GLOMERULONEPHRITIS

Acute glomerulonephritis (AGN) is characterized by the sudden appearance of hematuria, proteinuria, and red blood cell casts, whereas subacute and chronic forms present more indolently. The differential diagnosis is listed in Table 82.1.[1] This discussion will include consideration of the incidence, pathogenesis, pathology, clinical presentation, prognosis and treatment, with emphasis on *primary* forms of the syndrome, including acute post-infectious GN, idiopathic membranoproliferative glomerulonephritis (MPGN) anti-glomerular basement membrane (GBM) disease and IgA nephropathy. Thrombotic microangiopathies will be discussed briefly, since its clinical presentation often mimics that of AGN. Our main focus is on human forms of the disease, and neither the differential diagnosis nor pathophysiology of asymptomatic hematuria or asymptomatic proteinuria is discussed as separate entities, since non-glomerular disease entities may cause them. Nevertheless, these findings may be discovered in patients with less severe forms of diseases discussed below. Furthermore, other diseases may present with features that mimic acute glomerulonephritis and should be considered in the differential diagnosis (Table 82.2). Overall, the history, physical exam, serology and pathology are useful in distinguishing primary renal diseases from systemic diseases with renal manifestations, determining the extent of inflammation and fibrosis, and defining the optimal therapeutic approach.

Acute Post-Streptococcal and Post-Infectious GN

Many infections have been associated with acute GN (e.g., Table 82.3), but acute post-streptococcal glomerulonephritis (APSGN) remains the prototype. It is distinguished by typical clinical presentation, serology, pathology and course. APSGN occurs in episodic/sporadic or in epidemic form; children are affected more often than adults (peak age 2–6y), and males more commonly have overt nephritis despite a higher penetrance in females.[2,3] Group A streptococci account for most cases, and specific subtypes predominate.[4] However other infectious organisms have been associated with the syndrome. Pharyngeal infections dominate in temperate zones, whereas skin infections are more commonly precede disease in the tropics.

Pathogenesis

Three major theories have been proposed with evidence supporting each one. All involve infection with nephritogenic strains (Table 82.4). Unique antigenic determinants are responsible for glomerular localization that leads to alternate complement pathway activation. Amplification of disease occurs initially by anti-streptococcal antibodies binding to glomerular bound antigen, and subsequently by anti-IgG response. The latter results from enzymatic modification of IgG by streptococcal enzymes that lead to altered IgG, production of anti-IgG, localization of the altered IgG in

TABLE 82.1 Major Causes of Acute Nephritis

Low Serum Complement Level*	Normal Serum Complement Level
Systemic Diseases	**Systemic Diseases**
• Systemic Lupus Erythematosus (focal ~75%, diffuse ~90%)*	• Polyarteritis nodosa
• Cryoglobulinemia (~85%)	• Wegener's granulomatosis
• Subacute bacterial endocarditis (~90%)	• Hypersensitivity vasculitis
• "Shunt" nephritis (~90%)	• Henoch-Schonlein purpura
	• Goodpasture's syndrome
	• Visceral abscess
Renal Diseases	Renal Diseases
• Acute poststreptococcal GN (~90%)	• IgG-IgA nephropathy
• Membranoproliferative GN	• Idiopathic RPGN (rapidly progressive GN)
– Type I (~50–80%)**	– Anti-GBM disease
– Type II (~80–90%)	– Pauci-immune*** (no immune deposits)
	– Immune-deposit disease

Table from Madaio, MP, Harrington, JT: The diagnosis of glomerular diseases: Acute GN and the nephrotic syndrome. Arch Intern Med: 161: 25-34, 2001.[1]
**Percentages indicate the approximate frequencies of depressed C3 or hemolytic complement levels during the course of disease*
***Most common pathologic findings associated with hepatitis C infection (see text)*
****Pauci-immune indicates lack of significant glomerular deposition of immunoglobulin by direct immunofluorescence. Many patients have circulating ANCA (see text)*
Normal serum complement levels indicate that production of complement components is keeping up with consumption; it does not exclude participation of complement in the inflammatory process. Repeat measurements useful (2–3x, one week apart) consistently normal serum levels are useful in narrowing the diagnostic possibilities

TABLE 82.2 Disorders Mimicking Acute GN

- Hereditary Nephritis
- Hemolytic-Uremic Syndrome (HUS)
- Thrombotic Thrombocytopenic Purpura (TTP)
- Atheroembolic Renal Disease
- Malignant Hypertension
- Acute Interstitial Nephritis
- Acute Tubular Necrosis

Infectious Agent	Pathology
Viral Infections	
Hepatitis B	Membranous GN
	MPGN
	Polyarteritis nodosa
Hepatitis C	MPGN
	Membranous GN
CMV	MPGN
Parovirsus	Proliferative GN
Malaria	
P. faliciparum	Proliferative GN, Membranous GN
P. malaria	MPGN
Schistosomiasis	Proliferative GN
	Occasionally FSGS, Amyloid
Endocarditis	
Streptococcal	Proliferative GN
S. aureus Meth Sens.	
S. aureus Meth Res.	
Others	
Infected A-V Shunts	
Staphlococcal	Proliferative GN, MPGN
Other	
Visceral Abscess	
Many organisms	Proliferative GN
Syphilis	
Adults	Proliferative GN
Children	Membranous GN

TABLE 82.4 Pathogenesis of APSGN: Potential Mechanisms

1. In situ immune complex formation. Cell wall antigens from nephritogenic strains bind to glomeruli, activate complement (alternative pathway) and serve as planted antigen for anti-streptococcal antibodies.[325–329]
2. Molecular Mimicry. Anti-streptococcal antibodies cross-react directly with glomerular antigens.[330–337]
3. Enzymatic modification of IgG. Enzymatic alteration of IgG leads to glomerular localization; Rheumatoid factor binds to glomerular bound IgG.[338–342]
4. Deposition of circulating streptococcal antigen-anti-streptococcal antibody immune complexes (i.e. deposition based on affinity of exposed and complexed streptococcal protein fragments for glomeruli).[343,344]
5. Disease susceptibility/severity influenced by genetic factors.[3,345]

glomeruli, with FcR engagement and complement activation; binding of the latter to glomerular IgG deposits, further exacerbates disease.

Pathology

There is diffuse or focal GN with cellular infiltration and endogenous cellular proliferation.[5–7] Early in the course ("exudative phase") there are neutrophils, eosinophils, lymphocytes and monocytes in capillaries, associated with endothelial and mesangial cell proliferation.[4,6,8,9] Mesangial expansion and lumen occlusion is

common, and there may be fibrin thrombi;[5] capillary wall thickening is typical. Focal but not diffuse crescents are often seen.[4,10] Over time monocytes replace neutrophils, thereafter the hypercellularity slowly resolves. Acute tubular necrosis, interstitial infiltrates, and vasculitis have been occasionally observed.[11–14]

Initially, IgG and C3 deposits (Figure 82.1) are invariably present within the mesangium and capillary walls,[5,15–18] although the C3 deposits persist longer. Alternative complement pathway proteins predominate, whereas C1q and C4 are often absent.[15–17]

Subepithelial humps (dome-shaped, dense immune deposits) are characteristic on electron microscopy.[15–17] They are prominent in the first month in epithelial slit pores,[17,19–21] associated with nephrotic range proteinuria and persist for one to two months. Their remnants appear as electron-lucent areas.[22] Subendothelial, mesangial and intramembranous deposits are often present and persist after resolution of the humps.[22]

Clinical Presentation; Laboratory Features

The latent period after infection is usually 1–3 weeks after pharyngitis and 3–6 weeks after skin infection.[2] Shorter latent periods suggest an alternative diagnosis. Often a source of infection is not identified. The acute nephritic syndrome usually resolves within a week in children but takes longer in adults, especially those with crescentic GN or nephrotic syndrome. Recurrent episodes are uncommon, however repeated bouts of hematuria may occur during the initial episode. The disease does not usually recur in transplants, although *de novo* disease has been observed.[23]

The laboratory findings provide clues but are not diagnostic. Hematuria, dysmorphic RBCs, and proteinuria are always present, casts are common, and pyuria may be observed in patients with severe inflammation. Nephrotic syndrome occurs in 5% of patients at initial presentation, and is sometimes present with resolution of disease.[24,25] The GFR is typically reduced, and 25% have a serum creatinine >2 mg/dl. Throat or skin cultures may be positive in affected individuals. C3 and CH50 levels are significantly depressed early (>90%) but return to normal at one month.[4,26–29] C4 and C2 are normal. High and persistent titers of C3 nephritic factor suggest MPGN.[28] Hypergammaglobulinemia, cryoglobulinemia and Rheumatoid factor activity may be present but are not diagnostic, whereas Streptozyme antibodies are frequently positive,[2,4,30–32] although also not diagnostic. Antibiotic therapy often prevents the rise in antibody titer but not the disease.

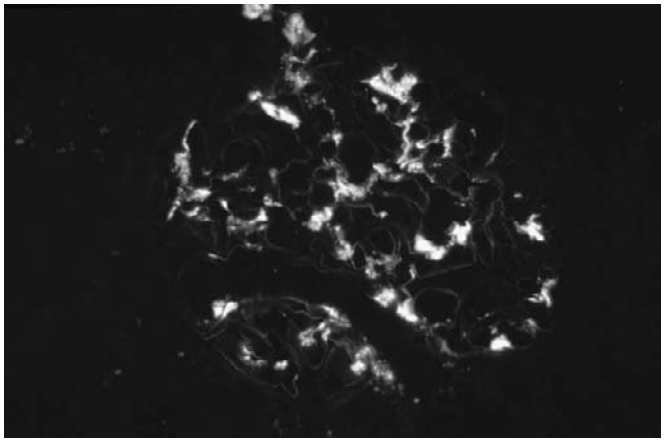

FIGURE 82.1 Post-infectious glomerulonephritis Immunofluorescence microscopy demonstrating relatively discrete granular staining of C3 along all glomerular capillary walls.

Prognosis

Less than 0.5% die of the initial disease and less than 2% die later from disease or develop ESRD.[24,33–43] Children have a better prognosis than adults, and patients older than 40 years with RPGN have the worst prognosis,[36,41,44] although their outcome is better than with other forms of RPGN. There is no difference in outcome between epidemic and sporadic forms. Urinary and histologic abnormalities may persist for years,[45–47] and persistent, heavy proteinuria and/or decreased GFR carry a worse prognosis.[15–17,42,48]

Treatment and Prevention

Therapy is symptomatic, with an emphasis on control of blood pressure and edema. Steroids, immunosuppressive agents, and/or plasmapheresis are generally not indicated, although a short course of steroids may be indicated with crescentic disease (i.e., RPGN). Specific therapy for streptococcal infections is essential and includes treatment of both the patient and any infected family member or close personal contact, to limit spread, e.g., Penicillin G 250 mg q.i.d. or erythromycin 250 mg q.i.d. for 7–10 days. During epidemics, empirical prophylactic treatment of close contacts and family members is recommended.[49]

Anti-GBM Disease and Goodpasture's Syndrome

Anti-GBM disease may occur as a disease limited to the kidney or as part of a pulmonary-renal syndrome (Goodpasture's syndrome).[50,51] The syndrome is rare[52] accounting for approximately 1–2% of all GN[51] and 10–20% of RPGN.[53] Peak incidence occurs in a bimodal distribution in the third and sixth decades,[54] with male predominance in younger patients. Lung hemorrhage is more common in younger men,

smokers[55] and individuals with pulmonary disease,[56] and less common in blacks.[50,57]

Pathogenesis

Genetic susceptibility is suggested by occurrence of disease in siblings and twins,[58,59] and analysis of MHC class II genes demonstrated that some confer susceptibility, while others confer resistance.[60] There is a strong association with HLA-DR2 (and DR15, a subspecificity of DR2), DRB1*1501 and DRB1*1502[61] and a negative association with DR7 and DR1.[60] Clearly, additional factors play a role since approximately one third of Caucasians have the DRB1*1501 allele. An environmental trigger is suggested by temporal and geographic clustering,[62,63] and some have developed disease after prolonged hydrocarbon exposure.[64] A case control study in the North of England suggested that occupational exposure to petroleum-based mineral oils led to higher anti-GBM antibodies.[65] Cigarette smoking has also been associated with the disease, and pulmonary hemorrhage is more common in smokers than in non-smokers.[55]

The onset of either pulmonary inflammation or nephritis may be linked to inflammation;[66–68] 10% of patients with ANCA-mediated vasculitis will develop anti-GBM antibodies,[69–71] and there are case reports of anti-GBM disease in patients with membranous nephropathy.[72–76] These reports suggest that glomerular disease may lead to release of α3(IV) collagen, and initiate an autoimmune response in susceptible individuals.

Anti-GBM antibody-mediated disease may occur following renal transplantation in patients with Alport syndrome,[77–79] as these patients lack α3, α4, α5 type IV chains.[80] Although most patients have a mutation in the coding region for α5(IV), expression of the α3α4α5 complex requires all three chains. These individuals only express the fetal form containing the α1, α2 chains, which is more sensitive to proteolysis and linked to progressive renal failure. Following transplantation with exposure to α3, some patients develop anti-α3(IV) antibodies, presumably due to "foreign" antigen exposure,[81] however, nephritis is uncommon in the transplanted kidney,[82] perhaps because of ongoing immune suppression.

The Goodpasture antigen: α3(IV) collagen.[83,84] Collagen IV is composed of six distinct α chains (α1–α6); each chain contains three domains: a short 7S domain at the N-terminus, a non-collagenous domain (NC1) at the C- terminus, and a long collagenous domain in the middle. The chains assemble into three sets of triple helical protomers: α1α1α2, α3α4α5 or α5α5α6. While the α1 and α2 have a wide distribution, the expression of α3α4α5 is restricted to basement membranes in glomeruli, alveoli, seminiferous tubules, choroid plexus, cochlea and retina.[85] Three dimensional and quaternary organization analyses of the alpha chains revealed head to head association of 2 protomers at the C-terminal, forming an NC1 hexamer. In addition, association of four triple helical 7S domains at the N-terminus forms a tetramer. Supercoiling and looping of the triple helixes and disulfide cross-links between triple helical domains further contribute to the meshwork.[86]

Analysis of antibodies from patients with anti-GBM disease established the non-collagenous domain of the α3 chain (α3 IV NC1) as the autoantigen.[84,85,87–89] Detailed mapping revealed that two conformational epitopes within the N-terminal part of NC1 region (designated E_A and E_B)[90–94] are major targets and account for approximately 90% of autoantibody activity.[95,96] These epitopes are sequestered at the interface between NC1 domains and are relatively inaccessible to autoantibodies.[97] However, when the hexamer structure is denatured, the epitopes are exposed for autoantibody binding. Thus, it has been postulated that "two hits" are required for disease: autoantibody production and exposure of the autoantigen. This may account for the lack of nephritis in some patients with circulating antibodies. Nevertheless, human anti-GBM antibodies have a high affinity for α3(IV) NC1; they bind rapidly to their target antigen and remain tightly bound.[98,99] This property contributes to both the rapidity of disease onset and treatment resistance, once GFR is significantly impaired.

Insights into the pathogenesis have also been derived from animal models. Immunization of normal mice with either recombinant or native antigen induces nephritis,[100,101] however not all strains are susceptible.[102] Disease in rodents is MHC-dependent and both T and B cell responses are required for severe disease expression,[103] although transfer of antibodies alone is capable of inducing nephritis.[104] Nevertheless, T cells are required for severe disease.[105–109] Transfer of α3(IV)-specific CD4 T cells induce nephritis in normal mice,[110] and Th1-related cytokines augment nephritis, whereas Th2 cytokines have a protective effect.[111]

Pathology

The light microscopic findings are typical of crescentic GN.[51,56,112] The majority of patients (>95%) have crescents at the time of biopsy, most often involving over 50% of glomeruli.[113] Tubulointerstitial nephritis is often present.[114] Intense, diffuse linear staining for IgG along the GBM is characteristic (Figure 82.2), and rarely IgA is found. Linear TBM staining may be present. C3 deposits are often found in a discontinuous, linear or granular pattern.[115–117] In the lung, there may be patchy IgG staining, which can be missed, although erythrocytes within disrupted alveoli and hemosiderin-laden macrophages should raise suspicion.[118]

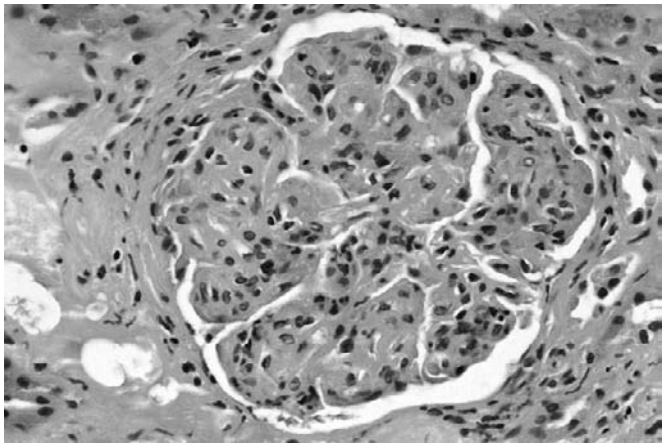

FIGURE 82.2 Antiglomerular basement membrane glomerulonephritis. Immunofluorescence microscopy demonstrating linear staining of IgG along all glomerular capillary walls.

TABLE 82.5 General Characteristics of Apsgn

Age:	Children > Adults (5% < 2y; 5–10% >40y)
Sex:	Male > Female
Site of Infection:	Pharynx (temperate zones); Skin (tropics)
Clinical Features	
edema	85%
gross hematuria	30%
back pain	5%
oliguria (transient)	50%
hypertension	60–80%
nephrotic syndrome	5%
Laboratory	
Urinalysis:	proteinuria, hematuria, casts: 100%
Nephrotic range proteinuria:	~10% over course of disease
Serum Creatinine	≥2 mg/dl –25%
Streptococcal antibody profile (streptozyme):	
>95% positive in patients with pharyngitis	
80% positive in patients with skin infections	
5% false positive rate	
early antibiotic Rx prevents antibody response	
C3, C4 and/or CH50 depressed in >90%	
Hypergammaglobulinemia –90%	
Cryoglobulinemia –75%	

Clinical Presentation

Abrupt onset of renal failure due to rapidly progressive GN is typical.[119] Rarely, patients have a more insidious course with mild symptoms and slow progression over months. Systemic symptoms suggest the possibility of a coexisting vasculitis, whereas, acute onset of hemoptysis raises suspicion of Goodpasture's syndrome. The pulmonary hemorrhage may be life threatening, leading abruptly to respiratory failure, although some patients have a subacute presentation with only fleeting infiltrates on chest x-ray. Unexplained anemia and heme-positive stools may occur after hemoptysis and swallowing blood.

Laboratory findings are typical of acute GN with proteinuria in the non-nephrotic range (< 3 gm/day). GFR is typically reduced at presentation and rapidly deteriorates. Circulating anti-GBM antibodies can be detected in over 90% of cases (i.e., by ELISA), and Western blotting is confirmatory (2–4% false negative).[120] One third of patients also have anti-neutrophil cytoplasmic antibodies (ANCA), with the majority as P-ANCA (i.e., vs. myeloperoxidase MPO).[70,121] These "double positive" patients may develop small vessel vasculitis in organs other than the kidney and lung, and vasculitis may recur after resolution of anti-GBM disease.

Prognosis and Therapy

Untreated, the prognosis is dismal,[51] with death from pulmonary hemorrhage or progressive renal failure prior to the introduction of treatment with corticosteroids, cyclophosphamide and plasma exchange (i.e., patient survival <50%: ESRD >90%)[122] (Table 82.6). Patient and renal survival rates have since improved with early recognition and prompt therapy.[122,123] Patients with an initial creatinine of <6 mg/dl (500 μmol/L) generally have a good prognosis if treated with plasma exchange and immunosuppression,[124] whereas those with a creatinine of >6 mg/dl have a greater likelihood of both ESRD and death. Dialysis-dependent patients are unlikely to recover renal function, particularly if either crescents involve 100% of the glomeruli or there is extensive interstitial fibrosis.[54,56,119,125–128] Aggressive therapy should either be withheld or abbreviated in these patients, as the risks of long-term immunosuppressive therapy outweigh the likelihood of benefit.[128] There are exceptions. A short trial of aggressive therapy may be considered in younger patients with evidence of acute deterioration (e.g., non-oliguric, early active crescent formation) and limited fibrosis on biopsy,[119,129,130] since some of them respond to treatment.

The rationale for plasmapheresis is removal of pathogenic antibodies and other inflammatory mediators.

TABLE 82.6 Therapy for Anti-GBM Antibody Diseases

Oral cyclophosphamide* (2–3 mg/kg/day) OR
IV cyclophosphamide (0.5 g/m^2 BSA)**
IV methylprednisolone (7 mg/kg/day for 3 days)
Prednisone 1 mg/kg/day after IV methylprednisolone***

*rounded down to the nearest 50 mg; reduced to 2 mg/kg/day in patients over 55 y
**for 4–12 months after antibody titers negative; in patients with higher risk for drug toxicity, azathioprine may be substituted as maintenance therapy
***for 4–6 weeks and then tapered off

Despite widespread use, support for efficacy is limited.[122,128,131,132] The standard of care is daily or alternate day 4-liter plasma exchanges for two weeks, with the frequency and duration determined by reduction of anti-GBM antibody titers and clinical response. Lung hemorrhage is an indication for plasmapheresis regardless of the presence and/or severity of renal failure. Corticosteroids and immunosuppressive therapy are required to control the ongoing inflammation and prevent new antibody formation.[122,124,133–138]

Cyclophosphamide is usually continued for 6–12 months, but in patients with higher risk for drug toxicity, azathioprine may be substituted as maintenance therapy. "Double positive" patients (+ ANCA and anti-GBM) present special issues.[139] The patients should receive the same initial treatment, although since their course is more typical of ANCA-associated vasculitis (see Chapter 83), they usually require longer-term maintenance immunosuppression. Those who are dialysis-dependent at presentation, should be considered for a trial of immunosuppression, as some studies suggest that the presence of ANCA is associated with better outcomes,[70] despite an initial need for dialysis,[140] although not all reports have been confirmatory.[139]

Transplantation

Kidney transplantation is an option for patients who have progressed to end stage renal disease. Although linear deposition of IgG along the GBM may be seen in up to 50% of transplanted kidneys, recurrence of nephritis is unusual, unless transplantation is performed in the presence of circulating antibodies.[141–143] Current practice is to delay transplantation for six months after the antibody levels have become undetectable, and this approach results in a 1-year renal survival rate of greater than 90%.

IgA Nephropathy (IgAN)

Initially thought to be a benign form of recurrent hematuria associated with mesangial proliferative GN and IgA deposition, it is now recognized that the clinical and pathologic presentations are diverse, and it may lead to end stage renal disease.[144–146] Most cases are idiopathic, but there is an association with a variety of autoimmune, infectious and chronic inflammatory diseases (Table 82.7).

Henoch-Schonlein Purpura
Behcet's syndrome

Incidence

IgAN is the most common primary GN worldwide with geographic variation,[147] (30–40% Asia; to 5–10% North America).[148–150] The differences are likely due to variations in the actual incidence, screening practices and indications for renal biopsy. It is rare in Blacks[151,152] and more common in Caucasians and Native Americans (Zuni and Navajo tribes).[153] The

disease is typically diagnosed in young adults in the second and third decades of life, and it affects males more commonly than females.[154–156]

Pathogenesis

The precise etiology is unknown, although a variety of factors contribute to the pathogenesis.[157] The key element common to idiopathic and secondary forms appears to be decreased glycosylation of IgA. In normal human sera, IgA1 exists as a monomer or as a polymer, whereas IgA2 is mainly found as a monomer. Patients who develop IgA nephropathy have reduced galactosylation of polymeric IgA1,[30,31] the fraction of polymeric IgA (or IgA complexes) is increased, and there is overrepresentation of IgA1λ.[158–161] There is also an exaggerated response to infectious agents or other stimuli by mucosal lymph, although a specific environmental antigen has not been identified. Many patients have reduced production of polymeric IgA1 within the mucosal immune compartment,[162] but increased numbers of polymeric IgA1 plasma cells in the bone marrow[163] is consistent with systemic involvement.[160,164–166]

Nevertheless, increased IgA levels alone are insufficient to cause disease, since patients with other diseases associated with increased serum IgA (e.g., human immunodeficiency virus infection (HIV), hepatobiliary disease and IgA secreting myeloma) infrequently develop nephritis.[167,168] Thus, either the circulating IgA and IgA-IC among IgAN patients differ qualitatively, or the renal response to IgA deposition is different.[169,170] There is evidence for both of these postulates.[171]

IgA1 has heterogeneous O-glycan moieties in its hinge region, and serum IgA1 from IgAN patients demonstrate altered glycan side chains, with reduced terminal galactose in O-linked oligosaccharides.[172–175] This incomplete galactosylation exposes the terminal sugar, N-acetyl-D galactosamine (GalNAc), generating neo-epitopes that are recognized by naturally occurring IgG and IgA1 antibodies specific for GalNac.[175] It has been suggested that this leads to immune complex formation.[176–178] Additionally, reduced galactosylation results in non-covalent self-aggregation with formation of IgA1-IgA1 complexes.[175,179] This defect is restricted to IgA1 (rather than due to generalized failure of O-glycosylation),[176] and reduced expression or function of the enzyme, core β1,3 galactosyltransferase (C1β3GalT1) that promotes addition of Gal to GalNAc residues, may be responsible. This enzyme is co-dependent on C1β3 galT1specific molecule (cosmc) for its stabilization. In the absence of cosmc, there is a decrease C1β3GalT1 which leads to decreased glycosylation.[180] Another enzyme that can lead to less glycosylation is N-acetyl galactosamine-specific α-2,6 sialyltransferase (ST6GalNacII). If this enzyme acts first on polymeric IgA, then C1β3GalT1 cannot properly glycosylate IgA.[180] In support of this hypothesis, one group reported decreased activity of this enzyme in circulating B cells in IgAN patients.[181]

Other circulating immune complexes have also been implicated,[182,183] including those containing IgA rheumatoid factors,[184] IgA-fibronectin[185] and IgA-soluble FcRI receptors (CD89),[186,187] although their pathogenic role is uncertain.[188,189] Nevertheless, decreased clearance of IgA-containing complexes may contribute to pathogenesis, and this may be especially relevant in patients with liver disease. In this regard, hepatic asialoglycoprotein receptor (ASGP-R)[190,191] and the myeloid FcRI receptor/CD89 are involved in IgA catabolism and clearance of IgA1 immune complexes.[192] Abnormal O-glycosylation or antibodies bound to GalNac may prevent the interaction of IgA with hepatocyte receptors (and monocytes and neutrophils), and therein decreased clearance occurs.

Cellular immunity may also contribute to pathogenesis, with Th2 cytokines (e.g., IL-4 and IL-5) influencing IgA galactosylation.[193–195] In a mouse IgAN model, Th2 bias in response to mucosal infection regulated glycosylation of IgA, and promoted glomerular IgA deposition.[196] Lymphocytes from patients with IgAN produce more IL-4 in response to mitogenic stimulation than controls, and this appears to be more pronounced in patients with severe renal dysfunction. Furthermore, clinical remissions have been associated with more normal IL-4 responses.[194]

Activation of mesangial cells, through cytokine priming, is most likely required for inflammation.[197,198] Nevertheless binding of polymeric, Gal-deficient IgA1 (possibly mediated by transferrin Tfr/CD71 and Fcα/μ receptors) may directly activate mesangial cells.[199–203] A prominent role for IL-6 has also been proposed,[204,205] and this may be especially relevant to patients with liver disease. IL-8, PDGF, TNFα, TGF-β and MCP-1 may also have important roles.[206,207] In any case, either polymeric IgA or aberrantly glycosylated IgA are very efficient at directly activating the complement cascade, either via the alternative or lectin pathways, and this may play a major role.[208–210] Podocyte injury may be involved in progressive disease with proteinuria, as polymeric IgA stimulates podocytes to produce TNF-α.[211]

Several findings suggest that genetic factors contribute to pathogenesis, including familial clustering and a higher risk of disease in identical twins.[212–215] In a large kindred study, linkage analysis revealed an association with 6q22–23 (IgAN1), although since only 60% of patients had IgAN1, other genes are likely involved.[216] Other proposed candidates include MHC, uteroglobin, selectin and angiotensin-1 converting

enzyme genes (DD genotype), however the results have been conflicting.[217–223] Interestingly, a genome-wide search in the ddY murine model revealed that syntenic regions of IgAN1 and selectin genes are major genetic determinants for IgAN.[224]

Pathology

Immunofluorescence (IF) demonstrates prominent deposits of IgA in a diffuse, granular pattern, predominantly within the mesangium (Figure 82.3), and occasionally in the glomerular capillary wall,[225] typically accompanied by C3 and IgG, and less frequently by IgM. There is often a predominance of λ light chains.[226] Light microscopic findings are variable.[225,227] Glomeruli may show mild lesions without mesangial expansion or limited mesangial cell proliferation, mesangioproliferative GN, focal or diffuse proliferative GN, crescents, chronic sclerosing GN, or rarely an MPGN pattern.[227] Electron microscopy typically reveals electron dense deposits, predominantly within the mesangium, although capillary wall deposits are common in more severely affected individuals.

Clinical Presentation

IgAN has many clinical presentations[146,228] (Table 82.9). Recurrent episodes of macroscopic hematuria are more common in younger patients.[229] These episodes often occur within 2–3 days of an upper respiratory tract or other infection. Loin pain may accompany the hematuria, (i.e., due to renal capsular swelling. In 30–40% of patients, the disease is asymptomatic with persistent or intermittent microscopic hematuria or proteinuria discovered incidentally. Acute renal failure occurs in less than 5% due to either crescentic GN,[230] renal tubular obstruction by red blood cells[231] or acute tubular necrosis.[232] Nephrotic syndrome is a less common presentation, although given IgAN's overall prevalence, it accounts for a significant fraction of adults with idiopathic nephrotic syndrome (i.e., 20–25%).

Asymptomatic microscopic hematuria
Acute GN
RPGN with acute renal failure (<5%)
Nephrotic syndrome

Prognosis

Overall prognosis is variable and depends on the severity of clinical and pathologic findings at presentation.[233,234] It has been estimated that ESRD occurs in 15 percent of cases at 10 years and 20–40% percent at 20 years, although this likely reflects selection of patients with more severe disease.[231,235] Some patients have a slow progressive decline in renal function over 10–20 years. Patients with non-nephrotic proteinuria and normal GFR at presentation progress more slowly (e.g., 1–3 ml/min/year). Elevated serum creatinine and heavy proteinuria at either presentation, or within the first year of diagnosis are independent predictors of poor outcome;[236–238] hypertension, glomerulosclerosis, and interstitial fibrosis are others.[228,234,239–244]

Biomarkers and Treatment

Secretory IgA, urinary complement factor H/urine creatinine ratio, serum galactose deficient IgA (HAA-IgA)[245] and urinary ratio of epidermal growth factor and monocyte chemotactic peptide-1 are being investigated as potential biomarkers. No therapeutic approach has consistently been shown to slow progression,[242,246,247] and variations in pathogenesis, pathology, clinical severity, co-morbid conditions and other factors contribute to this limitation. Clinical trials have compared conservative therapy, renin angiotensin aldosterone system (RAAS) blockade, and various immunosuppressive strategies. The consensus is that patients with normal renal function, (including <1 gm of proteinuria, minimal lesion on biopsy, and blood

TABLE 82.10 IgA Adverse Prognosis Factors (overall ESRD 15% at 10y; 20–49% at 20y)

pressure of 120/80) do not require treatment. Patients with hypertension, proteinuria (>1 gm/day), reduced GFR, or more severe pathological lesions on biopsy may require treatment. The specific approach remains somewhat controversial. Multiple studies have shown RAAS inhibition (e.g., with ACEI or ARB) slows progression of the disease.[248,249] Although the combination may have additional benefits, acute renal failure may complicate this approach.[250–252] Fish oils, rich in omega 3 fatty acids (ω-3PUFA), eicosapentanoic acid (EPA) and docosahexanoic acid (DHA) may provide anti-inflammatory effects and retard renal progression by competing with arachidonic acid to produce biologically less effective prostaglandins and leukotrienes, and by decreasing platelet aggregation,[253] although clinical trials of efficacy have produced conflicting results.[243,254–257] Nevertheless, given the possible benefit and lack of toxicity, high dose fish oil therapy in combination with ACEI/ARB therapy in patients with proteinuria (>1 g/day) and/or mildly impaired renal function is reasonable.

The efficacy of high dose steroids and other immunosuppressive agents is not certain.[258,259] One prospective multi-center trial randomized IgAN patients (SCr <1.5 mg/dl, proteinuria 1.0–3.5 g/d) to either six months of steroid treatment or supportive therapy.[260] At 6 and 10 years, there was a lower incidence of the doubling of serum creatinine in the steroid group, and this was associated with a decrease in proteinuria.[261] Thus, steroids may be warranted in IgAN patients with heavy proteinuria and relatively normal renal function. Patients with either nephrotic syndrome and histologic findings characteristic of minimal change disease or clinical and pathologic features of RPGN may also benefit from steroid therapy.[262] Other immunosuppressive approaches have been inconclusive.[30,259,263–271] Similarly, removal of the palatine tonsils to reduce serum IgA levels and limit progression[272,273] has not been associated with preservation of renal function.[274,275]

Transplantation

Immunohistologic recurrence develops in as many as 60% of allografts by 10 years and 5–10% of affected allografts are lost to progressive disease.[276–280] Contemporary immunosuppression regimens using MMF have not altered recurrence rates.[281]

Idiopathic MPGN

MPGN or mesangiocapillary GN may be idiopathic or associated with systemic diseases.[282] Pathologically, they share light microscopic features including glomerular capillary wall thickening, hypercellularity and matrix expansion (Figure 82.4). MPGN is further classified as type I, II or III, based on IF and EM patterns.[283–285] This section focuses on primary or idiopathic forms of the disease.

Incidence

Overall these forms represent less than <10% of primary glomerular disease GN,[286–288] although they are somewhat more prevalent in children.

Pathology

MPGN I is characterized by subendothelial and mesangial immune deposits, with IgG and complement deposition predominating. Diffuse thickening of capillary walls is typical, and the loops often have a double-contoured or "tram track" appearance when stained with silver methenamine or periodic acid-Schiff (Figure 82.5). Widespread electron-dense deposits in subendothelial sites are the hallmark of type I disease (Figure 82.6). The hallmark of MPGN type II is the presence of electron dense deposits

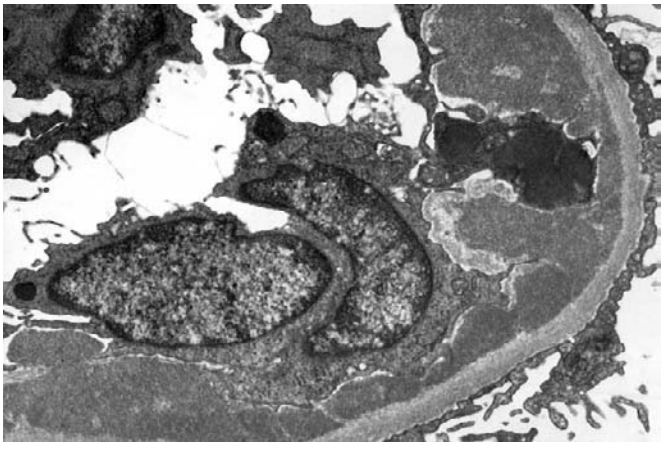

FIGURE 82.4 Membranoproliferative glomerulonephritis (MPGN). Mesangial hypercellularity and increased mesangial matrix with lobular accentuation. There is diffuse thickening of peripheral glomerular capillary walls (H&E, X330).

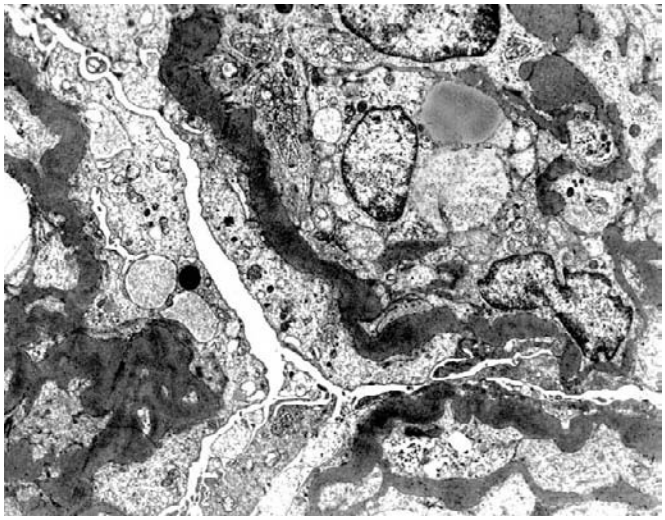

FIGURE 82.5 MPGN Silver stains showing double contoured glomerular capillary walls by enclosing silver-negative subendothelial deposits and mesangial interposition (Jones silver methenamine, X400).

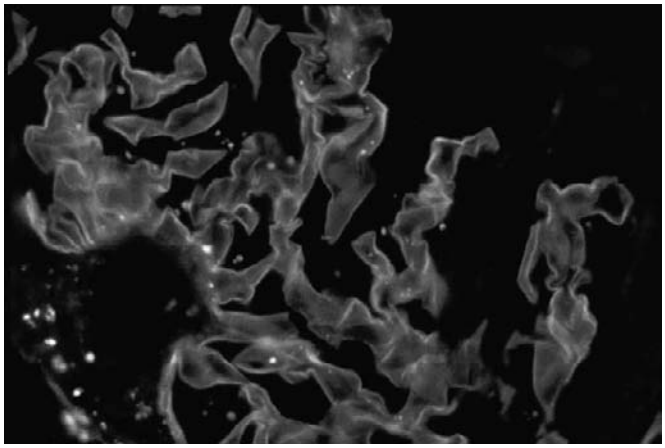

FIGURE 82.6 MPGN, type I Electron micrograph showing large electron-dense subendothelial deposits.

within the lamina densa layer of the GBM that are often visible by conventional eosin and PAS stains (hence the designation Dense Deposit Disease).[289] The dense intramembranous deposits seen by electron microscopy are diagnostic (Figure 82.7) and may involve tubular and vascular basement membranes in the kidney, Bruch's membrane in the eye,[290,291] and sinusoidal membranes in the spleen.[292] The deposits may also be seen within the mesangium and within the basement membranes of Bowman's capsules and tubules.[293] The chemical composition of the electron dense deposits is not known,[294] but they stain with thioflavin T and bind lectin wheat germ agglutinin,

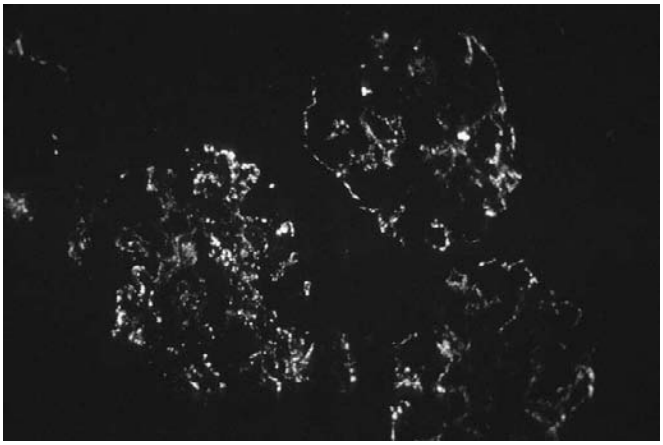

FIGURE 82.7 MPGN, type II Electron micrograph showing intramembranous electron-dense deposits with ribbon-like thickening of glomerular capillary walls. The mesangium is expanded by increased matrix and cells.

suggesting that they are composed of N-acetyl-glucosamine, glycoproteins and lipids rich in unsaturated fatty acids.[295,296] Immunofluorescence reveals intense staining of C3 along capillary walls and within the mesangium. Absence of immunoglobulins is a distinguishing feature of Type II MPGN. By contrast Type III MPGN, also called the Burkholder variant,[297] displays features of MPGN type I and membranous nephropathy, with subepithelial, subendothelial and mesangial deposits.[298] Successive generation of subendothelial and subepithelial deposits disrupt the basement membrane, and concurrent formation of new lamina densa material are often observed.

