thus filling the deepest portion of the triangle, lose this parallel grouping, but extend into the stalk of the glomerular tuft mixing with mesangial cells proper. The cells are separated by a conspicuous matrix which appears to be different from the intraglomerular mesangial matrix by the fact that microfibrils are rarely found in the EGM[20]; details are largely unknown.

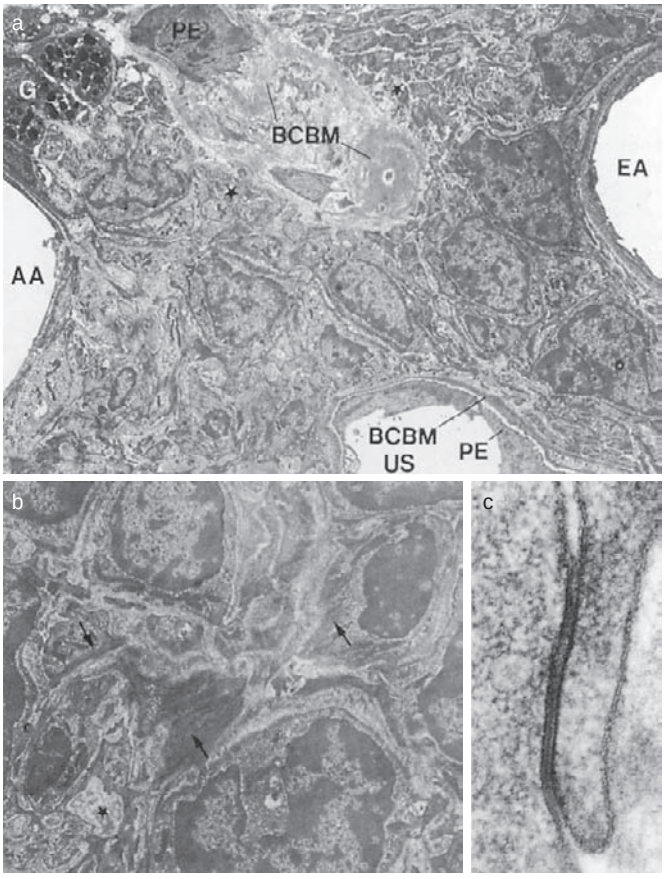

FIGURE 20.69 **Flat section through the extraglomerular mesangium (rat).** (a) The section crosses the afferent (AA) and the efferent (EA) arteriole; it grazes the top of Bowman's capsule, showing the basement membrane of Bowman's capsule (BCBM), and the parietal epithelium (PE), as well as the urinary space (US). The extraglomerular mesangium forms a complicated texture by which the structures of the vascular pole are interconnected. Note that toward their insertion in the BCBM the extraglomerular mesangial cells fall apart into many processes (stars) (G: Granular cells; TEM: ×~2650). (b) Higher magnification of extraglomerular mesangial cells. Note the microfilament bundles within the periphery of cell bodies, as well as within cell processes (arrows). Note the irregular extracellular spaces filled with a matrix of varying appearance (star) (TEM: ×~6000). (c) Gap junction between two mesangial cells (rat: TEM: ×~147,000).

EGM cells are characterized by the scantness of their cytoplasm and their extensive ramifications (Figure 20.69).[778,784] A Golgi apparatus and some profiles of granulated endoplasmic reticulum are regularly encountered. Although direct evidence is lacking, EGM-cells can be expected to be contractile for several reasons. First, they contain a good amount of microfilaments, mainly in their processes and peripherally within cell bodies. Second, intimate structural similarities are found among arteriolar smooth muscle cells, granular cells, and intra- and EGM cells, suggesting that they have the same origin. Third, they are extensively coupled by gap junctions. Gap junctions not only bridge different cells, but also regularly bridge individual processes of the same cell.[785] Moreover, gap junction contacts consistently occur to all other cells of the JGA (except the macula densa!), i.e., to granular cells, to ordinary smooth muscle cells of both arterioles, and to the mesangial cells proper.[19]

From a biomechanical point of view, the contractile apparatus of EGM cells is conspicuous. Microfilament bundles are contained within the periphery of cell bodies and within the cell processes, which are connected to the walls of both glomerular arterioles and to the basement membrane of the parietal layer of Bowman's capsule (PBM) surrounding the glomerular hilum (Figures 20.68 and 20.69). As a whole, the EGM can be considered as a spider-like contractile clamp sitting above the glomerular entrance interconnecting all structures at this site.[20] The EGM probably represents some sort of closure device of the glomerular entrance, maintaining the structural integrity of the entrance against the distending forces exerted on it by the high intraglomerular pressure. Moreover, from the viewpoint that the glomerular mesangium represents a high pressure compartment (mesangial interstitial pressures are expected to range in the same magnitude as glomerular capillary pressures[147]), the EGM would seem to be the structure which mediates a gradual pressure drop toward the cortical interstitium and toward the base of the macula densa.[20]

The function of the EGM cells is obscure. Because of their central position within the JGA, their constant relationships to the macula densa and their gap junction coupling to all smooth muscle-derived cells of the JGA, the EGM cells have repeatedly been considered as the necessary functional link between the macula densa and any possible effector cell within the regulatory mechanisms of the JGA.[20,99] Thus, they are widely considered as an integrating system of signals derived

from the reabsorptive function of the MD and the function of the EGM as a pressure sentinel mirroring the blood pressure in the afferent–efferent arteriolar system, but details are unknown.

The intimate and systematic juxtaposition of tubular and vascular cells within the JGA has given rise to early speculations about a feedback system between tubular and glomerular function.[786] It has now become clear that the JGA serves two different functions: it regulates the flow resistance of afferent arterioles in the so-called tubuloglomerular feedback mechanism; and it participates in the control of renin synthesis and release from granular cells in the afferent arteriole.[787] Researchers originally assumed that the two responses might be related to each other, in that renin released from the granular cells not only has systematic relevance, but locally triggers the formation of angiotensin II, and thus is responsible for afferent vasoconstriction as well; however, it now appears that the final activation of smooth muscle and granular effector cells occurs through largely independent pathways. Renin release from granular cells is the major source of systemic angiotensin II, and thus plays an essential role in controlling extracellular volume and blood pressure, whereas the vasoconstriction of the afferent arteriole locally serves to modulate the filtration of this nephron.

For both mechanisms, it is well-established that a change in NaCl concentration in the tubular fluid at the MD initiates the appropriate signal. Thus, the MD, situated at the very end of the TAL, controls the work of the TAL; the short postmacula segment of the TAL may be interpreted to guarantee that the composition of the tubular fluid at the MD might not be influenced by the function of the subsequent DCT. Expressed in general terms, the MD translates changes in the tubular fluid Na-Cl concentration into a graded release of mediators that reach their target by diffusion, thus acting in a paracrine fashion. Note that the extraglomerular mesangium that mediates the contact between the MD and the effector cells is not vascularized, so that the build-up of any paracrine agent would not be perturbed by blood flow.

With respect to renin release, the most likely paracrine mediators of this process are prostaglandin E 2 and nitric oxide.[18,788–790] With respect to the vasoconstrictor response purinergic mediators, either ATP or adenosine, as first suggested by Oswald and colleagues[791] appear to play the major role.[62,787,792] For an up to-date discussion of the function of the JGA see the reviews by Schnermann and Levine,[787,793] Persson and colleagues,[794] and Komlosi and colleagues.[795,796]

THE RENAL MEDULLA

During phylogeny the renal medulla has developed in response to the necessity to conserve water by excreting concentrated urine.[29] Loops of Henle, collecting ducts, and a specific blood supply through vascular bundles have developed into a complex structural system that accounts for this function. However, the details are insufficiently understood.

The overall mechanism (Figure 20.70) is clear: reabsorption of NaCl from the MTALs in the outer medulla represents the driving force to produce an interstitial cortico-medullary osmotic gradient that provokes osmotic water withdrawal from the collecting duct when the latter descend toward the papillary tip. The reabsorbed water is brought back into the systemic circulation by venous vasa.[2,797]

The unresolved problem is the generation of a cortico-papillary solute gradient, notably in the inner medulla. In discussions concerning the formation of a medullary solute gradient "countercurrent multiplication" has occupied a center-stage as the decisive mechanism. This mechanism has been experimentally established in artificial tubes,[798] and has been imposed on the renal medulla, conceding immense deviations from the original conditions. From a structural point of view, the preconditions for countercurrent multiplication in the renal medulla would appear to be quite incompletely developed: at no site are the limbs of Henle's loop juxtaposed to each other. Even when allowing a mediating interstitial space between both loop limbs, the DTLs do not case behave homogenously in an adequate way, but they change their function gradually on their descent, and even change their transport characteristics to the ascending limb type a considerable distance before the bend; most relevant in the present context is that the terminal third of the SDTLs in the mouse kidney is equipped with TAL epithelium.[16,34] Without going into more details, everyone who has been engaged in this problem knows that the principle of countercurrent multiplication has been extensively bent to make it fit with the structural organization of the renal medulla – in our view, with little benefit in facilitating the understanding of the function of the renal medulla. If at all, this principle can only be applied to describe the mechanism in the outer medulla. In the inner medulla, a process that could be regarded as a "single concentrating effect" is not apparent. Several "passive models"[452,799–802] attempting to explain the concentrating mechanism in the inner medulla have greatly refined our understanding of the problem, but have never reached the level of a convincing theory.

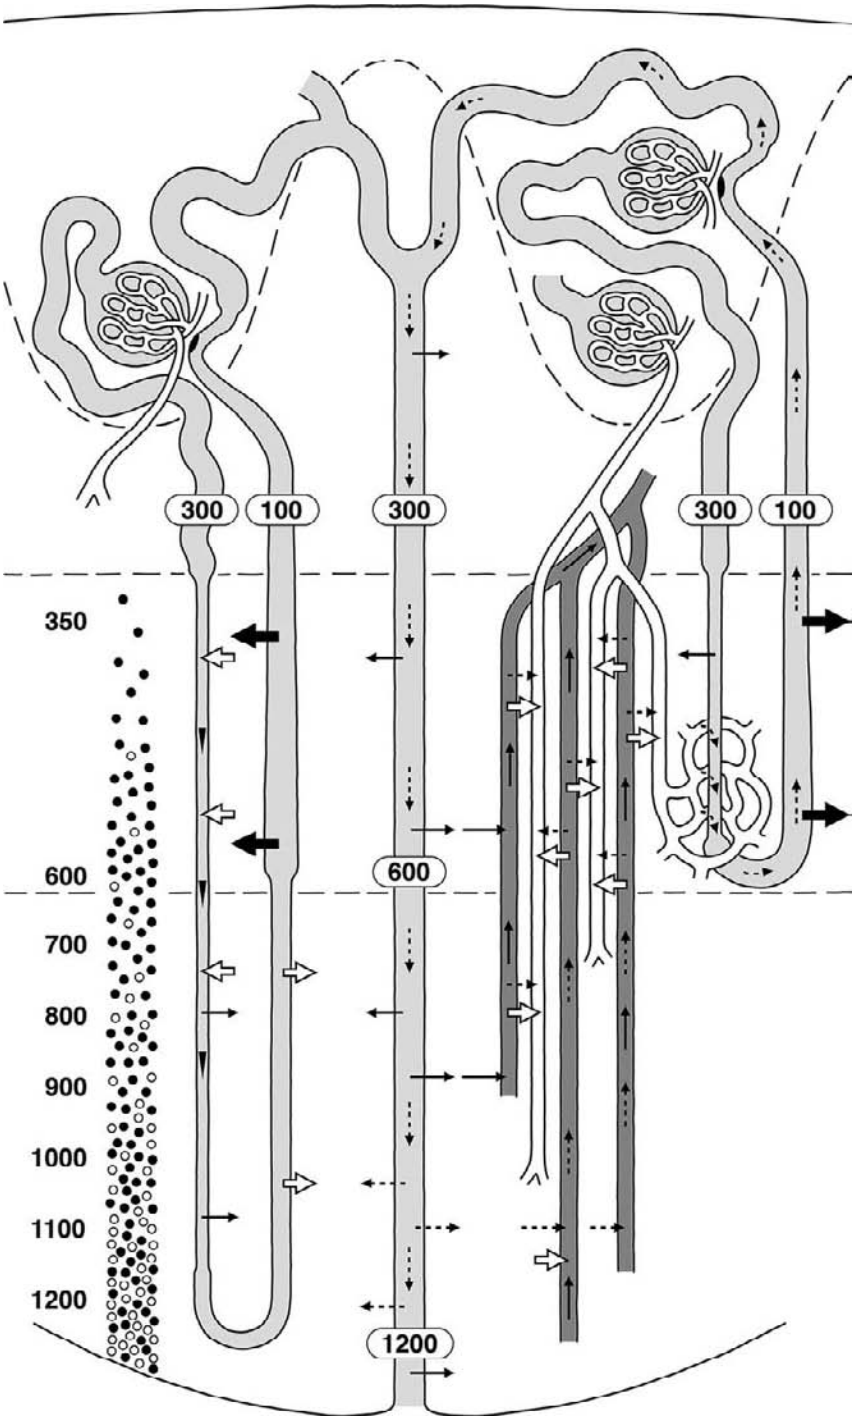

FIGURE 20.70 **Schematic to show the functional interactions in the medulla as they are derived from the histotopography of the structures, the distribution of channels and transporters and direct measurements of transport characteristics in the various tubular and vessel segments.** A long looped nephron, a short looped nephron, and a collecting duct are shown in light gray. Descending vasa recta (DVRs) derived from the efferent arteriole of a juxtamedullary glomerulus are shown in white (including the capillaries), ascending vasa recta (AVRs) in dark gray: both together establish a vascular bundle. The osmolar concentration in the medulla rises from the cortico-medullary border to the papillary tip from 300 to 12,000 mosmol/l, mainly established by the increase in the concentration of salt (indicated by dark dots) and urea (indicated by open circles). The driving force of the concentrating mechanism is the dumping of salt into the medullary interstitium from TALs (thick black arrows), leaving behind a diluted fluid (indicated by an osmolar concentration of 100 mosmol/l at the re-entry into the cortex). Osmotic water withdrawal from CCDs (slim arrows) into the cortical circulation again elevates the tubular urine to 300 mosmol/l upon re-entry into the medulla. Continuous water reabsorption along the MCDs (slim arrows) will produce a final urine concentration of about 12,000 mosmol/l (in humans). The source for the inner medullary solute gradient is shown to consist of: (1) dragging of salt from the IS into the IM by LDTLs (arrow heads); and (2) re-entry of urea from the CDs into the terminal portion of the IM (hatched arrows). The gain in osmotic energy by urea re-entry originates from urea recycling, which starts with a shift of urea from the AVRs into the SDTLs in the IS (follow the hatched arrows), and concentration of this urea by water reabsorption in the CCDs, OMCDs, and starting portions of IMCDs (see text for further explanation). The removal of the water from the medulla regained from the CDs (thus the final step in urine concentration) is effected by AVRs (follow the slim arrows). These vessels are the core structures in the complex countercurrent exchange system of the medulla equilibrating at any level with the local concentrations of salt and urea. Open thick arrows show passive movements of salt (see text).

In this situation it might be worth an attempt, opposite to the usual, to start with the available functional data – including the recent data on the distribution of transporters – confronting them with the structure, i.e., the architecture of the renal medulla, as well as the cellular organization of the individual components, in order to arrive at a novel view of "function–structure–correlation."

Let us first regard the three regions of the medulla with such an approach. The most constant region is the IS; there is no renal medulla known without an IS. In contrast, an OS is frequently quite incompletely developed, and an IM may be fully absent.

The Inner Stripe of the Outer Medulla

The IS (Figures 20.20 and 20.24) is made up of two portions: the vascular bundles (VBs) and the interbundle region (IBR). The IBR contains the tubules (DTLs, TALs, CDs) supplied by a dense capillary plexus which is drained upwards by the gradual transition of capillaries into AVRs that directly ascend into the OS. Since all the salt reabsorbed by MTALs accumulates in this area, the interstitium of the IBR is rich in salt.[803]

The VBs, structurally, are part of the IS but, functionally, they belong to the IM. They represent a quite perfectly developed countercurrent exchange system primarily handling the blood descending to and ascending from the IM by respective DVRs and AVRs. However, since the DVRs also supplying the capillary plexus of the IBR of the IS are contained within the VBs (not the respective AVRs), the VBs provide the possibility of shifting solutes coming up from the IM into the IBR of the IS. Since the dominating solute of the IM is urea, the VBs are rich in urea. The handling of urea as a main function of the VBs becomes most obvious in the complex bundles (see below).

The Inner Medulla

The IM (Figures 20.20 and 20.27) including the papilla, at the transverse level, is homogenously organized; a separation into VBs and an IBR is no longer possible. Even if there may be a certain prevalence that the ATLs are more frequently gathered around CDs than DTLs,[34,804] it appears quite doubtful that this is of any functional relevance. The AVRs (including the capillaries) are homogenously distributed among all other components and, most importantly, a wide homogenous interstitial space permits the interaction of every descending tube with every ascending tube. The IM provides strict countercurrent arrangements of all involved structures, but without giving prevalence to any specific lateral interaction. Thus, the IM as a whole may be considered as a countercurrent system that allows countercurrent exchange – mediated by the interstitium – between all descending (DVRs, DTLs, CDs) and all ascending tubes (AVRs, ATLs), according to the transport characteristics of the individual tubes.

A most important feature of the IM is its particular shape reflecting its longitudinal organization. The inner medulla tapers from a broad basis to a tiny papilla[2] (see also above). This shape perfectly reflects what happens with the structures within the inner medulla: loops of Henle, vasa recta, and collecting ducts (by fusing together) all decrease rapidly in number from the base to the tip of the papilla.[119,805] For the rat, it has been calculated that, of an estimated 10,000 long loops entering the inner medulla at its base, only about 1500 reach the papillary half of the inner medulla, and only a few of these the papillary tip.[2] The majority of long loops, the "short" long loops, turn back shortly after entering the inner medulla, a smaller but still substantial number of long loops reach the middle part of the inner medulla, and only a small population of "long" long loops really reach the papilla.

The Outer Stripe of the Outer Medulla

The OS (Figures 20.20 and 20.23) is a transitional region which separates the medulla from the cortex, mediating the transition between an hyperosmotic and an isoosmotic environment. The OS does not seem to make any particular contribution to the creation of the cortico-medullary solute gradient, but it greatly helps to maintain it. The OS contains the nascent (or dissolving) VBs (performing the same function as in the IS but quantitatively of minor importance) and the AVRs which are directly coming up form the IBR of the IS (Figure 20.71). Together with the AVRs spreading out from the dissolving VBs, the AVRs as a whole traverse the OS as individual vessels intimately associated with the tubules of this region; actually they represent the major "capillary" supply of the OS (see above). In addition, among all regions of the kidney, the OS exhibits the smallest fraction of interstitial space, thus the vessels are most closely juxtaposed to the tubules (note: lymphatics are absent from the entire medulla[25]). Since the PSTs of juxtamedullary nephrons, in contrast to their name, take a tortuous course when descending through the OS, the majority of tubular profiles in the OS consists of PSTs (S3 segments). This arrangement – AVRs closely associated with descending PTs (and, to some extent, also CDs) represent an ultimate countercurrent trap to prevent the loss of osmotic energy into the systemic circulation (Figure 20.71 right panel). Since reabsorption from PTs is isoosmotic, the hypertonic environment created by AVRs will allow water withdrawal not only from CDs (starting the concentrating process), but also from the PTs, increasing their osmolarity already at the level of the OS – with a clear prevalence of the PTs of juxtamedullary nephrons (tortuous course!) that give rise to the "long long loops." The TALs of the OS are already of the cortical type (equipped with a comparably flat epithelium; see above) capable of maintaining and even increasing a large salt gradient, but incapable of transporting large quantities.[308]

So far, we have a summary of the essential architectural features of the three medullary regions; let us now talk about the functional connections between them. This needs, first, to talk about the overall mechanism

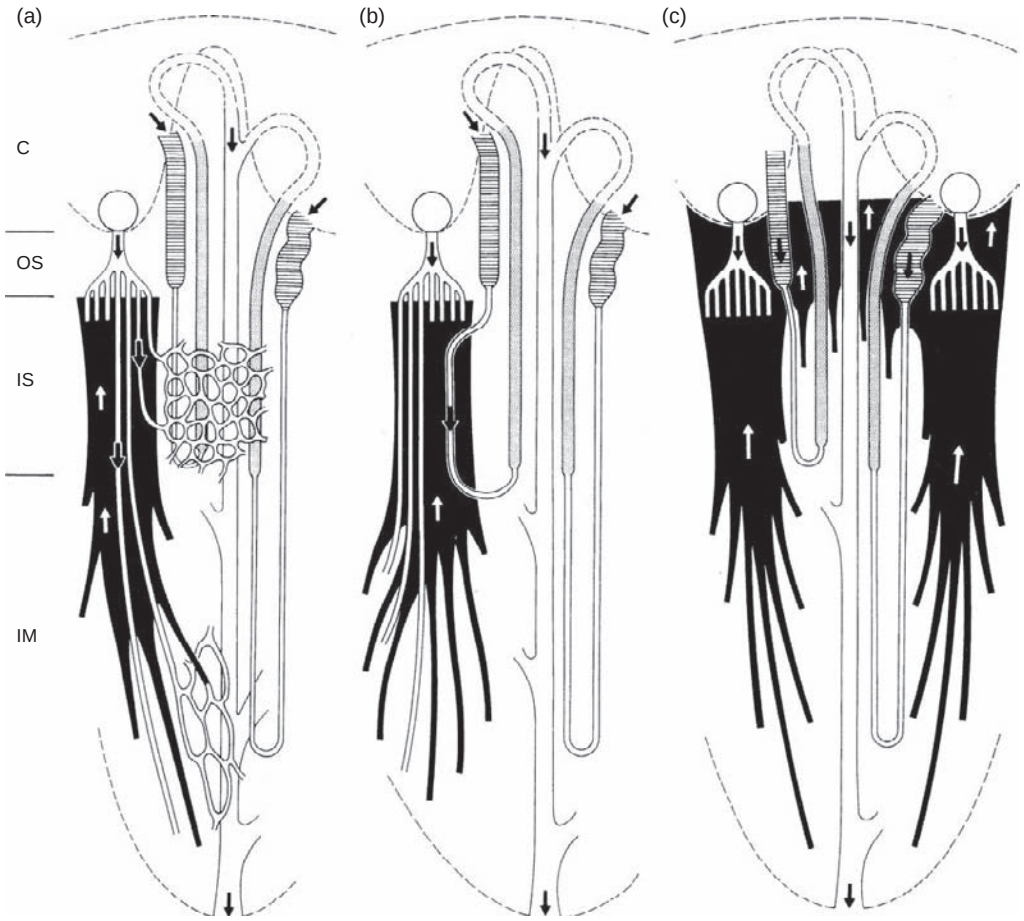

FIGURE 20.71 **Schematics to demonstrate the possible recycling routes within the medulla.** A short loop and a long loop of Henle and a collecting duct are shown. The straight proximal tubules are hatched; the thin limbs, collecting ducts, and capillaries are white; the thick ascending limbs are gray. Ascending vasa recta are drawn black en bloc (C: cortex; OS: outer stripe; IS: inner stripe; IM: inner medulla). (a) Simple type of medulla: recycling route from the ascending vasa recta in the inner stripe, via descending vasa recta, to inner stripe tubules. (b) Complex type of medulla: recycling route from ascending vasa recta in the inner stripe to descending thin limbs of short loops. (c) Recycling route from the ascending vasa recta in the outer stripe to descending tubules (proximal tubules and collecting ducts); valid for both the simple type and the complex type of medulla. *(Adapted from Kaissling, B., and Kriz, W. (1979). Structural analysis of the rabbit kidney. Adv. Anat. Embryol. Cell Biol.* ***56****, 1–123, and Kriz, W., and Barrett, J. M. et al. (1976). The renal vasculature. In "Anatomical–Functional Aspects. Kidney and Urinary Tract Physiology II, 1–21, Thruau, K. Tokyo University Park Press, Baltimore, London.)*

underlying urine concentration in some more detail, and afterwards to talk about the individual mechanisms.

The Basic Mechanism in Some Detail

The renal medulla contains the phylogenetically ancient "diluting segments" of the nephron, i.e., the TALs which separate salt from water (Figure 20.70). The salt is dumped into the medullary interstitium, the water is carried up into the cortex and – in the case that ADH is available – is recovered by the systemic circulation through osmotic withdrawl from the CCDs. Thus, the tubular urine that re-enters the renal medulla in the collecting duct is isoosmotic with respect to plasma concentration, and considerably reduced in quantity compared to the amount that originally entered the renal medulla in descending limbs after filtration. Thus, the salt that is available to drive the concentrating mechanism has emerged from a much larger quantity of isoosmotic fluid than the quantity of isoosmotic fluid that is subject to concentration. Moreover, along with the increasing concentration of the CD urine, less and less water has to be reclaimed to achieve the same increment in concentration; the work that is necessary to account for a progressively increasing urine concentration decreases steeply toward the tip of the papilla.

In the IM, in addition to salt, urea is a major solute accounting for the solute gradient toward the tip of the papilla. Since in the IM neither any up-hill transport of salt nor of urea is known, the crucial problem consists of explaining the increasing concentration of salt (flat increase) and of urea (steep increase) in the IM toward

the papillary tip. If both depend on the work of the TALs in the OM, how can part of the osmotic energy be carried down from the OM into the IM and piled up there to a steep solute gradient toward the tip of the papilla?

In our view, three major mechanisms have become apparent that are responsible for the distribution of salt and urea into a cortico-papillary gradient in the IM (Figure 20.70). They all depend on salt reabsorption by TALs in the OM; they all fit with the morphology, even more: specific structural elaborations in highly concentrating species support their relevance. These are: (1) salt dragging by flow to deeper medullary levels; (2) countercurrent exchange of solutes and water to maintain the cortico-papillary gradient; and (3) urea recycling by short loops of Henle as a major mechanism to create the solute gradient toward the papilla.

Dragging of Solutes by Flow to Deeper Medullary Levels

In all descending tubes of the renal medulla (DVRs, DTLs, CDs) solutes are dragged by flow to deeper medullary levels. This appears to be relevant for salt in the DTLs and for urea in the CDs (see urea recycling).

Continuous uptake and dragging of salt by SDTLs down to their bends at the end of the IS has been considered as an essential mechanism in the original countercurrent multiplication concept. In the light of current knowledge such a mechanism in short DTLs may not be of crucial importance. In contrast to previous reports, SDTLs (apart from some of them; see above) do not express aquaporin, and thus must be considered as fairly water-impermeable. Also, the Na^+ and Cl^- permeability was found to be low.[806] Thus, the increasing concentration towards the bend of SDTLs seems to be predominantly accounted for by urea entry into the lower part (see below: urea recycling). However, in any case the salt left from filtration at the end of the proximal tubule that enters the SDTLs in the OS will be dragged down by flow until the loop bends and will return in the TALs to be reabsorbed there. In case that, despite low salt permeability, a small part of the reabsorbed salt may – via the interstitium – re-enter the descending limb, thus being trapped within the SDTLs, this salt transfer from the TALs to the SDTLs represents the only esssential step that would be left from the countercurrent multiplication principle.

In contrast, continuous uptake of salt by LDTLs in the OM and dragging it by flow down into the IM appears to be the essential mechanism for salt accumulation in the IM; no other source of salt (apart from a small quantity reabsorbed by IMCDs) for the IM is obvious. Available models of the inner medullary concentrating process do not put so much emphasis on this mechanism, but the structural data strongly do suggest it. Layton and colleagues[452] were the first to include this idea into a model. The structural arguments are the following:

1. The upper portions of the LDTLs, most obvious in the IS, have an epithelial organization that suggests ion transport through extensively developed (Figure 20.48a) claudin 2 (cation pore) and claudin 10 (anion and cation pore) containing tight junctions.[261,807] Since the salt concentration is certainly higher outside the LDTLs (see below), salt can readily be expected to diffuse into the lumen. This process may become reinforced by active salt-secretion into the lumen, based on the abundant occurrence of Na^+-K^+-ATPase in the upper portions of LDTLs.[446,447] Moreover, the LDTLups are the only thin limb segments with abundant expression of aquaporin 1 channels (see below). No question, the salt concentrations within LDTLs at the transition from the OM to the IM may be expected to be quite high. Measured data are not available, but it seems reasonable to suggest considerably higher salt concentrations inside than outside.
2. The LDTLs on their descent through the inner stripe always pass through the sodium richest area, i.e., distant from the vascular bundles among the TALs of short loops[803] (Figure 20.22). In the mouse kidney, two specific modifications in this system appear to reinforce the ability of LDTLs for salt uptake. First, the LDTLs take a tortuous course when descending through the IS (increasing their length by 27%[34]) and, second, at the end of the IS before entering the IM, they traverse the so-called "innermost stripe," which has a thickness of about half of the IS proper and in which the SDTLs are already equipped with the TAL epithelium.[16,34] Thus, the density of TALs dumping salt into the interstitium at this level is dramatically higher (5 versus 3 per unit area) than at any other level of the OM. Consequently, the interstitial salt concentration should be very high. The LDTLs traverse this region and may readily be expected to take up some of the accumulated salt.
3. After challenging urine concentration in rats by water deprivation (or treatment with ADH) the TALs hypertrophy, with the most prominent increase in epithelial salt transport capacity of the initial portions in the deep IS.[520,808] Thus again, a prominent "surplus" in salt accumulation occurs just at the border to the inner medulla.
4. As described above, the LDTLs are quite heterogeneous with respect to their actual length,

and with respect to the epithelial differentiation of their upper parts.[435,803] Most important, the actual length of an LDTL strictly correlates with the degree of epithelial elaboration of its upper part in the IS. The small fraction of longest long loops extending down into the papilla clearly have the most prominent upper parts in the IS: they are thicker, with larger lumina and with more elaborate epithelia composed of heavily interdigitating cells; also their abundance in Na-K-ATPase is spectacular.[446] Comparing these longest long loops with those extending down into the IM for only short or intermediate distances, there is a continuous spectrum also with respect to the epithelial elaboration in the IS. Thus, the idea is plausible that salt is taken up by the upper portions of LDTLs, and subsequently carried down through the salt impermeable lower portions to the bend region. Beginning abruptly with a prebend segment, the loop becomes ion-permeable, allowing the salt to be dumped into the interstitium. In the mouse, the prebend segments are quite prominent comprising a length up to 700 μm.[34] Thus, the entire loop bend appears to represent a loop segment that delivers salt into the interstitium.

Since the lower portions of LDTLS are also water-permeable (to what extent is not clear[452,453]), water withdrawal may further increase the salt concentration in these segments. The problem consists of the driving force for such a process. A possibility offered from a structural view is that the heterogeneous longitudinal distribution of loops within the inner medulla (as describe above) might account for a cascade-like transport of salt toward the papilla. The large fraction of "short" long loops carries salt into the first third of the IM. Together with some urea (emerging from reabsorption by papillary CDs and subsequent recycling; see later) the total interstitial osmolality will be elevated above DTL fluid osmolality at the respective level allowing reclaimation of water from DTLs, elevating the total osmolality and salt concentration in all the DTLs underway to deeper medullary levels. A major fraction of those will reach an intermediate level of the IM before bending, dumping a major fraction of its salt at this level into the interstitium. Again, together with some urea a driving force will be established accounting for some water withdrawal from the small fraction of "long" long loops that will carry their salt into the papillary tip. No question, this is quite a hypothetical idea, but from a structural point of view would be worth modeling. Ideas in this direction have been published previously,[435] and also mathematical models for some features of such a mechanism have been presented.[452]

Countercurrent Exchange of Solutes and Water

Countercurrent exchange in a U-type countercurrent exchanger may have two functions: (1) trapping of solutes within the system by transfer of solutes from the ascending to the descending limb; and (2) preventing water from entering the system by short circuiting from the descending to the ascending limb. Both mechanisms *per se* do not build up any solute gradient; they are only capable of maintaining a gradient (with little loss). However, incorporated into the complex countercurrent arrangement of the renal medulla they decisively participate in the creation of the cortico-papillary gradient. In agreement with others,[797] in our view, the relevance of countercurrent exchange has always been underestimated compared to countercurrent multiplication in the urine concentrating mechanism. Actually, from a structural point of view, the renal medulla should best be considered as an extremely complex countercurrent exchange system that is fuelled by two mechanisms at two sites: by salt reabsorption through TALs in the OS; and by urea addition through terminal CDs in the IM. These solutes are distributed by countercurrent exchange into a cortico-medullary gradient that − due to continuous fueling − allows water withdrawal from CDs and the transport of this water into the systemic circulation in the cortex.

As already discussed above, a more-or-less direct countercurrent exchange between juxtaposed countercurrent tubes may only occur within the VBs of the IS. In contrast, in the IBR of the IS, and within the entire IM, the countercurrent tubes are consistently separated from each other by comparably wide interstitial spaces, thus any exchange at a transverse level is mediated by the interstitium. No doubt, this decreases the effectiveness of the exchanges, but allows countercurrent exchanges between more than two structures. Any solute dumped into the inner medullary interstitium, i.e., predominantly salt from LDTLs (at their bends) and urea from CDs (at their terminal portion) or left in ATL and AVRs at their beginning in the IM, will be subject to countercurrent trapping (or used to drive countercurrent short-circuiting of water; see below), between AVRs and ATLs on the one site and DVRs and DTLs on the other.

In addition to solute trapping, countercurrent exchange of water preventing the flow of water to deeper levels by short circuiting seems of major relevance. The recent elucidation of the distribution of aquaporins in medullary structures has shed considerable light on the handling of water in the urine concentrating process. Among the thin limbs only the LDTLups have regularly been found to be equipped with aquaporin 1 channels; in rat, also, the LDTLlps have been reported to express AQP1[453]; DVRs are abundantly equipped

with AQP1 channels[453]; the water permeability of CDs is ADH-dependent (see above). The only ascending structures that are water-permeable are the AVRs (based on the hydrophilic fenestrae providing a direct route of water flow through the endothelium). Thus, any water withdrawn from any descending structure finally enters an AVR, by which it is brought back to the cortex. This cardinal function of AVRs has recently been analyzed in detail by Pallone and colleagues.[797]

The ability of AVRs to take up water appears to be based on an elevated oncotic pressure (resulting from short circuiting of water between DVRs and AVRs within the VBs), and on the reasonable assumption that the blood in capillaries at any level of the medulla is in osmotic equilibrium with the interstitial fluid (due to the hydrophilic fenestrae in capillary and AVR endothelia). Thus, when capillary blood at any level of the medulla starts to assemble in AVRs and to ascend, it will – after any small ascent – become hyperosmotic compared to the surrounding interstitium. Due to the abundant hydrophilic fenestrae of the AVR endothelium osmotic equilibrium will most easily be achieved by water uptake.

The water to be taken up originates mainly from the CDs, but water may also originate from DTLs. In LTDLs, the upper parts have abundant aquaporins (type 1) in both membranes surprisingly contained in an epithelium that exhibits the features of an ion-permeable epithelium, i.e., an extremely lengthened leaky tight junction due to extensive cellular interdigitation. Thus, this epithelium, in addition to being water-permeable, obviously allows the transport of large amounts of ions. From what we have argued above, that salt dragging by flow in LDTLs appears to be the only mechanism to bring down the salt into the IM, large volumes of salt-enriched urine would be the best precondition for this goal. It appears to us that the actual transport capabilities of the upper portions of LDTLs have not been completely elucidated. Along the lower portions of LDTLs in the IM, the water permeability progressively decreases and fully ceases at the transition to the prebend segment.[437,438] This offers the possibility (described already above) that water withdrawal from the LDTLs by an osmotic driving force established at each medullary level by salt and urea might lead to a "cascade-like" transport of salt toward the tip of the papilla.

Urea Recycling

Solute recycling is a different mechanism compared to solute trapping by countercurrent exchange; this difference is rarely appreciated. Urea appears to be the only solute, recycling of which plays an essential role in the urine concentrating process. Recycling of urea defines a process that starts with a molecule of urea in the inner medullary interstitium and brings this molecule back into the IM via the normal tubular route, finally re-entering the inner medullary interstitium via exit from the terminal IMCD (Figure 20.70). As described above, the terminal portion of the IMCDs contains the urea transporters UTA_1 and UTA_3 which allow the facilitated diffusion of urea from the CD into the surrounding interstitium.[809] A precondition for this reuptake of urea is that the concentration of urea in the tubular urine of IMCDs has reached a higher level than in the medullary interstitium at the same level. This is achieved by water removal through urea-impermeable tubular segments, i.e., CNTs and CCDs in the cortex, OMCDs and upper IMCDs in the medulla. The reabsorption of urea through IMCDs compromises the reclaiming of water through IMCDs, decreasing urine concentration instead of increasing it. Thus, urea does both: on the one hand, reabsorption of urea increases the inner medullary solute gradient, thereby decreasing urine osmolality; on the other hand, the increased solute gradient increases the driving force for water reabsorption, thereby increasing urine osmolality. This sounds like a story from Baron Münchhausen, who was able to help himself getting out of a swamp by pulling on his own hairs.

However, the two opposing functions of urea have a solid base: a given molecule of urea may become active a second (or a third) time, this is what urea recycling means. After entering the inner medullary interstitium from an IMCD, a given molecule of urea will travel towards the cortex within an AVR, thereby balancing (together with other molecules and other solutes) a certain amount of water that enters the AVR along its ascent, and that finally has to be delivered into the systemic circulation at the cortico-medullary border. However, this specific molecule of urea participates in water balancing on its way from a hyperosmotic to an isoosmotic environment only up to an intermediate level, i.e., up to the IS. Here it re-enters the nephron; its relevance in balancing water that continuously enters the AVR and needs to be transported further up into the cortex is taken over by salt which, due to the active Na^+ reabsorption by TALs, is available in abundance at this level. Thus, the urea molecule has spent only part of its osmotic energy for the transport of water before it re-enters the nephron, precisely the SDTL, and becomes again subject of a concentrating process in subsequent urea-impermeable, but water-permeable, tubular segments. This urea molecule started the intratubular concentrating process at a higher energy level than a urea molecule that entered the tubule by filtration. In our view, this difference in osmotic energy between a recycling

and a freshly filtered urea molecule, entering the nephron in the IS versus in the cortex, and becoming subject to a concentrating process by water removal along the DCT, CNT, CCD, OMCD, and upper IMCD represents a real gain in osmotic energy that is finally available for water reabsorption in the inner medulla. Entry of urea to the LTDLs somewhere in the IM (i.e., recycling of urea via long loops) would not have a similar effect, simply because at this site there is no surplus salt available to replace urea in its role of water balancing.

At the present stage of knowledge, urea recycling via short loops appears as an essential process in urine concentration, and represents the most obvious evidence for the numerical dominance of short loops of Henle in every highly concentrating species. Note that also species which by definition are commonly reported to have 100% long loops (e.g., *Psammomys obesus*) in reality have a majority of short loops.

Moreover, as described above, the SDTLs in such highly concentrating rodent species are directly incorporated into the vascular bundles, and thus provide a more direct route for urea recycling than the simple bundles (Figures 20.22, 20.25, 20.26, and 20.71).[16,32,115,435] Within the VBs of such species, AVRs coming up from the IM are arranged in a countercurrent fashion not only with DVRs but, most prominently, also with the SDTLs. Thus urea, by countercurrent exchange, may directly enter the SDTLs through the urea transporter UT-A2[441,809] (the hydrophilic fenestrae of the endothelium of the AVRs may readily be expected to be highly permeable for urea). In a renal medulla with "simple" vascular bundles (as they are found in most species) countercurrent exchange of urea first occurs from AVRs to DVRs (which contain the urea transporter UT-B1[810,811]), which afterwards will deliver their blood to the capillary plexus of the IBR in the IS, which perfuses the SDTLs on their descending way. Thus, even if probably much less effective, urea from the inner medulla has access to the SDTLs[435,803,809] and may start its recycling route to the terminal CD in the papilla.[435,809,811]

The locus of urea redelivery, i.e., in the papilla, thus at the "ultimate bend" of the complex countercurrent exchange system in the papilla, is optimal, since by countercurrent exchange in vasa recta and thin limbs, urea is largely trapped and distributed in a longitudinal gradient within the inner medulla. The fraction of urea that escapes this process in the inner medulla is subject to recycling via short loops (starting in the IS) back into the inner medulla, and is thus available another time within the papillary interstitium ready to withdraw and/or to balance water reabsorption from the collecting duct.

CONCLUSION

The urine concentrating mechanism certainly does not belong to the most urgent of problems in medicine, but it represents a highly challenging biological enigma. We are aware that several aspects of our view are hypothetical, but they are based on particular structural features (the ultrastructural organization and particular histotopographical relationships of LDTLs, the incorporation of SDTLs into the VBs in highly concentrating rodent species) for which no better functional relevance is available. Whether the proposed mechanisms are sufficient to build up an effective solute gradient in the IM (in rodents up to several osmoles) or whether there are additional sources complementing the solute gradients (continuous production of osmotic active substances) is presently unknown.

CHAPTER

21

Biophysical Basis of Glomerular Filtration

Scott C. Thomson and Roland C. Blantz

University of California and VA San Diego Healthcare System, San Diego, CA, USA

INTRODUCTION

Marcello Malpighi (1628–1694) discovered the renal corpuscle and proposed that each glomerular body embraces the ampullar extremity of a tubule to form a "glandular follicle".[81] Thereafter, progress toward understanding the structure and function of the nephron stalled for two centuries, until William Bowman finally established the proper anatomic relationship between the glomerular arterioles, capillary tuft, and uriniferous tubule in 1842.[1,16] In that same year, Carl Ludwig, in his *Habilitations* thesis, addressed the driving force that separates the watery and crystalloid constituents of the plasma from its "proteid" constituents. He dismissed both the "nonexistent" vital force and chemical theories for converting blood to urine, and deduced from geometric considerations that local hydraulic forces drive filtration of blood plasma through porous glomerular capillary walls[78] (Figure 21.1). Ludwig's theory was not universally accepted at the time and other influential figures, such as Heidenhain, continued to advocate the secretory formation of urine.[54] Ludwig also had the foresight to envision that the hyperproteinemia resulting from glomerular filtration causes concentration of the urine by endosmosis into the peritubular capillaries.[79] Several decades later, vant Hoff and others began to describe osmosis in terms of pressure using thermodynamic principles,[143] which inspired Ernest Henry Starling to contemplate a role for the osmotic pressure of the plasma colloids in glomerular filtration. Starling wondered whether the minimum blood pressure below which formation of urine ceases might equal the osmotic pressure of the plasma colloids that oppose filtration. In 1897, he tested this hypothesis using a colloid osmometer of his own design[131] with which he estimated the osmotic pressure of the blood plasma protein to be 25–30 mmHg or about 0.4 mmHg-gram^{-1}/liter^{-1}. Then he observed that raising the ureteral pressure to within 30–45 mmHg of the arterial blood pressure would stop the flow of urine in a dog undergoing diuresis. Thus, the hydraulic pressure across the glomerular epithelium must exceed the plasma colloid osmotic pressure by some small amount in order for urine to form. On this basis, Ludwig's filtration hypothesis was deemed credible. Further evidence for glomerular filtration was published in 1924 by Wearn and Richards, who directly visualized the passage of indigo carmine into Bowman's space from the blood in the course of performing the first-ever micropuncture experiments. Wearn and Richards interpreted their own findings as "indirect evidence that the process in the glomerulus is physical".[148]

Glomerular filtration eventually received theoretical consideration as a case of coupled transport, subject to the basic rules of non-equilibrium thermodynamics, which were articulated by Onsager in 1931[95] and adapted to describe the permeability of biological membranes by several investigators in the 1950s. Prior to the 1950s, the conventional description of transport through membranes simply combined Fick's diffusion equation for solute flux with Darcy's equation for water flux, such that the function of a membrane which is to "prescribe the road along which the system strives toward equilibrium",[132] was defined by two permeability coefficients, one for diffusion of solute and one for bulk flow of water. By the 1950s it had become clear that these "conventional" permeability equations for solute and volume flow could not fully describe the physical behavior of membranes, so attempts were made to supplement them. The most cited contribution in this area came from Kedem and Katchalsky,[69] who pointed out that the prior approach was incomplete due to the fact that it included only two coefficients, whereas Onsager's theory calls for exactly three coefficients to characterize permeability for a solute–solvent system. Qualitatively, the

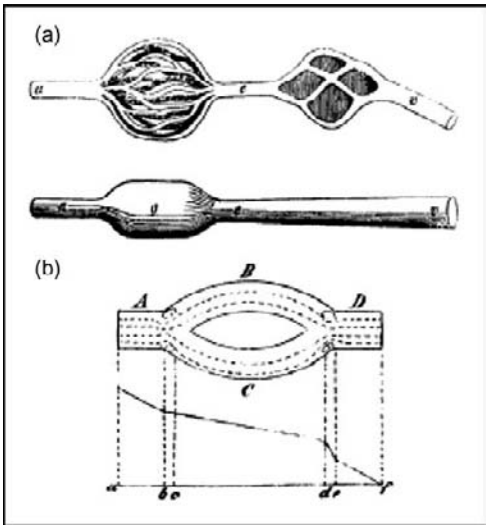

FIGURE 21.1 **Ludwig's representation of renal microvasculature (a) and (b) pressure profiles along the glomerular capillary** *(from ref. [56]).*

hydrodynamic resistance to free diffusion is due to friction between solute and solvent alone, and is determined by a single diffusion coefficient. But passage through a membrane involves two additional factors, namely, the friction between solute and membrane, and the friction between solvent and membrane. Hence, three processes are at play, and three coefficients are required to account for them all. Kedem and Katchalsky then proceeded with a formal argument, starting from the rate of entropy production and invoking Onsager's theory for a solute–solvent system which is paraphrased as follows:

For present purposes, we are interested in the transmembrane flux of a two-component system consisting of a water (w) and a non-electrolyte solute (s). Each of these components is driven by a conjugate force equivalent to its difference in free energy across the membrane. The conjugate forces for water and non-electrolyte solute are:

$$\Delta\mu_w = V_w\Delta P + RT\Delta\ln\gamma_w X_w \qquad (21.1a)$$

$$\Delta\mu_s = V_s\Delta P + RT\Delta\ln\gamma_s X_s \qquad (21.1b)$$

where V is a partial molar volume, ΔP is the pressure difference, X is the mole fraction, and γ is an activity function, empirically derived as a function of X. Since water flux affects X_s and solute flux affects X_w, the two conjugate forces and fluxes are coupled. For a small deviation from equilibrium this coupling can be taken into account by the following linear flux equations:

$$J_w = L_{11}\Delta\mu_w + L_{12}\Delta\mu_s \qquad (21.2a)$$

$$J_s = L_{21}\Delta\mu_w + L_{22}\Delta\mu_s \qquad (21.2b)$$

where Lxy are the so-called phenomenological constants. Onsager's theory says that $L_{21} = L_{12}$. Therefore, if the three coefficients, L_{11}, L_{22}, and $L_{21} = L_{12}$ are known, along with baseline values of J_w and J_s, then one can predict the changes in J_w and J_s that will arise from any alteration in $\Delta\mu_w$ or $\Delta\mu_s$. However, the physical meanings of the phenomenological constants are difficult to appreciate, and a more familiar form of the Onsager equations was provided in 1958 by Kedem and Katchalsky to describe transport across biological membranes[69]:

$$J_v = L_P\cdot(\Delta P - \sigma_s\Delta\Pi) \qquad (21.3a)$$

$$J_s = P_s\cdot\Delta C_s + J_V(1-\sigma_s)\cdot\overline{C_s} \qquad (21.3b)$$

When applied to movement across a capillary wall, J_v and J_s denote respectively the flux of volume (substituting volume for water is allowable for dilute solutions) and solute; ΔP, $\Delta\Pi$, and ΔC are differences in hydrostatic pressure, osmotic pressure, and concentration integrated across the membrane; σ_s is the reflection coefficient of the membrane for s; L_p is the hydraulic permeability per unit area of membrane; and P_s is the diffusive permeability of the membrane to s; $\overline{C_s}$ is the mean concentration of s within the membrane. Π is a function of C. σ_s assumes a value between zero and one. Three of these parameters, L_p, P_s, and σ_s, are characteristics of the membrane, in keeping with the Onsager theory which requires exactly three coefficients to describe the coupled transport of the two entities, v and s. Equation (21.3a) is often referred to as the "Starling equation." Equation (21.3b) expresses J_s as the sum of diffusive and convective components. Equations (21.3a) and (21.3b) are coupled. J_s explicitly depends on J_v. J_v depends on J_s because J_s affects $\Delta\Pi$.

There are limitations to irreversible thermodynamics and to the simplified equations, beginning with the assumption of a linear relationship between fluxes and forces. For example, one can imagine how increasing ΔP might cause a capillary wall to stretch, thereby changing the geometry of its pores and altering L_p. Also, $\overline{C_s}$ can take a variety of forms, depending on whether σ is taken to be active throughout the membrane or to be a membrane entrance phenomenon, and this will affect how J_s is parsed into its diffusive and convective components.[67] Finally, protein accumulates near the capillary wall during filtration, which could raise the local colloid osmotic pressure at the wall and cause L_p to be underestimated when calculated based on Π for the bulk plasma. Nonetheless, these equations remain the basis for all current understanding of the physical factors that determine transport of water and solutes between the glomerular capillary plasma and the urinary space.