Pathogenesis

Local activation of the complement cascade is operative in all forms. Catalyst destabilization (e.g., through either acquired antagonism or deficiency in the inhibitory pathway), results in unopposed complement activation in glomeruli. Hypocomplementemia results from local consumption and/or circulating autoantibodies against individual complement components (i.e., nephritic factors).[105,299] Three nephritic autoantibodies[300] have been commonly described in MPGN type 1, including: (1) C4Nef,[301–303] an IgG that stabilizes the C3 convertase, C4b2a, thereby preventing the decay of 2a from C4b2a; (2) C3Nef (see below); and (3) NFt, an autoantibody against C3bBbP that activates the terminal pathway.[303,304] Their precise pathogenic role is uncertain,[299] as they are occasionally detected in either unrelated diseases (e.g., post-streptococcal GN, SLE, meningococcal meningitis)[305–307] or healthy individuals.[307]

Clinical Presentation

MPGN has variable presentations, from microscopic hematuria and sub-nephrotic proteinuria (35%), to nephritic syndrome with mild renal impairment (35%), to an aggressive glomerulonephritis (20%) with rapidly deteriorating renal function, heavy proteinuria, and RBC casts (10%). Laboratory findings often display decreased complement levels [C3, C4, and total complement (CH50)], depending on the variety of MPGN (Table 82.11).

Treatment

Control of hypertension and proteinuria reduction are key, and focus should be on identifying and treating secondary causes of the lesions. For idiopathic disease, treatment is based on disease severity. Patients with sub-nephrotic proteinuria and preserved renal function are treated conservatively. Patients with impaired renal function and/or nephrotic proteinuria can undergo a trial of prednisolone (1 mg/kg/d) for proteinuria reduction.[308] If a response is noted, steroids can be continued at the minimally-effective dose. If there is no response after three months, steroids should be stopped, and a trial of a calcineurin inhibitor or mycophenolate mofetil can be attempted.[309] Patients with rapidly declining renal function, or with crescents on biopsy should be treated as those with other forms of RPGN.

Asymptomatic urinary abnormalities (i.e. proteinuria and hematuria. 20–30%)
Recurrent macroscopic hematuria (< 10%)
Hypertension may be mild or severe
Note that MPGN Type II often presents with acute nephritis and/or macroscopic hematuria, MPGN Type III often presents with more insidious onset
MPGN III low C3 levels, normal C4

Thrombotic Microangiopathies (TMA)

Thrombotic microangiopathy (TMA) is characterized by the syndrome of microangiopathic hemolytic anemia, thrombocytopenia, and variable organ dysfunction due to platelet thrombosis in the microcirculation, which can mimic acute GN.[310] Depending on the predominant distribution of organ involvement, pathologically identical, but clinically separable entities have been designated as: Hemolytic-Uremic Syndrome (HUS) and Thrombotic Thrombocytopenic Purpura (TTP).[311] Since their pathophysiology overlaps, both topics are presented.

Typical HUS commonly affects children under five, is characterized by moderate to severe renal involvement, and is self-limited. It is caused by specific serotypes of *E. coli* or other bacteria that produce Shiga-like toxin.[312] Atypical HUS may be familial or sporadic. The familial forms are associated with genetic abnormalities in complement system proteins. The sporadic forms are often triggered by drugs, malignancy, infection or autoimmune disease that lead to dysregulation of complement system proteins (Table 82.15).

TTP occurs in adults and typically manifests with more neurologic sequelae and variable renal involvement. Prompt recognition of these disorders is essential, as delay in therapy may lead to organ failure or death (i.e., with TTP).

Incidence

The TMAs occur in 1−4 cases per 1,000,000 people, although it has been reported more frequently in patients with malignancy, HIV infection, or various drug exposures (Table 82.15). As previously mentioned, acquired HUS may be associated with Shiga toxin-producing *E. coli* (or other bacterial) infection and commonly affects infants and children infected with the O157:H7 strain.[313]

Pathophysiology

The involved pathways and distinguishing features of HUS and TTP are summarized in Table 82.16.[312,314–316] TTP is mediated by dysfunction of the metalloprotease ADAMTS13, which degrades large von Wildebrand factor (vWF) multimers.[317] Without this activity, vWF multimers aggregate within vascular lumen, propagating platelet congregation, aggregation, and activation, thus leading to further microthrombosis and sequelae. Low ADAMTS13 activity can result from a constitutive deficiency or acquired circulating IgG autoantibodies to the ADAMTS13 protein.[316]

As mentioned previously, acquired HUS may be associated with Shiga toxin-producing *E. coli* (or other bacterial) infection and commonly affects infants and children infected with the O157:H7 strain. Once thought entirely due to inflammatory cytokine effect on renal endothelial cells,[310] it is now understood that the abnormal regulation of the alternative pathway of the complement cascade augments pathophysiology driving the disorder,[318,319] with excessive activation of C3 leading to formation of the membrane attack complex (C5−9), that in turn, propagates platelet activation and accumulation.

A non-infectious, atypical form of HUS (aHUS) has been identified involving either inherited or acquired defects within the alternative pathway. Initial reports of loss-of-function of regulatory factors (namely, Factor H) appeared in up to 30% of familial cases.[320] Recently,

TABLE 82.16 Distinguishing Pathophysiology of TTP and HUS

TTP
- decreased ADAMTS13 (enzyme that cleaves large vWF multimers)
- large vWF complexes in blood and thrombi, accumulate on the surface of endothelial cells
- fibrinogen in thrombi
- platelet adhesion, aggregation, thrombosis, thrombocytopenia
- microthrombi small vessels
- lack of inflammation or endothelial damage
HUS
- Shiga exotoxin subunit binds to cell surface globotriaosylceramide receptors (e.g., colon, glomerular endothelia)
- Endothelial cells produce TNF-, IL-6, IL-1
- Glomerular endothelial cells produce large vWF multimers
- Fibrin, platelets, microthrombi accumulate
- Microthrombi involving small vessels

a gain-of-function of complement factor B has been identified.[321] Both Factor H and Factor B defects have also been identified in acquired cases. These factors regulate complement activity locally; therefore loss of regulation within the kidney (or other vascular sites) may lead to unregulated complement activation and inflammation.

The genetic form of aHUS is prevalent more in children, where the acquired aHUS manifests more in adults. Systemic disease and conditions associated with TMA are listed in Table 82.15.

Pathology

The histological lesions of TMA are characterized by thickening of arterioles and capillaries, endothelial swelling and detachment, subendothelial accumulation of protein and cell debris, intraluminal platelet thrombi, and partial or complete occlusion of the vessel lumina.[312] These changes can also be seen in other renal pathology, such as scleroderma, malignant nephrosclerosis, and calcineurin inhibitor toxicity. TTP, Shiga toxin-associated HUS and atypical HUS are indistinguishable on microscopy.

Clinical Presentation; Laboratory Features

TMA manifests as a microangiopathic, hemolytic anemia with thrombocytopenia; schistocytes and helmet cells are visualized on peripheral blood smear. Platelet counts vary depending on the syndrome; HUS typically presents with platelet counts between $30-100\times10^9$ cells/L, while TTP is usually manifest by a more severe thrombocytopenia, with $<30\times10^9$ cells/L present. The hemolytic anemia (Coombs' negative) can be severe, with hemoglobins <6.5 g/dl present. Reticulocytosis, hyperbilirubinemia (often indirect), low haptoglobin, and elevated lactate dehydrogenase (LDH) are also present. Hypocomplementemia (especially C3) may be present. The acute kidney injury is more common with HUS and can sometimes mimic RPGN. Clinical presentation varies with HUS typically having more renal manifestations, while TTP displays more neurologic sequelae.

Prognosis and Treatment

Treatment for the TMAs is mostly supportive. Plasma exchange therapy is effective in both TTP and aHUS. Corticosteroids have yielded inconsistent results. Rituximab has had anecdotal success in a few patients with refractory TTP.[322] Recently, the monoclonal C5 antibody eculizumab was effective in a few patients with HUS and aHUS,[323,324] although widespread use requires validation in larger series.

PRIMARY RENAL DISEASES CAUSING NEPHROTIC SYNDROME

The nephrotic syndrome is defined by clinical and laboratory abnormalities common to a variety of primary and secondary kidney diseases, each characterized by increased permeability of the glomerular capillary wall to circulating plasma proteins. The clinical manifestation of filtration barrier dysfunction caused by these disorders is proteinuria (greater than 3.5 g/24 hr) which leads to hypoalbuminemia. Other manifestations such as edema, hyperlipidemia, lipiduria and coagulation disorders occur commonly. This section of the glomerular disease chapter addresses primary or idiopathic kidney diseases, which lead to the nephrotic syndrome. The most common causes of idiopathic nephrotic syndrome, membranous nephropathy, focal and segmental glomerulosclerosis, and minimal change disease are discussed in detail.

Membranous Nephropathy

Membranous nephropathy (MN) is also referred to as membranous glomerulopathy or membranous glomerulonephritis, reflecting morphologic abnormalities of the glomerular basement membrane. MN is one of the most common causes of nephrotic syndrome in adults, comprising an estimated 15–25% of all cases of primary/idiopathic nephrotic syndrome.[376] However, the incidence of FSGS and IgAN is increasing,[376] rivaling MN as the most common etiologies, and

representing a greater cause of nephrotic syndrome than MN in some subpopulations, such as FSGS in African American men.[376–378] MN exists in idiopathic and secondary forms,[379] due to systemic diseases (systemic lupus erythematosus, less commonly mixed connective tissue disease or rheumatoid arthritis), malignancies (lung, colon, gastric and breast carcinomas),[380] infections (hepatitis B and C,[381] syphilis, malaria, schistosomiasis, filariases, leprosy, tuberculosis, parvovirus[382]) and drugs (gold, penicillamine, mercury, probenecid, and perhaps high doses of captopril[383–386]) (Table 82.17). The prevalence of MN varies according to geography, with the highest rates in European-Americans, which exceeds rates in Japan and Australia.[387] However, these data may be biased by biopsy practices, as well as variation in relative frequency of predisposing conditions for secondary MN in each region.[388,389] Idiopathic MN is most common in middle age men,[390–394] rarely occurs in children, and appears to have no racial predilection.[387]

Clinical Presentation and Natural History

Approximately 70–80% of patients diagnosed with idiopathic MN present with features of the nephrotic syndrome, including hypoalbuminemia, peripheral edema, and hyperlipidemia,[393,395–403] though this may be an overestimation, since patients with lesser degrees of proteinuria may not be biopsied. Most MN series indicate that at the time of diagnosis, GFR, as determined by serum creatinine, is typically normal or mildly increased, with less than 10% of patients presenting with diminished GFR.[400,403] However, in a study by Shemen et al., wherein GFR was estimated by inulin clearance in 20 patients with MN and heavy proteinuria versus 20 controls, mean GFR was only 58 ml/min/1.73 m^2 in the MN group.[404] Although this study may have enrolled a population with advanced disease, it still highlights that GFR may be abnormal in MN. Patients with MN are generally normotensive,[390,405] with the reported incidence of hypertension at time of diagnosis ranging from 13 to 55%.[387,400]

The natural history of MN can be discerned from untreated controls from therapeutic trials[391,400,406–416] or observational studies,[380,392,393,395,398,417–420] and indicate that the course can be relatively benign in many patients, especially those with sub-nephrotic range proteinuria. In a study of 100 patients with biopsy-proven MN, Schieppati et al. demonstrated that the probability of retaining GFR was 88% at five years and 73% at eight years; 16% developed ESRD over an average of 8 years.[414] Ten year follow-up data from the Ponticelli group showed that 40% of untreated controls developed ESRD.[416] Figures from both of these Italian studies are consistent with those of Pei et al., which demonstrated that 26% of subjects developed chronic kidney disease (defined as GFR <60 ml/min/1.73 m^2) after a mean follow-up interval of 5.8 years.[421] The best outcomes are reported by Kida et al., in a series of 104 Japanese patients, which demonstrated that 80, 70 and 50% of patients had a GFR exceeding 80 ml/min at five, 10 and 15 years, respectively.[402] A comprehensive review by Hogan et al. showed that renal survival probability in untreated patients was 86% at five years, 65% at 10 years and 59% at 15 years.[422] Of patients with MN that experience GFR decline, the course is generally protracted, with a mean time to doubling of creatinine of 30 months in one series[398] and an average of 30 months from presentation to ESRD in another study.[415] More abrupt diminution in GFR should warrant investigation of alternative etiologies of acute kidney injury. MN with fibrocellular crescents (RPGN) has been rarely described,[423] and should be considered in this differential diagnosis.

If proteinuria is used as a surrogate marker of MN disease course, Schiepatti et al. demonstrated partial or complete remission in 65% of subjects at five years,[414] similar to a report from Davison et al., which showed complete remission in 25% of patients at five years.[398] Pooled data from Hogan et al. showed complete remission in 10% at one year, 16% at two years and 22% at three years,[422] consistent with the commonly quoted statement that approximately 25−30% of patients with idiopathic MN spontaneously remit.[387,424] A study from Troyanov et al. demonstrates that dialysis-free renal survival at 10 years is 100% in MN patients with complete proteinuria remission, 90% in those with partial remission (defined as reduction in proteinuria by >50% and to <3.5 g/24 hr), and 45% for those without remission.[425]

Because some patients with MN progress to ESRD, many groups have tried to identify clinical parameters, which predict likelihood of progression. Multiple clinical risk factors have been identified, including massive proteinuria, male gender, advanced age, hypertension, and diminished GFR at clinical presentation. An algorithm has been published, which takes many of these factors into account and yields a quantitative risk for progression.[426] Most,[380,392,398−400,403,415,420,427,428] but not all[414] studies have shown that at the time of diagnosis, patients with non-nephrotic proteinuria have a better prognosis than those with nephrotic range proteinuria. In a biopsy series of 140 patients with MN, initial presentation with more than 10 g proteinuria/24 hours predicted a 60% probability of renal disease progression.[415] Persistent proteinuria of >8 g/24 hr for ≥6 months, >6 g/24 hr for ≥9 months or >4 g/24 hr for ≥18 months was also associated with increased risk of progression to chronic kidney disease.[421]

Most MN case series contain a preponderance of men,[392] suggesting male gender is a risk for more severe disease. Numerous studies have specifically identified male sex as a risk for progression,[394,398,399,403,406,414,415,429] though a few have not.[400,421] Advanced age at time of diagnosis has generally been shown to be associated with risk of progressive GFR decline,[398,400,414,419,430] but not in all reports.[399] Most studies simply evaluated age as a continuous variable, though others defined age >50 years as a categorical risk.[414] Like other glomerular diseases, uncontrolled hypertension has also been shown to be a risk for progression of MN.[399,415,420] A notable exception to this finding is the series from Schiepatti et al.[414] As with most other glomerular diseases, patients presenting with MN and decreased GFR are at risk for progression.[399,400,415,421]

One of the most common complications of MN is thrombosis, venous more commonly than arterial, and particularly involving the renal vein. The incidence of MN-associated renal vein thrombosis is unclear, but estimates for all-cause nephrotic syndrome range from 4% to 62%.[387,431,432] Because many series of renal vein thrombosis contain a disproportionate number of patients with MN,[433−436] it has been suggested that renal vein thrombosis in the context of MN is more common than with other causes of the nephrotic syndrome.[432,437] The classic clinical presentation is acute onset of unilateral flank pain and tenderness, accompanied by gross hematuria and decreased GFR, though a more chronic presentation with indolent features has also been described.[432] Patients with MN and chronic renal vein thrombosis tended to be older and unlikely to progress to ESRD,[436,437] and demonstrate collateral veins on angiographic studies. The purported mechanism is enhanced urinary excretion of anti-thrombotic proteins, but conflicting blood coagulation factor levels have cast doubt on this mechanism.[431,432]

Diagnosis

The diagnosis of MN is made by renal biopsy. However, there are several other supporting laboratory findings. As mentioned previously, nephrotic range proteinuria is present in the majority of patients at the time of diagnosis, and is usually accompanied by other features of the nephrotic syndrome.[393,395−403] Proteinuria of 10 to 20 g per 24 hr is atypical but not unusual.[438] Microscopic hematuria is present in 30 to 50% of patients,[393,403] although gross hematuria is rare.[439] Approximately 90% of patients with MN have a normal or increased GFR at the time of diagnosis.[400,403] Autoantibody titers and complement levels are characteristically normal; low complement levels should raise suspicion of a secondary cause (e.g., lupus nephritis). C5b-9 membrane attack complex has been detected in urine of patients with MN,[440−444] consistent with the conclusion that proteinuria is complement-dependent in the early phases of disease.[445−448]

Since MN can be associated with other systemic diseases, it is advisable to obtain a serologic work-up, particularly if the patient has consistent clinical findings. Appropriate tests could include systemic lupus erythematosus, hepatitis B and C, and syphilis serologies. Because MN is associated with some malignancies, including after the MN diagnosis is established,[449] routinely recommended cancer screens should certainly be performed in patients with MN. Although more extensive screening is often pursued, cost-effectiveness of this strategy, in the absence of suggestive symptoms, is unclear.

Pathology

There are characteristic features on light, IF and EM, which distinguish MN.[386,387,450] Typical histologic findings on light microscopy depend on the stage

(Table 82.18) and duration of the disease (Figure 82.8). There is a lack of hypercellularity. Early on, the basement membranes appear normal, but as the immune deposits increase in size, the basement membrane reaction gives the appearance of spikes. This is best visualized on Masson's trichrome or methenamine silver stains of thinly cut sections. The relatively small deposits often require higher resolution images, which are only achievable with electron microscopy. Light microscopy is also characterized by lack of glomerular or tubulointerstitial inflammatory infiltrates. Fibrocellular crescents are rare, and if present in the context of MN features, often represent concomitant glomerular diseases.[451–456] Similar to other glomerular diseases,[457,458] when tubular atrophy and interstitial fibrosis are observed, these findings portend a poor prognosis in MN.[459,460]

Immunofluorescence microscopy evaluation of kidneys affected by MN reveals granular deposition of immunoglobulins and complement components (IgG [especially IgG4] > C3 > IgM > IgA >> C1q) in a diffuse, granular pattern along glomerular capillary walls.[386,387] The presence of IgA and C1q suggests lupus nephritis,[386,387] though rarely observed in idiopathic MN.[386] Subendothelial, mesangial or/and tubular deposits are rare and if present should raise suspicion of another diagnosis (e.g., lupus). Although C5b-9 staining is not routinely performed in most pathology laboratories, the terminal membrane attack complex characteristically decorates the glomerular capillary wall in MN.[387]

On EM, the pathognomonic finding is glomerular subepithelial, electron-dense deposits by transmission electron microscopy (Figure 82.9). The pathologic stage of disease is based on the size of deposits along with the surrounding basement membrane reaction.[461] This pathology staging scheme has been advocated as a means of assessing prognosis.[427,462] However, most studies have found that pathologic staging does not correlate well with renal outcomes.[380,406,412,415,416,419,420,463,464] The presence of dense deposits within the mesangium is rare with idiopathic MN, but is occasionally observed with secondary forms of MN.[387]

Pathophysiology

The body of evidence indicates that MN lesions result from circulating antibody binding to a resident or planted antigen on podocytes, and proteinuria is complement-dependent. In some cases, DNA, viral and tumor antigens have been identified within immune complexes,[465–470] and it is presumed that these antigens are pathogenic. It has been postulated that these antigens induce an antibody response, and by nature of their physical properties, localize within the basement membrane and podocytes. They persist in the subepithelial location (e.g., due to a physical interaction of the antigen and either the basement membrane or podocyte cell surface) and permit binding of circulating antibodies, (the latter may be facilitated by slightly altered permeability induced by circulating cytokines or chemokines). The antibodies then activate complement, eventually leading to formation of the membrane attack complex (C5b-9),[471] which induces sublethal (or perhaps lethal) injury to podocytes, causing their effacement.[472,473] Clinically, this leads to proteinuria, which is likely mediated through reactive oxygen species generation.[474–477] As the deposits continue to grow, their physical presence also contributes to podocyte foot process effacement.

TABLE 82.18 Pathologic Staging of Membranous Nephropathy Lesions

Pathologic Stage	Histologic Features	Podocyte Foot Process Effacement?
I	Small, diffuse electron-dense immune deposits in a subepithelial (between the GBM and podocyte foot processes) location	Yes
II	Subepithelial "spikes", which are generated by incomplete surrounding of deposits by GBM	Yes
III	Electron-dense deposits appear as intra-membranous due to GBM between the deposit and podocyte foot process	Yes
IV	Deposit loss of electron density, GBM thickened, with pronounced areas of clearing	Yes

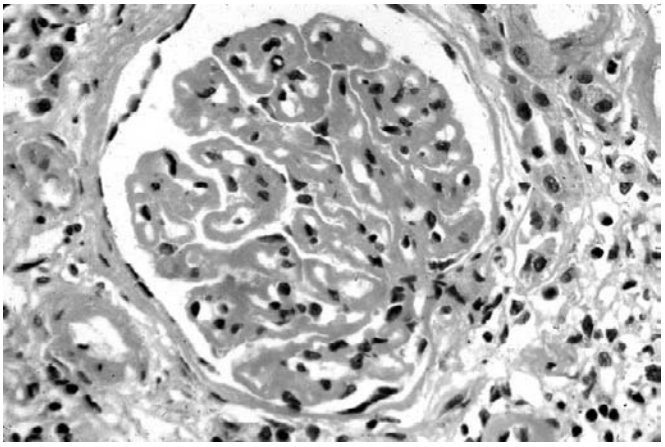

FIGURE 82.8 Membranous glomerulonephritis. All glomerular capillary walls are markedly thickened without significant cellular proliferation (H&E, X320).

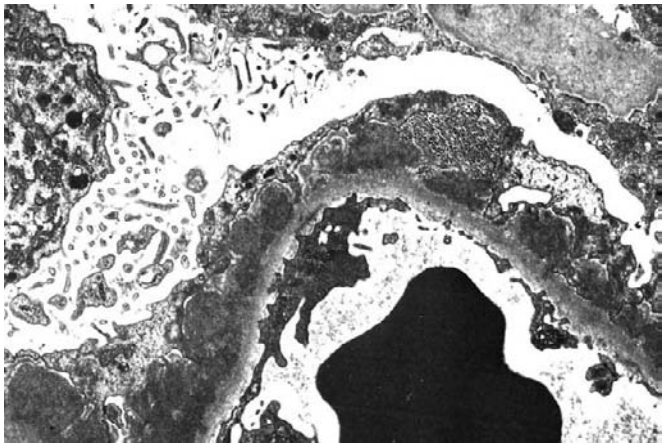

FIGURE 82.9 Membranous glomerulonephritis. Electron micrograph demonstrating multiple electron-dense subepithelial deposits. There is diffuse effacement of overlying epithelial foot processes.

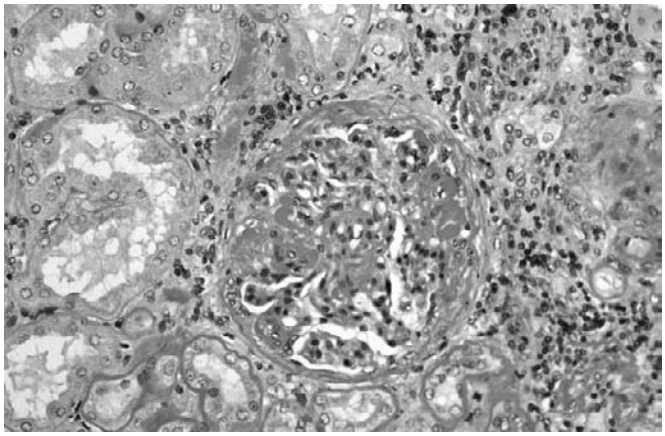

FIGURE 82.10 Focal segmental glomerulosclerosis. Segmental glomerular sclerosis with hyalinosis and partial adhesions to Bowman's capsule. There is patchy tubular loss and interstitial mononuclear cell infiltrate (H&E, X250).

Although C5b-9 staining is not routinely performed in most pathology laboratories, the terminal membrane attack complex is characteristically deposited within the glomerular capillary wall in MN.[387] Since the immune deposits form on the subepithelial side of the basement membrane, chemotactic factors are excreted in the urine and cells are not recruited, nor can they cross an intact GBM. There is podocyte activation and secretion of matrix metalloproteinases,[478,479] which leads to changes in GBM composition. This loss of appropriate extracellular cues then facilitates podocyte apoptosis and detachment,[447] with accompanying cytoskeleton disruption,[480] nephrin-cytoskeleton dissociation[481] and loss of nephrin expression.[482]

Much of the evidence to support pathogenesis is derived from experimental models of MN [e.g., Heymann nephritis[406,483–485]], though translation of these findings to human MN pathophysiology has not always been straightforward. However, in a recent screen of serum from patients with idiopathic MN, a circulating IgG4 subclass autoantibody, which is immunoreactive with the M-type phospholipase A2 receptor, was identified in 70% of samples.[486] The autoantibodies localized to subepithelial deposits in biopsies from MN patients, and antibody titers correlated with disease activity. No immunoreactivity was detected in serum from lupus MN patients, suggesting that the phospholipase A2 receptor is a major antigen for idiopathic MN. Because anti-PLA2 receptor antibodies were not present in all samples, the possibility of other MN antigens exists. Debiec and Ronco described a pregnant patient, who was deficient in neutral endopeptidase (NEP). She developed and transferred anti-NEP antibodies to her baby, who was replete with NEP, and was then born with congenital MN.[487,488] Anti-NEP antibodies were determined to be pathogenic in this case.[489] Antibodies to aldose reductase and manganese superoxide dismutase, both of which are expressed in podocytes, have recently been identified in serum and glomeruli of MN patients.[490]

Genetic Susceptibility

There are rare reports of familial MN.[491–494] Klouda et al. determined that HLA DR3 expression was highly associated with MN,[495] a finding that has subsequently been corroborated in other European populations.[496,497] HLA B18 may also pose a MN risk, and the combination of HLA-DR3, B18 and Bf1 is associated with MN and a rapidly deteriorating clinical course.[498] In studies from Japan, DR2 and DQw1 are more prevalent in patients with MN,[499] and an overall better prognosis for MN in the Japanese has been attributed to genetic differences.[500] Despite these associations between genetic markers and MN, the effect on clinical course is uncertain.

Treatment

The therapy for secondary MN is to treat the underlying disorder or withdraw the offending agent.[379] Because spontaneous remission occurs in approximately one-third of idiopathic MN cases,[501] and most treatment regimens contain drugs with potentially serious side effects, patients with few risk factors for progression, such as women and patients with normal GFR and <3.5 g/d proteinuria should be treated conservatively and monitored closely,[424,426] with an emphasis on anti-hypertensive therapy to control blood pressure and reduce proteinuria, preferably with an ACE inhibitor or angiotensin receptor blocker.[424,502–504]

Diuretics often control edema, and HMG CoA reductase inhibition is recommended for hyperlipidemia.[505,506] Prophylactic anticoagulation therapy to prevent thromboembolism is controversial, and should be reserved for patients with previous events or at high risk for thrombosis.[387,507]

The largest MN trials enrolled subjects with persistent nephrotic range proteinuria and stable GFR, with varying risks for progression. Corticosteroids as a sole agent for reducing proteinuria or preserving GFR are ineffective.[406,407,411,422,508] The Ponticelli group has published extensively about a six-month regimen for idiopathic MN that prescribes methylprednisolone (1 g/d for the first three days of each month) with alternating monthly prednisone (0.5 mg/kg/d) or chlorambucil (0.2 mg/kg/d).[462] At ten years follow-up, renal survival was 92% in the treatment group versus 60% in controls.[416] Because of concern about chlorambucil toxicity, this same group has conducted a randomized trial comparing prednisone combined with cyclophosphamide versus chlorambucil for MN treatment. These studies demonstrated no difference in outcome, and patients in the cyclophosphamide arm experienced fewer side effects,[509] suggesting that cyclophosphamide plus prednisone is also an acceptable choice. In a trial of 94 patients randomized to a six-month regimen with prednisone and cyclophosphamide versus supportive treatment (no immunosuppression), 10-year outcomes for mortality, dialysis-free survival, doubling of serum creatinine and relapse rates were all superior in the experimental group.[510] Another randomized trial involving 42 patients and one-year follow-up, demonstrated that prednisone plus either intravenous cyclophosphamide or cyclosporine was more effective than prednisone alone.[508] These results are consistent with some,[511] but not all studies,[403,408,413,512] though comparisons are difficult because patient populations, entry criteria and treatment regimens differed.[422,513] Nevertheless, in patients with MN that includes the nephrotic syndrome and stable GFR, in addition to supportive therapy, treatment with corticosteroids and an alkylating agent is preferable, particularly if patients have poor prognostic factors for progressive disease.

MN patients presenting with deteriorating GFR represent a special group, since they are at high risk for further progression. However, few trials have been specifically designed to address this subgroup of patients. A retrospective study by Torres et al. demonstrated efficacy of a chlorambucil plus prednisone regimen compared to a historical, untreated control group with equivalent MN progression.[514] Similar results were observed by Warwick et al., though toxicity was significant.[515] Two small studies showed efficacy of oral cyclophosphamide and prednisone in MN subjects with pre-existing, depressed or declining GFR.[516,517] Cattran et al. showed that in MN patients developing GFR decline with conservative therapy, subsequent treatment with cyclosporine slowed progression compared to a placebo control group.[518] More sobering results were obtained in the prospective trial by Falk et al., which demonstrated that prednisone with or without cyclophosphamide did not prevent renal disease progression in a MN cohort with a mean serum creatinine of 2.3 to 2.7 mg/dl and proteinuria greater than 10 g/24 hr,[519] suggesting that salvage therapy may be ineffective, once renal function has deteriorated. Therefore, in patients with serum creatinine exceeding 2.5 to 3.0, though there is no consensus regarding optimum treatment, it would be reasonable to manage conservatively, and prepare for dialysis or transplantation, rather than subjecting these patients to the potential perils of immunosuppressive therapy.

Cyclosporine has been shown to be effective for inducing and sustaining MN remission,[520,521] but concerns about nephrotoxicity render it less desirable for chronic treatment. Among newer agents, mycophenolate mofetil (MMF) and rituximab have been examined in small, mostly uncontrolled trials with MN patients. MMF has the benefit over cyclosporine and other calcineurin inhibitors because of less nephrotoxicity. Miller et al. demonstrated some benefit of MMF in a small study of 16 patients, most of whom had already failed other MN treatments.[522] Similar results were observed in an MMF trial by Choi et al. involving 17 patients with MN.[523] In two recent, small, controlled trials, with 1−2 year follow-up, MMF was no more effective than conservative therapy (no immunosuppression) or cyclophosphamide-containing regimens.[524,525] Rituximab is a chimeric monoclonal antibody, which binds to the B cell CD20 receptor and depletes B cells (but not plasma cells). Remuzzi and Ruggenenti observed that four weekly injections of rituximab conferred a sustained benefit in proteinuria reduction for up to one year in eight patients with MN, who had failed conventional treatment.[526,527] Rituximab, given every two weeks and at six months, may also be effective.[528] In a study of 13 MN patients dependent on MMF, cyclosporine or tacrolimus, four weekly doses of rituximab appeared to enable calcineurin inhibitor withdrawal, with sustained remission at 30 months.[529]

A diagnosis of MN is not a contraindication to renal transplantation. Although there are little outcome data, a recent study of 35 MN patients versus 70 non-MN controls demonstrated no difference in mortality at 10 years, but there was a trend toward decreased allograft survival and a 34% recurrence rate in the MN group.[530] The MN recurrence rate, with associated poor prognosis, was similar in a European transplantation cohort.[531]

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) describes a histological lesion that is found in patients with idiopathic nephrotic syndrome.[532] FSGS is the most common cause of idiopathic nephrotic syndrome among African Americans. However, patients with FSGS constitute an increasingly larger fraction of idiopathic nephrotic individuals in the general, adult population. A survey of renal biopsies from 1995 to 1997 in adult patients with idiopathic nephrotic syndrome showed that FSGS is the most common lesion, accounting for 35% of all patients and for 50% of cases in African-American patients.[533–535] Focal segmental glomerulosclerosis accounts for approximately 3% of adult cases of end stage renal disease in North America.[535] Persistent non-nephrotic-range proteinuria is associated with good long-term renal survival, but declining glomerular filtration rates characterize patients with persistent nephrotic-range proteinuria. Evidence-based treatment guidelines are now being developed, but as discussed below, many experts recommend corticosteroids as initial therapy in patients with a poor prognosis for renal survival.

TABLE 82.19 Classification of FSGS

PRIMARY
Idiopathic FSGS
Classic
Glomerular tip variant
Collapsing or "malignant" variant
Superimposed on minimal change nephropathy
Familial (caused by mutations in podocyte genes encoding components of the slit diaphragm)
SECONDARY
Sickle-cell disease
Unilateral renal agenesis
HIV infection
Intravenous drug abuse
Vesicoureteral reflux
Diabetes mellitus (rare)
Postinflammatory scarring
Morbid obesity

Diagnosis and Course

Proteinuria, often in the nephrotic range, is the hallmark of FSGS. Hypertension is a presenting feature in approximately one-third of patients, and some degree of renal insufficiency is also present in one-third of patients at the time of diagnosis. Over half the patients with FSGS have hematuria. Proteinuria without hypertension is more common in children than adults with FSGS.[536]

FSGS may be primary (idiopathic) or secondary (Table 82.19). By definition, the term "idiopathic FSGS" is only used if evidence is lacking for other causes of focal glomerulonephritis that could result in focal scarring after healing.

The prognosis and clinical course of idiopathic FSGS are determined primarily by the severity of proteinuria.[537,538] Persistent non-nephrotic-range proteinuria is associated with good long-term renal survival. In contrast, declining glomerular filtration rates characterize patients with persistent nephrotic-range proteinuria. In this latter group of FSGS patients, the prevalence of end-stage renal disease 10 years after initial diagnosis is greater than 50%, and FSGS accounts for approximately 15% of pediatric and 5% of adult cases of end stage renal disease in North America. Patients with HIV-induced FSGS or the collapsing variant of FSGS (see description below) may progress rapidly to end-stage renal disease, often requiring dialysis within several months to 2–3 years after diagnosis, although the outcomes for most HIV patients has improved significantly after introduction of more effective anti-retroviral therapies.[539] The course of secondary forms of FSGS varies according to the severity and activity of the underlying disease.

Pathology

FSGS is a glomerular disease defined by a characteristic histologic pattern of scarring.[540–544] Sclerosis, or scarring, is present in parts (segmental) of some (focal) glomeruli.[543,544] By light microscopy, the typical FSGS lesion demonstrates mesangial collapse, scarring in parts of glomerular capillary tufts and adhesions to Bowman's capsule. However the light microscopic changes are non-specific and can be seen in other renal diseases, including those associated with glomerular inflammation. Immunoglobulin and complement deposition is generally not detected, although IgM and, less frequently, C3 staining can be detected in non-sclerotic glomeruli of some patients with FSGS. Demonstration of abundant immunoglobulin deposits by immunofluorescence should suggest another, superimposed primary or secondary glomerulonephritis. Similar to light microscopy, ultrastructural analysis by electron microscopy shows non-specific changes, predominantly foot process effacement in FSGS patients with heavy proteinuria, but can demonstrate other causes of glomerular disease, which are not apparent by light microscopy. Sometimes the focal, segmental glomerular scar is only identified by electron microscopy.

In addition to this typical lesion, there are additional, structural variants of FSGS that have been recently defined by a Working Group of pathologists.[545] In addition to the lesion described in the preceding paragraph (which is now classified as FSGS, not otherwise specified), the glomerular tip lesion is characterized by swelling, vacuolation, and proliferation of visceral epithelial cells (podocytes) and by sclerosis in the glomerular segments closest to the proximal tubule. Limited evidence suggests that patients with this histology tend to exhibit a more benign course and to be more responsive to steroid therapy compared to patients with classic FSGS. A second variant is characterized by focal or global glomerular capillary collapse and sclerosis with visceral epithelial cell swelling. This lesion is associated with a less favorable prognosis and is identified more commonly in African-American patients and in patients with human immunodeficiency virus (HIV) nephropathy. Additional morphologic variants include the perihilar (perihilar sclerosis and hyalinosis involving >50% of segmentally sclerotic glomeruli) and cellular (at least one glomerulus with segmental endocapillary hypercellularity occluding lumina) patterns. Severe tubulointerstitial disease associated with any of the structural, FSGS lesions correlates with poor long-term renal survival. Because the remission rate after treatment is similar among patients with the histologic variants, response to therapy cannot be predicted on the basis of histology alone.[546]

Pathophysiology

The molecular etiology of the sporadic forms of FSGS has not been determined, but several landmark studies have identified genetic mechanisms of FSGS and nephrotic syndromes, which cluster in families and is often steroid-resistant.[547–551] Mutations in several genes have been linked to familial FSGS, demonstrating the genetic heterogeneity of this disorder. The protein products of the human FSGS and nephrotic syndrome genes identified to date appear necessary for the maintenance of the filtration barrier (specifically the slit diaphragm) by the podocyte. These genes include *NPHS1* (encoding the slit diaphragm protein, nephrin), *NPHS2* (encoding the slit diaphragm protein, podocin), and *ACTN4* (encoding the cytoskeletal protein, α-actinin-4). More recently, mutations in a gene encoding a cation channel (*TRPC6*) have been identified in families with familial glomerulosclerosis. The genetic basis of sporadic FSGS is less well-defined, but mutations in the genes encoding a podocyte-selective transcription factor, *WT1*, and *NPHS2* have been described in approximately 5 and 11% of patients with non-familial, steroid-resistant FSGS. Mutations in the phospholipase C epsilon gene were identified as causing early-onset nephrotic syndrome with end-stage kidney disease.[552] Kidney histology of affected individuals showed diffuse mesangial sclerosis (DMS) as well as FSGS.

The recent discovery that common *APOL1* variants associate with sporadic focal segmental glomerulosclerosis (FSGS) and other non-diabetic kidney diseases in African American patients will likely be a critical turning point in understanding and management of these glomerular diseases.[553] Two genome wide admixture scans had identified a highly significant association on chromosome 22q12 between non-diabetic kidney disease and African ancestry.[554,555] This region contains many genes, and initial investigations focused on non-muscle myosin heavy chain IIA, encoded by *MYH9*, due to its podocyte expression and association with rare, mendelian giant platelet disorders that are also characterized by variably penetrant glomerular diseases. However, attempts to identify the *MYH9* causal variant(s) underlying this association were unsuccessful. Coding variants within the neighboring *APOL1* gene, which is centromeric to *MYH9* on 22q12.3, were shown to account for the association signal.[556] The biology responsible for the association is under intense investigation, but previous work had characterized APOL1 as the trypanosome lytic factor in human serum. Variant APOL1, which encodes the kidney disease risk variants, can kill disease-causing trypanosomes by circumventing the parasite's mechanism to evade lysis. This observation provided a biological explanation for the frequency of the kidney disease associated variants in populations of African ancestry. Similar to sickle cell disease, the parasite killing effect is dominant, requiring a single copy of the risk variant *APOL1* gene, and would be under positive selection in Africa. In contrast, association with kidney disease is best fit by a recessive model.

In addition to genetic factors, accumulating data suggest that steroid-sensitive nephrotic syndrome, as well as a subset of steroid-resistant nephrotic syndrome (particularly those recurring after transplantation) result from circulating a permeability factor(s).[540,557,558] T cells in these patients may promote the production of a circulating factor that alters permeability of the glomerular filtration barrier, but the nature of this factor remains elusive. Serum soluble urokinase receptor (suPAR) is elevated in two-thirds of subjects with primary FSGS, but not in people with other glomerular diseases and a higher concentration of suPAR before transplantation correlates with increased risk for FSGS recurrence after transplantation.[559] As mechanisms responsible for FSGS are better defined, therapy may be tailored for individual patients. The common mechanistic denominator for both the genetic and "acquired" etiologies of FSGS is that these diseases are

podocytopathies, a concept extensively covered in a number of excellent reviews.[540,541,547,551,560]

Treatment

The therapy of FSGS remains controversial, and data for evidence-based decisions are lacking. Most studies of therapy for FSGS patients have employed regimens used for treatment of minimal change nephropathy and have reported variable responses to therapy. However, recent case series, in which FSGS patients were treated with high dose corticosterioids (1 mg/kg/day) for prolonged courses (at least 16 weeks and for as long as 6 months), report response rates of up to 60 to 70% and improved long-term renal survival.[542,561] Many experts recommend a course of corticosteroids be offered to patients with likelihood of progressing to ESRD.

The potential efficacy and side effects of therapy must be considered for each patient. The amount of proteinuria, presence and degree of renal insufficiency, and the extent of scarring on biopsy are appropriate variables to evaluate before administering anti-inflammatory drugs. Non-specific therapy is probably an appropriate first approach in patients with mild proteinuria and normal renal function. Blood pressure should be normalized, if possible, in all hypertensive patients with FSGS. All patients with nephrotic-range proteinuria and FSGS should be treated with angiotensin-converting enzyme (ACE) inhibitors and/or angiotensin receptor antagonists (ARBs), unless otherwise contraindicated. Nephrotic-range proteinuria of any cause is an independent risk factor for progression of chronic renal failure, and ACE inhibitors and AT1 receptor blockers are the most potent anti-proteinuric agents available. Angiotensin stimulates aldosterone synthesis, and small case series suggest that spironolactone, an aldosterone antagonist, also may slow progression in patients with parenchymal renal disease. Hyperlipidemia should be controlled with appropriate medications to lower elevated cholesterol and tryglycerides, if dietary modifications fail to achieve target serum levels. Salt restriction and diuretics should be used to control edema in nephrotic FSGS patients.