Depending on the context, different simplifying assumptions are made that streamline the description of capillary flux in the glomerulus. For example, when considering J_v (i.e., glomerular filtration), the solutes

are divided into two groups, large and small. Large solutes are the colloids, and it is assumed that P_s for these is zero and σ_s is unity. All other solutes are assumed to be small, and it is assumed that σ_s (and ΔC) for these is zero. Solutes with intermediate permeability are ignored. Therefore, $\Delta\Pi$ can be substituted by the colloid osmotic pressure of the glomerular plasma, and a full description of J_v is provided by Eq. (21.3a). This obviates the need to consider coupled transport. Although the contribution of filtered macromolecules to the transcapillary oncotic pressure may be negligible, there are times when it is critical to understand the sieving properties of the glomerulus for large molecules. In such cases, simplifying assumptions are made regarding the geometry of the filtration barrier and the shape of the solute molecules, so that the process can be conveniently described using hydrodynamic theory.

THE MAGNITUDE OF RENAL BLOOD FLOW AND GLOMERULAR FILTRATION

In humans, the kidneys constitute 0.5% of the body weight, but receive 20% of the cardiac output. The low resistance to renal blood flow is owing to the large number of parallel conductances, with each human kidney containing about 1 million glomeruli.[124] Approximately 8000 liters per day of blood plasma transits the extrarenal organs, of which about 20 liters is filtered into interstitial spaces and returned to the blood as lymph.[71] In contrast, the kidneys form 180 liters per day of glomerular filtrate from 900 liters of blood plasma. The high rate of filtration by the kidney relative to other organs is due to a greater ultrafiltration coefficient, not to greater Starling force.[44,99,149] The surface area available for filtration in the human kidney is in the order of 1.2 m^2 overall or 0.6 mm^2 per glomerulus. A meaningful number is difficult to assign to the capillary surface area in other major organs where the number of capillaries perfused at any given moment is highly variable. The hydraulic permeability L_p of fenestrated glomerular capillaries has been estimated from 2.5–4.0 $\mu l/min/mmHg/cm^2$ in rats and humans,[33,114,115] which is 50-fold higher than L_p for non-fenestrated skeletal muscle.[123]

GLOMERULAR HEMODYNAMICS BY INFERENCE

Having first identified inulin and PAH as a markers of GFR renal plasma flow (RPF),[121,126] Homer Smith and colleagues used clearance of these markers to make logical judgments about the regulation of GFR. Smith observed a reciprocal relationship between RPF and filtration fraction in human subjects injected with pyrogens,[23] and recognized that this is contrary to what should occur if the changes in RPF were mediated by a preglomerular resistance. He used equations to argue that the renal resistance changed in these experiments due to dilation and constriction of the efferent arteriole. His formulation required a strong inverse effect of efferent resistance on filtration fraction, which could be achieved by assuming that the net ultrafiltration pressure vanishes at some point along the capillary, as hydrostatic pressure declines and plasma oncotic pressure increases. Based on knowledge that this occurs in the mesenteric circulation, Smith was willing to assume that this also happens in the kidney, and coined the term "filtration pressure equilibrium" in reference to the phenomenon[125] (see Figure 21.2). Smith later recanted his notion of filtration pressure equilibrium in the glomerular capillary, arguing on teleologic grounds that the hydrostatic null point should occur in the proximal portion of the efferent arteriole in order to promote maximal GFR and maximal reabsorption in the peritubular capillary.[124] His revised thinking was likely influenced by the contemplations of Gomez.[47]

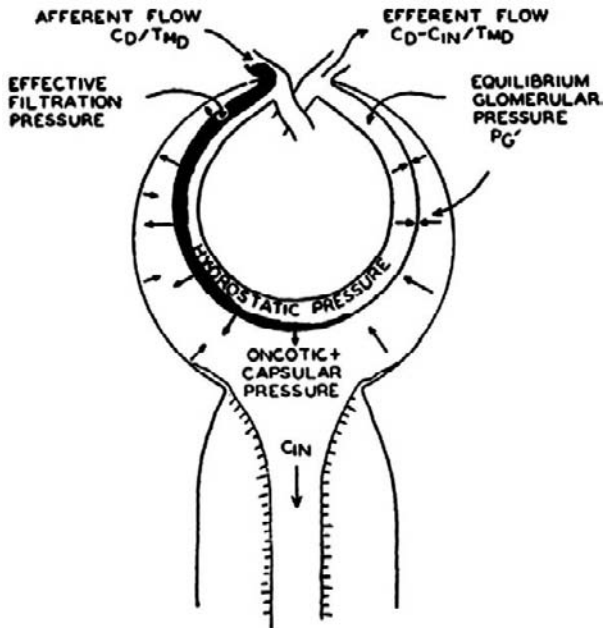

FIGURE 21.2 **Filtration equilibrium illustrated in the glomerulus** *(from ref. [29]).*

GLOMERULAR HEMODYNAMICS AND MICROPUNCTURE

A full and direct assessment of the filtration forces and hydraulic permeability in a mammalian glomerulus was first published by Brenner et al. in 1971.[19] Three

developments made this possible. First, a mutant rat strain (Munich Wistar) was discovered with glomeruli on the kidney surface making them accessible for glomerular micropuncture. Second, a servo-null device was invented that enabled accurate and rapid pressure measurements in capillaries and tubules.[41] Third, a microadaptation of the Lowry method[77] was developed for measuring the protein concentration in a few nanoliters of plasma which could be obtained by micropuncture from a postglomerular arteriole.[17]

Given values for the pressure in the glomerular capillary P_{GC} and Bowman's space P_{BS}, pre- and postglomerular plasma protein concentrations c_0 and c_1, single nephron ^{3}H-inulin clearance *SNGFR*, and a simple mathematical model for computing changes in the ultrafiltration pressure P_{UF} along the glomerular capillary, it is possible to obtain values for the glomerular plasma flow Q_0 and ultrafiltration coefficient *LpA*. *LpA* is the product of the hydraulic permeability *Lp* (see Eq. (21.3a)) and the filtration surface area *A*.

The mathematical model for computing the physical determinants of *SNGFR* from micropuncture data was developed by Deen, Robertson, and Brenner in 1972.[31] This model treats the glomerular capillary as a circular cylinder of unit length and surface area, uniform permeability to water and small solutes, and zero permeability to protein (see Figure 21.3). As in Eq. (21.3a), the filtration flux at any point along the capillary is equal to the product of the Starling force, $\Delta P - \Delta\Pi$, and the hydraulic permeability, *Lp*. *SNGFR* is obtained by integrating the flux along the capillary length:

$$\begin{aligned} SNGFR &= \int_0^1 Jv \cdot dx \\ &= LpA \int_0^1 (\Delta P - \Delta\Pi) dx \\ &= LpA \langle P_{UF} \rangle \end{aligned} \tag{21.4}$$

where $\Delta P = P_{GC} - P_{BS}$, $\Delta\Pi + \Pi_{GC} - \Pi_{BS}$ and $\langle P_{UF} \rangle$ is the mean ultrafiltration pressure. The term *LpA* represents the product of the hydraulic permeability *Lp* and filtration surface area *A*. For the non-dimensionalized capillary, *A* equals unity. For the real capillary, micropuncture data do not distinguish between changes in *Lp* and changes in *A*.

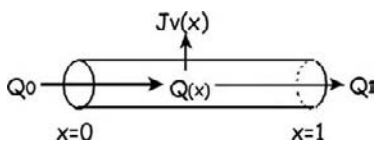

FIGURE 21.3 **Glomerular capillary represented by a homogerous circular circular cylinder with unit length and surface area (Q: Plasma flow; Jv: Filtration water flux; X: Axial position along the capillary).**

To perform the integration in Eq. (21. 4) it is necessary to know how the integrand varies along the capillary. In theory, both ΔP and $\Delta\Pi$ should change along the capillary, since P_{GC} must decline due to axial flow resistance and Π_{GC} must rise as water moves from the plasma into Bowman's space. It has always been assumed that the decline in P_{GC} along the capillary is small relative to the increase in Π_{GC}. This assumption was eventually justified by a three-dimensional reconstruction of the rat glomerulus submitted to computational analysis.[104] It is our custom to ignore the small axial pressure drop and represent ΔP as a constant, since including a 1−2 mmHg axial pressure drop in the model has a minimal effect on $\langle P_{UF} \rangle$. However, to better illustrate certain principles in this chapter, we have incorporated a 1 mmHg decline in P_{GC} from the beginning to the end of the glomerular capillary.

For the purposes of determining $\Delta\Pi$ it is assumed that all solutes in the system are either completely impermeant plasma proteins that exert their full osmotic potential ($\sigma = 1$, $Ps = 0$) and reside solely in the plasma or small molecules that are freely filtered ($\sigma = 0$) and contribute nothing to $\Delta\Pi$. Thus, $\Delta\Pi$ is reduced to the plasma oncotic pressure, Π_{GC}. The oncotic pressure in a plasma sample is determined from the protein concentration *c*, according to an empiric relationship developed by Landis and Pappenheimer:

$$\Pi = \alpha_1 c + \alpha_2 c^2 \tag{21.5}$$

The values of α_1 and α_2 in Eq. (21.5) vary according to the ratio of albumin to globulin in the plasma. When Π is expressed in mmHg and *c* in grams per 100 ml, for rat plasma, α_1 and α_2 are 1.73 and 0.28, respectively.[71] According to Eq. (21.5), Π_{GC} will increase from 18 to 35 mmHg along the length of a glomerular capillary if the systemic plasma contains 6 g/dl of protein and the nephron filtration fraction is 0.29. Such values are typical of the rat.

LpA is computed from *SNGFR* and $\langle P_{UF} \rangle$, according to Eq. (21.4). To obtain $\langle P_{UF} \rangle$ it is necessary to know the profile for Π_{GC} along the capillary. This profile is computed from the following mass balance considerations for protein and water. First are three conservation of mass equations:

$$Q_0 = SNGFR\left(\frac{c_1}{c_1 - c_0}\right) \tag{21.6a}$$

$$cQ = c_0 Q_0 \tag{21.6b}$$

$$J_v = -\frac{dQ}{dx} \tag{21.6c}$$

where Q_0 is the nephron plasma flow and c_0 and c_1 are the pre- and post-capillary plasma protein

concentrations. Differentiating Eq. (21.6b) and substituting Eqs. (21.6c), (21.5), and (21.3a):

$$\frac{dc}{dx} = \frac{c^2}{c_0 Q_0} J_v \tag{21.7a}$$

$$= \frac{Lp \cdot c^2}{c_0 Q_0} (\Delta P - (\alpha_1 c + \alpha_2 c^2)) \tag{21.7b}$$

A standard root-finding algorithm is used to obtain a value for *LpA* by numerical integration of Eq. (21.7) along the entire capillary to obtain an estimate for the plasma protein concentration at the end of the capillary (c_1*) and adjust the value of *LpA* until c_1* is arbitrarily close to the measured value of c_1.

$$c_1^* = c_0 + \frac{LPA}{c_0 Q_0} \int_0^1 c^2 (\Delta P - (\alpha_1 c + \alpha_2 c^2)) \cdot dx \tag{21.8}$$

In a typical experiment, *SNGFR*, ΔP, and c_1 are measured in several nephrons. Most often, these parameters are not obtained from the same nephrons. The mean values for an experiment are inserted into the model to calculate the determinants of SNGFR for an idealized nephron.

From the foregoing description, we see that *SNGFR* is fully determined by ΔP, Q_0, c_0, and *LpA*. Typical values for these parameters are shown in Table 21.1 for Munich Wistar rats from two different breeding colonies under different volume states. Conceptually, *SNGFR* can be made to increase by raising ΔP, Q_0 or *LpA* or by reducing c_0. But the magnitude of the dependence on each of the four determinants depends on the values of the other three. Some of these interactions are shown in Figures 21.4–21.7 and discussed below.

Ultrafiltration Coefficient, *LpA*, and Filtration Pressure Equilibrium

If the ratio of *LpA* to Q_0 is great enough, then Π_{GC} will rise to become arbitrarily near to ΔP at some point along the glomerular capillary, resulting in filtration pressure equilibrium. The remaining capillary surface downstream from the equilibration point will not contribute to the flux. It is possible to infer the presence of filtration equilibrium from micropuncture data, but it is not possible to know at what point along the length of the capillary equilibrium occurs. Therefore, it is not possible to compute actual values for $\langle P_{UF} \rangle$ or *LpA* for nephrons in filtration equilibrium. When Eqs. (21.4)–(21.8) are applied to data from a nephron in filtration pressure equilibrium, the values generated for *LpA* and $\langle P_{UF} \rangle$ are respective

TABLE 21.1 Representative Micropuncture Data in Munich Wistar Rats from the Blantz Lab in San Diego and Brenner Lab in Boston.

Laboratory	State of Hydration	SNGFR (nl/min)	ΔP (mmHg)	Π_0 (mmHg)	Q_0 (nl/min)	*LpA* (nl/s/mmHg)	Filtration Pressure Equilibrium	Reference
Blantz	Hydropenia	30	30.5	18.3	86	0.08*	Yes	9
	Euvolemia	31	37.2	19.7	121	0.06	No	137

**Minimum estimate due to filtration pressure equilibrium. LpA values that show differently from the original papers were originally calculated based on a linear estimate of the oncotic pressure profile and are recalculated here using the non-linear model.*

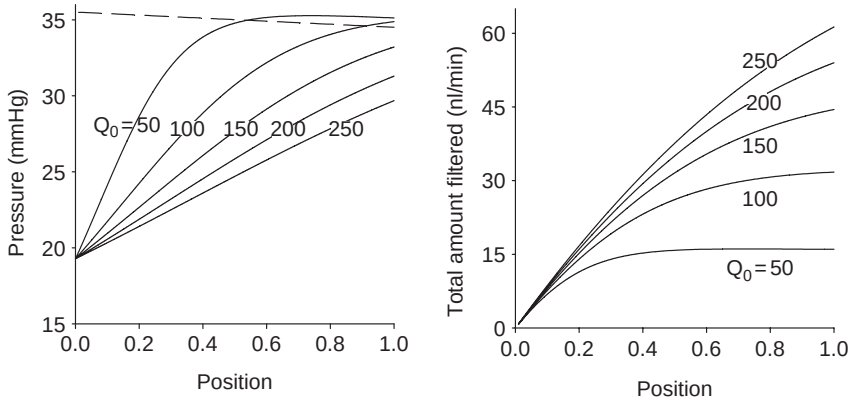

FIGURE 21.4 Pressure (left) and total flux (right) along the length of the glomerular capillary. In left panel solid curves represent plasma oncotic pressure which rises due to removal of water, while dashed line represents ΔP, which declines by 1 mmHg along the capillary due to flow resistance. *SNGFR* is the total amount filtered at position 1. Other inputs include systemic plasma protein concentration 5.8 mg/dl, and LpA 0.08 nl/s/mmHg. Filtration ceases where oncotic pressure rises to equal ΔP, which occurs when incoming plasma flow, Q_0, is low.

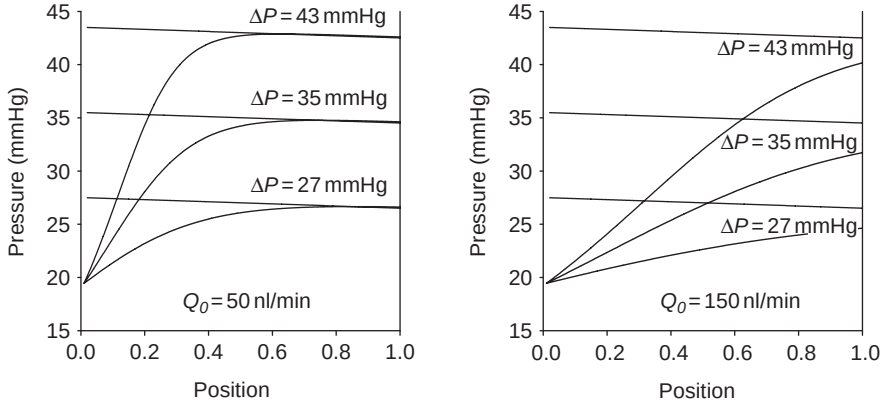

FIGURE 21.5 **ΔP (lines) and Π_{GC} (curves) along the length of a glomerular capillary for three different values of ΔP.** Left panel: $Q_0 = 50$ nl/min. Right panel: $Q_0 = 150$ nl/min. Other inputs include systemic plasma protein concentration 5.8 g/dl, and LpA = 0.06 nl/s/mmHg. ΔP has little effect on whether or not filtration pressure equilibrium is achieved. In contrast, increasing Q_0 from 50 to 150 nl/min eliminates filtration equilibrium regardless of ΔP.

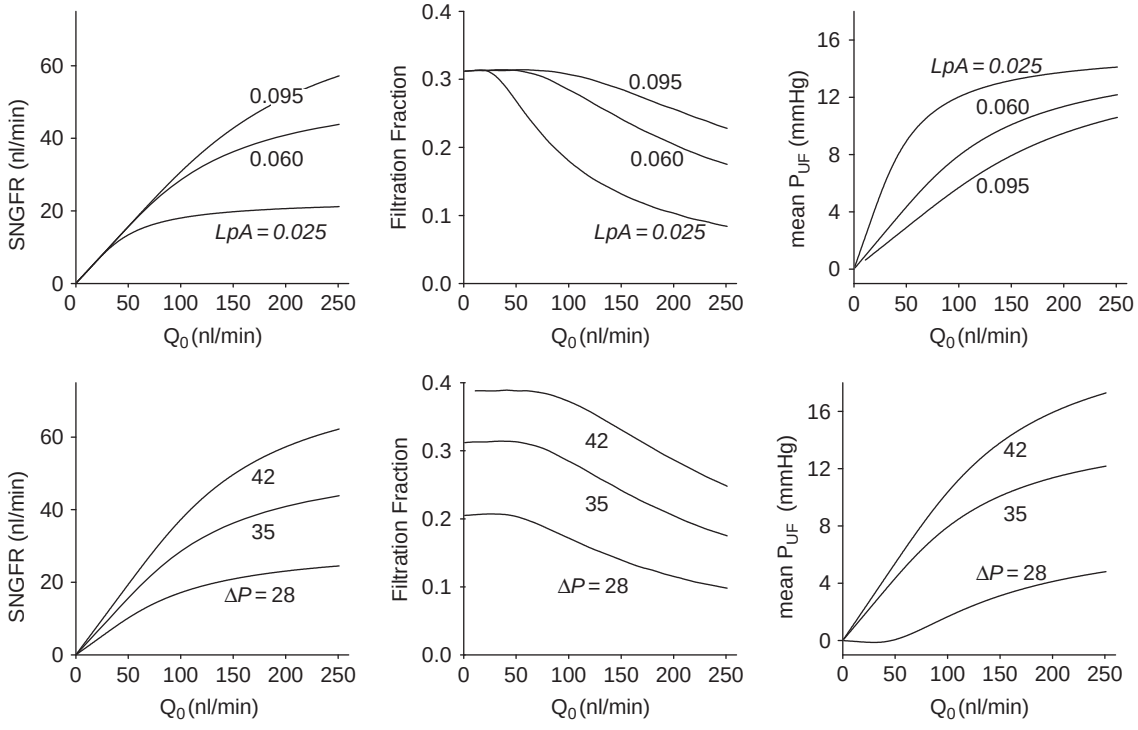

FIGURE 21.6 ***SNGFR*, filtration fraction or mean ultra-filtration pressure (P_{UF}) as a function of nephron plasma flow, Q_0.** Curves in top panels were generated for three different values of LpA. Curves in the bottom panel were generated for three values of ΔP. Unless otherwise stated, LpA = 0.06 nl/s/mmHg; ΔP = 35 mmHg; Systemic plasma oncotic pressure = 19.5 mmHg. Values over this range occur in the rat under varying levels of volume expansion.

minimum and maximum estimates for actual *LpA* and $\langle P_{UF} \rangle$. If a change in *LpA* occurs while a nephron remains in filtration pressure equilibrium, the equilibrium point will shift along the capillary, but *SNGFR* will not be affected. In order for *SNGFR* to be affected by a change in *LpA*, the nephron must not be in filtration equilibrium.

A debate over whether filtration pressure equilibrium occurs dates back to Homer Smith, who used conjecture and teleology to argue both sides of the issue at different points in his career (*vide supra*). Brenner and colleagues found filtration equilibrium in each of 12 consecutive published series, suggesting that filtration equilibrium is universal for hydropenic or euvolemic Munich Wistar rats. However, contrary data were generated by other micropuncture laboratories. At one point, this led to consternation.[92] The issue was resolved after experiments done with rats exchanged between different laboratories led to the conclusion that filtration equilibrium prevails in some rat strains or breeding colonies but not in others, and that the difference is attributable to differences in *LpA*.[4] This finding detracts somewhat from teleologic arguments for or against filtration pressure equilibrium.

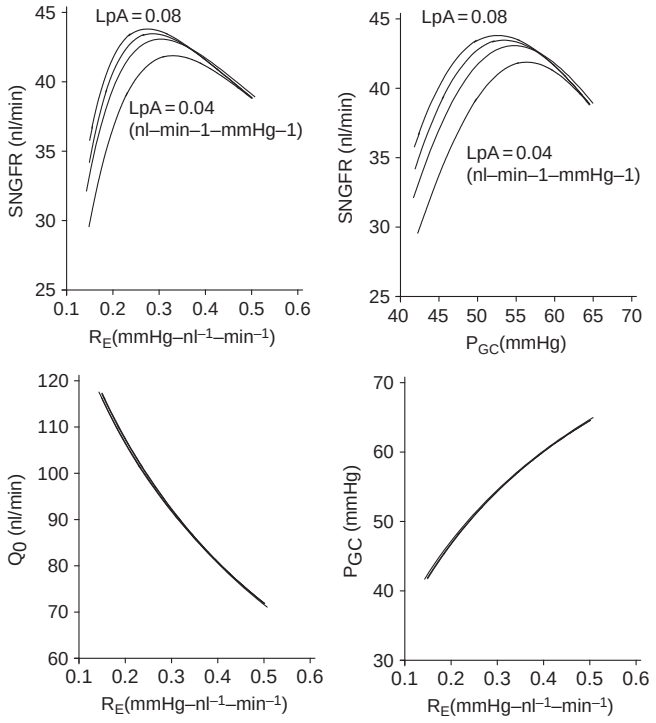

FIGURE 21.7 **Effects of efferent arteriolar resistance (R_E) on *SNGFR*, nephron plasma flow (Q_0), and glomerular capillary pressure (P_{GC}).** In top right panel, P_{GC} is made an independent variable by manipulating R_E. Effects on Q_0 and P_{GC} are nonlinear, because the filtration fraction rises along with R_E such that a lesser fraction of the blood flow transits the efferent arteriole. The Q_0 and P_{GC} curves (bottom) are insensitive to LpA. The apex of the *SNGFR* curve occurs within the physiological range of P_{GC} (48–52 mmHg). Medical treatments for glomerular capillary hypertension that reduce R_E until P_{GC} is normal will not reduce *SNGFR*. However, for P_{GC} <48 mmHg, reducing R_E will cause *SNGFR* to decline.

Nephron Plasma Flow, Q_0

Q_0 does not appear in the Starling equation for water flux (Eq. (21.3a)) or in the flux integral that defines *SNGFR* (Eq. (21.4)). Nonetheless, Q_0 is an important determinant of *SNGFR*. In fact, increased renal plasma flow underlies many of the physiologic increases in GFR that occur in the normal course of life, such as during pregnancy[6] or after protein feeding.[57,103,120] *SNGFR* is the simple product of *LpA* and $\langle P_{UF} \rangle$ (Eq. (21.4)). $\langle P_{UF} \rangle$ becomes greater if the average plasma oncotic pressure along the capillary is less. Removing a given amount of water from the plasma will cause a lesser increase in the plasma oncotic pressure if that water is subtracted from a larger initial plasma volume. Hence, increasing Q_0 will cause oncotic pressure to rise more slowly along the capillary. Therefore, increasing Q_0 causes $\langle P_{UF} \rangle$ to increase. The precise effect of Q_0 on the rate of rise in plasma protein concentration along the nephron is described mathematically in Eq. (21.7). *SNGFR* will be most sensitive to changes in Q_0 under conditions of filtration pressure equilibrium where the filtration fraction remains constant as Q_0 increases. In filtration disequilibrium, c_1, *ergo* filtration fraction, will decline with increasing Q_0 to reduce the impact of Q_0 on *SNGFR*. Homer Smith recognized that renal plasma flow should affect GFR by this mechanism, and that his experiments (*vide supra*) failed to confirm a plasma flow dependence of *GFR* only because the particular tools that he employed to manipulate the renal blood flow were confounded by offsetting effects on P_{GC}.[125]

Systemic Plasma Protein Concentration, c_0

In the idealized glomerulus, an isolated change in c_0 will cause opposite changes in $\langle P_{UF} \rangle$ and, therefore, *SNGFR*. However, it is difficult to demonstrate this experimentally because it is nearly impossible to manipulate oncotic pressure of the arterial plasma without affecting the neurohumoral milieu of the entire body, thereby altering other determinants of *SNGFR*. In fact, the circumstances associated with low oncotic pressure in real life (e.g., generalized capillary leak, sepsis, malnutrition or nephrosis) are generally associated with a low GFR. When c_0 is manipulated by whatever means, changes in other determinants occur to offset the impact on *SNGFR*. These changes are discussed below under "Interactions Among the Determinants of SNGFR."

Hydrostatic Pressure, P_{GC}, and ΔP

Whereas *SNGFR* is insensitive to *LpA* when Q_0 is low and insensitive to Q_0 when *LpA* is low, *SNGFR* will always be sensitive to an isolated change in ΔP unless ΔP is so low as to be exceeded by the incoming plasma oncotic pressure, in which case *SNGFR* will be zero. This is true because the proportional increase in $\langle P_{UF} \rangle$ brought about by any increment in $\Delta P - \Pi_0$ is relatively insensitive to the other determinants of SNGFR. This is illustrated in Figure 21.5 and in the lower half of Figure 21.6.

The interposition of the efferent arteriole between the glomerulus and peritubular capillary provides a simple mechanism for regulating ΔP independently of Q_0. Furthermore, this arrangement provides an opportunity to elicit reciprocal changes in P_{GC} and pressure in the downstream peritubular capillary P_{PTC}. Tying an increase in P_{GC} to a decrease in P_{PTC} has teleologic appeal, as this will facilitate homeostasis of the effective circulating blood volume while stabilizing GFR. If the efferent arteriole reacts to sustain P_{GC} and reduce P_{PTC} during a decline in renal perfusion pressure or effective circulating blood volume, then GFR will be relatively spared from declining while filtration

fraction will increase, thus affecting both the hydraulic and oncotic components of the Starling force that drives reabsorption by the peritubular capillary.

Regulating the efferent arteriole in this way is largely the purview of the renin–angiotensin system, which figures prominently among the myriad neurohumoral mechanisms contained in models of blood pressure and salt homeostasis. Angiotensin II is antinatriuretic and constricts arterioles throughout the body but, on balance, its effect on the glomerulus is always to elevate ΔP.[52,55,119,142] Thus, in spite of being a renal vasoconstrictor, angiotensin II protects GFR from total decline when the arterial blood pressure is low or when the preglomerular resistance is high.

While unduly low P_{GC} must impair glomerular filtration, P_{GC} and *SNGFR* are poorly correlated under normal circumstances, as are P_{GC} and arterial blood pressure. This implies that the kidney generally protects P_{GC} against the influence of arterial blood pressure and employs determinants other than ΔP to effect physiologically those changes in *SNGFR* that normally occur throughout life. Furthermore, it has recently been demonstrated that the preglomerular myogenic elements, long associated with static renal blood flow autoregulation, efficiently buffer the glomerular capillary against systolic pressure pulses delivered at the heart-rate frequency.[76] Teleologic reasoning behind sheltering the glomerular capillary from high pressure is that high P_{GC} augments wall stress in the glomerular capillary, which elicits a trophic response. If unchecked, this response will ultimately sclerose and destroy the glomerulus. Therefore, high P_{GC} is always pathologic, and treating glomerular capillary hypertension has been a cornerstone of nephrology practice for more than two decades. Some examples of glomerular capillary hypertension include angiotensin II-mediated hypertension,[46] experimental glomerulonephritis,[10,45] and residual nephrons after subtotal nephrectomy.[3] It has been asserted, and commonly accepted, that glomerular capillary hypertension also underlies glomerular hyperfiltration in early diabetes mellitus.[58,151] However, there are more than 10 published micropuncture studies in which diabetic hyperfiltration occurred in the absence of glomerular capillary hypertension or in which glomerular capillary hypertension was treated with no mitigating effect on diabetic hyperfiltration.[27,62,79,83,84,89,90,106,118,122,141,152] This does not detract from the salutary effect of therapy to reduce P_{GC}, which applies to all glomerular diseases.[5,73,82,136]

Interactions Among the Determinants of *SNGFR*

According to the standard model of Deen and Brenner, *SNGFR* is completely determined by a set of four parameters, which include P, Q_0, LpA, and c_0 (or Π_0). To state that *SNGFR* can be calculated from these four determinants is a mathematical truism which requires no consideration of how the four determinants might correlate in actual physiology. In fact, the individual components of the glomerular microvasculature that influence determinants of *SNGFR* generally affect more than one of them at a time. For example, an isolated increase in resistance of the preglomerular arteriole will directly reduce both ΔP and Q_0 and will reliably reduce *SNGFR*. In contrast, an isolated increase in resistance of the efferent arteriole will directly augment ΔP and reduce Q_0. Since these two effects exert opposing influences on *SNGFR*, increasing efferent arteriolar resistance might cause *SNGFR* to increase, decrease or remain the same, depending on other circumstances. For example if P_{GC} is low enough to be at or below Π_{GC}, then raising the efferent resistance can only cause *SNGFR* to increase whereas, if efferent resistance increases toward infinity, Q_0 must tend toward zero while P_{GC} cannot exceed the arterial blood pressure and, therefore, *SNGFR* must decline. The point where the impact of increasing the efferent resistance switches from positive to negative is within the domain of values that occur *in vivo*. Much of the acute renal failure encountered in contemporary medical practice occurs when drugs that reduce the ratio of efferent: afferent resistance are taken by patients who operate to the left of that point (see Figure 21.7).

There are other correlations between determinants of *SNGFR* that are more difficult to explain. For example, since *LpA* is computed as the ratio of *SNGFR* to $\langle P_{UF} \rangle$, random uncorrelated errors in ΔP and SNGFR will cause an inverse correlation to appear between ΔP and *LpA*. Also, an isolated reduction in *LpA*, if sufficient to reduce *SNGFR*, will remove a shunt pathway for fluid to bypass the efferent arteriole, thereby increasing ΔP. Furthermore, the physical orientation of the glomerular mesangium relative to the intraglomerular portion of the efferent arteriole allows activation of the same contractile elements to simultaneously reduce *LpA* and constrict the efferent arteriole.[40] This appears to explain why angiotensin II, the prototype effector of glomerular hemodynamics, simultaneously increases ΔP and reduces *LpA*,[12] and why lyzing mesangial cells with an antibody negates the effects of angiotensin II on both ΔP and *LpA*.[11]

Another interesting interaction among two determinants of *SNGFR* involves ΔP and the systemic plasma oncotic pressure Π_0. As mentioned above, experiments targeted at confirming the role of Π_0 as a determinant of *SNGFR* are encumbered by the difficulty in manipulating the plasma protein concentration independent of the neurohumoral environment. To get around this, Brenner[7] and Blantz[9,13,140] drew

upon a wide variety of infusion and exchange protocols to alter the systemic plasma protein concentration in multiple ways that were likely to yield contrary effects on the effective circulating volume and hematocrit. These differences were roughly intended to cancel each other out and reveal the underlying impact of Π_0 on *SNGFR*, ΔP, Q_0, and *LpA*. Both groups of investigators confirmed that the four determinants of *SNGFR* are not independent of one another. In particular, they discovered that, regardless of the experimental means for invoking a change in Π_0, a change in Π_0 causes a parallel change in ΔP, and reciprocal change in *LpA*. In contrast, neither *SNGFR* nor Q_0 are predictably tied to Π_0. Most remarkably, ΔP is so strongly dependent on Π_0 that the afferent effective filtration pressure, $\Delta P - \Pi_0$, is independent of Π_0. A biophysical or anatomic explanation for this interaction between Π_0 and ΔP has not been forthcoming. It seems, instead, that a physiological mechanism is involved in autoregulating the afferent effective filtration pressure (see Table 21.2).

Brenner and Blantz also both observed an inverse correlation between Π_0 and *LpA*. It is possible that this is an artifact of concentration polarization which causes plasma proteins to accumulate near the capillary wall. Concentration polarization will lead to an overestimate of P_{UF}, because the calculation of P_{UF} will be based on a lower value of Π than is present at the plasma interface with the capillary wall. Using an overestimate of $\langle P_{UF} \rangle$ in Eq. (21.4) will lead to an underestimate for *LpA*. If concentration polarization occurs in the glomerular capillary, the effect will be greatest when c_0 is least. Hence, the appearance could arise of an inverse dependence of *LpA* on c_0, even though c_0 has no actual effect on the capillary wall. However, there is likely to be enough scrubbing by red blood cells to prevent concentration polarization. Furthermore, concentration polarization cannot explain the correlation between Π_0 and ΔP. Finally, we have already discussed a mechanism for the inverse relationship between ΔP and *LpA*.

TABLE 21.2 Multivariate Regression Applied to Combined Micropuncture Data from Brenner[7] and Blantz[126] to Test for Interactions between ΔP and the other Determinants of SNGFR*

Dependent Variable	Independent Terms in Multivariate Regression		
P (mmHg)	Π_0 (mmHg)	*LpA* (nl/sec/mmHg)	Q_0 (nl/min)
Regression coefficient	0.84 ± 0.09	-72 ± 10	~ 0
P-Value associated with regression coefficient	2×10^{-10}	1×10^{-10}	0.750

*The original regression model included the protocol for manipulating the systemic plasma protein and the lab where the work was performed, neither of which influenced the result.

Therefore, the inverse correlation of between *LpA* and Π_0 might arise because *LpA* is affected, as an innocent bystander, by a mechanism that is postulated to autoregulate afferent P_{UF}.

THE FILTRATION BARRIER AND FILTRATION OF MACROMOLECULES

A striking feature of glomerular filtration is the ability of the capillary wall to discriminate among molecules of varying size. Solutes up to the size of inulin pass freely from the plasma to Bowman's space, while passage becomes progressively difficult for substances that are larger such that all but the smallest plasma proteins are screened almost entirely. Hence, when describing the determinants of SNGFR, the concentration of macromolecules in the filtrate is low enough that these contribute negligibly to the Starling forces. However, the filtration of small amounts of macromolecules is important for other reasons. For example, the plasma transiting a normal pair of human kidneys in one day contains 50,000 grams of protein, while the appearance of one gram per day of protein in the urine is sufficient to establish the presence of glomerular disease. Discerning how this small amount of protein winds up in Bowman's space is key to explaining how the filtration barrier operates normally, and to understanding the physical aspects of glomerular disease.

The filtration of a macromolecule is most often quantified in terms of its sieving coefficient, Θ, which is the ratio of solute concentration in the filtrate relative to filtrand. The earliest direct test for protein in mammalian glomerular filtrate was performed by Walker in 1941, who reported that micropuncture fluid obtained from Bowman's space in rat, guinea pig or opossum contained "either no protein or, at most, very small amounts." The assay in use at the time would have detected an overall sieving coefficient for protein of 0.4%, which made it insensitive by later standards.[146] Several subsequent micropuncture studies during the 1970s yielded widely varying amounts of albumin in proximal tubular fluid, even within an experiment. This variability was reasonably ascribed to contamination of samples by extratubular proteins, since only 1% contamination of a tubular fluid sample with plasma from the peritubular capillary would markedly alter the apparent result.[93] Performing micropuncture with a system of concentric pipettes to reduce contamination, Tojo succeeded in confirming a strong inverse relationship between TF/P inulin and albumin concentration in fluid collected from rat proximal tubules due to removal of filtered albumin along the proximal tubule. By linear extrapolation to TF/P inulin of unity,

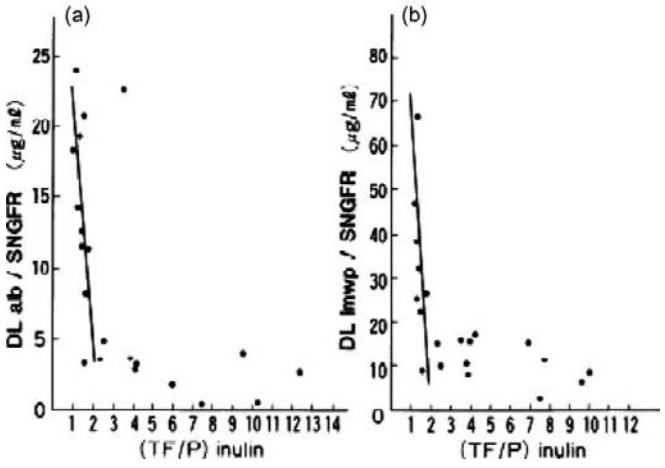

FIGURE 21.8 **Albumin (a) and low molecular weight protein (LMWP) delivery (b) along the nephron.** Linear regression over the domain of TF/Pinulin from 1 to 2 was used to calculate the protein concentration in Bowman's space *(from ref. [80])*.

which represents Bowman's space, the sieving coefficient for albumin was estimated at 0.062%. Meanwhile, the sieving coefficient of low molecular weight proteins was almost 99%, confirming the size-selective nature of protein sieving[138] (see Figure 21.8). However, micropuncture remains an unwieldy technique for studying glomerular sieving of macromolecules, and most of what is known about glomerular sieving has been learned by other means (*vide infra*).

Pore Theory

The glomerular capillary wall clearly screens solutes according to size, and it is usually taught that the glomerulus also screens macromolecules according to charge. The physical basis of molecular sieving is often modeled using pore theory. In pore theory, the coupled flux equations (Eq. (21.3a,b)) are modified to fit an idealized model of the glomerular capillary wall. The usual model consists of a solid barrier perforated by cylindrical pores. In some models, the pores form a homogenous population, while other models employ a mixture of pores of different sizes. This paradigm for describing the flow of material through porous membranes was applied to diffusion and filtration of solutes by capillaries, and an early review of the subject was published by Pappenheimer in 1953.[98] Mathematical descriptions were developed for pores shaped like circular cylinders or rectangular slits. At about the same time, theories were developed by others to explain the migration of large solutes through fibrous gels.[91] Given what is now known about the physical structure of the glomerular capillary wall, pores, slits, and fibrous gels are all relevant to glomerular sieving. Hence, descriptions based solely on cylindrical pores have become more obviously phenomenological. Nonetheless, pore theory remains the most popular paradigm for describing nuances of glomerular sieving in humans.[13,29,72,86]

Pore theory builds on the Kedem–Katchalsky flux equations (Eq. (21.3a,b)) by associating the three membrane parameters, Lp, P_s, and σ_s with an idealized physical structure. This structure incorporates the membrane geometry, the Stokes–Einstein radius of the solute molecules, temperature, viscosity, and the Boltzman constant. The solutes are represented by rigid spheres that interact with the solvent medium and with the pores, but not with each other. This makes the problem mathematically tractable. The filtration properties of a membrane with circular pores turn out to depend on two things: (1) the ratio of pore diameter to membrane thickness; and (2) the overall fraction of the membrane area covered by pores.

An explanation begins with Fick's first law of diffusion for a solute s:

$$J_s^{diffusion} = -D_s \frac{dC_s}{dx} \tag{21.9}$$

where:

$$D_s = \frac{RT}{fN} \tag{21.10}$$

is the diffusion coefficient, N is Avogadro's number, and f is the frictional force that opposes diffusion of s.

According to Stokes' law, a sphere of radius a falling at unit velocity in a medium of viscosity:

$$J_s^{diffusion} = D_0 \frac{A_p}{\delta} \Delta C_s$$

η faces a frictional force given by:

$$f = 6\pi\eta a \tag{21.11}$$

Einstein[39] combined Fick's law of diffusion and Stokes law to derive the diffusion coefficient for a spherical molecule in free solution, D_0, in terms of its molecular radius a:

$$D_0 = \frac{RT}{6\pi\eta a N} \tag{21.12}$$

Since actual molecules are not spherical, the Stokes–Einstein radius, a, of a molecule is a virtual quantity represented by a sphere of equivalent radius. Using the Stokes–Einstein radius of a marker solute to estimate the size of pores in a membrane will overestimate the actual pore radius if the marker solute is flexible and can squeeze through a smaller pore than a rigid sphere with the same Stokes-Einstein radius.

For the diffusion of small molecules through a membrane that contains large pores, Fick's first law is rewritten:

$$J_s^{diffusion} = D_0 \frac{A_p}{\delta} \Delta C_s \tag{21.13}$$

where A_p is the fraction of the membrane surface covered by pores and δ is the membrane thickness. Therefore, the diffusion through a membrane of a small solute with known D_0 is a convenient method to determine the ratio of pore area to thickness for the membrane.

However, when the molecular radius of the solute molecule is on the same scale as the pore size, diffusion through the membrane is less than predictable from Eq. (21.13). In other words, mobility of the solute is restricted. There are two factors that contribute to restricted mobility. First, there is steric hindrance to the solute entering or residing within the pore. Second, solute molecules within the pore experience greater friction than predicted by Stokes' law for solute molecules in free solution. While it makes sense to us to represent the steric hindrance by a reduced effective pore area and the increased friction as a reduced effective diffusion coefficient, most of the literature combines both effects into an expression for the effective pore area. This is described below.

Diffusion through a Porous Membrane: Steric Hindrance and Altered Friction

Restricted passage of solutes of increasing molecular radius is a basic property of membrane structures made of impermeable matrix with pores or fibrous gels. The basis for molecular sieving in all cases is the exclusion of large solute molecules from a portion of the membrane that is otherwise available to be occupied by water and other small molecules. The formulae for describing steric hindrance are different for pores than for gels. Here we will describe the phenomenon for cylindrical pores.

The center of a spherical molecule cannot approach any closer than its own radius to the edge of any pore. Hence, the fraction of a cylindrical pore, area Vp and radius r, that is available to be occupied by a solute with molecular radius a, is:

$$\frac{V}{V_p} = \frac{\pi(r-a)^2}{\pi r^2} = \left(1-\frac{a}{r}\right)^2 \tag{21.14}$$

Introducing solvent flow makes the steric hindrance more complex. This was first addressed by Ferry who added a term to account for laminar flow within the pore[43]:

$$\frac{V}{Vp} = \left(1-\frac{a}{r}\right)^2 \cdot \left(2-\left(1-\frac{a}{r}\right)^2\right) \tag{21.15}$$

The frictional drag on a solute molecule moving through a pore is also different from that described by Stokes' law for a solute in an unbounded free solution. The drag according to Stokes' law for the unbounded condition and the drag encountered in a pore are given by Eq. (21.16a,b) for a solute moving with velocity u in a fluid with velocity v. k_1 and k_2 are component drag coefficients that weight the contributions of the particle and fluid velocities. k_1 and k_2 are functions of a/r.

Theoretical treatments have provided approximate solutions for k_1 and k_2 for particles in cylindrical tubes.[51] Determining values for k_1 and k_2 is computationally intense. For this reason, k_1 and k_2 were originally provided for only a few values of a/r and a polynomial equation was fit to these points to allow interpolation. This approximation expression was inaccurate for $a/r > 0.6$, but this was the only method available until better computers were built in the 1970s.[97]

$$f_{unbounded} = 6\pi\eta a(u-v) \tag{21.16a}$$

$$f_{pore} = 6\pi\eta a(u\cdot k_1 - v\cdot k_2) \tag{21.16b}$$

Accounting for steric hindrance and dividing Eq. (21.16b) by Eq. (21.16a) to correct for the departure from Stokes' law, the diffusive flux is rewritten from Eq. (13) to become:

$$\begin{aligned} J_s^{diffusion} &= D_0 \frac{A_p}{\delta}\left(\left(1-\frac{a}{r}\right)^2\left(2-\left(1-\frac{a}{r}\right)^2\right)\right) \\ &\quad \cdot \left(\frac{u-v}{uk_1 - vk_2}\right)\Delta C_s \\ &= D_0 \frac{A_{eff}}{\delta}\Delta C_s \end{aligned} \tag{21.17}$$

where A_{eff} represents the "effective" pore area and depends on a/r as well as the solute and bulk flow velocities. The combined effects of steric hindrance and friction on A_{eff} are illustrated in Figure 21.9 using published values for k_1 and k_2.[97] The approximation equation used by Landis and Pappenheimer in 1963 is also shown[71] where:

$$\frac{f_{unbounded}}{f_{pore}} = 1 - 2.104\cdot\left(\frac{a}{r}\right) + 2.09\left(\frac{a}{r}\right)^3 - 0.95\left(\frac{a}{r}\right)^5 + \cdots \tag{21.18}$$

From Figure 21.9 it is clear that restricted diffusion will cause a membrane to discriminate between two solute molecules of different radii, even when the radii of both are considerably less than the radius of the pore. Also, note that Eq. (21.17) reduces to Eq. (21.13) in the absence of bulk flow and as a/r approaches zero.

Pore Theory and Hydrodynamic Flow

It is allowable to describe bulk flow within a cylindrical pore using Poiseulle's law as long as the pore

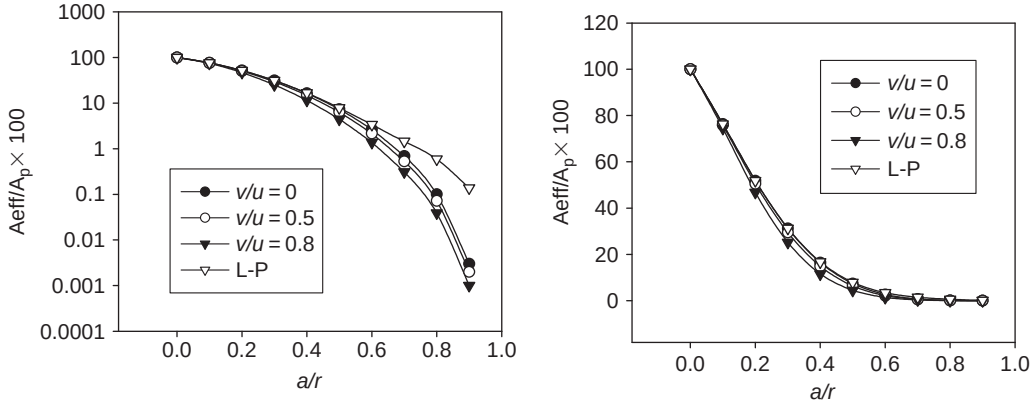

FIGURE 21.9 **Ratio of effective pore area A_{eff} to physical pore area A_P that applies to diffusion of solute with radius a through circular pore with radius r.** The model accounts for steric hindrance and for friction; u and v are respective solute and bulk flow velocities. Friction is calculated based on published coefficients.[97] L–P refers to result generated by older method of Landis and Pappenheimer, which works well for a/r <0.6. Results shown in semi-log (left) and linear (right) formats.

radius is several-fold the radius of a water molecule. Accordingly:

$$q = \frac{-\pi r^4}{8\eta}\frac{dP}{dy} \tag{21.19}$$

where q represents bulk flow within a single pore and dP/dy is the axial pressure gradient along the pore. For flow per unit area across a membrane, pressure is replaced by the Starling forces[113,117] such that:

$$Jv = \frac{n\pi r^4}{8\eta\delta}(\Delta P - \Delta\Pi) = \frac{A_w r^2}{8\eta\delta}(\Delta P - \Delta\Pi) \tag{21.20}$$

where n is the number of pores per unit area and A_w is the restricted pore area available to water. Comparing Eq. (20) to Eq. (3a), the hydraulic permeability L_p for an isoporous membrane is given in terms of the pore radius r and the ratio of total pore area to membrane thickness A_w/δ.

$$L_p = \frac{A_w r^2}{8\eta\delta} \tag{21.21}$$

Combining Bulk Flow and Restricted Diffusion

The solute flux equation (Eq. (21.3b)) includes terms for diffusion and advection. Advective transport and restricted diffusion occur simultaneously in the glomerulus, and each contributes to the presence of large molecules in the filtrate. Furthermore, convection and diffusion are coupled, and this coupling must be unraveled for a full understanding of glomerular sieving. We shall present two approaches to this that are both based on pore theory and rely on the sieving coefficient, Θ, to draw inferences regarding the filtration barrier. The first approach is the early work of Pappenheimer, and the second approach is that of Chang and Deen who based their method on the prior work of Patlak. It is the latter approach to interpreting sieving data that is used by most authors who publish in the physiology or clinical literature nowadays.

There are some intuitive features of glomerular sieving, and some that are not so intuitive. First, it is intuitive that Θ cannot be a negative number, nor can it exceed unity. If Θ exceeds unity, a model other than pore theory is required to explain the flux. It is also intuitive that Θ will approach unity for small solutes, and that Θ will equal zero for any solute that is larger than the largest pore. A feature that is not so intuitive is how intermediate Θ can arise from an isoporous membrane, although we have shown intermediate A_{eff} for an isoporous membrane in Figure 21.9. Intermediate Θ also owes to the effect of filtration rate on molecular sieving, which appears as the second term in Eq. (21.3b). If the passage of a solute is restricted relative to the passage of water, then the filtrate will become diluted during filtration. This will give rise to a concentration gradient for diffusion. Thus, the overall sieving coefficient is determined by competition between the filtration rate, which tends to dilute the filtrate, and the restricted diffusion, which fights to reduce the concentration difference that arises from molecular sieving.

It is intuitive that, if A_{eff} is non-zero and J_v is low enough, then solute will eventually equilibrate between the plasma and Bowman's space ($\Theta = 1$). It is also intuitive that, at high rates of J_v, Θ will approach the ratio of restricted pore area for solute relative to water. Pappenheimer provided a quantitative expression for Θ that satisfies these two conditions.[71] This derivation begins with a bulk-flow sieving step to create an initial filtrate to plasma concentration ratio:

$$\frac{C_{fitrate}}{C_{plasma}} = (1 - \sigma_s) = \frac{A_s}{A_w} \tag{21.22}$$

where C is the concentration of the solute in question, A_w and A_s are the effective pore areas for water and solute, and σ_s is the sieving coefficient from Eq. (21.3). Next, diffusion is superimposed according to Fick's law. Assuming that the concentration gradient is constant within the membrane:

$$J_s^{diffusion} = D_0 \frac{A_s}{\delta}(C_{plasma} - C_{filtrate}) \tag{21.23}$$

where D_0 is the free solute diffusion coefficient and δ is the membrane thickness. Summing the effects of bulk-flow sieving and diffusion:

$$C_{filtrate} = \left(\frac{A_s}{A_w}\right) C_{plasma} + \frac{J_s^{diffusion}}{J_v} \tag{21.24}$$

Inserting Eq. (21.23) into Eq. (21.24) and rearranging yields:

$$\Theta = \frac{C_{filtrate}}{C_{plasma}} = \frac{\left(1 + \frac{D_0 A w}{J_v \delta}\right)}{\left(\frac{A_w}{A_s} + \frac{D_0 A w}{J_v \delta}\right)} \tag{21.25}$$

The assumption of a constant solute gradient within the membrane is a shortcoming of Pappenheimer's approach. This shortcoming was later overcome, based on the work of Patlak[100] who developed a more rigorous approach for quantifying filtration–diffusion interactions in isoporous membranes. Variations on the Patlak approach form the basis for the pore models that are applied to animal and clinical investigations of glomerular sieving nowadays.[2] A modified Patlak equation for solute flux begins again with the Kedem–Katchalsky solute flux equation (Eq. (21.3b)). Diffusion-advection coupling in Eq. (21.3b) is contained in the parameter $\overline{C_s}$, which is the average value of C_s within the membrane. However, $\overline{C_s}$ can't be measured or derived without prior knowledge of the coupled flux that we are trying to determine. Therefore, the challenge is to come up with a form of Eq. (21.3b) that doesn't contain $\overline{C_s}$. The first step toward accomplishing this is to divide the capillary wall of thickness δ into a series of infinitesimally thin laminae. The Kedem–Katchalsky equation for a thin lamina is:

$$J_s = -D_s \frac{dC_s}{dy} + J_v(1 - \sigma_s)C_s \tag{21.26}$$

where y is the position along the length of the pore, which runs perpendicular to the membrane surface. Next, separating variables and integrating across the membrane yields:

$$\int_{plasma}^{filtrate} \frac{dy}{-D_s} = \int_{plasma}^{filtrate} \frac{dC_s}{J_s - J_v(1 - \sigma_s)C_s} \tag{21.27a}$$

$$\frac{\delta}{-D_s} = \frac{1}{-P_s} = \frac{1}{-J_v(1 - \sigma_s)} [\ln(J_s - J_v(1 - \sigma_s)C_s)]_{plasma}^{filtrate} \tag{21.27b}$$

$$\exp\left(\frac{J_v(1 - \sigma_s)}{P_s}\right) = \left[\frac{J_s - J_v(1 - \sigma_s)C_{filtrate}}{J_s - J_v(1 - \sigma_s)C_{plasma}}\right] \tag{21.27c}$$

Making the substitutions:

$$P_e = \frac{J_v(1 - \sigma_s)}{P_s} \quad \text{and} \quad C_{filtrate} = \frac{J_s}{J_v} \tag{21.28}$$

and rearranging Eq. (21.24c) to solve for J_s yields:

$$J_s = \frac{C_{plasma} J_v(1 - \sigma_s)}{1 - \sigma_s \exp(-P_e)} \tag{21.29}$$

Equation (21.29) expresses the solute flux as a function of plasma solute concentration, filtration rate, and the membrane characteristics σ_s and P_s, without referring to C_s anywhere inside the membrane. P_e is the Peclet number, which represents the ratio of advective to diffusive solute flux.

The remaining steps involve relating P_s and σ_s to the idealized membrane geometry using the equations for the hydrodynamics of cylindrical pores developed above.

$$P_s = \frac{D_0 A_s}{\delta A_p} \quad \text{and} \quad \sigma_s = 1 - \frac{A_s}{A_w} \tag{21.30}$$

PORE THEORY AND EXPERIMENTS IN THE GLOMERULUS

To characterize the filtration properties of a particular membrane by applying pore theory as described above, one begins with tracer solute(s) of known concentration (s) and Stokes–Einstein radii and a membrane of unknown microscopic dimensions. The water flux and sieving coefficient of the tracer solute(s) are measured along with the filtrand tracer concentration(s) and transmembrane pressure. A best fit of these data is made to the theoretical model, in order to determine the size and density of idealized pore(s). A better fit can always be achieved by allowing subpopulations of pores with various sizes. This is often justifiable on grounds of common sense. For example, in glomerular disease there is increased permeability to macromolecules, but not to water. This is easily explained by the appearance of a small population of large pores (sometimes called "shunts") that allow for the passage of macromolecules that are excluded from the main population of small pores. A scant population of shunt pores could account for most of the macromolecular sieving, but contribute negligibly to the ultrafiltration coefficient, LpA, because the pore area available to water is much larger.

To convert solute flux to overall sieving for the glomerulus, flux must be integrated over the entire capillary surface. Using C_{plasma} to represent the plasma concentration of s and x as the position along the capillary:

$$\Theta_s = \frac{1}{C_{plasma}(0)} \cdot \frac{\int_0^1 J_s dx}{\int_0^x J_v dx} \tag{21.31}$$

But the forces driving J_v and J_s change along the length of the capillary, since C_{plasma} rises as filtration occurs and J_v declines as oncotic pressure in the capillary pressure rises. For the idealized cylindrical capillary of unit length:

$$C_{plasma}(x) = \frac{C_{plasma}(0)Q_0 - \int_0^x J_s(z)dz}{Q_0 - \int_0^x J_v(z)dz} \quad (21.32a)$$

$$J_v(x) = Lp(\Delta P - \Pi(x)) \quad (21.32b)$$

where Q_0 is the incident plasma flow, and the oncotic pressure Π is given by Eq. (21.5).

To solve for the total sieving of solute by a glomerular capillary, Eq. (21.32) is iterated to provide the inputs for Eq. (21.29), which is then integrated along the capillary according to Eq. (21.31). Although the actual glomerular capillary bed is a complex and heterogeneous network of branching blood vessels, the sieving coefficients predicted for the idealized homogeneous circular cylinder differ negligibly from those predicted from a reconstruction that incorporates the complex anatomy.[105]

SIEVING CURVES

In order to compute the size-selective properties of the glomerular barrier it is necessary to know the sieving coefficient Θ for multiple tracer solutes with different radii. Therefore, tracer solutes are required whose concentration in Bowman's space can be measured or inferred. Direct sampling from Bowman's space is inconvenient or impossible in most circumstances, so it is usually necessary to infer sieving coefficient(s) from urinary clearance(s). The sieving coefficient of a tracer solute is equal to its urinary clearance divided by the GFR, as long as the test solute is not secreted, reabsorbed or metabolized by the tubule. Polysaccharides fulfill this criterion of being impervious to processing by the tubule. Also, it is possible to generate mixtures of polysaccharides with a range of Stokes–Einstein radii. These mixtures can be used to plot Θ as a function of Stokes–Einstein radius with many data points in a single experiment. These sieving curves can be used to determine pore size and relative abundance of different pores in heteroporous models.

The most commonly used tracer polysaccharide is dextran, an inert polymer of glucopyranose. There are over 50 published human and animal studies in which the size selective characteristics of the glomerular barrier have been analyzed from dextran sieving curves. As a rule, dextran sieving data are consistent with a two pore model[109] of the glomerular capillary wall where the vast majority are small pores with radius of 4.8–6.0 nm and the remainder are shunt pores with radius exceeding 10 nm (reviewed in [144]). However, this use of dextran is seriously encumbered because the equations of pore theory were developed for rigid spheres, whereas dextran exists as a flexible random coil.[48] Due to its flexibility, a dextran molecule is far less hindered at crossing the filtration barrier than a rigid spherical molecule of equivalent Stokes–Einstein radius.[108] Based on pore sizes computed from dextran sieving data, Θ for albumin (Stokes–Einstein radius 3.6 nm) should exceed the experimental value by roughly 500-fold. The realization that this discrepancy in Θ between albumin and 3.6 nm neutral dextran owes mainly to the flexibility of the dextran molecule has reduced the need explain the low sieving coefficient for albumin based on something other than size. Hence, there is a lesser emphasis placed on the charge selectivity of the glomerular capillary wall these days than there was during the 1970s. Clearly, one must be cautious when using dextran sieving data to predict the sieving of non-dextrans. Nonetheless, dextran sieving is reproducible and precise, and predicts the structural changes that befall diseased glomeruli, even though they give a biased estimate of pore size.

Ficoll is an inert spherical sucrose polymer with internal cross-linking that confers some rigidity.[14] Ficoll has been tested against dextran in rats and found to have a sieving coefficient substantially less than size-matched dextran for Stokes–Einstein radii greater than 3 nm.[15,94] Lower sieving coefficients for Ficoll relative to size-matched dextran have also been confirmed in healthy and nephrotic humans.[1,13] However, Ficoll is less convenient to use than dextran in humans, because potential toxicity limits the amount that can be given. Also, Ficoll molecules are more compressible than globular proteins, such that pore sizes estimated from Ficoll sieving data will overestimate the sieving coefficients of like-sized globular proteins, albeit to a lesser degree than dextran.[144]

The glomerular sieving of polysaccharides is useful to the extent that it helps explain the permselectivity for endogenous proteins. Ultimately, however, the predictions based on polysaccharide sieving must be verified for proteins. As already discussed, the direct approach of measuring protein sieving by micropuncture is difficult. There are other strategies that have been employed to estimate sieving coefficients for proteins without requiring micropuncture. We will mention two of these. One alternative to micropuncture is to reduce the tubular processing of proteins by cooling the isolated perfused rat kidney to 8°C (cold IPK) to stop the tubule from degrading or transporting filtered proteins, then assuming that the filtered protein equals the protein excretion. Adding furosemide and nitroprusside to the cold IPK eliminates water reabsorption almost completely, and reportedly yields stable values for albumin fractional clearance. However, GFR is low in the

cold IPK and perfusate flow is high, which means that the determinants of glomerular filtration are quite different than *in vivo*. This should pose a problem for the cold IPK, since fractional solute clearance must depend on the determinants of glomerular filtration rate given that convection and diffusion both contribute to solute transport.[22] Nonetheless, cooling seems to have minimal effect on the urine to plasma ratio for Ficoll, and the cold IPK has been used to address a variety of issues related to glomerular protein sieving.[53,64–66,74,75,128]

More recently, Tenstad et al. have made direct estimates of glomerular sieving coefficents for proteins based on tracer radioactivity retained in the kidney six minutes after administering radiolabeled proteins to rats. The rationale behind this approach is that there exists a several-minute window of opportunity when a tracer protein will remain in the kidney after being filtered and taken up by the proximal tubule, and before being degraded or reabsorbed back into the body. An estimate of this time window was first made using cystatin C, which is a freely filtered protein that is completely degraded by the tubule. As such, the rate at which cystatin C enters the urinary space is equal to its plasma concentration × GFR. Administering a bolus of labeled cystatin C along with a GFR marker, then stopping the experiment at various time points and counting tracer activity in the kidney, revealed that cystatin C remains in the kidney for at least six minutes after undergoing filtration.[135] In tracer uptake experiments using neutral horseradish peroxidase, myoglobin, and charge-neutralized albumin, the sieving coefficients for each of these proteins was significantly less than for Ficoll or dextran of equal hydrodynamic radius.[80] The principle pore radius computed by pore theory is 3.75, 4.6, and 5.5 nm for protein, Ficoll, and dextran, respectively[144] (see Figure 21.10).

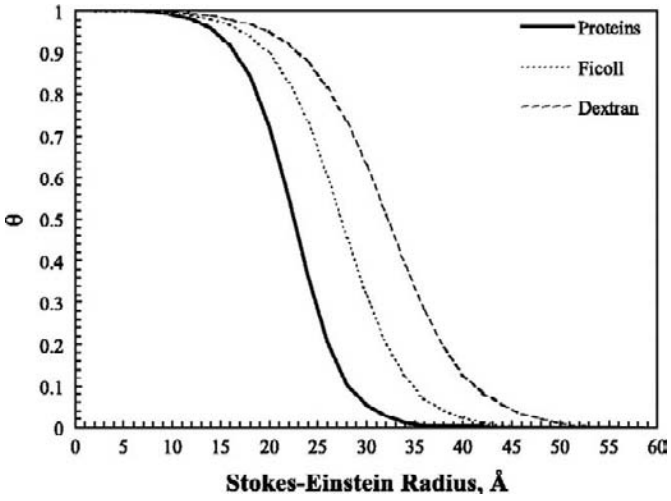

FIGURE 21.10 **Sieving curves for dextran, Ficoll, and neutral proteins constructed from the literature** *(taken from ref. [98]).*

COMBINING FIBER MATRIX THEORY WITH THE PORE MODEL

Using a wider range of dextran radii than previously employed by others, Katz generated dextran sieving curves that were not uniformly convex upward, but flattened out slightly above 4 nm.[68] This nuance could be explained by a two-pore model in which the pores were filled with a fiber matrix, but it could not be explained by any open-pore model of equal complexity. Citing the location of albumin molecules found in glomerular sections[112] and confocal tracking of dextran in isolated glomeruli,[25] it was hypothesized that the albumin barrier does not reside in the GBM anyway, and that the endothelial fenestrae, filled with fibrous glycocalyx, justify the mathematical model. The pore-matrix model has features corresponding to the pore theory model described above. For example, there is steric hindrance due to the presence of the gel fibers. There is also reduced solute mobility due to the gel fibers. The specific formulae for these were developed from the theoretical groundwork for gel permeation by solutes provided by Ogston,[91] and combined with pore theory by Katz.[68]

Intravital Microscopy and Albumin Sieving

Glomerular permeability to albumin has also been examined using intravital dual-photon microscopy. The first measurements of glomerular albumin sieving by the dual-photon method were reported in 2007 by Russo et al. who administered fluorophore-labeled albumin to rats, compared fluorescence intensity in Bowman's space to plasma, and concluded that the albumin sieving coefficient is approximately 0.03, which is 50-fold higher than previously reported by any other method dating from the 1940s.[113] Subsequent application of the dual-photon technique by Tanner, who used the same facility but a different brand of microscope, failed to reproduce the finding, instead corroborating the traditional view of an albumin sieving coefficient less than 0.004, which was his lower limit of detection.[133] Peti-Peterdi also examined the filtration barrier using dual-photon microscopy and came to the same conclusion as Tanner, namely that the Russo finding was in error.[101] Peti-Peterdi has also argued that fluorescence imaging is poorly suited to measuring glomerular sieving coefficients, because light absorption and scattering by RBCs suppresses the apparent fluorescence of plasma proteins, which will lead to an overestimate of Θ.[102] So, after initial excitement over the Russo finding, the prevailing opinion among

investigators in this field remains that the glomerular sieving coefficient of albumin is approximately 0.0006.

Charge Selectivity of the Filtration Barrier

Since the 1970s it has been generally accepted that the glomerular capillary wall is less permeable to proteins that are negatively charged. In addition to the low Θ for albumin compared to neutral dextran for equivalent Stokes–Einstein radius, the impression of charge selectivity was supported by experiments that compared sieving of anionic, neutral, and cationic dextrans.[18,21] It has since been learned that anionic dextran sulfate can be taken up by glomerular cells, desulfated, then secreted to appear in the urine as neutral dextran.[134,145] In addition, sieving of dextran sulfate is reduced through binding to plasma proteins.[49] These effects could create the appearance of charge selectivity of the filtration barrier where none exists. Furthermore, other experiments using Ficoll or hydroxyethyl starch failed to show a charge-selective barrier to either of these alternative polysaccharide molecules.[50,116]

Although the notion of charge selectivity for polysaccharides has lost some of its currency, the bulk of evidence still favors the notion that charge selectivity applies to the filtration of globular proteins. Rennke showed a lesser sieving coefficient for anionic horseradish peroxidase (HRP) than neutral HRP in rats,[107] allowing that part of the effect may have been due to degradation of anionic HRP during filtration.[96] Lindström showed charge selectivity for the somewhat larger protein, lactate dehydrogenase.[75] Making use of the tissue tracer uptake technique described above, Lund calculated sieving coefficients and reflection coefficients for several proteins, including charge-neutralized and native anionic human serum albumin. Θ for anionic albumin was remarkably similar to the micropuncture result of Tojo (*vide supra*) while Θ for neutral albumin was 10-fold higher[80] (Table 21.3).

TABLE 21.3 Charge Permselectivity of the Glomerulus in Rats Confirmed by the Tracer Uptake Method Using Neutralized or Native Anionic Human Serum Albumin

	Stokes–Einstein Radius (Å)	Isoelectric pH	Θ	σ
neutral albumin	35.0	7.4	0.0055	0.996
anionic albumin	35.5	4.9	0.0006	0.9997

Adapted from data in Lund et al. (2003). Am. J. Physiol.[80]
Θ: glomerular sieving coefficient; σ: Staverman reflection coefficient. Since these experiments were performed *in vivo*, they reflect the normal contributions of diffusion and convection to albumin flux.

Theory of Charge Selective Sieving

Deen presented a theory for glomerular filtration of charged solutes based on a homogeneous distribution of fixed negative charges within the glomerular capillary wall[32] as idealized in Figure 21.11. The mathematical description of this model begins with an equation for flux through an imaginary thin surface within a membrane. This is the same as Eq. (21.26), except that the full electrochemical potential is included in the diffusion force to yield:

$$Js = -D_s\left(\frac{dC_s}{dx} + z_s C_s \frac{d\psi}{dx}\right) + J_v(1-\sigma_s)C_s \qquad (21.33)$$

where $D_s = D_0 \cdot A_{eff}$, z_s is the valence of s and ψ is a dimensionless electrical potential.

Next, it is assumed that there is electrochemical equilibrium at both membrane-solution interfaces. This allows the step change in C_s at each interface to be calculated from the Nernst equation and the steric hindrance:

$$\begin{aligned} C_s'(0) &= C_{plasma}(1-\sigma_s)\exp(z_s(\psi_{plasma} - \psi'(0))) \\ C_s'(\delta) &= C_{filtrate}(1-\sigma_s)\exp(z_s(\psi_{B.S.} - \psi'(\delta))) \end{aligned} \qquad (21.34)$$

where (′) refers to values within the membrane just inside its interface with the plasma or Bowman's space, and *B.S.* refers to Bowman's space. Within the membrane, $d\psi/dx$ is small so that the same integration can be done as was done to Eq. (21.27). Integrating from 0 to δ within the membrane and substituting and rearranging yields the following charged-solute flux equation which is analogous to Eq. (21.29):

$$J_s = \frac{C_{plasma}J_v(1-\sigma)\exp(z_s(\psi_{plasma} - \psi'(0)))}{1-\exp(-P_e)(1-(1-\sigma)\exp(z_s(\psi_{B.S.} - \psi'(\delta))))} \qquad (21.35)$$

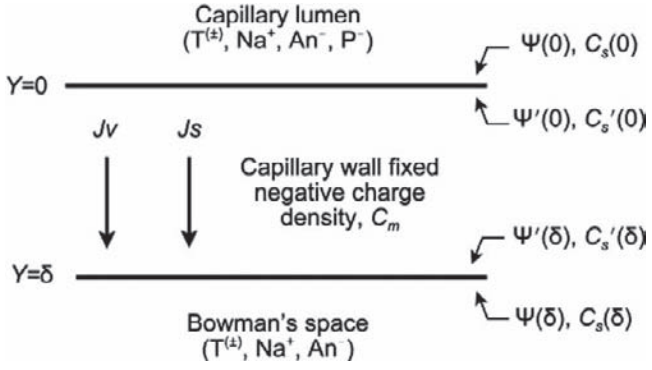

FIGURE 21.11 **Idealized capillary wall with fixed negative charge density C_m, which causes Donnan potentials ($\Psi - \Psi'$) to form at interfaces of the membrane with the capillary lumen and Bowman's space.** These Donnan potentials retard the flux of anionic tracer T^- and accelerate the flux of cationic tracer T^+ according to formulae developed in the text (A_n: mobile anions; P^-: anionic proteins) *(adapted from ref. [125]).*

The two electrical potential differences in Eq. (21.35) are next to be determined. These cannot be measured, but are given by the Donnan potentials for Na^+:

$$\psi - \psi' = \ln\left(\frac{C'_{Na^+}}{C_{Na^+}}\right) \tag{21.36}$$

Since there must be zero net charge in each compartment:

$$C_{Na} = C_{An} \text{ and } C'_{Na} = C'_{An} + C_m \tag{21.37}$$

where *An* refers to mobile anions and *Cm* is the density of negative charges in the membrane. At Donnan equilibrium:

$$\frac{C'_{An}}{C_{An}} = \frac{C_{Na}}{C'_{Na}} \tag{21.38}$$

Combining Eqs. (21.37) and (21.38) yields a quadratic equation for C'_{Na} with the positive root:

$$C'_{Na^+} = \frac{C_m + \sqrt{C_m^2 + 4C_{Na^+}C_{An^-}}}{2} \tag{21.39}$$

Inserting Eq. (21.39) into the numerator of Eq. (21.36) gives the Donnan potentials. Inserting these into Eq. (21.35) gives an expression for solute flux that incorporates the effect of C_m. If C_m or z_s is zero, this reduces to Eq. (21.29), as it should. Θ_s for the glomerulus is obtained by integrating J_s along the capillary surface as per Eq. (21.31).

Deen's model predicts that a single parameter, C_m, can account for charge selective sieving. This is shown in Figure 21.12, where the theory was applied to anionic dextran sulfate based on other model inputs from the normal rat in which neutral dextran was used to determine a pore radius.

This theory of charge-selective filtration has been criticized, because isolated GBM was found to have too low a density of anionic charge to satisfy model predictions for what is required of the GBM to operate as barrier to albumin.[24] However, the inflated 5 nm pore radius calculated from neutral dextran sieving may account for the discrepancy. It should also be noted that this model explains charge-related sieving entirely on the basis of Donnan potentials at the two membrane interfaces. It makes no allowance for any effect that the fixed membrane charges might have on the steric hindrance or friction within the pore. Such effects are likely, and would further reduce the amount of fixed negative membrane charge required to account for any degree of charge selectivity. To date, there is no theory for quantifying this, although it has been argued that the phenomenon of "charge screening" can be used to show reduced partitioning of anionic proteins in the glomerular capillary wall (*vide infra*). Furthermore, the relevant Donnan potential may arise at the plasma

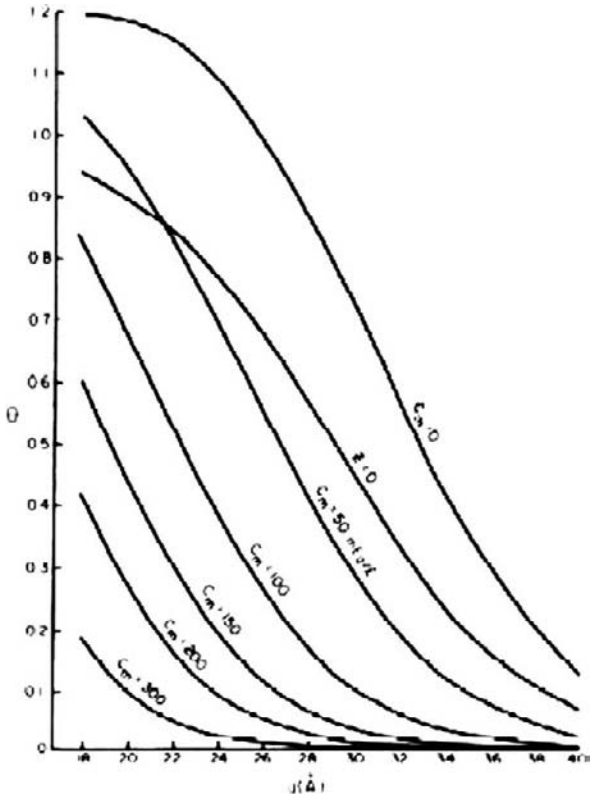

FIGURE 21.12 **Sieving coefficent (Θ) for dextran sulfate as function of Stokes–Einstein radius, a.** Cm-membrane fixed negative charge density in mEq/liter. Valence, z, of dextran = 0.245 × a. z = 0 is curve for neutral dextran *(from ref. [126]).*

interface with the negatively charged endothelial glycocalyx rather than the basement membrane, in which case the charge density of the GBM is not the appropriate straw man for arguments against charge-based sieving (*vide infra*).

Endothelial Glycocalyx as the Barrier to Macromolecules

It has been a challenge to determine which individual layer of the glomerular filtration barrier contributes most to macromolecular sieving. Various investigators at various times and with various methods have argued for the GBM,[20,42,60] filtration slit diaphragm,[139] and endothelium.[112] Overall, the glomerular endothelium has received less attention than GBM and slit diaphragm with respect to permselectivity. Nonetheless, it is arguably unwise to ignore the possibility of a proximal barrier, since the filter should clog if albumin is allowed to permeate downstream and wedge against the slit diaphragm.[127]

The glomerular endothelium is perforated with fenestrae 20 times the diameter of albumin. So if the

endothelium serves as a selective barrier to filtration of macromolecules this property owes to the glycocalyx that fills these fenestrae. Information about the molecular dimensions and electrical properties of the endothelial glycocalyx has accrued slowly, and lack of such information has forestalled a definitive analysis. Nonetheless, both experimental data and logical arguments have emerged for the glycocalyx as an important size and charge-selective barrier. The endothelial glycocalyx forms a hydrated gel within the fenestrae, and contains fixed negative charges on its gel fibers. The effective permeability of a solute in a gel relative to free solution (D_{eff}) can be expressed as the product of its diffusion coefficient in the gel relative to free solution (D_{gel}/D_0) and the fraction of the gel volume available to be occupied by the protein (e.g., its partition coefficient, Φ).

$$D_{eff} = \frac{D_{gel}}{D_0}\Phi \tag{21.40}$$

Considering charge selectivity, it is conceivable that electrostatic interactions with a negatively charged gel might impede the transit of like-charged molecules by reducing D_{gel} or Φ.

One way to study the role of electrostatic interactions between proteins and gels is to inhibit these interactions by increasing the ionic strength of the solvent, which is the standard method for separating proteins by size and charge on agarose gels in the laboratory. Ions in the solvent have the effect of screening the charged solute protein from the coulomb forces that would otherwise be exerted on it by the fixed charges on the gel fibers.

The following brief digression into the physical theory of colloids (also known as Debye–Hückel theory) explains how this phenomenon works. Adding a point charge at a fixed position in any medium generates an electric field that attracts mobile ions of opposite charge. An electric field formed by those charges will offset the field associated with the fixed charge so that at some distance from the fixed charge, one can no longer "sense" its presence. If a fixed charge is added, mobile charges will reposition in response, and it can be shown from the density of repositioned charges that the influence of the fixed charge decays exponentially with distance. The reciprocal of the decay constant is known as the Debye length. The Debye length can be deduced by rearranging the equation for electrochemical potential into a Boltzman distribution for the concentration of redistributed charges, using a linear approximation for the Boltzmann distribution to obtain charge concentration as a function of voltage, then inserting the result into the Poisson equation from classical electrical theory, which expresses the second derivative of voltage as a function of charge density. This yields:

$$C(r) = \frac{l}{d}\exp\left(\frac{-r}{d}\right) \text{where } d = \sqrt{\frac{k_B T\varepsilon}{q^2 C_0}} \tag{21.41}$$

$C(r)$ is the probability density of relocated charges at distance r from the fixed charge, d is the Debye length, k_B is Boltzmann's constant, ε is the permittivity, q is the elementary charge, and C_0 is the baseline concentration of mobile charges, e.g., the ionic strength of the buffer. Accordingly, increasing the salinity of the buffer will shorten the Debye length and the influence of the fixed charge wanes almost completely beyond two or three Debye lengths. For a material with a typical dielectric constant and 0.15 molar mobile charges, the Debye length is about 0.2 nm, which is similar to the difference between the main pore radius estimated from sieving of neutral proteins (3.75 nm, *vide supra*) and the molecular radius of albumin (3.6 nm).

Johnson et al. made use of charge screening to examine the role of electrostatic interactions on diffusion and partitioning of bovine serum albumin in 6% sulfated agarose gels by varying the ionic strength of the buffer from 0.01 to 1.0 molar. Increasing the ionic strength to shorten the Debye length and reduce the distance over which repulsive coulomb forces from gel anions can be "felt" had minimal effect on the diffusion coefficient for albumin, but caused a major increase in its partitioning coefficient, Φ. Therefore, the anionic gel poses a selective barrier to sieving of anionic proteins not because it restricts the diffusive mobility of albumin within the gel, but because electrostatic forces reduce the amount of space available within the gel to be occupied by albumin.[63]

The notion of altering buffer strength to manipulate the Debye length has also been applied to study the filtration of charged proteins in the cold isolated perfused kidney.[129] Perfusion with physiologic concentration of buffer salts (152 mM) yielded respective sieving coefficients of 0.11 and 0.045 for neutral and anionic horseradish peroxidase (HRP). Reducing the total salts in the buffer from 152 to 34 mM did not affect the sieving of neutral HRP, but reduced the sieving coefficient for anionic HRP by about half. Thus, there appears to be selective screening-out of anionic HRP by the glomerulus that increases along with the distance over which coulomb forces between the barrier and albumin are able to act. A note of caution is warranted when ascribing the effect of buffer salinity to charge screening within the membrane, since increasing the buffer salinity will also reduce the Donnan potential at the membrane–solution interface, according to Eqs. (21.35)–(21.39).

Glomerular sieving properties have also been examined in the cold isolated perfused kidney of mice

treated with glycosaminoglycan-degrading enzymes intended to disrupt the endothelial glycocalyx. This treatment was estimated to reduce the fiber charge density by 10% and increased the sieving coefficient for albumin by five-fold, but only increased sieving of Ficoll by 1.5-fold, thus demonstrating that hyaluronic acid, chondroitin sulfate, and heparan sulfate are important for glomerular charge selectivity.[61] If the endothelial glycocalyx contributes to the screening of albumin, this removes some of the burden of showing how the GBM can do this when it appears that the GBM contains too few fixed charges. Screening by the glycocalyx at the interface with the well-stirred plasma also reduces the burden on the epithelial slit diaphragm which might otherwise clog.

Recent inroads to understanding the filtration properties of the endothelial glycocalyx have also been made with mathematics. Using computed autocorrelation functions of electron micrographs, Squire et al. found quasi-periodic 20 nm spacing of 10 nm fibers in the endothelial glycocalyx of frog mesentery, and suggested that the glycocalyx in fenestrated glomerular capillaries could be similarly organized.[131] Inspired by Squire et al., Zhang developed a formula for reflection coefficients in a periodic array of parallel fibers. The Zhang model predicts a reflection coefficient for albumin of approximately 0.6, but it does not account for electrical charge, and requires that flow occurs parallel to the fiber axis.[150] Bhalla and Deen also developed a model based on Squire's version of glycocalyx geometry in which they applied Debye–Hückel theory to incorporate the effects of charge on osmotic reflection coefficients of macromolecules in a membrane of parallel fibers bearing like surface charge with flow parallel to the fiber axis.[8] This involved computing the electrostatic free energy for a charged sphere interacting with a hexagonal array of charged fibers. The sphere was assigned a size and surface charge resembling albumin (-0.2 coulomb-m^{-2}). Charge densities were ascribed to the fiber array up to the predicted charge density on chondroitin sulfate. At zero fiber charge, the reflection coefficient matched the prediction of the Zhang model. The reflection coefficient was steeply dependent on fiber charge, rising almost to unity within the tested range. So the current idealized models suggest that the endothelium is a major barrier to albumin, whereas the GBM is probably not.

Serial Membrane Models

The glomerular filtration barrier is built of multiple layers arranged in series. The sieving coefficient for the whole assembly differs from what is predicted by deriving individual sieving coefficients for each layer based on its own physical properties, then multiplying these coefficients together. Conversely, the physical characteristics of a given layer cannot be inferred from its sieving coefficient as measured *in situ*. This is because the sieving coefficient of a given layer is determined by its own physical characteristics, and by the physical characteristics of all downstream layers. In other words, for a filtration barrier consisting of two layers arranged in series with upstream and downstream layers denoted by respective subscripts 1 and 2 and overall sieving coefficient $\Theta = \Theta_1\Theta_2$, it can be shown that Θ_1 depends on Θ_2. There are several consequences of this. The most striking is that placing a less selective layer upstream of a more selective layer actually causes the upstream sieving coefficient to exceed unity, and causes the overall barrier function to deteriorate. This counterintuitive result can be deduced from the solute flux equation, as follows.

We wish to describe the sieving of a solute that exists in low concentration in the plasma. Solute concentration at the boundary interface between the two layers is C_B. By conservation of mass, J_s and J_v are constant throughout the barrier and solute concentration in the terminal filtrate is J_s/J_v. $\Theta_2 = C_{filtrate}/C_B$ rearranges to $C_B = J_s/(J_v\Theta_2)$. Starting with the solute flux equation for the downstream layer, separating variables, integrating, defining the Peclet number, and rearranging to solve for Θ_2 gives:

$$\exp(-Pe_2) = \frac{Js - Jv(1-\sigma_2)C_B}{Js - Jv(1-\sigma_2)C_{filtrate}}$$

$$\Theta_2 \equiv \frac{C_{filtrate}}{C_B} = \frac{1-\sigma_2}{1-\exp(-Pe_2)+(1-\sigma_2)\exp(-Pe_2)} \tag{21.42}$$

Next, we take the same approach to the upstream layer and substitute $J_s/(J_v\Theta_2)$ for C_B to yield

$$\exp(-Pe_1) = \frac{Js - Jv(1-\sigma_1)C_{plasma}}{Js - Jv(1-\sigma_1)\left(\frac{Js}{Jv\cdot\Theta_2}\right)}$$

$$\Theta_1 \equiv \frac{C_B}{Cplasma} = \frac{1-\sigma_1}{\Theta_2(1-\exp(-Pe_1))+(1-\sigma_1)\exp(-Pe_1)} \tag{21.43}$$

Note that the expression for Θ_2 (Eq. (21.42)) contains no reference to upstream events, whereas Θ_1 is affected by Θ_2 (Eq. (21.43)) such that reducing the sieving coefficient of the downstream membrane increases the sieving coefficient of the upstream membrane without altering any of its physical properties Extending this approach to the ith component of a membrane with n series components gives:

$$\Theta_i = \frac{1-\sigma_i}{\Theta_{i+1}\Theta_{i+2}\ldots\Theta_n(1-\exp(-Pe_i))+(1-\sigma_i)\exp(-Pe_i))} \tag{21.44}$$

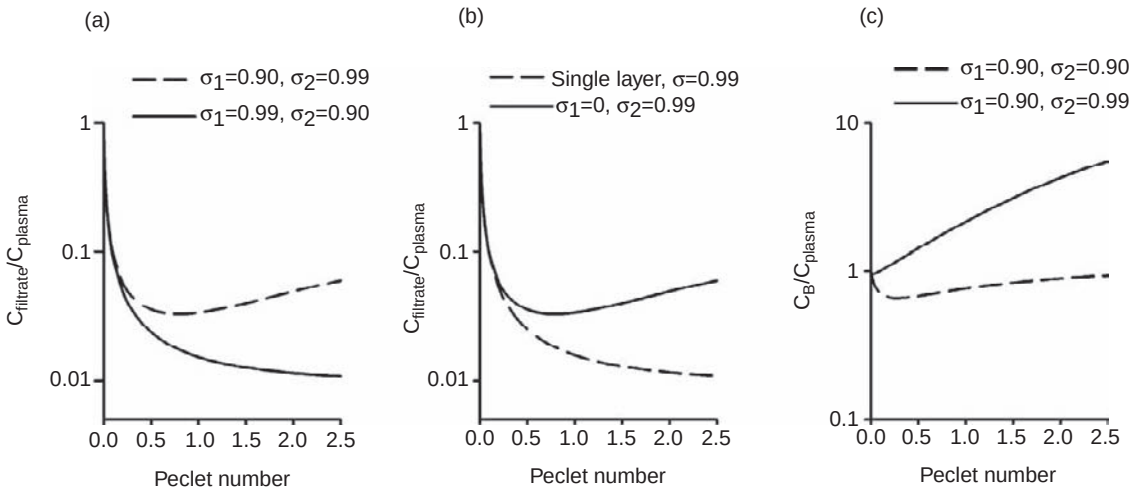

FIGURE 21.13 **Sieving coefficients for a filtration barrier consisting of two layers shown over a range of Peclet numbers.** The upstream and downstream layers are designated *1* and *2*, respectively. Each layer has its own inherent reflection coefficient, σ. C_{plasma}, $C_{filtrate}$, and C_B are the respective solute concentrations in plasma, filtrate, and at the boundary between the two layers. When the Peclet number is zero, there is no bulk flow and the system comes to diffusion equilibrium with equal solute concentrations everywhere (all sieving coefficients = unity). (a) One layer has $\sigma = 0.99$ and the other has $\sigma = 0.90$. The overall efficiency as a filtration barrier is markedly diminished when the less restrictive layer is placed upstream of the more restrictive layer. (b) Placing a permeable layer ($\sigma = 0$) upstream of a restrictive layer yields a barrier that is less efficient than the restrictive layer alone. (c) The sieving coefficient of the upstream layer (C_B/C_{plasma}) is strongly influenced by the reflection coefficient of the downstream layer. Remarkably, when the downstream layer is only 10% more restrictive than the upstream layer, the upstream sieving coefficient can exceed unity by several-fold. In other words, there is concentration polarization in the upstream layer. This acts like a force for diffusion through the downstream layer, and explains the separation of the two curves in panel (a).

Some implications of the double layer filtration barrier are shown graphically in Figure 21.13. Note that all components of Θ approach unity as the Peclet number approaches zero. This corresponds to zero *SNGFR*, where the solute comes to diffusion equilibrium across the membrane. For a single layer membrane at high Peclet number (corresponding to high *SNGFR*) diffusion becomes irrelevant, and Θ approaches $1 - \sigma$. Placing a more selective layer downstream of a less selective layer actually causes the upstream sieving coefficient, Θ_1, to exceed unity, and the overall barrier function deteriorates. Adding an upstream layer of equivalent selectivity to the downstream layer is equivalent to doubling the thickness of a homogeneous membrane. As expected, this halves the diffusion permeability, as manifest by $\Theta_1 \approx 0.5$ at low Peclet number. Peclet numbers haven't been measured for cell layers of the glomerular filtration barrier, but Deen has presented a logical argument against small Pe for albumin in the endothelial or epithelial layers.[28]

Structure-Based Models of the Glomerular Capillary

Since the 1990s there has been progress toward relating the filtration properties of the glomerulus to its actual physical structure. This is mainly the work of Deen and colleagues, who apply modern numerical methods in fluid mechanics to a specific structural model that is based on morphometry.[30,35] The defined structural elements of the model include the endothelial cells and fenestrae, the GBM represented as homogeneous porous material, and the epithelial cell foot processes with filtration slits bridged by slit diaphragms. These elements form a filtering subunit that is repeated many times to comprise the glomerular capillary. Each filtration subunit consists of one filtration slit, several fenestrae, and the GBM in between (see Figure 21.14). Water movement is assumed to be paracellular. In some instances

consideration is given to the endothelial glycocalyx, although untestable assumptions are required for this, since the permeability characteristics of the glycocalyx are not known.

The hydraulic conductances of the endothelium, GBM and filtration slits are treated as separate conductances arranged in series such that the overall conductance is given by a reciprocal of summed resistance:

$$\frac{P_{UF}}{Jv} = \frac{1}{k} = \frac{1}{k_{endo}} + \frac{1}{k_{GBM}} + \frac{1}{k_{epi}} \tag{21.45}$$

where P_{UF} is the ultrafiltration pressure and k is the hydraulic permeability.

By analogy to the first term in Eq. (21.3a), the hydraulic permeability for a single endothelial fenestra is equal to:

$$k_{endo} = \frac{\varepsilon_F \overline{v}_Z}{(P_G - \overline{P}_0)} \tag{21.46}$$

where z is the direction perpendicular to the membrane, v_Z is the average z-component of the flow velocity within the fenestra, P_0 is the average pressure at the outflow, P_G is the capillary pressure, and ε_F is the fraction of the endothelial surface covered by fenestrae. P_0 and v_Z are determined from pressure and velocity fields calculated by finite element analysis applied to a simplified Navier–Stokes'equation, which relates fluid flow to pressure and external forces acting on a fluid.

Hydraulic permeability of the basement membrane is estimated from Darcy's law, which describes the flow of water through porous media when the structural details of the media are unknown:

$$v = -\nabla P \frac{k_D}{\mu} \tag{21.47}$$

where v is the velocity vector, μ is the viscosity and k_D is the so-called Darcy permeability of the medium. The Darcy permeability is related to Lp in Eq. (21.3a), and must be determined empirically. Values for k_D/μ are available from measurements made on isolated glomerular basement membrane.[26,37,110] It is a complicated problem to solve for the pressures and flows within the GBM due to streaming and bulging of the velocity and pressure fields that arise, because fluid must enter only through fenestrae and leave only through epithelial slits that cover only part of the basement membrane. These pressure and flow fields are determined numerically after setting the appropriate conditions for zero flow in the z-direction at boundary areas covered by cells, and setting the divergence of flow equal to zero to satisfy conservation of mass for a noncompressible fluid. Calculating k_{GBM} in this way is somewhat artificial, inasmuch as the apparent conductance of the GBM will increase along with the fraction of its surface that is covered by fenestrae and filtration slits. Therefore, as the number of fenestrae and filtration slits declines, the apparent hydraulic resistance of the GBM will increase even though there has been no actual change to the GBM.

Hydraulic permeability of the epithelial layer is calculated, again by applying the simplified Navier–Stokes' equation, this time to an ultrastructural model of the filtration slit as a rectangular channel bridged by fibers.[34] This particular geometry for the slit diaphragm is based on microscopy of Rodewald and Karnovsky, who suggested that the filtration slit consists of a central fiber connected by bridging fibers to the cell membranes on either side (see Figure 21.15).[111] Solving the model reveals that the slit diaphragm is the main site of resistance to flow through the filtration slit, and that there is little resistance to flow along the remainder of the filtration slit, which is a channel whose walls are formed by two adjacent foot processes. One caveat to these predictions has arisen from molecular sieving data, which suggest that the true pore dimensions provided by the Rodewald–Karnovsky model are too small, and are better explained if the slit diaphragm is represented by a single row of parallel cylindrical fibers rather than two rows of pores separated by a central fiber.[38] However, a more detailed image of the slit diaphragm has now been obtained by electron tomography which validates the basic zipper-like configuration with pores on each side that approximate the dimension of

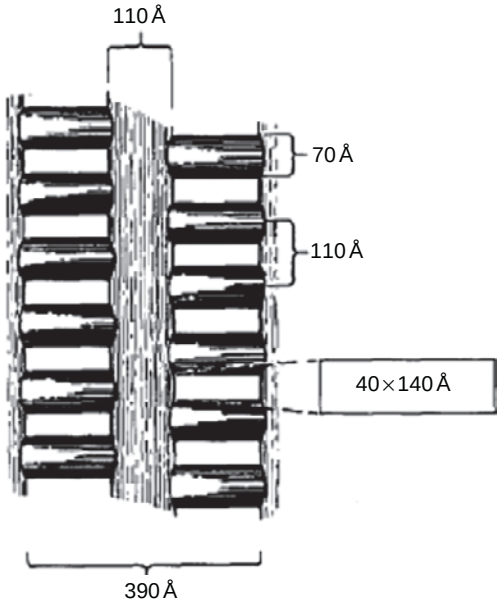

FIGURE 21.15 **Schematic drawing of the epithelial slit diaphragm.** Typical cross-sectional dimensions of pores between cross-bridges are 40 × 140 D *(from ref. [144])*.

k_{endo}	2.0×10^{-7} m-s^{-1}-Pa^{-1}
k_{GBM}	8.3×10^{-9} m-s^{-1}-Pa^{-1}
k_{epi}	8.6×10^{-9} m-s^{-1}-Pa^{-1}
k	4.1×10^{-9} m-s^{-1}-Pa^{-1}
k estimated from micropuncture and morphometry	3×10^{-9}–5×10^{-9} m-s^{-1}-Pa^{-1}

Drumond et al. (1994). Am. J. Physiol. Renal Fluid Electrolyte Physiol. 266, F1–F12.[35] See also Figure 21.14.

albumin. As depicted by electron tomography, these pores appear more irregular and tortuous than previously imagined.[147]

The morphometric parameters and hydraulic permeabilities calculated from the ultrastructural model of Deen et al. are shown in Table 21.4, which also shows that the hydraulic permeability predicted by the model is consistent with values obtained by micropuncture in normal rats. Some other predictions of the model cannot be tested by micropuncture. For example, a main prediction of the model is that the GBM and epithelial layers contribute equally and, together, account for most of the resistance to glomerular filtration. The endothelial fenestrae pose little resistance to bulk flow, except that reducing their fractional area reduces the apparent permeability of the GBM. Furthermore, as already mentioned, most resistance of the filtration slit is due to the slit diaphragm, rather than to drag along the length of the slit.

An important test of the model is that it predicts changes in the ultrafiltration coefficient that occur when the glomerular structure is altered. The model has successfully forecast changes in ultrafiltration coefficient brought about by manipulating dietary protein and/or renal mass to alter glomerular morphology in rats with adriamycin nephrosis.[85]

Computation based on morphometry has also been employed to estimate glomerular ultrafiltration coefficient from renal biopsies in patients with reduced GFR due to membranous or minimal change nephropthies[36] and pre-eclampsia.[70] In each of these conditions, GFR was reduced in spite of normal PAH clearance. In order for GFR to decline while nephron plasma flow remains constant, there must be a decrease in either glomerular ultrafiltration pressure or ultrafiltration coefficient. While it is not possible to measure ultrafiltration pressure in humans, the determinants of *SNGFR* have been extensively evaluated in a wide range of animal models of glomerular disease. With the single exception of cyclosporine toxicity,[137] low pressure in the glomerular capillary does not provide the basis for low *SNGFR* in any of these models. Therefore, it is reasonable to assume that ultrafiltration pressure is not reduced in humans with idiopathic nephrotic syndrome or pre-eclampsia, and that the low filtration fraction in these patients is likely to be the consequence of a decline in ultrafiltration coefficient. Once this premise is accepted, there are several potential explanations for an apparent decline in ultrafiltration coefficient in a glomerulus. First, this could be due to a loss of capillary surface area. Second, it could result from mismatched blood flow among capillary loops within the glomerulus, such that those loops with low flow manifest filtration equilibrium early in their course, which eliminates their latter portions from contributing to the working area. A third mechanism for reducing ultrafiltration coefficient could be to alter the chemical composition of the GBM or slit diaphragm to make them less permeable to water. Finally, ultrafiltration coefficient could decline due to changes in geometry of the individual filtration unit. The latter of these possibilities is amenable to testing by applying computational fluid dynamics to morphometry. Based on this approach, changes in geometry of the filtration unit predict that the ultrafiltration coefficient will be different between normal subjects and those with minimal change disease, membranous nephropthy, and pre-eclampsia. Although each disease has its own morphology, reduced frequency of filtration slits, increased basement membrane thickness, loss of fenestral area or loss of capillary surface area predicted changes in the ultrafiltration coefficient consistent with what would be necessary to explain the associated declines in GFR, given the reasonable assumption that glomerular capillary pressure was not profoundly reduced, and a less certain assumption that the Darcy permeability for the GBM is unaffected. One interesting prediction of the model is that, while the GBM is thickened in membranous nephropathy, this has little importance to the GFR because an even greater augmentation of the average distance traveled from fenestra to slit diaphragm results from the lower filtration slit density, which requires much of the filtrate to stream obliquely through the GBM rather than crossing it directly.