Patients with persistent nephrotic proteinuria and renal insufficiency should be considered for more aggressive therapy with corticosteroids or other immunosuppressants. Prednisone, 1 mg/kg/day for at least four months, is now the recommended treatment regimen for patients with FSGS and is usually continued for one to two weeks after induction of remission and then slowly tapered.[561,562] Prolonged prednisone therapy of five to eight months has been advocated by some experts. Some patients, who initially respond to prednisone therapy, may exhibit frequent relapses or become steroid-dependent. Significant tubulointerstitial disease on renal biopsy, an elevated creatinine, and massive proteinuria of more than 10 gm daily suggest that the clinical response to steroid therapy may be poor. Patients with these risk factors may be candidates for early withdrawal from treatment if the steroids are tolerated poorly or cause significant side effects.

High quality evidence for use other immunosuppressive agents in patients with FSGS, who do not respond to corticosteroids alone or who are steroid-dependent or frequently relapse, is limited.[561,562] However, there are a number of reports that alternative immunosuppressive therapy may be beneficial. The North American Nephrotic Syndrome Study Group recently demonstrated, in a randomized controlled trial that steroid-resistant FSGS patients treated with cyclosporine and prednisone had better outcomes compared to patients that were not treated with cyclosporine.[563] Relapse is common when cyclosporine is discontinued, but cyclosporine-treated FSGS patients have a long term decrease in proteinuria and better preservation of GFR. Cyclosporine itself can be nephrotoxic and should be used judiciously. Cyclophosphamide or other cytotoxic drugs can be added to the therapeutic regimen, and small case series suggest that these drugs may induce complete or partial remission in up to 75% of these individuals.[561,562] A NIH-funded, multicenter randomized study of FSGS treatment compared the efficacy of a 12-month course of cyclosporine to a combination of oral pulse dexamethasone and mycophenolate mofetil in children and adults with steroid-resistant primary FSGS and found no difference in proteinuria remission rates.[564] Rituxamab has also been used to treat FSGS in case series and may prevent FSGS recurrence in transplants by regulating sphingomyelinase activity.[565]

Minimal Change Nephropathy

Minimal change disease (MCD), which is also known as minimal change glomerulopathy, nil disease or lipoid nephrosis, is characterized, as the name suggests, by normal histologic appearance by light microscopy. MCD accounts for more than 70% of cases of nephrotic syndrome in children less than 10 years of age, with a decline in incidence in older children. In adults, MCD represents 10 to 15% of cases of idiopathic nephrotic syndrome. Because of the predominance in children, most of the clinical studies have been conducted in pediatric populations.

Clinical Presentation and Natural History

The typical clinical presentation is relatively rapid onset of the nephrotic syndrome, with heavy

proteinuria. In children, hypertension is rare,[566] while in adults, hypertension is variable, but more common.[567] As described later in this chapter, MCD has been associated with infections, malignancies and pharmaceutical agents. Of note, non-steroidal anti-inflammatory agents have been linked to MCD with concomitant tubulointerstitial disease, which is characterized by interstitial lymphocytic infiltrates and pyuria.[568,569] In children, MCD rarely is associated with decreased GFR, whereas a syndrome with combined MCD and acute renal failure has been described in adults.[570] In adults MCD may include episodes of acute kidney injury from low oncotic pressures due to hypoalbuminuria that results in residual renal dysfunction,[571] but rarely progresses to ESRD.

Pathology

As previously mentioned, light microscopy is characteristically normal, with occasional mesangial prominence. In most cases, immunofluorescence microscopy is also negative, although there may be some IgM or complement C3 deposition in a mesangial pattern. The key diagnostic test is electron microscopy (Figure 82.11), which reveals podocyte foot process effacement, and cytoskeletal matting. Although these EM findings are similar in other causes of the nephrotic syndrome, the combination with normal light and immunofluorescence microscopy is diagnostic for MCD.

Pathophysiology

The mechanisms regulating MCD pathogenesis have not been completely defined, though some evidence supports a role for T cell activation, the most compelling being responsiveness to corticosteroid therapy (see below). In addition, evidence exists for a T cell-derived glomerular permeability factor,[572] which is perhaps a lymphokine.[573] The most prominent manifestation of this permeability factor is loss of filtration barrier electrostatic charge, with relative sparing of molecular size selectivity.[574] Overexpression of angiopoietin-like 4 in rat podocytes leads to steroid-sensitive nephrotic syndrome[575]

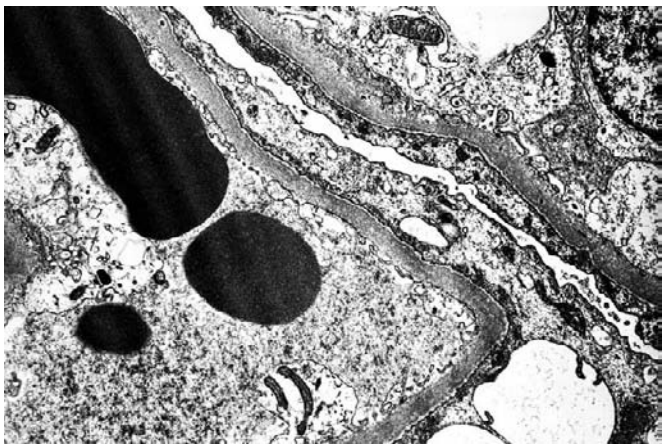

FIGURE 82.11 Minimal change disease. Electron micrograph demonstrating extensive foot process effacement. The glomerular capillary walls appear normal in thickness without any deposits.

Treatment

Standard therapy for MCD is corticosteroids (prednisone 60 mg/m^2/d for children and 1 mg/kg/d for adults). In children, this regimen results in prompt resolution of albuminuria in more than 90% of cases, generally within four to six weeks of initiating treatment. Lack of responsiveness should raise suspicion of alternative pathologies, such as focal and segmental glomerulosclerosis (FSGS), and may warrant repeat biopsy to definitively establish the diagnosis. In children who respond within six weeks, it is recommended to slowly taper the prednisone dose over an additional six weeks. This can be accomplished by decreasing the daily dose or with an alternate day regimen.[572,576,577]

In adults, MCD is also steroid-responsive, though efficacy is generally less, and time of response longer, compared to pediatric patients. In a study by Nalasco et al.,[567] in which 89 adults with MCD were analyzed, remission rates with 60 mg prednisone per day were 60% at 8 weeks, 76% at 16 weeks, and albuminuria eventually resolved in 81% of study subjects. Similar results were obtained in two subsequent, smaller series.[578,579]

Long-term studies indicate that approximately 25% of children achieve permanent remission, 50% relapse frequently (more than one episode per year) and the remaining 25% relapse infrequently.[580] Protocols with alkylating agents cyclophosphamide (2 mg/kg/d for 8 to 12 weeks)[567,574,581,582] or chlorambucil (0.1 to 0.2 mg/kg/d for 8 weeks)[583,584] have an efficacy of approximately 75% in relapsing patients. Because these agents have the potential for serious side effects, such as gonadal dysfunction, malignancy, and infection, protocols containing less toxic immunosuppressive drugs have been developed for relapsing, steroid-dependent and steroid-resistant MCD. In general, cyclosporine has been shown to achieve short term remissions, even in steroid-resistant cases, though long-term remission rates are poor.[585] However, one case series of steroid-dependent and resistant nephrotic syndrome, that included 5 cases of MCD, demonstrated that cyclosporine treatment for a mean of 22 months resulted in good long-term remission.[586] In a randomized trial of eight weeks of cyclophosphamide versus nine months of cyclosporine, involving both adults and children with MCD, both drugs induced remissions, though long-term remission rates were superior in the

cyclophosphamide group.[587] Small studies with newer agents, such as mycophenolate mofetil[588] or rituximab[589] show promise, including the theoretical advantage of less nephrotoxicity compared to cyclosporine, though there is insufficient experience with either drug as alternative treatment for complicated MCD.

Systemic Diseases Associated with the Nephrotic Syndrome

The most common causes of "secondary" nephrotic syndrome, such as diabetic nephropathy (Chapter 78) and lupus nephritis (Chapter 78) are discussed in detail elsewhere. The following section focuses on amyloidosis, multiple myeloma, and nephrotic syndrome associated with infectious diseases, malignancies and drugs.

INFECTIOUS CAUSES OF THE NEPHROTIC SYNDROME

HIV-Associated Nephropathy (HIVAN)

Shortly after the discovery that HIV caused AIDS, several case series of AIDS-related renal disease were reported.[590–592] These reports described a sclerosing glomerular lesion and very poor prognosis. As discussed below, with the advent of effective antiretroviral therapy, the clinical course is now more benign. Furthermore, other nephropathies resulting from HIV infection have been described. Nevertheless, HIVAN is still the most common cause of ESRD among HIV-positive patients, and the third most common cause of ESRD among African Americans in the U.S. between the ages of 20 and 64 (www.usrds.org). The predilection for HIVAN in patients of African descent has been noted in the U.S. and Europe.[593,594] In addition to HIVAN, HIV patients are vulnerable to opportunistic infections (tuberculosis, CMV, fungal) and malignancies (Kaposi's sarcoma, lymphoma), which may lead to glomerular disease.[595]

Clinical Presentation and Natural History

Patients with HIVAN typically present with nephrotic range proteinuria and renal insufficiency. In contrast to most proteinuric renal diseases, hypertension and edema are less common,[596] consistent with the notion that HIVAN involves tubular epithelia and leads to salt-wasting.[594] Kidneys tend to be large and echogenic on ultrasound examination.[597,598] A definitive diagnosis can only be made with a renal biopsy, though recent reports indicate that urinary neutrophil gelatinase-associated lipocalin (NGAL) and growth factors may be sensitive biomarkers for HIVAN.[599,600] Although HIVAN is still typically diagnosed after prolonged exposure to high HIV viral load,[601] it can present early, and rarely at the time of HIV diagnosis.[602,603] The clinical course of HIVAN has become markedly more protracted since introduction of highly active anti-retroviral therapy (HAART) regimens, and should now be considered a cause of chronic, rather than acute kidney injury.

Less commonly, HIV-positive patients can develop thrombotic microangiopathies with renal involvement, such as hemolytic uremic syndrome (HUS). A distinguishing feature is that nephrotic range proteinuria is typically absent,[595] though it can occur due to coexistence of typical HIVAN.[604] Results from small, uncontrolled trials suggest that HIV-associated HUS is resistant to treatment with glucocorticoid hormones, plasmapheresis, immunoglobulin infusion, anti-platelet agents, vincristine or splenectomy.[604–606]

Proliferative glomerulonephritis with immune complex deposition, including with IgA,[607,608] has also been described in HIV-infected patients.[595,609,610] In contrast to African American HIV patients with renal disease, who almost exclusively develop typical HIVAN lesions, HIV-associated immune-mediated GN is observed primarily in Caucasians.[595,609]

Pathology

Although many pathologies have been observed, the classical histologic lesion in HIVAN is a form of focal and segmental glomerulosclerosis called collapsing glomerulopathy, which is characterized by segmental or global glomerular collapse, resulting in widened Bowman's space, and GBM wrinkling[611] (Figure 82.12). Glomerular pathology also includes podocyte hypertrophy and/or hyperplasia,[612,613] which may play a pathophysiologic role. In some cases, robust podocyte proliferation can result in the formation of pseudocrescents. Additional common findings include lymphocytic interstitial infiltrates, tubular microcystic dilation and glomerular endothelial reticular inclusion bodies,[614] though the latter finding is less common since effective anti-retroviral therapies have been widely prescribed. Like most glomerular diseases, tubular atrophy and interstitial fibrosis correlate with progression. Unlike other causes of the nephrotic syndrome, which invariably show podocyte foot process effacement and cytoskeletal rearrangement, podocytes in HIVAN assume a more de-differentiated phenotype, with absence of foot processes, paucity of cytoskeletal elements, and loss of podocyte markers, such as synaptopodin, WT1, podocalyxin and GLEPP1.[612] Immunofluorescence microscopy is typically non-diagnostic, but may show deposition of IgM, C3, and less frequently, C1q.[615]

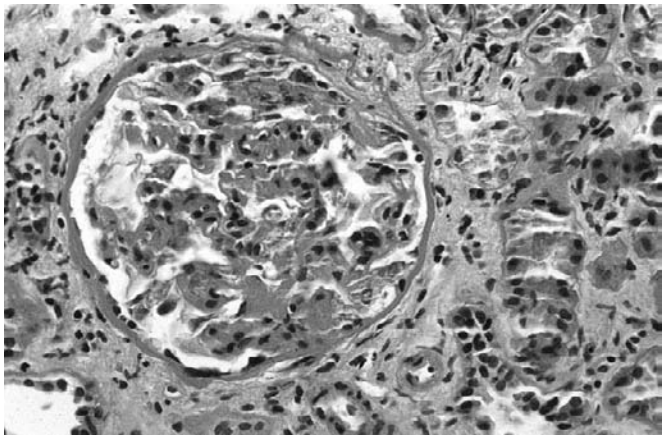

FIGURE 82.12 Collapsing glomerulopathy associated with HIV. Global collapse of glomerular capillary walls with hypertrophy and hyperplasia of podocytes (H&E, X330).

Pathophysiology

Most patients with HIVAN have low CD4 counts,[616] but clinical immunodeficiency is not required for development of HIVAN.[595] HIVAN is caused primarily by infection of resident renal epithelial cells with HIV, which then serve as a viral reservoir. HIV mRNA has been localized to podocytes and tubular epithelial cells from human renal biopsies,[617,618] suggesting that HIV infection is pathogenetic. Furthermore, HIV transgenic mice mimic pathologic findings observed with HIVAN in humans.[619,620] In these animals, the HIV transgene was expressed in epithelial cells prior to demonstrable renal lesions, suggesting a pathophysiologic mechanism involving direct cytopathic effects of HIV, rather than effects from exogenously released cytokines.[621] This conclusion is supported by the observation that HIVAN developed in transgenic kidneys transplanted into wild-type littermates, whereas normal kidneys remained disease free when transplanted into HIV transgenic littermates.[621] Furthermore, transgenic lines that expressed the transgene in extrarenal tissues, but not kidney, did not develop HIVAN pathology.[622] Phylogenetic analysis of HIV sequences from microdissected infected human kidney tubular epithelial cells and circulating blood mononuclear cells revealed evidence of tissue-specific viral evolution, indicating localized kidney HIV replication and existence of renal epithelial cells as HIV reservoirs.[623] Transgenic mice that express HIV accessory proteins, but not the intact virion, also develop typical HIVAN histologic features, indicating that viral proteins, such as nef and vpr, rather than replicating virus, are essential for signaling dysregulation and cytotoxicity.[622,624–626] Neither the specific mechanisms by which HIV gains entry to renal epithelial cells, nor how HIV infection regulates podocyte de-dedifferentiation, collapsing FSGS and other pathologic features is known.

Predisposition for HIV patients of African descent, but living in different environments, as well as HIVAN clustering in African American families, suggests that there may be a genetic component to HIVAN susceptibility.[627] Human mapping studies have implicated a susceptibility region on chromosome 22 that includes the MYH9 and ApoL1 genes,[628] while linkage analysis and expression profiling identified two susceptibility loci in HIV transgenic mice.[629]

Treatment

The current standard of care for HIVAN (as well as for HIV infection, in general) is highly active antretroviral therapy (HAART). Since HAART was introduced in the U.S. 10 years ago, the incidence of ESRD due to HIVAN has only slightly decreased,[630] despite reduction in AIDS-related mortality. Because of the unequivocal benefit of HAART on survival in HIV-infected patients, it is doubtful that a placebo control trial for HIVAN will ever be conducted. Nevertheless, evidence for the efficacy of HAART on HIVAN can be derived from work by Lucas et al., which demonstrated a 60% risk reduction for HIVAN in a large, HIV-infected population followed for 12 years.[631] An uncontrolled, retrospective trial demonstrated that protease inhibitor therapy slowed GFR declines in a small HIVAN cohort,[632] and several case reports or series also document benefit of HAART.[602,618,633,634]

Renal side effects of HAART are fairly common, (reviewed in[635]), including acute kidney injury and crystalluria-induced tubulointerstitial disease with protease inhibitors,[636,637] as well as acute renal and proximal tubule dysfunction with Fanconi syndrome from nucleotide reverse transcriptase inhibitors.[638–642] The latter is due to tubular mitochondrial toxicity.[635]

Two small series have demonstrated benefit of prednisone for the treatment of HIVAN, though many patients relapsed after prednisone was discontinued, and several developed serious infectious complications.[643,644] Because of short-term follow-up, and the potential for complications, larger randomized trials are necessary before prednisone can be recommended as therapy for HIVAN.

HIVAN patients with serum creatinine less than 2.0 mg/dl benefited from ACE inhibitor therapy, as determined by serum creatinine, proteinuria and requirement for renal replacement therapy.[645,646] Renal disease progression was also prevented in HIV transgenic mice treated with angiotensin receptor blockers.[647] In our opinion, ACE inhibitor or ARB therapy is sensible for HIVAN patients with proteinuria, particularly those with concomitant hypertension.

Hepatitis C

Long-term complications of chronic hepatitis C virus (HCV) infection can include glomerular disease, either with or without cryoglobulinemia. The cryoglobulinemia is mixed, with complexes containing HCV virions, anti-HCV immunoglobulins, and rheumatoid factor, which is comprised of IgMκ chains. In populations of patients with mixed essential cryoglobulinemia, approximately 90% will have measurable anti-HCV titers. The exact etiology of the cryoglobulinemia is unknown, but is presumed to be due to B cell proliferation in response to HCV antigenic stimulation.

Clinical Presentation and Natural History

Most patients with renal manifestations of HCV infection have membranoproliferative glomerulonephritis (MPGN) due to type II cryoglobulinemia, which is characterized by polyclonal IgG and anti-globulin IgMκ rheumatoid factor.[648,649] It has been suggested that most cases of idiopathic MPGN are due to underlying viral hepatitis.[650] The exact proportion of HCV-infected patient that develop MPGN is not known, but the risk appears to be greater in subjects with chronic infection and liver disease. In cryoglobulinemic patients, symptoms typically include malaise, weakness, and arthralgia. Common physical findings include hypertension, peripheral edema, palpable purpura and hepatomegaly. Renal involvement is characterized by proteinuria (nephrotic range in approximately 20% of cases), microscopic hematuria and decreased GFR.[648,649,651–655] Serologies commonly reveal detectable serum anti-HCV titer and HCV RNA, elevated liver transaminases (ALT >AST), rheumatoid factor, low C3 and C4 complement levels and cryoglobulinemia.

Pathology

The most common finding is MPGN, especially in patients with cryoglobulinemia, although membranous glomerulopathy, FSGS, mesangial proliferation with IgA deposition, post-infectious, fibrillary and immunotactoid lesions have been reported.[653,654,656] With MPGN, there is typically glomerular tuft lobulation and endothelial cell swelling, GBM splitting, and infiltrates containing lymphocytes, neutrophils and activated macrophages. Mesangial sclerosis is observed in advanced cases. Tubular atrophy and infiltrates are observed with progressive disease. Immunofluorescence generally shows IgG, IgM and C3 in a glomerular capillary pattern, and to a lesser extent, IgA and C1q in mesangium and/or glomerular capillaries. On EM evaluation there are electron-dense deposits, with a fibrillar appearance, in subendothelial, and less commonly, intramembranous or mesangial locations.[648] Mesangial interposition within the GBM has also been described. In the subset of chronic HCV-infected patients with non-cryoglobulinemic MPGN, the histopathology is similar, with the exception that leukocyte infiltrates and the fibrillar pattern of immune complexes are less prominent.

Pathophysiology

The pathophysiologic mechanism regulating HCV infection and glomerular disease is not well established, but presumably is related to immune complex formation with HCV, rheumatoid factor and/or anti-HCV antibodies. The paucity of information is due, in part, to lack of a suitable animal model for HCV-induced renal disease. Currently, chimpanzees are the only model that permits HCV propagation, though studies have been limited to liver pathophysiology and investigation of immune mechanisms.[657]

Treatment

With the assumption that renal manifestations of HCV are related to viral exposure and resulting immune response, therapies have been designed with anti-viral and immunosuppressive agents to suppress viremia and B cell activation, respectively. In small trials in patients with mixed essential cryoglobulinemia, interferon-α treatment resulted in reductions of serologic markers and serum creatinine.[658,659] In several case reports involving patients with chronic HCV infection, cryoglobulinemia and biopsy-proven MPGN, interferon-α administration as a single agent has resulted in modest improvement in GFR and/or proteinuria.[648,660–663] However, these studies uniformly demonstrated that the effect was transient, with high relapse rates of viremia and glomerular disease.

To enhance the anti-viral response, interferon-α is often given in conjunction with ribavirin. This combination therapy has been shown to have some effect, particularly on proteinuria, though complete resolution of glomerular lesions and renal function is exceptional.[664–667] Improvement in GFR and proteinuria is generally associated with successful suppression of HCV viremia.[668] A decision to treat HCV-induced MPGN with combination therapy is complicated by reports of worsening renal function with interferon-α[669,670] and impaired ribavirin clearance in patients with depressed GFR.[671] The duration of anti-viral therapy is dictated by HCV genotypes.[668]

Prior to the realization that most cases of mixed cryoglobulinemia are due to chronic HCV infection, many patients were empirically treated with plasma exchange and immunosuppression (primarily cyclophosphamide and prednisone), with variable success.[652,668] In part due to concerns about the potential for worsening HCV infection, these regimens

are not currently considered first line therapies for cryoglobulinemia or HCV-related MPGN. A recent meta-analysis demonstrated superior reduction of proteinuria with interferon-α-containing regimens compared to immunosuppression with prednisone ± cyclophosphamide.[672] In rare instances of HCV-induced vasculitis with renal involvement, or MPGN with heavy proteinuria and/or rapid decline in GFR, treatment with glucocorticoids and cyclophosphamide should be considered as first-line therapy, though responses have been variable.[668,673]

Finally, humanized anti-CD20 antibodies (rituximab) have been shown to improve the serologic response in cryoglobulinemia,[674] with the rationale that rituximab would reduce B-cell IgM secretion and cryoglobulin formation. However, data regarding effect on HCV-associated glomerular diseases is limited. Two small case series in cryoglobulinemic HCV-related MPGN patients demonstrated that four weekly doses of rituximab reduced proteinuria, but had little effect on serum creatinine.[675,676] Rituximab would theoretically be most effective in conjunction with anti-viral therapy to diminish the stimulus for antibody production; a very recent small trial indicates that this combined approach was indeed effective for resolution of GFR, proteinuria and hematuria in patients with cryoglobulinemia.[677]

Hepatitis B

Hepatitis B virus (HBV) has been most commonly associated with the nephrotic syndrome and a pathologic picture which is predominantly membranous nephropathy.

Clinical Presentation and Natural History

The mode of transmission and clinical course varies between endemic areas, such as Southern Africa, Southeast Asia, and the United States. In endemic regions, HBV is often transmitted from mother to child or between siblings, and the incidence of nephropathy occurs at a 4:1 male:female ratio.[678–680] In the US, HBV-associated glomerular disease affects primarily adults, and the mode of transmission is primarily through sexual contact.[681–683]

Most patients present with proteinuria, often in the nephrotic range. Urinalysis is generally benign, though microscopic hematuria can be seen. Serum hepatic aminotransferase levels may be normal to mildly elevated, consistent with viral carrier status or mild hepatitis. Detection of hepatitis B surface antigen (HBSAg) in serum is helpful diagnostically,[684–692] and hepatitis antigen-containing circulating immune complexes have also been isolated.[688,693] Liver biopsies often reveal chronic active hepatitis, occasionally cirrhosis, and rarely acute hepatitis.[694,695]

Pathology

The most common lesion is membranous nephropathy, although occasional reports of FSGS and MPGN have been described.[678–683,696,697] Rarely, fibrocellular crescents have been associated with membranous lesions.[698,699] Immunofluorescence demonstrates IgG, and less commonly C3, IgM and IgA in a glomerular capillary pattern. EM typically reveals electron-dense deposits in subepithelial locations. Glomerular endothelial tubuloreticular structures,[700] variable detection of HBV antigens within immune deposits,[679,684,686–690,692,701] and electron-dense deposits occasionally in mesangial and subendothelial sites[690] are useful in distinguishing from idiopathic membranous nephropathy.

Pathophysiology

HBSAg, core (HBcAg), e (HBeAg) antigens[702] and viral DNA[680,703] have been detected in glomeruli from biopsies, and circulating immune complexes containing hepatitis viral particles have been detected in HBV-associated glomerular disease,[688,693] thereby implicating viral antigens in pathogenesis.

Treatment

Because spontaneous remission of HBV-related membranous nephropathy is common in children from endemic areas,[694,695] supportive therapy is generally sufficient. Patients with HBV-associated progressive renal disease pose a greater challenge, inasmuch as no therapy has proven unequivocally effective. In small series, glucocorticoid hormones, which are a component of most regimens for idiopathic membranous glomerulopathy, have shown some efficacy in reduction of proteinuria, though a sustained benefit has not been demonstrated, and therapy was associated with enhanced viral replication.[704,705] An initial report, involving five patients, indicated that interferon-α may be effective in reducing HBV viral load and ameliorating associated glomerular disease, as demonstrated by reduction in proteinuria.[706] However, subsequent, larger studies with longer follow-up have produced less optimistic results,[707,708] particularly in those patients with a poor initial response and MPGN histopathology.[708] Case reports with nucleoside analogues, such as adenine arabinoside (vidarabine) or 3TC (lamivudine, Epivir), have shown some promise,[697,709,710] though large trials are necessary before these agents can be confidently recommended for HBV-associated glomerular disease.

Syphilis

Patients with congenital, secondary or latent syphilis have been demonstrated to have associated glomerular disease.[711–722] Typical clinical manifestations are those of the nephrotic syndrome, accompanied by hypertension. In cases of congenital syphilis, a large percentage may have renal involvement.[712] Symptoms, which generally include proteinuria with or without hematuria, appear within weeks after birth. Light microscopic histologic findings are variable, ranging from minimal change disease to proliferative glomerulonephritis with crescents and interstitial infiltrates,[723] although membranous lesions are common. Transmission electron microscopy findings are more consistent, with frequent observation of subepithelial deposits of varying sizes and podocyte foot process effacement. Immunofluorescence microscopic findings typically reveal fine or coarse granular IgG and C3 deposits in a glomerular capillary pattern. Treponemal antigen and antibodies have been detected in glomeruli from biopsies,[711,712] suggesting immune-mediated pathogenesis.

In glomerular disease associated with secondary or latent syphilis, patients usually present with the nephrotic syndrome, though they can be asymptomatic. Serum complement levels are usually normal, though rare cases of hypocomplementemia and circulating complement-containing immune complexes have been described.[720,721] Microscopic pathologic features are similar to that of congenital syphilis, with the most common appearance resembling membranous nephropathy, although minimal change disease is sometimes found. Treponemal antigen and antibodies have been identified in glomeruli from patients with secondary and latent syphilis.[718,720,724]

In all forms of syphilis-associated glomerular disease, response to penicillin therapy is excellent with remission of nephrotic syndrome,[713,723] although residual proteinuria has rarely been observed.

Malaria

Malaria is one of the most common infectious diseases in the world, with an annual incidence of approximately 300-500 million cases.[725] Of the strains of malaria, infection with *P. malariae* (also known as quartan malaria) and *P. falciparum* have been associated with glomerular disease. In cases of falciparum malaria, renal manifestations are rare, but often mild, with hematuria and sub-nephrotic proteinuria, usually with normal GFR.[726,727] Oliguric acute tubular necrosis is the most serious complication of falciparum malaria.[726] One small biopsy series demonstrated that the most common glomerular lesions were mesangial proliferation or MPGN.[728] IgM, C3 and occasionally IgG deposits can be observed, most commonly in a mesangial pattern.[729]

Although quartan malaria is less common than falciparum malaria, renal complications are more frequent. Fortunately, quartan malaria has become a relatively rare cause of glomerular disease in areas where malaria remains endemic.[730] In general nephropathy associated with quartan malaria can be acute, occurring within two to three weeks of infection. This form tends to be mild and transient, with associated features including non-nephrotic proteinuria and glomerular lesions characterized by deposition of IgM, complement and malaria antigens.[725] A more chronic variety, which disproportionately affects children, presents with fever, hypertension, edema, hepatosplenomegaly, nephrotic range proteinuria, and absence of hematuria. Children with the nephrotic syndrome have higher levels of parasitemia compared to infected children without renal involvement. Biopsy series in African children most commonly revealed a variety of pathologic lesions, including focal and diffuse proliferative glomerulonephritis, membranous nephropathy and focal glomerulosclerosis.[731–733] Immunofluorescence microscopy reveals IgG, IgM, C3 and *P. malariae* antigens within glomeruli, suggesting that the pathophysiology is due to immune complex deposition. This mechanism is supported by transmission EM studies demonstrating thickened GBM and intramembranous,[734] fine granular subendothelial or coarse granular subepithelial deposits.[729] Children with quartan malarial renal involvement generally progress to ESRD, with little documented benefit of anti-malarial or immunosuppressive therapies.[735,736]

Schistosomiasis

The most common clinical manifestations of schistosomiasis are cirrhosis, due to *S. mansoni* and *S. japonicum*, and cystitis from *S. haematobium*. However, schistosomiasis has also been identified as a rare cause of glomerular disease. In biopsy series involving patients with coincident *S. mansoni* infection and renal dysfunction, most have MPGN, but membranous glomerulopathy and FSGS have also been observed.[737–739]

A pathology staging systems has been created,[740] with class I lesions demonstrating mesangial proliferation with IgM and C3 deposits, and an associated self-limited clinical course. Stage II lesions occur in the context of symbiotic salmonellosis, and are characterized by glomerular neutrophils and C3 deposition. The accompanying clinical course is typified by fever, vasculitic skin lesions, anemia and rapid onset of the nephrotic syndrome.[741] Combined therapy directed against schistosoma and salmonella is effective.[740]

Stage III and IV lesions occur primarily in patients infected with *S. mansoni* and hepatic fibrosis,[740] with predominance in Caucasian and Hispanic patients. The clinical presentation in stages III and IV includes hypertension, the nephrotic syndrome, hematuria and even red blood cell casts. Extrarenal manifestations often include stigmata of portal hypertension. Class III lesions resemble idiopathic MPGN, with immune complexes comprised of IgG, IgA and C3 in mesangial, subendothelial and subepithelial locations. Stage IV lesions occur most commonly in the African population, and have a focal glomerulosclerosis pattern, which can also be associated with glomerular IgG, IgA and C3 deposition. Schistosomal antigens and antibodies have been detected in eluates from the majority of biopsy samples, as well as within glomerular deposits from human biopsies and animal models,[734,742] strongly suggesting an immune-mediated mechanism of disease. The clinical course tends to be more serious in stages III and IV, often culminating in progression to ESRD. Therapy with anti-parasitic agents directed against *S. mansoni* has been shown to have no effect on the course of kidney disease.[742,743] In a case series of two patients with *S. haematobium* and the nephrotic syndrome, treatment with niridazole resulted in remission of proteinuria.[738]

Stage V glomerular disease is amyloidosis,[744] and it can be caused by infection with either *S. mansoni* or *S. haematobium*. The clinical presentation is similar to stages III and IV, and schistosomiasis-associated amyloidosis is resistant to treatment with glucocorticoid hormones, colchicine or anti-schistosomal agents.

Mycobacterial Diseases

The major mycobacterial diseases with renal manifestations are *M. tuberculosis* and *M. leprae* (leprosy). The epidemiology of tuberculosis is well-chronicled, but leprosy is also a very common problem worldwide, with a prevalence of approximately 12 million cases, 3 million of which are in India.[745] Renal involvement in leprosy often occurs in conjunction with erythema nodosum, and the clinical spectrum can include hematuria, ranging from asymptomatic/microscopic to acute glomerulonephritis, proteinuria, either in the asymptomatic or nephrotic range, and azotemia. In patients with leprosy-associated nephrotic syndrome, the most common renal pathology is amyloidosis.[729,746,747] However, in a large biopsy series of nephrotic syndrome cases in India, 34 of 2827 biopsies revealed membranous nephropathy attributed to infection with *M. tuberculosis* and *M. leprae*.[748] Other lesions include mesangial proliferation, MPGN, focal and diffuse glomerulosclerosis.[729] Immunofluorescence microscopy typically reveals staining with IgM, IgA or fibrin in a mesangial or glomerular capillary pattern. In cases with glomerular deposits, electron microscopy findings include dense deposits in subendothelial and subepithelial locations, as well as GBM thickening and mesangial interposition.[729,749–751] The pathophysiology is most likely due to deposition of immune complexes, which may contain mycobacterial antigens.[749,752–754]

Despite the enormous worldwide prevalence of tuberculosis, associated glomerular disease is relatively uncommon. In biopsy series from third world countries, tuberculosis is one of the most common causes of secondary amyloidosis, with a prevalence ranging as high as 50%.[729,755,756] However, other glomerular lesions have been associated with tuberculosis and the nephrotic syndrome, including minimal change disease and FSGS.[757,758] Several case reports indicate that eradication of tuberculosis infection with antibiotic therapy can result in remission of secondary renal amyloidosis.[759–761]

MALIGNANCY-ASSOCIATED GLOMERULAR DISEASES

Membranous Nephropathy (MN)

Paraneoplastic syndromes including the nephrotic syndrome have rarely been described (in less than 1% of malignancies[762]), most commonly with MN. Estimates for the coincidence of malignancies with documented MN vary widely, but is on the order of 7 to 8%.[763–769] The association between carcinomas of the lung and gastrointestinal tract was first described by Lee et al. in 1966.[763] Since that time, it has been recognized that MN is associated with a variety of carcinomas (Table 82.20). Because most of these malignancies are more common in elderly patients, a new diagnosis of MN in a patient older than age 50 should probably warrant investigation for neoplastic diseases, or at least performance of recommended age-specific cancer screening test.

Clinical Presentation and Natural History

The clinical presentation of malignancy-associated MN is similar to idiopathic MN.[783] A cancer diagnosis precedes the nephrotic syndrome in 30–60% of cases.[782,784] In the remainder, in which the nephrotic syndrome comes first, a cancer diagnosis can usually be established within one year of MN diagnosis,[763,769] though an increased cancer risk extends for up to 15 years.[784] There are reports of MN remission in conjunction with cancer cures[785,786,769] and MN relapse with malignancy recurrence or metastasis.[769,787,788] However, these data linking malignancy with MN

TABLE 82.20 Malignancies Associated with Membranous Nephropathy[767,769–782]

OTHER TUMORS
Testicular seminoma
Melanoma
Carcinoid

should be interpreted with caution, since approximately one-third of patients with MN will spontaneously remit, many cancer chemotherapy regimens may independently be effective treatment for MN,[782] and MN resolution does not always parallel malignancy remission.[764,771]

Pathology

Diagnostic renal biopsy findings may be indistinguishable from idiopathic MN. However, additional features, such as glomerular inflammation, mesangial cell proliferation, subendothelial, mesangial, IgA and C1q deposits are suggestive of malignancy-associated MN.[782,783]

Pathophysiology

The pathophysiology of malignancy-associated MN is not well established, but based upon known pathophysiology in idiopathic MN, it has been postulated that tumor antigens are filtered and planted within the subepithelial space, allowing for in situ immune complex formation and complement activation.[762,782] Few cases of documented subepithelial lung and colon cancer antigen deposition have been described.[769,789–792] However, tumor antigen deposition cannot be documented in every case,[764,771] and delineation of relevant epitopes for all tumors precludes definitive testing of an in situ immune complex hypothesis. Alternative hypotheses include cross-reactivity of antitumor antibodies with podocyte and glomerular endothelial cell antigens.[782]

Treatment

Therapy for malignancy-associated MN is generally directed toward the primary malignancy. However, there should be some consideration that immunosuppressive regimens, which have been demonstrated to be beneficial for idiopathic MN, may be detrimental for some cancers. In patients with malignancy-associated nephrotic syndrome, standard supportive care should include angiotensin converting enzyme inhibitor or angiotensin receptor blocker therapy for proteinuria reduction, HMG-CoA reductase therapy for hyperlipidemia, and diuretics for edema. Since there are potential adverse consequences with anticoagulation, and treatment duration is not established, it is unclear whether prophylaxis for thrombosis is warranted.

The magnitude and cost-effectiveness of the workup for malignancy in patients with a preceding MN diagnosis is also controversial. Because malignancy incidence increases with age, it is reasonable for MN patients over 50 years of age to strictly follow screening guidelines for the general population.[782] Symptoms or physical signs suggestive for other malignancies, which would not be diagnosed by standard screening tests, should obviously be pursued with more appropriate studies.

Minimal Change Disease (MCD)

MCD has been observed to accompany lymphomas (Hodgkin's more frequently than non-Hodgkin's),[793–795] leukemia,[794,796] and less commonly, thymoma,[797] renal cell carcinoma,[798] cecal carcinoma[799] or bronchial carcinoma.[800] Onset of the nephrotic syndrome from MCD is generally simultaneous with tumor presentation.[762] Case reports of lymphomas, leukemia, thymoma, mycosis fungoides, and multiple myeloma have also been associated with FSGS.[794,795,801–803]

Proliferative Glomerulonephritis

Membranoproliferative glomerulonephritis (MPGN) with or without fibrocellular crescents has rarely been linked to lymphoma, especially chronic lymphocytic leukemia,[804–806] as well as carcinomas.[807,808] Unlike other malignancy-associated glomerular diseases, MPGN characteristically presents with an active urinary sediment, and often with rapid decline in GFR. The pathophysiology of MPGN, particularly in conjunction with CLL, may be due to cryoglobulinemia.

Vasculitis

The prevalence of ANCA-positive vasculitis and malignancy has been described.[809] An association between malignancies involving respiratory, urinary or GI tract and ANCA-positive rapidly progressive glomerulonephritis (RPGN) has been reported.[810–814] It has been postulated that the tumors stimulate autoantibody generation.

Amyloidosis

Renal amyloidosis has been linked to chronic inflammatory states, which may include some malignancies, especially renal cell carcinoma, Hodgkin's disease, chronic lymphocytic leukemia and adrenal carcinoma.[762,815,816]

DRUG-INDUCED GLOMERULAR DISEASES

Membranous Nephropathy (MN)

Drug-induced MN has been described most commonly with medications prescribed for rheumatoid arthritis, such as oral and parenteral gold, D-penicillamine and bucillamine.[817–822] These drugs have also been linked to minimal change disease (MCD),[820,823,824] though less frequently than with MN. Rare cases of anti-GBM disease and vasculitis due to D-penicillamine have also been reported.[823,825,826] D-penicillamine-induced MN has been associated with HLA-B8/DR3 antigen,[820,827,828] suggesting a genetic predisposition. MN from gold or D-penicillamine generally develops within 6 to 12 months of starting the drugs.[762,782] Decreased GFR is usually not observed. If gold or D-penicillamine are discontinued when MN is diagnosed, proteinuria generally resolves within 12 months.[820,828] However, in a retrospective series of 53 patients with biopsy-proven nephropathy from gold or D-penicillamine, 21 subjects continued therapy for up to 11 months, without adverse effects on GFR, peak proteinuria values, or resolution of proteinuria.[829]

Mercury-containing substances, such as older, infrequently prescribed diuretics, some skin creams, and industrial exposures, have been associated with the nephrotic syndrome, due to MN and MCD.[830–836] When captopril was initially released, high doses were associated with MN.[837–840] Substitution with enalapril resulted in resolution of nephropathy,[841] suggesting that sulfhydryl groups unique to captopril may be a stimulus. Lithium has been associated with a variety of glomerular diseases, including MN and FSGS,[842–844] though the most common glomerular lesion is MCD.[845,846]

Heroin-Induced Focal and Segmental Glomerulosclerosis (FSGS)

An association between chronic heroin use and the nephrotic syndrome was noted over 30 years ago.[847–853] The glomerular lesion most commonly associated with intravenous heroin is FSGS, which occurred predominately in young, African-American men, whereas heroin is associated with MPGN in whites.[854] More recently, it has been demonstrated that the most common etiology of idiopathic nephrotic syndrome in African-American men is FSGS,[855] and MPGN from heroin use coincides with hepatitis C infection,[856] suggesting that heroin use may not be an independent risk for FSGS. Furthermore, the nephrotic syndrome resulting from intravenous drug use is now almost exclusively due to HIV-associated nephropathy. In the original descriptions, heroin-associated FSGS frequently resulted in progression to ESRD, though progression was not inevitable if heroin was discontinued.[762]

In heroin-associated FSGS, glomerular C3 complement and IgM deposits may be observed, though this is likely due to non-specific trapping within areas of sclerosis, and unlikely to be pathophysiologically relevant.[762] Tubulointerstitial inflammation has also been noted. The mechanism of heroin-associated FSGS has never been clearly established, though it has been speculated to be immune-mediated, with heroin metabolites or substances used to cut heroin representing potential antigens. That heroin-related FSGS predominates in African Americans suggests that there may be a genetic predisposition.