In 2005 it was recognized that the visceral epithelial cell body attaches to the GBM in such a way as to create a semi-confined space downstream of the filtration

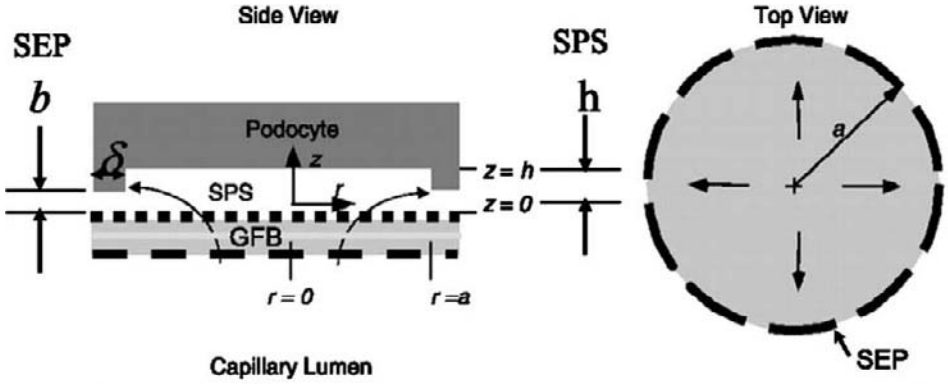

FIGURE 21.16 **Flow across the glomerular filtration barrier and through the subpodocyte space (SPS).** Resistance depends on height of subpodocyte space (h), the path length (a), and the area draining into SPS (πa^2) *(reprinted from ref. [88]).*

slit and upstream of the rest of Bowman's space[87] (see Figure 21.16). It was further estimated that 60% of the filtration surface is covered by this subpodocyte space, and that the space between attachments constitute pores through which filtrate must pass en route to Bowman's space. When analyzed in greater detail and subject to mathematical modeling, it was estimated that the resistance encountered by filtrate in exiting the subepithelial space is likely to exceed that of the traditional 3-layer filtration barrier, and that pressure in this space could, therefore, be three-fold greater than in Bowman's space.[88] This poses a problem for prior structure-based models, which accurately predict the hydraulic permeability without this contribution to the barrier.

SUMMARY

Details about the physics of glomerular filtration have become known over the past century. Different approaches to describing glomerular filtration employ different admixtures of phenomenology and structural detail. The spectrum of useful models extends from the glomerular capillary as an idealized circular cylinder with homogenous permeability to water and small solutes and zero permeability to macromolecules, to a tube perforated by discreet cylindrical pores with differential permeability to solutes based on size and electrical charge, to fiber matrix models based on the physical theory of colloids, to representations that incorporate actual physical dimensions to determine the contributions of endothelial, basement membrane, and epithelial layers to the filtration barrier.

CELL BIOLOGY OF THE GLOMERULUS

Structure and Function of the Glomerulus (Renal Corpuscle)

The glomerulus or renal corpuscle is comprised of the glomerular tuft surrounded by Bowman's capsule and space. The tuft is a specialized microvascular bed which contains three cell types including the fenestrated or sinusoidal glomerular endothelial cells, the visceral epithelial cells known as podocytes, and mesangial cells. The glomerular filtration barrier is made up of the endothelial cells and podocytes together with an intervening glomerular basement membrane, and is the site of formation of the primary urinary filtrate. In the average adult human with normal renal function, 180 L of primary urinary filtrate is formed each day. The filtration barrier must permit free passage of water and small solutes into the urine, while retaining larger macromolecules in the blood. The demands of such "high flux" filtration require that the cell types of the glomerulus exhibit many specialized features, which will be discussed in this chapter.

In all mammals, the renal corpuscle appears as a spherical structure, although its diameter varies to some degree with the size of the organism. In humans, glomeruli are approximately 200 μm in diameter, in elephants 300 μm, in rats 120 μm, and in rabbits 150 μm.[209,215,271] A normal human kidney contains approximately one million individual glomeruli.

The central component of the renal corpuscle is composed of a plexus of sinusoidal or fenestrated capillaries that extend into Bowman's space where the primary urinary filtrate accumulates. The capillary loops are held together by the mesangial cells, and they are covered by a continuous layer of podocytes (Figure 22.1). At the vascular pole, the podocyte layer is continuous with the parietal epithelium of Bowman's capsule. Cells with intermediate phenotypes (between podocyte and parietal epithelium) can be observed at the transition zone. At the urinary pole of the renal corpuscle, the parietal epithelium is continuous with the epithelium of the proximal tubule (Figure 22.2c).

At the site of transition between parietal and visceral epithelium, the afferent and efferent arterioles enter and exit the glomerulus respectively, this is known as the glomerular hilum. After entering, the afferent arteriole branches to form a complex plexus of fenestrated capillaries with loops at the urinary pole.[64,197] The mesangium is required for proper structure and formation of this plexus, and in its absence only a single ballooned capillary loop forms.[64] The capillary loops come into direct contact with the mesangium at discrete points in a small region known as the juxtamesangial portion. However, the majority of the loops are found within Bowman's space and are covered entirely by the glomerular basement membrane and podocyte foot processes.[246] This is the surface area across which filtration occurs. The branches of the afferent arteriole give rise to individual vascular lobules within the glomerular tuft; each of these lobules contains its own afferent and efferent capillary with some connections between lobules. After looping at the urinary pole, the efferent capillaries join to form the larger efferent arteriole, which exits the tuft at the glomerular hilum. Along the length of the efferent arteriole, the

extraglomerular mesangium is gradually replaced by typical smooth muscle cells[64] (Figures 22.3 and 22.4).

GLOMERULAR ENDOTHELIAL CELLS

General Description

Glomerular endothelial cells are large, highly flattened cells that form the innermost layer of the glomerular capillary. Peripherally these cells are extremely thin, and the cell body contains the nucleus and all the cell organelles. The peripheral portions of the endothelial cells contain numerous fenestrae, which are 50−100 nm pores that penetrate the cytoplasm[158,241] (Figure 22.5). The luminal side of endothelial cells is covered by a thick layer consisting of glycoproteins that form "sieve plugs" in the fenestrae and the glycocalyx.[241]

Formation of Glomerular Capillaries

Several transplantation studies have demonstrated that the glomerular capillaries are formed largely by vasculogenesis: endothelial cells are derived from angioblasts believed to be intrinsic to the metanephric mesenchyme.[120,234,235] At E12.5, in mice before the formation of immature vasculature, kinase insert domain receptor (Kdr, also known as vascular endothelial growth factor receptor 2 (Vegfr-2) or Flk-1) positive angioblasts are present in the metanephric mesenchyme.[235] In the S-shaped stage of the developing nephron, immature podocytes start expressing vascular endothelial growth factor-A (Vegfa), thereby attracting Kdr-expressing endothelial cells to migrate to the vascular cleft.[65,68,225] Transforming growth factor-β1 (Tgfb1) induces apoptosis of the endothelial cells and opens the capillary lumens.[73]

Fenestrae and Diaphragms

Ultrastructural analysis demonstrates that diaphragms are often observed in fenestrae of glomerular endothelial cells in rodent embryos. Diaphragmed fenestrae are formed in the S-shaped stage, and then the diaphragms disappear from the capillary loop stage onwards.[121] The main component of the fenestration diaphragm is type II transmembrane glycoprotein plasmalemmal vesicle-associated protein-1 (Pv-1), but its precise function is still unknown.[249] Fenestrae in adult glomerular endothelial cells do not have diaphragms[121] (Figure 22.5); however, fenestrae bridged by diaphragms can be found along the intraglomerular segment of the efferent arteriole and its derivatives.[64] Diaphragms can also be observed in a drug-induced nephritis model, suggesting that diaphragms are required in the development and remodeling of fenestrations, thereby compensating for the immaturity of the barrier function in these settings.[121]

Glycocalyx/Sieve Plugs

The luminal membrane of endothelial cells is covered by a highly negatively-charged layer called the endothelial surface layer (ESL). The relatively dense, membrane-associated part of this layer is called the glycocalyx, and the larger, less compact component is known as the endothelial cell coat (Figure 22.6). The main components of the ESL are glycoproteins, glycoaminoglycans (GAGs), and membrane-associated and secreted proteoglycans.[104] Ultrastructural examinations with sophisticated specialized fixation techniques have revealed that this layer also fills the fenestrae with slit diaphragm-like "sieve plugs".[241] The thickness of the glycocalyx is estimated to be 50−100 nm, and that of the loose endothelial cell coat is considered to be 200−400 nm.[115,129,165,242] The relative importance of the ESL and sieve plug in the glomerular filtration barrier is still controversial.

Functional Maintenance of Glomerular Endothelial Cells: Insights from Studies of Angiogenic Factors

A number of factors are involved in the maintenance of glomerular endothelial structure and function, and coordinate an elaborate cross-talk between endothelial

The capillary loops are outlined by podocytes. Mesangial cells are located within the capillary tuft and connect capillary loops with each other (× 400). *(a and b: Courtesy of Dr. Paul S. Thorner, The Hospital for Sick Children, Toronto, ON.)*

cells and other cell types of the glomerulus (Figure 22.7).

Pdgfb/Pdgfrb

Platelet-derived growth factor B (Pdgfb) is secreted from endothelial cells and binds its receptor (Pdgfrb) on mesangial cells.[161,165,272] Pdgfb or Pdgfrb knockout mice have a defect in mesangial migration and a single, dilated glomerular capillary loop[14,161,272] (Figure 22.8). Endothelial specific deletion of Pdgfb results in the same phenotype as that seen in mice with a systemic knockout.[14,166] Also, this paracrine system requires retention of the ligands in the pericellular space, because mutants with deletion of the Pdgfb retention motif demonstrate delayed mesangial migration and, later on, proteinuria and glomerulosclerosis.[69,166]

Vegfa

Vegfa facilitates the formation of fenestrae in cultured glomerular endothelial cells.[67,69] Podocytes produce large amounts of Vegfa that can bind to Kdr on endothelial cells.[67,68] Cell-selective deletion of Vegfa from podocytes demonstrates that Vegfa signaling is required for formation and maintenance of the glomerular vasculature, its fenestrated phenotype and the filtration barrier. Mice treated with soluble fms-related tyrosine kinase-1 (sFlt-1, discussed below), a decoy receptor of Vegfa, show striking attenuation of endothelial fenestration, highlighting the necessity for Vegfa in the maintenance of fenestration[132] (Figure 22.5). In mutant mice that carry a podocyte-specific gene deletion of *Vegfa*, a few endothelial cells migrate into the developing glomeruli but they fail

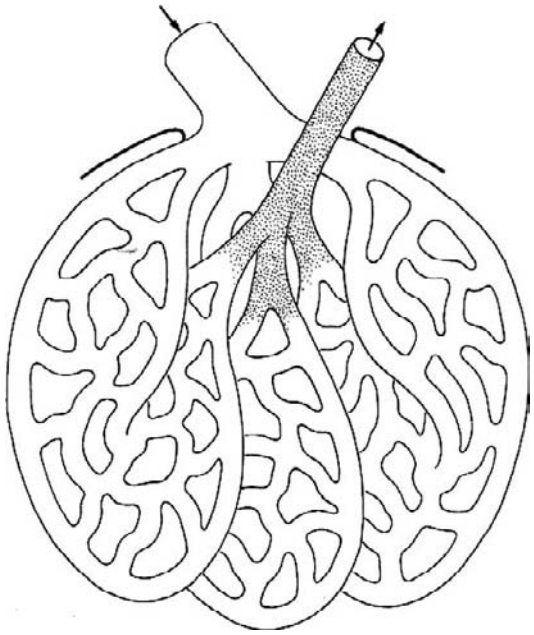

FIGURE 22.3 **Schematic diagram shows the branching pattern of glomerular capillaries.** As soon as the afferent arteriole enters the glomerulus, it divides into two to five branches to form the glomerular capillaries. The capillaries run toward the urinary pole, continuing to branch, and then loop back to the vascular pole to unify and form the efferent arteriole within the glomerular tuft. The efferent arteriole possesses a significant intraglomerular portion (*stippled*), whereas the afferent arteriole does not. *(From Winkler, D., Elger, M., et al. (1991). Branching and confluence pattern of glomerular arterioles in the rat. Kidney Int. Suppl.* ***32****: S2–8, with permission.)*

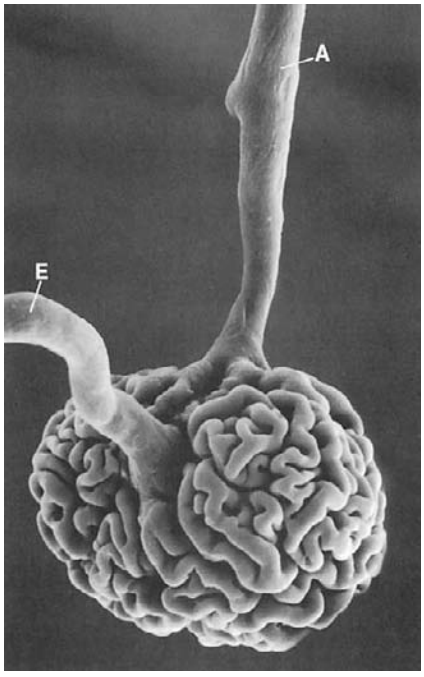

FIGURE 22.4 **Scanning electron micrograph of a glomerular vascular cast.** Afferent (A) and efferent (E) arterioles can be seen.

to develop fenestrations and rapidly disappear, causing renal failure and neonatal death.[67,68] The deletion of one allele of the *Vegfa* gene from podocytes leads to a glomerular defect known as endotheliosis, characterized by endothelial swelling and loss of fenestrations – a universal feature found in thrombotic microangiopathies. Overexpression of the major angiogenic Vegfa 164 isoform in podocytes results in collapse of the glomerular tuft.[67,98] Additionally, patients receiving anti-VEGF therapy may develop proteinuria due to thrombotic microangiopathy (TMA) of the glomerulus with prominent endotheliosis[66,98] (Figure 22.9). Indeed, deletion of *Vegfa* in mature podocytes of adult mice leads to TMA.[66,162] Taken together, these results indicate an indispensable role for Vegfa in the development, maintenance, and function of the glomerular vasculature and filtration barrier. They also highlight the importance of Vegfa paracrine signaling from the podocyte to Kdr on glomerular endothelial cells.

sFlt-1 is an alternatively spliced soluble form of VEGF receptor 1 (VEGFR-1)/Flt-1, and binds to VEGF as a decoy, thereby acting as a potent inhibitor of VEGF activity. Treatment of mice with adenoviral-induced sFlt-1 leads to a massive reduction of endothelial fenestrae[133] (Figure 22.5b). sFlt-1 blood levels are elevated in patients with pre-eclampsia[162,179] and administration of sFlt-1 to pregnant rats causes hypertension and proteinuria with histological glomerular endotheliosis. The endothelium is the most common glomerular region affected in pre-eclampsia,[157,179] suggesting a functional role for sFlt-1 in the function of the glomerular endothelium. A recent study also implicated sFlt-1 in the pathogenesis of PR3-ANCA-associated vasculitis affecting the glomeruli.[157,167]

Tgfb1

Infusion of a neutralizing antibody against transforming growth factor β1 (Tgfb1) to neonatal rats causes a delay in glomerular capillary formation, including the development of fenestrations.[167,173] In the choroid plexus, neutralization of both Tgfb1 and Vegfa leads to decreased cerebral perfusion, vascular thorombi, and a defect of fenestration, which does not occur when either of these treatments are administered individually.[173,279] Thus, Tgfb1 also plays a crucial role in the development and maintenance of glomerular endothelial cells, and may work in concert with Vegfa. Additionally, blood levels of soluble endoglin, an antagonist of Tgfb1 are elevated in patients with pre-eclampsia, and correlate with disease severity. Administration of soluble endoglin in combination with sFlt-1 to pregnant rats results in severe pre-

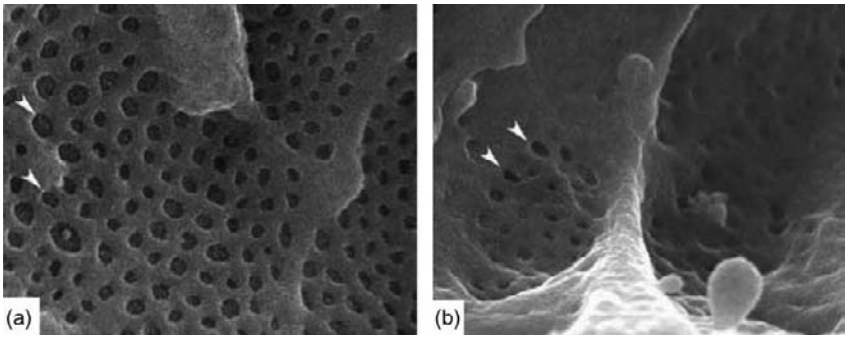

FIGURE 22.5 (a): Scanning electron micrograph shows the inner surface of a healthy glomerular capillary and its beautifully fenestrated endothelium. FIGURE 22.6 **Schematic diagram showing the endothelial surface layer (ESL).** The relatively dense part of the layer close to the endothelial cells form the glycocalyx, which consists of membrane-bound proteoglycans (PG), including syndecan and glypican. Syndecan carries both chondroitin sulfate (CS) and heparan sulfate (HS) side chains, and glypican carries HS side chains. The ESL is comprised of secreted proteoglycans such as perlecan (mainly HS) and versican (mainly CS), as well as secreted glycosaminoglycans (GAG) including hyaluronan. It also traps some plasma proteins such as albumin. *(Modified from Haraldsson, B., Nystrom, J., and Deen, W. M. (2008). Properties of the glomerular barrier and mechanisms of proteinuria. Physiol. Rev.* ***88****: 451–487, with permission.)*

eclampsia, including HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets).[292]

Angiopoietins

Another family of angiogenic factors required for the development and homeostasis of glomerular endothelial cells is the Angiopoetin–Tek signaling system. Angiopoietin 1 (Angpt1) and Angiopoietin 2 (Angpt2) are ligands for Tek tyrosine kinase (Tek/Tie-2). Angpt1 binds to the Tek receptor expressed on endothelial cells, and causes its phosphorylation. This signal leads to enhanced survival of endothelial cells, stabilization of the endothelial cell-to-cell connection, and reduced permeability.[174,253,279] Angpt2 is considered to be a competitive antagonist of Angpt1 by binding Tek but not activating any intracellular signaling.[174,253,320] There is some data, however, that suggests that Angpt2 can activate Tek signaling under certain conditions.[319,320] Angpt1, Angpt2 and Tek are all expressed in developing kidneys.[319] Angpt1 is expressed widely in the condensing mesenchyme in the developing kidney and its derivatives,[250,319] and in mature podocytes.[250,318] Angpt2 shows a more restricted expression pattern, localizing to endothelial cells, pericytes, smooth muscle cells of cortical and large blood vessels, and immature mesangial cells.[318,319] Tek is expressed

both in mature and immature glomerular endothelial cells.[279,319] Angpt1 conventional knockout mice die at embryonic day 12.5, thus precluding any analysis of its role in the glomerular vasculature.[146,279] In mouse metanephric organ culture, recombinant Angpt1 enhances the growth of interstitial capillaries.[146,247] A recent report demonstrated that Angpt1 treatment of isolated rat glomeruli reduced vascular permeability and increased the depth of the glycocalyx layer.[159,247] Cell type-specific/inducible knockout approaches, however, have revealed a crucial role for Angpt1 in glomeruli. Deletion of Angpt1 at E10.5 leads to a single, dilated glomerular capillary loop without mesangial migration in a portion (~10%) of glomeruli that is reminiscent of the Pdgfb/Pdgfrb mouse mutant phenotype (Figure 22.10a,b). Although deletion of Angpt1 after E13.5 doesn't cause any immediate vascular phenotype, streptozotocin-induced diabetic mice with global or glomerular-specific Angpt1 deletion develop increased urinary albumin excretion, severe mesangial expansion, glomerular sclerosis, and early mortality (Figure 22.10c,d). Another report also demonstrated that treatment of diabetic mice with Angpt1 recombinant protein is protective for renal function.[127,159] Angpt1 is therefore dispensable in quiescent, mature glomeruli, but is essential in development and in the vascular response to injury.[80,127,217]

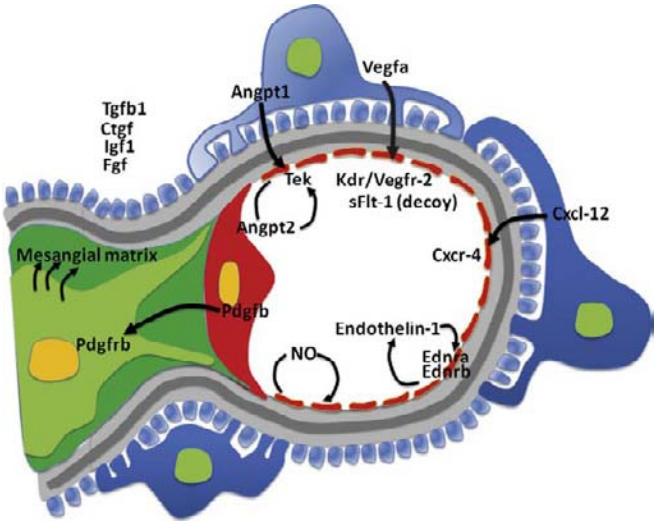

FIGURE 22.7 **Soluble factors involved in the maintenance of endothelial cells and the glomerular capillary structure.** Schematic diagram shows the location of secretion of soluble factors, and where the associated receptors are expressed. Vegfa from podocytes is required for the recruitment, survival, and maintenance of the endothelial cells, and binds to its receptor Kdr. sFlt-1 works as a decoy, but its precise function is still unknown. Angpt-1 is expressed in podocytes and binds to the endothelial Tie-2/Tek receptor in a paracrine fashion, whereas its antagonist, Angpt-2 is secreted from endothelial cells and binds to the Tie-2/Tek receptor in an autocrine fashion. Cxcl12 is secreted from podocytes and interstitial cells, and acts on Cxcr4 in endothelial cells to regulate vascular development and function. Pdgfb secreted by endothelial cells signals to the Pdgfrb receptor expressed by mesangial cells, and is a critical factor for their migration and maintenance. Endothelial cells also express some vasoactive factors including NO and endothelins. Expression of growth factors such as Tgfb, Ctgf, Igf, and Fgf are increased in disease conditions such as diabetic nephropathy, but their precise functions under normal conditions are still unclear.

Angpt2 knockout mice are briefly viable in the postnatal period, and exhibit increased pericyte coverage of peritubular capillaries. The mice die soon after birth however, precluding analysis of the role of Angpt2 in more mature capillary beds.[52,80,217] Angpt2 overexpression in podocytes causes proteinuria and podocyte apoptosis in formed glomeruli.[52,308]

Angiopoietin ligands seem to function in concert with Vegfa. In Vegfa-rich conditions, Vegfa and Angpt2 work together to promote sprouting.[84,299,308] The precise degree of cross-talk between these pathways is still under investigation.

Ephrin-Eph Family

Ephrin-Eph molecules are another family of tyrosine kinase signaling factors that are widely expressed in the developing kidney. In other organs, they are involved in the specification of arteries and veins, as well as in neural development.[84,282,299] In the developing kidney, the Ephrin B2 ligand is expressed in podocyte precursors, but later it is expressed by endothelial

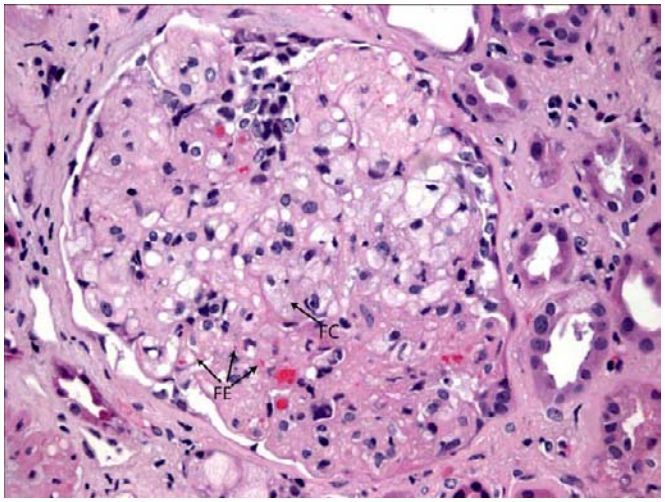

FIGURE 22.9 A glomerulus showing thrombotic microangiopathy from a patient who received anti-VEGF therapy, showing fragmentation of erythrocytes (FE: arrows) and foamy change (FC: arrow) of endothelium.*(Courtesy of Dr. Laura Barisoni, New York University School of Medicine, New York, NY.)*

and mesangial cells.[282,307] In adults, the EphB4 receptor is mainly expressed in podocytes.[5,307] Overexpression of the EphB4 receptor causes defects of glomerular arteriolar formation.[5,307] Deletion of Ephrin B2 from Pdgfrb-expressing pericytes and the mesangial cell population results in abnormal glomerular tuft formation.[7,76] Pharmacologic inhibition of EphB4 leads to delayed recovery and extended injury of endothelial cells and podocytes in a rat mesangial injury model.[280,307] Therefore, it seems this family is involved in glomerular tuft formation and maintenance, but the precise mechanism is still unclear.

CXCR4/CXCR7/CXCL12 Axis

Chemokine CXC motif receptor type 4 (CXCR4), CXCR7, and Chemokine CXC motif ligand 12 (CXCL12) are also critical factors in the development and maintenance of glomerular vasculature. Cxcr4 and Cxcr7 are seven-transmembrane G-protein coupled receptors, and Sdf-1/Cxcl12 is their cognate chemokine ligand.[7,281] A deficiency of Cxcr4 or Cxcl12 leads to a

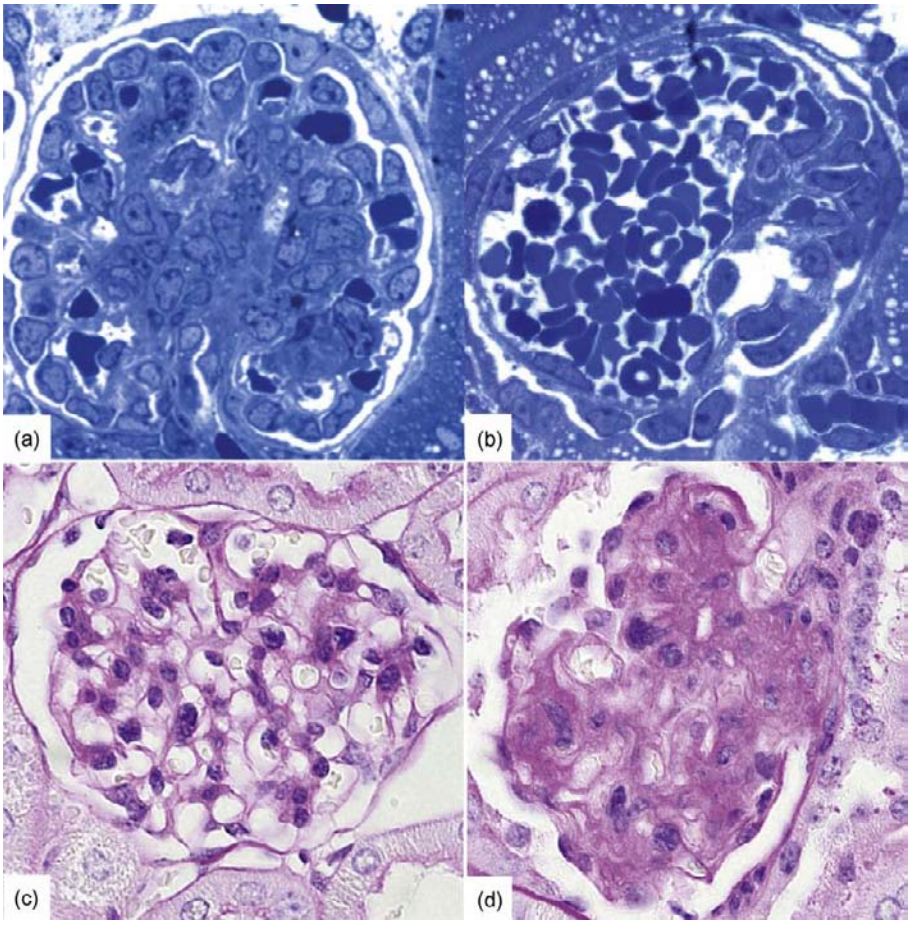

FIGURE 22.10 **Conditional deletion of Angpt1 results in glomerular developmental defects and enhanced diabetic glomerular injury.** (a): A normal glomerulus at embryonic day 17.5 (E17.5). (b): Early conditional deletion of Angpt1 gene at embryonic day 10.5 (midgestation) results in some abnormal glomeruli with single open capillary loops similar to that of Pdgfb-null mouse at E17.5. (c) and (d): Late deletion of Angpt1 at E16.5 doesn't lead to any immediate phenotype. However, after 20 weeks of streptozotocin-induced diabetes, the diabetic mutant mice that carry Angpt1 deletion show an increase in mesangial matrix expansion and sclerosis (d) compared with that of diabetic controls (c) (LM × 1000). *(Courtesy of Dr. Marie Jeansson, Mount Sinai Hospital, Toronto, ON.)*

failure of vasculogenesis and embryonic lethality.[55,280] During renal development, Cxcr4$^{-/-}$ or Cxcl12$^{-/-}$ knockout mice show a ballooning of the glomerular capillary loops which is reminiscent of Pdgfb/Pdgfrb knockout mice.[51,251,281] On the other hand, activation of the CXCR4/CXCR7/CXCL12 axis appears to underlie some glomerular diseases, such as rapidly progressive glomerulonephritis (RPGN),[55,216] diabetic nephropathy,[51,251,281] and hemolytic uremic syndrome (HUS).[116,212,216] It appears that Cxcl12 is secreted from podocytes or interstitial cells, and acts on Cxcr4 expressed by the endothelial cells to regulate vascular development and function.[212,281]

Glomerular Endothelial Cells as a Source of Vasoregulators

Glomerular endothelial cells produce both nitric oxide, a vasodilator, and endothelin-1, a vasoconstrictor. Nitric oxide is produced by NO synthases. Both endothelial and inducible NO synthases are expressed by glomerular endothelial cells *in vitro* and *in vivo*.[116,212,288,310] eNOS expression and activation is at least partially influenced by Vegfa.[212,288] In many rodent disease models and human patients with kidney diseases, overproduction of NO and its derivatives has been observed.[116,288,310] It is considered that excessive NO production generated by inducible NO synthase (iNOS) results in glomerular injury, whereas NO generated from endothelial NO synthase (eNOS) is protective by preserving endothelial survival and function.[200,288,324] In diabetic patients, eNOS expression is increased in renal endothelial cells, whereas iNOS expression is preferentially upregulated in inflammatory cells. The degree of eNOS expression is related to the severity of the glomerular lesion and proteinuria.[116,286] Diabetic eNOS knockout mice develop more severe glomerular lesions and greater albuminuria.[114,200,324] In addition, excretion of NO-related products is often reduced in diabetic patients with nephropathy.[286,305]

Endothelin-1 is a potent vasoconstrictor which binds to one of two receptors: endothelin receptor type A (Ednra); and endothelin receptor type B (Ednrb). Binding of endothelin-1 to Ednra results in vasconstriction, while binding to Ednrb causes vasodilation.[114,315] In glomerular endothelial cells, Ednrb is dominant, whereas Ednra is expressed by mesangial cells.[71,305]

Glomerular endothelial cells are also involved in the renin–angiotensin–aldosterone system (RAAS). They express angiotensin-converting enzyme (ACE) and produce angiotensin II.[63,315] The relative contribution of the glomerular endothelium compared to the systemic endothelium with regard to angiotensin II production, however, is still unknown. Furthermore, the potential role of angiotensin receptors in endothelial cells is also unknown.

Summary

Glomerular endothelial cells form the first permselective barrier in the glomerulus. The relationship between their elaborate, fenestrated cell shape and function is maintained by a network of various angiogenic factors. Glomerular endothelial cells also contribute to the charge-selective barrier through the negatively-charged glycocalyx.

MESANGIAL CELLS

Description

Mesangial cells are irregularly shaped cells which extend processes from their cell body towards the glomerular basement membrane (GBM). The "mesangium" refers to the mesangial cells together with the mesangial matrix they produce[71,141] (Figures 22.11 and 22.12). Mesangial cells provide structural support to the glomerular tuft, produce and maintain mesangial matrix, communicate with other glomerular cells by secreting soluble factors, and may contribute to the glomerular capillary flow via their contractile properties.

Mesangial Cells Provide Structural Support to the Glomerular Tuft

The mesangium forms the central core of the glomerular tuft. The processes which they extend towards the GBM are densely populated by bundles of actin, myosin, and β-actinin microfilaments.[63,152] These processes attach directly or by interposition of microfibrils to the GBM. They also extend underneath glomerular endothelial cells toward the mesangial angles of the GBM, anchoring two opposing mesangial angles together through their microfilament bundles (Figure 22.12b). These microfilament bundles cross the mesangial cells to tether opposing parts of the GBM through α3β1 integrin and the basal cell adhesion molecule (BCAM) glycoprotein, which bind laminin α5 in the GBM.[141] These structures are believed to supply protection from hydraulic pressure by providing inward-directed tension.[152]

Mesangial Cells Produce and Maintain Mesangial Matrix

The *mesangial matrix* fills the remaining spaces between the mesangial cells and the perimesangial glomerular basement membrane (GBM, for review

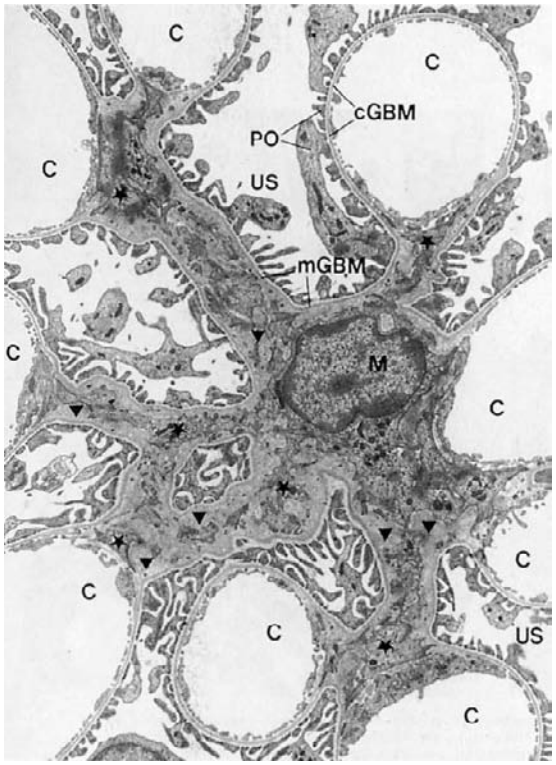

FIGURE 22.11 **Transmission electron micrograph showing all components of the glomerular tuft.** The glomerular tuft is marked by the GBM, which includes the pericapillary GBM (cGBM; between podocytes and the endothelium) and the perimesangial GBM (mGBM; between podocytes and mesangium). Glomerular capillaries (C) are covered by podocytes at the periphery, and connected to the mesangium, proximally. The mesangial cell body (M) possesses several processes (some are marked by *stars*) which extend toward the peripherally located capillaries. In the mesangial area, abundant mesangial matrix (*triangles*) can be seen (US: urinary space; TEM × 5500).

see [152]). This matrix is composed of a diverse array of common matrix proteins including collagens type III, IV, V, and VI; heparan sulfate proteoglycans including biglycan and decorin[252]; and the elastic fiber proteins fibronectin, laminin, entactin, and fibrillin-1, among others.[42,87,172,177,276] Fibronectin is the most abundant of these, and is associated with microfibrils which network to form the basic ultrastructure of the matrix.[42,260] These microfibrils are unbranched and non-collagenous with a diameter of 15 nm, and form a dense three-dimensional network that contributes to the anchoring of mesangial cells to the GBM.[152] It is thought that these microfibrils allow for the transmission of mesangial cell contractile forces to the GBM.

Mesangial phenotypic changes are a hallmark of certain glomerular diseases such as diabetic nephropathy. This condition is characterized by glomerular sclerosis due to an accumulation of mesangial matrix and thickening of the GBM. The sclerotic lesion contains an abundance of type IV collagen normally present in the glomerulus, but also contains types I and III collagen which are usually absent but are produced by injured mesangial cells.[175]

Signaling Molecules Involved in Mesangial Cell Biology

Integrins

In addition to $\alpha3\beta1$ integrin observed in connections between the GBM and mesangial processes, $\alpha1\beta1$, $\alpha2\beta1$, and fibronectin receptors $\alpha5\beta1$ and $\alpha8\beta1$ integrins are expressed in the mesangial cells,[13,142] and are able to activate integrin-linked cell signaling. In the

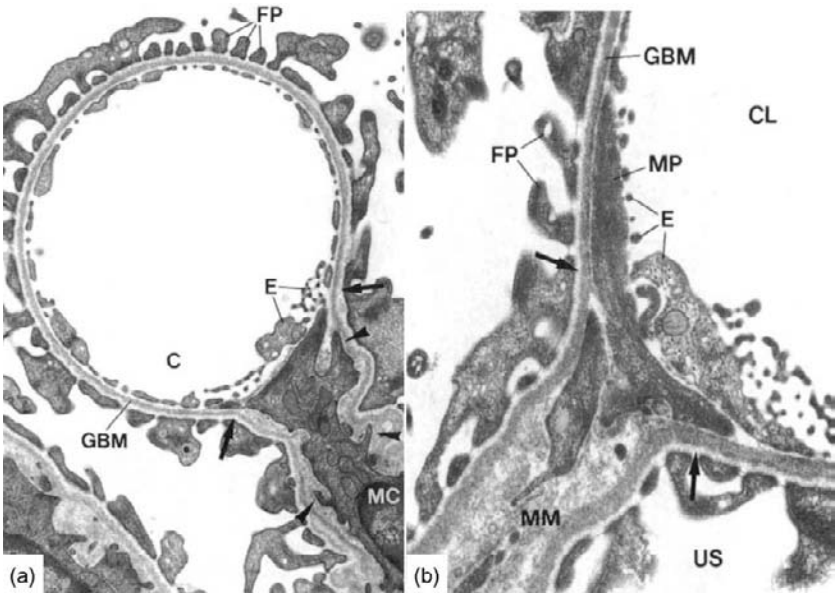

FIGURE 22.12 (a): Transmission electron micrograph showing a mouse glomerular capillary. A mesangial cell (MC) extends its processes to a capillary loop (C). Microprojections (*arrowheads*) from the primary process run toward the glomerular basement membrane (GBM). As shown by arrows, the endothelial cells are directly connected to the mesangium. Podocyte foot processes (FP) and fenestrated endothelium (E) are shown (TEM × 13,500). (b): High magnification of the juxtamesangial part of the capillary loop showing direct contact of mesangium to endothelium. Endothelial cells are attached to the mesangial cell processes (MP) that connect opposing mesangial angles. (arrows) (CL: capillary lumen; US: urinary space; MM: mesangial matrix; FP: foot processes; TEM × 23,000).

absence of α1 integrin, cultured mesangial cells show decreased proliferation, increased matrix production, and altered intracellular signaling. Mice lacking α1 integrin exhibit more severe Adriamycin and diabetes-induced glomerular injury,[34,323] highlighting the importance of matrix-related signaling. On the other hand, removal of α2 integrin in mice leads to amelioration of glomerular damage in an Adriamycin and partial renal ablation model.[18] α8 integrin seems to promote adhesion, but inhibits migration and proliferation of mesangial cells *in vitro*.[13]

Pdgfrb

Pdgfb is secreted from endothelial cells and binds to Pdgfrb expressed in mesangial cells, where it exerts a crucial role in mesangial migration and glomerular tuft formation. Without mesangial cell migration, the looping of glomerular capillaries does not occur. This interaction is discussed further in the endothelial section.

Ephrin B2

As mentioned in the section on the glomerular endothelium, deletion of Ephrin B2 from mesangial cells and pericytes leads to abnormal glomerular tuft formation and reduced numbers of capillary loops.[76] It's receptor, EphB4 is expressed in podocytes, suggesting an interaction between the mesangium and podocytes.

Other Secretary Molecules and Receptors

Mesangial cells produce, and are also influenced by, many growth factors including Tgfb1,[257] connective tissue growth factor (Ctgf),[44,297] insulin like growth factor (Igf),[220,221] fibroblast growth factor (Fgf),[75,221] and hepatocyte growth factor (Hgf).[46,48] Among these factors, Hgf antagonizes the pro-fibrotic actions of Tgfb1, whereas the other factors are upregulated by mesangial cells in disease conditions including diabetes or Thy1.1 nephritis, and facilitate glomerular matrix accumulation.[75,297] Vasoactive factors such as angiotensin II and endothelins promote mesangial proliferation, and this effect may be mediated by transactivation of the Egf receptor.[54,118] However, because of the lack of effective tools for deleting genes specifically from mesangial cells, the precise functions of these factors in normal physiology remain to be determined.

Contractile Ability of Mesangial Cells

Because of the microfibrils and the contractile ability of cultured mesangial cells, it has been assumed that the mesangial cells regulate glomerular filtration by controlling the capillary surface area, but concrete *in vivo* evidence is lacking.[85]

THE GLOMERULAR BASEMENT MEMBRANE

Description

The glomerular basement membrane (GBM) is a specialized extracellular matrix that sits between the podocytes and vascular side of the filtration barrier. During glomerulogenesis, components of the GBM are synthesized by both the glomerular endothelial cells and podocytes, forming a bilayered structure that later fuses.[189] Compared to basement membranes in other tissues the GBM is unusually thick, measuring 240–370 nm in adults.[189,210,274] Ultrastructural analysis of the mature GBM shows a trilaminar structure made up of a lamina densa surrounded by the lamina rara interna and externa, which appear less dense.

Similar to other basement membranes, the GBM is primarily made up of laminin, collagen type IV, nidogen, and heparan sulfate proteoglycans. However, the GBM contains different members of some of these families compared to other basement membranes, including laminin-521, collagen a3a4a5(IV), and agrin.[2] Laminin and collagen type IV appear to be particularly important for function of the GBM, as mutations in these factors are associated with glomerular filtration defects and renal disease.[189] Components of the GBM are continuously "turned over",[1] but it is not yet clear how new components are added and old ones removed.

Given the location of the GBM between the relatively "open pores" of the endothelium and the podocyte foot processes and filtration slits bridged by the slit diaphragms, a major role for the GBM is to restrict the passage of plasma proteins into Bowman's space. From the time of classic electron micrographic studies of the GBM in the 1950s attempting to define the specific characteristics of the GBM that impart its permselective properties, to the current molecular era, it is still hotly debated which component represents the major barrier. Current models suggest that all three layers of the filtration barrier are likely important (including the glycocalyx of the endothelial layer), but relative contributions remain unknown. However, it is clear that mutations in genes encoding specific GBM proteins are sufficient to cause proteinuria and renal failure, underscoring the importance of this layer to the barrier.[189]

Laminin

Laminins are secreted as heterotrimers, which are stabilized by disulfide interchain bonding. Each laminin heterotrimer is composed of α, β, and γ chains that combine with each other in nonrandom combinations to form at least 15 different heterotrimers. The laminins

are named by their composition; for example: α5β2γ1 is named laminin-521 or LM-521.[40,192] The heterotrimer structure appears as a "cross" with one longer and three shorter arms. At the COOH end of all α chains is a laminin globular chain (LG) that extends beyond the long arm. This LG domain interacts with cell surface receptors such as integrins and dystroglycans that are expressed by the podocytes.

Interactions between the laminin heterotrimers themselves are mediated by subdomains found in the shorter arms of the "cross." Laminin also binds to the network of type IV collagen via nidogen, and to agrin, a heparan sulfate proteoglycan of the GBM.[189] The combined network of type IV collagen (see below) and laminin provides mechanical properties to the basement membrane, serving as a scaffold for the placement of other matrix components.

During glomerular formation, laminin trimer compostion changes from LM-111 to LM-511, and finally to LM-521.[150,187,192] In the adult, laminins continue to be produced by both endothelial cells and podocytes, as the protein can be identified in the endoplasmic reticula of both cell types.[273]

A series of reports confirm an important role for laminins in GBM function. A mutation of laminin β2 results in Pierson syndrome in humans that is characterized by ocular and neurological symptoms, and congenital nephrotic syndrome.[204] This observation was confirmed using knockout mice of laminin β2 that develop proteinuria even before the onset of visible ultrastructural changes to the podocytes.[125] Recently, the phenotype of the laminin β2 knockout mouse was rescued by overexpression of laminin β1, suggesting redundancy between laminin β1 and β2.[117] Also, deletion of laminin α5 in mice prevents the transition from LM-111 to the mature LM-521 that leads to breakdown of the GBM and failure of glomerular vascularization.[185] A mouse carrying a hypomorphic mutation of laminin α5 also shows glomerular proteinuria, hematuria, and cystic kidneys, suggesting the gene dosage of the laminin α5 chain is crucial for the maintenance of the GBM.[119]

Type IV Collagen

Collagen IV is another major component of the GBM. Similar to other collagens, collagen IV is a trimeric extracelluluar matrix component made up of α chains that are rich in Gly-X-Y amino acid repeats.[119,154] The type IV collagen family includes six genetically distinct α chains that trimerize with each other in specific combinations to make three types of trimers with each other: $(\alpha1)_2\alpha2$; $\alpha3\alpha4\alpha5$; and $(\alpha5)_2\alpha6$. Each of these trimers is referred to as a protomer. Protomers are secreted into the extracellular matrix, where they self-polymerize and are subsequently cross-linked by specific enzymes.[188]

Similar to laminin, the composition of type IV collagen trimers undergoes a developmental switch in the GBM. Early in glomerulogenesis (S-shaped stage), the GBM is composed of α2/α1 chains, which are replaced at the capillary loop stage by α3α4α5.[3] Although a basement membrane can form in the absence of type IV collagen its structure is compromised, resulting in variable defects in the filtration barrier depending on the specific genetic mutation.[188] In the adult kidney, the type IV collagen α3α4α5 network is produced only by podocytes.[3]

Mutations in any of the α3, α4 or α5 genes are associated with glomerular disease in patients, emphasizing the key role that type IV collagen plays in glomerular barrier function. The defects can be minimal, as observed in patients with thin basement membrane disease (also known as benign familial hematuria). This disease is inherited in an autosomal dominant fashion, and patients present with isolated microscopic hematuria. As suggested by its name, the GBMs show thinning. Thirty to forty per cent of the patients exhibit mutations in COL4A3 or COL4A4. Although originally assumed to be benign, FSGS has been reported in Cypriot families with this disease.[295]

The same mutations in COL4A3 and COL4A4 inherited in a homozygous fashion as an autosomal recessive disease result in a more severe disease known as Alport's syndrome, a hereditary basement membrane disease associated with progressive glomerulopathy that leads to renal failure, and is associated with deafness and ocular abnormalities. The commonest form of Alport syndrome is X-linked, caused by mutations in the α5 chain (Figure 22.13). Goodpasture syndrome, an autoimmune disease characterized by glomerulonephritis and lung hemorrhage, is mediated by antibodies against the type IV collagen α3 chain.[119]

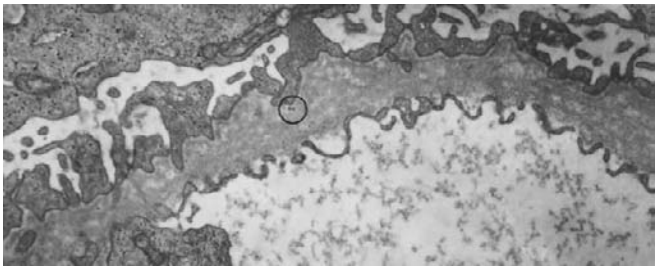

FIGURE 22.13 **Transmission electron micrograph of the GBM in a patient with Alport syndrome.** Thickening, splitting and lamination of the GBM can be seen (TEM × 14,900). *(From Rumpelt, H. J. (1987). Alport's syndrome: Specificity and pathogenesis of glomerular basement membrane alterations. Pediatr. Nephrol. **1**: 422–427, with permission.)*

Intriguingly, recent studies have shown that a mutation of the type IV collagen α1 chain causes hereditary angiopathy with nephropathy, aneurysms, and muscle cramps (HANAC syndrome); the renal manifestations are characterized by hematuria and large bilateral cysts.[107] A rodent model of this mutation leads to defects of the GBM,[89] suggesting a functional role for the α1 chain in the GBM, despite the prominence of a3a4a5 trimers in mature type IV collagen.

Nidogen

Nidogen-1 and -2 (previously known as entactin-1 and entactin-2) are virtually ubiquitous basement membrane glycoproteins. Nidogen-1 binds both laminin and type IV collagen,[77] suggesting that it is involved in forming the GBM. However, it was demonstrated that a single knockout of either nidogen-1 or nidogen-2 in mice results in no GBM phenotype.[199,262] Although deletion of both nidogen genes results in perinatal lethality, suggesting some overlapping roles of the two genes,[11] the glomerular basement membrane still forms apparently normally. The exact role and requirement of nidogen in the GBM is not yet known.