Subcutaneous injection of drugs (skin popping), including heroin, can result in chronic infections and abscesses, which are associated with renal amyloidosis.[857–861] One case report demonstrated efficacy of colchicine therapy, as determined by resolution of proteinuria and GFR.[860]

Non-Steroidal Anti-Inflammatory Drug (NSAID)-Induced Minimal Change Disease

NSAIDs have been associated with several different renal abnormalities, including the nephrotic syndrome and allergic interstitial nephritis.[862–864] In contrast to acute renal failure from NSAID-induced vasomotor etiology, the onset of NSAID-mediated nephrotic syndrome occurs from two weeks to over a year after initiation of NSAID use. Clinical features may include hypertension, edema, oliguria and depressed GFR; systemic manifestations of allergic interstitial nephritis, such as fever, rash, and arthralgias are rarely observed. Urinalysis commonly reveals overt proteinuria, microscopic hematuria and pyuria. Unlike allergic interstitial

nephritis from other drugs, eosinophiluria is rarely observed.

Renal biopsies in patients with NSAID-induced nephrotic syndrome reveal MCD, usually in conjunction with interstitial nephritis. Interstitial infiltrates are characteristically comprised of lymphocytes, most commonly cytotoxic T-cells.[865,866]

Proteinuria routinely resolves after NSAID discontinuation, and additional supportive therapy is rarely required.[867] However, complete resolution may require up to one year.[864]

Hemolytic-Uremic Syndrome (HUS) and Thrombotic Thrombocyto-Penic Purpura (TTP)

HUS/TTP has most commonly been associated with infections, but over 50 drugs, particularly cancer chemotherapy drugs, have also been implicated as triggers for HUS/TTP.[868,869] It is difficult to decipher cause and effect in many cases, both because a definitive diagnosis can be elusive, and underlying diseases are also associated with HUS/TTP. However, among chemotherapeutic agents, mitomycin C is best recognized as a cause of HUS/TTP,[869,870] occurring in 5 to 15% of patients receiving a cumulative dose of at least 20 to 30 mg/m^2.[762] The most common clinical presentation is hypertension, hemolytic anemia and acute kidney injury. Despite supportive therapy, which may include hemodialysis, *Staphylococcus* protein A immunoabsorption[871–873] and/or plasmapheresis,[874–876] mortality is extremely high,[877] reflecting concurrent malignancy. Other drugs that have been repeatedly associated with HUS/TTP include cyclosporine A, ticlopidine, quinine, and clopidogrel.[869,878]

The mechanism of drug-induced HUS/TTP has not been established for every agent, but at least for mitomycin C and cyclosporine, both drugs have been postulated to induce formation of circulating immune complexes or autoantibodies,[870,873] which either directly or via an immune-mediated mechanism,[878–880] result in endothelial cell damage. Glomerular capillary endothelial damage may then lead to platelet aggregation and thrombosis.[872]

CHAPTER

83

Immunologic Mechanisms of Vasculitis

Jonathon W. Homeister[1], *J. Charles Jennette*[1] *and Ronald J. Falk*[2]

[1]Department of Pathology and Laboratory Medicine,
University of North Carolina, Chapel Hill, North Carolina, USA
[2]Department of Medicine, University of North Carolina, Chapel Hill, North Carolina, USA

The kidneys are among the most vascularized tissues of the body. Thus, it is not surprising that they are among the organs most commonly affected by many forms of systemic vasculitis. Vasculitis is inflammation of vessel walls that shares many of the pathophysiologic characteristics of inflammation in any tissue. The seminal pathogenic event is the recruitment and activation of leukocytes in vessel walls with resultant injury. This always involves elements of the innate inflammatory response. In some, if not most, forms of vasculitis, elements of the adaptive immune response also are involved in the induction of the inflammation. This may be an appropriate adaptive immune response (e.g., against rickettsial organisms in the vasculitis of Rocky Mountain spotted fever), an idiosyncratic allergic hypersensitivity response (e.g., in some drug-induced vasculitides), or a maladaptive autoimmune response (e.g., vasculitis caused by antineutrophil cytoplasmic autoantibodies or autoantibodies to capillary basement membrane collagen).

This chapter will review the etiology and pathogenesis of several of the variants of vasculitis that most often affect the kidneys. The focus will be on vasculitides that are not known to be caused by direct invasion of vessel walls by infectious pathogens (i.e., the noninfectious vasculitides). This does not mean that an infection is not involved in the pathophysiology of the vasculitis, only that there is no evidence that the inflammation is directly targeted against intact microbes in the vessel wall. Infection still could be involved indirectly, for example by providing antigens that form pathogenic immune complexes with antibodies or by stimulating a pathogenic autoimmune response. The greatest emphasis will be on vasculitis that predominantly targets small vessels, including glomerular capillaries, because of the frequency and clinical importance of renal involvement in this category of vasculitis.

IMMUNOPATHOLGIC CATEGORIES OF VASCULITIS

Ideally, a classification system for vasculitis would be based on specific etiologies or distinct pathogenic mechanisms especially in a discussion of the pathophysiology of vasculitis. Table 83.1 lists some of the putative etiologies and pathogenic mechanisms for vasculitides that may involve the kidneys. Unfortunately, the etiology and pathogenesis of many forms of vasculitis remain poorly understood and controversial, and thus cannot be used as the sole basis for classification systems that are used for the diagnosis of patients. Instead, categorization of vasculitides is based on a combination of features that includes the types of vessels involved, the pattern of inflammation, the evidence for various immunopathologic processes, and the clinical expression of disease (Table 83.2, Figure 83.1).[56,58,64] The major general subdivisions of vasculitis are large-vessel vasculitis, medium-sized vessel vasculitis, and small-vessel vasculitis. Each subdivision is characterized by a pathologic pattern of inflammatory injury that can be caused by more than one clinicopathologic form of vasculitis and that is a final common pathophysiologic pathway of injury that can result from more than one etiology.

Large-vessel vasculitis affects the aorta or its major arterial branches or both, and is characterized pathologically by chronic inflammation that often includes multinucleated giant cells.[56] Giant cell arteritis and

TABLE 83.1 Categorization of Noninfectious Vasculitis Based on known or Putative Etiologies and Pathogenic Mechanisms

Mediated by Immune Complex Deposition or in Situ Formation
Henoch-Schönlein purpura (IgA vasculitis)
Cryoglobulinemic vasculitis
Lupus vasculitis
Rheumatoid vasculitis
Serum sickness vasculitis (Serum-sickness-associated immune complex vasculitis)
Infection-induced immune complex vasculitis (e.g., hepatitis B and C)
Anti-glomerular basement membrane (anti-GBM) disease
Kawasaki disease (possibly via anti-endothelial antibodies)
Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)
Mediated by antineutrophil cytoplasmic autoantibodies (ANCAs)
Microscopic polyangiitis
Wegener granulomatosis (Granulomatosis with polyangiitis)
Churg-Strauss syndrome (Eosinophilic granulomatosis with polyangiitis)
Renal-limited vasculitis (pauci-immune crescentic glomerulonephritis)
Cell mediated
Giant cell arteritis
Takayasu arteritis

Takayasu arteritis are the two primary categories. When the kidneys are affected by large-vessel vasculitis, the most commonly involved vessels are the main renal artery and interlobar arteries, and the most common clinical manifestation is renal artery stenosis with renovascular hypertension. The pattern of inflammation in large-vessel vasculitis with a predominance of T lymphocytes, monocytes, and macrophages (including multinucleated giant cells) suggests a type IV cell–mediated immune pathogenesis, however, no exogenous or endogenous (auto) antigen target for a pathogenic T-lymphocyte response has been identified.

Medium-sized vessel vasculitis is necrotizing inflammation of arteries in the absence of involvement of capillaries or venules.[56,58] The primary clinicopathologic categories are polyarteritis nodosa and Kawasaki disease. Although the pathophysiology of these two diseases appears to be quite distinct, both are characterized in the acute phase by arteritis with localized transmural necrosis and infiltration by activated neutrophils and monocytes that cause lytic destruction of the vessel wall.[59,62] Within several days, the acute inflammation and necrosis are replaced predominantly by lymphocytes and macrophages that orchestrate the progressive replacement of the necrosis with fibrosis. In the kidneys, medium-sized vessel vasculitis has a predilection for the lobar and arcuate arteries, but any artery, including the main renal artery, may be involved. Common intrarenal manifestations include pseudoaneurysm formation, thrombosis, infarction, and hemorrhage.

Small-vessel vasculitis is characterized by acute, often necrotizing, inflammation of many small vessels in multiple organs.[58,59] Involvement of glomerular capillaries causing glomerulonephritis is a frequent component of most forms of small-vessel vasculitis, and may be the dominant feature. Involvement of dermal venules causing leukocytoclastic angiitis with palpable purpura also is a frequent feature. Small-vessel vasculitis caused by antiglomerular basement membrane antibodies (anti-GBMs) and antineutrophil cytoplasmic autoantibodies (ANCAs) represent life-threatening forms of small-vessel vasculitis that have a predilection for attacking glomerular and pulmonary capillaries. Although the defining feature of small-vessel vasculitis is the involvement of capillaries and venules, small-vessel vasculitis also may affect small and even medium-sized arteries resulting in a necrotizing arteritis that is histologically indistinguishable from a medium-sized vessel vasculitis such as polyarteritis nodosa.

The kidneys are affected much more often by small-vessel vasculitis than by medium-sized vessel vasculitis or large-vessel vasculitis. Thus, the focus of this chapter will be on the pathophysiology and immunopathology of small-vessel vasculitis. The two major immunopathogenic categories of small-vessel vasculitis are immune complex–mediated vasculitis and antineutrophil cytoplasmic autoantibody (ANCA)–mediated vasculitis. Immune complex vasculitis is characterized immunohistologically by conspicuous localization of immunoglobulin in vessel walls, whereas ANCA vasculitis is characterized by the absence or paucity of immunoglobulin in vessel walls.[58,62,63] Although these two categories of vasculitis have different etiologies, they share many common histologic features and use common inflammatory mediators and pathways. The next section of this chapter will review some of these common inflammatory pathways. The subsequent two sections will review the pathogenic features of immune complex vasculitis and ANCA vasculitis.

BASIC PATHOGENIC EVENTS IN SMALL-VESSEL VASCULITIS

The seminal pathophysiologic event in small-vessel vasculitis is segmental acute inflammation

TABLE 83.2 Names and Definitions of Vasculitis Adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis

Large-Vessel Vasculitis[a]	
Giant cell arteritis	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery. Often involves the temporal artery. Usually occurs in patients older than 50 and often is associated with polymyalgia rheumatica.
Takayasu arteritis	Granulomatous inflammation of the aorta and its major branches. Usually occurs in patients younger than 50.
Medium-Sized Vessel Vasculitis[a]	
Polyarteritis nodosa	Necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules.
Kawasaki disease	Arteritis involving large, medium, and small arteries and associated with mucocutaneous lymph node syndrome. Coronary arteries are often involved. Aorta and veins may be involved. Usually occurs in children.
Small-Vessel Vasculitis[a]	
Wegener's granulomatosis (Granulomatosis with polyangiitis)	Granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium vessels (e.g., capillaries, venules, arterioles, and arteries). Necrotizing glomerulonephritis is common.
Churg-Strauss syndrome (Eosinophilic granulomatosis with polyangiitis)	Eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels, and associated with asthma and blood eosinophilia
Microscopic polyangiitis	Necrotizing vasculitis with few or no immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles. Necrotizing arteritis involving small and medium-sized arteries may be present. Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs.
Henoch-Schönlein purpura (IgA vasculitis)	Vasculitis with IgA-dominant immune deposits affecting small vessels (i.e., capillaries, venules, or arterioles). Typically involves skin, gut, and glomeruli and is associated with arthralgias or arthritis.
Cryoglobulinemic vasculitis	Vasculitis with cryoglobulin immune deposits affecting small vessels (i.e., capillaries, venules, or arterioles) and associated with cryoglobulins in serum. Skin and glomeruli are often involved.

[a]Large artery refers to the aorta and the largest branches directed toward major body regions (e.g., to the extremities and the head and neck); medium-sized artery refers to the main visceral arteries (e.g., renal, hepatic, coronary, and mesenteric arteries); and small artery refers to the distal arterial radicals that connect with arterioles (e.g., renal arcuate and interlobular arteries). Small vessel includes small arteries, arterioles, capillaries, and venules. Note that large and medium-sized vessel vasculitides are confined to arteries. Involvement of capillaries or venules is indicative of small-vessel vasculitis.

of small vessels, often accompanied by necrosis (Figure 83.2).[59,62] Many of the basic inflammatory processes that occur in small-vessel vasculitis also occur in the necrotizing arteritis of medium-sized vessel vasculitis (Figure 83.3). The primary initial effector cells in small-vessel vasculitis are neutrophils and monocytes, although macrophages and T lymphocytes are rapidly recruited in response to the injury and are active participants in the subacute and chronic progression of injury. Targeting of leukocytes to specific vascular segments involves multiple cell adhesive and cell signaling events in both the leukocytes and the vessel walls, particularly the endothelium. Collectively these events (discussed below) comprise a leukocyte adhesion cascade. They have been characterized most thoroughly at sites of physiologic diapedesis of neutrophils and monocytes through small vessels, especially postcapillary venules, as they traffic toward tissue sites of innate and adaptive immune surveillance or sites of immune response to microbial invasion or other pathogenic stimuli.[82,137] The events of the leukocyte adhesion cascade are generally accepted to occur in most tissues. However, recent work has demonstrated that some tissue- and organ-specific variation does occur,[107] although there is no current evidence to suggest that such variation accounts for the vascular and organ predilections of certain of the vasculitides.

In physiologic diapedesis, leukocyte transmigration through vessel walls causes only minor and transient disruption of the vessel wall structure. In vasculitis, the

leukocytes undergo full activation as they attach to and enter the vessel wall rather than waiting until after they have transmigrated into the tissue. Neutrophils survive for only a few minutes, or at most a few hours, at sites of acute inflammation.[62,137] Monocytes transform into activated macrophages after entry into sites of acute inflammation.[54] Activated macrophages release cytokines that modulate the inflammation. For example, macrophages release factors that enhance T-lymphocyte adhesion to nearby venular endothelial cells and induce targeted chemotaxis of T lymphocytes toward the site of the macrophage activation. If the stimulus for acute inflammation does not persist, neutrophils and monocytes are quickly replaced by macrophages and T lymphocytes at the site of small-vessel vasculitis. Thus, sites of small-vessel vasculitis in biopsy specimens, including renal biopsy specimens, often have predominantly macrophages and T

lymphocytes in the injured vessels although the initial injury was induced earlier by neutrophils and acutely activated monocytes.

Chemoattractants, Cytokines, and Chemokines

Chemoattractants for neutrophils and monocytes play a central role in mediating vasculitis not only by attracting leukocytes but also by activating leukocytes and endothelial cells to participate in inflammatory events.[22,91,150] Modulation of the expression of adhesion molecules and cytokine/chemokine molecules by endothelial cells, leukocytes in the circulation, and leukocytes in the tissue orchestrates the inflammation at sites of vasculitis. In small-vessel vasculitis, the balance is tipped toward neutrophil recruitment and activation in the acute phase, but within only one or two days the balance shifts toward recruitment of predominantly monocytes and T lymphocytes. However, if the pathogenic process that initiated the initial injury persists, as often is the case, lesions will include a mixture of acute and chronic inflammatory cells for extended periods of time.

Important chemoattractants for neutrophils and monocytes include C5a (which can be generated by activation of either the classical, lectin or alternative complement pathway), leukotriene B4, platelet-activating factor (PAF), and CXC chemokines such as interlukin-8 (IL-8, CXCL8), platelet factor 4 (PF4, CXCL4), GRO1 oncogene (GROα, CXCL1), and stromal cell-derived factor-1 (SDF-1, CXCL12). Progression of vasculitic lesions from an acute to a subacute or chronic phase is mediated primarily by a different set of chemoattractants that preferentially recruit monocytes and T lymphocytes, such as the CC chemokines macrophage inflammatory protein-1α (MIP-1α, CCL3), monocyte chemotactic protein-1 (MCP-1, CCL2), and regulated upon acitivation, normal T-cell expressed, and secreted (RANTES, CCL5). Chemoattractants not only attract leukocytes through direct engagement of ligands on the leukocytes, but also by enhancing the expression and binding of leukocyte adhesion molecules (e.g., β2 and β1 integrins) to their ligands on endothelial cells and elsewhere in the tissue.[150]

Chemokines on the surface of endothelial cells attract leukocytes to the cells in concert with the adhesion molecules reviewed below, and provide a gradient for directional migration toward the intercellular junction (or transcellularly through the endothelial cytoplasm). Once through the endothelium, gradients of bound and free chemokines in the extracellular matrix and interstitial fluid continue to provide directional signals until the leukocyte encounters enough stimulation to undergo full activation. In physiologic diapedesis of leukocytes across postcapillary venules, full activation is not attained until after the leukocyte has migrated away from the vessel wall. In the absence of an adequate pathogenic stimulus in the extravascular compartment, a leukocyte eventually will undergo senescence and apoptosis without becoming activated. In vasculitis, leukocytes are activated as they attach to or enter the vessel wall resulting in inflammatory vascular damage. There are many etiologies for this mural activation, including the presence of infectious organisms in the vessel wall (e.g., *Rickettsia rickettsii* in Rocky Mountain spotted fever), immune complexes in the vessel wall (e.g., cryoglobulins in cryoglobulinemic vasculitis), or activation

by antineutrophil cytoplasmic autoantibodies (e.g., in microscopic polyangiitis).

Leukocyte Recruitment

Leukocyte recruitment into the vessel wall is accomplished by the events of the leukocyte adhesion cascade. This is a multistep process that sequentially involves leukocyte tethering to endothelium followed by leukocyte rolling, activation, arrest, spreading and crawling on the endothelium, and finally paracellular or transcellular migration (diapedesis) across the endothelium[82] (Figure 83.4). Important initial events are the tethering and rolling of leukocytes on the surface of endothelial cells. This allows the leukocytes to sample the endothelial surface for chemokine signals derived from the underlying tissue and for upregulated endothelial adhesion molecules that can modulate rolling and mediate firm adherence. Engagement of these molecules allows static adhesion to the endothelium followed by crawling toward endothelial cell junctions where transmigration between the cells can be accomplished by further engagement of adhesion molecules in the junction.[22] Transmigration through endothelial cells may also occur.[161] Once through the vessel wall, movement into the perivascular interstitial tissue involves chemoattractant gradients and further engagement between integrins and ligands on extracellular matrix molecules.[22,137]

Leukocyte Tethering and Rolling

The first step in the exit of leukocytes from flowing blood within the vessel lumen is margination toward the endothelial surface. The resulting juxtaposition of these cells facilitates capture or tethering of the leukocyte to the endothelial surface. Once tethered, shear stress pushing on the leukocyte, combined with the formation of new adhesive bonds at the downstream leukocyte edge and disruption of adhesive bonds at the upstream leukocyte edge, allows for rolling of the leukocyte along the endothelial surface. The adhesive interactions necessary for leukocyte tethering and rolling are mediated primarily by the binding of selectin adhesion molecules to their ligands.[82,107] E-selectin and P-selectin are expressed on activated endothelium, and P-selectin is also expressed on activated platelets. L-selectin is constitutively expressed on most leukocytes. P-selectin is pre-formed and stored in Weibel-Palade bodies or alpha granules, respectively, and therefore is rapidly translocated to the cell surface quickly in response to mediators released at sites of acute inflammation, such as histamine and thrombin.[88] In contrast, cell surface expression of E-selectin is dependent on RNA and protein synthesis stimulated by inflammatory cytokines such as tumor necrosis factor (TNF) and interleukin-1 (IL-1),[11] and is therefore delayed for several hours after an inflammatory stimulus is received.

A number of selectin ligands (or counter receptors) have been described.[13,63] The best characterized is P-

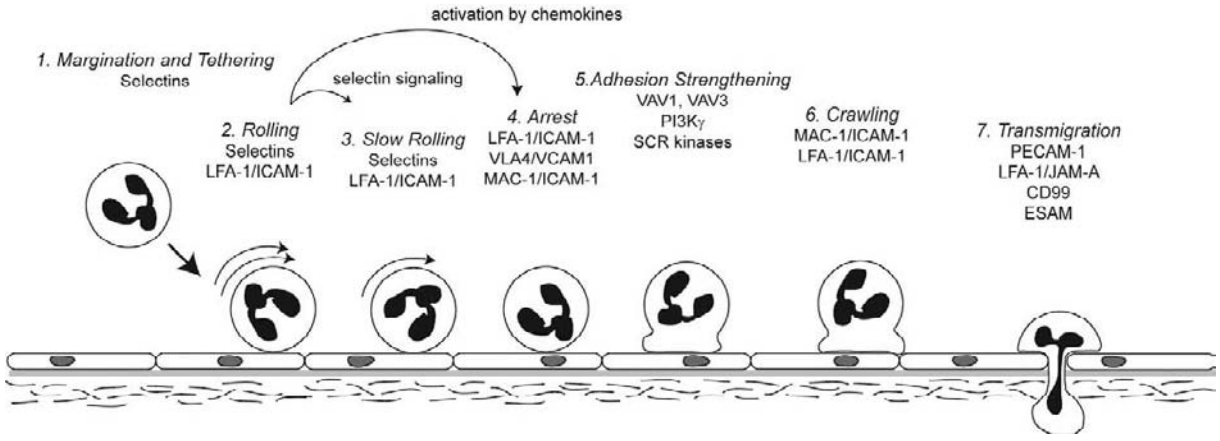

FIGURE 83.4 Diagram depicting the stereotypical events involved in neutrophil diapedesis at a site of inflammation. Activated endothelial cells display upregulated adhesion molecules and bound chemoattractants (e.g., CXC chemokines) that initially induce neutrophil tethering and rolling mediated primarily by interactions between selectins and their ligands (see Table 83.3). This stimulates inside-out signaling events that facilitate the engagement of neutrophil integrins (especially β 2 integrins) with upregulated immunoglobulin superfamily adhesion molecules on endothelial cells (e.g., intercellular adhesion molecule-1, ICAM-1) and result in slow rolling and arrest. Outside-in signaling events strengthen the adhesive interactions by modulating the affinity of the integrins, and facilitate lateral migration toward the inflammatory stimulus. Specialized adhesion molecules at the endothelial cell junctions (e.g., junctional adhesion molecule-1, JAM-1; platelet endothelial cell adhesion molecule-1, PECAM; CD99; endothelial cell-selective adhesion molecule, ESAM) mediate endothelial transmigration. Once through the endothelial barrier, additional leukocyte adhesion molecules (especially β 2 integrins) mediate migration into the extracellular space by engagement of ligands on extracellular matrix (e.g., fibronectin and collagen). The depicted abbreviated adhesion molecules are defined in Table 83.3.

selectin glycoprotein ligand-1 (PSGL-1). PSGL-1 was originally described as a P-selectin ligand but is now known to function as a ligand for all three selectins. It is expressed on most leukocytes, endothelial cells, and platelets. Ligands for E-selectin also include E-selectin ligand -1 (ESL-1) and correctly glycosylated forms of CD44, both of which are expressed on leukocytes. L-selectin ligands include PSGL-1 on other leukocytes, and peripheral node addressins including glycosylation-dependent cell adhesion molecule-1 (GLYCAM-1), podocalyxin, and CD34, which are found on peripheral lymphoid tissue high endothelial venules (HEV).

Binding of the selectins to their ligands is modulated by several molecular features. High affinity selectin binding is dependent on ligand glycosylation, in part requiring the sialyl Lewis X tetrasaccharide as a recognition epitope. The final step in the synthesis of this critical binding epitope is the addition of an α(1,3)-linked fucose, mediated by α(1,3)-fucosyltransferases type VII and IV.[50] L-selectin binding to ligands on peripheral lymph node HEV, or at sites of chronic inflammation, utilize a sulphated version of this epitope, 6-sulph-sialyl Lewis X.[121] Lastly, high affinity binding of P-selectin or L-selectin to PSGL-1 requires sulphation of certain tyrosine residues near the N-terminus of the molecule.[13] The molecular features of the selectins and their ligands result in binding interactions with very high on- and off-rates, allowing bonds to form and break quickly.[85] In addition, shear stress is required and also enhances L-selectin and P-selectin binding. Combined, these binding features result in interactions called catch bonds that are particularly suited to mediating the tethering and rolling of leukocytes on the endothelium.[174]

At sites of small-vessel vasculitis, increased expression of P-selectin and E-selectin on endothelial cells is induced by inflammatory chemokines. Subsequent binding to their ligands on leukocytes allows for and modulates primary leukocyte tethering and rolling. Rolling may also be triggered by secondary tethering.[70,107] In this process, leukocytes previously captured onto the endothelium bind, via their PSGL-1, to L-selectin on other marginated leukocytes and mediate their capture and tethering to the endothelium. The physiologic significance of secondary tethering remains unclear,[76] although it can be observed in vivo.

In addition to selectin-mediated rolling, it is known that some integrin adhesion molecules can mediate and modulate this process. For example, the β_1 integrin very late antigen 4 (VLA4) has been shown to mediate rolling of monocytes and T cells. Similarly, the β2 integrin lymphocyte function-associated antigen 1 (LFA-1) can interact with endothelial intercellular adhesion molecule 1 (ICAM-1) to modulate slow rolling. In this process, neutrophil signaling events triggered by binding to E-selectin result in expression of an intermediate-affinity form of LFA-1 that transiently interacts with endothelial ICAM-1 to decrease rolling velocity. A second β2 integrin, macrophage-1 antigen (MAC-1) can also mediate slow rolling. Thus, the additive ligation of more than one class of adhesion molecule may be required for efficient transition from fast rolling to a state of arrest.

Leukocyte Activation and Arrest

Leukocyte transition from rolling to arrest is the next step in leukocyte transmigration. Leukocyte activation is rapidly triggered by chemokines and other cell activators, and leukocyte arrest is mediated primarily by binding of leukocyte integrin-type adhesion molecules to members of the immunoglobulin superfamily expressed on the endothelium.[70,82,107] Leukocyte rolling facilitates activation by slowing transit time which allows for increased exposure to soluble activating factors and also exposure to endothelial-bound activating factors. Evidence suggests that chemokines that facilitate engagement of integrins and direct endothelial transmigration are bound to glycosaminoglycans (GAGs) or the Duffy antigen/receptor for chemokines (DARC)[90] on the surface of endothelial cells. The type of chemokine that occupies these binding sites depends on the relative availability and concentration of the chemokines. These sites can engage different cytokines depending on the type of leukocyte that is being recruited for a particular physiologic or pathophysiologic process.[91] Thus, if high levels of CXC chemokines are present in the vessel wall, CXC chemokines will occupy the endothelial binding sites and will attract predominantly neutrophils. In contrast, if high levels of CC chemokines are present in the vessel wall, CC chemokine will occupy the endothelial binding sites and will attract predominantly T lymphocytes. Chemokines can reach the luminal surface of endothelial cells by vesicular abluminal-to-luminal transcytosis, or be deposited there by circulating platelets or microparticles, or the exocytosis of intracellular granules derived from other cells.[147]

Integrins with the β_1 or β2 subunit are particularly important in the arrest of neutrophils and monocytes and their recruitment to sites of acute vascular inflammation. These include CD49d/CD29 (VLA-4), CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), and CD11c/CD18. The avidity of certain integrins on leukocytes can be rapidly upregulated by chemokines at sites of inflammation[78] and enhance arrest and accumulation of inflammatory cells.[73,137,173] Ligation of specific heterotrimeric G-protein coupled receptors (GPCRs) by

chemokines triggers a complex intracellular signaling cascade that results in integrin transition to intermediate and high affinity forms to promote arrest. This process, termed inside-out signaling, is incompletely understood but is thought to sequentially involve phospholipase C signaling, small GTPase activation, and induction of integrin conformational changes.[82]

Several members of the immunoglobulin superfamily are the ligands on the surface of endothelial cells for the leukocyte integrins. Important examples are the intracellular adhesion molecules (ICAMs) that include ICAM-1, ICAM-2, and ICAM-3. Up-regulation of these ligands, especially ICAM-1, on endothelial cells at sites of vascular inflammation works in concert with the up regulation of integrins on circulating leukocytes to induce leukocyte infiltration at sites of vasculitis. Ligation of CD11a/CD18 (LFA-1) on neutrophils to ICAM-1 on endothelial cells causes adhesion and ligation of CD11b/CD18 (MAC-1) to ICAM-1, promoting arrest and diapedesis.[140] Ligation of β2 integrins to ICAMs is particularly important for neutrophil influx at sites of acute vascular inflammation, whereas lymphocyte recruitment to sites of inflammation depends more on the binding of the β4 integrin VLA-4 (CD49d/CD29) to a different immunoglobulin, vascular cell adhesion molecule-1 (VCAM-1 [CD106]).[22,135]

Many of the leukocyte adhesion cascade processes and events described thus far can contribute to the specificity of leukocyte recruitment and arrest. Specificity can be accounted for by the combinatorial effects of differential expression of integrins and their receptors, differential expression of the chemokines and their receptors, and varied intracellular signaling to regulate integrin function.[82]

ADHESION STRENGTHENING

Recent work[82,107] has begun to delineate events following integrin engagement that are thought to strengthen binding to the endothelium and thereby promote leukocyte recruitment into the inflamed vascular wall. These events are triggered by integrin-mediated outside-in signaling, characterized by ligand-induced integrin conformational changes, and cell surface integrin clustering that result in the recruitment of protein tyrosine kinases (PTKs) and initiation of PTK-dependent signaling pathways.[43] Also, the signaling adaptor molecule paxillin has been shown to bind to the α_4 integrin chain of VLA-4 only in its high-affinity conformation,[120] suggesting that ligand binding initiates outside-in signaling through this adapter protein. In addition, studies have shown that neutrophils lacking phosphatidylinositol 3-kinaseγ (PI3Kγ)[136] or the guanine nucleotide exchange factors VAV1 and VAV3[40] exhibit accelerated detachment. Although these signaling pathways are not fully elucidated, these studies provide evidence that integrin binding events that mediate leukocyte arrest also trigger intracellular signaling processes that stabilize post-arrest leukocyte adhesion.

Leukocyte Crawling and Transmigration

Static leukocyte adhesion to the endothelium is followed by transmigration of the cell across the endothelial barrier. Adherent leukocytes crawl over the endothelial surface (termed lateral migration) to locate a preferred site at which to cross the endothelium. Neutrophil crawling on venular endothelium is dependent MAC-1 and its ligand ICAM-1, and disruption of these binding events results in a delay of transmigration.[108] Crawling is likely to also occur as an integral part of the prominent leukocyte recruitment that occurs on the arterial side of the circulation in the vasculitides.

Once at an endothelial cell junction, neutrophils and monocytes are able to crawl through the junctions between endothelial cells (paracellular transmigration) by progressive engagement and disengagement of a series of adhesion molecules on the surface of the leukocytes with ligands on the junctional surfaces of the endothelial cells.[22,102,130] Platelet/endothelial cell adhesion molecule-1 (PECAM-1) (CD31), an immunoglobulin superfamily member, is expressed on leukocytes and on endothelial cell surfaces and intercellular junctions. Homophilic PECAM-1 adhesion is particularly important for transmigration of leukocytes through intercellular junctions between endothelial cells.[2,22,97] Transmigration of neutrophils and monocytes also involves the interactions of LFA-1, VLA4, or MAC1 on the leukocytes with immunoglobulin superfamily adhesion molecules in the endothelial intercellular junction, JAM-A (junctional adhesion molecule-A), JAM-B, or JAM-C, respectively.[22,82,102] Distal to the PECAM-1-mediated and JAM-mediated events, homophilic binding between CD99 on leukocytes and CD99 in the intercellular junction between endothelial cells takes over to facilitate completion of diapedesis.[22,130] Recent work also shows that endothelial cell-selective adhesion molecule (ESAM) at the endothelial junction facilitates transmigration of neutrophils but not lymphocytes, possibly by activation of the Rho GTPase and destabilization of the tight junction.[151] Leukocytes may also cross the endothelial barrier by a transcellular route through the body of the endothelial cell (transcellular migration). The significance of this route *in vivo*, and the underlying mechanisms involved in this process are currently poorly understood.[82,107]

During the process of diapedesis, there are endothelial cytoskeletal and junctional events that result in localized retraction of endothelial cytoplasm and opening of the intercellular junction. These events result from signals transduced from the ligation of endothelial adhesion molecules (e.g., ICAM-1 and PECAM-1).[22] Endothelial stimulation by inflammatory cytokines and adhesion molecule ligation, activation of membrane bound and interstitial matrix metalloproteinases (MMPs), and release of serine proteinases at the surface of migrating leukocytes cause altered distributions and integrity of junctional adhesion molecules (JAMs), vascular endothelial cadherins, and other junctional complex components so that leukocytes can crawl between endothelial cells into the intima, muscularis, or perivascular interstitium.[22,102,150] Once past the endothelial barrier, leukocyte migration through the underlying lamina and matrix involves progressive engagement of matrix molecules by leukocyte adhesion molecules, especially PECAM-1, β1 integrins (e.g., VLA-4, VLA-5) and carcinoembryonic antigen–related cell adhesion molecules (CEACAMs).[26,100,148]

At sites of vasculitis, the endothelium may be absent because of inflammatory damage. Denudation of endothelium will expose surfaces that contain ligands for neutrophils, monocytes and other inflammatory cells (Table 83.3). At sites of acute necrotizing vasculitis, the lumen often is immediately adjacent to zones of fibrinoid necrosis that contain fibrin that has been generated by the activation of the coagulation cascade by

tissue factor and other thrombogenic materials at the site of injury. Mac-1 and other neutrophil and monocyte adhesion molecules can adhere to fibrin and begin the process of activation and migration into the inflamed tissue.[94] Matrix molecules exposed by endothelial denudation, such as fibronectin, laminin, entactin, and collagen also present ligands for leukocyte adhesion molecules, especially β1 integrins such as VLA-4 and VLA-5. Serine proteinases (e.g., elastase) released at the surface of migrating leukocytes act synergistically with β1 integrins and upregulated leukocyte PECAM-1 to allow the leukocytes to migrate into the tissue.[148]

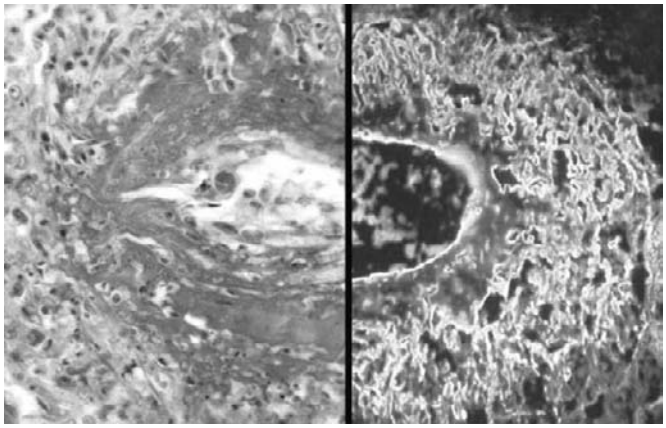

FIGURE 83.5 The *left panel* shows necrotizing arteritis with replacement of the vessel wall by amorphous fibrinoid material (hematoxylin and eosin stain); and the *right panel* shows the staining of fibrinoid necrosis in a artery wall with a fluoresceinated antibody specific for fibrin.

Mechanisms of Tissue Injury

Leukocytes attach to and migrate into the vessel wall at sites of vasculitis, and also undergo concomitant activation. The engagement of leukocyte adhesion molecules sends outside−in activating signals to the leukocyte, stimulating them to release inflammatory mediators. Cytokines and chemokines released by leukocytes, endothelial cells, and tissue cells at the sites of inflammation further amplify leukocyte activation and tissue injury.[150] Neutrophil activation results in the generation of reactive oxygen species and the release by degranulation of lytic and toxic mediators that injure vessel wall components. Production of reactive oxygen species by NADPH oxidase and other cellular sources contributes to vascular tissue injury by causing oxidation of matrix macromolecules as well as cellular molecules including lipids, proteins, and DNA. Neutrophil production of reactive oxygen species may be triggered be mechanisms specific to the pathogenesis of a particular vasculitis, such as engagement of Fcγ receptors in ANCA disease, or by more general inflammatory mediators such as TNFα.[16,38,115]

Other inflammatory events at sites of small-vessel vasculitis include edema, hemorrhage, thrombosis, cell death (both apoptotic and necrotic), and matrix lysis with fibrinoid necrosis. Fibrinoid necrosis results when there is enough destruction to the vessel walls to allow plasma constituents, including the coagulation factors, to seep into vessel walls or the perivascular tissue. Here, the coagulation factors encounter multiple thrombogenic substances, including tissue factor, which results in the generation of fibrin. Fibrin can be demonstrated by immunohistochemistry at sites of fibrinoid necrosis (Figure 83.5). The necrosis of cells and lysis of matrix may erode through the vessel wall into the perivascular tissue resulting in a pseudoaneurysm (often referred to as an aneurysm) (Figure 83.6).[62]

The lysis of matrix in vessel walls and perivascular tissue that results in fibrinoid necrosis is mediated by

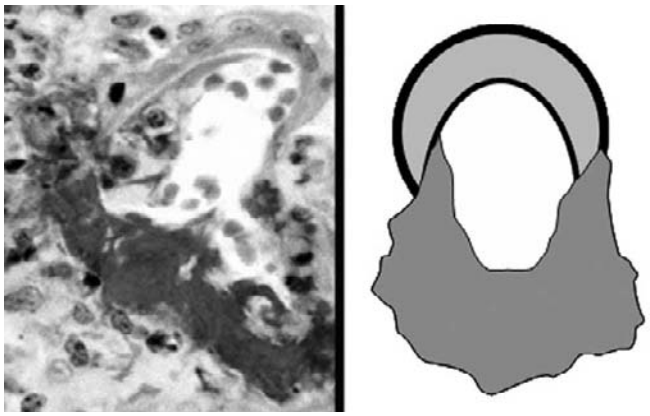

FIGURE 83.6 The *left panel* shows segmental fibrinoid necrosis and pseudoaneurysm formation in a renal interlobular artery (Masson trichrome stain), and the *right panel* illustrates the process diagrammatically.

cytotoxic and lytic enzymes released by leukocyte degranulation, and generated within the inflamed tissue. For example, a number of destructive serine proteinases, such as elastase, proteinase-3, and cathepsin G, are stored in the granules of neutrophils and monocytes and are released when these leukocytes are activated at sites of inflammation.[103] Serine proteinases can be detected at sites of fibrinoid necrosis by immunohistochemistry.[5,101] In addition, matrix metalloproteinase (MMPs), such as collagenase and gelatinase, are produced by leukocytes and tissue cells at sites of inflammation.[81] Most MMPs, which comprise a family of more than 20 endopeptidases, function in the extracellular space, but some are bound to cell membranes (membrane-type MMPs, MT-MMPs). Normally, serine proteinases are held in check by serine proteinase

inhibitors (serpins) and MMPs are held in check by tissue inhibitors of MMPs (TIMPs) (Figure 83.7).[49,81] However, in the microenvironment at sites of necrotizing acute inflammation, this homeostatic balance is tipped in favor of the destructive enzymes.

Serine proteinases, such as elastase, proteinase-3, and cathepsin G, can degrade the constituents of vascular basement membranes, the extracellular matrix of the muscularis of vessels, and perivascular extracellular matrix. Major matrix molecules that can be digested by serine proteinases include collagen, laminin, fibronectin, and proteoglycans.[103,159] Elastase and proteinase-3 also contribute to tissue injury by causing apoptosis and necrosis of cells.[169,170] Elastase also induces leukocytes and endothelial cells to release inflammatory cytokines. Elastase[101] and proteinase-3[5] can be identified by immunohistochemistry at sites or glomerular necrosis in crescentic glomerulonephritis that is a component of ANCA vasculitis.

The potential for tissue injury by serine proteinases is counteracted by serine proteinase inhibitors in the plasma, most important α_1-proteinase inhibitor (α1-antitrypsin), which is produced primarily in the liver.[49] Other serpins are produced to a greater degree at the site of inflammation, for example by neutrophils and macrophages.[49] These include secretory leukocyte protease inhibitor (SLPI) and elafin.[49] α_2-Macroglobulin is a broad-spectrum antiproteinase that inhibits not only serine proteinases but also cysteine proteinases, aspartic proteinases, and MMPs. In the microenvironment at sites of inflammation, inactivation of serine proteinases by serpins is counteracted by the inactivation of serpins by oxidants, such as hypochlorous acid, that are generated by the respiratory bursts of activated neutrophils and monocytes. For example, Donavan and associates have performed in vitro experiments that have demonstrated the ability of oxidants to abolish the inhibitory effect of α_1-antiproteinase on elastase-mediated GBM degradation.[31]

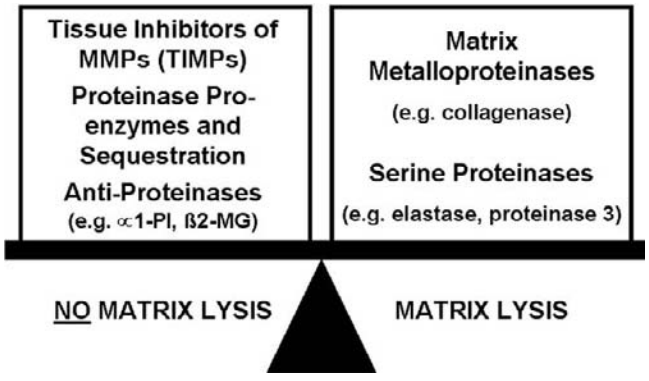

FIGURE 83.7 Diagram depicting the homeostatic balance that exists between matrix metalloproteinases and serine proteinases and the protective mechanisms that hold them at bay until they are needed or until they break free in pathologic processes.