Proteoglycans

Heparan sulfate proteoglycans of the GBM are concentrated in the laminae rarae internae and externae, and provide an electronegative charge to the GBM.[136,277] The major proteoglycans of the GBM are heparan sulfate proteoglycans; most prominent is agrin, but perlecan is also present.[92,205] Although classical studies suggested that the negative charge of the GBM was essential to retard passage of neutral and negatively-charged macromolecules across the barrier, this model has been challenged due to results obtained from genetically modified mice. Podocyte-specific knockout mice for agrin and/or perlecan, either in isolation or together, does not result in proteinuria or overt filtration defects.[88,108] Current thoughts on the glomerular charge barrier are discussed later in the chapter.

PODOCYTES

Podocyte Morphology

Mature podocytes are highly-differentiated, polarized epithelial cells that sit on the glomerular basement membrane in Bowman's space. They function as vascular support cells, wrapping around the underlying glomerular capillaries, providing growth factors necessary for endothelial health and survival. Podocytes are characterized by a highly arborized and unique cytoskeleton. They have a large cell body (Figure 22.14a) that gives rise to a complex network of processes including primary, major processes, which then continue to branch as they extend around the glomerular capillary loops until they form terminal foot processes. The foot processes are the only point of contact between the podocyte and the GBM (Figure 22.15a). The foot processes of neighbouring podocytes interdigitate (Figure 22.14b), and are connected to one another through a specialized intercellular junction known as the slit diaphragm (SD). The SD bridges the porous filtration slits; these structures have been recently visualized at high magnification[79,236] (Figures 22.14b, and 22.15b). In disease, these structures can be dysregulated, causing a disorganization of foot processes and breakdown of the GFB (Figure 22.15c,d).

While the podocyte is terminally differentiated and largely post-mitotic, the podocyte cell body contains a number of organelles that are crucial to maintain its high metabolic activity and secretory function, including a large nucleus, abundant lysosomes, and many mitochondria.[196] In addition to producing factors necessary for maintaining their own specialized architectural cytoskeleton and protecting adjacent endothelial cells, podocytes must synthesize many of the components of the GBM in the mature glomerulus (reviewed in [189]).

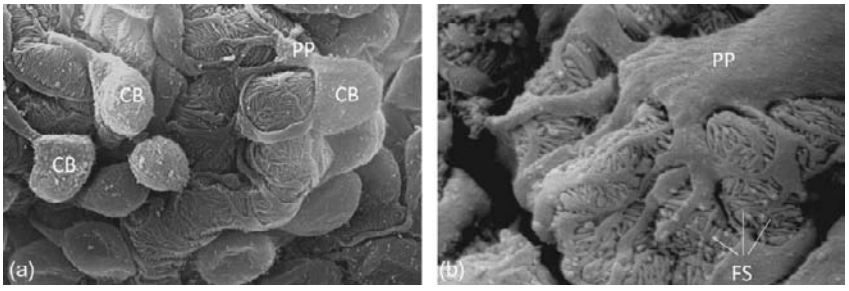

FIGURE 22.14 **Scanning electron micrograph shows podocytes wrapping around glomerular capillary loops.** (a): Mouse podocytes have a large, smooth-surfaced cell body (CB) which branches into primary processes (PP), which continue to branch as they wrap around the capillary loop forming the actin-based foot processes (SEM × 5600). (b): Scanning electron micrograph of rat podocytes. The filtration slits are created between the interdigitating foot processes, the terminal ends of the branching processes (FS) (SEM × 5670). Note the space (*) between the cell body and the basement membrane as the foot processes are the only point of contact between the podocyte and the GBM. (b): High power transmission EM shows podocyte foot processes (FP) attached to the glomerular basement membrane (GBM). Foot processes contain actin bundles (AB), and adjacent foot processes are attached by their slit diaphragms (SDs). (c): Transmission electron micrograph of podocyte foot process effacement in human focal segmental glomerulosclerosis (FSGS). (d): Scheme of podocyte foot process flattening. Left panel shows normal podocyte foot processes, actin cytoskeleton supports its elaborated shape. Once the actin cytoskeleton is disorganized, podocytes are no longer able to keep the foot process assembly, which results in fusion and flattening of foot processes (right panel). *((a)–(c): Courtesy of Dr. Dontscho Kerjaschki, Medical University Vienna, Vienna, Austria; (b): From Ronco, P. (2007). Proteinuria: Is it all in the foot? J. Clin. Invest.* ***117****: 2079–2082, with permission.)*

The structure of the cell body and the primary major processes is determined by microtubules and intermediate filaments (vimentin, desmin, and nestin), while the shape (width and length) of the foot processes is largely determined by actin microfilament bundles. The actin bundles form continuous loops that run longitudinally in the foot processes and end at the sole plates, connecting adjacent foot processes associated with a single, primary, major process (Figure 22.15b). The loops of actin bundles are tethered to the microtubules and intermediate filaments of the major processes.[196] This connection is thought to be mediated by Tau, which is known to form connections between microtubules and microfilaments and is concentrated at these areas.[145] In the foot processes, a complex system links the slit diaphragm proteins, GBM receptors on the basolateral side, and the actin cytoskeleton to regulate the functional morphology of podocytes; this will be discussed at greater length later.

Podocyte Development, Transcription Factors, and Notch

Podocyte precursors first appear in the "S-shaped body" phase of glomerular development as a columnar epithelium attached along their lateral membrane by a cadherin junction containing P-cadherin.[36] This nascent glomerulus is also populated by a thin epithelial layer called the Bowman's capsule, and a capillary loop that begins to enter the glomerular cleft. As glomerular development progresses, the primitive podocytes

extend themselves around the capillary loop by an unknown mechanism and differentiate into mature podocytes. A number of transcription factors have been identified that are expressed in the immature and mature podocytes, including Wt-1, Pod1 (Tcf21), Lmx1b, Kreisler (Maf1), and Foxc2.

Wt-1

The transcription factor Wt-1 is first expressed in the metanephric mesenchyme, which contains progenitors of the tubular and glomerular epithelium. As renal development continues, its expression becomes restricted to the renal vesicle, comma, and the S-shaped body. Later on, its expression is observed in immature and mature podocytes, which persists throughout life.

Wt-1 is a transcription factor with four zinc fingers that can bind both DNA and RNA.[24,25,61] There are four major splice variants of Wt-1 mRNA, which may be responsible for its variety of functions in development and normal physiology.[99] Embryonic loss of Wt-1 in mice leads to complete renal and gonadal agenesis,[149] defects in the epicardium, lack of sub-epicardial mesenchymal cells, and adrenal agenesis,[194] suggesting its important role in multiple organs.

Several mouse models underscore the importance of Wt-1 function during nephrogenesis and in podocytes. Postnatal deletion of the Wt-1 gene results in glomerulosclerosis with loss of podocyte foot processes and molecular markers of differentiation such as nephrin, atrophy of the exocrine pancreas and spleen, severe reduction in bone and fat mass, and failure of erythropoiesis.[30] In Wt-1 knockout mice, restitution of Wt-1 expression using a human derived Wt-1-YAC transgene leads to a rescue of cardiac defects, but incomplete glomerular development.[194] Furthermore, Wt-1 haploinsufficient mice develop adult onset mesangiosclerosis and glomerulonephritis.[96,184]

In humans, Wt-1 mutations are associated with two glomerulopathies: Denys–Drash syndrome (DDS) and Frasier syndrome (FS), which can both present early in life and cause abnormal glomerular development. DDS is caused by heterozygous mutations of the *Wt-1* gene that predominantly affect the zinc finger regions in exons 8 (zinc finger II) and 9 (zinc finger III), and directly interfere with the DNA-binding capacity of Wt-1.[214] The characteristic clinical picture of DDS is a triad of congenital nephrotic syndrome, XY pseudohermaphroditism, and Wilm's tumor.[53,59] The characteristic renal lesion in these patients is diffuse mesangiosclerosis due to increased matrix deposition on the vascular side of the glomerular basement membrane. Expression of the DDS mutation in mice, either in podocytes or systemically, leads to various glomerular lesions similar to those of humans. Wt-1 is expressed in podocytes, which are found on the opposite side of the glomerular basement membrane (GBM) to the mesangium. The glomerular lesion in DDS therefore highlights the importance of interactions that occur between podocytes on one side of the GBM and endothelial cells or mesangial cells on the other side of the GBM. Frasier syndrome (FS) is characterized by focal segmental glomerular sclerosis, male-to-female sex reversal, but no tumors. It results from a dominant mutation that causes an inability to include an alternatively spliced lysine-threonine-serine (KTS) sequence after the third zinc finger[102] of *Wt-1*. Interestingly, mice engineered to exclusively express the variant that is +KTS or −KTS display normal induction of the metanephric mesenchyme by the ureteric bud, but have malformed glomeruli. These findings suggest different roles for the alternatively spliced variants of Wt-1 in glomerular development and maintenance.

While the contribution of Wt-1 to renal development and maintenance is undeniable, its precise role is still being elucidated. Human and animal models seem to indicate it plays a role in regulating the expression of a number of developmental genes. During early renal development the regulatory gene Pax-2 is expressed in the induced metanephric mesenchyme and ureteric bud, but is absent in the mature renal epithelium. In podocytes, the expression of Wt-1 coincides with a downregulation of Pax-2, suggesting a role for Wt-1 in transcriptional repression of this gene.[244] Indeed, in patients with DDS, downregulation of Wt-1 was associated with increased Pax-2 expression[311]; however, it is unclear if this increased Pax-2 expression is pathogenic. Recent advances in high-throughput technology for assessing transcription factor activity have elucidated a number of other Wt-1 regulated genes that are known to play a role in renal development, including Six2, Bmp7, Sall1, and HeyL.[107]

Wt-1 also plays a role in maintaining podocyte homeostasis beyond development. The essential podocyte slit diaphragm protein nephrin has been identified as a transcriptional target of Wt-1, and is downregulated in the glomeruli of mice lacking the Wt-1(−KTS) splice variant.[95,298] Furthermore, Wt-1 modulates the podocyte glycocalyx through transcriptional regulation of Podocalyxin[213] and 6-O-endosulfatases Sulf1 and Sulf2,[259] which play a role in maintaining the charge of the glomerular filtration barrier, podocyte foot process separation, and bioavailability of essential growth factors such as vascular endothelial growth factor-α (Vegfa) and fibroblast growth factor (Fgf)-2. In addition to post-translational regulation of Vegfa bioavailability, Wt-1 can also directly regulate expression of Vegfa, which is essential to the maintainenance of the glomerular vasculature.[103,107] Given this wide range of regulatory functions, it is still unclear what is responsible for the pathology observed in DDS and FS patients, but it

is likely a convergence of a number of these signaling networks.

Lmx1b

Lmx1b encodes a Lim-domain protein that is mutated in Nail–Patella syndrome.[31,60] In mice lacking Lmx1b, podocytes retain their immature cuboidal phenotype, fail to form foot processes or endothelial fenestrations, and have a split glomerular basement membrane.[237] These findings are associated with a concomitant downregulation of Vegfa, Synaptopodin, Nphs2, type III collagen α4 (Col3a4), and type IV collagen α4 (Col4a4). Lmx1b-binding elements in the Nphs2 and Col4a4 promoter regions suggest that this occurs through direct transcriptional regulation.[191,237]

Tcf21

Tcf21 (also known as Pod1/Capsulin/Epicardin) encodes a basic helix-loop-helix transcription factor that is highly-expressed in the developing kidney, lung, intestine, and pancreas at sites of mesenchymal–epithelial interaction.[224] In the developing mouse kidney, it is expressed in the condensing mesenchyme, and knockdown of Tcf21 expression in renal explants causes decreased mesenchymal condensation and ureteric bud branching.[224] Subsequently, *Tcf21* expression is restricted to the primitive podocytes of the S-shaped bodies, and genetic deletion of Tcf21 in mice leads to failure of podocyte terminal differentiation[223] (Figure 22.16). $Tcf21^{-/-}$ knockout mice have a marked reduction in glomerular number, and the remaining glomeruli are developmentally arrested between S-shaped body and capillary loop stages.

Kreisler

Kreisler (Mafb) encodes a basic domain leucine zipper transcription factor that is expressed in podocytes at the capillary loop stage of glomerular development.[245] Mice with a homozygous enu mutation of Kreisler show a similar but milder phenotype to those with a Tcf21 deletion. They are born with glomeruli arrested at the capillary loop stage, and podocytes that adhere to the GBM but fail to form foot processes.[245] Kreisler mutants, however, express Tcf21, suggesting that Tcf21 is either upstream of Kreisler in podocyte development or acts by a different mechanism.

Foxc2

Foxc2 is a winged helix transcription factor that was identified during a screen of enriched genes in mRNA isolated from glomeruli at different stages of development.[284] Foxc2 is first expressed in putative podocytes during the comma shaped body stage of glomerular development, and as such is the earliest known podocyte marker. Glomeruli from $Foxc2^{-/-}$ mice display aberrant podocyte foot process formation, mesangial cell clustering at the base of the glomerular tuft, and swollen endothelial cells lacking fenestrae,[284] similar to $Tcf21^{-/-}$ mutant mice. In these mice, the endothelial and mesangial defects are thought to be secondary to the podocyte defects. Gene array of $Foxc2^{-/-}$ glomeruli identified over 700 differentially regulated genes. Notably, however, there was a strong downregulation of Nphs2, Col4α3, and Col4α4, which are fundamental to slit diaphragm assembly and GBM formation.

Notch

The Notch family includes four well-conserved genes that encode transmembrane receptors involved in cell fate specification and development from invertebrates to mammals. Notch is fundamental in the segmentation of the metanephric mesenchyme into 20 functionally-distinct cell types segregated into different compartments along the nephron.

During normal development, Notch2 is expressed in condensing structures of the metanephric mesenchyme, such as the metanephric vesicles, comma-shaped bodies, and S-shaped bodies, but is eventually restricted to differentiating podocytes in more mature glomeruli.[181] Jag1 is the Notch2 ligand thought to be important for glomerular differentiation. During development, it is expressed in renal vesicles, comma-shaped bodies, and S-shaped bodies.[32] In more mature glomeruli it then localizes to the inner region of the glomerular tuft to endothelial and/or mesangial cells.[181] Mice homozygous for a hypomorphic mutation

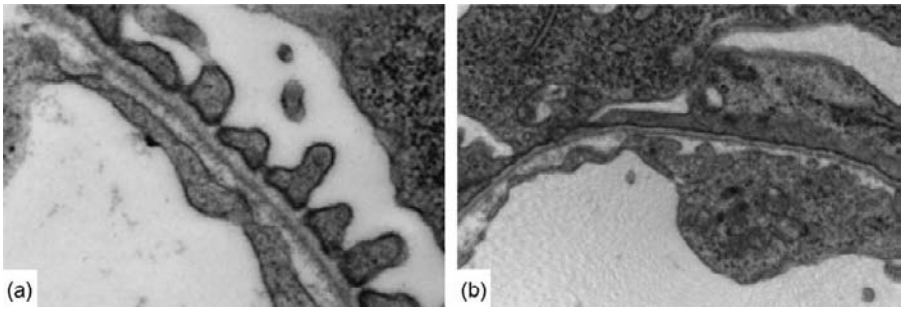

FIGURE 22.16 **Transmission electron micrograph of podocyte foot processes at E18.5.** Normal mouse podocytes show organized foot processes assembly (a), whereas Tcf21 null mouse podocytes demonstrate defects of foot process development (b).

in the *Notch2* gene exhibit hypoplastic kidneys, and an arrest of glomerular development prior to the capillary loop stage.[181] A conditional inactivation of Notch2 from nephron progenitor cells results in a more severe "distal tubule only" phenotype, with a complete failure of glomerulogenesis and proximal tubule formation.[35]

In humans, mutations in Jag1 or Notch2 cause Alagille syndrome, an autosomal dominant disorder characterized by the presence of cholestatic liver disease, cardiac disease, ocular abnormalities, skeletal abnormalities, and characteristic facial features.[164,182,206] A large proportion of Alagille patients also develop renal disease characterized by glomerular lesions, cystic kidneys, and ultimately renal failure.[182] Taken together these studies suggest an important role for Notch signaling in establishing the proximal–distal orientation of the nephron, and segmentation of the proximal structures.

Recent evidence also reports a crucial role for the Notch pathway in the maintenance of mature podocytes. In patients with a variety of proteinuric nephropathies, including diabetic nephropathy and FSGS, activation of the Notch pathway was observed in podocytes.[198,202] Furthermore, upregulation of Notch expression in podocytes of transgenic mice results in severe proteinuria and glomerulosclerosis with dedifferentiation of podocytes.[300]

Podocyte Slit Diaphragm Assembly

The attachments between foot processes are comprised of the "slit diaphragm" (SD). SD assembly is an important part of glomerular development, as it is integral to the correct interdigitation of podocyte foot processes. The SD, which is visible by high power electron microscopy, is a structure that connects adjacent foot processes. It consists of a complex of transmembrane proteins and cytoskeletal adaptor proteins that link adjacent foot processes to the complex actin cytoskeleton of the podocyte and make up a component of the protein barrier (reviewed in [101,115,129,242,289]). While the relative importance of the endothelial layer versus the glomerular basement membrane versus the podocyte SD in maintaining the perm-selectivity of the glomerular filtration barrier is debatable, studies in humans and mice have shown that SD components are essential to this function.

In 1974 Rodewald and Karnovsky described the slit diaphragm as rod-like units connected in the center to a linear bar forming a zipper-like pattern with pores.[76,236] They hypothesized that because of the size of these pores (40 Å × 140 Å), the slit-diaphragm was the principal filtration barrier to plasma proteins in the kidney.

Nephrin

While this first description of the SD shed light on the filtration function of podocytes, the molecular composition of the SD remained poorly-defined. However, the discovery that a mutation in the *NPHS1* gene causes Congenital Nephrotic syndrome of the Finnish variety[143,160] suggested that dysregulation of SD structure can cause glomerular disease. This disease is characterized by massive proteinuria *in utero*, lack of a slit diaphragm, and abnormal foot process formation. The *NPHS1* gene encodes a 180 kDa transmembrane protein of the immunoglobulin superfamily called nephrin that is expressed in the glomerular podocyte, and localizes specifically to the SD.[117,243] These findings defined the importance of nephrin to the formation and maintenance of a normal SD, and led to the postulation of a "zipper-like model" of nephrin assembly in the SD. Accordingly, it is considered that the SD is the principle structure of the glomerular filtaration barrier and nephrin is its main component. Subsequent work, however, has also elucidated an important role for nephrin as a mediator of actin cytoskeletal organization by binding Src homology domain SH2/SH3 containing Nck adaptor proteins.[131] The cytoplasmic tail of nephrin contains three tyrosine-aspartic acid-x-valine (YDxV) residues which, when phosphrylated by Src family kinases, recruit the SH2 Nck adaptor proteins and induce local actin polymerization[15] (Figure 22.17). Following the identification of nephrin, intensive research has led to the discovery of several other transmembrane proteins that participate in the formation of the slit diaphragm (Figure 22.18).

Podocin

NPHS2 is a gene that is mutated in some forms of steroid-resistant nephrotic syndrome[19] that cause early onset proteinuria, and focal and segmental glomerulosclerosis. This gene encodes a protein called podocin, which associates in podocyte lipid rafts with nephrin and another SD component, CD2AP, via its C-terminal domain.[163,261,268] Nephrin is thought to contribute directly to the formation of the SD, while podocin and CD2AP are thought to mediate its connection to the podocyte actin cytoskeleton. Mouse models in which any of these three components are disrupted lead to a congenital nephrotic syndrome.[222,239,269]

Neph Proteins

The C-terminal domain of podocin also interacts with another group of three immunoglobulin superfamily transmembrane proteins called Neph1, 2, and 3 that bear significant homology to nephrin. This family is defined by their well-conserved cytoplasmic tail with a centrally located tyrosine residue required for

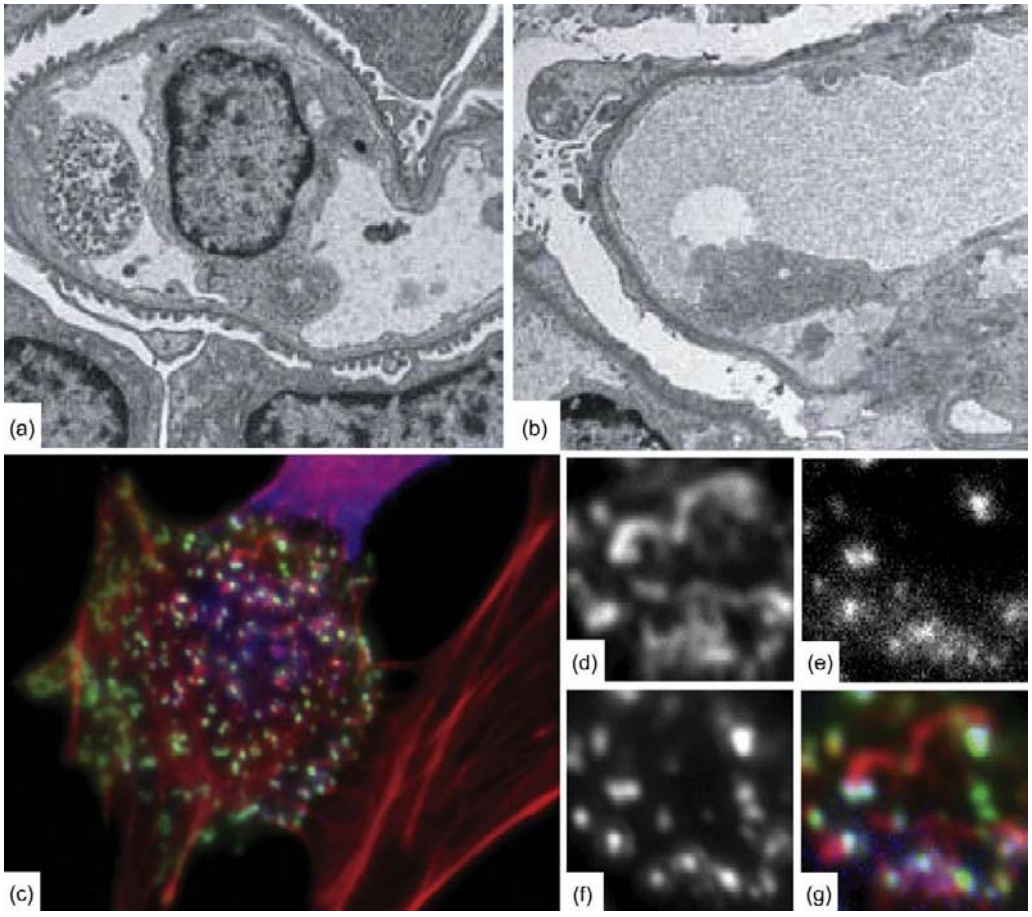

FIGURE 22.17 Transmission electron micrograph of distinct mouse podocyte foot-processes present at 4 days of birth (a), but absent in Nck knockout mice (b). (c)–(g): Cellular immunostaining showing co-localization of Nck2, nephrin at the actin tail. Nck-nephrin interaction is required for nephrin-dependent actin reorganization (Green: nephrin; purple: Nck2; red: palloidin = actin). interacting with podocin.[265] The extracellular domain of Neph1 interacts with nephrin in the SD, and is essential for the regulation of glomerular perm-selectivity.[168] In addition to podocin, the C-terminal (intracellular) domain binds the tight junction protein-1 (Tjp-1/ZO-1), which in turn tethers it to the podocyte actin cytoskeleton.[168] Like nephrin, Neph1 plays a role in intracellular signaling, and is tyrosine phosphorylated at the SD, particularly in certain disease models.[105] Mutations in Neph1 result in proteinuria and perinatal lethality in mice, but the phenotype is less dramatic than that observed in nephrin knockout mice, suggesting that nephrin may be more crucial to maintain the SD.[57] This Nephrin-centric view of the slit diaphragm was called into question by a recent study showing that chickens and developing chicks lack nephrin, but express all three Neph proteins.[296] Ultrastructurally, however, chickens are still able to assemble a SD in the glomerular filtration barrier. These SDs lacking nephrin still express P-cadherin and the large protocadherin Fat-1, suggesting that heterophilic interactions between Neph proteins and these other cadherins may be sufficient to allow SD assembly.[190]

Cadherin and Catenins

In addition to these atypical junctions, the slit diaphragm contains adherens junction proteins P-cadherin, and α, β, γ catenins.[230] P-cadherin is a transmembrane protein, and the extracellular domain is thought to contribute to slit diaphragm formation, while its cytoplasmic tail connects to β or γ catenin. Linkage of this complex to the actin cytoskeleton is believed to occur through an interaction between α catenin and Tjp-1/ZO-1 or α-actinin-4, both of which can directly bind actin.

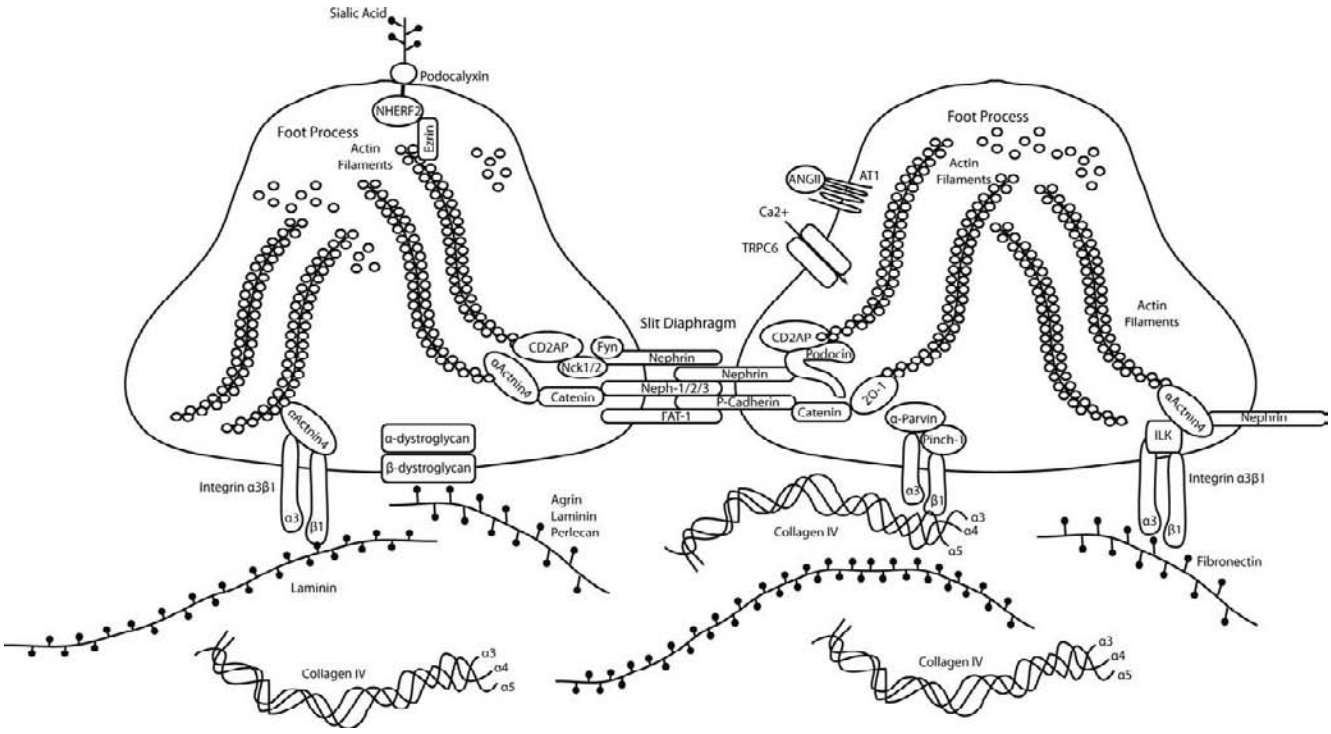

FIGURE 22.18 **Schematic diagram of the podocyte foot process and slit diaphragm with associated molecules.**

The occludens protein Tjp-1/ZO-1 is expressed specifically at the points of insertion of the slit diaphragms in mature glomeruli.[256] Tjp-1/ZO-1 appears early on in podocyte development when the apical junctional complexes between podocytes are composed of typical tight and adherens junctions, and persists as these junctional complexes migrate to the basolateral side and ultimately form the SDs. These findings suggest that tight junction proteins play a role in podocyte SD development and function, independent of their ability to form tight junctions.

α-Actinin-4

In humans, mutations in α-actinin-4 result in an autosomal dominant familial FSGS.[111,137] *In vitro* the mutant form of α-actinin-4 binds F-actin more strongly than wild-type. This is thought to reduce the podocytes' ability to respond dynamically to the hydrostatic pressure required for normal glomerular filtration, and ultimately leads to podocyte injury.[303] In addition, α-actinin-4 is thought to mediate the interaction between the actin cytoskeleton and integrins to regulate podocyte adhesion to the glomerular basement membrane.[50]

FAT1

FAT1 is another member of the cadherin superfamily expressed in the podocyte at the SD, and has 34 tandem cadherin-like extracellular repeats. With its large extracellular domain, FAT1 is a major molecular component of the SD, and is required for normal foot process formation as FAT1 knockout mice lack SDs.[37,123] Because of its localization to the cell−cell contact sites and tips of cellular processes, FAT1 may be involved in the initial steps of cell−cell interaction between podocytes.[313]

Rho GTPases

Given the actin rich nature of the podocyte cytoskeleton, it is not surprising that Rho GTPases − master regulators of cytoskeletal dynamics − are important in podocyte biology. At the leading edge, Rac1 and Cdc42 promote lamellipodia and fillipodia formation, thus enhancing cell motility. In contrast, RhoA promotes a contractile phenotype by inducing formation of actin-myosin stress fibers.[70,227] In this sense, it is believed that a balance between the opposing activities of RhoA and Cdc42/Rac1 regulates podocyte cytoskeletal dynamics. Both overexpression and inhibition of these small Rho GTPases in podocytes causes glomerular injury in mouse models. Podocyte-specific deletion of Cdc42 leads to a congenital nephropathy in transgenic mice by impairing actin polymerization at sites of nephrin clustering[263] (Figure 22.19), while RhoA deletion does not result in proteinuria. By contrast, overexpression of RhoA in podocytes results in an FSGS phenotype in mice.[325]

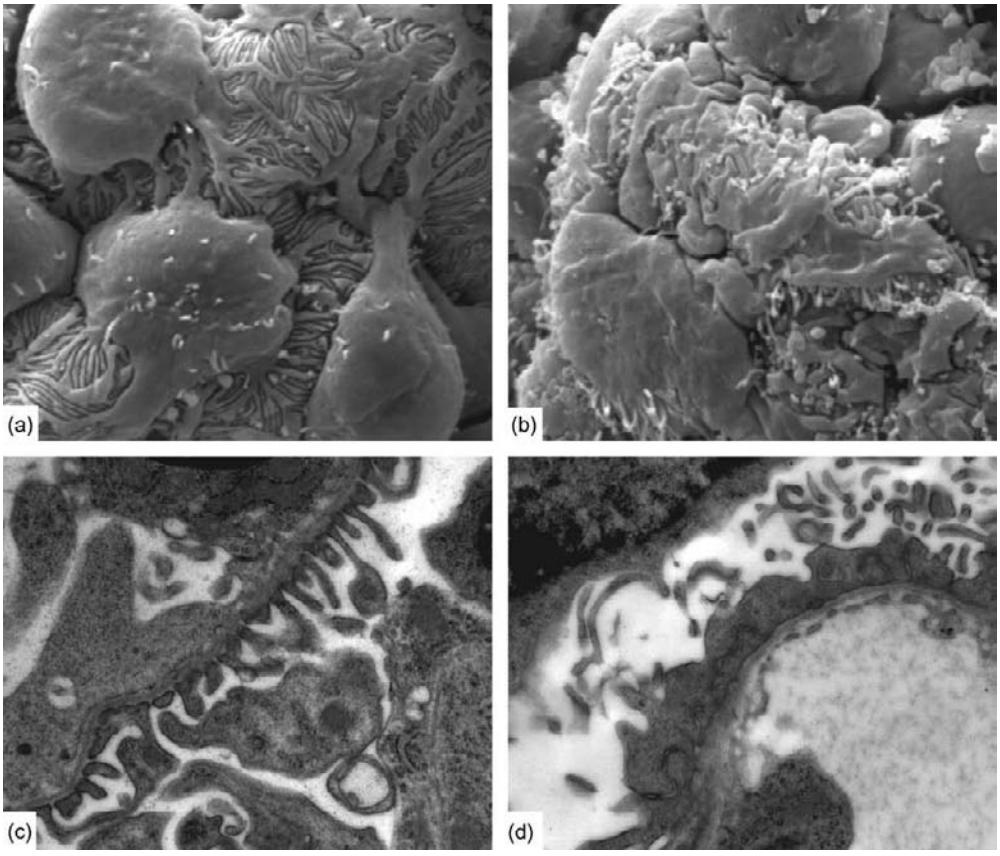

FIGURE 22.19 **Scanning ((a) and (b)) and transmission ((c) and (d)) electron micrograph of murine podocytes.** (a) and (c): Normal appearance of podocytes. (b) and (d): Podocytes lacking Cdc42 show extensive effacement of foot process at postnatal day 5 ((a), (b) × 11, 000; (c), (d) × 27,000). *(From Scott, R. P., et al. (2012) Podocyte-specific loss of Cdc42 leads to congenital nephropathy. J. Am. Soc. Nephrol. **23**(7): 1149–1154 with permission.)*

Recently, dysregulation of Rho-GTPase signaling has also been linked to human glomerular disease. *ARHGAP24* is a RhoA-activated Rac1 GTPase-activating protein (Rac1-GAP); a mutation that impairs Rac1-GAP activity results in FSGS in humans.[4] Two recent reports also showed that mutations in the Inverted Formin 2 (*IFN2*) gene result in autosomal dominant FSGS.[20,82] INF2 interacts with other diaphanous related formins such as Cdc42; disease causing mutations in *INF2* result in decreased CDC42 targeting to the plasma membrane, and impaired actin polymerization and depolymerization in podocytes.[20]

Podocyte–GBM Interaction

The podocyte actin cytoskeleton is not only required for formation of podocyte foot processes and the slit diaphragm, but is also involved in a dynamic and bidirectional cross-talk with the glomerular basement membrane (GBM). In addition to production of GBM components, podocytes also express transmembrane molecules on their basolateral surface which interact with the GBM to regulate intracellular signaling. These include α3β1 integrin, αvβ3 integrin, and α- and β-dystroglycans.

α3β1 Integrin

α3β1 integrin is a heterodimeric cell adhesion receptor with specificity for collagen types I and VI, laminins, fibronectin, and nidogen.[147] α3β1 integrin is highly-expressed on the basolateral surface of mature and developing podocytes, and plays an important role in the development and maintenance of podocyte foot processes.[147,228] Mice with a targeted mutation of the α3 integrin gene lack podocyte foot processes, and have a reduced number of capillary loops.[148] Furthermore, the podocyte-derived basement membrane fails to fuse with the endothelium-derived basement membrane and becomes fragmented and disorganized. A recent paper reported three paediatric patients who have mutations in *ITGA3*, which encodes α3 integrin; they presented with congenital nephrotic syndrome and severe basement membrane abnormalities.[109] Taken together, these findings indicate that

α3β1 integrin is not only a receptor for GBM components, but is also required for its development and maintenance. Similarly, podocyte specific ablation of the β1 integrin gene in mice results in massive proteinuria, abnormal capillary morphogenesis, podocyte foot process effacement, and podocyte apoptosis.[134,219]

αvβ3 Integrin

While α3β1 integrin is the primary integrin expressed in podocytes, more recent work has identified a role for αvβ3 integrin in podocyte homeostasis. αvβ3 integrin is a vitronectin receptor that localizes to podocyte foot processes, and is predominantly associated with non-lipid raft fractions of the cell membrane. Genetic deletion of β3 integrin does not result in an overt renal phenotype, but these mice are protected from LPS-induced proteinuria,[302] suggesting that αvβ3 integrin activation may play a role in the pathogenesis of proteinuria in the setting of glomerular injury. Further work by Wei et al. showed that activation of β3 integrin by soluble urokinase receptor (suPAR) may occur in primary focal segmental glomerular sclerosis; the authors suggest that suPAR may be the circulating factor responsible for recurrence of FSGS after transplant.[301] While these data suggest that αvβ3 integrin activation may injure the podocyte, other work shows that αv integrins act as receptors for osteopontin, which is a protective factor in stretch-induced podocyte injury.[258]

Dystroglycan

Integrins are not the only adhesion proteins to be expressed in podocyte foot processes. The dystrophin−glycoprotein complex (DGC) is a group of proteins that includes α- and β-dystroglycan, utrophin, and dystrophin, and plays a central role in stabilizing skeletal muscle cell membranes by tethering the cytoskeleton to the basement membrane components laminin, perlecan, and agrin. α- and β-dystroglycan have also been localized to podocyte foot processes, and their expression is diminished in several mouse models of glomerular disease and human minimal change disease.[226,229] However, recent studies have shown that genetic deletion of dystroglycan from podocytes in mice does not result in a glomerular phenotype or increased susceptibility to injury, suggesting that integrins may be the primary functional extracellular matrix receptors in the podocyte.[126]

Integrin-Linked Kinase

Given the central, non-redundant role of α3β1 integrin in the development and maintenance of the glomerular filtration barrier, it is of interest to identify its interacting proteins in podocytes. Integrin-linked kinase (ILK) is a serine/threonine kinase with kinase-dependent and -independent functions that interact with the cytoplasmic domains of β1 and β3 integrins.[309] Detailed molecular studies have elucidated a role for ILK in podocyte morphology and health. ILK forms a complex with Pinch1 and α-Parvin to regulate matrix adhesion, foot process formation, and inhibit podocyte apoptosis.[312] ILK also forms a ternary complex with α-actinin-4 and α3β1 integrin, providing a link between the GBM, the actin cytoskeleton, and nephrin in the SD.[47] ILK was first identified as a potential mediator of glomerular disease by two groups showing that it is upregulated in glomeruli of patients with diabetic nephropathy,[97] congenital nephrotic syndrome of the Finnish type, and two proteinuric mouse models.[151] Indeed, activation of ILK *in vivo* using a rodent model of puromycin-associated nephropathy, and *in vitro* by overexpression of a kinase-active ILK transgene, caused activation of β-catenin, podocyte detachment and apoptosis, and transcriptional repression of the SD components P-cadherin and Cd2ap.[285] However, while ILK activation may contribute to podocyte injury in disease, it also plays a fundamentally important role in normal podocyte physiology. Mice with a podocyte-specific deletion of the ILK gene appear normal at birth, but develop focal segmental glomerular sclerosis with GBM thickening, and podocyte foot process effacement characterized by an aberrant distribution of α-actinin-4 and nephrin.[47,62,134] The deletion of ILK causes an upregulation of focal adhesion kinase (FAK),[134] a non-receptor tyrosine kinase which is involved in focal adhesion turnover, cell spreading, and motility. This result is supported by recent work showing that FAK is activated in LPS and anti-GBM models of podocyte injury, and genetic deletion of FAK protects mice from proteinuria.[171]

Tetraspanin CD151

CD151 is a tetraspanin family protein with affinity for α3β1 integrin[314] that is expressed abundantly in the glomerulus.[275] While CD151 is not absolutely required for α3β1 integrin binding to the extracellular matrix, it stabilizes the active conformation of α3β1 integrin and strengthens this interaction.[203] A nonsense mutation in CD151 causes hereditary nephropathy in patients characterized by a splitting and thickening of the GBM, along with pretibial epidermis bullosa, sensorineural deafness, and thalassemia.[138] A podocyte specific knockout mouse model recapitulates this renal phenotype. Mechanistically, CD151 causes a redistribution of α3β1 integrin at the interface between the podocyte and GBM, increasing its binding affinity for laminin-511/521. These findings suggest that CD151 may strengthen the adhesion of podocytes to the GBM, protecting them from higher glomerular pressures.

Negative Charge on the Surface of Podocytes

Although heparan sulfate proteoglycans are key components of the GBM and endothelial cell layer (as discussed above), they are also expressed by podocytes. The two major families of heparan sulfates expressed by the podocyte are Podocalyxin and Syndecans (primarily Syndecan I and Syndecan IV). Podocalyxin and Syndecans are transmembrane proteins involved in regulation of the podocyte actin cytoskeleton through regulation of signaling pathways (see below). While heparan sulfates provide a negative charge to the surface of the podocyte, sialyation of glycoproteins (including podocalyxin) and gangliosides also imparts a negative charge. Both are important components of glomerular barrier function.[33]

Podocalyxin

Podocalyxin is a CD34-related sialomucin protein that is highly-expressed by podocytes and also by mesothelia, vascular endothelial cells, hematopoietic stem cells, and platelets. Mice with a conventional knockout of the podocalyxin gene die within the first 24 hours of life from renal failure. Importantly, podocyte foot processes do not form, and intercellular junctions between adjacent foot processes are abnormal and appear immature. These data provide functional evidence that podocalyxin is a key molecule in podocyte development.[58] Cell biologic experiments have shown that podocalyxin interacts with the Na^+/H^+ exchanger regulatory factor 2 (NHERF2) and phosphorylated ezrin in a complex, connecting it to the actin cytoskeleton of the podocyte foot process. Disruption of this interaction results in nephrotic syndrome.[178,255,283] Podocalyxin appears to regulate foot process architecture through activation of the small Rho-GTPase, RhoA, mediated by its interaction with the NHERF/Ezrin complex.[255]

Sialyation Defects and the Podocyte

Podocytes express a number of sialyated proteins including podocalyxin (as described above), other proteoglycans, and gangliosides. Loss of sialyation of podocalyxin has been identified in various nephrotic syndrome experimental models, such as in rodents injected with sialidase, puromycin aminonucleoside or protaimine sulfate, which neutralizes negative charges.[140,153,264] All of these compounds cause an abrupt onset of proteinuria, together with foot process effacement. Simultaneous infusion of sialic acid prevents the proteinuria and podocyte foot process fusion observed with puromycin injection, presumably due to resialylation of critical glomerular proteins.[195] More recently, loss of sialyation of podocalyxin was observed in a transgenic rat model of minimal change disease due to overexpression of Anptl4.[39]

Although many studies have focused on sialylation defects of podocalyxin, the podocyte expresses other sialylated glycoproteins and gangliosides. Mutations in sialylating enzymes have also been associated with glomerular defects and proteinuria. For example, a point mutation in a gene encoding one of the key enzymes needed for sialic acid biosynthesis (uridine diphospho-N-acetylglucosamine (UDP-GlcNAc) 2-epimerase/N-acetyl-mannosamine (ManNAc) kinase (GNE/MNK)) results in severe perinatal glomerular disease in mice, characterized by splitting of the glomerular basement membrane, hematuria, and proteinuria.[81] The phenotype was partially rescued by dietary supplementation with ManNAc. Intriguingly, ManNAc supplementation also appeared to rescue the Anptl4-induced sialyation defect in rats, suggesting it might represent a new therapy for certain forms of glomerular disease.

Podocytes and Metabolism

Although the majority of podocyte studies to date have focused on its unique cytoskeletal architecture and its role as a structural component of the filtration barrier, recent studies have highlighted the importance of metabolic regulatory pathways in podocyte function.

mTOR

The mechanistic target of rapamycin (mTOR) is an evolutionarily-conserved serine-threonine kinase that interacts with regulatory associated protein of mTOR (Rptor) or Rptor-independent companion of MTOR (Rictor) to form mTORC1 and mTORC2 complexes, respectively. mTORC1 is a key regulator of cellular metabolism, including protein translation, ribosomal biogenesis, cell growth and proliferation, and suppression of autophagy in response to amino acids, growth factors, and elevated cellular ATP levels.[326] mTORC2 is regulated primarily by growth factors to promote actin cytoskeletal rearrangement, cell survival, and cell cycle progression.[124] Rapamycin is an mTOR inhibitor that is used clinically and is thought to specifically inhibit mTORC1 function.[94] In certain cell types including the podocyte, however, chronic inhibition of mTORC1 by rapamycin also results in downregulation of mTORC2 functions.[248,294,321] The importance of mTOR in podocyte biology was first suggested by the clinical observation that rapamycin causes proteinuria.[23,266]

Deletion of *mTOR* itself or R*ptor* in podocytes of mice results in proteinuria.[38,90] Conversely, ectopic mTORC1 activation in mouse podocytes, accomplished by deletion of its suppressor *Tsc1*, results in kidney

disease with many of the features of diabetic nephropathy (DN), including podocyte hypertrophy and loss and proteinuria, and is attributed to endoplasmic reticulum stress.[122] Although mTORC1 appears to be crucial for podocyte function, loss of Rictor from podocytes of mice does not result in a phentoype.[90]

Given its central role in cellular metabolism, mTOR is likely to play multiple roles in podocyte biology. Regulation of autophagy is one pathway regulated by mTOR that appears to be crucial for podocyte function. Autophagy is a lysosomal-dependent cellular survival response to starvation or lack of growth factors in which cells degrade cellular constituents from proteins to entire organelles, such as mitochondria, in order to provide a supply of nutrients under conditions of stress. A basal level of autophagy is, however, necessary to remove damaged organelles, excessive lipids, and long-lived or misfolded proteins. The basal level of autophagy appears to be increased in podocytes,[106,201] and it has been suggested that autophagy may be required to protect this long-living cell from injury. In keeping with this model, deletion of Atg5, a key component of the autophagic pathway, results in late onset of glomerular disease in mice at 20 to 24 months of age due to the accumulation of damaged organelles and ubiquitinated protein complexes.[106] In contrast, deletion of mTOR from podocytes results in disruption of autophagic flux, with subsequent accumulation of autophagolysomes in the podocyte[38] (Figure 22.20). Clinically, dysregulation of autophagy is observed in patients with lysosomal storage diseases such as Fabry's disease, Aspartilglucoseaminuria or Scheie's disease, where the inability to acidify lysosomes causes a failure of lysosomal reformation[317]; these patients are prone to developing proteinuria,[74] providing additional support that the autophagic pathway is clinically relevant.

(2012). Inhibition of MTOR disrupts autophagic flux in podocytes. J. Am. Soc. Nephrol.* ***23****: 412–420, with permission.)* (c): LC3 positive autophagosomes are visualized by green fluorescent protein in cultured human podocyte. (d): Treatment of the podocytes with rapamycin induces massive activation of autophagy.

Insulin Signaling

mTORC1 hyperactivation is associated with a phosphorylation of IRS1/2 and decreased insulin sensitivity, suggesting that podocytes might be a direct cellular target for insulin.[155] A recent study confirmed this hypothesis; genetic deletion of the insulin receptor from podocytes recapitulates many of the features of diabetic nephropathy (DN).[304] *In vitro*, insulin binds the insulin receptor on podocytes and acts through the mitogen-activated protein kinase and phosphor-inositol-3-kinase pathways to induce cytoskeletal rearrangement.[43,304] Taken together, these findings suggest that strategies aimed at increasing insulin sensitivity in podocytes may be a therapeutic option in DN.

Calcium Signaling

TRPC6

The identification of mutations in the Transient Receptor Potential Cation Channel 6 (TRPC6) in patients with autosomal dominant familial FSGS[231,306] emphasizes the key role that calcium signaling plays in glomerular function. Atlhough a variety of different mutations were identified, a number of them result in enhanced calcium signaling within the podocyte. These human genetic findings helped explain results why other factors (such as complement 5b-9,[45] protamine sulfate,[264] bradykinin,[8] and angiotensin (ANG) II[112]), which are associated with increased cytosolic Ca^{2+} concentrations in cultured podocytes, also cause injury. Furthermore, ANG II was shown to signal to the non-selective cation channels TRPC5 and TRPC6 through the AT1 receptor,[287] suggesting that these channels may play a role in podocyte injury beyond the familial FSGS described by Winn et al.[306]

Calcineurin and Synaptopodin

Calcineurin-mediated, NFAT-independent[72] and -dependent[254] signaling pathways in podocytes have also been associated with activating mutations of TRPC6. The link between Ca^{2+}, calcineurin, and synaptopodin provided a clue that TRPC channels may be involved in regulating the actin cytoskeleton, as synaptopodin is known to regulate small Rho GTPases – master regulators of actin cytoskeletal dynamics. The opposing action of RhoGTPases – RhoA which promotes F-actin stabilization, and Cdc42 or Rac1 that promote F-actin turnover – are thought to maintain the podocyte FP dynamic.[91] Podocyte-specific overexpression of TRPC6 led to a Ca^{2+}-mediated increase in RhoA activity,[130] while genetic deletion of TRPC6 led to increased Rac1 activity and podocyte motility.[287] This cumulative body of work outlines an important role for intracellular Ca^{2+} in regulating the actin cytoskeleton of podocytes, and more work in the area will yield interesting insights into the intersection of metabolism, Ca^{2+} signaling, and cytoskeleton in podocytes.