MMPs, including MT-MMPs, can be identified by immunohistochemistry at sites of vascular inflammation.[47] Most MMPs are synthesized by leukocytes and other cells after stimulation by inflammatory cytokines.[81,90,159] However, MMP-8 (collagenase) and MMP-9 (gelatinase) are preformed and stored in the granules of neutrophil and monocyte. Thus, collagenase and gelatinase are released in concert with elastase, proteinase-3, and cathepsin G when neutrophils and monocytes undergo degranulation at sites of acute inflammation. This is a very lytic and toxic brew that can not only degrade the vascular and perivascular extracellular matrix but also can kill the endothelial and smooth muscle cells that comprise the vessel wall.

MMPs are released as proenzymes that must be activated before they can cause tissue injury or remodeling. At sites of inflammation, MMP proenzymes are activated by a variety of inflammatory mediators, including serine proteinases released by leukocyte degranulation, oxidants from leukocyte respiratory bursts, and other MMPs (especially MT-MMPs) that already have undergone activation. The counterbalance that TIMPs provide is counteracted at sites of acute inflammation by neutralization of TIMPs by serine proteinases.[159]

As already discussed, neutrophils and monocytes are important sources of destructive factors that cause injury during acute vasculitis and glomerulonephritis. The innate immune response to tissue injury caused by acute inflammation eventually also recruits T lymphocytes to the sites of acute inflammation. If neutrophil-driven acute inflammation ends, neutrophils disappear through apoptosis or necrosis within a day or two and are replaced by predominantly macrophages and T lymphocytes. In some forms of vasculitis, such as giant cell arteritis and Takayasu arteritis, T lymphocytes may play a dominant role even in the early phase of inflammation. T lymphocytes are able to mediate vascular injury through a variety of mechanisms. T lymphocytes can produce MMPs that degrade matrix.[34] T lymphocytes also release granzymes, which are serine proteinases that are toxic for cells and can digest proteoglycans. Activated T lymphocytes cause matrix degradation indirectly by inducing release of serine proteinases and MMPs by neutrophils and monocytes.

In summary, a broad spectrum of cellular and humoral inflammatory mediator systems are involved in the pathophysiology of inflammation at any site, including vasculitis. These mediators are common to many different pathogenic pathways to vasculitis that are initiated by many different etiologies, some of which are known and others not. The two most common pathways to renal vasculitis are immunoglobulin-

rich immune complex–mediated vasculitis and immunoglobulin-poor pauci-immune antineutrophil cytoplasmic autoantibody (ANCA)–mediated vasculitis. These will be reviewed in the following section.

IMMUNE COMPLEX–MEDIATED VASCULITIS

Basic Pathogenic Events in Immune Complex Vasculitis

In 1942, Arnold Rich observed that patients who were treated intravenously with serum developed systemic vasculitis.[119] Rich hypothesized that the vasculitis was caused by an immunologic response to the serum proteins and he obtained experimental support for this by inducing vasculitis in rabbits by injecting horse serum.[118] In the 1950s and 1960s, many investigators, including Germuth, Dixon, and Cochrane, documented the role for vascular localization of immune complexes containing antigen, immunoglobulin, and complement as a cause for vascular inflammation.[21,41,74,158] This was prompted by the identification by immunofluorescence microscopy of granular deposits of immunoglobulin and complement in the walls of vessels in patients and experimental animals with vasculitis (Figure 83.8).

Numerous experiments demonstrated that immune complexes in vessel walls cause inflammation by activating humoral and cellular inflammatory mediator systems in the blood, including the complement, kinin, and coagulation systems. Activation of humoral inflammatory mediator systems acted in concert with recruitment and activation of leukocytes, especially neutrophils and monocytes, to cause inflammation in the vessel wall. As with systemic immune complex vasculitis in humans (e.g., Henoch-Schönlein purpura or IgA vasculitis, and cryoglobulinemic vasculitis), most animal models of systemic immune complex vasculitis have involvement of glomeruli resulting in an immune complex glomerulonephritis as well as the systemic vasculitis. Of course, glomerulonephritis is in essence a form of vasculitis that is affecting glomerular capillaries.

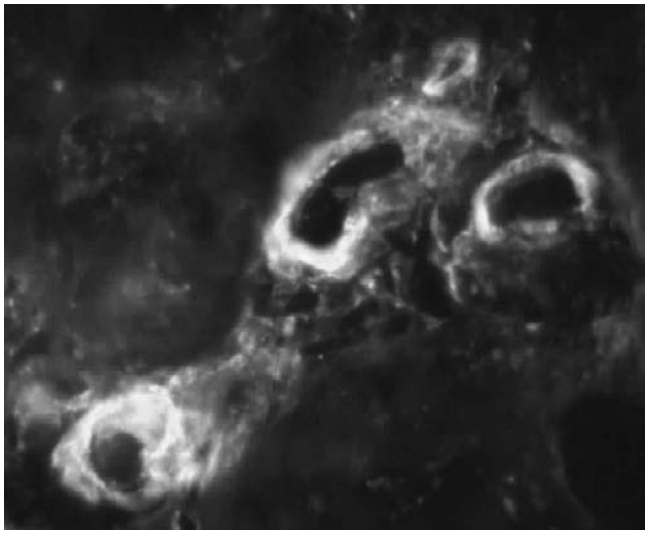

FIGURE 83.8 Granular staining for immunoglobulin A (IgA) in the walls of small dermal vessels in a patient with Henoch-Schönlein purpura (fluoresceinated anti-IgA).

A variety of animal models of immune complex vasculitis have been used to elucidate the pathophysiologic events that cause the vascular inflammation. For example, Kniker and Cochrane used a serum sickness model in rabbits to demonstrate a major role for neutrophils in immune complex vasculitis by ameliorating the vasculitis by depletion of neutrophils.[74] One of the most powerful in vivo experimental systems for dissecting the pathogenic events in immune complex mediated injury is the Arthus reaction.[4,9,20,21,117,166,168] The Arthus reaction mimics the events that take place in a vessel wall at the site of immune complex mediated vasculitis. The classic Arthus reaction involves repeated injection of a foreign antigen into the skin of an experimental animal until circulating antibodies to the antigen develop and react with the antigens at the site of injection to produce immune complex–mediated acute inflammation.[41] However, this process is difficult to control and thus the reverse passive Arthus reaction is a more useful model for investigating the inflammatory events that are induced by immune complexes.[166] This involves local injection of antigen in the tissue at the site of interest along with intravenous injection of the antibody that will form pathogenic immune complexes with the antigen.

Use of the reverse passive Arthus reaction with various knockout mouse strains indicates that immune complex-mediated inflammation involves all of the mediator systems that were discussed in the earlier sections on pathogenic mechanisms that are shared by different forms of vasculitis. Neutrophils are the major effector cells of the acute injury, although mast cells also play a role. Neutrophils are recruited and activated by the interplay of cytokines/chemokines, adhesion molecules, Fcγ receptor engagement, and complement activation.[9,20,117,166–168] There has been controversy over the relative importance of Fc receptor engagement versus complement activation.[9,117] The preponderance of evidence indicates that both are extremely important to the full development of immune complex-mediated inflammation and the two together have a synergist rather than merely additive effect.

Immune complexes that contain antibodies that are capable of activating complement by the classic or alternative pathway can induce acute inflammation. Knockout mouse experiments have demonstrated that the anaphylatoxin C5a, which is generated by the classic, lectin and alternative pathways, is a particularly potent mediator.[9] C5a induces increased vascular permeability, attraction of neutrophils and monocytes, activation of neutrophils and monocytes, and enhanced release of inflammatory cytokines from a number of cell types. C5 knockout mice and C5a receptor knockout mice have a marked reduction in the acute inflammation caused by the reverse passive Arthus reaction.[51] This is in the context of normal immunoglobulin Fc receptors on leukocytes. In addition to C5a, complement activation also generates the anaphylatoxins C3a and C4a, and the cytotoxic membrane attack complex C5b-9. These factors probably play a role in immune complex-mediated vasculitis, but C5a appears to be the dominant complement mediator in immune complex vasculitis.

Immunoglobulins in immune complexes activate complement and they also present their Fc regions for engagement by Fc receptors on leukocytes. Most experimental studies have focused on the importance of the receptors for the gamma heavy chains of IgG (Fcγ receptors) in the pathogenesis of immune complex disease.[117] There are two classes of Fcγ receptors: activating receptors and inhibiting receptors. Both types of receptors are expressed on most leukocytes and thus co-engagement of both types may occur on the same cell. Fcγ receptors occur on neutrophils, monocytes, macrophages, eosinophils, mast cells, and natural killer cells. B lymphocytes have only the inhibitory receptors. In mice, the absence of an activating Fcγ receptor, FcγRIII, results in an impaired Arthus reaction,[48] whereas the absence of an inhibitory Fcγ receptor, FcγRII, results in an enhanced Arthus reaction.[141] Likewise, in a mouse model of anti-GBM disease, which is an example of in situ immune complex-induced inflammation, mice with a deficiency of activating Fcγ receptor develop no disease[105,140] whereas mice with a deficiency of an inhibitory Fcγ receptor develop more severe disease.[140] It is reasonable to conclude that in animals and patients with activating and inhibiting Fc receptors, the outcome of Fc engagement by Fc receptors on leukocytes is the result of the balance between the activating and inhibiting signals to the cell. This in turn is controlled by the number of receptors expressed on the surface and the affinity of the receptors, which is influenced by the cytokines that the leukocyte is exposed to.[79] Thus, once again, there is evidence for a complex interplay between the various mediator systems at sites of inflammation.

Immune complexes in vessel walls must attract leukocytes to the vessel wall and induce them to infiltrate to cause vasculitis. Endothelial and leukocyte adhesion molecules are involved in this process. Once again, the Arthus reaction provides insights into this process. Genetic deficiency of selectins or blockade of selectins with antibodies reduces the severity of the passive reverse Arthus reaction in mice and in particular reduces the number of infiltrating neutrophils.[166,167] Likewise, mice deficient in ICAM-1 have diminished Arthus reaction.[166] Not surprisingly, given their functional redundancy, the absence of a single type of adhesion molecule is not as effective as the absence of multiple types of adhesion molecules in preventing an Arthus reaction. The importance of adhesions molecule in immune complex-mediated vascular inflammation also has been demonstrated in murine glomerulonephritis and alveolar capillaritis that is induced by in situ immune complex formation with anti-GBM antibodies.[98] There is evidence for involvement of selectins, β1 integrins, and β2 integrins. The relative importance of various types of leukocyte adhesion molecules seems to differ among different types of immune complex vascular inflammation.[98] The redundancy of the adhesion molecules and the difference in usage in different diseases presents a problem when contemplating therapeutic strategies that are designed to ameliorate vascular inflammation by blocking leukocyte binding to adhesion molecules.

As in any type of inflammation, cytokines and chemokines and their receptors are very important in orchestrating the inflammatory events in immune complex mediated vasculitis.[98,99,149,168] As with adhesion molecules, there is tremendous redundancy in the cytokines and chemokines that mediate vascular inflammation such that elimination or neutralization of one or a few is not sufficient to completely prevent the inflammation. This has been observed in diverse in vivo experimental systems, including the reverse passive Arthus reaction[168] and rodent models of glomerulonephritis or pulmonary capillaritis.[98] The regulation of immune complex-mediated vasculitis by cytokines includes upregulation and downregulation of inflammatory processes, often through modulation of the activation of leukocyte transcription factor nuclear factor-κB (NF-κB).[121]

The inflammatory events that have been characterized in the Arthus reaction and other experimental models of immune complex-induced vascular inflammation almost certainly occur in all forms of immune complex vasculitis in patients,[20] although there probably are differences in the precise repertoire of mediators that are most important in the various immunopathologic types. For example, cryoglobulinemic vasculitis with a predominance of IgG and IgM in

the vascular immune deposits probably induces somewhat different inflammatory pathways than Henoch-Schönlein purpura vasculitis with a predominance of IgA in the immune deposits.

Hepatitis B-Induced Immune Complex Vasculitis Including Polyarteritis Nodosa

Vascular immune complex deposition has been incriminated in the pathogenesis of clinically and pathologically diverse types of human vasculitis (Table 83.1). The source of the antigen can be exogenous as in serum sickness and vasculitis caused by hepatitis B or endogenous (e.g., an autoantigen) as in cryoglobulinemic vasculitis and lupus vasculitis.

As noted earlier, the first form of human vasculitis in which immune complexes were incriminated in the pathogenesis was serum sickness vasculitis.[119] Vasculitis associated with hepatitis B virus infection was the second well-recognized category of vasculitis caused by a foreign antigen, although in this instance it is being produced internally by the virus. The hepatitis B–associated vasculitis often is thought to mimic idiopathic polyarteritis nodosa, however, the vascular inflammation in patients has a broad spectrum of manifestations that includes necrotizing arteritis as well as small-vessel vasculitis such as leukocytoclastic angiitis in the skin and glomerulonephritis, which most often is a membranous glomerulopathy but may be proliferative or membranoproliferative glomerulonephritis.[44,46,89,109,144,145,154] This broad spectrum of immune complex disease is reminiscent of lupus vascular disease that can range from necrotizing arteritis to small-vessel vasculitis to varied forms of glomerulonephritis[75] and probably results from quantitative and qualitative differences in the amount and composition of circulating and vessel-wall immune complexes in different patients.

Granular deposits of immunoglobulin and complement, and sometimes hepatitis B antigens, have been detected in vessel walls at sites of necrotizing arteritis, cutaneous leukocytoclastic angiitis, and glomerulonephritis.[89,154] HBe antigen has been Identified most often.[145] The complement deposits include C1q, which indicates that the complement system has been activated by the classical pathway with release of the potent inflammatory mediators discussed earlier in this chapter. Thus the pathogenic mechanism could center on the typical sequence of inflammatory events that are set into motion by immune complex formation and complement activation. However, Mason et al. have demonstrated the presence of hepatitis B RNA and DNA as well as surface antigens and core antigens in endothelial cells in patients with extrahepatic disease.[86] They hypothesize that both immune complex formation and viral replication occur in vessel walls and both contribute to the induction of vascular inflammation. This putative role for vascular viral proliferation in the pathogenesis of hepatitis B–associated vasculitis awaits confirmation.

Cryoglobulinemic Vasculitis Including Hepatitis C-Induced Immune Complex Vasculitis

Cryoglobulinemic vasculitis is a small-vessel vasculitis that is caused by the localization of predominantly mixed cryoglobulins in vessel walls.[10,15,39] Clinical manifestations include arthralgias, palpable purpura, and glomerulonephritis. Mixed cryoglobulins are immune complexes and are classified as type II or type III.[123,142] Type II cryoglobulins contain a mixture of monoclonal antibodies with rheumatoid factor activity (usually IgMκ) that is bound to polyclonal immunoglobulin (usually IgG). Type III cryoglobulins are a mixture of more than one polyclonal immunoglobulin, often including one that has rheumatoid activity (usually IgMκ). Some patients have what appears to be a transitional stage between production of polyclonal rheumatoid factor and evolution to a dominant monoclonal rheumatoid factor and are classified as type II–III.[142]

Antibodies with rheumatoid factor activity have specificity for other antibodies, and thus are autoantibodies. Rheumatoid factor antibodies (RFs) often have anti-idiotypic specificity that allows them to bind to the antigen binding region of immunoglobulins (Fab). However, most rheumatoid factor antibodies in cryoglobulinemia can bind to both the Fc and Fab portions of the target immunoglobulins and thus can form more stable and larger immune complexes than anti-idiotypic antibodies that bind to Fab alone.[123] A genetically distinct k light chain is present in RFs in >80% of patients with HCV cryoglobulinemia.[15]

Type I cryoglobulins, which cause vasculitis less often, are not immune complexes because they are composed of monoclonal immunoglobulin, usually IgM and much less commonly IgG. Type I cryoglobulins often are produced by clones of abnormal B cells and often are associated with identifiable lymphoproliferative neoplasms. Aggregates of type I immunoglobulins can accumulate in and occlude the microvasculature resulting in a hyperviscosity syndrome. Less often, these aggregates induce inflammation similar to that caused by types II and III cryoglobulins.

In contrast, type II and type III cryoglobulins are immune complexes with RF antibodies bound to target immunoglobulin acting as antigen. These complexes

activate complement and induce small-vessel vasculitis and glomerulonephritis. The usual histologic expression is a type I membranoproliferative glomerulonephritis with hyaline thrombi (Figure 83.9). The complement activation involves the classical pathway as evidenced by immunostaining for C1q and C_4 along with other complement components in cryoglobulin vascular deposits and by the typical serologic finding of low or undetectable C_4 with normal or near-normal C_3.[39]

Depending on the geographic location, 40 to 90% of patients with mixed cryoglobulinemia have hepatitis C virus (HCV) infection, with the highest incidence in the Mediterranean basin.[100] HCV interacts with B lymphocytes to produce polyclonal B cell activation with a marked increase in the proportion of CD^{5+} lymphocytes, which are the prime suspects in the rheumatoid factor (autoantibody) formation.[25,123] The initial polyclonal activation that produces polyclonal rheumatoid factors and type III cryoglobulins evolves, in some patients, through an intermediate II-III phase into the emergence of a dominant single clone producing monoclonal rheumatoid factor and type II cryoglobulins.[123,142] Type II cryoglobulins from the circulation patients with HCV contain monoclonal IgM rheumatoid factor, polyclonal IgG with specificity for HCV, HCV core protein, and complement component C1q.[123,124] HCV proteins and RNA are present in cryoglobulins, possibly as antigenic components of immune complexes.[15]

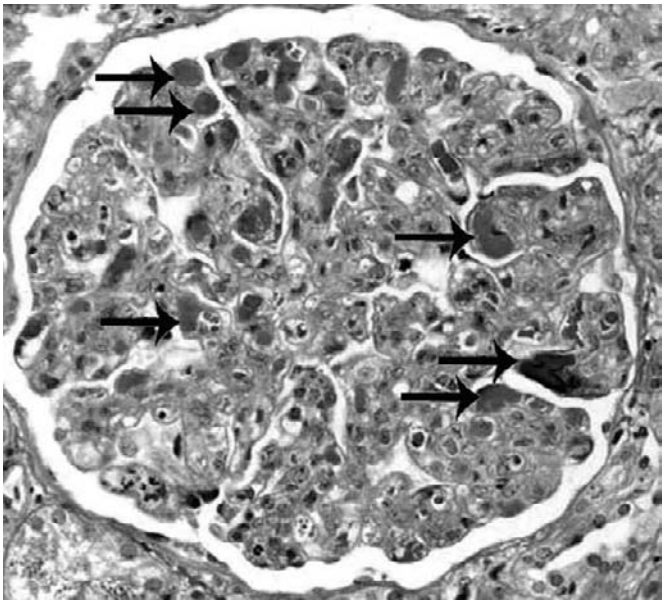

FIGURE 83.9 Glomerulus from a patient with cryoglobulinemic showing numerous hyaline thrombi (arrows) and histologic features of type I membranoproliferative glomerulonephritis.

Mediators of Cryoglobulinemic Vasculitis

Immunostaining of vasculitic lesions in the skin, nerves, kidneys, and elsewhere demonstrate cryoglobulin immune complexes that have the same composition as circulating cryoglobulins, including IgM, IgG, C1q, and HCV proteins.[10,123] In renal biopsy specimens with cryoglobulinemic glomerulonephritis, large intravascular cryoglobulin aggregates appear by light microscopy as hyaline thrombi in glomerular capillaries (Figure 83.9) and by immunofluorescence microscopy as globular staining for IgM and IgG.[10] In addition, there are subendothelial, mesangial and occasionally subepithelial electron dense immune deposits, often with a vague microtubular substructure.[63] The glomerulonephritis most often has a type I membranoproliferative pattern but occasionally can have a focal or diffuse proliferative or mesangioproliferative pattern and rarely a membranous pattern.[10,63] A minority of renal biopsy specimens will have necrotizing vasculitis affecting arterioles or small arteries.[10]

Immunohistology of skin and renal biopsy specimens identifies mediators of inflammation in the glomeruli that implicate many components of the leukocyte-adhesion molecule–cytokine axis that would be expected for immune complex–mediated vasculitis. For example, immunophenotyping of leukocytes in glomeruli affected by cryoglobulinemic glomerulonephritis demonstrates conspicuous infiltration by monocytes and macrophages.[42,116] The infiltrating macrophages express activation markers such as HLA class II molecules.[116] There also is glomerular upregulation of CC chemokine MCP-1 (CCL2), TNF-α, and IL-1α gene and protein expression,[42,116] which would attract and activate neutrophils and monocyte to glomeruli. In a study of cryoglobulinemic glomerulonephritis, endothelial leukocyte adhesion molecule ICAM-1 but not VCAM-1 was upregulated on endothelial cells.[96] However, in a study of small vessels in peripheral nerves from patients with cryoglobulinemic vasculitis, there was greater immunostaining for VCAM-1 compared with ICAM-1.[69] This study also found circulating VCAM-1 in patients with cryoglobulinemia and high levels of circulating VCAM-1 correlated with severe vasculitis.

Animal Models of Cryoglobulinemic Vasculitis

There are good mouse models of cryoglobulinemic vasculitis that have been used to elucidate the pathophysiology of this disease.[45,55,72] An early version used intraperitoneal injection of a mouse rheumatoid factor-producing hybridoma that had been derived from an MRL-lpr/lpr mouse.[45] The pathogenic rheumatoid factor was an IgG3 antibody with specificity

for IgG2a. Intraperitoneal injection of this clone resulted in circulating cryoglobulins and the development of cutaneous leukocytoclastic angiitis and glomerulonephritis that closely mimicked human cryoglobulinemic vasculitis. Monoclonal IgG3 without rheumatoid factor activity self-aggregates to form cryoglobulins but these are not pathogenic immune complexes and mimic glomerular lesions of type I cryoglobulinemia with hyaline thrombus formation but no glomerular inflammation.[55] Depletion of neutrophils from mice that received IgG3 with rheumatoid activity also had hyaline thrombi but no glomerular inflammation, indicating the importance of neutrophils in the mediation of vascular injury.[55] Neutrophils are not conspicuous in renal biopsies of human cryoglobulinemic glomerulonephritis, but one must realize that these are chronic lesions that have been evolving for months or at least weeks prior to renal biopsy, which would favor accumulation of long-lived macrophages. Skin biopsies of acute cryoglobulinemic vasculitis lesions typically show extensive leukocytoclasia indicative of neutrophilic influx and subsequent apoptosis.

A variation on the mouse model uses transgenic expression of the heavy and light chains of the pathogenic IgG_3 without rheumatoid factor activity to cause disease.[72] This model of chronic cryoglobulinemic injury shows the evolution of the glomerulonephritis from a proliferative to a membranoproliferative and eventually a sclerosing pattern and has visceral arteritis rather than cutaneous leukocytoclastic angiitis.

In summary, in both animals and humans, mixed cryoglobulins, which contain rheumatoid factor autoantibodies and target antibodies, cause immune complex–mediated vasculitis with complement activation, cytokine/chemokine secretion, adhesion molecule upregulation, leukocyte infiltration, and inflammatory injury to vessel walls.

Henoch-Schönlein Purpura Vasculitis (IgA Vasculitis)

Henoch-Schönlein purpura is a small-vessel vasculitis caused by immune complexes with IgA-dominant immunostaining.[56,58] Henoch-Schönlein purpura is the most common form of systemic vasculitis in childhood.[126] The mean age at onset is six years and 90% of patients are younger than 10 years. However, Henoch-Schönlein purpura can occur in adults at any age. Virtually all patients with Henoch-Schönlein purpura have palpable purpura caused by dermal leukocytoclastic angiitis. Over three-fourths have arthralgias, two thirds have abdominal pain, and a third to a half have evidence for glomerulonephritis. Glomerulonephritis is more common in older children and adults with Henoch-Schönlein purpura.[126]

The immunopathologic findings in Henoch-Schönlein purpura indicate an immune complex–mediated pathogenesis. Immunostaining of involved and uninvolved small vessel in the skin demonstrates the presence of IgA, C3, C3c, C3d, and fibrin/fibrinogen (Figure 83.8).[29] C_4 and C1q typically are absent; suggesting that the alternative complement activation pathway and not the classical pathway is involved in pathogenesis. This is in contrast to hepatitis B-associated immune complex vasculitis and hepatitis C-associated cryoglobulinemic vasculitis, both of which have conspicuous immunostaining for C_4 and C1q.[39,89] An important feature of the immune deposits is that they contain IgA1 rather than IgA2.[3] Glomerular immune deposits in Henoch-Schönlein purpura glomerulonephritis have the same composition as dermal vascular deposits and are similar to the deposits of IgA nephropathy, although they tend to have more frequent and more intense staining for fibrin/fibrinogen.

The exclusive participation of IgA1 and not IgA2 in the immune deposits of Henoch-Schönlein purpura and IgA nephropathy is in accordance with the hypothesis that the pathogenic immune aggregates of IgA result from abnormal glycosylation of the hinge region of IgA1 molecules.[3,8,77,125,139,140] The heavy chains of IgA1, but not IgA2, contain a praline-rich hinge region between the CH1 and CH2 domains. This hinge region has O-linked glycosylation sites. In fact, IgA1 and IgD are the only immunoglobulin isotypes that contain O-linked glycosylation sites. Multiple studies have demonstrated that most patients with Henoch-Schönlein purpura nephritis or IgA nephropathy have abnormalities in the O-linked glycans of the hinge region, such as diminished galactose or sialic acid or both. One study suggests that patients with Henoch-Schönlein purpura and nephritis have abnormal IgA hinge region glycosylation whereas those with no nephritis do not[29] but this has not been confirmed.

Abnormal IgA1 hinge region glycosylation could lead to the localization of pathogenic complexes of IgA1 in vessel walls by a number of mechanisms. Altered glycosylation can[1] reduce the hepatic clearance of IgA1 by asialoglycan receptors, which have a high affinity of o-linked glycans;[2] cause self-aggregation of circulating and deposited IgA1;[3] increase binding of IgA1 to extracellular matrix, including vascular basement membranes and glomerular mesangium;[4] enhance interactions between IgA1 and inflammatory mediators such as complement and Fcα receptors on leukocytes; and 5) development of IgG antibodies that recognize the aberrant glycosylation.[139,140] An intriguing although conjectural concept is that galactose-deficient hinge region is the target for circulating

antibodies that have been produced in an immune response to infectious pathogens that have α-galactosyl residues on their cell surfaces.[28,143] This might also explain the frequent association of a recent upper respiratory tract infection with the onset of both Henoch-Schönlein purpura and IgA nephropathy.[126] An alternative explanation for this association with infections is that a foreign antigen released by the pathogen is the target of the IgA immune response. In line with this theory, Masuda et al.[87] demonstrated a group A streptococcal antigen, nephritis-associated plasmin receptor, in the mesangial immune deposits of 30% of patients with Henoch-Schönlein purpura nephritis.[87] However, it is possible that the circulating and deposited aggregates of IgA that cause Henoch-Schönlein purpura and IgA nephropathy are not true immune complexes with antibodies specifically bound to antigens, but rather are predominantly homoaggregates of IgA1 with no bound antigens. This concept is supported by the observation that Henoch-Schönlein purpura can develop in patients with IgA1 multiple myelomas that are producing IgA1 paraprotein with abnormal hinge region glycosylation but not in patients with IgA1 multiple myelomas that are producing IgA1 paraprotein with normal hinge region glycosylation.[146]

It is likely that more than one mechanism can result in circulating pathogenic IgA1 complexes, some of which are true immune complexes with bound antigens and other that are homoaggregates of IgA1 without bound antigens. In either instance, the IgA1 complexes localize in the walls of small vessels and the glomerular mesangium and cause inflammatory injury, by alternative pathway complement activation, and by attraction and activation of leukocytes. In addition to IgA and complement, a variety of constituents have been identified in circulating and deposited IgA complexes in IgA nephropathy and Henoch-Schönlein purpura including fibronectin and Fcα receptors (CD89).[79]

The pathogenic importance of fibronectin and CD89 is controversial, but experimental animal data at least support the possibility that they may have a role in pathogenesis.[79,172] Launay et al. created IgA nephropathy in mice with transgenic expression of human CD89.[79] These mice developed circulating CD89 that complexed with IgA, deposited in the mesangium, and caused glomerulonephritis.

IgA-fibronectin aggregates occur in patients with IgA nephropathy and Henoch-Schönlein purpura.[6,60] Uteroglobulin is an anti-inflammatory protein in the plasma with high affinity for fibronectin that prevents the formation of IgA-fibronectin aggregates by binding to fibronectin.[172] Uteroglobin knockout mice and uteroglobulin antisense transgenic mice develop IgA nephropathy,[172] suggesting that reduced uteroglobulin may play a role in human disease. However, Coppo et al.[23,24] determined that patients with IgA nephropathy in fact have increased levels of circulating uteroglobulin and that circulating IgA macromolecular complexes contain both fibronectin and uteroglobulin.[23]

A variety of in vivo and in vitro studies of Henoch-Schönlein purpura and IgA nephropathy demonstrate that the chemokine/cytokine, adhesion molecule, and leukocyte activation pathways typical of immune complex–mediated vasculitis are participating in these diseases. For example, Yang et al.[169,170,171] observed that patients with acute Henoch-Schönlein purpura had increased serum levels of IL-8 and that incubation of endothelial cells with serum from patients with Henoch-Schönlein purpura but not from healthy controls caused increased IL-8 production.[171] Duque et al.[32] demonstrated that mesangial cells exposed to aggregated IgA1 had increased expression of IL-8 and MCP-1 genes and that this was mediated in part by NF-κB activation.[32] In renal biopsy specimens from patients with IgA nephropathy and Henoch-Schönlein purpura, there is increased immunostaining of endothelial cells and mesangial cells for ICAM-1.[95] Thus, there is evidence that the localization of IgA complexes in vessel walls induces the release of cytokines and the upregulation of adhesion molecules that attracts leukocytes and induces injury.

A possible role for IgA antineutrophil cytoplasmic autoantibodies (IgA-ANCA) in Henoch-Schönlein purpura is controversial.[24,104] There is no doubt that some indirect immunofluorescence microscopy assays that use normal neutrophils as substrate and some enzyme immunoassays that use neutrophil proteins as substrate detect increased binding of IgA from patients with Henoch-Schönlein purpura. However, the major issue is whether this is the result of specific recognition of a neutrophil antigen by the antigen binding domain of IgA or is merely the result of nonspecific binding of the abnormal IgA or IgA complexes to the substrate, possibly mediated by the abnormal glycosylation of the IgA or the presence of fibronectin in the complex or some other factor other than the antigen specificity of the IgA.[24] In our judgment, there is no compelling evidence for true IgA-ANCA with specificity for neutrophils proteins in patients with Henoch-Schönlein purpura.

PAUCI-IMMUNE ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODY VASCULITIS

Pauci-immune small-vessel vasculitis is a necrotizing polyangiitis that can affect capillaries, venules, arterioles, and arteries.[58,59] Glomerular capillaries often

are involved, resulting in a glomerulonephritis that typically has segmental fibrinoid necrosis and crescent formation in the acute phase. Approximately three fourths of patients with pauci-immune necrotizing and crescentic glomerulonephritis also have evidence for involvement of small vessels in other organs. Virtually any organ can be involved. Frequent manifestations are alveolar capillaritis with pulmonary hemorrhage, dermal venulitis with palpable purpura, epineural arteritis with peripheral neuropathy, and inflammation of small arteries and arterioles in abdominal viscera. There are three major clinicopathologic categories of pauci-immune small-vessel vasculitis: microscopic polyangiitis, Wegener's granulomatosis (granulomatosis with polyangiitis), and Churg-Strauss syndrome (eosinophilic granulomatosis with polyangiitis) (Table 83.2; Figure 83.1).[56] The defining feature of Wegener's granulomatosis is necrotizing granulomatous inflammation, most often in the upper or lower respiratory tract. The defining features of Churg-Strauss syndrome are blood eosinophilia and asthma. Microscopic polyangiitis has the systemic vasculitis in the absence of granulomatous inflammation or asthma.

The defining immunopathologic feature common to the pauci-immune small-vessel vasculidities is the absence or paucity of immunohistologic staining of vessels for immunoglobulin. This feature distinguishes pauci-immune small-vessel vasculitis from small-vessel vasculitis that is caused by classical vessel wall immune complex deposition, such as cryoglobulinemic vasculitis or Henoch-Schönlein purpura vasculitis, and from anti-GBM disease with linear staining for IgG along glomerular and pulmonary alveolar capillary basement membranes.[56,58] The absence or paucity of immunoglobulin in the vessel walls does not mean that immunoglobulin is not involved in the pathogenesis of the vasculitis and glomerulonephritis. This does suggest, however, that if immunoglobulin is involved, it is by a mechanism that differs from that of classical immune complex disease. In fact, the data discussed in subsequent sections of this chapter offer compelling evidence that ANCAs are the primary pathogenic factors in the induction of pauci-immune small-vessel vasculitis, at least in those patients who have circulating ANCAs, which is the majority.[115,157] We note, however, that there may be other factors involved in in the pathogenesis of a specific pauci-immune vasculitis. For example, it is becoming increasingly evident that B cells and certain T cell subsets contribute to the development of Wegener's granulomatosis.[155] The possibility that anti-endothelial cell antibodies might contribute to the pathogenesis of pauci-immune vasculitis, either in the presence or absence of ANCAs, has been suggested but is not supported by strong clinical and experimental evidence.

Antineutrophil Cytoplasmic Autoantibodies

Approximately 80% of patients with active, untreated pauci-immune small-vessel vasculitis have circulating ANCAs.[63,64,115,157] ANCAs are specific for proteins in the primary granules of neutrophils and the peroxidase-positive lysosomes of monocytes. In patients with vasculitis or glomerulonephritis, almost all ANCAs are specific for myeloperoxidase (MPO-ANCAs) or proteinase-3 (PR3-ANCAs). Only rare patients have both MPO-ANCAs and PR3-ANCAs.

The preferred method for clinical laboratory detection of ANCAs is enzyme-linked immunosorbent assay (ELISA) using purified MPO and PR3 as target antigen substrate; however, indirect immunofluorescence microscopy assays using normal human neutrophils as substrate often are used as a screening tool.[83,129] When normal, alcohol-fixed neutrophils are used as the substrate, PR3-ANCAs produce a cytoplasmic staining pattern that is referred to as a positive C-ANCA result, whereas MPO-ANCAs produce staining at the periphery of the nucleus (i.e., perinuclear staining) that is referred to as a positive P-ANCA result (Figure 83.10). In vivo, PR3 and MPO are in the same cytoplasmic location in neutrophil primary granules but, in alcohol-fixed neutrophils, the MPO has been solubilized during the substrate preparation and artifactually redistributes to the surface of the nucleus.[17] If a fixative is used for neutrophil preparation that immobilizes proteins by covalent cross linking, such as formalin, PR3-ANCAs and MPO-ANCAs produce an identical staining of the cytoplasm of the neutrophils.

Each of the clinicopathologic phenotypes of pauci-immune small-vessel vasculitis can be associated with PR3-ANCAs (C-ANCAs) or MPO-ANCAs (P-ANCAs), although there are differences in the frequency of these specificities in the different phenotypes (Table 83.4). MPO-ANCAs are most frequent in patients with renal limited disease and PR3-ANCAs are most frequent in Wegener granulomatosis. Microscopic polyangiitis does not have a clear dominance of one antigen specificity over the other. It is important to note that not all patients with pauci-immune small-vessel vasculitis have ANCAs. Patients with ANCA-negative pauci-immune small-vessel vasculitis have disease that is clinically and pathologically identical to the disease in ANCA-positive patients.[33] As discussed in subsequent sections, ANCAs are strongly implicated in the pathogenesis of ANCA-positive small-vessel vasculitis.[115,157] The pathogenesis of ANCA-negative small-vessel vasculitis is unknown. One possibility is that these patients have an autoantibody that can activate neutrophils in the same way as MPO-ANCAs and PR3-ANCAs but this autoantibody is not detected in the current ELISA or indirect immunofluorescence assays.

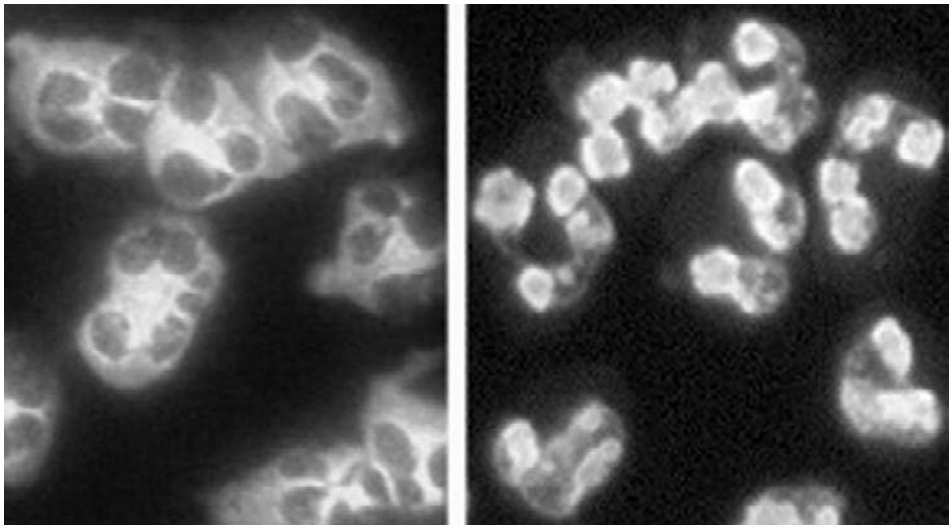

FIGURE 83.10 Immunofluorescence microscopy of alcohol-fixed normal human neutrophils that have been reacted with human PR3–antineutrophil cytoplasmic autoantibody (ANCA) (left) or MPO-ANCA (right) and secondarily stained with fluoresceinated antihuman immunoglobulin G (IgG) resulting in cytoplasmic staining (C-ANCA pattern) or perinuclear staining (P-ANCA pattern), respectively.

TABLE 83.4 Approximate Frequency of ANCA with Specificity for PR3-ANCA or MPO-ANCA in Patients with Active Untreated Renal-Limited Pauci-Immune Crescentic Glomerulonephritis, Microscopic Polyangiitis, Wegener's Granulomatosis, and Churg-Strauss Syndrome

	Renal-Limited Pauci-Immune Crescentic Glomerulonephritis, %	Microscopic Polyangiitis, %	Wegener's Granulomatosis, %	Churg-Strauss Syndrome, %*
PR_3-ANCA	20	40	75	5
MPO-ANCA	70	50	20	40
Negative	10	10	5	55

*75% of Churg Strauss syndrome patients with glomerulnephritis are ANCA positive.
ANCA, antineutrophil cytoplasmic autoantibody; MPO, Myeloperoxidase; PR3, proteinase-3.

Clinical Evidence for the Pathogenicity of ANCA

The high frequency of ANCAs in patients with pauci-immune small-vessel vasculitis raises the possibility that ANCAs are involved in the pathogenesis of this distinctive category of vasculitis. However, this association could be secondary to the vasculitis rather than the cause of the vasculitis. ANCA titer correlate to a degree with the course of ANCA vasculitis and glomerulonephritis,[115] however, this is not a tight correlation. Better clinical evidence for a pathogenic role for ANCAs is the concurrent induction of both MPO-ANCAs and pauci-immune crescentic glomerulonephritis by certain drugs, such as propylthiouracil and hydralazine.[30,93] ANCAs disappear after discontinuation of the drug and the glomerulonephritis remits. More compelling clinical evidence that ANCAs mediated small-vessel vasculitis and glomerulonephritis is the observation that a neonate developed signs and symptoms of glomerulonephritis and pulmonary capillaritis secondary to maternal transfer of MPO-ANCA IgG.[7,131] However, no confirmatory cases of transplacental transmission of disease have been reported. The in vitro and in vivo experimental data discussed in the subsequent sections substantiate the pathogenicity of ANCA IgG and shed light on the mechanisms of injury that are incited by ANCA.