GLOMERULAR PARIETAL EPITHELIUM

Description

The parietal layer of Bowman's capsule consists of a heterogenous population of squamous and cuboidal epithelial cells resting on a basement membrane.[100] The heterogeneity of this population is rendered more complex by the identification of a peripolar cell population, which by morphology[86] and molecular markers[12] resemble visceral podocytes, and extend up to 100 μm along Bowman's capsule. The glomerular parietal epithelial cells (PECs) are rich in actin microfilament bundles which are particularly prominent in the cells surrounding the vascular pole.[64] In this cell population, the actin bundles are located in cytoplasmic grooves that run circularly around the vascular stalk.[64]

As the visceral and parietal layers of the glomerulus are continuous, so are the basement membranes. The transition region occurs around the vascular stalk, and is connected to the smooth muscle cells of the afferent and efferent arterioles and the extraglomerular mesangial cells. Despite this continuity, however, the parietal basement membrane layer is considerably different. Ultrastructurally, the parietal basement membrane is multilayered, with translucent laminae on the extracellular matrix.[180] Further immunohistochemical studies have identified type I, III, IV, and V collagens, heparin sulfate proteoglycans, laminin, enactin, fibronectin, and nidogen.[180] Of these, however, only type IV and V collagen[238] and heparin sulfated proteoglycans[277] have been confirmed by electron microscopy. Compared to the tubular and glomerular basement membrane, the parietal basement membrane is particularly enriched in collagen type IV as opposed to laminin.[238]

Podocyte Progenitors

It has been long assumed that because of podocytes' limited replicative ability, podocyte loss is a largely irreversible event, ultimately leading to end-stage kidney disease. However, under physiologic conditions and in the event of reversible glomerular disease in humans and animals, podocytes are reportedly shed into the urine at a rate that is not compatible with recovery.[78,176,293,316] This would suggest that there is another mechanism allowing for the replenishment of podocytes. Indeed, seminal experiments involving

irreversible triple labeling of parietal epithelial cells in the Bowman's capsule of mice show the existence of a population of cells near the glomerular vascular stalk that can migrate into the glomerulus and differentiate into podocytes.[6]

Parietal Epithelial Cell-Fate Specification and Wnt Signaling

Given the presence of podocyte progenitors in the parietal epithelium and the podocyte-like cells that seem to populate the transition zone between visceral and parietal epithelium, it is important to understand the developmental cues that push their common progenitors in the S-shaped body stage of glomerular development towards either phenotype. To elucidate this, a conditional deletion of *β-catenin* from the renal epithelium and developing collecting ducts showed that in the absence of β-catenin/Wnt signaling, well-differentiated podocytes replace the parietal epithelium of Bowman's capsule.[93] These "parietal podocytes" were not a result of podocytes migrating from the glomerular tuft, but rather were derived from parietal precursors in the S-shaped body phase by direct lineage switch.

PECs in Glomerular Injury

Glomerulosclerosis

While PECs can promote recovery from physiologic podocyte loss or milder forms of injury, they can also contribute to sclerotic lesions in certain mouse models of glomerulosclerosis.[270] Lineage tracing of podocytes in a mouse model of podocyte depletion showed that PECs, but not podocytes, avidly proliferated and migrated into the visceral side, developing a lesion that is similar to idiopathic FSGS.[10]

Crescent Formation

A role for PECs has also been demonstrated in crescentic formation in inflammatory models of murine glomerular injury. Unlike in the sclerotic lesions, anti-GBM glomerular nephritis induced the proliferation of both podocytes and PECs.[193] In this model, podocytes undergo a profound phenotypic change, losing all their typical markers, and form a bridge between the tuft and Bowman's capsule.[156,193] This bridging event then induces the proliferation of PECs, and both cell types can be found in the cellular crescents that are the hallmark of severe inflammatory glomerular injury.[270]

Glomerular Permeability

In the setting of inflammatory injury, the tight junctions between PECs are also disturbed and become permeable to texas-red labeled dextran and ovalbumin.[207] These findings suggest that, along with their basement membrane, PECs also form a second barrier to protein, and the perturbation of this cell layer may be responsible for the periglomerular inflammation typical of anti-GBM glomerulonephritis.

THE GLOMERULAR FILTRATION BARRIER

As discussed above, the glomerular filtration barrier has multiple components that contribute to its size and charge perm-selectivity.[104] It begins at the glomerular capillary loop with its fenestrated endothelium, endothelial surface layer, and glycocalyx, then progresses to the glomerular basement membrane, and finally to the podocyte foot processes with their filtration slits bridged by the slit diaphragms.

Size Barrier

Many classical experiments using dextrans,[29] ficolls,[16] and proteins[170] have incontrovertibly established the existence of a size barrier to permeability. Some reports support the idea that the GBM is the principle filtration barrier. Infusion of dextrans with different molecular weights in rats shows that the particles can reach the subendothelial part of the GBM, but cannot go further.[26] Knockout mice for laminin β2, a major component of the GBM, develop massive proteinuria, even before the onset of visible ultrastructural changes to the podocytes.[125] Mutations in this gene cause Pierson syndrome in patients, an autosomal recessive condition characterized by nephrotic syndrome and ocular abnormalities.[322] Mutations in the gene encoding type IV collagen α5 chain (*COL4A5*) cause X-linked Alport syndrome, characterized by hereditary nephrotic syndrome, hearing loss, and lens defects. Furthermore, homozygous mutations in *COL4A3* or *COL4A4* also affect the collagen network of the GBM structure, and result in an autosomal recessive form of Alport syndrome.[139]

On the other hand, the sieve-like structure of the slit diaphragm[290] also seems to be of paramount importance to the size-selective glomerular filtration barrier. Evidence from human mutations and genetic mouse models which affect slit diaphragm components (discussed above), leads to massive proteinuria, providing evidence that the slit membrane plays a major role in size selectivity. Therefore, current literature supports a role for both the GBM and the podocyte slit diaphragm in size perm-selectivity.

TABLE 22.1 Genetic Mutations that Result in Glomerular Disease (Humans)

Gene	Protein	Disease	Inheritance	Clinical Features	Reference
NPHS1	Nephrin	Congenital nephrotic syndrome of the Finnish type	AR	Massive proteinuria *in utero* and treatment resistant nephrotic syndrome	143
NPHS2	Podocin	Steroid-resistant nephrotic syndrome	AR	Variable onset nephropathy that is steroid resistant	19
CD2AP	CD2AP	Sporadic FSGS	n/a	FSGS	144
ACTN4	α-Actinin-4	FSGS	AD	Progressive proteinuria starting in adolescence with adult onset FSGS (variable penetrance)	137
COQ2	Coenzyme Q10 biosynthesis mono-oxigenase 2	Steroid-resistant nephrotic syndrome	AR	Steroid resistant nephrotic syndrome,epileptic encephalopathy	56
COQ6	Coenzyme Q10 biosynthesis mono-oxigenase 6	Steroid-resistant nephrotic syndrome	AR	Nephrotic syndrome with sensorineural deafness	110
PLCE1	PLCε1	Inherited nephrotic syndrome	AR	Nephrosis and diffuse mesangial sclerosis leading to renal failure	113
LAMB2	Laminin β2	Pierson's syndrome	AR	Congenital nephrosis, mesangial sclerosis, and microcoria	322
ITGA3	Integrin α3	Congenital nephrotic syndrome	AR	Congenital nephrotic syndrome, interstitial lung disease, and skin fragility	109
TRPC6	TRPC6	FSGS	AD	High grade proteinuria with adult onset, and progression to renal failure	306
MYH9	MYH9	Epstein syndrome Fechtner's syndrome	AD	Proteinuria, microhematuria, thrombocytopenia, and sensorineural deafness	9
LMX1B	LMX1B	Nail–Patella syndrome	AD	Nephrotic syndrome with nail and skeletal abnormalities in children	60
WT1	WT1	Denis–Drash syndrome (DDS) Frasier syndrome (FS)	AD	Pseudohermaphroditism, diffuse mesangial sclerosis and renal failure with varying onset depending on the mutation	214
SYNPO	Synaptopodin	Sporadic FSGS	n/a	FSGS risk in Chinese patients	49
MYOE1	Myosin 1E	Childhood FSGS	n/a	Childhood onset FSGS	183
APOL1	Apolipoprotein L-1	Sporadic FSGS	n/a	Risk of FSGS in African-American patients	83
GPC5	Glypican 5	Acquired nephrotic syndrome	n/a	Increased risk of nephrotic syndrome	208
INF2	Formin	Charcot–Marie Tooth	AD	Adolescent onset proteinuria with progression to FSGS and renal failure	20,82
PTPRO/ GLEPP1	Protein-tyrosine phosphatase receptor type O [PTPRO or GLEPP1]	FSGS	AR	Childhood nephrotic syndrome with FSGS and progression to renal failure	211
COL4A1	Collagen IV α1	Alport's syndrome	X-linked	Nephrotic syndrome with hematuria and sensorineural hearing loss (α1,3,4,5)	41,169,186,218,233
COL4A3	Collagen IV α3		AR		
COL4A4	Collagen IV α4		AR		
COL4A5	Collagen IV α5			Intracerebral hemorrhage and strokes (α1)	
ARHGAP24	Arhgap24	FSGS	AD	Early onset FSGS	4

AR: autosomal recessive; AD: autosomal dominant.

Charge Barrier

The presence of a charge barrier was demonstrated by sequential classical analyses that show retardation of anionic macromolecules from passing through the glomerular filtration barrier as compared to neutral molecules with a similar size.[21,22,28]

GBM as a Charge Barrier

Electron microscopy with perfusion of cationic lysozyme demonstrated the presence of anionic sites in all three layers of the GBM.[27] Studies using ferritins with different isometric points showed that cationic ferritin could distribute widely into the GBM, whereas filtration of its neutral counterpart was restricted at the level of the endothelium and subendothelial layer of the GBM.[232] Treatment of rats with heparinase reduced the restriction of neutral ferritin and allowed the ferritin particles[135] and bovine albumin[240] into the GBM. These results were considered to be conclusive evidence that the negative charges of heparan sulfate proteoglycans in the GBM play a major role in maintaining the charge barrier. Recently, however, podocyte-specific genetic deletion of agrin, both agrin and the heparan sulfated side chains of perlecan, and a systemic deletion of COLXVIII[88,108,291] were reported. Although they are the main components of heparan sulfate proteoglycans in the GBM, none of the mutant mice developed significant proteinuria, as discussed above in the section on GBM. Moreover, a study using isolated GBM showed the sieving coefficients of negatively-charged ficoll sulfate were not different from those of neutral ficoll at physiological ionic strength.[17] Given these recent results, it is unlikely that the GBM is the main charge selective barrier in the glomerulus.

Endothelial Surface Layer as a Charge Barrier

Several experiments have been performed to reduce the endothelial charge barrier by enzymatic digestion of glycosaminoglycans (GAGs). GAGs are major contributors to the GBM negative charge, but they are also expressed on the endothelial surface layer. Perfusion of mice with heparanase, chondroitinase, and hyaluronidase reduces the charge density and thickness of the endothelial surface layer and increases the fractional clearance of albumin.[128,129] In these studies the authors assume that it is most unlikely that the enzymes affect the GBM or podocytes, because they are large molecules and are therefore restricted largely to the vascular lumen. Indeed, the ultrastructure of the endothelium, GBM, and podocytes were not affected by this enzymatic digestion. Since the GBM is no longer considered as the principal charge barrier, these data support the notion of an endothelial charge barrier.

Function of the Juxtaglomerular Apparatus: Control of Glomerular Hemodynamics and Renin Secretion

Jürgen B. Schnermann[1] *and Hayo Castrop*[2]

[1]National Institute of Diabetes, and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD, USA
[2]Institute of Physiology, University of Regensburg, Germany

CELLULAR ELEMENTS OF THE JUXTAGLOMERULAR APPARATUS (JGA)

More than a century ago, Golgi observed that "the ascending limb of the loop of Henle returns with invariable constancy to its capsule of origin".[1] At this point of contact at the glomerular hilum, the afferent and efferent arterioles together with the adherent distal tubule form a wedge-shaped compartment which contains the three defining cell types of the juxtaglomerular apparatus (JGA) (Figure 23.1). The *macula densa* (MD) cells in the wall of the tubule abut on a cushion of closely packed interstitial cells called *Goormaghtigh* or lacis cells. These cells are indistinguishable in their fine structure from mesangial cells[2] and are also referred to as extraglomerular mesangial (EGM) cells. The third specialized cell type of the JGA is the *juxtaglomerular granular* (JG) cell, a modified smooth muscle cell in the media of the arteriolar wall.

The anatomical relationships in the vicinity of the JGA have been extensively studied, since they may reveal pathways for functional connections. The most extensive and regular contact of the MD cells is with the underlying extraglomerular mesangium.[3] Regions of adherence between the afferent arteriole and the thick ascending limb outside the MD, and between afferent arterioles and the distal and connecting tubule, have also been observed.[4–7] Less extensive and consistent contacts exist between the MD and efferent arterioles, although the efferent arteriole can be adjacent to the distal tubule and to the thick ascending limb, either immediately before or immediately after the MD.[2,8]

Macula Densa Cells

Morphology

The MD cells form an elliptical plaque of epithelial cells located at the distal end of the thick ascending limb, approximately 100 to 200 μm upstream from the transition to the distal convoluted tubule.[2,9] An MD plaque has been reported to consist of 14 cells in rat and about 25 cells in rabbit.[10,11] Cellular plasticity is suggested by the finding that this number increased by about 30% following chronic angiotensin II receptor blockade, probably by transdifferentiation of adjacent TAL cells.[11] MD cells are morphologically characterized by a high nucleus-to-cytoplasm ratio, absence of basal infoldings, and numerous mitochondria that are typically not in contact with the basal membrane.[2,12] The basement membrane is thinner than that found in other areas of the tubule, and shows discontinuities in scanning electron micrographs.[13] The difference in basement membrane appearance is paralleled by a macromolecular composition that differs from that of adjacent TAL cells.[14]

NaCl and Water Movement

Although morphologically distinct, MD cells and neighboring thick ascending limb (TAL) cells share similar NaCl transport mechanisms (Figure 23.2). As in TAL cells, NaCl uptake is mostly through the apical Na,K,2Cl co-transporter (NKCC2/BSC1). Conventional electrophysiology and patch-clamp evidence has established its presence functionally.[15–17] Presence of the NKCC2 co-transporter has also been shown at mRNA

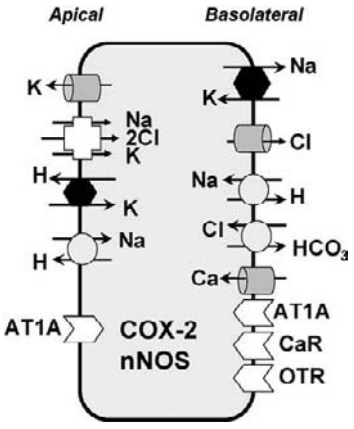

FIGURE 23.2 **Representation of transport proteins and receptors in apical and basolateral membranes of macula densa cells.** Experimental evidence comes from work in both rats and rabbits.

and protein expression levels.[18–20] Of the three full length isoforms of the co-transporter, both the A and the B types are expressed in the MD.[20–23] In contrast to TAL cells, in which NKCC2 phosphorylation is strongly enhanced by vasopressin, MD cells have a constitutively high presence of phospho-NKCC2 even in the complete absence of vasopressin.[24] From the rates of MD cell acidification by luminal ammonium it has been concluded that apical NKCC2-mediated flux rates are not markedly different from those in TAL cells.[25] Apical membranes of MD cells are rich in low conductance K channels of the ROMK type that are required for K recycling.[16,17,26–28] Na/H exchange through NHE2 provides a second pathway for a smaller fraction of Na uptake by MD cells.[29–32] In the rabbit, the apical membrane may also be a site of active Na extrusion, since the luminal presence of ouabain has been found to elevate intracellular Na concentration in both MD and TAL cells; in addition, luminal ouabain prevented the recovery of intracellular Na from the elevated levels resulting from increased luminal NaCl.[33] Apical Na efflux in MD cells may be mediated by a luminal H,K-ATPase, as colonic H,K-ATPase has been shown previously to mediate active Na efflux.[34] Its presence in MD cells is supported by immunocytochemical and functional evidence.[33,35]

Na,K-ATPase abundance and activity in the basolateral membrane of MD cells in rabbit kidneys appears to be low compared to neighboring TAL cells, a finding that is probably mainly due to the absence of basolateral membrane infoldings.[33,36,37] In the rat, basolateral membranes of MD cells identified by nNOS counterstaining clearly express α1 Na,K-ATPase, together with β1- and γ-subunits.[38–43] Cl exit across the basolateral membrane occurs through abundant Cl channels.[17,44] Immunocytochemical evidence indicates the presence of the AE2 anion exchanger in basolateral membranes of MD cells in both the rat and the mouse, and Cl/HCO_3 exchange activity has been observed in isolated rabbit JGA preparations.[45,46] Together with the apical Na/H exchanger, basolateral AE2 may play a role in the absorption of HCO_3 or it may act as a pHi-controlling housekeeping gene.

The effect of changes in luminal fluid composition on the volume of macula densa cells has remained a controversial issue. At constant luminal osmolarity of around 300 mOsm, changes in luminal NaCl concentration caused parallel changes in the volume of MD cells.[47–49] Changes in volume were to some extent transient, indicating some ability of MD cells for volume regulation.[49] Both increases and decreases in MD cell volume have been observed with concomitant increments in Na (25 to 135 mM) and osmolarity (210 to 300 mOsm).[10,47] When NaCl concentration was kept constant, MD cells behaved like osmometers, swelling with a reduction and shrinking with an increase in osmolarity.[49] Transcellular osmotic water permeability of MD cells, assessed from the initial cell volume change in response to an osmotic step change, was estimated to be similar to that of cortical collecting tubules in the absence of ADH.[50,51] The main restriction to water movement resides in the apical membrane.[50] Transmembrane channels for water movement have not been identified; apical membranes of MD cells lack aquaporin 1,[52] and the presence of other aquaporins has not been established. Vasopressin receptors of both the V1a and V2 varieties have been found in MD cells, but there is no evidence that MD water permeability is regulated.[24,53]

Other Cellular Characteristics

Nitric oxide synthase type I (NOS I or nNOS), a constitutive and Ca-dependent NOS isoform, is highly and

selectively expressed in MD cells, and has become a useful marker of this cell type.[54,55] Alternative splicing leads to the generation of several nNOS variants with NO synthase activity.[56] The presence of three of these variants, nNOSα, β, and γ in MD cells and their regulation by salt intake has recently been demonstrated.[57] Catalysis of the conversion of L-arginine to NO and L-citrulline by NOS requires the participation of a number of co-factors. One of these co-factors is NADPH, and it is possible that the relatively high activity of glucose-6-phosphate dehydrogenase (G6PDH) in MD cells is related to the NADPH requirement of NOS.[58] A functional connection between nNOS and G6PDH is suggested by the parallel upregulation of the expression of both enzymes during NaCl restriction.[58–60] Alternatively, the high pentose shunt activity suggested by the abundance of G6PDH may serve to provide ribose-5-phosphate for nucleic acid synthesis. Avid uptake of labeled uridine has been shown to occur in MD cells, a process inhibited by actinomycin D, and therefore indicative of incorporation of the pyrimidine precursor into the RNA pool.[61]

Cyclooxygenase-2 (COX-2), typically induced by LPS and cytokines in the inflammatory process, is constitutively expressed both in the renal medulla and to a lesser extent in the cortex.[62,63] Cortical expression of COX-2 in the mature rat and rabbit kidney is restricted to a subgroup of MD and perimacular cells of the TAL.[62,64–66] MD expression of COX-2 has also been observed in humans older than 60 years, and in patients with Bartter syndrome.[67,68] Condensation of COX-2 expression is the remnant of a more intense expression in early postnatal kidneys, where the enzyme can be found in a more contiguous pattern in TAL cells proximal and distal of the MD. At this early stage, COX-2 appears to be specifically excluded from MD cells.[69] Conversion of PGH_2 into the bioactive PGE_2 is catalyzed by prostaglandin E2 synthases, of which both a microsomal and cytosolic isoform have been described.[70] Immunocytochemical evidence has demonstrated the presence of a membrane-associated PGE_2 synthase in MD cells of both rats and rabbits.[71,72] Co-localization of COX-2 with phospholipase A2 has been described in the MD at the level of single cells.[66] Table 23.1 lists a number of other differences in the expression pattern of MD compared to surrounding TAL cells where the function has remained unclear.

TABLE 23.1 List of Proteins with an Expression Pattern that Differs between Macula Densa and Surrounding Tubular Cells

Macula Densa	Comments	Reference
Tamm-Horsfall protein	Neg, ideal negative selection marker	596
Epidermal growth factor	Neg, present in TAL and DCT	597
Hepcidin	Neg, present in TAL, apical	598
PKD2	Neg, present in TAL, mostly basolateral	599
TRPV4	Neg, present in TAL and DCT	600
Oxytocin receptors	Pos, not in TAL, mostly basolateral	601
Angiotensin II receptors	Pos, apical and basolateral	602
Benzodiazepine receptors	Pos, peripheral type receptors	603
Ca-sensing receptor	Pos, basolateral	604
PTHrP	Pos, microvessels, PCT and DCT	605
Stanniocalcin	Pos, also in TAL, DCT, and CD	606
Integrin-β6	Pos, fibronectin receptor	607
P2Y receptors	Pos, basolateral	608
WNK4	Pos also in TAL and DCT	609
P38 MAP Kinase	Pos more than other tubular segments	610
SGLT1	Pos also in cTAL	611
IQGAP1	Pos apical, also in DCT, less inTAL	612

Extraglomerular Mesangial (EGM) Cells

Morphology

The EGM cells (Goormaghtigh or lacis cells are synonyms) are the cells of the JGA which have the most intimate and regular contact with the MD.[3] MD cells and EGM cells are separated by an interstitial cleft of variable width that does not appear to be bridged by gap junctional connections. In three-dimensional reconstructions EGM cells are elongated cells with long cytoplasmic processes, which in general run parallel to the base of the MD cells.[73] Commensurate with extensive gap junctional coupling of EGM cells with each other as well as with mesangial cells and granular cells,[74,75] connexins 40, 37, and perhaps 43 or 45 are expressed to various degrees in extra- and intraglomerular mesangium.[76,77] The presence of myofilaments in EM cells suggests that EGM cells, like mesangial cells, have contractile potential.[78]

The extraglomerular mesangial cell field is free of capillaries, lymph terminals or nerve fibers. The absence of blood capillaries may cause a retardation of fluid entry and fluid removal from this compartment. In fact, the interstitial volume density of the EGM cell field increased from 17% during volume depletion to 29% during volume expansion, while no changes were

noted in the peritubular interstitium.[79] Nevertheless, recent studies of the flow dynamics across the JGA interstitium using lucifer yellow as a fluorescent marker indicate rapid exchange between afferent arterioles and tubular lumen, presumably mediated by bulk fluid flow.[80]

Biochemical and Functional Aspects

Localization studies using histochemical, autoradiographic or immunological methods usually do not distinguish between intra- and extraglomerular mesangial expression patterns. Nevertheless, in some cases it seems justified to assume parallel expression in both cell types. For example, autoradiographic localization of angiotensin II and atrial natriuretic factor binding suggests the presence of receptors on both intra- and extraglomerular mesangial cells.[81,82] Relative predominance of AT1 receptor mRNA in EGM cells has been observed by *in situ* hybridization.[83] While EGM cells normally do not synthesize renin, they can be recruited to form renin with long-standing stimulation such as chronic diuretic abuse.[7,84]

Differential expression patterns in intra- and extraglomerular mesangium are relatively discrete. EGM cells do not stain with antibodies against Thy-1, while the glomerular mesangium does.[85] Conversely, decay accelerating factor (DAF), a glycoprotein that limits complement activation on cell surfaces, is restricted to the EGM cells, at least in the human kidney.[86] HSP 25 expression has also been reported in extraglomerular, but not intraglomerular, mesangium.[87] Of unknown significance is the observation that two Na,K-ATPase-associated proteins, the FXYD protein phospholemman (FXYD1) and the β2-subunit, are expressed in the extraglomerular mesangium, while being excluded from both MD cells and intraglomerular mesangial cells.[43] Conventional mesangial cell cultures have been used as a model to study JGA-specific issues such as NO and PGE_2 production, but whether or not this approach permits inferences about the JGA signaling mechanisms *in vivo* has remained unclear.[88–90]

Granular Cells

Morphology

The granular cells in the arteriolar walls are the main renin-producing cells of the kidney. With a rough endoplasmic reticulum, a well-developed Golgi apparatus, and numerous cytoplasmic granules, they have the fine structure of protein-secreting cells.[2,78] The renin-containing granules are membrane-bound. Some granules, believed to be the more newly formed, have a crystalline lattice appearance and may mainly contain pro-renin; others, with an amorphous electron-dense content, are believed to represent the mature form.[7,91] Myofibrils and smooth muscle myosin are sparse, and may be even absent in granular cells at the vascular pole.[92] In the mature rat kidney under control conditions, granular cells are clustered at the vascular pole over a length of about 30 μm or about 20% of the afferent arteriole, but single ring-like renin-positive regions in more proximal locations are sometimes seen.[93] In the developing kidney, as well as during stimulation of renin synthesis, for example with converting enzyme blockade, renin-positive cells can be found all along the afferent arteriole and also in larger vessels.[94,95]

Coexistence of renin and angiotensin II in granules of rat and human epithelioid cells has been shown by light and electron microscopy.[96,97] Granular angiotensin II appears to increase in parallel to renin following adrenalectomy and renal artery stenosis.[97,98] Granular angiotensin II may reflect uptake through either nonspecific endocytosis, receptor internalization or intracellular *de novo* generation.[99,100] Not unexpectedly, granular cells contain AT1 receptor mRNA, with rats expressing both AT1A and AT1B receptor mRNA and mice expressing only AT1A receptor mRNA.[101,102] Granular cells express the mRNA for both D1-like and D2-like dopamine receptors mediating stimulation and inhibition of renin secretion.[103,104] The gap junctional connexins 40 and 37 have been shown to co-localize with renin, indicating functional connections among granular cells.[105–107] Other proteins found in JG cells include cyclic guanylate kinase II,[108] the ubiquitous basolateral form of the Na,2Cl,K co-transporter NKCC1/BSC2,[109] and GLUT4.[110]

Functional Aspects

Renin release has been found to be episodic or quantal, an observation most consistent with granule exocytosis.[111] Nevertheless, EM images rarely document the classic omega configuration with an open pore to the cell exterior,[7] and no evidence in support of the presence of vesicle or target membrane SNARE proteins in JG cells has been published. On the other hand, isoproterenol and cAMP caused an increase in membrane capacitance in isolated JG cells, an observation usually interpreted to be the result of an exocytotic membrane fusion event.[112] An attempt to observe exocytosis has been made in dissected glomerulus/vessel preparations using optical labeling of renin granules with quinacrine and LysoTracker-Red, fluorophores that are taken up into acidic organelles. When stimulated by isoproterenol or a low arteriolar pressure, labeled granules disappeared at a rate of about 5–10 granules per minute.[113] In renin-releasing As4.1 cells, the extinction of individual granules was followed by the appearance of an extracellular quinacrine cloud, presumably representing the released granule contents.[113]

Studies of the membrane characteristics of JG cells in the hydronephrotic mouse kidney by the whole cell patch-clamp technique have identified an inward rectifying K current whose inhibition was shown to be partly responsible for the depolarizing effect of angiotensin II.[114] In addition, JG cells expressed Ca-activated Cl channels in high density.[114] In contrast, inwardly rectifying K channels were not detected in isolated JG cells from rat kidneys.[115] Instead, Ca-dependent and voltage-gated large conductance K channels (BK_{Ca}) were identified that largely determined the resting potential of −32 mV.[115] Presence of BK_{Ca} channels was verified at the mRNA level by RT-PCR, and at the protein level by immunocytochemistry. The increased outward current caused by cAMP was also due to activation of BK_{Ca} channels, suggesting that they were of the cAMP-stimulated ZERO splice variant.[115] There is also evidence for the presence of K-ATP channels in JG cells, but their functional role is not clear.[116] While earlier studies failed to obtain functional evidence for the presence of voltage-dependent Ca channels,[117] the presence of L-type Ca channels and their activation by strong depolarizations has been established in isolated JG cells.[118] JG cells express NKCC1, the ubiquitous isoform of the Na,K,2Cl co-transporter, and its inhibition by furosemide stimulates renin exocytosis, as evidenced by increased membrane capacitance.[119]

MACULA DENSA CONTROL OF VASCULAR TONE

The Tubuloglomerular Feedback Loop

Effect of Distal Tubule Flow Perturbations on SNGFR

The tubuloglomerular feedback (TGF) response is defined as the change of *SNGFR* resulting from a change in tubular fluid flow exiting the proximal convoluted tubule, a practical experimental variable to predictably alter tubular fluid composition in the MD segment of the tubule.[120] The average reduction of *SNGFR* in superficial nephrons of rats caused by a saturating flow increase in 15 independent studies was 13 ±1 nl/min or 40 ±3%.[52] In addition to the rat, TGF responses were found in all mammalian species tested thus far (dog, hamster, mouse, humans), as well as in two non-mammalian species (*Amphiuma means* and *Necturus maculosus*).[52] Fitting *SNGFR* measurements at eight different loop perfusion rates to a four parameter logistic equation (Figures 23.3 and 23.4) revealed that TGF responses occur over a defined flow range and show nonlinear saturation kinetics.[121] $V_{½}$, the flow resulting in the half-maximum response, was 17.5 nl/min, a value close to the ambient end-proximal flow rate in the rat (Figure 23.3). The precise location of the TGF operating point has been determined by adding or withdrawing small volumes of fluid from the proximal tubule and determining the resulting changes in proximal flow rate.[122] In these studies, small increases and decreases in loop flow rate were equally and maximally effective in altering *SNGFR*, an observation that directly demonstrates the position of the operating point at the midpoint of the feedback function curve.[122,123] Consistent with the conclusion of tonic suppression of GFR by TGF are observations showing

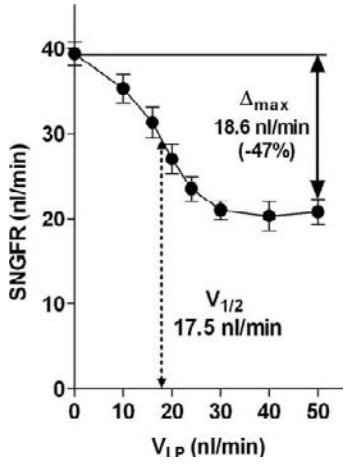

FIGURE 23.3 **Relationship between *SNGFR* and loop of Henle perfusion rate (V_{LP}).** The diagram shows mean values from 9 tubules in which *SNGFR* was determined at 8 different flow rates[121] (Δ_{max}: maximum reduction of *SNGFR*; $V_{½}$: perfusion rate causing half-maximal reduction of *SNGFR*).

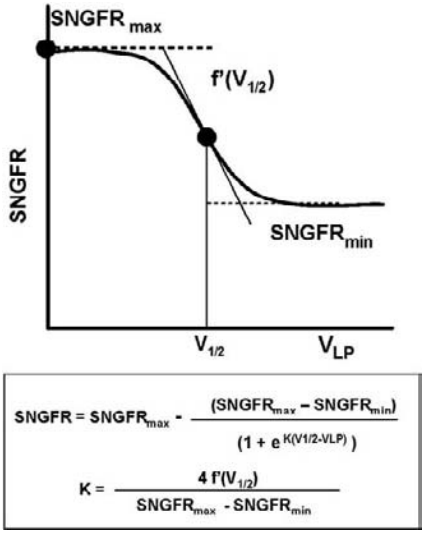

FIGURE 23.4 **Four parameter equation (logistic equation) used to describe the sigmoidal relationship between *SNGFR* and lat proximal flow rate (V_{LP}).** Parameters are $SNGFR_{max}$, $SNGFR_{min}$, $V_{½}$, the flow rate at which the response is half-maximum, and f′ $V_{½}$, the slope at the midpoint.[594]

that *SNGFR* based on fluid collections in the proximal tubule where the TGF signal is eliminated is usually higher than *SNGFR* based on distal collections where the TGF signal is intact (Figure 23.5[52]). Systematically higher values of *SNGFR* of superficial nephrons determined in proximal compared to distal tubule segments have also been demonstrated in the dog and mouse.[124,125] TGF responses were also observed in juxtamedullary nephrons of both rats and hamsters, where increased flow past the MD by perfusion of thin ascending limbs produced a reduction in *SNGFR* by about 25 nl/min or approximately 50%.[126,127]

The vasoconstriction elicited by TGF at the level of the JGA may be partially offset by a tubular vasodilator effect that appears to be mediated by a tubulovascular contact area at the level of the connecting tubule.[128] This dilator mechanism, called cTGF, is activated by high Na concentrations and inhibited by amiloride or benzamil, suggesting that it is initiated by activation of ENaC-dependent Na transport.[128] Activation of cTGF seems to require relatively high flow rates, and may therefore play an important role only under special circumstances.[129] Nevertheless, the implications of these observations are potentially far-reaching for the interpretation of previous microperfusion studies, and for the understanding of the physiology of TGF regulation of GFR.

TGF Oscillations

In both rats and mice the operation of the TGF system in the closed-loop mode can result in stable oscillations of filtration pressure and filtration rate with a periodicity of 2–3 cycles/min (30–50 mHz).[125,134,135] Synchronous pressure oscillations were seen in efferent arteriolar blood flow, with blood flow leading tubular pressure by about a 1 second lag. This phase shift suggests that oscillations in blood flow were the cause of changes in tubular pressure.[130] Oscillations were principally of single nephron origin, since oscillations in random nephrons were not in phase.[131] However, synchronized pressures were observed in adjacent nephrons whose afferent arterioles originate from the same interlobular artery.[132,133] The simultaneous assessment of the oscillatory pattern of many nephrons on the surface of the kidney using the novel approach of laser speckle contrast imaging has shown that synchronized TGF oscillations can sometimes be observed among nephrons that are not located in the immediate vicinity of each other.[134] Pressure oscillations were abolished by loop diuretics, and they were absent in mice that lack TGF responses, suggesting that they were generated by the TGF system.[125,135] This contention was further supported by the finding that distal flow rate and Cl concentrations oscillate with the same frequency, but with a fixed phase shift.[136] Mathematical modeling of the TGF system indicates that oscillations are the result of a relatively high feedback gain, in combination with delays in the transmission of the signal across the JGA and along the nephron.[137,138]

In addition to the slow TGF-dependent oscillations, laser-Doppler velocimetry identified oscillations in star vessel blood flow with a frequency of about 100–200 mHz, probably reflecting myogenic vessel activity.[130] Since TGF and myogenic mechanisms are targeted to identical arteriolar smooth muscle cells, they are expected to interact and become synchronized. As an expression of the interaction, the power of the myogenic oscillations increased during inhibition of TGF, and decreased during TGF saturation.[130,139] In contrast to the synchronized oscillations of normal animals, irregular fluctuations of proximal tubular pressure have been observed in spontaneously hypertensive as well as Goldblatt hypertensive rats, but not in salt-sensitive Dahl rats with hypertension.[140–142] Mathematical modeling has shown that desynchronizations like those seen in the hypertensive models can result from parameter variations of the TGF system or from increases in interaction strength, particularly when nephrons are electrotonically coupled.[143,144] Oxygen tension on the renal surface has also been found to oscillate at the 30 mHz TGF frequency,

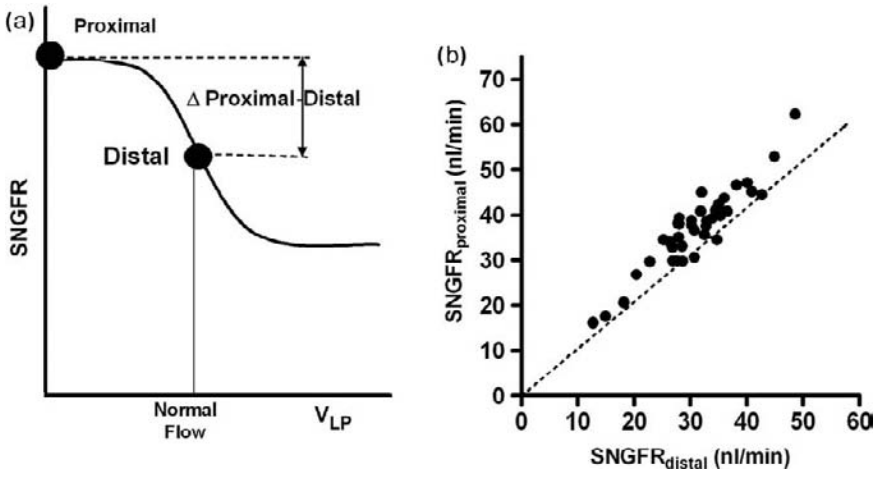

FIGURE 23.5 (a) Difference between *SNGFR* measured in the distal and in the proximal tubule (Δ proximal–distal); its magnitude is an index of the *SNGFR*-reducing effect of ambient flow rates past the macula densa. (b) Relationship between measurements of *SNGFR* in proximal and distal segments of the same nephron. Each point is the mean of an experimental series taken from the literature (for references see [52]). Proximal *SNGFR* exceeded distal *SNGFR* by an average of 6.0 ± 0.54 nl/min, suggesting TGF-dependent suppression of the GFR of superficial nephrons by about 16%

and it has been speculated that a switch of TAL cell energy production from aerobic to anaerobic metabolism may cause the instability in MD NaCl concentration that activates TGF oscillations.[145]

The Tubular Signal and the Sensing Mechanism

Effect of Loop of Henle Flow on MD NaCl Concentration

Although flow rate changes are frequently used to activate TGF, their mechanical consequences *per se* do not appear to be sufficient cause for vasomotor responses *in vivo*. Flow rate changes do not elicit TGF responses as long as they are not accompanied by changes in NaCl, and conversely, full TGF responses can be induced by low flows, as long as NaCl is supplied at sufficiently high concentrations.[120,146–148] Furthermore, widely varying TGF responses can be observed at identical flow rates.[148,149] However, in a recent study using the isolated perfused JGA preparation, changes in flow even in the absence of NaCl were observed to elicit vasoconstriction and increases of cytosolic calcium in vascular cells at the glomerular pole, an effect attributed to the consequences of mechanical deflection of the central cilium of MD cells.[150,151] The reasons for this major discrepancy between the *in vivo* and *in vitro* effects of flow are not known.

Nevertheless, extensive experimental evidence *in vivo* favors the notion that the MD cells respond to changes in luminal NaCl concentration, and that the flow dependency of TGF responses reflects flow dependence of luminal [NaCl] in the MD region of the nephron.[152] *In situ* microperfusion of loops of Henle has revealed a biphasic relationship between flow rate and distal [NaCl] measured 300–600 μm downstream from the MD, the earliest accessible site along the distal convoluted tubule.[120,153,154] The increase of distal solute concentrations at subnormal flow rates is the result of modifications of tubular fluid between the MD region and the distal tubule. NaCl influx along the early post-MD epithelium causes [NaCl] to increase over the levels existing at the MD, and the effect of this addition of NaCl is particularly evident at low flow rates.[153,155]

Effect of MD NaCl Concentration on SNGFR

The precise relationship between MD NaCl concentration and *SNGFR* was established by perfusing loops of Henle from their distal ends in a retrograde direction.[148] In this approach, the distance between perfusion and sensing sites is greatly shortened, the changes in perfusate composition by tubular transport activities are minimized, and the effects of perfusate composition on *SNGFR* can be studied at constant flow rate and pressure. At a flow rate of 20 nl/min, *SNGFR* varied inversely with changes in perfusate NaCl concentration between 15 and 60 mM (or 30 and 120 mOsm), values which extend over the hypotonic range normally occurring at the end of the thick ascending limb.[146,148,156] Increments in NaCl concentration above 60 mM did not further suppress filtration rate. Maximum changes of *SNGFR* caused by saturating flow rates during orthograde perfusion and by saturating NaCl concentrations during retrograde perfusion were identical. Fitting the equation of a hyperbolic tangent to these results (Figure 23.6) indicates that the half-maximum decrease in *SNGFR* is caused by a NaCl concentration of 33.5 mM, and that the maximum slope is about 0.5 nl/min mM.

Studies designed to discriminate between ionic or osmotic effects of the perfusion fluid indicate that total solute concentration at the MD does not seem to measurably participate in TGF-mediated reductions of *SNGFR*. Orthograde perfusion with isotonic mannitol solutions in the rat is usually not associated with sustained reductions in *SNGFR*, even though distal tubular fluid osmolality is greatly increased.[120,147,157] TGF responses correlating with alterations in osmolality have been observed during orthograde perfusion with various perfusion solutions, but the variations in distal osmolality were outside the critical osmolality range of 30 to 120 mOsm observed in retrograde perfusion studies.[158] In retrograde perfusion experiments in which fluid osmolality and NaCl concentration were varied independently, TGF responses were exclusively determined by NaCl concentration, and not by osmolality in a range between 130 and 400 mOsm.[149] Finally, the pattern of *SNGFR* responses during retrograde perfusion with isotonic solutions in which either Na or Cl was replaced, but in which osmolality was kept constant, indicates dependence on the ionic composition and independence of osmolality.[148,156]

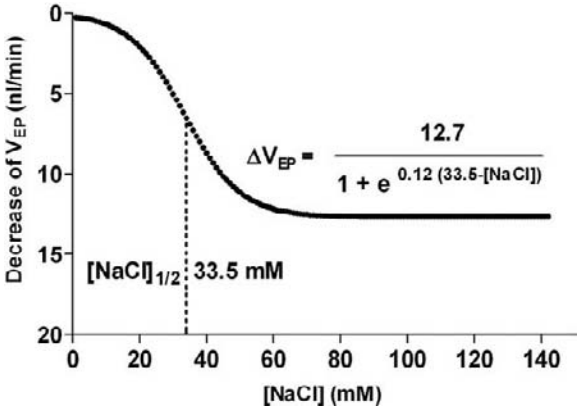

FIGURE 23.6 **Logistic equation describing the relationship between NaCl at the macula densa and early proximal flow rate (V_{EP}), a close correlate of *SNGFR*.** Changes in NaCl concentration at the macula densa were produced by retrograde microperfusion.[148] $[NaCl]_{1/2}$, NaCl concentration causing half-maximum reduction of V_{EP}.

TGF Response and NaCl Transport

EFFECTS OF LOOP DIURETICS

The observation that inhibition of NaCl transport along the loop of Henle is associated with blockade of the TGF mechanism has been of fundamental importance in understanding the initiation of the TGF signaling pathway.[159] TGF inhibition has been rather uniformly observed in the presence of loop diuretics such as furosemide, bumetanide, piretanide, ethacrynic acid, triflocin or l-ozolinone.[52] Concentrations causing half-maximal inhibition of transport and feedback appear to be similar, about 5×10^{-5} M for furosemide and about 10^{-6} M for bumetanide[160] (own unpublished data). Furosemide also blocked TGF responses during retrograde perfusion, suggesting that metabolic consequences of TAL inhibition are not transmitted by convective transport to the MD cells.[161,162] Since distal Na and Cl concentrations are greatly elevated during loop NaCl transport inhibition, TGF responses do not appear to be caused by luminal NaCl concentration changes *per se*, but by changes in cellular NaCl uptake mediated by the furosemide-inhibitable Na,K,2Cl co-transporter NKCC2. The concentration dependence of feedback responses is probably the result of concentration dependence of NaCl uptake. Studies in mice with selective deletions of the A or B isoform of NKCC2 indicate that NKCC2B mediates TGF in the low NaCl concentration range, while NKCC2A is required for responsiveness to higher NaCl concentrations.[22,163] Thus, the presence of two isoforms of NKCC2 in the macula densa extends the NaCl range over which TGF operates (Figure 23.7). The concept that TGF responses are generated by the successive activation of NKCC2B and NKCC2A is supported by expression studies in *Xenopus* oocytes that have shown a higher Cl affinity of NKCC2B than NKCC2A, 9 mM versus 45 mM.[21] Other aspects, such as the dependence of the inhibitory potency of furosemide on Cl concentration, have also been found to hold true for the TGF response.[162,164] Diuretic agents with primary actions outside the loop of Henle such as acetazolamide, chlorothiazide, and amiloride do not possess TGF-inhibitory properties.[159,165]

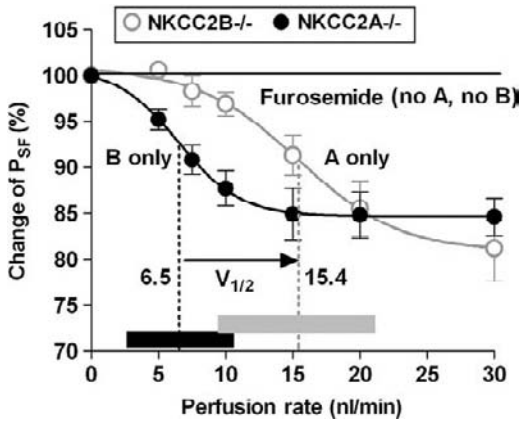

FIGURE 23.7 Relationship between loop of Henle perfusion rate and the relative reduction of P_{SF} (± SEM) in mice lacking NKCC2B (circles: (A) only) or NKCC2A (dots: (B) only). Dashed lines indicate the positions of $V_{1/2}$, the flow rates causing half-maximum reduction of P_{SF}; bars indicate the flow ranges over which 90% of the total responses occur. *(Data from .[22,163])*

EFFECT OF K CHANNEL BLOCKADE

Retrograde application of the K channel blocker U37883A caused an almost complete inhibition of TGF responses.[166] This effect is mediated by inhibition of ROMK type K channels, since TGF responses were largely absent in mice with targeted ROMK deletion,[167] a finding that has been confirmed in mice in which selective breeding of surviving animals has generated ROMK-deficient mice with less compromised kidney function and well-maintained blood pressure.[168,169] The observation that inhibition of NKCC2 and ROMK has similar effects on TGF responses argues against a specific "sensor" function of these transport proteins, and for a critical role of some consequence of MD NaCl transport. Since ambient distal K concentrations near the MD are close to the K affinity of the co-transporter, it is possible that variations in luminal K may in part regulate TGF response magnitude.[166] Nevertheless, the increase in distal K concentration accompanying acute hyperkalemia was associated with attenuation, not enhancement, of TGF responses.[170]

ION SUBSTITUTION STUDIES

That NaCl uptake by NKCC2 is the initial step in the feedback transmission pathway is further supported by parallels in the ionic requirements for both TGF- and NKCC2-mediated NaCl transport across TALH. During retrograde perfusion of the MD segment (Figure 23.8a), TGF responses were not seen during perfusion with isotonic or hypotonic solutions of Na salts such as $NaHCO_3$, $NaNO_3$, NaI, NaSCN, Na acetate, Na gluconate or Na isethionate.[148,156] In contrast, isotonic solutions of Cl salts (Figure 23.8b) accompanied by small monovalent cations such as K, Rb, Cs or NH_4 elicited full TGF responses, as did the bromide salts of Na and K[148]. It is to be noted that some of these small cations have been found to be substrates for either the Na or the K site on the NKCC2 co-transporter.[164,171]

The requirement for sizable Cl or Br concentrations, and the apparent lack of dependence on Na concentration, are consistent with an involvement of Na,K,2Cl co-transport, since the apparent overall affinity of NKCC2 for Cl in both TAL and MD cells is much lower than that for Na or K.[172,173] Thus, the relatively low Cl affinity would predictably create an apparent Cl dependency of transport, while the small amounts of Na or K entering

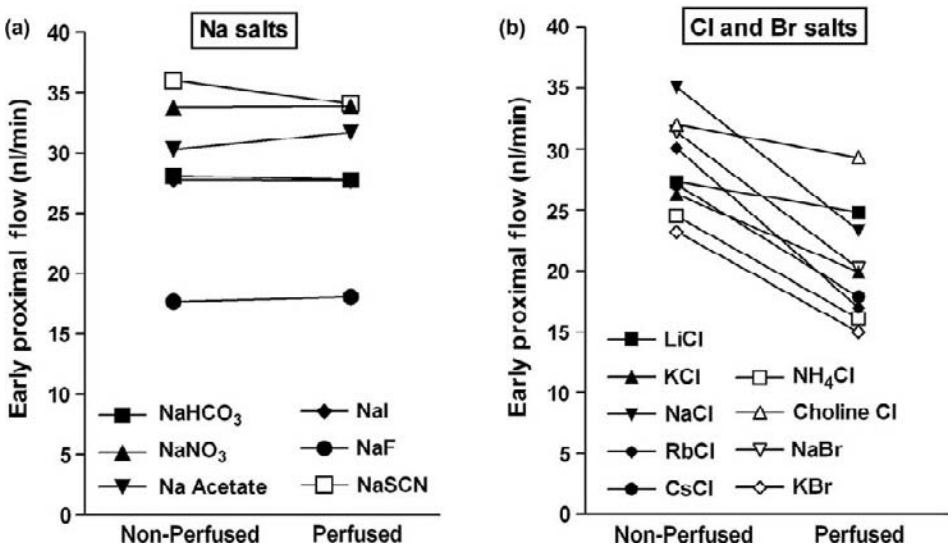

FIGURE 23.8 (a) Effect of Na salts with various anionic substitutions on the response of V_{EP} to retrograde perfusion of the macula densa segment. (b) Effect of Cl and Br salts with various cationic substitutions on the response of V_{EP} to retrograde perfusion of the macula densa segment. *(Data from ref. [148]).*

initially Na- or K-free solutions are sufficient to sustain near normal NKCC2 activity. When Na was replaced with large cations such as choline or TMA, TGF responses of normal magnitude were not seen, even though Cl was present in sufficiently high concentrations.[148,156] Considering the cationic selectivity of the paracellular shunt, replacing luminal Na for choline will result in a sizable lumen positive Na diffusion potential[172] that is predicted to reduce NaCl absorption by increasing Cl backflux. This explanation is consistent with the observation that NaCl transport rates of isolated TAL were found unaltered when studied under symmetric conditions with high choline Cl on both sides of the epithelium.[172] In this case, Na backdiffusion and voltage-dependent inhibition of NaCl absorption is not to be expected as long as low concentrations of Na and K are present.

ACTIVE NaCl TRANSPORT

Transport inhibition caused by metabolic inhibitors such as cyanide, antimycin A or uncouplers of oxidative phosphorylation has also been found to reduce TGF responsiveness.[159,174] TGF responses are not affected by peritubular application of ouabain, and this is probably related to the fact that the α1 Na,K-ATPase in rodents is rather insensitive to cardiac glycoside inhibition.[175] In fact, when α1 Na,K-ATPase was genetically engineered to become ouabain-sensitive, intravenous or luminal administration of the glycoside caused marked reductions of TGF responses.[176] The effect of luminal ouabain may not be related to H,K-ATPase inhibition, since TGF responses were unaltered in H,K-ATPase-deficient mice.[176] The striking effect of loop transport blockade suggests that NaCl uptake through the furosemide sensitive Na,K,2Cl co-transporter, and Na extrusion through an energy-dependent pathway are critical steps in generating feedback responses.

The Vascular Effector Mechanism

The vascular response to a change in perfusion of single loops of Henle occurs without alterations in systemic arterial pressure, renal sympathetic tone or in the resistance of larger renal vessels such as the cortical radial arteries (interlobular arteries). Therefore, the alteration in the hemodynamic determinants of filtration must be caused by a change in the contractile state of glomerular vascular elements. To determine the effect of TGF on glomerular arteriolar resistance, both the pressure fall and the rate of arteriolar blood flow have to be assessed while the perfusion in the loop of Henle of the same nephron is altered.

Pressure Gradients

GLOMERULAR CAPILLARY PRESSURE (P_{GC})

Direct measurements in superficial glomeruli of Munich-Wistar rats have shown that saturating flow increments cause a significant fall in P_{GC}, with fractional decreases ranging between 15 and 22%.[123,177–180] The slope of the P_{GC} change in the most sensitive flow range was 1.3 mmHg min/nl.[123] P_{GC} measured directly in an *in vitro* preparation of juxtamedullary nephrons also fell during TGF activation.[181] P_{GC} in nephrons without superficial glomeruli can be estimated from measurements of stop flow pressure (P_{SF}).[182] In response to a saturating increase in loop flow, mean P_{SF} of 23 studies fell by 22%, from 39.0 ± 0.8 to 30.3 ± 0.8 mmHg.[52] A reduction in P_{SF} was also observed in the dog when loop flow was increased from zero to normal and supranormal values.[183,184] In the mouse, TGF responses of P_{SF} are similar in magnitude as those seen in rats, but the sensitivity range is shifted to lower flows.[185] Since multiple determinations of P_{SF} can be made in the same nephron with small

perfusion flow increments, the nonlinear relationship between loop of Henle flow and P_{SF} was apparent long before a similar feedback function for *SNGFR* was defined.[186] In 15 experimental series, the maximum P_{SF} decrease averaged 7.9 ± 0.6 mmHg, with a mean $V_{½}$ of 20.1 ± 1.1 nl/min. The maximum sensitivity varied substantially between different studies, but in general was between 1 and 2 mmHg min/nl.[52] Two laboratories have reported that the TGF-induced change in P_{SF} was identical to the TGF-induced change in P_{GC}.[178,179]

The main uncertainty in the determination of feedback-induced changes in the glomerular arteriolar pressure drop results from the evidence that, at least in the rat, a portion of the preglomerular resistance resides in the cortical radial arteries rather than in the afferent arterioles.[187,188] As a consequence, afferent arteriolar resistance, calculated from the artery-to-glomerulus pressure difference, overestimates true afferent resistance, while the relative change caused by the TGF mechanism is underestimated. If preglomerular resistance is equally apportioned between interlobular artery and afferent arteriole, the TGF-induced resistance change along the afferent arteriole would be about 15% greater.

Glomerular Plasma Flow

Estimation of glomerular plasma flow (GPF) by micropuncture requires measurements of *SNGFR* and single nephron filtration fraction (SNFF), with SNFF being derived from the increase in protein concentration or hematocrit in collected samples of early postglomerular blood. Increasing loop perfusion rate reduced plasma flow entering the glomerulus by about 20%, a change accompanied by a fall in SNFF.[189,190] Laser-Doppler shift analysis showed that saturation of the TGF mechanism caused about a 40% reduction in efferent arteriolar blood flow, while TGF inhibition with furosemide increased blood flow by about 25%.[130] Supportive evidence for TGF-induced reductions in GPF came from the observation that glomerular blood flow, estimated from the change in the arrival of fluorescent particles in a single glomerular capillary,[191] fell by about 25–30% when loop flow was increased (M. Steinhausen and J. Schnermann, unpublished). A 30% reduction in afferent arteriolar blood flow was also seen in *Amphiuma* and *Necturus* kidneys when distal flow rate was increased.[192,193]

Effector Site

PREGLOMERULAR RESISTANCE

The micropuncture studies agree that increasing loop of Henle flow produces a 30–40% increase in preglomerular resistance.[189,190] TGF-induced reductions in afferent arteriolar diameter have been directly observed in the blood-perfused juxtamedullary nephron preparation, and in an isolated perfused tubule/vessel preparation.[181,194,195] TGF-induced resistance changes estimated from such diameter observations are consistently much larger than those measured with the micropuncture approach. As suggested above, the location of a sizable resistance along large intrarenal arteries would lead to an underestimation of the TGF-induced resistance change. It is also possible that in the small preglomerular arterioles resistance estimates may deviate from Poiseuille's law. Finally, cTGF, the vasodilator effect at the level of the connecting tubule, may blunt TGF *in vivo*, but would be absent in the perfused tubule.[128,196]

The ultimate cause for TGF-induced vasoconstriction is a rise in intracellular calcium that, at least to a large extent, is mediated by activation of voltage-dependent calcium channels. Depolarization of afferent arteriolar smooth muscle cells during TGF activation has recently been demonstrated using voltage-sensitive dyes.[197] A role for the resulting activation of L-type Ca channels in TGF is supported by the TGF inhibitory effects of intravenous or peritubular application of Ca channel blockers.[198–200] A decrease in protein kinase A activation may be an additional component of TGF-mediated vasoconstriction of the afferent arteriole, since Db-cAMP in the presence of 50 μM IBMX or the luminal application of forskolin, a stimulator of adenyl cyclase, significantly reduced the TGF response magnitude.[201,202]

Observation of the TGF response indicates that the afferent arteriole immediately adjacent to the glomerulum is the main direct target of the TGF mediator.[181] The glomerular entrance segment of the vessel is the part of the afferent arteriole in which agents affecting TGF response magnitude, such as adenosine and angiotensin II, exert their largest constrictor action.[203,204] TGF-induced local constriction may elicit a vascular conducted response that spreads to proximal portions of the arteriole by electrotonic coupling or myogenic excitation.[205,206] Spreading of contractile responses during local application of KCl has been observed in juxtamedullary nephrons, indicating electrotonic coupling of afferent arteriolar smooth muscle cells.[207] Upstream propagation of TGF-induced vasoconstriction is also responsible for the functional coupling of nephrons that are supplied by a common interlobular artery.[132,208,209] It is probable that conducted vasoconstriction relies on the presence of various connexins in endothelial and smooth muscle cells.[76,210] In view of the functional connection between afferent arteriolar smooth muscle cells, one may conclude that the total vasoconstrictor response to a NaCl step-change is composed of a local MD-generated effect and an upstream myogenic constrictor component.

POSTGLOMERULAR RESISTANCE

Evidence for a concomitant constriction of efferent arterioles during TGF activation has been obtained by micropuncture studies showing a reduction of GFR with unaltered glomerular capillary pressure, therefore suggesting proportional increases in the tone of afferent and efferent vessels.[179,190,211] Furthermore, an increase of flow within the low-to-ambient flow range is associated with a greater change of *SNGFR* than of P_{SF}, suggesting that either there was balanced afferent and efferent vasoconstriction, with the *SNGFR* fall being a consequence of the reduced plasma flow or that total resistance did not change and the *SNGFR* change was a consequence of a reduced K_f.[123,212] Direct observations of juxtamedullary efferent arterioles during TGF activation did not reveal any vasoactivity.[181] In contrast to these observations, luminal NaCl has been observed to dilate efferent vessels in the double-perfused nephron preparation of the rabbit, an effect that was prevented by antagonists of A2 adenosine receptors.[213] There is some experimental evidence in support of the possibility that a reduction in the filtration coefficient may contribute to TGF-induced reduction of GFR.[190]

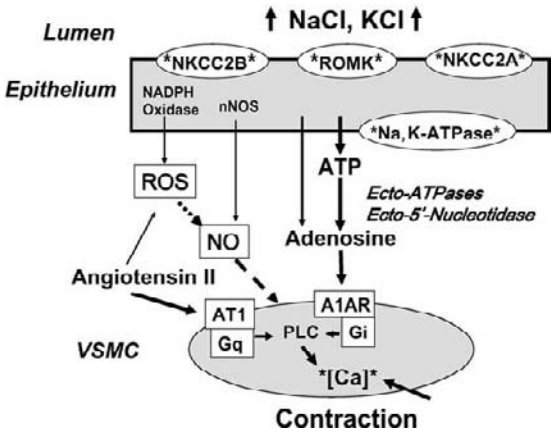

FIGURE 23.9 **Schematic summary of our current understanding of the pathway by which an increase in luminal NaCl at the macula densa causes activation of vascular smooth muscle cells (VSMC) in the afferent arteriole.** Some consequence of NaCl uptake is linked to the release of ATP, subsequent generation of adenosine, interaction with adenosine 1 receptors (A1AR), Gi-dependent activation of PLC, and increases in Ca by release from stores and opening of Ca channels. Angiotensin II is an important co-factor that augments the impact of A1AR activation. NO is a response-attenuating factor whose levels are to some extent modulated by reactive oxygen species (ROS).

Purinergic Mediation of the Vascular Response

As discussed in the previous sections, an increase in loop of Henle flow rate produces increases in NaCl concentration and NaCl transport at the MD, and this functional alteration elicits a vasoconstrictor response of the glomerular microvasculature, as well as a reduction in the rate of renin secretion. Propagation of the signal across the JGA interstitium and subsequent changes in vasomotor tone occurs through the transport-dependent generation and action of purinergic mediators (Figure 23.9).

ADENOSINE

Adenosine was originally proposed as a mediator of the TGF response, since it provided a conceptual link between the energy expended for NaCl transport and the generation of a vasoactive ATP metabolite.[214,215] Stimulation of Na transport in the proximal tubule is in fact associated with a decrease in cellular ATP, and increased NaCl secretion in the shark rectal gland causes a decrease in ATP, as well as an increase in adenosine release.[216,217]

The vasomotor action of adenosine in most organs and vascular beds consists of vasorelaxation that reflects the wide distribution of the two types of A2 adenosine receptors, A2aAR and A2bAR. Although the kidney is usually considered an exception to this rule,[218] several studies have shown that the steady-state response to an intravenous administration of adenosine is a clear reduction of renal vascular resistance, whereas the initial constrictor response is only short-lasting.[219] In contrast, persistent vasoconstriction of afferent arterioles by adenosine and A1 adenosine (A_1) analogs was observed in the hydronephrotic kidney and in isolated perfused afferent arterioles when adenosine receptors were activated from the interstitial aspect of the vessel.[203,220–222] The constrictor effect was absent in arterioles from A1 adenosine receptor (A1AR)-deficient mice.[203,223] Thus, adenosine causes a lasting vasoconstriction only when the nucleoside is generated in a restricted interstitial region so that A1AR can be accessed without general activation of the more dominant A2 receptors. Expression data, as well as functional observations, indicate that the terminal afferent arteriole is a vessel with high representation of A1AR.[222,224] A1AR-mediated vasoconstriction of afferent arterioles is initiated by Gi-dependent activation of phospholipase C, release of Ca from intracellular stores, and subsequent Ca entry through L-type Ca channels.[203,225,226] The A1AR-mediated vasoconstrictor effect of adenosine in afferent arterioles was stable for extended periods of time, indicating absence of rapid receptor desensitization.[203,225] Tubular administration of A1AR agonists augments the vasoconstrictor response to increased loop flow rates.[161,227] This effect does not appear to be mediated through apical A1AR, but rather to reflect a direct interaction with A1AR on afferent arterioles, and it thereby demonstrates the vasoconstrictor potency of A1AR activation and its effect on glomerular capillary pressure *in vivo*.[228]

Two laboratories have independently generated mouse strains with targeted deletion of A1AR, and both groups observed a complete absence of TGF responses in $A1AR^{-/-}$ animals using micropuncture measurements of stop flow pressure or single nephron GFR (Figure 23.10).[229,230] Furthermore, specific A1AR antagonists such as 8-cyclopentyl-1,3-dipropylxanthine (DPCPX) or PSB-36 inhibit TGF responses when added to either the tubular lumen or the peritubular blood.[228,231] A similar effect has been seen earlier with non-specific blockers such as theophylline or 3-isobutyl-1-methylxanthine, IBMX.[161,201,214,232] Addition of the nonxanthine A_1 receptor antagonist FK838 to the perfusate or bath also eliminated TGF responses in an isolated tubule preparation.[233] There is evidence that adenosine generated during TGF activation may also interact with A2 adenosine receptors, but the site of action is unclear. Enhanced TGF responses have been observed during A2AR blockade, suggesting that activation of A2AR tonically diminishes A1AR-mediated vasoconstriction of afferent arterioles, perhaps through the release of nitric oxide.[231,234] On the other hand, adenosine is able to vasodilate preconstricted efferent arterioles through A2AR, and A2AR inhibition has been found to block TGF-mediated vasodilatation of efferent arterioles in the isolated perfused JGA preparation.[213,235] The latter findings are difficult to reconcile with the absence of *in vivo* evidence for a reduction of efferent arteriolar resistance during TGF activation.

ATP

The preponderance of current evidence indicates that extracellular ATP serves as the major source for the generation of adenosine in the JG interstitium. Strong support for this notion is furnished by the demonstration that basolateral membranes of MD cells appear to have an ATP release pathway that is modulated by changes in luminal NaCl. Release of ATP by MD cells is suggested by the observation that PC12 or mesangial cells placed near the basolateral MD cell membrane responded to changes in luminal NaCl over the 20−60 mM range with an increase in cytosolic calcium.[236,237] This Ca response of the biosensor cells reflects P2 receptor activation, since it was inhibited by suramin.[236,237] Patch-clamp studies in cell-attached and excised patches of the basolateral membrane of MD cells showed the presence of an anion channel of 380 pS whose activity was dependent on the presence of extracellular NaCl, and that was active in the presence of ATP as the only anion.[236,237] Channel activity was blocked by gadolinium, but not by the Cl channel inhibitors DPC or NPPB.[236] The molecular nature of this large conductance anion channel has not been identified, but it may be identical to a functionally described maxi-anion channel that is widely expressed throughout the body.[238] Release of ATP across connexin hemichannels would be another possibility, but the evidence for the presence of connexins in the basolateral membrane of MD cells is weak.[76,239]

It is likely that ATP released into the JGA interstitium serves as substrate for membrane-bound ecto-ATPases and nucleotidases, ultimately resulting in the formation of the vascular mediator adenosine. In fact, TGF responses have been found to be greatly reduced in mice with deletion of NTPDase1/CD39, the major renal ecto-ATPase that dephosphorylates both ATP and ADP to AMP.[240] Furthermore, evidence has been obtained suggesting that adenosine formation by

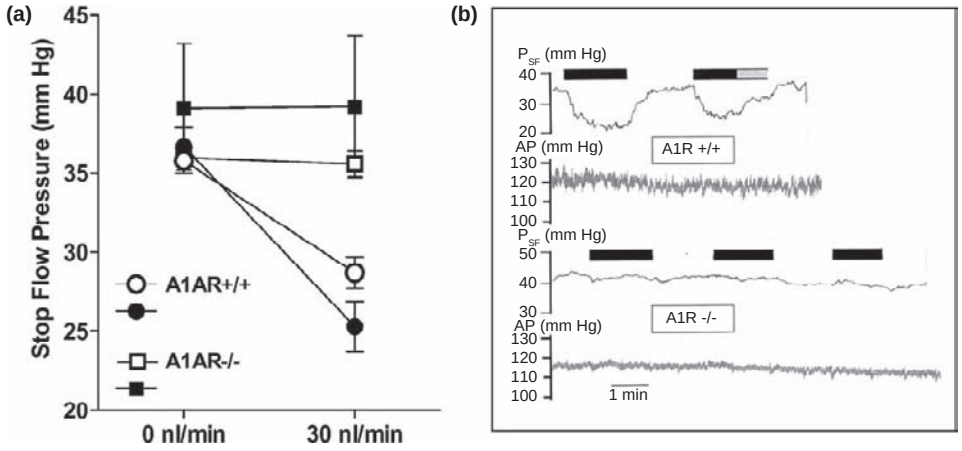

FIGURE 23.10 (a) Mean responses of stop flow pressure to an increase in loop of Henle perfusion rate from 0 to 30 nl/min in wild-type ($A1AR^{+/+}$) and in adenosine 1 receptor-deficient mice ($A1AR^{-/-}$). Gene targeting and phenotypic studies were performed by two independent groups of investigators (Closed symbols: data from [229]; Open symbols: data from [230]). (b) Recordings of stop-flow pressure (P_{SF}) and arterial blood pressure (AP) in a wild-type mouse ($A1R^{+/+}$) and in an adenosine 1 receptor-deficient mouse ($A1R^{-/-}$). During periods indicated by black bars, loop of Henle perfusion rate was increased to activate the TGF mechanism. Note absence of perfusion-related changes of P_{SF} in the nephron of the A1 receptor-deficient animal.

e-5′NT/CD73 may be critical in the generation of adenosine during the TGF response. Blocking adenosine formation with the e-5′NT-inhibitor α,β-methylene adenosine 5′-diphosphate (MADP) significantly reduced the compensatory TGF efficiency and the slope of the TGF relationship.[241] When the level of TGF activation was fixed by saturating concentrations of CHA, TGF efficiency was further reduced, and retrograde administration of MADP in combination with CHA caused vasoconstriction and abolition of TGF response.[241] Consistent with these data are observations in mice with targeted deletion of e-5′NT/CD73 in which TGF responses were found to be markedly compromised.[242,243] Finally, in the double-perfused JGA preparation, bath addition of the ecto-ATPase apyrase enhanced, and MADP abolished, TGF responses, suggesting that extracellular generation of adenosine from ATP is critical for JGA signaling.[244] Exogenous e-5′NT was also found to improve the defective TGF component of renal autoregulation in Thy-1 nephritic rats.[245] Dephosphorylation of ATP and AMP is likely to occur through enzymes anchored to the surface of mesangial cells.[246,247] Whether adenosine levels in the JG interstitium are regulated by adenosine release across equilibrative nucleoside transporters (ENT) is unclear, since evidence based on the effect of ENT inhibitors such as dipyridamole or dilazep on TGF responses is inconclusive.[214,248,249]

As an alternative to a role of ATP as precursor for adenosine, it has been proposed that ATP may directly elicit TGF responses, most likely through activation of P2 receptors on extraglomerular mesangial cells and gap junctional transmission of the resulting increase of cytosolic Ca to the afferent arteriole.[150,236,250,251] ATP may also directly activate arteriolar P2 receptors, with P2X1 receptors being the most likely receptor subtype since its presence in afferent arterioles has been well-documented.[252] In fact, ATP causes rapid and reversible constriction of afferent arterioles, an effect that may be more pronounced in juxtamedullary than superficial nephrons.[222,250] A similar effect is seen with the P2X receptor-specific ligand α,ß-methylene ATP, suggesting mediation of vasoconstriction by P2X purinoceptors.[250] Nevertheless, unequivocal evidence in support of a P2 receptor-mediated action of ATP in TGF *in vivo* is not available. TGF responses in superficial nephrons of P2X1 knockout mice were not statistically distinguishable from wild-type animals.[169] Likewise, TGF responses were not significantly affected by the infusion of the broad-spectrum inhibitors of P2 receptors PPADS or suramin, although these agents clearly diminished the blood pressure response to the P2 agonist α,ß-methylene ATP.[253] Results from the double-perfused JGA preparation are controversial. In an earlier study on rabbit tissue, suramin had been without effect on the response of afferent arteriolar diameter to an increase of luminal NaCl.[244] Since acceleration of ATP breakdown enhanced, and inhibition of 5′-ecto nucleotidase and of A1 adenosine receptors blocked, the arteriolar diameter response, these results were consistent with the ATP dephosphorylation/adenosine paradigm.[233,244] However, in similar preparations from rabbit or mouse, suramin was recently found to abolish afferent arteriolar Ca and constrictor responses, while the A1AR antagonist DPCPX was without effect.[150,151] The reasons for this divergence are presently unclear, but it is to be noted that a novel approach was used in at least part of the latter study, in that only the macula densa cells of the perfused nephron were maintained, while all thick ascending limb cells were removed by microdissection.[151] While it is conceivable that the presence of thick ascending limb cells is required for the "conventional" TGF response that is flow-independent, NaCl-dependent, and affects vascular tone through A1AR activation, the possibility of technical reasons for the obvious discrepancies cannot be excluded.

LINK BETWEEN NaCl TRANSPORT AND TGF

Exactly how an increase of NaCl transport by MD cells is coupled to the release of ATP or the subsequent activation of the purinergic signaling pathway is one of the major open questions in TGF physiology. Cell swelling is a very common cause for eliciting ATP release, and this mechanism may be the critical factor for linking NaCl transport to ATP egress in MD cells. Nevertheless, as discussed above, the relationship between the compositional changes associated with elevated loop flow rates and MD cell volume is not entirely clear. ATP release could also be related to any of the changes caused by stimulation of NaCl transport acrosss apical or basal membranes of MD cells. NKCC2 activation is followed by increases in cytosolic Na and Cl concentrations, increases in cytosolic pH, and membrane depolarization.[16,30,33,173,254] MD depolarization by about 30 mV following an increase of luminal [NaCl] to 150 mM occurs over the 20−60 mM range, and it therefore parallels the TGF response curve.[255] Depolarization may be directly involved in TGF responses, since the cation ionophore nystatin elicited afferent arteriolar vasoconstriction in the presence of low luminal NaCl and furosemide.[256] TGF responses were also seen when MD cells were depolarized by luminal application of the K ionophore valinomycin, together with 50 mM KCl. The valinomycin-induced vascular response was not affected by the Cl channel inhibitor NPPB (5-nitro-2-(3-phenylpropylamino) benzoic acid), whereas the normal NaCl-induced response was fully blocked by NPPB.[256] Thus, it appears that TGF responses depend upon MD cell depolarization

independent of the specific mechanism underlying the PD change, but evidence is needed to establish that the depolarization by valinomycin or nystatin is restricted to MD cells, and does not affect arteriolar smooth muscle cells.

MD cell depolarization may be linked to TGF responsiveness through its effect on MD cytosolic calcium $[Ca]_i$. Transport-induced changes in MD $[Ca]_i$ have been suggested to play a specific role in coupling the luminal electrolyte signal to the vascular response.[257] The Ca ionophore A 23187 in the presence of luminal Ca enhanced TGF responsiveness, whereas blocking Ca release from intracellular stores with 8-(N,N-diethyl-amino)-octyl-3,4,5-trimethoxybenzoate (TMB 8) and chelation of Ca with BAPTA-AM diminished it.[257–259] Ca entry may occur through a voltage-activated and nifedipine-sensitive Ca channel in the basolateral membrane,[260] but increased flux across a 20 pS non-selective cation channel with finite Ca permeability reduced Ca extrusion by Na/Ca exchange, and utilization of a conductive Ca entry pathway across the apical cell membrane is an alternative possibility.[259,261,262] Despite the evidence supporting an important role of $[Ca]_i$ it is far from certain that the $[Ca]_i$ changes occurring in response to fluctuations of luminal NaCl between 20 and 60 mM *in vivo* are large and consistent enough to establish a systematic and causal association between MD $[Ca]_i$ and the TGF response. In fact, the relationship between luminal NaCl and MD cytosolic calcium has been described as positive,[260] negative[49] or entirely absent,[150] perhaps indicating that the changes of $[Ca]^i$ in MD cells may be too small to be safely distinguishable from experimental noise in this technically demanding experimental approach.

A novel role for MD cell depolarization may be activation of NADPH oxidase and generation of superoxide that may directly or by scavenging NO enhance TGF.[263] An increase in NaCl delivery to the MD in the isolated perfused JGA preparation caused about a three-fold increase in superoxide production that was largely inhibited by tempol or apocynin.[264,265] Activation of NADPH oxidase appears to be the direct result of depolarization, since depolarization with valinomycin increased superoxide production and the hyperpolarization following furosemide-induced inhibition of NaCl uptake reduced it.[265] The enhanced activity of the NOX2 isoform of NADPHase oxidase following membrane depolarization may be associated with translocation of the small GTP-binding protein Rac to the plasma membrane.[266–268]

Integrated Function of the TGF Mechanism

The JGA control system is constructed as a negative, homeostatic feedback loop. The physiological purpose of this regulatory loop has been the subject of a substantial body of investigation using both experimental approaches and mathematical modeling. One potential effect of the operation of the TGF feedback loop is to reduce fluctuations of NaCl concentration at the MD, thus reducing the variability in the delivery of NaCl into the relatively low-capacity transport system of the distal nephron. Another role hypothesized for the TGF loop is in the autoregulatory adjustments in vascular resistance that promote constancy of GFR when arterial pressure changes.

The two hypothesized roles, regulation of distal salt delivery and control of GFR, are functionally interrelated; the feedback loop may contribute to stabilization of NaCl excretion, rendering it relatively independent of fast and irregular fluctuations in perturbing forces that are not the expression of an adaptation to a change in body Na balance. Such variations are represented, for example, by the marked fluctuations in blood pressure that have been observed to occur throughout the day and with changing body activities.[269] In the absence of tight control of vascular resistance, glomerular capillary pressure, and hence GFR, would be expected to fluctuate in parallel with blood pressure, causing changes in Na excretion unrelated to the NaCl status of the organism. Since, however, changes in GFR will in general be followed by parallel changes in distal NaCl concentration, the TGF system can dampen the amplitude of the predicted GFR changes. Similar rapid hemodynamic adjustments will occur with other acute perturbations of MD NaCl concentration resulting from variations in cardiac output, renal blood flow or proximal tubular transport. As discussed below, the TGF mechanism changes its response characteristics when perturbations of MD NaCl concentration are sustained for extended periods of time.[270] The homeostatic efficiency of TGF in the regulation of distal salt delivery and *SNGFR* is greatest in the vicinity of the operating point where fractional compensations of small input perturbations may be between 0.6 and 0.75, corresponding to an open loop gain of around 3.[122,271]

Participation of TGF in autoregulation

Acute changes in mean arterial pressure induce adjustments in renal vascular resistance which stabilize renal blood flow and glomerular filtration rate over a wide range of pressures. Pressure-induced resistance changes in the kidney have been proposed to be TGF-mediated.[272,273] A role of TGF in steady-state autoregulation was first supported by the observation in both dogs and rats that interruption of the TGF loop in single nephrons causes *SNGFR* and P_{SF} to vary directly with arterial pressure.[124,184,274–279] Pressure dependency of *SNGFR* was noted regardless of whether the TGF loop was physically disrupted by injecting an oil

block, blocked acutely by adding furosemide to the perfusate[274] or inhibited by chronic treatment with DOCA and a high salt diet.[274] In contrast, arterial pressure had little effect on GFR when the TGF loop was intact.[124,274–278] In the *in vitro* perfused juxtamedullary nephron preparation, interference with the TGF mechanism by furosemide or physical interruption of the feedback loop markedly diminished autoregulatory diameter alterations of afferent arterioles,[195,280,281] and constancy of afferent arteriolar blood flow was no longer maintained.[281]

There is equally solid evidence for the existence of TGF-independent autoregulatory resistance changes. Glomerular arterioles in kidney tissue transplanted to the cheek pouch of the hamster showed marked autoregulation of vessel diameters.[282] In the hydronephrotic kidney model which does not possess an operating TGF system, a decrease in arterial pressure increased vessel diameters along the entire preglomerular vasculature, except for the portion of the afferent arteriole near the glomerulus.[283] Isolated afferent arterioles and interlobular arteries of the rabbit maintained their diameter when luminal pressure increased,[284,285] while perfused afferent arterioles from the mouse showed an 11% diameter reduction with a doubling of perfusion pressure from 40–80 mmHg accompanied by a linear increase in wall tension.[286] The nature of the TGF-independent regulator is unclear, but an intrinsic myogenic mechanism responding to wall tension or mechanical stress is the most likely possibility.

Existence of at least two regulators is further supported by studies in which the dynamic response of renal blood flow to random fluctuations of blood pressure has been analyzed. Frequency domain analysis of renal blood flow using linear techniques revealed the presence of a regulator with a frequency response compatible with the TGF mechanism, about 0.01 Hz, and a faster mechanism with a frequency characteristic consistent with myogenic vasomotion, about 0.1 Hz.[287–289] Since the TGF system is nonlinear, it is important that a similar conclusion has been reached from the more recent application of nonlinear system analysis.[290–292] The existence of two regulators with similar frequencies has also been established in spontaneously hypertensive and Dahl rats.[293–295] There is evidence for the operation of two regulating mechanisms in conscious dogs and mice.[296,297] Interference with the slow component was observed in a number of experimental models of TGF interruption, including A1AR-deficient mice, ureteral obstruction, converting enzyme inhibition, and the perfused hydronephrotic kidney.[294,298–300] Temporal resolution of the adjustment of renal vascular resistance to step-changes in renal arterial pressure is consistent with the sequential operation of several mechanisms with different response times.[301–303] Various approaches and analyses have concluded that the quantitative contribution of TGF to autoregulation may be between 30 and 60%.[181,274,275,278,281,302] In addition to the TGF and myogenic components, evidence for the presence of a third mechanism with a slow response time has been obtained that may be of particular importance at low perfusion pressures.[302,303] Furthermore, an afferent arteriolar constrictor mechanism has been identified that responds to the systolic pressure peaks rather than to mean arterial pressure, and therefore must possess a response time in the frequency of the heart rate.[304,305] This mechanism is thought to protect the glomerular vasculature against the high pressures exerted during systole.

Interaction between the two autoregulatory mechanisms may lead to amplification of vascular responses. Models of autoregulation suggest that a TGF-dependent vasoconstriction can induce a myogenic response in upstream vascular regions and amplify the resistance increase.[206,306,307] In fact, mathematical modeling suggests that a myogenic contribution from proximal vascular segments is necessary for distal mechanisms such as TGF to contribute to resistance regulation.[308] Spatial separation between the two regulatory mechanisms along the afferent arteriole has been noted, with TGF being most effective in the region of the afferent arteriole close to the glomerulus, and the myogenic component being more pronounced in more proximal portions of the afferent arteriole.[195] Interactions between the myogenic response and TGF have been demonstrated at both the single nephron and the whole kidney level,[290,309] and they have been the subject of extensive mathematical modeling.[292,310,311] One of the conclusions is that elimination of a variable TGF signal enhances myogenic responsiveness.[301,309,310,312] Recent evidence indicates that the restraining effect of TGF on the myogenic mechanism is mediated by nitric oxide.[313,314] Functional coupling of small ensembles of nephrons by ascending myogenic or conducted vascular responses adds to the complexity of regulation of preglomerular vascular tone.[132,209] Enhanced nephron-to-nephron coupling has been suggested to be responsible for the more efficient dynamic autoregulation in spontaneously hypertensive rats.[133,207,293]

Role of TGF in Response to Transport Alterations

HYPERTONIC NaCl

Administration of hypertonic NaCl causes vasodilatation in most vascular beds, but in the kidney it results in an anomalous vasoconstriction.[315] This response may be a whole kidney equivalent of the response of *SNGFR* to increased loop flow rate. Both TGF- and NaCl-induced vasoconstriction are enhanced by salt

depletion[316,317] and inhibited by furosemide, theophylline or DOCA-salt treatment.[159,232,318–320] Furthermore, hypertonic non-chloride containing solutions usually do not produce vasoconstriction.[317] A micropuncture study in the rat revealed that an infusion of hypertonic NaCl reduced proximal tubular fluid absorption and increased loop flow rate, and that *SNGFR* fell as a result of these changes.[321]

PROTEIN FEEDING

The vasodilatation caused by acute and chronic protein feeding may include a TGF-dependent component. In conscious dogs, furosemide and ethacrynic acid blocked the acute rise in GFR following a meat meal, suggesting that the postprandial vasodilatation may be TGF-dependent.[322] It has been proposed that the rise in filtered amino acids causes an increase in proximal Na and fluid absorption, and a decrease in MD Na delivery.[322]

Chronic consumption of a high-protein diet induced a rightward resetting in the feedback curve of normal and Goldblatt hypertensive rats, so that higher flows were necessary to suppress GFR than in control or low-protein fed animals.[323,324] In normotensive animals the response amplitude and the slope of the feedback function were unaltered.[324] These effects appear to be due to alterations in transport along the loop of Henle, since NaCl concentrations in distal tubular fluid during loop perfusion were 30% lower in rats on a high-protein diet than in rats on a low-protein diet.[325] Consistent with this notion is the observation that TGF responses were the same in the two groups of rats when loops of Henle were perfused in a retrograde fashion, indicating that functional changes in the loop of Henle rather than at the level of the JGA were responsible for the protein-induced changes in TGF characteristics. The increased rate of NaCl transport along the loop of Henle caused by high-protein feeding may result from structural adaptations.[326]

INHIBITION OF PROXIMAL TRANSPORT

Diuretics that inhibit predominantly proximal tubular fluid absorption may cause a TGF-dependent decrease in GFR as a result of increased distal NaCl delivery. In support of this hypothesis, several studies using carbonic anhydrase inhibitors, as well as chlorothiazide, suggest that these agents cause *SNGFR* to fall more with the TGF loop intact than with the TGF loop interrupted.[165,211,327] In view of the Cl dependency of TGF, however, the acute TGF activation by carbonic anhydrase inhibition is unexpected since these drugs, while causing an increase of early distal [Na], do not elevate distal Cl concentrations.[165,327] There is no evidence to show that HCO_3 can substitute for Cl in initiating TGF responses. In fact, recent studies have shown that the effect of benzolamide to reduce GFR and RBF was maintained in $A1AR^{-/-}$ mice which are unable to generate a TGF response.[328] Thus, the mechanism of the renal vasoconstriction caused by CA inhibitors is not entirely clear, but a rise in tubular pressure may be an important contributor.[329,330] In addition, studies in rats and mice indicate that major increases in urine flow, including those caused by furosemide, may lead to increases in total renal vascular resistance even when participation of TGF is *a priori* unlikely.[331,332]

SNGFR of mice with targeted deletion of AQP1 was found to be significantly reduced compared to wild-type when it was determined in distal nephron segments with the TGF pathway intact.[333] The fall in GFR was dependent upon distal fluid delivery, since it was not observed when *SNGFR* was measured in the proximal tubule with the TGF loop interrupted.[333] Mice deficient in both AQP1 and A1AR which combine a proximal transport defect with absent TGF responsiveness, have been found to have a normal distal *SNGFR*, supporting the notion that the fall of GFR in $AQP1^{-/-}$ mice is TGF-mediated.[334]

Very similar results were obtained in mice with a knockout mutation in the apical Na/H exchanger NHE3, another model of established proximal tubular NaCl and fluid malabsorption.[335] Considering that distal flow rates were not different between wild-type and AQP1 or NHE3 knockout mice, it seems unlikely that TGF activation is due to an increased NaCl concentration at the MD. Resetting of the TGF function curve (discussed below) subsequent to extracellular volume depletion seems to be more likely as causation for enhanced TGF engagement.

Adaptation of TGF Response Characteristics

EXTRACELLULAR FLUID VOLUME

Adaptations in the TGF function occur whenever MD NaCl concentrations deviate from normal for an extended period of time. Typically, such deviations result from alterations in body Na content, with volume expansion associated with persistently increased, and volume depletion associated with decreased, MD NaCl concentrations. Formally, two types of adaptation in the TGF relationship can be distinguished. TGF *resetting* refers to a shift in the range over which the system is operating, either a shift to the right, to higher flows or concentrations or a shift to the left, to lower flows or concentrations. A change in TGF response *sensitivity* refers to an altered response, either altered slope and/or maximum response magnitude. By and large, volume depletion is associated with a left shift and an increase in response magnitude, and volume expansion with the opposite, but the actual adaptation observed has varied with the protocol used.

A number of studies have established that acute expansion of the extracellular space by infusion of isotonic saline or plasma reduces the TGF response magnitude and slope, and increases $V_{½}$ in both superficial and juxtamedullary nephrons.[127,336–341] Impaired TGF responses have been observed during chronic volume expansion caused by the administration of DOCA together with isotonic saline as drinking fluid.[274,320,342] The combination of a right shift and a reduced response magnitude is not invariant. Short-term volume expansion by a bolus injection of dilute rat plasma shifted the responsive range to higher flows, although this protocol produced an increase rather than a decrease in the maximum response magnitude[343]; *SNGFR* at zero loop flow rose 60%, whereas kidney GFR and free flow *SNGFR* rose only moderately with the position of the operating point and a large proximal–distal *SNGFR* difference indicating that the suppressing effect of the TGF mechanism was greater than normal. Thus, in these studies, the TGF mechanism appeared to counteract TGF-independent vasodilator influences on the renal vasculature. These data are consistent with closed-loop studies in which acute volume expansion with plasma did not reduce the maximum homeostatic efficiency, but shifted it away from ambient flows to lower flows, enhancing its dilatory and reducing its constrictor potency.[122]

The effects of an acute decrease of ECV have been studied in rats after acute hypotensive hemorrhage,[344,345] and in dehydrated rats.[346] In general, these interventions are accompanied by an increase in TGF response magnitude. Hypotensive hemorrhage induced a shift of the feedback curve to the left.[344,345,347] Since proximal absorption increased at the same time, the operating point tended to move toward the shoulder of the reset feedback function.[344] Thus, in this circumstance, the resetting results in reduced dilatory and enhanced constrictor capacity.

Studies have been performed to determine the time course of TGF adaptation. When single nephrons were perfused for extended periods of time, resetting developed over the initial 30–40 minutes of hyperperfusion, whereas changes in response magnitude were slower, requiring 40–60 minutes.[270] Similarly, acute volume depletion by furosemide restored TGF responses in chronically volume-expanded rats within 60–120 minutes.[342]

Other Conditions Associated with TGF Adaptation

URETERAL AND NEPHRON OBSTRUCTION

In the first few hours following complete unilateral ureteral obstruction (UUO), TGF reactivity appears to be completely abolished.[348–350] Elimination of the restraining effect of TGF is reflected by increased renal and glomerular plasma flows and elevated glomerular capillary pressures.[351] After persistence of ureteral obstruction for 24 hours, TGF activity is restored and possibly slightly enhanced, as indicated by a reduced $V_{½}$.[350,352] Augmentation of TGF responses in hydronephrotic kidneys appears to be caused by increased superoxide formation and NO deficiency, since nNOS blockade was without effect and tempol administration normalized TGF responsiveness in hydronephrotic animals.[353,354] The dominant effect of prolonged ureteral obstruction is a marked reduction of glomerular capillary pressure and glomerular plasma flow, changes which result in a dramatic reduction of GFR.[349,355] The apparent absence of a luminal signal suggests that vasoconstriction is not equivalent to the standard TGF response discussed so far. On the other hand, obstruction of a single nephron for 4 hours also causes marked vasoconstriction, indicating that persistent interruption of distal delivery produces a local constrictor signal of unknown nature.[356–358]

Following release of short-lasting ureteral obstruction TGF reactivity is increased,[349] and it is maintained in its somewhat activated state after release of an obstruction of 24 hours duration.[350,352] It is possible that the activated TGF mechanism is in part responsible for the continued vasoconstriction following release of both ureteral and single nephron obstruction.[352] However, additional mechanisms appear to contribute to the reduction in filtration after release of obstruction, since *SNGFR* at zero flow increased only slightly above distal values.[352] Furthermore, nephron and kidney filtration rates were also markedly suppressed after release of bilateral ureteral obstruction, even though in this experimental condition TGF responses were blunted rather than enhanced.[350,352]

During partial unilateral ureteral obstruction for 3–6 weeks, TGF reactivity appears to be in the normal range.[359,360] During volume expansion, on the other hand, TGF reactivity increased in the hydronephrotic kidney whereas it was strongly inhibited in the nonobstructed contralateral kidney.[359] The enhanced TGF reactivity seen in hydronephrotic kidneys during volume expansion could be prevented by thromboxane synthase inhibition.[360] A similar paradoxical enhancement of TGF reactivity by volume expansion was less pronounced during chronic bilateral ureteral obstruction.[361]

LOSS OF RENAL MASS

In the first hours following unilateral nephrectomy, TGF responses in the residual kidney may be enhanced and ambient distal flows may exert a GFR-depressing effect as judged from an increase in the proximal–distal *SNGFR* difference, without a change in the proximal value.[362] However, at later time points

uninephrectomy or 5/6 ablation has been shown to shift the TGF function to the right, with[363] or without increasing the maximum response.[364,365] A similar response to nephrectomy was noted in transplanted kidneys.[364] On the other hand, a striking variability in *SNGFR* responses to loop of Henle perfusion was noted in rats with subtotal nephrectomy, in which the average TGF response was zero. Unexpectedly, AT1 blockade restored TGF responses for reasons that are not clear.[366] To the extent that the most striking change is a TGF-independent increase in GFR (Y-intercept of the TGF function or proximal *SNGFR*) these results are reminiscent of the findings during growth-related increases in renal weight, and suggest an adaptation of the TGF function curve to a primary increase in GFR.[121,367]

HYPERGLYCEMIA

Moderate hyperglycemia produced by either acute glucose infusion[368] or streptozotocin-induced diabetes mellitus[369] reduced the amplitude of the TGF response and shifted $V_{1/2}$ to higher flow rates.[368] Type 2 diabetic rats of the OLETF strain have significantly diminished TGF responses accompanied by reduced autoregulatory efficiency even in the pre-diabetic stage.[370] Reduced TGF responses have also been observed in the Akita mouse model of type 1 diabetes mellitus, as well as in hydrated db/db mice, a model of type 2 diabetes.[371,372] This reduced capacity to compensate for experimentally-induced perturbations was also demonstrable under closed-loop conditions.[373] The reduction in the TGF response magnitude may in part be caused by a reduction in NaCl concentration, and the presence of glucose in tubular perfusion fluid.[368,374,375]

It has been suggested that the hyperfiltration of early diabetes is caused by TGF, as a result of excessive salt reabsorption in nephron segments upstream from the MD and the resulting reduction in MD NaCl concentration.[376,377] This hypothesis is supported by the demonstration that tubular transport proximal to the macula densa is in fact enhanced in diabetic animals.[378,375] Structural adaptations participate in tubular hyper-reabsorption; inhibition of the enzyme ornithine decarboxylase blocked the renal hypertrophy in a rat model of diabetes mellitus,[379] and attenuated both the enhanced proximal reabsorption and the increase in GFR.[378] On the other hand, it has been argued that TGF may actually prevent excessive hyperfiltration in diabetes.[380] A protective action of TGF is supported by the finding that diabetic mice of the Akita strain display an exaggerated hyperfiltration when TGF is rendered inoperative by A1AR deletion.[371] Hyperfiltration in alloxan-diabetic mice deficient in A1AR also suggests that TGF is not the primary cause of hyperfiltration in this diabetic model.[381]

Both in streptozotocin-treated rats and in diabetic humans, a paradoxical relationship between salt intake and GFR or renal plasma flow has been observed, with high salt intake producing a decrease instead of the expected rise of GFR,[375,382] an effect which was absent when kidney growth was suppressed by inhibition of ornithine decarboxylase.[383] These observations are consistent with the notion that the TGF adaptation during changes in extracellular fluid volume may be defective in diabetic animals. Whereas TGF desensitization normally prevents a non-homeostatic reduction of GFR during volume expansion, absent or incomplete resetting of TGF in diabetes appears to permit persistent GFR deviations. Altered resetting in diabetic animals could be a consequence of abnormal RAS activation or dysregulation of NO generation, factors thought to be involved in TGF adaptation.[372,384,385] Nevertheless, the paradoxical low salt-induced increase and high salt-induced decrease of GFR has not been found in all studies of diabetic patients and animals.[386–388] Differences in the dietary background, aside from NaCl content, may be an important modifying factor.[389]

RENAL SYMPATHETIC NERVE ACTIVITY

Whereas some experiments did not detect an effect of acute denervation or renal nerve stimulation on the TGF function curve in normotensive animals,[390,391] other studies have reported that denervation causes a time-dependent resetting of TGF to higher values of $V_{1/2}$ without changes in the maximum response.[392] Changes in TGF function persisted for at least one week, and were associated with increased GFR and Na excretion.[393]

Mechanisms of TGF Adaptation

RENIN–ANGIOTENSIN SYSTEM

The local activity of the renin–angiotensin system appears to be the most consistent determinant of TGF sensitivity. Converting enzyme inhibitors or angiotensin-receptor blockers in relatively high doses cause a reduction of the TGF response magnitude by about 50–60%.[394–398] An essentially complete inhibition of TGF responsiveness was seen in mice with a null mutation in the AT1A receptor, the major renal receptor for angiotensin I[185]. Similarly, TGF responses were essentially absent in ACE knockout mice, an effect that was in part reversible with infusion of subpressor doses of angiotensin II.[399] Studies in mice with deletion of tissue ACE or with selective expression of ACE in either blood vessels or proximal tubules suggest that the angiotensin II that is required for full TGF responsiveness is derived both from the action of membrane-associated ACE in endothelial cells, and from systemic

ACE,[400] while exclusive expression of ACE in proximal tubules is unable to sustain normal TGF responses.[401] This conclusion is consistent with earlier observations that angiotensin infusion partly restored feedback responsiveness during captopril-induced TGF inhibition.[402,403] Intravenous or peritubular infusion of angiotensin II enhanced TGF responses in untreated control rats, a property not shared by other vasoconstrictors such as vasopressin and norepinephrine.[404,212] Conversely, the arteriolar constrictor response to angiotensin II was greater during simultaneous TGF activation in both the isolated afferent arteriole/MD double-perfusion approach, and in the blood-perfused juxtamedullary nephron preparation.[405,406] Since local adenosine levels are thought to increase during TGF activation, this augmentation is possibly due to the effect of adenosine in preventing angiotensin II desensitization.[407] In accordance with the role of TGF in autoregulation, angiotensin II has been noted to enhance the TGF component of dynamic autoregulation.[408–410] The suppression of TGF responsiveness caused by acute volume expansion could be fully overcome by the infusion of angiotensin II at doses that restored normal plasma angiotensin II levels.[341] Taken together, these results indicate that an AT1A receptor-mediated effect of angiotensin II is a required constituent of the TGF pathway. The requirement for angiotensin II may result from the well-described synergistic interaction between the vascular effects of angiotensin II and of the TGF mediator adenosine.[223,226,411–413] The mechanism of this interaction has been suggested to result from an intracellular action of adenosine that enhances the calcium sensitivity of myosin light chain phosphorylation or prevents desensitization of angiotensin II receptors.[407,414] Contributing factors may be upregulation of MD NaCl transport by angiotensin II or enhanced production of feedback-enhancing superoxide radicals.[266,415]

The TGF-modifying effect of angiotensin II gains special importance in view of the fact that changes in NaCl in the tubular fluid in the MD region not only affect vascular tone, but also regulate renin secretion (see below). This dual effect of MD NaCl has the potential to automatically adjust TGF sensitivity to the NaCl status of the organism. When the combined external forces determining GFR and proximal and loop of Henle absorption cause deflections in MD NaCl concentration which exceed the range over which TGF operates effectively, persistent changes in MD NaCl occur which will cause an inverse change in renin secretion. The change in angiotensin II concentration resulting from the altered rate of renin secretion, in turn, is predicted to alter TGF sensitivity. For example, an increase in MD NaCl resulting from extracellular volume expansion will decrease renin secretion, and the decrease of angiotensin II concentration expected to gradually develop is then predicted to uncouple GFR from MD control.