In Vitro Evidence for the Pathogenicity of ANCA

Numerous in vitro studies have demonstrated that both PR3-ANCA and MPO-ANCA IgG can activate neutrophils and monocytes to release mediators of

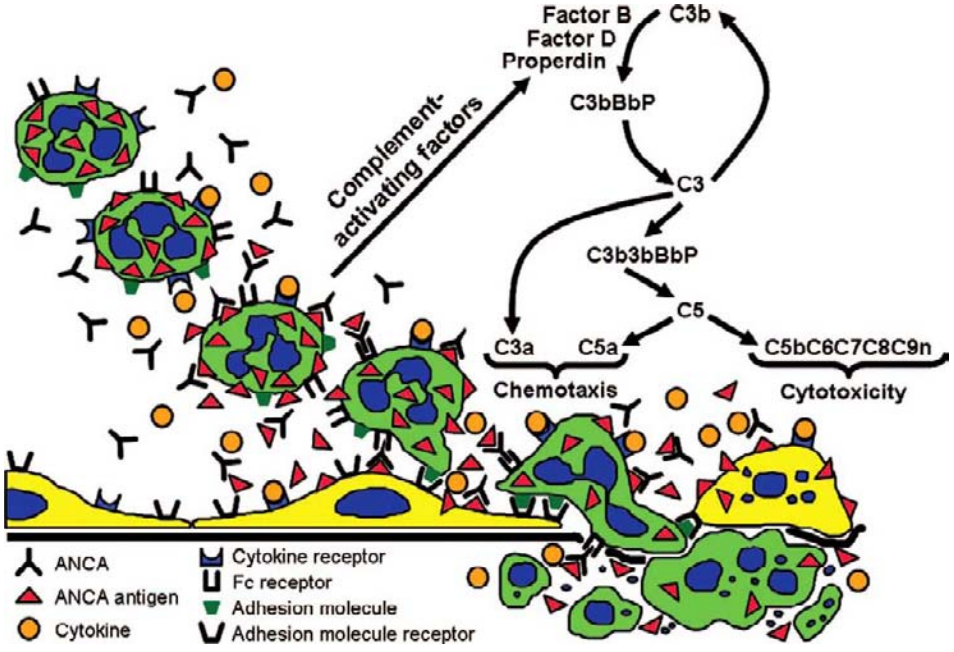

FIGURE 83.11 Diagram depicting induction of vasculitis by antineutrophil cytoplasmic autoantibody (ANCA) immunoglobulin G (IgG). Beginning in the upper left, priming of neutrophils by cytokines results in the expression of ANCA antigens at the cell surface. Neutrophils are activated by both Fc and Fab'2 binding. Activated neutrophils release factors that activate the alternative complement pathway, which amplifies the inflammatory events through further neutrophil recruitment and activation. Activated neutrophils adhere to and destroy endothelial cells and other components of the vessel wall and perivascular tissue. *(From Xiao H, Schreiber A, Heeringa P, Falk RJ, Jennette JC. Alternative complement pathway in the pathogenesis of disease mediated by antineutrophil cytoplasmic autoantibodies. Am J Pathol 2007; 170:52–64 with permission.)*

acute inflammation and injury that are capable of killing endothelial cells (Figure 83.11).[57,65,66,115,127]

One issue to clarify is how antigens that are in cytoplasmic granules can interact with autoantibodies that are in the plasma and interstitial fluid. Although most MPO and PR3 are in the cytoplasm of neutrophils, there appears to be a minor amount of antigen on the surface of circulating neutrophils, although this is controversial, in part because it is difficult to measure surface expression of these antigens without perturbing the cells, which could stimulate them to release the antigens at the surface of the cells. The percentage of circulating cells that have ANCA antigens on their surface may be genetically determined and may be a risk factor for developing ANCA vasculitis.[132,133] There may be a link between increased membrane PR3 expression on neutrophils and expression of CD177 (NB1 glycoprotein).[1] Patients with ANCA disease have epigenetically regulated increased transcription of PR3 and MPO genes in circulating neutrophils, which could result in more ANCA target antigens (MPO and PR_3) available to stimulate the ANCA autoimmune response and more autoantigens available for pathogenic interaction with neutrophils.[19]

In addition to constitutive expression, there is no doubt that circulating neutrophils express more ANCA antigens at their surfaces when they are primed by a variety of proinflammatory factors. These include cytokines, such as tumor necrosis factor alpha (TNFα), and microbial products, such as bacterial formyl peptides. Enhanced expression of small amounts of ANCA-antigens at the surface of neutrophils can be documented in vitro by flow cytometry and by immuno-electron microscopy.[13,34] Thus, viral and bacterial infections could prime circulating neutrophils to interact with ANCAs. Of interest with respect to a possible synergistic role for infections is the observation that the clinical onset and exacerbations of ANCA vasculitis and glomerulonephritis often occur shortly after flulike illnesses.[37]

When neutrophils that have been primed with TNF-α are incubated with ANCA IgG, they are stimulated to release toxic reactive oxygen species and lytic granule enzymes.[13,34] The resultant activation of neutrophils is mediated by both Fc receptor dependent events[78,90] and Fab'2-mediated events.[71,156,160] An essential step in this process is the binding of ANCA IgG to ANCA antigens. Thus, in essence, the neutrophil activation is the result of immune complex formation in the microenvironment of the neutrophil. However, the overall nature of the process by which the ANCA reaction with ANCA antigens results in

neutrophil activation is different from conventional immune complex-mediated disease. This difference is reflected in the paucity of vessel wall accumulation of immune complexes in ANCA vasculitis compared with the overt accumulation of immune complexes in vessel walls in typical immune complex vasculitis. Nevertheless, small amounts of immune complexes probably form in the microenvironment at sites of ANCA-induced inflammation and may contribute to the induction of inflammation. MPO and PR3 are cationic proteins that bind to cells and matrix at sites of neutrophil degranulation. In vitro studies have demonstrated that MPO and PR3 can bind to cultured endothelial cells and that the bound antigens can subsequently bind to MPO-ANCA and PR3-ANCA, respectively.[127]

When neutrophils are activated by ANCA IgG in the presence of endothelial monolayers, the endothelial cells are killed.[36,128] This cytotoxicity can be inhibited with antibodies to β2 integrins,[35] which indicates that close approximation of the activated neutrophils to endothelial cells is required for killing. A role for adhesion molecules in ANCA vasculitis also is supported by the observation that exposure of neutrophils to ANCA IgG causes integrin (CD11a/CD18, CD11b/CD18) and cytokine receptor (CXCR2)- mediated adherence to cultured endothelial cells and endothelial transmigration in an in vitro flow-based adhesion assay.[12,112,113] Stimulation of neutrophils with ANCA IgG causes a conformational change in β2 integrins that enhances ligand binding.[12] Evaluation of renal biopsy specimens from patients with pauci-immune crescentic glomerulonephritis demonstrates upregulation of adhesion molecules in support of their role in leukocyte recruitment. For example, ICAM-1 (CD54), which is the ligand for the β2 integrin CD11a/CD18 (LFA-1), and VCAM-1 (CD106), which is the ligand for the β1 integrin CD49d/CD29 (VLA-4), are upregulated in cellular crescents with increased mRNA and protein.[92] ICAM-1 is expressed to a greater degree than VCAM-1 in glomerular endothelial cells. Thus, ICAM-1 may be more important for initial leukocyte recruitment into glomerular tufts whereas VCAM-1 may be more important for further migration into crescents after capillary wall transmigration.

Monocytes and neutrophils contain MPO and PR3, although these proteins are lost as monocytes transform into macrophages.[17] In vitro studies have demonstrated that ANCA IgG can activate monocytes as well as neutrophils. For example, incubation of monocytes with ANCA IgG induces release of toxic oxygen radicals,[153] monocyte chemoattractant protein-1,[14] and interleukin-8.[114] Thus activation by ANCA IgG could cause activation of both neutrophils and monocytes, which is consistent with the observation that neutrophils and monocytes are the most prevalent leukocytes at sites of acute glomerular injury in ANCA glomerulonephritis.[152] In fact, monocytes/macrophages typically are more conspicuous than neutrophils. However, this could be misleading with respect to the relative importance of these cell types in pathogenesis, because neutrophils are consumed as they cause injury, whereas monocytes transform into macrophages and persist at the site of injury.

In summary, numerous in vitro studies demonstrate that ANCA IgG can activate neutrophils and monocytes and cause them to release toxic products and mediators of inflammation. If this happens in vivo, ANCA IgG could cause vasculitis in humans and in an animal model. As noted earlier, there is clinical evidence to support this.[7,65,131] The following section will describe animal models that also support the pathogenicity of ANCA IgG.[66]

Animal Models of ANCA Glomerulonephritis and Vasculitis

One convincing animal model of ANCA glomerulonephritis and vasculitis uses MPO knockout mice ($MPO^{-/-}$) as a source for pathogenic anti-MPO antibodies and anti-MPO lymphocytes.[66,162,163] To induce this model, $MPO^{-/-}$ mice are immunized with purified mouse MPO. As expected, the $MPO^{-/-}$ mice develop a robust immune response to the mouse MPO because they recognize MPO as a foreign antigen. To induce disease, this anti-MPO reactivity is transferred to mice that do have MPO ($MPO^{+/+}$ mice) in their circulating neutrophils and monocytes. Two different strategies have been used that produce different expressions of disease. One approach involves transfer of anti-MPO lymphocytes and the other transfer of anti-MPO immunoglobulin alone. The lymphocyte transfer model requires that the recipient mice are immune deficient because transfer of autoreactive anti-MPO lymphocytes into immune-competent mice results in a rapid downregulation of the anti-MPO immune response. Transfer of anti-MPO immunoglobulin can be into immune-competent wild type mice or immune-deficient $Rag2^{-/-}$ mice. Both methods of transfer of anti-MPO reactivity into mice with MPO in their circulating neutrophils results in necrotizing and crescentic glomerulonephritis in virtually 100% of recipient mice that receive adequate anti-MPO doses. Some, but not all mice, develop systemic small-vessel vasculitis, including necrotizing arteritis (Figure 83.12) and pulmonary alveolar capillaritis. The disease is relatively mild, with less than 25% of glomeruli involved by necrosis and crescents 6 days after injection of the pathogenic autoantibody. The anti-MPO lymphocyte transfer model causes much

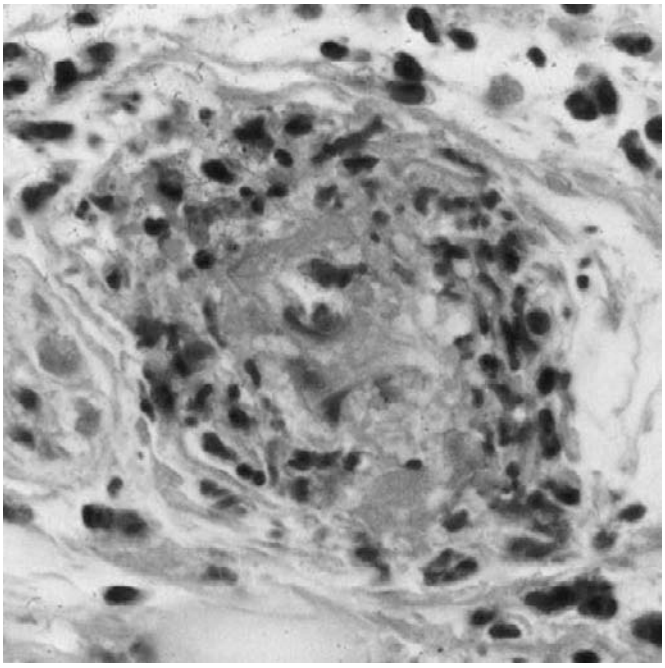

FIGURE 83.12 Necrotizing arteritis in a small artery in the ear of a mouse that received anti-myeloperoxidase IgG. There is a central are of fibrinoid necrosis surrounded by infiltrating leukocytes including neutrophils with leukocytoclasia.

more severe disease with approximately 90% of glomeruli with fibrinoid necrosis and crescents 13 days after lymphocyte transfer. However, the transfer of immune-competent lymphocytes into immune-deficient recipients results in a background of mild to moderate immune complex deposits in glomeruli and thus is not pauci-immune, whereas the transfer of anti-MPO IgG alone causes glomerular necrosis and crescents in the absence of significant glomerular immunoglobulin deposits and thus more closely mimics human pauci-immune ANCA glomerulonephritis.[162]

Induction of ANCA Disease in Mice by Injection of Anti-MPO Lymphocytes

For the lymphocyte transfer experiments, donor $MPO^{-/-}$mice were immunized intraperitoneally with purified murine MPO or bovine serum albumin (BSA) in complete Freund adjuvant.[162] $Rag2^{-/-}$ mice that lack both B-cell and T-cell antigen receptors were used as permissive recipients of the transferred immune-competent lymphocytes. $Rag2^{-/-}$ mice that were injected intravenously with 1×108 or 5×107 anti-MPO splenocytes developed renal insufficiency whereas those that received 1×107 anti-MPO splenocytes, anti-BSA splenocytes, or control splenocytes did not. Postmortem examination of the mice 13 days after the splenocyte transfer revealed glomerular crescents in all mice that received 1×108 or 5×107 anti-MPO splenocytes. $Rag2^{-/-}$ mice that received 1×107 anti-MPO splenocytes, anti-BSA splenocytes, or control splenocytes developed no glomerular crescents or necrosis. In addition to glomerulonephritis, some but not all mice that received 1×108 or 5×107 anti-MPO splenocytes developed hemorrhagic pulmonary capillaritis, necrotizing granulomatous inflammation, and necrotizing arteritis in multiple organs, including lungs, spleen, lymph nodes, and skin. None of the control mice developed vasculitis. Thus, not only does the splenocytes transfer model have crescentic glomerulonephritis as in human ANCA-disease, but also small-vessel vasculitis.

The problematic finding was that all $Rag2^{-/-}$ mice that received the higher doses of splenocytes of any type developed mild to moderate glomerular immune deposits. It appears that the transfer of a competent immune system into immune-deficient $Rag2^{-/-}$ mice caused mild immune complex glomerulonephritis. However, severe necrotizing and crescentic glomerulonephritis develops only after adoptive transfer of anti-MPO splenocytes and not after transfer of anti-BSA or control splenocytes. This observation supports the hypothesis that proinflammatory stimuli augment the induction of glomerulonephritis and vasculitis by increasing the availability of target antigens (e.g., MPO) at the surface of neutrophils. In this instance, the mild to moderate vascular immune complex localization could have acted as the synergistic factor that primed neutrophils to be activated by the anti-MPO antibodies, because, as described later, transfer of anti-MPO IgG alone, which is not accompanied by glomerular immune deposits, causes much less severe glomerulonephritis.

What about anti-MPO T lymphocytes? Are they pathogenic in the absence of anti-MPO antibodies or are they synergistic with factors that augment the injury induced by anti-MPO IgG? The preliminary observations in our experimental model of ANCA disease indicate that anti-MPO T lymphocytes do not play a major role in the pathogenesis of the vascular inflammation.[61] To investigate the respective roles of T cells and B cells, splenocyte preparations with different proportions of anti-MPO T cells and B cells were transferred into $Rag2^{-/-}$ mice. The three different preparations were (1) unfractionated splenocytes (25% T cells, 62% B cells); (2) enriched T cells (79% T cells, 9% B cells); and (3) highly purified T cells ($>$99% T cells). The T-cell enrichment was attained by depletion of B cells by adherence to plastic coated with polyvalent antimouse immunoglobulin antibodies and depletion of monocytes by adherence to nylon columns. The purified T cells were obtained by negative cell sorting using anti-CD19 and anti-MHC class II to selectively exclude remaining B cells and monocytes respectively.

Suspensions of 5×107 cells with the three different proportions of T cells and B cells were administered intravenously to groups of Rag $2^{-/-}$ mice, which lack functional T and B cells of their own. Successful transfer of T lymphocytes with anti-MPO reactivity was confirmed by interferon gamma enzyme-linked immunosorbent spot (ELISpot) assay. Mice that received purified T cells had no detectable anti-MPO antibodies by ELISA whereas the other two groups did. Urine analysis after 12 days showed severe renal disease in mice that received unfractionated splenocytes, mild disease in mice that received preparations enriched for T cells, and no urinary abnormalities in mice that received purified T cells. Pathologic evaluation of kidneys after 13 days demonstrated that administration of unfractionated splenocytes induced crescents and necrosis in approximately 80% of glomeruli whereas splenocytes that had been enriched for T cells caused necrosis and crescents in approximately 5% of glomeruli and pure T cells caused no crescents or necrosis. These data indicate that anti-MPO T cells alone from mice immunized with MPO cannot cause glomerulonephritis in this animal model. This indicates that the B cells in the transferred splenocytes are the critical cell type because they give rise to the ANCA antibody response.

Induction of ANCA Disease in Mice by Injection of Anti-MPO IgG

In contrast to anti-MPO T cells alone, intravenous passive transfer of anti-MPO IgG alone causes pauci-immune crescentic glomerulonephritis and small-vessel vasculitis in either Rag$2^{-/-}$ mice that have no functioning T or B cells of their own, or in immune-competent wild type B6 mice.[162,163] The disease in these mice is pathologically identical to ANCA-associated pauci-immune crescentic glomerulonephritis and vasculitis in humans. All mice (100%) that received adequate doses of anti-MPO IgG developed focal segmental fibrinoid necrosis and crescents in glomeruli whereas no mice that receive control anti-BSA IgG developed glomerular lesions. Immunofluorescence microscopy demonstrates a paucity of immunoglobulin and complement in the glomeruli of mice with anti-MPO IgG induced glomerulonephritis, thus mimicking the pauci-immune feature of human ANCA glomerulonephritis.

Immunoenzyme microscopy of renal tissue for the distribution of neutrophils, macrophages and T lymphocytes demonstrated that induction of glomerulonephritis by injection of anti-MPO IgG is accompanied by glomerular influx of neutrophils and macrophages.[163] Neutrophils were concentrated at sites of segmental necrotizing glomerular injury, and also were identified in Bowman's space in glomeruli with necrosis or crescents. Macrophages were most numerous in crescents. T lymphocytes were not increased in the acute glomerular lesions.

To confirm the importance of neutrophils in the pathogenesis of the glomerulonephritis in this model, NIMP-R14 rat monoclonal antibody that is known to selectively deplete mouse neutrophils in vivo was used.[163] Within one day after a single injection of NIMP-R14 antibody into B6 mice, the number of circulating neutrophils was reduced from 14% of white blood cells to 1%, and remained at this low level for up to five days. This depletion of neutrophils completely protected mice from the development of glomerulonephritis after injection of anti-MPO IgG, which confirms a major pathogenic role for neutrophils.

As noted earlier, in vitro experimental data indicate that ANCAs are more effective at activating neutrophils if the neutrophils have been primed by proinflammatory stimuli. To test this hypothesis in the mouse model of anti-MPO IgG-induced glomerulonephritis, bacterial lipopolysaccharide (LPS) was injected into mice that received anti-MPO.[52] The LPS caused a dose-dependent increase in glomerular necrosis and crescents and increased neutrophil accumulation in glomeruli. The LPS induced increased circulating levels of TNF-α, and treatment with antibodies to TNF-α reversed the enhancement of anti-MPO IgG-induced glomerulonephritis by LPS. These observations suggest that LPS stimulates increased levels of TNF-α that in turn primes neutrophils to interact more effectively with the anti-MPO IgG to induce glomerulonephritis.

Activation of human neutrophils by human ANCA in vitro involves the engagement of Fcγ immunoglobulin receptors (FcγR) on the surface of neutrophils by ANCA IgG after binding to ANCA antigens on the surface of neutrophils.[58,78,90,126] FcγR engagement appears to be more dominant but ANCA Fab'2 binding to ANCA antigens also is important in the activation of neutrophils.[71,156] To evaluate the importance of FcγR in the mouse model of ANCA disease, mice with the absence of certain FcγRs were injected with nephritogenic doses anti-MPO IgG to assess any changes in the induction of glomerulonephritis and vasculitis compared to wild type mice. Preliminary data indicate that mice with an absence of FcγRI and FcγRIII develop no glomerulonephritis.[164] FcγRI$^{-/-}$ mice have reduced incidence of glomerulonephritis with a lower percentage of crescents. FcγRIII$^{-/-}$ mice have little or no reduction in glomerulonephritis. Thus, the preliminary results indicate that the engagement of FcγRI seems to be most important in this model.

In mice, the engagement of FcγR1 and FcγRIII enhances inflammatory and immune events whereas

engagement of FcγRIIb inhibits inflammatory and immune events. Thus FcγRII$^{-/-}$ mice would be hypothesized to have more severe disease in the absence of this anti-inflammatory pathway. Interestingly, when injected with anti-MPO IgG, FcγRIIb$^{-/-}$ mice developed less severe glomerulonephritis than wild type mice, however, they had a higher incidence and greater severity of pulmonary vasculitis.[164] In addition, many of the mice had not only pulmonary capillaritis but also pulmonary necrotizing granulomatous inflammation that closely resembled the necrotizing granulomatous inflammation of patients with Wegener granulomatosis. This observation raises the possibility that the pathophysiologic basis for different clinicopathologic phenotypes of disease in patients (e.g., microscopic polyangiitis versus Wegener granulomatosis) may be dictated by differences in the innate inflammatory response of the patients rather than by differences in the ANCA antibodies or antigens (e.g., different antibody classes or antigen epitope specificity).

Studies in mice with disease induced by not only anti-MPO IgG but also anti-MPO splenocyte transfer, have demonstrated an important role for complement activation.[53,134,165] Anti-MPO IgG induced glomerulonephritis in mice is completely blocked by complement depletion with cobra venom factor.[30] After injection of nephritogenic anti-MPO IgG, C4$^{-/-}$ mice, which have no classic or lectin pathway complement function but normal alternative pathway activity, developed disease comparable to wild type disease; however, C5$^{-/-}$ and factor B$^{-/-}$ mice, which have no alternative pathway function, developed no disease.[165] In vitro, IgG isolated from patients with MPO-ANCA or PR3-ANCA incubated with normal human neutrophils primed with TNF-alpha caused the release of factors that activated complement in serum with generation of C3a.[134,165] In vitro experiments using human material also have shown that neutrophils incubated with ANCA IgG release factors that activate complement, which in turn primes neutrophils for further activation by ANCA.[134] These in vitro event depend on generation of C5a and engagement of C5a receptors on neutrophils.[53,134] Blockade of C5 or C5a ameliorates disease induction in the mouse model, suggesting possible novel therapies in patients.

In summary, this mouse model of ANCA disease that is induced by mouse anti-MPO strongly supports a pathogenic role of ANCA IgG. The experimental animal data also suggest that the induction of disease by ANCA IgG is facilitated and modified by synergistic proinflammatory events, such as cytokine priming of neutrophils, is modulated by engagement of leukocyte Fcγ receptors, and requires amplification of the inflammation by activation of the alternative complement system.[65]

Induction of ANCA Disease in Rats Immunized with Human MPO

Little and associates have induced glomerulonephritis and vasculitis (pulmonary capillaritis) in Wistar-Kyoto rats by immunizing with human MPO resulting in the development of anti-MPO antibodies that cross react with human and rat MPO.[84] Focal segmental pauci-immune glomerulonephritis with crescents developed in 61% of rats and focal pulmonary capillaritis in 41%.

The interaction of leukocytes with the walls of small vessels was directly observed in this model using intravital microscopy of mesenteric vessels. Changes in leukocyte rolling, adherence and transmigration were monitored after application to the mesentery of recombinant CXCL-1, which is a homologue of human interleukin-8, in rats with anti-MPO compared to control rats immunized with human serum albumin. Application of the CXCL-1 to rats with circulating anti-MPO resulted in increased firm adherence and transmigration of leukocytes. This effect could be transferred to unimmunized rats by injection of IgG isolated from the rats that had been immunized with MPO. Induction of circulating anti-MPO by either active immunization or passive transfer also resulted in focal areas of hemorrhage in the mesenteric microvasculature at sites of CXCL-1 application. This animal model provides strong evidence that ANCA IgG can activate leukocytes (presumably neutrophils and monocytes) and induce them to adhere to vessel walls and cause vessel wall injury.

Kain et al.[67] patients with MPO-ANCA and PR3-ANCA have autoantibodies to another neutrophil protein, lysosome-associated membrane protein 2 (LAMP2).[67] LAMP-2 has homology with is a bacterial adhesin FimH. Immunization of rats with FimH induces circulating anti-FimH antibodies that crossreact with LAMP-2, and induces a pauci-immune glomerulonephritis and small vessel vasculitis. The authors postulate that infection of humans by fimbriated bacteria bearing FimH induces an immune response that cross-reacts with LAMP-2 resulting in the mediation of pauci-immune necrotizing glomerulonephritis and vasculitis. To date, no confirmatory reports have been published. Our research group has been unable to reproduce the serologic finding of anti-LAMP-2 antibodies in ANCA patients or the induction of disease in rats by immunization with FimH or LAMP-2.[122]

Immunogenesis of the ANCA Autoimmunity

Clinical and experimental animal data indicate that ANCAs are the major pathogenic factors in ANCA

small-vessel vasculitis. The origin of the ANCA autoimmune response is less clear. Factors that might lead to the ANCA autoimmune response include environmental stimuli (e.g., silica, drugs, and microbial pathogens), dysregulation of granule protein gene expression, autoantigen mimicry, aberrant T cell regulation and immune responses to antisense (complementary) autoantigen peptides.[65] As noted above, autoantigen mimicry by an infectious pathogen is one consideration.

Intriguing observations raise the possibility of a role for peptides that are mimics of not the sense but rather the antisense complementary peptides of the autoantigen, i.e., complementary peptides of PR3 and MPO.[106] Some patients with PR3-ANCA glomerulonephritis and small-vessel vasculitis have not only antibodies to the autoantigen (PR3) but also antibodies to a peptide translated from the antisense DNA strand of PR3 (complementary PR3) or to a mimic of this peptide. Immunization of mice with a complementary PR3 peptide resulted in production of antibodies not only against the complementary PR3 but also against PR3. Both mouse anti-PR3 and anticomplementary PR3, and human anti-PR3 (PR3-ANCA) and anticomplementary PR3 bound to each other, indicating that the anti-PR3 and anticomplementary PR3 have an idiotypic and anti-idiotypic relationship. These findings support the hypothesis that the anti-PR3 autoimmune response could be initiated through an immune response against a peptide that is antisense or complementary to the autoantigen, which in turn induces anti-idiotypic antibodies (autoantibodies) that cross-react with the autoantigen (Figure 83.13). The antisense peptide could arise endogenously by translation of the antisense DNA strand of PR3, or a mimic of this complementary peptide could be introduced into the body as a constituent of an infection microorganism.

Staphylococcus aureus contains a protein that has a sequence that mimics the antisense sequence of PR3. Approximately two thirds of patients with Wegener's granulomatosis have chronic nasal infection with *S. aureus*, and this carriage of *S. aureus* is a risk factor for relapses and prophylactic treatment with antibiotics that eliminate staphylococcal nasal carriage reduces the frequency of relapse.[106] According to the theory proposed by Pendergraft, an antibody response to the S. aureus peptide that mimics a complementary PR3 peptide could result in an anti-idiotypic immune response that cross reacts with the anticomplementary PR3 antibody and with PR3, with the latter being PR3-ANCA. Also in support of this theory that microbial peptide that mimic the complementary peptide of PR3 can induce PR3-ANCA is the association between PR3-ANCA and infection with Ross River virus[138] and *Entamoeba histolytica*.[27] Both of these infectious pathogens contain proteins with amino acid sequences that mimic complementary peptides of PR3.[84]

In summary, one theoretic concept that is supported by substantial clinical and experimental data is that the ANCA autoimmune response is initiated by an appropriate immune response to an antigen introduced into the body by an infectious pathogen. This immune response elicits an anti-idiotypic immune response that includes antibodies that have the capability of cross reacting with self proteins (PR3 or MPO) that have antisense sequences that would produce peptides that

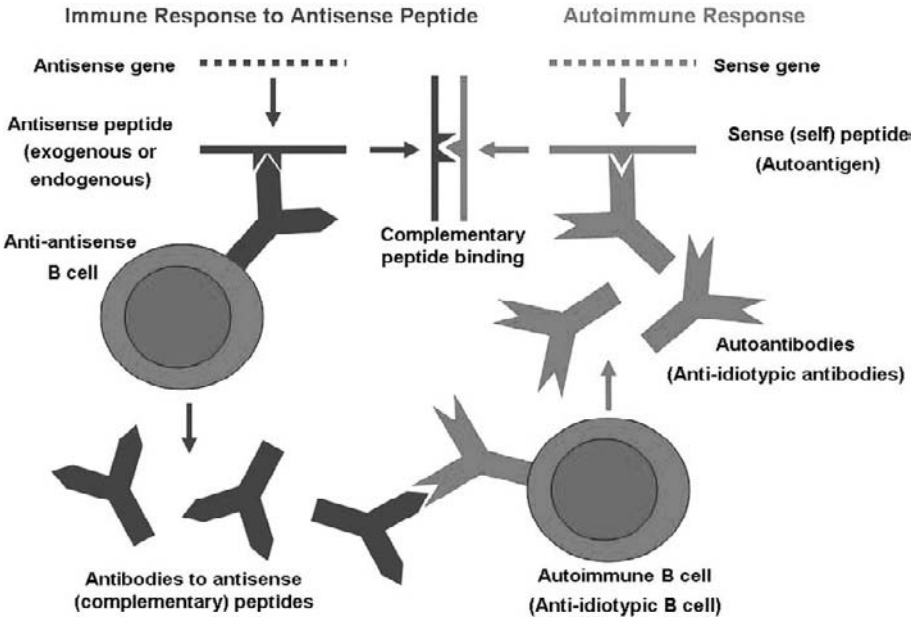

FIGURE 83.13 According to the theory of autoantigen complementarity, an autoimmune response can be initiated by an immune response to an antigen that is either the endogenous product of the antisense strand of the gene for the autoantigen or is an exogenous peptide that mimics this antisense product, possibly derived from an infectious pathogen. This immune response elicits an anti-idiotypic immune response that includes antibodies that have the ability to cross-react with the autoantigen and thus function as autoantibodies.

mimic the microbial peptide that initiated the immune response. These antibodies that cross react with PR3 or MPO are PR3-ANCA or MPO-ANCA respectively. Once in the circulation, these autoantibodies are able to activate neutrophils and monocytes, possibly with synergistic priming from concurrent infections or other processes that result in high levels of circulating cytokines that prime neutrophils and monocytes causing them to express ANCA antigens at the cell surfaces. Activation of neutrophils and monocytes by ANCA IgG causes the cells to adhere to endothelial cells in small vessels and to release inflammatory mediators and destructive products such as oxygen radicals and numerous toxic and lytic enzymes. This results in acute inflammation and necrosis in vessel walls.

INTRODUCTION

The study of inherited diseases arising from single gene defects can provide a wealth of data about the roles that particular proteins normally play in tissue structure and function. The identification of the specific genetic abnormalities underlying several inherited renal disorders has allowed investigators to draw inferences regarding the specific activities of certain glomerular proteins, and the consequences of mutations of these proteins for glomerular function.

In this chapter we will discuss some recent advances in the understanding of genetic kidney diseases that primarily involve the glomerulus. We have organized the chapter according to the site or mechanism of the primary abnormality (Table 84.1): abnormalities of extracellular matrix, storage diseases affecting the glomerulus, primary defects in the slit diaphragm, cytoskeletal defects and defective transcriptional regulation.

DISORDERS OF EXTRACELLULAR MATRIX

Alport Syndrome

The investigation of the molecular biology of Alport syndrome (AS) has provided important insights into the role played by type IV collagen in maintaining the structure and function of the glomerular basement membrane (GBM).The clinical features of AS represent the phenotypic consequences of mutations that alter the expression of type IV collagen in basement membranes.X-linked, autosomal recessive and autosomal dominant forms of AS have been characterized at the gene and protein levels. Absence of three specific isomers of type IV collagen, the α3(IV), α4(IV) and α5(IV) chains, from Alport GBM results early in life in GBM attenuation, manifesting clinically as hematuria. Over time, GBM deficient in these chains undergoes progressive thickening and disorganization, with the development of proteinuria and, ultimately, renal failure.

Clinical Features

Renal Findings: The cardinal finding of AS is hematuria effected males have persistent microscopic hematuria, often first detected during infancy.[1,2] Many also have episodic gross hematuria during the first two decades of life.[2] Boys who are free of hematuria during the first 10 years of life are unlikely to be affected.[2]

Females who are heterozygous for X-linked AS (XLAS) may have intermittent hematuria, and about 7% of obligate female heterozygotes never manifest hematuria.[3] Hematuria appears to be persistent in both males and females with autosomal recessive AS (ARAS). Proteinuria is usually absent in the first few years of life, but develops eventually in all XLAS males, many XLAS females and in both males and females with recessive disease.[2–4] Proteinuria increases progressively with age, and may eventuate in the nephrotic syndrome.[2,5]

Hypertension also increases in incidence and severity with age. Like proteinuria, hypertension is more likely to occur in affected males than in affected females with XLAS, but there are no gender differences in the autosomal recessive form.

End-stage renal disease (ESRD) develops in virtually all affected males with XLAS, but the rate of progression shows significant interkindred variability.[4] Renal

half-life in men with XLAS is about 25 years.[4] Several authors have observed that the rate of progression to renal failure is fairly constant among affected males within a particular family[6,7] although significant intra-kindred variability in the rate of progression to renal failure has occasionally been reported.[2,8]

Progression to ESRD in females with XLAS was, until recently, considered an unusual event.However, in a landmark study of several hundred XLAS females published in 2003, Jais and colleagues found that about 12% developed ESRD before age 40 (compared with 90% of XLAS males), increasing to 30% by age 60 and 40% by age 80[3] as previously described by Grunfeld et al.[3,9] Both males and females with ARAS appear likely to progress to ESRD during the second or third decade of life.

Hearing Deficit: About 50% of XLAS males display sensorineural deafness by age 25 and by age 40 approximately 90% of XLAS males are deaf.[4] Although it has been clear for some time that the hearing defect in Alport syndrome localizes to the cochlea, histological correlates of deafness in Alport patients have only recently been recognized. Merchant and colleagues found unique and consistent abnormalities in the cochleae of Alport patients, consisting of a zone of separation between the basilar membrane and the cells of the organ of Corti, associated with a cellular infiltrate in the tunnel of Corti and extracellular spaces of Nuel.[10] Electron microscopy showed that the zone of separation occurred between the basement membrane of the organ of Corti and the basilar membrane.These authors speculated that abnormal adhesion of the organ of Corti to the basilar membrane might disrupt the mechanical relationships between outer hair cells and the basilar membrane, resulting in hearing impairment.

Hearing loss in AS is never congenital and usually becomes apparent by late childhood to early adolescence in boys with XLAS.[2] Hearing impairment in members of families with AS is always accompanied by evidence of renal involvement.[2] There is no convincing evidence that deaf males lacking renal disease can transmit AS to their offspring.In females with XLAS hearing loss is less frequent, tends to be less severe and occurs later in life.[3] There do not appear to be gender differences in the incidence or course of deafness in autosomal disease.

In its early stages the hearing deficit is detectable only by audiometry, with bilateral reduction in sensitivity to tones in the 2000 to 8000 Hz range. In affected males the deficit is progressive and eventually extends to other frequencies, including those of conversational speech. Although these males frequently require hearing aids, their deafness tends to stabilize once they develop ESRD.

Ocular Defects: Ocular defects are not unusual in patients with AS, occurring in at least 15 to 30% of patients.[4,11–13] Anterior lenticonus, the conical protrusion of the central portion of the lens into the anterior chamber of the eye, is virtually pathognomonic of AS. Nielsen[14] found that all reported patients with anterior lenticonus who had been adequately examined exhibited evidence of chronic nephritis and sensorineural deafness. Anterior lenticonus is almost entirely restricted to AS families with rapid progression to ESRD (i.e., before age 30) and deafness. Anterior lenticonus is absent at birth, usually appearing during the second to third decade of life.[15] Marked attenuation and fractures of the central portion of the anterior lens capsule have been observed histologically.[16,17]

A variety of other ocular lesions has been reported in patients with AS. Perhaps the most commonly occurring abnormalities are pigmentary changes in the perimacular region, consisting of whitish or yellowish granulations surrounding the foveal area.[13,18–20] Retinal flecks are frequently accompanied by anterior lenticonus but may also occur in the absence of lenticonus. These lesions may arise as a result of abnormalities of Bruch's membrane, the basement membrane that supports the retinal pigment epithelium.[21]

Corneal endothelial vesicles (posterior polymorphous dystrophy) have been observed in AS patients by several investigators,[19,22,23] and may be indicative of abnormalities in Descemet's membrane, the basement membrane underlying the corneal endothelium. Rhys et al. recently described recurrent corneal erosion in AS patients, which they ascribed to abnormalities of the corneal epithelial basement membrane.[24]

Diffuse Leiomyomatosis: The association of AS with leiomyomas of the esophagus and tracheobronchial tree has been reported in approximately 20 families.[25–28] Affected females in these kindreds typically exhibit genital leiomyomas as well, with clitoral hypertrophy and variable involvement of the labia majora and uterus. Symptoms usually appear in late childhood and include dysphagia, post-prandial vomiting, retrosternal or epigastric pain, recurrent bronchitis, dyspnea, cough and stridor. Leiomyomatosis may be suspected by chest X-ray or barium swallow, and confirmed by computed tomography or magnetic resonance imaging.

Arterial Disease: There have been several reports of arterial disease in males with Alport syndrome, including aneurysms of the thoracic and abdominal aorta and the cerebral arterial system.[29–32]

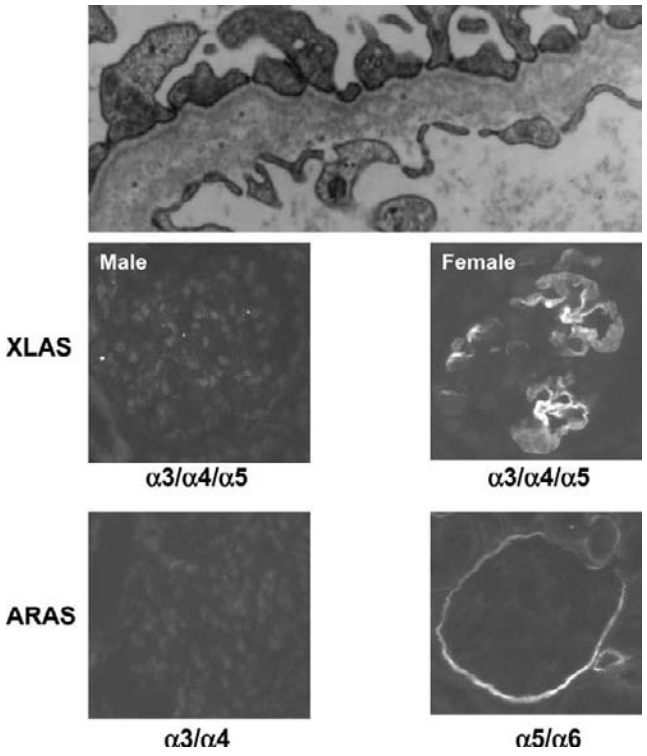

FIGURE 84.1 Glomerular capillary wall ultrastructure and type IV collagen immunostaining in Alport syndrome. The characteristic ultrastructural lesion of Alport syndrome consists of diffuse GBM thickening, scalloping of the epithelial aspect of the GBM, splitting of the lamina densa into multiple layers and dense granular bodies in lucent zones between strands of lamina densa material, all of which are depicted here. There is also variable broadening of podocyte foot processes.In the typical male with X-linked Alport syndrome (XLAS) the type IV collagen network formed by the α3(IV), α4(IV) and α5(IV) chains is completely absent from the kidney.In the typical female heterozygote there is mosaic expression of this network in the kidney. In both males and females with autosomal recessive Alport syndrome (ARAS), the α3α4α5 network is typically absent from GBM, and there is no expression of α3(IV) or α4(IV) chains in Bowman's capsule or tubular basement membranes. However, the α5(IV) and α6(IV) chains are expressed in Bowman's capsule and tubular basement membranes.

Pathology

There are no pathognomonic lesions by light microscopy or direct immunofluorescence in AS. Electron microscopy frequently reveals diagnostic abnormalities. The cardinal ultrastructural feature of the kidney in AS is the variable thickening, thinning, basket-weaving, and lamellation of the GBM (Figures 84.1 and 84.2). Identical morphologic features are apparent in some patients without a family history of nephritis. Such patients may represent new COL4A5 mutations, they may be offspring of asymptomatic female carriers, or may have autosomal recessive disease.

Ultrastructural alterations of GBM were noted in several reports of hereditary nephritis in the 1960s.[1,33–37] The most prominent abnormality is the irregular appearance of the lamina densa, which demonstrates zones of thickening, thinning, and splitting that may be interposed with segments of GBM that appear entirely normal. The abnormalities can affect a portion of a capillary loop, an entire loop, some or all loops, and can even spare individual glomeruli.

The thick segments measure up to 1200 nm, usually have irregular outer and inner contours, and are found more commonly in males than in females. The lamina densa is transformed into a heterogeneous network of membranous strands, which enclose clear electron-lucent areas. The electron-lucent zones may be entirely clear or contain round granules of variable density that measure between 20 and 90 nm in diameter. The origin of these granules is unknown, but Rumpelt has hypothesized that they represent degenerating islands of visceral epithelial cell cytoplasm.[38] Young children and females, and adult males on occasion,[39] may have diffusely attenuated segments of GBM measuring as little as 100 nm or less;in some instances, discontinuities of the GBM have been observed.[2,40]

The specificity of the GBM changes has been questioned.[41] Focal lamina densa splitting and lamellation may be observed in renal biopsies from patients with a variety of glomerular disorders. Clinical correlation and immunofluorescence microscopic examination of all biopsies are necessary when AS is the suspected diagnosis. Diffuse thickening and splitting of the GBM

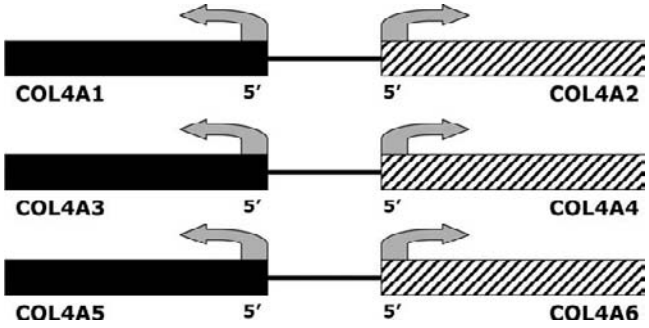

FIGURE 84.2 Type IV collagen genes.The six type IV collagen a chain genes are arranged in pairs on three chromosomes. The 5′ ends of each pair are adjacent to each other, separated by sequences containing regulatory sites.The 5 exons at the 3′ end of each gene encode the carboxyterminal noncollagenous (NC1) domain of the chain. Most of the remaining exons encode the repetitive Gly-X-Y motif of the collagenous portion of the chain.

is strongly suggestive of AS.In the absence of immune deposits, these changes are pathognomonic.

Not all Alport kindreds demonstrate these characteristic ultrastructural features.[42–44] Thick, thin, normal and nonspecifically altered GBM have all been described. Although diffuse attenuation of GBM has been considered the hallmark of "benign familial hematuria" or thin basement membrane nephropathy,[45–47] some patients with this abnormality are members of kindreds with a history of progression to renal failure.[2,42] Thus the signficance of an ultrastructural finding of thin GBMs must be considered in the context of the family history, basement membrane expression of type IV collagen α chains (see below), and genetic information.

Rumpelt described a correlation between the percent of GBM showing splitting of the lamina densa and the degree of proteinuria in AS patients,[5] suggesting that impaired permselectivity may be a functional consequence of the GBM alteration. Kim and colleagues observed that morphometric parameters such as mesangial volume fraction, cortical interstitial volume fraction, and percent global glomerular sclerosis were inversely correlated with creatinine clearance in AS, while creatinine clearance and surface density of peripheral GBM were directly correlated.[48] Similar relationships have been observed in other diseases, such as diabetic nephropathy and membranoproliferative glomerulonephritis (MPGN). However, patients with AS showed significantly greater impairment of filtration for any degree of structural change in comparison with patients with diabetic nephropathy or MPGN. This observation suggests that these morphologic abnormalities only partially account for reductions in creatinine clearance in AS. Decreased conductivity of water across the altered glomerular capillary wall could contribute to the decrement in filtration.

Genetics and Pathophysiology

GENETICS AND BIOCHEMISTRY OF TYPE IV COLLAGEN

Glomerular basement membranes are composed of several major constituents, including type IV collagen, laminin, nidogen and heparan sulfate proteoglycan. The type IV collagen family of proteins comprises six isomeric chains, designated α1−α6(IV),[49,50] (Table 84.2). These chains show extensive sequence homology and share basic structural features, including: (1) a major collagenous domain of about 1400 residues containing the repetitive triplet sequence glycine (Gly)-X-Y, in which X and Y represent a variety of other amino acids. (2) A carboxy-terminal noncollagenous (NC1) domain of about 230 residues. (3) A noncollagenous amino-terminal sequence of 15−20 residues. The major collagenous domain of each chain contains about 20 interruptions of the collagenous triplet sequence, while each noncollagenous domain contains 12 completely conserved cysteine residues which participate in critical disulfide bonds.

Each type IV collagen molecule is a trimer composed of three α chains.The classical type IV collagen trimer isolated from the extracellular matrix of the murine EHS sarcoma has the composition $\alpha1(IV)_2$-$(\alpha2(IV)_1$.[51] Type IV collagen α chains form trimers through

TABLE 84.2 Type IV Collagen Chains

Chain	Gene	Chromosome	Collagenous Domain # Residues (Interruptions)	Noncollagenous Domain # Residues
α1(IV)	*COL4A1*	13	1413 (21)	229
α2(IV)	*COL4A2*	13	1449 (23)	227
α3(IV)	*COL4A3*	2	1410 (23)	233
α4(IV)	*COL4A4*	2	1421 (26)	231
α5(IV)	*COL4A5*	X	1430 (22)	229
α6(IV)	*COL4A6*	X	1417 (25)	228

associations between their carboxy-terminal NC1 domains, accompanied by folding of the collagenous domains into triple helices.[51–53] Variable residues within the NC1 domains confer specificity upon chain-chain associations.[54] Type IV collagen triple helices form networks through several types of intermolecular interaction:end-to-end linkages between the carboxy-terminal domains of two type IV collagen triple helices, covalent interactions between four triple helices at their aminoterminal ends, and lateral associations mediated by binding of the carboxy-terminal domains of one trimer to the collagenous region of another trimer.[55,56] Disulfide bonds involving conserved cysteine residues are critical to the interactions between NC1 domains. These linkages between type IV collagen molecules produce a nonfibrillar, open-network assembly that associates with laminin through interactions mediated by nidogen.[57]

Various integrins mediate cell attachment to type IV collagen.Attachment of glomerular epithelial cells to the α3(IV) chain appears to involve the α3β1 integrin.[58]

The six type IV collagen genes are arranged in pairs on three different chromosomes (Figure 84.2, Table 84.2). The human α1(IV) and α2(IV) chains are encoded by the genes *COL4A1* and *COL4A2*, respectively, on chromosome 13.[59] *COL4A3* and *COL4A4* are located on chromosome 2 and encode the α3(IV) and α4(IV) chains of type IV collagen, respectively,[60] while the α5(IV) and α6(IV) chains are encoded by the *COL4A5* and *COL4A6* genes on the X chromosome.[61,62,63] The 5′ ends of each gene pair are adjacent to each other, separated by sequences of varying length containing motifs involved in the regulation of transcriptional activity.[64–66]

Evidence from a variety of sources indicates the existence of at least three type IV collagen networks in mammalian basement membranes. Studies of the distribution of these networks in basement membranes using monospecific antibodies have revealed a high degree of tissue specificity (Table 84.3). A network composed of heterotrimers with the composition $\alpha1(IV)_2$-α2(IV) is found in all basement membranes, although it is a relatively minor component of mature GBM.A network comprising α3(IV)-α4(IV)-α5(IV) heterotrimers is the predominant collagen in mature GBM, and also occurs in Bowman's capsules and the basement membranes of distal and collecting tubules. The network consisting of $\alpha5(IV)_2$-α6(IV) heterotrimers is present in Bowman's capsule and distal and collecting tubule basement membranes, but is not present in GBM. The epidermal basement membraneand basement membranes surrounding aortic smooth muscles cells (EBM) contains

BM: basement membrane; GBM: glomerular basement membrane; BC: Bowman's capsule; dTBM: distal tubular basement membrane; DEJ: dermal-epidermal junction (epidermal basement membrane)

$\alpha1(IV)_2$-$\alpha2$(IV) and $\alpha5(IV)_2$-$\alpha6$(IV) networks, but not the $\alpha3$(IV)-$\alpha4$(IV)-$\alpha5$(IV) network.[67,68]

The $\alpha3$(IV) chain has been identified as the target of anti-GBM autoantibodies in Goodpasture syndrome.[69–71] The Goodpasture epitope resides in the carboxy-terminal NC1 domain of $\alpha3$(IV).[72]

ABNORMALITIES OF TYPE IV COLLAGEN GENES AND PROTEINS IN ALPORT SYNDROME

There are three genetic forms of Alport syndrome (Table 84.4).The X-linked form (XLAS), resulting from mutations in *COL4A5*, accounts for about 80% of patients with the disease. About 15% of patients have autosomal recessive Alport syndrome (ARAS), which arises from mutations affecting both alleles of *COL4A3* or *COL4A4*. The heterozygous parents of children with ARAS often have asymptomatic hematuria, although some have normal urinalyses.Finally, approximately 5% of patients have autosomal dominant Alport syndrome (ADAS), due to heterozygous mutations in *COL4A3* or *COL4A4*. Heterozygous mutations in *COL4A3* or *COL4A4* have also been found in families with thin basement membrane nephropathy (see below). It is not yet clear why many, perhaps most, individuals with heterozygous mutations in these genes have asymptomatic hematuria, while others have progressive disease.

XLAS: Several hundred *COL4A5* mutations have been reported in XLAS families.These mutations are distributed throughout the gene, and with few exceptions each mutation is unique. About 20% of reported *COL4A5* mutations are large rearrangements, predominantly deletions.[4,73] Missense mutations account for about 35-40%, about 15% are splice-site mutations, and 25–30% are nonsense mutations or small frame-shifting deletions or insertions that result in premature stop codons.[4,73] About 10 to 15% of *COL4A5* mutations occur as spontaneous events in the proband, explaining why some patients with XLAS lack a family history of the disease.

TABLE 84.4 Molecular Genetics of Alport Syndrome

Affected Inheritance	Locus	Gene Product
X-linked	*COL4A5*	$\alpha5$(IV)
X-linked + leiomyomatosis	*COL4A5* + *COL4A6*	$\alpha5$(IV) + $\alpha6$(IV)
Autosomal recessive	*COL4A3*	$\alpha3$(IV)
	COL4A4	$\alpha4$(IV)
Autosomal dominant	*COL4A3*	$\alpha3$(IV)
	COL4A4	$\alpha4$(IV)

The association of XLAS with leiomyomatosis of the esophagus and tracheobronchial tree has been reported in several dozen families.[74] Affected members of these families exhibit large deletions that span the adjacent 5′ ends of the *COL4A5* and *COL4A6* genes.[75,76] These deletions involve varying lengths of *COL4A5*, but the *COL4A6* breakpoint is always located in the second intron of the gene.[77–79] Leiomyomatosis does not occur in patients with deletions of *COL4A5* and *COL4A6* that extend beyond intron 2 of *COL4A6*.Mutations of *COL4A6* alone do not appear to cause Alport syndrome, consistent with the absence of the $\alpha6$(IV) chain from normal GBM.[80]

The great majority of missense *COL4A5* mutations are guanine substitutions in the first or second position of glycine codons that result in the replacement of a glycine residue in the collagenous domain of $\alpha5$(IV) by another amino acid.[4,73] Such mutations are thought to interfere with the normal folding of the mutant $\alpha5$(IV) chain into triple helices with other type IV collagen α chains.[81] Glycine lacks a side chain, making it the least bulky of amino acids, and small enough to allow three glycine residues to fit into the interior of a tightly wound triple helix.[82] The presence of a bulkier amino acid in a glycine position presumably creates a kink or an unfolding in the triple helix. Glycine substitutions in the $\alpha1$ chain of type I collagen account for the majority of mutations causing osteogenesis imperfecta, and are common in other genetic disorders of collagen.[83,84] Abnormally folded collagen triple helices exhibit increased susceptibility to proteolytic degradation.[84] The position of the substituted glycine, or the substituting amino acid itself, may influence the effect of the mutation on triple-helical folding, and ultimately the impact of the mutation on the severity of the clinical phenotype.[85]

ARAS: To date, mutations causing ARAS have been found in the *COL4A3* or *COL4A4* gene in several dozen patients.[86–91] Some of these patients are homozygous for their mutations and others are compound heterozygotes. As with *COL4A5*, there appear to be no mutation hot spots in *COL4A3* or *COL4A4*. Although it is possible that ARAS could result from the combination of a mutation in one allele of *COL4A3* and a mutation in one allele of *COL4A4*, no such example has been described. It is worth noting that the mating of two individuals with asymptomatic hematuria due to heterozygous *COL4A3* or *COL4A4* mutations can result in a child who has mutations in both alleles of *COL4A3* or *COL4A4* and, as a result, ARAS.

The reported *COL4A3* and *COLA*4 mutations in ARAS include nonsense, frame-shift, splicing and missense mutations. As with XLAS and other heritable collagen disorders, a common type of mutation in ARAS is a glycine substitution in the collagenous domain of $\alpha3$(IV) or $\alpha4$(IV).

ADAS: Heterozygous *COL4A3* and *COL4A4* mutations have been described in several families transmitting Alport syndrome as an autosomal dominant disease.[92–94] It is not clear why some individuals with heterozygous *COL4A3* or *COL4A4* mutations are asymptomatic or exhibit only isolated microhematuria,[86,88,95] while others have a progressive nephropathy. Several possibilities can be proposed: the type and/or site of the mutation may be critical, the presence of certain polymorphisms in these genes may influence the effect of a pathogenic mutation,[94] or a polymorphism or mutation in another gene may modify the effect of the mutation. In some cases, a heterozygous missense mutation in *COL4A3* or *COL4A4* might be more detrimental than a deletion or nonsense mutation, because the mutant chain can then induce the degradation of normal chains with which it forms abnormal trimers (Figure 84.1C).

Genotype-Phenotype Correlations in Alport Syndrome: Male patients with *COL4A5* deletions consistently exhibit sensorineural deafness and progression to ESRD during the second or third decade of life.[4] Most of the missense, nonsense and splicing *COL4A5* mutations described thus far have also been associated with early progression to ESRD in the second or third decade of life and sensorineural deafness. Single amino acid substitutions that alter an mRNA splice site, leading to exon skipping, or small deletions or insertions that shift the transcriptional reading frame, can clearly produce such aberrant protein products that a severe phenotype results. Several missense mutations in *COL4A5* have been associated with late-onset (after the third decade) ESRD and deafness.[4,85] Mutations near the 5′ end of the *COL4A5* gene are associated with earlier onset of ESRD.[96]

The severity of disease in a female heterozygous for a *COL4A5* mutation is probably influenced to some extent by the nature of the mutation, but the extent of inactivation of the X chromosome carrying the normal *COL4A5* allele may be a more important factor. Jais et al. were unable to demonstrate a genotype effect on outcome in XLAS heterozygotes, presumably due to the stronger influence of X-inactivation.[3] Guo et al. described a woman with a severe Alport phenotype (ESRD at age 30), one of whose *COL4A5* alleles carried two missense mutations.[97] Analysis of DNA isolated from the patient's kidney and leukocytes showed inactivation of greater than 90% of the X chromosomes carrying the normal *COL4A5* allele. Other investigators, however, have not been able to confirm that X-inactivation pattern of leukocytes predicts phenotype in XLAS heterozygotes.[98] In a mouse model of X-linked Alport syndrome[99] the relative activity of the X chromosome carrying the mutant *COL4A5* allele determines the outcome of heterozygous females.[100]

Phenotypic information on patients with ARAS is as yet somewhat sparse. Available data indicate that patients with ARAS progress to ESRD before age 30 and have sensorineural deafness, regardless of gender.[87,90,91]

Type IV Collagen in Alport Basement Membranes: Several studies in the 1980s established that the native kidneys of male AS patients failed to bind anti-GBM antibodies from patients with Goodpasture syndrome or from AS patients with post-transplant anti-GBM nephritis.[101–105] These early studies, combined with the observation by Hudson and colleagues that type IV collagen was the target of Goodpasture antibodies,[71] provided the first indication that AS might represent a primary disorder of type IV collagen. The availability of chain-specific antibodies has more recently allowed detailed investigation of the expression of the six type IV collagen α chains in AS basement membranes.

GBM, distal and collecting tubular basement membrane (TBM) and Bowman's capsules of males with XLAS usually lack expression of the α3(IV), α4(IV) and α5(IV) chains, but do express the α1(IV) and α2(IV) chains[106,107] (Table 84.5, Figure 84.3). The α6(IV) chain is not expressed in Bowman's capsule or distal TBM of XLAS males whose basement membranes lack α5(IV) expression.[108,109] Women who are heterozygous for XLAS mutations frequently exhibit mosaicism of GBM expression of the α3(IV), α4(IV) and α5(IV) chains, while expression of the α1(IV) and α2(IV) chains is not

TABLE 84.5 Immunohistochemistry in Alport Syndrome*

	GBM	BC	dTBM	EBM
X-linked (males)				
α3(IV)	−	−	−	normally absent
α4(IV)	−	−	−	normally absent
α5(IV)	−	−	−	−
X-linked (females)*				
α3(IV)	mosaic			normally absent
α4(IV)	mosaic			normally absent
α5(IV)	mosaic			mosaic
Autosomal recessive (males and females)				
α3(IV)	−	−	−	normally absent
α4(IV)	−	−	−	normally absent
α5(IV)	−	+	+	+

**In some AS kindreds, staining of basement membranes for type IV collagen chains is entirely normal.Therefore, a normal result does not exclude a diagnosis of X-linked or autosomal recessive AS.*

***Some heterozygous females have normal basement membrane immunoreactivity for type IV collagen chains. Thus, a normal result does not exclude the carrier state.*

GBM: glomerular basement membrane; BC: Bowman's capsule; dTBM: distal tubular basement membrane; EBM: epidermal basement membrane

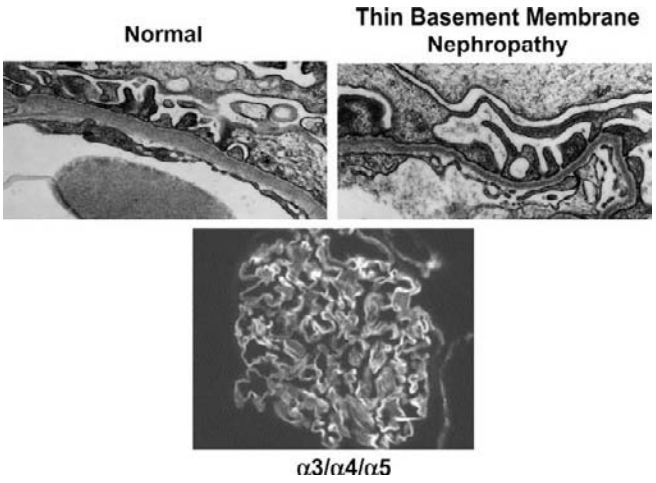

FIGURE 84.3 Glomerular capillary wall ultrastructure and type IV collagen immunochemistry in normal kidneys and in thin basement membrane nephropathy (TBMN). In normal kidneys, the glomerular basement membrane (GBM) has a homogeneous lamina densa, smooth innter (endothelial) and outer (epithelial) surfaces and a constant thickness. In TBMN kidneys, the GBM is diffusely attenuated, with a homogeneous lamina densa. Podocyte foot processes are intact. In both normal and TBMN kidneys, the type IV collagen network formed by the α3(IV), α4(IV) and α5(IV) chains is present in GBM, Bowman's capsule and distal and collecting tubule basement membranes.

affected.[107] The epidermal basement membrane (EBM) normally expresses the α1(IV), α2(IV), α5(IV) and α6 (IV) chains, but not the α3(IV) or α4(IV) chains[107,109,110] (Table 84.5). Most males with XLAS show no EBM expression of α5(IV) or α6(IV), while female heterozygotes frequently display mosaicism[110] (Table 84.5, Figure 84.1). Lens capsules of some males with XLAS do not express the α3(IV), α4(IV) or α5(IV) chains, while expression of these chains appears normal in other patients.[111]

In patients with ARAS, GBMs show no expression of the α3(IV), α4(IV) or α5(IV) chains, but α5(IV) and α6(IV) are expressed in Bowman's capsule, distal TBM and EBM[112] (Table 84.5, Figure 84.3). Therefore, XLAS and ARAS may be distinguishable by immunohistochemical analysis.

It is important to note that immunostaining for type IV collagen is normal in some patients with XLAS and ARAS. Consequently, normal expression of α3(IV), α4 (IV) and α5(IV) chains in basement membranes does not exclude a diagnosis of AS.

The abnormalities of type IV collagen expression observed in AS indicate that a mutation affecting one of the chains involved in the α3(IV)-α4(IV)-α5(IV) network can prevent GBM deposition of the entire network. Similarly, a mutation involving the α5(IV) chain can interfere with basement membrane expression of α5(IV)-α6(IV). Several lines of evidence suggest that the effects of a type IV collagen α chain mutation on the basement membrane expression of its "partner" chains are mediated by post-translational events. Substitution of glycine residues in the α1 chain of type I collagen comprise the majority of mutations causing osteogenesis imperfecta.[113] These mutations impair the folding of α1(IV) chains with α2(IV) chains into trimers, and the resulting trimers exhibit enhanced susceptibility to extracellular proteolytic degradation.[84] By similar means, an α5(IV) chain carrying a glycine substitution could bring about the destruction of normal α3(IV) and α4(IV) chains. Studies of mutations in the α1 chain of type IV collagen in *C. elegans* suggest another possible mechanism. Whether the α1(IV) mutation results in a null allele (deletion or nonsense mutation) or a glycine substitution, the α2(IV) chain accumulates intracellularly and never reaches the basement membrane.[114] Thus, mutations producing null COL4A5 alleles, or α5(IV) proteins that cannot form trimers (due to alterations of the carboxy-terminal domain), or some glycine substitutions, may simply prevent secretion of α3(IV) and α4(IV) chains, which are eventually degraded. Results of *in vitro* studies by Kobayashi and colleagues support the hypothesis that α5(IV) mutations impair the assembly of α3(IV)-α4(IV)-α5(IV) heterotrimers.[81]

Pathogenesis of Basement Membrane Lesions in Alport Syndrome: The tissue pathology of AS arises from abnormalities of basement membrane expression of the α3(IV)-α4(IV)-α5(IV) collagen network. This network is usually absent from or under-expressed in the basement membranes of AS patients, although in the basement membranes of some patients the networks are present but presumably defective in structure and function. The most straightforward demonstration of the consequences of the absence of this network may be anterior lenticonus. Absence or defective expression of these chains results in thinning and mechanical weakness of the anterior lens capsule, which fails to maintain the normal conformation of the lens.[17,111,115] Microhematuria, the first and invariable renal manifestation of AS, may likewise reflect GBM thinning and a tendency to develop focal ruptures early in life, due to the absent or defective expression of the α3-α4-α5(IV) network. Episodic gross hematuria precipitated by infections, which is not uncommon during the first two decades of life, may reflect increased susceptibility of the GBM to proteolysis.[116] On the other hand, the resolution of gross hematuria, which typically occurs by adolescence,[2] may be a function of progressive GBM thickening.[5]

The relentless thickening and lamellation of the Alport GBM features the accumulation of extracellular matrix proteins that are normally absent from GBM, or present in only small amounts. The α1(IV)−α2(IV)

network is highly expressed in the basement membranes of primordial glomeruli, but is normally replaced by the α3(IV)−α5(IV) network at the capillary loop stage of glomerular maturation.[117] In mature glomeruli the α1(IV)−α2(IV) network is confined to the mesangium and the subendothelial region of GBM.[118] This developmental switch fails to occur in Alport glomeruli.[116,119] The α1(IV)−α2(IV) network persists in mature Alport glomeruli and accumulates, spreading from its normal subendothelial location to occupy the full width of GBM.[112,106] Similarly, type V collagen and type VI collagen are normally found in the mesangium and in small quantities in the subendothelial GBM, but are markedly overexpressed in Alport GBM.[106] In addition, laminin chains that are normally confined to the mesangium are expressed in Alport GBM.[120,121] The molecular events that underlie these anomalies in protein expression remain to be elucidated. Whatever the mechanism, glomerulosclerosis in AS may result from the ectopic deposition of certain collagens in GBM.

AS resembles other chronic glomerulopathies in that deterioration of glomerular filtration rate is closely correlated with fibrosis of the renal interstitium.[122] Measurable increases in cortical interstitial volume are unusual in males with XLAS under age 10 years, but progressive expansion of the interstitium frequently occurs during the second decade of life.[122] It is not surprising that at least some of the factors driving interstitial fibrosis in AS are nonspecific, such as increased TGF-β1 activity, monocytic infiltration, epithelial-mesenchymal transformation and enhanced metalloproteinase expression.[123–127] If the pathogenesis of interstitial fibrosis in AS is not specific to the disease, it is conceivable that therapies that interfere with interstitial fibrosis may be of benefit to AS patients, without correcting the primary abnormalities of type IV collagen expression.[128,129]

Diagnosis

Alport syndrome should be considered in the differential diagnosis of patients with persistent microhematuria. Electron microscopic examination of renal tissue remains the most widely available and applied means for diagnosing AS. The presence of diffuse thickening and multilamellation of the GBM predicts a progressive nephropathy, regardless of family history. Unfortunately, ultrastructural information alone does not establish the mode of transmission in a particular family. In a patient with a negative family history, electron microscopy cannot distinguish *de novo* X-linked disease from autosomal recessive disease. In some patients the biopsy findings may be amibiguous, particularly females and young patients of either sex. Furthermore, rare families with progressive nephritis and *COL4A5* mutations in association with thin GBMs have been described, indicating that the classic GBM lesion is not present in all AS kindreds.

In families with a firm diagnosis of AS, evaluation of individuals with newly-recognized hematuria can be limited to ultrasound of the kidneys and urinary tract in most instances. In the absence of tumor or structural anomalies of the urinary tract, a diagnosis other than AS is unlikely. A suspected diagnosis of AS may be confirmed by immunohistochemical methods. Monospecific antibodies directed against type IV collagen α chains are available,[130,131] making it possible to reliably evaluate renal basement membranes for expression of α3(IV), α4(IV) and α5(IV) chains (Table 84.5). Since the α5(IV) chain is normally expressed in the epidermal basement membrane (EBM), examination of skin biopsies by immunofluorescence for expression of α5(IV) is an additional tool for making a diagnosis of AS. Absence of the α5(IV) chain from EBM is diagnostic of XLAS.[132] Given a male patient with a positive family history and clinical features characteristic of AS, examination of skin for α5(IV) expression may obviate the necessity for kidney biopsy. Unfortunately, a normal result does not exclude the diagnosis of AS, since in some XLAS kindreds (about 20%) affected males express α5(IV) in their renal and epidermal basement membranes.Heterozygous females frequently express α5(IV) mosaically in the skin. While clearly mosaic expression of α5(IV) is diagnostic of the carrier state, a normal result does not exclude heterozygosity.

Renal expression of type IV collagen α chains can serve to confirm a diagnosis of AS, and can in addition differentiate XLAS and ARAS (Table 84.5).In most males with XLAS renal basement membranes are devoid of the α3(IV), α4(IV) and α5(IV) chains, while females frequently show mosaic expression of these chains. In most males and females with ARAS the GBM, Bowman's capsule and distal TBM show no expression of the α3(IV) and α4(IV) chains, while α5 (IV) is expressed in Bowman's capsule and distal TBM but not GBM.[112]

The ability to diagnose Alport syndrome by skin biopsy may eventually reduce reliance on kidney biopsy for diagnosis of this disease. Skin biopsy is the initial diagnostic maneuver of choice when kidney biopsy is excessively risky, such as in patients with advanced renal insufficiency.

Genetic analysis provides the only means for reliably diagnosing the carrier state in asymptomatic female members of XLAS kindreds and for making a prenatal diagnosis of AS. There are also clinical situations in which a firm diagnosis of AS cannot be established, or in which it is not possible to determine the mode of transmission, despite careful evaluation of the pedigree and application of the full range of histological methods. In these situations genetic analysis has the

potential to provide information essential for determining prognosis and guiding genetic counseling. Genetic counseling based upon erroneous determination of the mode of inheritance may have unintended consequences.[133]

At the present time, the routine application of molecular analysis is limited by both specific and general problems. First, the sheer size of the type IV collagen loci (>50 exons), combined with the great variety of mutations, many of which are missense alterations of a single base pair, presents a formidable obstacle. Exon-screening methods, such as analysis of single-strand conformational polymorphisms, identify only about 50% of *COL4A5* mutations.[134,135] Detection schemes based on direct sequencing identify have a better detection rate (about 80–90%), but are relatively expensive.[136,137] Consequently, at the time this chapter was written, only a single commercial laboratory offered molecular diagnosis of Alport syndrome (www.genereviews.org).

In the future, automation and miniaturization of DNA analytic techniques may result in a relatively simple, rapid and inexpensive means of assaying a blood or tissue sample for mutations at genetic loci relevant to Alport syndrome, replacing other diagnostic methods. For now, genetic analysis is desirable, but not necessarily available, when there is ambiguity regarding the diagnosis of Alport syndrome or the mode of transmission, or when prenatal testing is desired.

Treatment

Replacement of renal function by transplantation is currently the only "treatment" of proven value for AS. Analysis of data from the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) documents equivalent allograft survival rates in patients with familial nephritis, in comparison to patients with other diagnoses.[138] However, some AS patients develop anti-GBM nephritis in the renal allograft, usually resulting in graft loss.Data from several transplant centers indicates an incidence of 3–4% in transplanted AS patients.[139–141] These patients are usually male, always deaf, and likely to have reached ESRD before the age of 30.[142] This profile describes the majority of AS patients presenting for renal transplantation, so its predictive value is rather limited. However, AS patients with normal hearing or late progression to ESRD appear to be at very low risk for the development of post-transplant anti-GBM nephritis. Females with XLAS also appear to be in a low-risk category.

The onset of post-transplant anti-GBM nephritis was within the first year following transplantation in approximately 75% of cases. Three-quarters of the allografts failed irreversibly, usually within a few weeks to months after diagnosis.Treatment with plasmapharesis and cyclophosphamide has been of limited benefit. Anti-GBM nephritis has recurred in seven of eight patients who underwent retransplantation. Post-transplant anti-GBM nephritis may recur despite an interval of many years between transplants, and in the absence of detectable circulating anti-GBM antibodies prior to retransplantation.

The target(s) of anti-GBM antibodies in some of these patients has been determined, with variable results. Most patients with XLAS exhibit antibodies that target the carboxy-terminal noncollagenous domain of the α5(IV) chain,[102,141,143,144] but anti-α3(IV) antibodies have also been described.[145] Antibodies against α3(IV) have been observed in ARAS patients with post-transplant anti-GBM nephritis.[143]

It has been proposed that mutations in the *COL4A5* gene that prevent expression of an immunogenic gene product, thereby preventing the establishment of tolerance for α5(IV), might be associated with an increased risk for the development of post-transplant anti-GBM nephritis.[144,103] Of 14 AS patients with post-transplant anti-GBM nephritis examined for a *COL4A5* mutation, seven, or 50%, had complete or partial deletions, compared with a deletion frequency of about 10% in the general AS population (discussed in[142]). Although the sample size is small, the data gathered thus far support the hypothesis that AS patients who develop anti-GBM nephritis after renal transplantation are more likely to carry deletions in the *COL4A5* gene than the AS population at large.

Females who are heterozygous for *COL4A5* mutations would not be expected to be at risk for the development of post-transplant anti-GBM nephritis, since the product of the normal *COL4A5* allele would allow establishment of immunologic tolerance for α5(IV). Nevertheless, post-transplant anti-GBM nephritis has been reported in two females with AS.[87,141] Both of these women were found to have ARAS, due to *COL4A3* mutations.[87,91]

Even if it were to prove true that certain *COL4A5* mutations are associated with a higher risk for the development of post-transplant anti-GBM nephritis, this information would be of limited value in planning transplantation. It is clear that AS males with *COL4A5* deletions can undergo renal transplantation without developing anti-GBM nephritis,[146,147] indicating that other factors, presently unknown, must influence the initiation and elaboration of the immune response to the allograft. At this time it appears that the only way to determine whether a previously untransplanted AS patient will develop post-transplant anti-GBM nephritis is to perform the transplant, although as noted previously certain patients are at very low risk.

Interventions aimed at preventing or slowing the inexorable decline in renal function typical of male AS

are currently under investigation. The role of angiotensin II in the pathogenesis of renal failure in AS is still not well understood. Studies of angiotensin inhibition in AS have involved small numbers of patients with proteinuria serving as their own controls, with relatively short follow-up, and have produced mixed results.[148–151] However, Gross and colleagues found that ramipril therapy initiated prior to the development of proteinuria delayed the onset of proteinuria and renal failure and lengthened survival in a murine model of ARAS.[128,129] Early angiotensin converting enzyme inhibition in dogs with XLAS had no effect on the onset of proteinuria, but did delay ESRD.[152] These observations suggest that angiotensin blockade, initiated early in the course of disease might be beneficial in human AS.

Callis and colleagues found, in an uncontrolled study of eight AS males, that cyclosporine appeared to suppress proteinuria and stabilize renal function, over several years of observation.[153,154] There has yet to be a published report that contradicts these findings. However, the results of trials presented in abstract suggest that patient responses to cyclosporine are variable, and that cyclosporine may accelerate interstitial fibrosis.[155,156] In dogs with XLAS, cyclosporine failed to suppress proteinuria, but treated animals did exhibit a delay in progression to ESRD.[157] At this time, it is the authors' view that the efficacy of cyclosporine as a treatment for AS has not been demonstrated with the degree of certainty needed to overcome concerns about its nephrotoxicity.

Gene transfer approaches aimed at delivering a normal copy of the *COL4A5* gene to glomeruli are currently undergoing investigation in canine models of AS.[158–161]

Thin Basement Membrane Nephropathy (TBMN)

TBMN, like AS, is an inherited disorder of glomerular basement membranes that is characterized clinically by persistent microscopic hematuria and episodic gross hematuria. TBMN differs clinically from AS in several important respects: (1) It is only rarely associated with extrarenal abnormalities. (2) Proteinuria, hypertension and progression to ESRD are unusual. (3) Gender differences in the severity of the signs and symptoms of TBMN are not apparent. (4) Transmission is autosomal dominant in nature.TBMN and early AS may be difficult to distinguish histologically, since diffuse GBM attenuation is characteristic of both. However, the GBM of TBMN patients remains attenuated over time, rather than undergoing the progressive thickening and multilamellation that is pathognomonic of AS.

Clinical Features

Individuals with TBMN typically exhibit persistent microhematuria that is first detected in childhood. In some patients microhematuria is intermittent, and may not be detected until adulthood. Episodic gross hematuria, often in association with upper respiratory infections, is not unusual. The hematuria of TBMN appears to be life-long.It has been estimated that 20–25% of patients referred to a nephrologist for evaluation of persistent hematuria will prove to have thin GBM on renal biopsy.[162]

Overt proteinuria and hypertension are unusual in TBMN, but have been described.[163–166] Some of these patients exhibit focal global glomerulosclerosis on renal biopsy.[164] In occasional adult patients with Alport syndrome the predominant GBM abnormality of is attenuation, rather than thickening and multilamellation. Other glomerular disorders such as IgA nephropathy may occur in patients with TBMN, altering the expected natural history and histopathology of the condition.

Pathology

Light and immunofluorescence microscopy are unremarkable in typical cases of TBMN or thin GBM disease. Most patients with TBMN exhibit diffuse thinning of the GBM as a whole, and of the lamina densa (Figure 84.3). Normal GBM thickness is age- and sex-dependent. Both the lamina densa and the GBM normally increase rapidly in thickness between birth and age two years, followed by gradual thickening throughout childhood, adolescence and into adulthood.[167] GBM thickness of adult men (373 ± 42 nm) exceeds that of adult women (326 ± 45 nm).[168] Thus it is important to consider the age and sex of the patient when evaluating GBM width.Each EM laboratory should establish a consistent technique for measuring GBM thickness, and determine its own means and standard deviations for GBM width, to make comparisons with published data meaningful.

The definition of "thin" GBM in the literature is imprecise, in part because of the use of different techniques to measure GBM width. When an EM laboratory's normal values for GBM width are similar to those of Steffes et al.[168] a cut-off value of 250 nm will accurately separate adults with normal GBM from those with thin GBM. Where the normal values are significantly higher, a cut-off value of 330 nm is appropriate.[169] For children, the cut-off is in the range of 200–250 nm (250 nm is within 2SD of the mean at age 11).[170,167] It is useful to note that the intraglomerular variability in GBM width is small in thin GBM disease.[165] Marked variability in GBM width within a glomerulus, in a patient with persistent microhematuria,

should raise suspicion of Alport syndrome, although focal lamina densa splitting has been described in TBMN.

Genetics and Pathophysiology

TBMN is usually transmitted as an autosomal dominant condition. A negative family history may not be reliable, since patients eventually diagnosed as having TBMN are frequently unaware that they have relatives with hematuria.[171] The first clue to the genetic basis of TBMN was provided by Lemmink and coworkers, who described a large Dutch TBMN kindred in which the disease locus was first mapped to chromosome 2 in the region of the *COL4A3* and *COL4A4* genes, and then affected individuals were found to be heterozygous for a missense mutation in *COL4A4*.[172] Since this landmark work, heterozygous mutations in *COL4A3* or *COL4A4* have been described in numerous TBMN families.[93,95,173,174] However, linkage to the *COL4A3* and *COL4A4* genes has been excluded in other TBMN families, indicating that TBMN is a genetically heterogeneous condition.[175]

To date, immunohistologic studies of type IV collagen in GBM of patients with TBMN or thin GBM disease have failed to uncover any abnormalities in the distribution of any of the six chains. However, it is tempting to speculate that in those kindreds with TBMN due to a heterozygous *COL4A3* or *COL4A4* mutation, a 50% reduction in the GBM α3(IV)$-\alpha$4(IV)$-\alpha$5(IV) network results in lamina densa and GBM thinning and fragility. This reduction is presumably insufficient to trigger the pathophysiologic events that produce the lamina densa splitting and GBM thickening characteristic of Alport syndrome (AS). Immunohistologic evaluation of GBM type IV collagen may be useful in the differentiation of TBMN and AS (see below).

Diagnosis

Patients with persistent, isolated microhematuria are usually candidates for kidney biopsy, once structural urinary tract abnormalities, urinary tract stones and tumors are excluded. If the patient's family history indicates autosomal dominant transmission of hematuria, and there is no history of chronic renal failure, a presumptive diagnosis of TBMN can often be made without kidney biopsy. When family history is negative or unknown, or there are atypical coexisting features such as proteinuria or deafness, renal biopsy may be extremely informative. A finding of thin GBM may be further characterized by examining the distribution of type IV collagen α chains in the kidney. Normal distribution of these chains provides supportive, although not conclusive, evidence for a diagnosis of TBMN (see also preceding section on Alport syndrome).

Treatment

Patients who are given a diagnosis of TBMN should be reassured, but not lost to follow-up examination. The risk of chronic renal insufficiency appears to be small but real.[163–166] Reasonable follow-up would include urinalysis and measurement of blood pressure and renal function every one to two years.

Hereditary Angiopathy with Nephropathy, Aneurysms and Cramps (Hanac Syndrome)

Missense mutations in the *COL4A1* gene encoding the α1 chain of type IV collagen have been associated with autosomal dominant transmission of an angiopathy characterized by nephropathy, aneurysms and muscle cramps in several families.[176] Renal symptoms include hematuria, renal insufficiency and renal cysts. Renal biopsies showed no abnormalities of glomerular basement membrane structure or type IV collagen expression, although basement membranes of Bowman's capsules, tubules and interstitial capillaries showed irregular thickening and lamellation.

Pierson Syndrome

Pierson and colleagues reported familial cases of infantile nephrotic syndrome and distinct ocular abnormalities.[177] The ocular abnormalities were marked by enlargement of the globe (buphthalmos) and reduction in the size and reactivity of the pupils (microcoria). All affected infants died within the first year of life.

Zenker and colleagues reported on consanguineous families with 11 children demonstrating similar clinical features.[178,179] Several of these children were identified by fetal ultrasound, variably demonstrating kidney enlargement and hyperechogenicity, oligohydramnios, placental enlargement and/or pulmonary hypoplasia. Infants surviving to term had congenital nephrotic syndrome, with kidney biopsy or autopsy specimens revealing diffuse mesangial sclerosis.These children also had ocular globe enlargement and microcoria, with sporadic findings of cataract, posterior rupture of the lens capsule (lenticonus) and retinal abnormalities. In additional case reports, affected children had muscular hypotonia, central nervous system hemangioma and genital abnormalities.[180,181] Kidney biopsy specimens from these patients also demonstrated diffuse mesangial sclerosis, as well as marked GBM irregularities. None of these children survived beyond the first year of life.