EICOSANOIDS

The presence of both isoforms of cyclooxygenase (COX) in the juxtaglomerular region raises the possibility of a participation of prostaglandins in JGA cell-to-cell signaling. COX-1 is expressed in mesangial cells and in endothelial cells of afferent arterioles,[416] whereas COX-2 activity has been demonstrated in epithelial cells of thick ascending limb and MD.[417] Maximum TGF responses have been found to be inhibited by the intravenous or luminal application of high concentrations of non-specific COX inhibitors, as well as specific inhibitors of both COX-2 and COX-1.[418–422] The conclusion that the net effect of PGs on TGF is enhanced vasoconstriction is supported by the finding that arachidonic acid elicits a constrictor rather than a dilator response when administered by retrograde luminal infusion.[423] Thromboxane (TP) is a vasoconstrictor prostaglandin that has been implicated in TGF on the basis of the finding that the intravenous administration of inhibitors of TP receptors or of TP synthesis reduced the magnitude of the TGF-induced vasoconstrictor response.[360,398,422] TP receptor blockade also interfered with the TGF reducing effects of COX-2 and COX-1 inhibitors, indicating that these effects were TP-dependent.[418] Conversely, activation of TP receptors by U-46,619 or by the isoprostane 8-isoprostaglandin F2α enhanced TGF responses,[424] and COX-1 generated prostaglandins, presumably TP, may contribute to the TGF-enhancing effects of angiotensin II.[425] Low levels of glomerular thromboxane synthase may limit thromboxane formation under basal and low-salt conditions[426,427]; in fact, attenuation of TGF responses by systemic or luminal application of blockers of TP receptors or of TP synthesis has not been found in all laboratories,[360,398,422,423] and normal TGF responses have been observed in TP receptor knockout mice.[428] Administration of a high-salt diet, on the other hand, caused a 20-fold increase of thromboxane synthase expression, as well as a stimulation of TP receptor levels.[426,429] These observations provide an explanation for the finding that the TGF response in the presence of the TP mimetic U-46,619 is augmented in high-salt fed animals.[426] TP receptor activation may also contribute to the exaggerated TGF responses observed in young spontaneously hypertensive rats (SHR).[430] In contrast to these conclusions, studies in the blood-perfused juxtamedullary nephron preparation indicate that TGF activation is accompanied by nNOS-dependent enhancement of COX-2 activity and subsequent generation of vasodilatory PG metabolites which counteract TGF-mediated vasoconstriction.[431]

There is some evidence that 20-hydroxyeicosatetraenoic acid (20-HETE), an arachidonic acid metabolite endogenously generated in afferent arterioles by the 4A family of cytochrome P450 enzymes, may be involved in the TGF response.[432] Two inhibitors of cytochrome P450 enzymes, 17-octadecynoic acid (ODYA) and clotrimazole, caused a marked attenuation of the TGF response when added to the luminal perfusate for an extended period of time, and this inhibition could be overcome by the administration of exogenous 20-HETE.[433] The presence of the mRNAs for cytochrome P450 4A2, 4A3, and 4A8 has recently been demonstrated by RT-PCR in glomeruli and most segments of the tubule, while preglomerular arterioles appear to express only the 4A2 isoform.[434] Immunocytochemistry with a polyclonal non-specific P450 4A antibody showed cortical presence of P450 4A protein in proximal tubules, thick ascending limbs, glomeruli, and preglomerular arterioles.[434] Exactly how locally formed 20-HETE affects the TGF pathway is unclear. In addition to its vasoconstrictor properties, 20-HETE has been shown to inhibit TAL NaCl transport by blocking Na,K,2Cl co-transport, Na,K-ATPase, and by closing K channels.[435] This combination of effects should result in a powerful inhibition of NaCl transport in thick ascending limb and presumably MD cells, so that increments in 20-HETE production would be expected to attenuate, not enhance, TGF responses. It is conceivable, therefore, that ODYA and clotrimazole inhibit the TGF response in a non-specific way by causing a reduction in baseline afferent arteriolar tone.[436] It is also possible that 20-HETE acts as an intracellular second messenger for the TGF-mediating agent.[432,437]

NITRIC OXIDE

Luminal application of non-specific and nNOS-selective inhibitors of NO synthases has been shown to enhance MD-mediated vasoconstrictor responses both *in vivo* and *in vitro*.[55,438–441] These findings demonstrate tonic attenuation of TGF responsiveness by NO generated by nNOS in MD cells, an effect that is cGMP-dependent.[442] TGF responses of stop flow pressure *in situ* and afferent arteriolar diameter reductions *in vitro* in response to elevated MD [NaCl] were similar in nNOS-deficient and wild-type mice,[443,444] but the specific mutation in these mice does not exclude the possibility of maintained expression of β and γ splice variants of nNOS.[57] Nevertheless, the proximal–distal *SNGFR* difference was significantly higher in the $nNOS^{-/-}$ animals, and luminal administration of a non-specific NOS inhibitor (NLA 10^{-3} M) caused an augmentation of TGF responses only in wild-type, but not in nNOS knockout, mice.[444] Luminal and systemic administration of NOS inhibitors reversed the attenuation of TGF responses caused by an acute saline infusion, suggesting that NO contributes to the TGF resetting caused by volume expansion.[445]

NO may affect TGF by altering the function of MD cells. In the isolated double-perfused JGA preparation, inhibition of soluble guanylate cyclase or cGMP-dependent protein kinase mimicked the TGF-potentiating effect of a nNOS inhibitor when administered from the tubular side, whereas there was no effect when inhibitors were added to the vascular perfusate.[446] The cGMP-dependent mechanism may be inhibition of NaCl uptake, since inhibition of Cl fluxes by NO is mediated by soluble guanylate cyclase in TAL cells.[447] Formation of NO may occur in MD cells, but a contribution of NO produced by eNOS in TAL cells appears to also affect MD cell function.[448]

The relationship between luminal NaCl concentration and NO formation in MD cells has been addressed by using the NO-binding agents DAF-AM DA and DAF-AM. Two independent studies agree that an increase in luminal NaCl causes an increase in fluorescence in MD cells, as well as in their surroundings, and that this increase was prevented by an inhibitor of nNOS.[48,449,450] Since the concentration steps causing increased NO formation were between 35 and 135 mM in one study and between 60 and 150 mM in the other, it has been concluded that supraphysiological NaCl changes are necessary to stimulate NOS.[449] That the stimulation of nNOS activity by high luminal NaCl is Ca-dependent is unlikely, since NaCl does not consistently elevate $[Ca]_i$, and since an activation of NOS was seen in Ca-free medium.[48] Another explanation for the increased formation of NO is based on the fact that the pH optimum of NOS is in the slightly alkaline range.[451] Since an increase in luminal NaCl caused cell alkanization, it is conceivable that pH-dependent disinhibition of nNOS is responsible for the enhanced NO generation.[30] This notion is supported by the observation that dimethyl amiloride increased TGF responses, and that an nNOS-specific inhibitor in the presence of the NHE blocker did not further enhance the TGF reaction.[450,452] Furthermore, amiloride as well as 7-nitroindazole blunted the increase in NO formation caused by elevated luminal NaCl.[450] Stimulation of NO formation by high-luminal NaCl is consistent with the earlier observations that the effect of NOS blockade on TGF-dependent vasoconstriction is greater at high than at low flows.[453] Increases in luminal flow rate also stimulate NO formation by TAL cells, but in contrast to MD cells stimulation is strictly shear stress-dependent, and independent of NaCl transport.[454,455] NaCl independence is difficult to reconcile with direct NO measurements performed with carbon fiber electrodes in the distal tubule which have shown an increase in the amount of NO and in NO concentration during perfusion of loops of

Henle with furosemide, suggesting that transport inhibition along the entire loop of Henle stimulates emission and downstream convection of NO.[456] These results seem consistent with observations in an MD cell line showing increased NO generation during exposure to low chloride or furosemide.[457]

In the absence of hemoglobin, the biological half-life of NO in relation to the diffusion distance across the JGA would seem long enough to permit a direct interaction of NO released by MD cells with smooth muscle cells of the afferent arterioles. Nevertheless, NO inactivation may be an important modulator of the effect of NO on TGF. Reactive oxygen species have been identified as a factor that can markedly reduce bioactive NO levels. MD cells express NADPH oxidase isoforms NOX2 and NOX4, together with the required constituents of the active enzyme complex p47phox, p67phox, p22phox, and Rac.[268,458] A high-luminal NaCl appears to activate NADPH oxidase, and this activation is pH-dependent since blocking Na/H exchange with dimethyl amiloride or acidification of the luminal perfusate diminished superoxide production.[459] Production of the NO scavenger may limit the impact of NO that is stimulated in MD cells at the same time by the same mechanism. The membrane-permeant superoxide dismutase mimetic tempol can diminish TGF responses *in vivo* and in the perfused JGA preparation, but this effect is usually not very pronounced under control conditions.[263,354,460,461] Since tempol had no effect in the presence of a NOS inhibitor, it appears that any effect is due to an increase in NO bioavailability.[263,460] In spontaneously hypertensive rats (SHR) the expression of NADPH oxidase subunits is elevated, and the TGF-inhibiting effect of tempol is enhanced compared to normotensive controls, suggesting increased oxidative stress in SHR and reduced bioavailability of NO.[458,461] This observation is in accordance with the earlier finding that inhibition of nNOS did not enhance TGF responses in SHR.[462] Angiotensin II may be in part responsible for the activation of NADPH oxidase in SHR, since candesartan restored normal TGF responses to NOS inhibition.[463] A high salt intake may be another situation in which the generation of superoxide is increased as indicated by increased expression of NADPH oxidase subunits, and increased excretion of isoprostanes.[464] However, the TGF-enhancing effect of NOS inhibition was augmented rather than reduced in rats on a high-salt diet.[465,466] NO availability may also be regulated by ADMA (asymmetric dimethylarginine), an endogenous NOS inhibitor that also inhibits cellular uptake of the NOS substrate arginine. In fact, ADMA in the luminal perfusate enhanced TGF responses, and this effect appears to be the result of both inhibition of arginine uptake and of NOS activity.[467,468] Finally, NO may reduce TGF responses by inhibition of ecto-5′-nucleotidase, an intervention that would be predicted to reduce extracellular adenosine levels.[469,470]

OTHER VASOACTIVE FACTORS

A reduction in TGF reactivity has been observed subsequent to the systemic administration of renal vasodilators such as atrial natriuretic factor,[471,472] histamine,[436] dopamine,[473] high concentrations of PGI_2,[474] bradykinin,[348] uroguanylin,[475] and a number of vasodilating drugs.[199,200,436,476] Inhibition of heme oxygenase with stannous mesoporphyrin enhanced TGF-induced vasoconstriction in the isolated tubule/vessel preparation, and the administration of the CO-releasing agent CORM-3 (tricarbonylchloro[glycinato]rutheniumII) inhibited it, suggesting that carbon monoxide reduces TGF.[477] Since the presence of heme oxygenases in the MD has not been established, it is likely that carbon monoxide affects TGF by its vasodilatory properties.[478,479] Furthermore, TGF reactivity is decreased by an acute reduction of arterial blood pressure,[309] probably as a consequence of non-TGF-mediated autoregulatory vasodilatation. It seems unlikely that all these agents specifically interact with the TGF mechanism at the JGA level to cause a reduction of renal vascular resistance. Rather, the adjustment of TGF responsiveness may be the non-specific consequence of vasodilatation, reflecting a dependency of vascular resistance changes on the initial wall thickness−radius ratio.[480] Since the predominant effector of the TGF response is the afferent arteriole, a resistance change at this site would appear to be most likely to modulate TGF sensitivity.

INTERSTITIAL PRESSURE

TGF reactivity has been shown to increase during peritubular capillary perfusion with a hyperoncotic solution, whereas perfusion with protein-free solutions reduced TGF responses.[481] Changes in response were seen after a time delay of about 20 minutes.[481] Based on these observations, the concept was developed that net interstitial pressure (the difference between interstitial hydrostatic pressure and interstitial oncotic pressure) may be an important determinant of TGF reactivity in general. It was subsequently shown that TGF reactivity correlated inversely with net interstitial pressure during acute NaCl infusion,[336,337,339,482] during short-lasting ureteral obstruction,[349] and after contralateral nephrectomy.[363,483] In all these conditions, $V_{1/2}$ increased and the TGF response amplitude decreased. Conversely, net interstitial pressure was found to be reduced by 24 hours of dehydration,[346,482] and before and after release of 24 hour unilateral ureteral occlusion.[350] TGF reactivity was increased in these experimental situations. Exactly how net interstitial pressure affects TGF reactivity is unclear.

RESETTING BY LUMINAL FACTORS

There are a number of circumstances in which unidentified factors in tubular fluid have been shown to modify responses. During chronic dietary salt-loading, TGF control was inhibited when native tubular fluid was used as perfusate, whereas responses were only slightly blunted during perfusion with an artificial fluid.[484] A luminal factor has also been reported to modify TGF during the infusion of atrial natriuretic peptide,[485] but this factor appears to enhance TGF responses compared to the blunting observed with artificial solutions. Loop of Henle perfusion with electrolyte-free plasma dialysates from patients with acute renal failure and liver dysfunction produced exaggerated TGF responses which could not be blocked by furosemide,[486] suggesting that the plasma in certain disease states contains a factor which can elicit NaCl-independent vasoconstriction when present in the tubular lumen.

MACULA DENSA CONTROL OF RENIN SECRETION

Following Goormaghtigh's early speculation,[487] Vander suggested that renin release might be influenced by tubular fluid composition at the macula densa.[488] During a variety of experimental conditions, plasma renin activity and sodium excretion appeared to be inversely correlated, whereas there was no correlation between renin and mean arterial pressure or renal blood flow.[489,490] The overall conclusion from these studies was that an increased delivery of NaCl to the MD cells inhibits renin secretion. These early observations have now been corroborated by additional evidence from whole animal studies and from isolated *in vitro* systems which have established the concept that a high NaCl concentration at the macula densa inhibits renin secretion.[488,491]

Evidence for Macula Densa Control of Renin Secretion

Studies in Intact Animals

Vander's proposal that renin secretion depends upon MD NaCl concentration was studied more directly by comparing renin secretion from normal or nonfiltering kidneys. In dogs in which basal levels of renin were elevated by thoracic caval constriction, intrarenal infusion of NaCl or KCl inhibited renin secretion, but such a response was not seen in similarly treated animals in which the infused kidney had been rendered nonfiltering by ureteral occlusion.[492] In conscious mice, acute infusion of isotonic saline, a maneuver that has been shown to result in increased distal tubular NaCl concentrations, leads to a suppression of renin secretion.[493,494]

Attempts have been made to evaluate the effect of changes in MD NaCl concentration at the single nephron level *in vivo*. In these studies in rats, renin concentration in proximal tubular fluid and in postglomerular blood collected by micropuncture was found to vary inversely with changes in distal NaCl.[495]

Studies in the Isolated Perfused TAL/Glomerulus Preparation

With the isolated perfused tubule technique it has been possible to study MD-dependent renin secretion in the absence of baroreceptor and regulated adrenergic inputs, and during precise control of tubular fluid composition.[491] Another important aspect of the isolated JGA preparation is that it limits the possible sites of tubulovascular information transfer to MD cells and possibly a small number of surrounding TAL cells as the only cells present in the area of contact. In this preparation (Figure 23.11) there is unequivocal

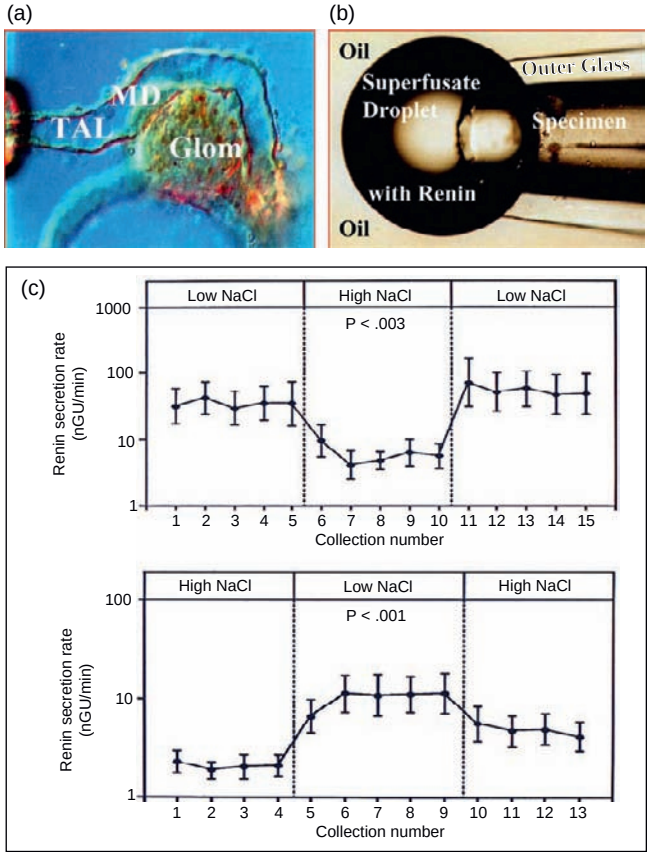

FIGURE 23.11 (a) Isolated perfused thick ascending limb (TAL) with attached glomerulus (glom); macula densa (MD) cells can be seen to protrude into the luminal space. (b) The perfused specimen is superfused through an outer glass pipette; emerging superfusate containing the secreted renin is collected under oil in defined time intervals.[595] (c) Macula densa-mediated changes in renin secretion showing the time course of changes in renin release to an increase (top) and decrease (bottom) in perfusate NaCl concentration.[497,498]

evidence that increasing NaCl concentration in the tubular perfusate suppresses renin secretion and reducing NaCl concentration stimulates it.[496–499] MD-dependent renin secretion is characterized by a rapid onset and offset following step-changes in NaCl concentration, and by reversibility of the induced changes.[497,499] Renin responses were independent of whether the tubule was perfused in an orthograde fashion from the TALH or in a retrograde fashion from the distal convoluted tubule.[497] Similar to the TGF response, MD-dependent renin secretion was not altered when NaCl concentration was reduced from isotonicity to about 80 mM, but the full renin response was seen when NaCl concentrations were varied between 7 and 61 mM of Cl and between 26 and 80 mM of Na, i.e., within the range that is physiologically relevant.[500] In the most sensitive concentration range between 7 and 47 mM of Cl, renin secretion increased by about 2 nGU/min per mM, whereas it fell by 0.4 nGU/min per mM when NaCl concentration was raised from 47 to 87 mM.[500] The NaCl concentration causing a half-maximum renin response is between 25 and 30 mM, values close to the estimated ambient NaCl concentration and close to the NaCl concentration causing a half-maximum TGF response. Although both decreases and increases of NaCl concentration are predicted to affect renin secretion, MD-dependent renin secretion is asymmetric around the operating point, with most of the responses occurring in the subnormal concentration range. Quantitative extrapolation from this *in vitro* system to the *in vivo* response must be made with caution, mainly because renin secretory responses *in vitro* are assessed in the absence of stabilizing feedback loops that may dampen MD-dependent changes in renin secretion *in vivo*.

Sensing Mechanism for Macula Densa-Mediated Renin Secretion

Renin Secretory Response and NaCl Transport

Early studies in intact animals suggested that, in certain conditions, renin secretion correlates more closely with distal tubular NaCl load than NaCl concentration, for example, during the infusion of hypertonic mannitol.[490,501,502] However, a reinvestigation of early distal NaCl concentration during mannitol diuresis showed a clear concentration decrease, in agreement with the stimulation of renin release typically seen in this condition.[503] In the isolated JGA preparation, an 80% reduction in luminal NaCl load by decreasing perfusate flow at constant NaCl concentration caused only a small, approximately two-fold increase in the rate of renin secretion. In contrast, when NaCl load was reduced to a similar degree by decreasing perfusate NaCl concentration, renin secretion increased nearly eight-fold, indicating that NaCl concentration is a more important determinant of renin release than NaCl delivery.[497]

Based on the stimulatory effect of loop diuretics in intact animals, it was concluded that MD NaCl transport plays a critical role as an early step in NaCl-dependent control of renin secretion.[488,490,504–507] Recent studies in mice deficient in the NKCC2A isoform of the co-transporter have shown that the inhibitory effect of an acute volume load on renin release is absent, supporting the notion that intact salt transport is required for salt-sensing by MD cells.[163] Direct evidence for an MD-mediated effect of transport inhibition on renin secretion was obtained in non-perfused afferent arterioles in which furosemide stimulated renin release only when the MD segment was included in the dissected specimen, but not in its absence.[508] In the isolated perfused JGA preparation, luminal application of bumetanide at 10^{-6} M increased renin secretion during perfusion with high NaCl solutions.[498] Furthermore, the presence of furosemide at 5×10^{-5} M essentially abolished the dependence of renin secretion on luminal NaCl concentration.[500]

Although NKCC2 mediates the bulk of MD Na reabsorption, apical expression of the Na^+/H^+ exchanger 2 (NHE2) may contribute to Na^+ transport, as well as to the regulation of intracellular pH.[30,32] In NHE2-deficient mice, renal renin content and plasma renin concentration were elevated compared to wild-type controls, and the stimulation of the renin system by a salt-depleted diet was blunted.[509] Increased baseline renin secretion in $NHE2^{-/-}$ mice was paralleled by enhanced MD COX-2 and mPGES expression. Recent studies have shown that plasma renin concentration is significantly elevated in NKCC1-deficient compared to wild-type mice.[510] Studies in isolated JG cells indicate that NKCC1 exerts a direct inhibitory effect on basal renin release.[119] This effect appears to be independent of the NKCC2-dependent inhibitory pathway through the macula densa, since the stimulatory effect of furosemide on renin release was essentially normal in $NKCC1^{-/-}$ mice.

Ion Specificity of Renin Secretion

MD control of renin secretion shows an apparent Cl dependency that is reminiscent of that described for TGF responses. Whereas the acute or chronic administration of various Cl or Br salts without Na inhibited renin secretion, Na salts without Cl as the accompanying anion had no effect.[493,511] Furthermore, changes in renin secretion under these conditions correlated with loop of Henle Cl absorption.[512] Conversely, an acute selective depletion of Cl by peritoneal dialysis increased plasma renin activity,[513] and substitution of

Cl by nitrate or thiocyanate in the perfusate of isolated kidneys stimulated renin secretion.[514] In the isolated perfused JGA, ion selectivity has been examined by measuring the inhibitory effect of adding various Na and Cl salts to a low NaCl perfusate. The inhibitory response was unchanged when most luminal Na was replaced by choline or rubidium.[498] On the other hand, substituting Cl by isethionate or acetate virtually eliminated the response to increased Na concentration.[498] Cl dependency is supported by studies in conscious mice showing that suppression of renin secretion following acute intravenous salt-loading is observed with infusion of NaCl, but not $NaHCO_3$.[515] These results support the hypothesis that the initiating signal for MD control of renin secretion is a change in the rate of NaCl uptake predominantly via a luminal Na,K,2Cl cotransporter whose physiological activity is determined by a change in luminal Cl concentration.

Organic Compounds and Renin Secretion

In addition to their function as sensors of TAL Cl concentration, MD cells are equipped with receptors for organic compounds, like the citric acid intermediate succinate. The succinate receptor GPR91 (succinate receptor 1, SUCNR1) has been shown to be localized in the apical membrane of cells of the cortical TAL, including the MD.[516] Increases in tubular succinate concentration result in the induction of the same intracellular signaling pathways that are activated by a low NaCl concentration. Incubation of cultured MD cells with succinate induced phosphorylation of p38 and Erk1/2 MAP kinases, and subsequent stimulation of COX-2 activity and expression in MD cells and enhanced PGE_2 release.[517] During streptozotocin-induced diabetes mellitus, renocortical COX-2 and renin content were upregulated in wild-type mice, and this stimulation of the renin system was markedly reduced in GPR91-deficient mice.[517] GPR91 expression in the vicinity of the JG cells, however, is not restricted to MD cells. GPR91 is also present in endothelial cells of the afferent arteriole, and may mediate renin release by stimulating endothelial prostanoid and NO formation.[518,519]

Furthermore, components of the olfactory system are present in MD cells.[520] MD cells rather specifically express the olfactory adenylate cyclase isoform 3 (AC3), as well as the olfactory trimeric G-protein G_{olf}. The olfactory receptor Olfr90 was detected in a MD cell line, and was also present in the native kidney.[520] Plasma renin concentration in AC3-deficient mice was reduced by about 50% compared to wild-types, despite increased MD COX-2 expression and augmented nNOS activity. The reason for these alterations of the MD–JG axis is unclear, and the ligands that may activate olfactory receptors on MD cells *in vivo* remain to be determined.

The Stimulus–Response Coupling Mechanism

Nitric Oxide

The presence of NOS I in MD cells raises the possibility that NO may act as an epithelium-derived factor that participates in MD control of renin secretion. This notion is supported by observations showing that the expression of MD nNOS changes in parallel with renin expression in a number of circumstances. MD cells of rats on a low-salt diet have increased levels of nNOS mRNA and protein expression.[59,60,521–523] Furthermore, the administration of furosemide also causes a marked increase in MD nNOS expression,[59,521] as does renal artery constriction.[59,521] The mechanism responsible for the upregulation of nNOS expression in these states is unclear, but a reduced NaCl transport at the MD is a common feature. Since the expression and secretion of renin is known to be elevated in these conditions, it is possible that NO generation is an upstream signal in the control of the RAS. The suggestion that a chronically reduced NaCl transport may stimulate MD nNOS expression is not immediately reconcilable with the evidence discussed earlier that acute increases in NaCl concentration appear to increase nNOS activity and NO formation. The expression of nNOS in MD cells is stabilized by negative feedback influences exerted by angiotensin II and PGE_2, since nNOS expression was markedly upregulated in mice with AT1 receptor or angiotensinogen deficiencies, as well as in COX-$2^{-/-}$ mice.[524–526]

Understanding the role of NO in renin secretion is complicated by the fact that NO can elicit both stimulatory and inhibitory effects. The inhibitory effect appears to result from activation of cGMP-dependent protein kinases (cGK), while the stimulatory effects are related to changes in intracellular cAMP levels. Two isoforms of cGK have been identified, cGK I and cGK II, and both isoforms have been found in granular cells.[108] A direct activator of cGK, 8-para-chlorophenylthio-cGMP, has been shown to inhibit isoproterenol- or forskolin-stimulated renin secretion in isolated perfused rat kidneys and microdissected afferent arterioles, and this stimulation could be reversed by an inhibitor of cGK.[527] A role for cGKII is suggested by the finding that 8-bromo-cGMP reduced basal and forskolin stimulated renin secretion in JG cells isolated from wild-type and cGK $I^{-/-}$ mice, but that it had no effect in cultures from cGK $II^{-/-}$ mice.[528]

The mechanism of the stimulatory effect of NO on renin secretion is related to an activation of the cAMP/protein kinase A pathway, and this activation results from an inhibition of PDEIII, a cAMP degrading phosphodiesterase that is inhibited by cGMP.[529] An early report showing that the PDEIII inhibitor milrinone increased basal and isoproterenol stimulated renin

release in conscious rabbits has now been corroborated by substantial additional evidence.[530] In the isolated perfused rat kidney, Na nitroprusside increased renin secretion, and this increase was attenuated by the protein kinase A inhibitor Rp-8-CPT-cAMPS. Since membrane-permeable cGMP analogs also reduced the stimulatory effect of SNP, stimulation of renin secretion by NO was clearly related to the A kinase, not G kinase pathway.[531] Inhibition of PDE IV, a phosphodiesterase with predominant effects on cGMP degradation, also increased renin secretion,[532] and this effect was blunted by nNOS inhibition suggesting that nNOS contributed to cGMP formation.

NO IN MD-DEPENDENT RENIN RELEASE

In view of the dual effects of NO on renin secretion and the ambiguity about the directional changes of juxtaglomerular NO with changes in loop of Henle flow rates, it is not surprising that the precise role of NO in MD control of renin release has remained equivocal. In the isolated perfused JGA preparation during perfusion with a low NaCl concentration, the luminal addition of l-arginine stimulated renin secretion and this stimulation was abolished by NOS blockade, suggesting that in this setting NO is renin-stimulatory.[533] Consistent with this conclusion is the observation that the NaCl dependency of renin secretion was essentially abolished in the presence of an NOS blocker in the tubular lumen, a change that was due entirely to prevention of the rise of renin secretion caused by a low luminal NaCl.[533] The conclusion that a low NaCl concentration at the MD stimulates renin secretion in an NO-dependent fashion is also supported by findings showing that the increased renin secretion caused by a reduction in arterial or perfusion pressure in kidneys of conscious dogs and in isolated rat kidneys was markedly and consistently blunted by NOS inhibition.[534,535] In other studies, the administration of a loop diuretic has been used to simulate a reduction in MD NaCl concentration. In dissected rat renal microvessels, NOS inhibition abolished the increase in renin release caused by furosemide pretreatment.[536] Similarly, the stimulation of renin secretion by furosemide *in vivo* was inhibited by the administration of NOS inhibitors.[504,537,538] Plasma renin activity in nNOS knockout mice and basal renin secretion in isolated perfused kidneys from $nNOS^{-/-}$ or $eNOS^{-/-}$ mice were found to be consistently lower than in wild-type animals, suggesting that tonic release of NO enhances renin release in mice.[505,526] The relative increases of renin secretion by furosemide were essentially normal in $nNOS^{-/-}$ or $eNOS^{-/-}$ mice, but were markedly reduced by general NOS inhibition.[505] Furthermore, the administration of the NO donor SNAP in kidneys in which endogenous NO production was blocked by L-NAME completely restored the stimulatory effect of loop diuretics. According to this recent evidence, it would appear that exposition of JG cells to NO regardless of its exact cellular source is necessary for the MD pathway to operate normally. The nature of this permissive effect of NO may be to inhibit PDEIII, and thereby to sensitize the renin secretory mechanism to the renin mediator that we assume to act through activation of the cAMP/PKA pathway (Figure 23.12).

Prostaglandins

Starting with the early observations by Larsson et al. that arachidonic acid increases and indomethacin reduces plasma renin activity,[539] various metabolites of arachidonic acid, most notably prostaglandins, have been established as potent regulators of renin secretion in a variety of experimental conditions.[506] Stimulation of renin secretion is most consistently seen with administration of prostaglandins of the E and I series.[540] The effect of prostaglandins on renin secretion are mediated by G_s-protein-coupled receptors, IP receptors in the case of PGI2, and EP2/EP4 receptors in the case of PGE_2.[541] Selective deletion of floxed $G_{s\alpha}$ in JG cells by cre recombinase driven by the endogenous renin promoter was associated with marked reductions of plasma renin concentration.[542]

RELATIONSHIP BETWEEN MD COX-2 AND RENIN

Cyclooxygenases catalyze the hydroxylation and oxygenation of arachidonic acid that lead to the generation of endoperoxides (or PGH2). Subsequent processing by a number of enzymes converts PGH2 into the biologically active spectrum of prostaglandins. The potential of prostaglandins to regulate renin secretion became highly relevant for the MD-dependent pathway by the demonstration that one of the cyclooxygenases, the inducible isoform COX-2, was constitutively expressed in MD

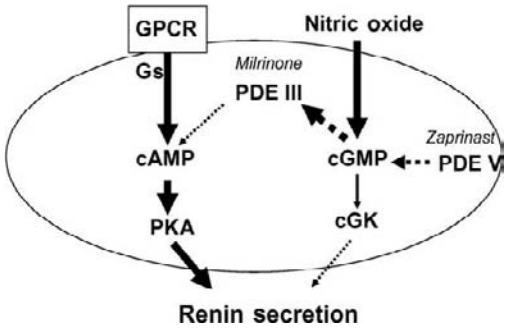

FIGURE 23.12 **Schematic representation of the pathways by which nitric oxide can inhibit or stimulate renin secretion.** Inhibition of PDEIII by cGMP and subsequent reduced degradation of cAMP appears to be the dominant pathway under many conditions. Milrinone, an inhibitor of PDEIII, consistently stimulates renin secretion.

cells.[62] The abundance of COX-2 in the MD and adjacent TAL cells is highly regulated, and the pattern of COX-2 regulation parallels that of nNOS in the macula densa and of renin in JG cells. Parallel increases in COX-2 and renin have been observed in rats treated chronically with furosemide, and in patients with Bartter syndrome, suggesting that COX-2 expression, like nNOS, may be in some way linked to NaCl uptake by MD cells.[543–547] An increase of MD COX-2 expression and of JG cell renin is induced by administration of a low NaCl diet or by renal artery stenosis.[62,63,548–550] Stimulation of COX-2 expression has also been found following partial renal ablation and in active lupus nephritis.[551,552] A low NaCl diet also caused a two- to three-fold increase in the expression of PGE_2 synthase in MD cells.[71] Conversely, mice with genetic COX-2 deficiency have a marked reduction of renin expression and of plasma renin concentration.[553,554] On the other hand, angiotensin II appears to play the role of a negative feedback regulator of COX-2 synthesis: a strong and consistent stimulation of COX-2 expression is induced by ACE inhibition or AT1 receptor blockade, and COX-2 expression is increased in AT1 receptor knockout mice,[543,555,556] as well as in other states of low angiotensin action.[542]

REGULATION OF PGE_2 PRODUCTION

The application of a biosensor technique has provided a missing piece of evidence linking MD NaCl delivery to local PGE_2 release.[557] In this approach, HEK293 cells were stably transfected with the mouse PGE_2 receptor EP1, a receptor subtype that is coupled to the IP3 pathway, and whose activation therefore causes an increase in cytosolic Ca. In perfused TAL/MD preparations dissected from kidneys of salt-restricted rabbits, a transfected and fura-2 loaded sensor cell was positioned at the basolateral aspect of MD cells, and changes in $[Ca]_i$ were used as an index of PGE_2 release. In this preparation, removal of luminal NaCl caused a significant increase in sensor cell $[Ca]_i$, while no effect was seen when NaCl was reduced to zero in the presence of luminal furosemide (Figure 23.13b). This effect appeared to be cell-specific, since the positioning of the sensor cell close to a TAL cell had no effect on $[Ca]_i$. Of major importance is the observation that most of the change in $[Ca]_i$ occurred in a NaCl concentration range of between 20 and 40 mM, exactly the concentration range in which NaCl concentration affects renin secretion in a similar preparation (Figure 23.13a).

Studies in the isolated rabbit JGA have shown that acute, non-specific COX inhibition with flufenamic acid or flurbiprofen virtually completely abolished the increase in renin secretion caused by a decrease in MD NaCl concentration.[496] Since the concentration change from minimal to maximal was done in a single step, it is not clear whether the effect of these agents was symmetrical around the midpoint or whether it mainly affected the stimulation in the subnormal concentration range. Direct evidence for a role of COX-2 has been obtained in an extension of these studies in which the specific COX-2 inhibitor NS-398 was also found to prevent the stimulation of renin secretion by low NaCl, while the putative COX-1 blocker valerylsalicylate did not have this effect (Figure 23.13c).[558] The significance of these findings is substantial since as pointed out earlier, the isolated perfused rabbit JGA preparation is the only currently available technique capable of assessing MD-dependent renin release unencumbered by simultaneous sympathetic and baroreceptor input.

The mechanisms by which a reduction in luminal NaCl may cause stimulation of PGE_2 release and COX-2 expression have been studied in cell lines derived from the MD and from TAL cells.[559,560] In both lines of cells a reduction in medium NaCl caused a prompt and dose-dependent increase in PGE_2 release that was essentially completely inhibited by NS-398, and was therefore largely mediated by COX-2. The onset of this response preceded any increase in COX-2 expression, suggesting that it was the result of an increase in COX-2 activity and/or of an activation of PLA2 followed by increased availability of arachidonic acid. Presence of PLA2 in macula densa cells and regulation of PLA2 in parallel to that of COX-2 has recently been demonstrated.[66] In both TAL and MD cells in culture, a reduction in medium NaCl also augmented the expression of the mRNA and protein expression of COX-2.[559,560] Ion substitution studies indicate that the extracellular signal for COX-2 stimulation appears to be a reduction in Cl rather than in Na concentration, a finding that is remarkably concordant with the Cl-dependency of renin secretion shown earlier in an entirely different preparation. The intracellular signaling events leading to the stimulation of COX-2 activity and expression are initiated by rapid phosphorylation of p38 and Erk1/2 kinases (Figure 23.14).[560] Participation of MAP kinases in COX-2 expression is supported by the inhibitory effects of SB 203580 and PD 98059, inhibitors of p38- and Erk1/2-mediated signaling events.[559,560] The role of the MAP kinase pathway in Cl-dependent COX-2 expression that appears to reflect both a transcriptional activation and an increased stability of the mRNA[561] is similar to the involvement of MAP kinases in mediating the effects of cytokines, growth factors, and hypertonicity on COX-2 expression in other cell types.[562–564]

Chronic interference with COX-2 signaling is associated with a reduction of renin expression that has secondary consequences for acute renin secretory responses. Thus, COX-2-deficient mice have been shown to have a markedly reduced renin mRNA expression and plasma renin, and this effect was greater on 129J or C57Bl/6 than on mixed genetic

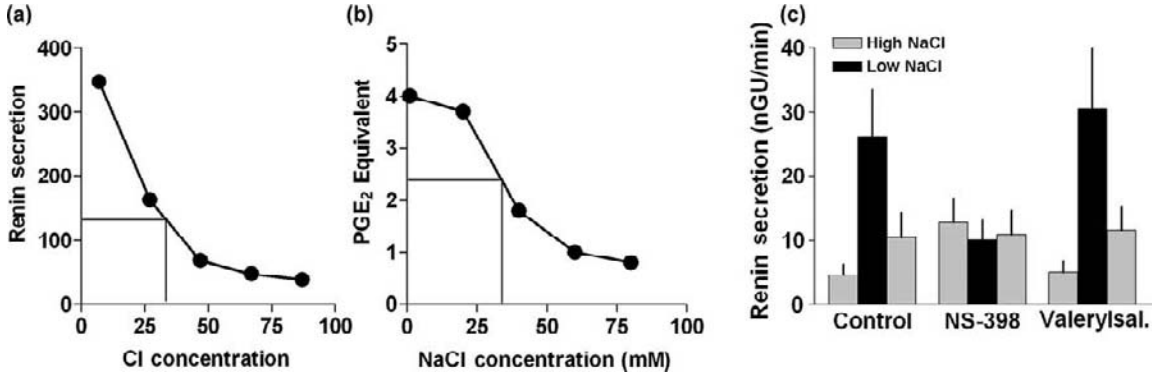

FIGURE 23.13 (a) Relationship between perfusate Cl concentration and renin release in the isolated perfused JGA preparation; data from [500]. (b) Relationship between perfusate NaCl concentration and PGE_2 release by macula densa cells.[557] The PGE2 equivalent corresponds to the EP1-mediated increase in cytosolic Ca in HEK cells transfected with EP1 receptor cDNA, and placed at the basolateral aspect of macula densa cells.[557] (c) Renin secretion in the perfused thick ascending limb/glomerulus preparation of the rabbit in response to perfusion with solutions containing high and low NaCl concentrations during control conditions, during inhibition of COX-2 with NS-398, and during inhibition of COX-1 with valerylsalicylate.[558]

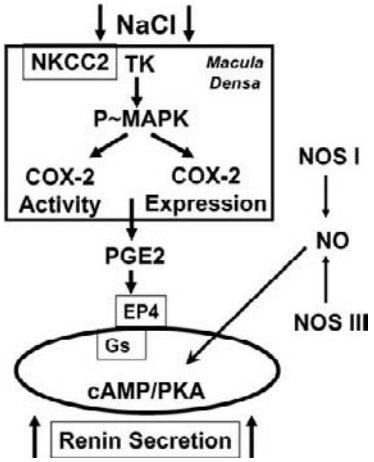

FIGURE 23.14 **Schematic summary of the pathway by which a decrease in luminal NaCl concentration causes stimulation of renin secretion.** Activation of several MAP kinases causes activation of COX-2, as well as transcriptional upregulation of COX-2 synthesis, augmented release of PGE2, and stimulation of the cAMP/PKA pathway through EP4 receptors. Nitric oxide, derived from both NOS I and NOC III, supports renin secretion by stabilizing cAMP.

background.[553,554,565] Chronic administration of COX-2 blockers, on the other hand, did not consistently reduce renin expression.[566–568] Acute stimulation of renin release by furosemide, hydralazine or isoproterenol was markedly reduced in COX-2-deficient compared to wild-type mice, suggesting that the acute release response was dependent upon basal renin expression levels.[553] Thus, when low renin release in COX-2-deficient mice was overcome by chronic prestimulation of their renin system, *acute* renin secretory responses to various stimuli were reconstituted to levels observed in wild-type animals. Furthermore, stimulation of renin release by angiotensin converting enzyme or AT1 blockers was also markedly reduced in animals with genetic or pharmacologic COX-2-deficiency.[553,555,565] Overall these studies reveal that the level of renin expression is an important and non-specific determinant of the acute secretory response, independent of whether the stimulus acts through the MD, baroreceptor, sympathetic or any other pathway. The strong relationship between basal levels of renin release or its surrogate, plasma renin, and the acute release response suggests the existence of an acutely releasable renin pool in JG cells whose magnitude depends on renin synthesis.[553,569]

In addition to the MD, the renal vasculature including the afferent arteriole appears to be a significant source of prostanoids in the vicinity of the JGA in some species. In humans, expression levels of COX-2 in the MD are low and are exceeded by vascular COX-2 expression, in particular in close vicinity to the JG cells.[570] In patients with renal artery stenosis this vascular expression of COX-2 was enhanced, and therefore prostaglandins from non-MD sources may contribute to enhanced renin secretion in this condition. In addition, stimulation of the renin system *in vivo* after loop diuretics may not be exclusively mediated by the MD pathway, but may be at least partly related to enhanced vascular prostanoid formation.[571] Furthermore, the reduced stimulatory capacity of loop diuretics on renin secretion in the presence of COX inhibitors appears to be to some extent related to blockade of vascular prostanoid formation.[572,573]

Adenosine

In general, exogenous adenosine inhibits renin release in intact rats or dogs,[574–576] an effect that is produced by activation of A1AR.[575] Nevertheless, it is unclear to what extent adenosine participates in the renin inhibition caused by high luminal NaCl concentrations. In the

isolated perfused JGA, the selective A1AR blocker 8-cyclopentyl-1,3-dipropylxanthine (CPX) blunted the fall in renin secretion caused by an elevation in luminal NaCl, but did not abolish it.[499] Adenosine itself was found to be only a weak inhibitor of MD-stimulated renin secretion when added to the bathing fluid.[577] This may reflect effective degradation of exogenous adenosine, since the addition of the adenosine deaminase inhibitor pentostatin (deoxycoformycin) augmented the renin-inhibitory effect of adenosine somewhat.[577] Additional studies may have clarified the role of adenosine in MD-dependent renin release. In isolated perfused kidneys, it was found that the stimulation of renin release by bumetanide was not measurably different between wild-type and A1AR-deficient mice.[578] This observation argues against a role of A1AR and adenosine in the stimulation of renin secretion during inhibition of NaCl transport below ambient levels. On the other hand, renin secretion fell when NaCl at the MD was acutely increased by a bolus injection of NaCl, and this effect was not seen in A1AR-deficient mice, suggesting that the renin-inhibitory effect of increased NaCl concentrations is mediated by adenosine, whereas the renin-stimulatory effect is not (Figure 23.15).

The cellular mechanisms of inhibition of renin release by adenosine are not clear, but it is likely that an increase in $[Ca]_i$ may play a role. Considerable progress has been made in understanding the paradoxical inhibition of renin release by elevated $[Ca]_i$. In primary cultures of JG cells it has been observed that an increase of $[Ca]_i$ by thapsigargin, angiotensin II or endothelin was associated with a marked decrease in isoproterenol- or forskolin-stimulated cellular cAMP and a decrease of renin release.[579] Conversely, a decrease of $[Ca]_i$ by the Ca chelator BAPTA-AM caused an increase in cellular cAMP, accompanied by an increase in renin release.[580] The inverse relation between $[Ca]_i$ and cAMP was suggested to reflect regulation of adenylyl cyclase (AC) by $[Ca]_i$. In fact, the Ca-inhibitable AC5 and AC6 isoforms were shown to be expressed in JG cells,[579,580] and siRNAs directed against AC5 and AC6 were able to prevent cAMP stimulation by forskolin or isoproterenol ,as well as renin secretion in As4.1 cells (Figure 23.16).[579]

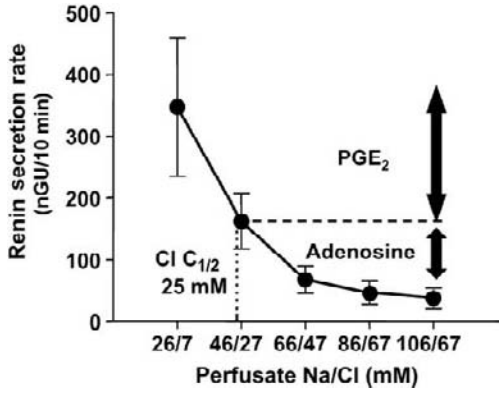

FIGURE 23.15 **Control of macula densa-dependent renin secretion by PGE2 and adenosine, with PGE2 being responsible for the larger stimulatory effect during reduced luminal NaCl, and adenosine causing a smaller inhibitory effect during increases in macula densa NaCl.**

Ionic and Osmotic Effects

Changes in external juxtaglomerular osmolarity may mediate the renin secretory response to a change of luminal NaCl. In a number of different preparations hypoosmolarity stimulates and hyperosmolarity inhibits renin secretion, and such changes would seem to be directionally plausible in mediating MD-dependent renin release.[581–584] Hypotonicity-stimulated renin secretion appears to be initiated by AQP1-mediated water flux leading to COX-2-dependent PGE_2 production and cAMP formation.[585] However, a recent study in isolated perfused rat or mouse kidneys established a direct rather than an inverse relationship between renin release and external osmolarity,[569] a finding that confirms an earlier *in vivo* observation.[586] Osmotic stimulation of renin release was not prevented by L-NAME, indomethacin or bumetanide, and was therefore

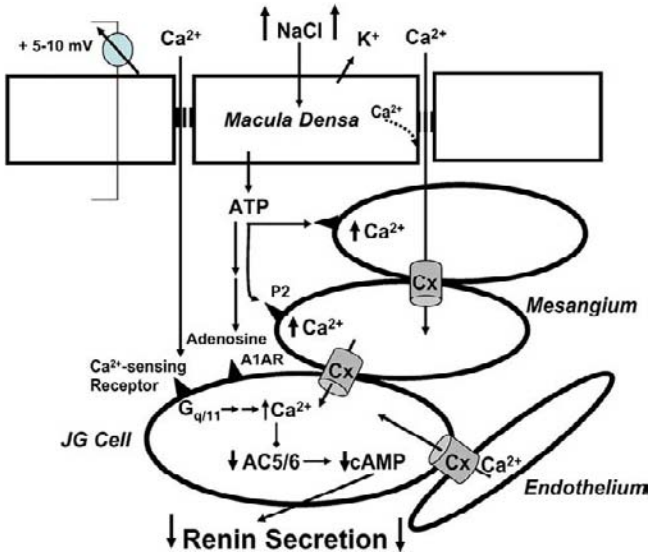

FIGURE 23.16 **Schematic summary of the pathways by which an increase in TAL/macula densa NaCl reabsorption mediates Ca-dependent suppression of renin secretion.** TAL/macula densa transepithelial NaCl transport and concomitant K recycling generate a lumen-positive potential which drives paracellular Ca absorption. Ca-sensing receptors on JG cells translate changes in interstitial Ca into a modulation of Ca_i. Cell coupling by calcium-permeable connexins (Cx), activation of Ca_i-mobilizing P2 receptors by ATP, and A1AR activation in JG cells are additional pathways for raising JG cell calcium. Ca-inhibited adenylyl cyclases (AC5 and AC6) link the increase of Ca_i to a reduction of cAMP formation in JG cells.

suggested to reflect a direct effect on JG cells.[569] In addition to changes in interstitial osmolarity, direct ionic effect may influence renin secretion. Thus, JG cells express the calcium receptor CaR which renders renin-producing cells capable of translating changes in extracellular calcium into changes in intracellular calcium.[587] In fact, the calcimimetic R-568 partially blunted the stimulation of renin secretion in response to isoproterenol, furosemide, and enalapril, while having little effect on basal renin release.[588] It remains to be determined under which conditions changes in interstitial Ca concentrations may occur *in vivo*. In theory, increased TAL/MD NaCl reabsorption would be expected to augment the tubular lumen-positive potential, and would enhance the driving force for paracellular Ca uptake; this would result in an increased interstitial Ca concentration. In line with this concept, interstitial renal cortical Ca concentration as determined by *in situ* microdialysis techniques in Wistar rats was shown to rise by 25% during chronic oral salt loading.[589] A role of Ca in the MD-JG signal transmission is further supported by the finding that an increased tubular flow rate triggers a Ca wave that originates around the MD, spreads throughout the JGA, and eventually increases Ca_i of the JG cells. Both cell–cell coupling in the JGA via connexins and ATP-dependent mechanisms appear to participate in the propagation of this Ca wave.[150,590] Gap junction uncoupling by α-glycyrrhetinic acid and ATP degradation by apyrase markedly diminished changes in Ca_i in the most distal portion of the afferent arteriole.[150] Connexin 45 expression was detected in vascular smooth muscle cells of the afferent and efferent arteriole, the mesangium, and JG cells. In cultured vascular smooth muscle cells from mice with local deletion of connexin 45 the speed of a cell-to-cell Ca wave was reduced by 60% compared to wild-type controls.[590] Furthermore, mice with deletion of connexin 45 in the JGA showed increased PRC accompanied by elevated blood pressure suggesting an inadequate inhibitory input on renin secretion.[590] However, connexin 45 probably is not the only connexin involved in a Ca-dependent signal transmission from MD cells to renin granular cells. In particular, connexin 40 was shown to mediate Ca transmission from endothelial to JG cells,[591] a finding consistent with major derangements in JG cell renin secretion and topology in connexin 40-deficient mice.[592,593]