Zenker and colleagues localized the Pierson syndrome gene to chromosome 3p14–p22 by homozygosity mapping.[182] Identifying the *LAMB2* gene encoding the β2 chain of basement membrane laminin as a

candidate, these workers went on to sequence homozygous and compound heterozygous mutations in five families, including two nonsense mutations, three frameshift mutations and one missense mutation.In one patient, a homozygous nonsense mutation of the *LAMB2* gene was associated with loss of β2 laminin from the GBM.

The β2 chain of laminin is one of four β chains of basement membrane laminin.[183,184,185] Individual laminins are heterotrimeric glycoproteins made up of variable α, β and γ chains, combining in 1:1:1 stoichiometric proportions to form cruciform structural subunits. In turn, laminin subunits self-assemble and generate macromolecular networks within basement membranes, serving myriad roles in overall extracellular matrix organization, determination of basement membrane properties and interactions with adjacent cells. The laminin β2 chain participates in the formation of several distinct αβγ laminins. In particular, laminin-11 comprised of α5β2γ1 is upregulated during development of the kidney glomerulus, in a characteristic mid-gestational switch of laminin and type IV collagen isoforms marking GBM maturation,[117,186]. Partially recapitulating Pierson syndrome, targeted deletion of the mouse *Lamb2* ortholog causes congenital nephrosis, with mesangial hyperceullularity and podocyte foot process injury.[187] Interestingly, laminin β2-deficient mice also demonstrate neuromuscular synapse abnormalities with resulting muscular weakness,[187] a feature with correlates in Pierson syndrome.

The mechanisms by which *LAMB2* mutations give rise to nephrotic syndrome and accelerated kidney disease are uncertain. Ultrastructural abnormalities in Pierson syndrome suggest disruption of GBM structural integrity. Defects in glomerular cell-GBM interactions are also likely, as laminin-11 is a ligand for integrin extracellular matrix receptors,[188,189] most importantly α3β1 integrin mediating glomerular cell attachment to the GBM.[190]

Further discussion on the laminins and their biological roles in kidney and other tissues can be found in several excellent reviews.[183–185,191,192]

STORAGE DISORDERS

Fabry Disease

Fabry disease is an X-linked disorder caused by deficiency of the lysosomal hydrolase enzyme α-galactosidase A (EC 3.2.1.22).Deficient α-galactosidase A (α-Gal A) activity results in accumulation of glycosphingolipid (globotrioacylceramide, or Gb3) in blood vessels and various organs leading to the clinical manifestations of the disease, including chronic renal failure. Also known as Anderson-Fabry disease or angiokeratoma corporis diffusum universale, Fabry disease was first described in 1898 in separate reports by Anderson in England and Fabry in Germany.[193,194] Although the incidence of Fabry disease is approximately 1:40,000, making it a rare cause of renal failure, much is known about the genetic pathophysiology of the disorder. Most importantly Fabry disease has the potential to be effectively treated by enzyme replacement.

Clinical Features

Since Fabry disease is an X-linked disorder, severe clinical manifestations occur in hemizygous males while heterozygous females exhibit a variable but typically less severe course. However, there is increasing recognition of disease-related morbidity in heterozygous females. Data from the Fabry Registry indicated that about 70% of heterozygous females have symptoms of Fabry disease.[195] Although median onset of symptoms was 13 years, and over 80% had a positive family history of Fabry disease, median age of diagnosis was 31 years. Major cerebrovascular, cardiac or renal events occurred in 20% at a median age of 46 years, and proteinuria and reduced glomerular filtration rate were common. These findings illustrate the importance of regular monitoring in females as well as males with Fabry disease.

The clinical features of Fabry disease are summarized in Table 84.6. In hemizygotes (affected males) the initial features of the disease are seen in childhood and early adolescence and consist of paresthesias and pain in the hands and feet with episodic pain crises. The course of the disease is variable but usually leads to end-stage renal disease in the third to sixth decade.

TABLE 84.6 Clinical Manifestations of Fabry Disease

Skin	Angiokeratomas
Nervous system	Painful neuropathy
	Acroparesthesias
	Hypohidrosis
	Stroke
	Dementia
Cardiac	Hypertrophy
	Coronary artery disease
	Cardiomyopathy
Renal	Proteinuria
	Renal failure
Eye	Corneal and lenticular opacities

Myocardial or cerebral infarctions are typically terminal events

The classic skin lesion, angiokeratoma corporis diffusum universale, consists of macules or maculopapules, cherry red to black in color and 1–3 mm in diameter. These lesions first appear in adolescence particularly in the scrotal area, lower back and trunk. There may be up to several dozen lesions. Other skin manifestations include palmar erythema, splinter hemorrhages, and conjunctival or buccal mucosal telangiectasias. One of the most profound and debilitating aspects of the disease is peripheral nerve involvement leading to painful crises, acroparesthesias, and hypohidrosis. Central nervous system involvement includes cerebral infarctions and dementia.Corneal and lenticular opacities occur in all hemizygotes and most heterozygotes.

The most common cardiac manifestation in Fabry disease is coronary artery disease but hypertrophy, congestive heart failure, valvular lesions, and arrythmias are common. A form of the disease limited to the heart has been described and is characterized predominantly by cardiac hypertrophy.[196,197] These patients often have mutations that result in detectable amounts of enzyme. In fact, among 230 consecutive male patients presenting with left ventricular hypertrophy 3% had low plasma α-Gal A activity and may represent cardiac limited variants of the disease.[196]

The earliest renal manifestation is a concentrating defect.Proteinuria, typically in the range of 0.5 to 2 g daily, is first detected in young adulthood.[198,199] Nephrotic-range proteinuria is unusual but may be seen. The urinary sediment is most often bland although some patients exhibit microscopic hematuria. There is increased urinary glycosphingolipid, and urinary myelin bodies, both free and within tubular cells, may be found.[200,201] Classic Maltese crosses can be seen when the urine sediment is examined with a polarizing microscope. Fabry disease has been reported in association with IgA nephropathy[202] and SLE.[203]

End-stage renal disease typically occurs in the third to sixth decade but has been reported in patients less than 20 years old.[198] The clinical course of the renal failure has been described by several investigators. Donati and colleagues followed 12 patients with end-stage renal disease. Eight patients were transplanted and all survived with the longest patient being 66 months post transplant.[204] Three dialysis patients died 9, 11 and 12 months after starting dialysis prompting these investigators to conclude the prognosis was better after transplantation. Nissenson and colleagues described 17 patients (including one woman) with Fabry disease who underwent treatment for end-stage renal disease.[198] Eighty three percent of the patients survived to 33 months and 41% were transplanted.

Pathology

Intracellular glycosphingolipid accumulation is found in most structures of the kidney including glomerular epithelial, endothelial and mesangial cells, tubular epithelial cells, interstitial cells, and blood vessels including endothelial, perithelial and smooth muscle cells.[205,206] During routine processing of paraffin-embedded sections lipids are dissolved by the xylene so that the cells which contained them look like foam cells with empty vacuoles (Figure 84.4). With fresh or fixed-frozen tissue lipids can be identified with fat stains such as Sudan III or oil red O. The glomerular epithelial cells are most prominently affected in the kidney.These cells are filled with small, uniformly sized vacuoles, giving them a foamy appearance (Figure 84.4). Vacuoles are often present in parietal epithelial cells but are not commonly seen in endothelial or mesangial cells. In the later stages of the disease the glomeruli become sclerotic.

Vacuolization of tubular cells is most prominent in the loop of Henle and distal convoluted tubule and is rarely seen in the proximal tubule. Most blood vessels are involved with vacuoles present in endothelium, smooth muscle cells and perithelial cells.In later stages insudative arteriolar changes are observed.[206]

Immunofluorescence is negative except in advanced glomerular sclerosis where non-specific uptake of immunoglobulin or complement can be seen.[206] Glycosphingolipid can be detected with antibodies to trihexosylceramide.[207]

The characteristic lesion of Fabry disease is seen on electron microscopy (Figure 84.8). Stacks or whorls of dense inclusions ranging in diameter from 0.3 to 10 μm (average 3 μm) are found in lysosomes of affected cells. Terms such as onion skin or myelin figures have been used to describe the concentric

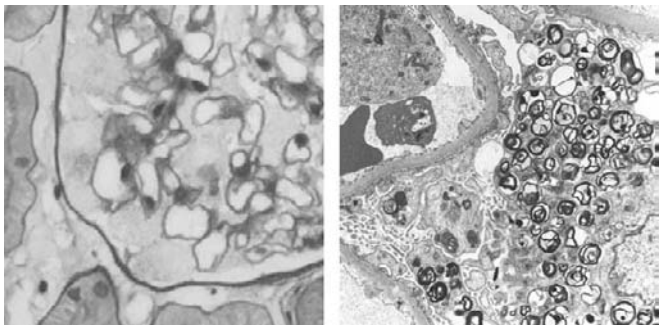

FIGURE 84.4 Renal biopsy findings in Fabry disease. Left: periodic acid-schiff staining demonstrates glomerular cell enlargment, vacuolization and fusion, without capsular adhesions. Right: Electron Microscopy demonstrates glycosphingolipid deposits within podocytes. Micrographs are courtesy of Drs. George Canas and Rahul Koushik.

dense layers of glycosphingolipid deposits.The deposits can also appear as parallel arrays ("zebra bodies").[208] Cells that appear normal on light microscopy can have inclusions.In the glomerulus, deposits are present in every cell type but are less numerous and smaller in endothelial and mesangial cells. Heterozygous females have similar but fewer inclusions. Other intracellular organelles appear normal. Foot process fusion occurs with heavy proteinuria.In the later stages of the disease the glomerular basement membrane becomes wrinkled and thickened and mesangial interposition may occur. These changes are suggestive of glomerular ischemia. Typical inclusions may be present in Bowman's space and tubular lumena, and cells containing glycosphingolipid may be found in the urine and can be used for making the diagnosis of Fabry disease.[200,201]

Genetics and Pathophysiology

The α-Gal A protein has a molecular weight of approximately 50 kDa. It is a homodimeric glycoprotein containing 5 to 15% oligosaccharide chains. Processing includes cleavage of the signal peptide and carbohydrate modifications resulting in the mature 100 kDa enzyme.The mature protein then moves to its site of action in the lysosome. The protein has been crystallized and analyzed in more detail.[209]

α-Gal A cDNA was first isolated in 1986.[210] The coding sequence comprises 1290 bp and codes for a protein of 429 amino acids including a 31 amino acid signal peptide. There are four possible N-glycosylation sites, three of which are used. The α-Gal A gene is located on the long arm of the X chromosome at Xq22.1. The gene is 12 kb in size and contains 7 exons ranging in size from 92 to 291 base pairs.[211] The sequence for the 5′ untranslated region, the signal peptide and the first 33 amino acids of the mature enzyme are contained in exon 1. The gene is *Alu*-rich, containing 12 *Alu* repetitive elements each containing 300 nucleotides that comprise 30% of the gene.[211] Polymorphisms of the α-Gal A gene have been described but are rare.[211,212] These polymorphisms along with other highly polymorphic markers near the α-Gal A gene can be used for diagnosis and carrier detection.[213]

Almost all unrelated families with Fabry disease have different mutations.[211,214–217] The majority of the mutations are single base substitutions in the coding region with two thirds occurring in exons 5 through 7.[212] Other mutations include gene rearrangements such as duplications, deletions, insertions, and RNA processing defects.[218]

Deficiency of α-Gal A leads to progressive intracellular accumulation of neutral glycosphingolipids, particularly those with α-galactosyl moieties, the most abundant of which is globotriaosylceramide (Gb3). Glycosphingolipids are normal constituents of the plasma membrane, the membranes of intracellular organelles, and circulate in association with apolipoproteins, particularly low density lipoprotein.[219] The glycosphingolipids that accumulate in Fabry disease are identical to those found in normal tissue.[220] All tissues except red blood cells accumulate Gb3 with the highest concentrations found in the diseased kidney.[221]

Accumulation of glycosphingolipids, particularly in the CNS and cornea, results from retention of endogenously metabolized glycosphingolipid. The presence of glycosphingolipid in vascular endothelium and smooth muscle may be due to uptake of circulating Gb3.[220] Vascular pathology results from the swollen endothelium narrowing or occluding the vascular lumen.In addition, the endothelium likely serves as an initiator of vascular thrombosis. Whether the renal pathology is entirely secondary to vascular disease or due to glomerular and/or tubular epithelial cell toxicity is unclear. The most prominent early lesion in the kidney is swelling and vacuolization of visceral epithelial cells which likely is the underlying basis for the proteinuria and may be an important factor in the development of glomerular sclerosis.[222]

Classically affected hemizygotes have a large variety of mutations. Patients with mutations that maintain some residual α-Gal A activity tend to have milder phenotypes. Examples include patients with disease confined predominantly to the heart, who most often have missense mutations and express low levels of α-Gal A activity.[223]

Mice in which the α-Gal A gene has been deleted by gene targeting techniques completely lack α-Gal A activity as expected.[224] No clinical phenotype is detectable at 10 weeks of age. However, ultrastructural and histochemical studies, and lipid analysis demonstrate the classic lamellar inclusions in the kidney and accumulation of Gb3 in the liver, kidneys and in cultured fibroblasts. In the kidney the lipid inclusions are first seen in renal tubular cells. Enzyme activity can be restored in cultured embryonic fibroblasts of the deficient mice by transducing the cells with a retrovirus containing the α-Gal A gene, resulting in decreased accumulation of Gb3 in the fibroblasts. Infusion of transduced bone marrow cells corrects the enzyme deficiency and reduces glycosphingolipid stores in α-Gal A-deficient mice.[225]

Diagnosis

Diagnosis of the hemizygote patient can usually be made on clinical grounds with the additional information from slit lamp examination of the eye. The diagnosis should be confirmed by demonstrating decreased to absent α-Gal A activity in serum, leukocytes, cultured skin fibroblasts or biopsied tissue. Atypical variants

may have enzyme activity up to 35% of normal.[220] A dissociation may also exist between serum and tissue enzyme activity.

Heterozygous females have intermediate levels of α-Gal A activity but values may be in the low normal range making measurement of enzyme activity an insensitive way of diagnosing carriers. Alternatives include careful slit lamp eye exam, measuring urinary ceramide digalactoside and trihexoside, or by molecular techniques using restriction fragment length polymorphisms of either the α-Gal A gene or closely linked markers on the X-chromosome.[213] Identification of carriers is particularly relevant when family members are being considered as living kidney donors.[226] Measurement of chorionic villus enzyme level or the enzyme level in cultured amniotic cells is possible.[227]

Treatment

Until recently, clinicians could offer little beyond palliative, symptomatic care to patients with Fabry disease, including carbamazepine and gabapentin, or narcotics, for neuropathic pain, antihypertensive therapy and platelet antagonists. However, the landscape of Fabry therapy has been transformed over the past several years by the introduction of enzyme replacement therapy using recombinant human α-Gal A (agalsidase).

Studies conducted in the 1970s showed that injection of α-Gal A purified from human plasma resulted in transient reduction in plasma Gb3.[228,229] Production of sufficient enzyme for clinical trials was not possible until the advent of recombinant DNA technology. In 2001, Ioannou and colleagues described pre-clinical studies in α-Gal A-deficient mice showing that recombinant human enzyme lowered tissue and plasma Gb3,[230] providing the rationale for human treatment trials.

Phase I/II clinical trials demonstrated that agalsidase produced dose-dependent reductions in plasma, tissue and urine Gb3 in Fabry patients.[231,232] Randomized clinical trials showed that agalsidase administration over 5–6 months resulted in reduced plasma and urine Gb3, amelioration of neuropathic pain, enhanced quality of life, clearing of Gb3 deposits from kidney, heart and skin, and improved cerebral blood flow.[233–235] A multicenter longitudinal study showed that algasidase stabilized renal function in patients with mild to moderate renal impairment at baseline, and reduced left ventricular mass in those with left ventricular hypertrophy at baseline, over one to two years of treatment.[236,237] Agalsidase therapy has been recommended for all affected males and symptomatic carrier females.[238]

Long-term therapeutic outcomes of agalsidase therapy are also promising.[239] Left ventricular mass index remained stable in patients without baseline ventricular hypertrophy and decreased significantly in those with ventricular hypertrophy at the onset of therapy. Pain severity decreased, and quality of life indicators increased, with therapy. Glomerular filtration rate was stabilized by therapy. Trials testing agalsidase therapy against placebo have shown reduced rate of loss of renal function in agalsidase-treated patients, although no effect on proteinuria was observed.[240]

A problem that may affect the long-term efficacy of agalsidase treatment is development of neutralizing antibodies to the enzyme. Linthorst and colleagues found that 11/16 Fabry males developed high titers of neutralizing IgG antibodies to α-Gal A. After six months of treatment, antibody-negative patients had significantly lower urine Gb3 levels compared to antibody-positive patients, suggesting that the antibodies interfered with renal tubular Gb3 clearance.[241] However, the impact of α-Gal A antibodies on the efficacy of agalsidase treatment remains to be determined. A recent analysis found no correlation between anti- α-Gal antibody titers and rate of change in glomerular filtration rate during treatment.[242]

Options for managing end-stage renal failure in Fabry patients include dialysis and transplantation. Initial reports of kidney transplantation for Fabry disease suggested that the allograft might serve to correct the underlying metabolic defect.[243–245] However, kidney transplantation does not improve the systemic manifestations of the disease.[246,247] Graft and patient survival rates for patients with Fabry disease are similar to those in patients with other diagnoses.[248] Glycosphingolipid can accumulate in the transplanted kidney but the deposits are detectable only by electron microscopy predominantly in capillary endothelial cells.[249,250] Loss of the allograft from recurrent disease has not been described. Transplanting the kidney from a heterozygote can result in recurrent disease making donor screening important.[226] Renal allograft recipients with Fabry disease are candidates for agalsidase treatment.[251]

Fabry Disease in Childhood

The signs and symptoms of Fabry disease, particularly pain crises, acroparesthesias, angiokeratomas and corneal opacities, typically have their onset in childhood, although a specific diagnosis is frequently delayed until well into adulthood.[252,253] Albuminuria and characteristic renal histological abnormalities have been described in children and adolescents with Fabry disease.[254,255] Agalsidase therapy in a small number of pediatric patients was associated with clearing of GL-3 from dermal capillary endothelium, and mild or moderate infusion-associated

reactions.[256] In another study, affected children treated with agalsidase resulted in reduced plasma and urine GL-3 levels and decreased pain severity.[257]

OTHER STORAGE DISORDERS ASSOCIATED WITH GLOMERULAR DYSFUNCTION

Glomerular dysfunction may be detected in patients with various inherited storage diseases, associated with accumulation of the storage material in glomerular cells, mesangium or GBM (see Table 84.1). Deficiency of the enzyme lecithin-cholesterol acyltransferase (LCAT) prevents esterification of plasma cholesterol and thus interferes with reverse cholesterol transport from tissues to the liver. The accumulation of free cholesterol in tissues results in a variety of clinical abnormalities, including proteinuria that frequently progresses to ESRD.[258] Light microscopic features of the kidney in LCAT deficiency include mesangial expansion and glomerular capillary wall thickening. The ultrastructural findings are distinctive, consisting of numerous, irregular lucencies in the mesangium and GBM that contain dense granular or membrane-like structures. These lesions regularly recur in renal transplants.

Sialidosis results from deficiency of sialidase, which removes terminal sialic acid residues from sialyl-oligosaccharides released during glycoprotein degradation. Consequently, sialic acid-rich material accumulates in various tissues.Renal involvement, manifested by proteinuria, occurs in type II, or dysmorphic-type, sialidosis.[259] Light and electron microscopy of renal biopsy specimens shows massively swollen podocytes, due to the presence of innumerable thin-walled cytoplasmic vesicles.[260,261] Vesicles may also be seen in mesangial, endothelial and tubular epithelial cells. Material within these vesicles binds the lectin wheat germ agglutinin, confirming the presence of terminal sialic acid moieties. Podocyte detachment has been observed in sialidosis and may be pathogenetically related to the proteinuria.[260,262] Prominent accumulation of storage material in podocytes has also been described in I-cell disease, in which a mixture of mucopolysaccharides, lipids, and oligosaccharides accumulates,[263] and in Hurler syndrome, in which the stored material is mucopolysaccharide.[264]

Although renal disease is not unusual in older patients with glycogen storage disease type 1 (GSD1) due to glucose-6-phosphatase deficiency,[265] it is not clear that the pathologic changes in the kidney arise from storage of glycogen. It has been proposed that proteinuria and glomerulosclerosis in patients with GSD1 result from hyperfiltration injury.

DISORDERS OF THE PODOCYTE SLIT DIAPHRAGM

Congenital Nephrotic Syndrome of the Finnish Type (CNF)

Clinical Features

This autosomal recessive condition is the predominant cause of massive proteinuria in the first month of life. While Finland appears to have the world's highest incidence of CNF (about 1.2 cases/10,000 pregnancies), cases in children of non-Finnish ancestry have been reported from every part of the globe. Fetuses with CNF exhibit proteinuria *in utero*, manifested by elevated levels of α-fetoprotein in the amniotic fluid.[266] Edema frequently appears during the first week of life.[267] Cerebral palsy-like neurological disease has been described in a subset of patients, although the mechanisms of association with CNF are unclear.[268] Infants with CNF eventually develop renal failure, however historically the effects of malnutrition, overwhelming infection and thrombosis frequently resulted in early death, prior to the development of ESRD. Today, with aggressive therapy these children can survive infancy and grow sufficiently to undergo renal transplantation, with excellent rates of patient and graft survival.[269,270] In recent years, the clinical spectrum of glomerular disease due to NPHS1 mutations (see below) has expanded to include childhood- and adult-onset steroid-resistant nephrotic syndrome.[271,272] Furthermore, the heterozygous state may, in some cases, contribute to nephrotic syndrome occurring sporadically.[273,274]

Pathology

Nephrogenesis appears to proceed normally in kidneys of fetuses with CNF.[275] However, histological abnormalities such as focal mesangial hypercellularity, dilatation of Bowman's spaces and renal tubules, and visceral epithelial cell foot process fusion and microvillous transformation, are not unusual in these kidneys. Postnatally, early histological findings include mesangial hypercellularity and matrix expansion. Bowman's spaces and proximal tubules may become cystically dilated.[276,277] After six months, progressive glomerulosclerosis, tubular atrophy and interstitial fibrosis are evident. Immunofluorescence microscopy is typically unremarkable, except for albumin reabsorption droplets in tubular epithelial cells. Electron microscopy shows visceral epithelial

foot process fusion and microvillous transformation, while the GBM typically appears to be structurally normal.Variants on the classical histology have been described.[278]

Genetics and Pathophysiology

For many years efforts to understand the mechanism of proteinuria in CNF focused on the composition on the GBM, particularly proteins contributing to the negative charge of GBM, such as heparan sulfate proteoglycan.[279–282] However, the results of genetic mapping studies carried out in the 1990s, culminating in positional cloning of the *NPHS1* gene encoding nephrin, brought about a dramatic shift in focus to the podocyte slit diaphragm.[283]

Nephrin, an integral membrane protein with a single transmembrane domain and 8 extracellular immunoglobulin-like domains, is expressed at the slit diaphragms between glomerular visceral epithelial cell (podocyte) foot processes[284]; it is the cardinal member of the nephrin family of proteins.[285] The critical role of nephrin in maintaining glomerular permselectivity was confirmed in nephrin-knockout mice, which develop massive proteinuria *in utero* and exhibit absence of podocyte foot processes and slit diaphragms.[286] Nephrin strands from adjacent foot processes appear to interact to form pores in the slit diaphragm.[287] Nephrin interacts with several proteins, including podocin,[288] CD2-associated protein (CD2-AP)[289] and the related adaptor protein CIN85/Ruk_L,[290] ion channels,[291,292] junctional proteins[293,294] and the nephrin analogs Neph1[295] and Neph2.[296] The cytoplasmic tail of nephrin undergoes phosphorylation at several tyrosine residues in a tightly regulated process involving Src family protein kinases.[297–300] Covalent modifications of nephrin and interactions with its binding partners have been implicated in a variety of slit diaphragm functions including barrier formation, turnover, cell signaling and cytoskeletal regulation. Further studies in model systems have shown that nephrin can activate transcription, and that this function is enhanced by the interaction of podocin with the tyrosine-phosphorylated cytoplasmic tail of nephrin.[288,301]

Disease-causing mutations have been identified throughout the *NPHS1* gene, attesting to the functional importance of both the intracellular and extracellular domains of the protein.[302] Two mutations in *NPHS1*, Fin major (nt121delCT) and Fin minor (R1109X), were found to account for >90% of Finnish NPHS1 patients.[283,303]A variety of other mutations in *NPHS1* (>140) have been found in non-Finnish patients.[278,302,304–308] Milder forms of kidney disease may occur in some homozygotes and compound heterozygotes in whom at least one mutation is "mild," resulting in a protein that traffics to the cell membrane and retains partial function.[302,271]

Diagnosis

NPHS1 mutations are the predominant, but not sole, cause of nephrotic syndrome in the first month and account for an estimated 40 to 60% of nephrotic syndrome cases in the first three months of life.[278,309,308] Some infants with clinical CNF have mutations in podocin, the product of the *NPHS2* locus, and a congenital form of focal segmental glomerulosclerosis (FSGS) has been described in patients with *NPHS1* mutations in conjunction with mutations in *NPHS2* (see below).[302] Other conditions that may present with early nephrotic syndrome include congenital infections, renal disorders that typically present in late infancy and childhood, such as minimal change nephrotic syndrome and FSGS, and diffuse mesangial sclerosis (DMS), with or without other features of Denys-Drash syndrome (see below). Features consistent with a diagnosis of CNF include placental enlargement (placental weight greater than 25% of birth weight), positive family history of early nephrotic syndrome and intrauterine proteinuria, indicated by elevated amniotic fluid levels of α-fetoprotein. Hypoalbuminemia is generally severe at presentation (<1 gm/dL).Infants with CNF characteristically maintain a normal GFR through at least the first six months of life, so rapid deterioration of renal function should suggest another diagnosis. Renal biopsy after three to six months will reveal the typical histology of CNF which, while not necessarily specific, differs substantially from the histology of DMS, FSGS and nephropathies associated with congenital infection.The cloning of *NPHS1* and *NPHS2* and the availability of commercial mutation analysis have enhanced diagnostic precision in infants with nephrotic syndrome. Because of the clinical and histological overlap between *NPHS1*- and *NPHS2*-related disease, molecular diagnostic approaches should incorporate analysis of both genes.[302] Screening for less frequent mutations in the *WT1*, *LAMB2* and *PLCE1* genes can be considered in cases in which *NPHS1*/*NPHS2* analysis is non-diagnostic or kidney biopsy demonstrates DMS.

Prenatal diagnosis of CNF due to *NPHS1* mutations is complex.[310] Fetuses with CNF due to *NPHS1* mutations exhibit elevated amniotic fluid α-fetoprotein (AFP) levels during the second trimester.[266] However, amniotic fluid AFP may be elevated in other conditions, such as neural tube defects, and there is overlap between the amniotic fluid AFP levels of fetuses with CNF and healthy carriers of *NPHS1* mutations.[311] Prenatal diagnosis of CNF is greatly facilitated if the disease-causing mutation in the family is known.[312] If the mutation is not known, sequencing of the entire

NPHS1 gene within the required time interval may not be possible. In this situation, the finding of elevated amniotic fluid AFP should prompt a fetal ultrasound to exclude a neural tube defect, followed by serial measurement of amniotic fluid AFP during the second trimester. In fetuses with CNF AFP levels will remain elevated, while levels will decrease in healthy carriers of *NPHS1* mutations.[310]

Treatment

With appropriate management, infants with CNF can thrive sufficiently to allow successful renal transplantation.[269,270] However, such treatment is complex, requiring meticulous attention to nutrition, albumin replacement, correction of hypothyroidism, prophylaxis and prompt recognition and treatment of bacterial sepsis, and prevention of thrombosis. Elective bilateral nephrectomies are performed once the child's real weight reaches about 7 kg. A period of hemo- or peritoneal dialysis for 6−8 weeks allows for optimization of nutrition and normalization of plasma proteins, and then the child undergoes transplantation. While this approach has resulted in excellent rates of patient and graft survival, others have advocated unilateral nephrectomy combined with captopril and indomethacin therapy and later renal transplantation.[313]

Autosomal Recessive Steroid-Resistant Nephrotic Syndrome

Clinical Features

Fuchshuber and colleagues first classified familial autosomal recessive SRNS as a subgroup of idiopathic nephrotic syndrome for genetic mapping studies that culminated in the identification of the *NPHS2* gene and its gene product podocin.[314,315] The defining clinical features included: familial occurrence, childhood-onset of nephrotic syndrome, resistance to steroid therapy, rapid progression to ESRD and absence of recurrence after kidney transplantation. It has since become evident that SRNS due to *NPHS2* mutations is the single most common cause of nephrotic syndrome during the first year of life, accounting for 30 to 40% of cases.[309] Furthermore, 10 to 30% of patients presenting as sporadic cases of childhood-onset SRNS represent homozygous or compound heterozygous offspring of unaffected heterozygous parents, with estimated frequencies dependent on racial and ethnic background.[316,317−320]

Among large cohorts of childhood-onset SRNS, age at presentation has been reported to range from <months to 24 years, with estimated means of 3 to 6 years.[320−322] Age at ESRD has been reported to range from 4 to >27 years, with estimate means of 8 to 10 years. Patients with SRNS and homozygous or compound heterozygous *NPHS2* mutations appear to suffer accelerated progression of disease, in comparison to patients with SRNS but without these mutations.[323,320]

Variable clinical presentations associated with pathogenic *NPHS2* mutations are well described. There are several reports of infantile SRNS demonstrating clinical overlap with CNF; these cases result from *NPHS2* mutations that may be associated with digenic inheritance of *NPHS1* mutations.[324,309,302,325] Familial forms of adult-onset focal glomerulosclerosis also result from *NPHS2* mutations.[326] By comparison to childhood-onset cases, adult-onset cases demonstrate variability in penetrance and clinical course, and association with compound *NPHS2* mutations including common polymorphisms (see below). Viewed in this light, childhood-onset SRNS may represent the most severe manifestation of *NPHS2*-linked glomerular disease, modified by other as yet incompletely undefined genetic and environmental factors.[327] The overall contribution of *NPHS2* mutations to sporadic cases of focal glomerulosclerosis is uncertain but almost certainly lower in adults than children.[328,316,329,330,331,332,326]

Extrarenal manifestations of SRNS associated with *NPHS2* mutations have not been described. Indeed, multisystem findings suggest the likelihood of an alternative primary diagnosis. Additional clinical features of familial SRNS are described below.

Pathology

In familial SRNS, more than 60% of kidney biopsy specimens demonstrate focal glomeruloscerosis as the principal finding.[319,321,333] Variable findings include mesangial expansion, and IgM, IgG and/or complement component deposition. Remaining biopsy specimens generally demonstrate minimal change, although other histological findings have been described.[319]

Genetics and Pathophysiology

Fuchschuber and colleagues first established linkage of a gene for autosomal recessive SRNS in eight families to chromosome 1q-25-q31.[315] Boute and colleagues later reported identification of the *NPHS2* gene and pathogenic mutations in these and several additional families.[314] The *NPHS2* gene spans eight exons over 25 kb, producing a 1853-base pair transcript and a 383-amino acid protein, termed podocin.

Podocin is a member of the prohibitin homology (PHB)-domain family, a family of membrane proteins that associate preferentially with cholesterol-rich lipid rafts in which they play specialized roles.[334] Podocin contains a 104-amino acid amino-terminal intracellular domain, a 17-amino acid amino-terminal-adjacent intramembranous domain

and a 262-amino acid carboxy-terminal intracellular domain; the intramembranous domain mediates attachment to the inner leaflet of the cell membrane and thus confers a hairpin structure.

Several important aspects of podocin function have recently been elucidated. Podocin is expressed in the kidney exclusively, within podocyte foot process plasma membranes at sites of insertion for slit diaphragms.[314,335,289] Podocin forms homo-oligomers and interacts with nephrin and other slit diaphragm proteins within specialized plasma membrane domains, suggesting roles in slit diaphragm formation, maintenance and/or signaling.[288–290] Like other PHB-domain proteins, podocin binding to cholesterol is required for important cellular effects: in particular, podocin regulates the activity of TRPC6 ion channels,[336] calcium-permeable cation channels associated with the slit diaphragm and implicated themselves in inherited glomerular disease (see below). The phenotypes of podocin-mutant mice have confirmed the importance of podocin in slit diaphragm development and maintenance.[337–339]

To date, over 100 *NPHS2* mutations have been identified. The majority are missense mutations, with the remainder nonsense, frameshift and splicing mutations.[319–321,340] Large genetic rearrangements have not been described. *NPHS2* mutations are distributed throughout the gene, with genotype-phenotype correlations suggesting that protein-truncating mutations correlate with earlier onset of disease.[341,320] Disease-associated amino acid-substitutions may alter expression levels and/or intracellular trafficking[301,342–344] and produce disturbances in homo-oligomerization, protein-protein interactions and/or recruitment of nephrin and other slit diaphragm protiens to specialized plasma membrane domains.[301,342,326,336,344] The R229Q variant of podocin has attracted particular attention. Present in various ethnic populations at a frequency of 1-6%, this variant may contribute to disease pathogenesis, most convincingly in the presence of additional genetic mutations.[273,326,327,330,332,345]

Diagnosis

SRNS is a clinicopathological entity diagnosed *a posteriori*. A positive family history can indicate a genetic basis for SRNS.The role of *NPHS2* mutational analysis in the diagnosis and management of nephrotic syndrome is evolving. On the basis of available data, a significant percentage of children and an unknown but much smaller percentage of adults will have *NPHS2* mutations at first presentation with nephrotic syndrome, suggesting that genetic testing may not be useful in adults. Nonetheless, identification of *NPHS2* mutations can minimize patient exposure to ineffective and potentially harmful treatments.Several investigators have advocated genetic testing in familial cases of nephrotic syndrome or concomitant with first-time empiric steroid therapy in non-familial cases.[323,340] Others have argued that knowledge of genetic status serve as an entry criterion for clinical trials.[346] *NPHS2* testing may reveal polymorphisms of uncertain clinical significance, posing challenges in diagnosis and management.

Treatment

Resistance to steroid therapy is a diagnostic feature of SRNS. Criteria for steroid resistance itself have been outlined.[347] Importantly, retrospective studies have now confirmed steroid resistance in large groups of patients with homozygous or compound heterozygous *NPHS2* mutations.[321,319] Partial response patterns with steroid-dependence have also been reported for a small number of patients with heterozygous *NPHS2* mutations.[321]

There are no established treatments for familial SRNS. In retrospective analyses of small groups of patients with *NPHS2* mutations, cytotoxic agents have not been effective.[319,348] Reports on the use of cyclosporine A are limited.[321,348]

Kidney transplantation is the preferred treatment for patients near or at ESRD. Recurrence of proteinuria after kidney transplantation for familial SRNS is infrequent. Weber and colleagues[320] reported the recurrence of proteinuria in only one of 32 patients with pathogenic *NPHS2* mutations, and Ruf and colleagues[319] in only two of 24 patients; in none of these cases were biopsy findings reported. By contrast, Ruf and colleagues reported recurrence of proteinuria in seven of 20 patients (35%) with SRNS but without *NPHS2* mutations. In a contrasting series of reports, Bertelli, Caridi and colleagues reported recurrence of proteinuria in patients with *NPHS2* mutations comparable in frequency to that in patients with SRNS but without *NPHS2* mutations.[348,349] However, several of these patients were *NPHS2* heterozygotes with polymorphisms of unclear significance, raising uncertainty regarding the primary diagnosis. In addition, the majority of patients classified with recurrence of proteinuria underwent empiric treatment for recurrent primary disease without report of biopsy findings.

Winn and colleagues have emphasized caution in selecting first-degree relatives of patients with familial focal glomerulosclerosis as donors for kidney transplantation,[350] suggesting genetic risks for poor outcome in donor and recipient. Outcomes of kidney transplantation in patients with homozygous or compound heterozygous *NPHS2* mutations and related donors have not been reported.

Nephrotic Syndrome, Early-Onset, Type 3

Clinical Features

In 2006, Hinkes et al. described linkage by homozygosity mapping to chromosome 10q23 in seven of 26 consanguineous families with SRNS. Candidate-gene sequencing identified homozygous mutations in the *PLCE1* gene encoding phospholipase Cε, thus the putative cause of NPHS3. Twelve affected children were proteinuric by four years of age and nine progressed to ESRD by age five. Remarkably, two children remitted in association with treatment by steroids or cyclosporine A.[351] Homozygous and compound heterozygous mutations have since been identified in 30% of cases of early-onset SRNS with biopsy findings of diffuse mesangial sclerosis (DMS)[352]; additional case series have also suggested a close association with this specific clinicopathological entity.[353,354] Disease-associated mutations have been identified in unaffected family members as well, indicating that the mutations are incompletely penetrant, perhaps variably expressive,[353,355] and thus confounding on the matter of treatment-responsiveness. Extrarenal manifestations of this disorder have not been described.

Pathology

DMS with its hallmark features, described below in connection with DDS, is the pathological entity most closely associated with NPHS3.Indeed, *PLCE1* mutations are those most frequently identified in DMS.[352] Focal glomerulosclerosis has been described in the balance of NPHS3 cases undergoing biopsy.[351,353]

Genetics and Pathophysiology

Human *PLCE1* is a large gene spanning 34 exons over >300 kb.It encodes at least two major forms of phospholipase Cε—PLCε1a of 2,303 amino acids and PLCε1b of 1,994 amino acids—that arise by alternative splicing of exons 1 and 2 to exon 3 and thus differ at their amino termini.[356–358] The *PLCE1* gene was cloned by homology to other phospholipase C family members. Accordingly, phospholipase Cε serves canonical signaling pathways, hydrolyzing phosphatidyl inositol 4,5-bisphosphate to generate inositol 1,4,5-triphosphate and diacylglycerol, involved respectively in downstream mobilization of intracellular Ca^{2+} stores and activation of protein kinase C Phospholipase Cε is one of 13 known human phospholipase C family members, and is alone in one of six subgroups encompassed by this family.[359]

Like other phospholipase C family members, phospholipase Cε contains core X and Y domains constituting the catalytic domain, and upstream pleckstrin-homology and EF-hand domains.[360] In recent years, it has become evident that phospholipase Cε is otherwise unique, integrating a multitude of signals that emanate from extra- and intracellular-sources and are mediated by major classes of heterotrimeric and monomeric G proteins. As investigated in a variety of cell culture and reconstituted systems, phospholipase Cε: (1) Binds activated Ras family members at a Ras association (RA) site downstream from the catalytic domain; these interactions direct patterns of subcellular localization and enzyme activation, and thus mediate cellular responses to receptor tyrosine kinase stimulation by ligands such as epidermal growth factor and platelet derived growth factor.[356,357,361–363] (2) Binds Rho family members independent of Ras, by which dual modulation of signaling inputs is achieved.[364] (3) Respond to stimulation via G protein-coupled receptors, through Gα subunits $G\alpha_{12/13}$[356,362] or Gβγ subunits,[360] and/or monomeric G-protein signaling intermediates including Rho and Rap.[365,366] (4) Catalyzes, by way of an amino-terminal CDC25 homology domain, guanine nucleotide exchange (GEF), by which GDP bound to G protein is exchanged for GTP, the activity of G proteins is regulated, and the possibilities for autoregulatory pathways expanded.[367]

Phospholipase Cε is in podocytes, where its roles are as yet poorly understood but with preliminary indications of specialized interactions with the IQ motif-containing GTPase-activating protein 1 (IQGAP1), a multifunctional protein implicated in slit diaphragm signaling,[294,351] and B-RAF, a serine/threonine kinase effecting diverse pathways of G protein signaling.[368,369]

Over 20 disease-associated *PLCE1* mutations have been reported, the majority homozygous, truncating mutations. Mutations span the gene and genotype-phenotype correlations are not clearly evident.[353] Inasmuch as mutations have been identified in unaffected individuals, future considerations will include modifier genes and oligogenic inheritance patterns, mechanisms compensating for mutation effects, environmental modifiers, etc., accounting for the multifunctional nature of the protein.

Diagnosis

The frequency of *PLCE1* mutations in childhood-onset SRNS is uncertain. At present, it seems prudent to reserve genetic testing for patients with biopsy findings of DMS, parental consanguinity or early-onset (age<4 years) manifestations with unrevealing *NPHS1*/*NPHS2* testing.The frequency of identified mutations may decrease with age of onset and appears to be negligible among adults.[370,371] Heterozygous mutations have been identified and remain of unclear significance.[371]

DISORDERS OF THE PODOCYTE CYTOSKELETON

Autosomal Dominant Focal Segmental Glomerulosclerosis

At least four loci—FSGS1, FSGS2, FSGS3 and FSGS4—have been implicated in genetic subtypes of focal glomerulosclerosis.By comparison to genetic causes of nephrotic syndrome in early childhood, those at the root of late-onset focal glomerulosclerosis occur in autosomal dominant patterns with perhaps wider variability in penetrance and expressivity. Mutations at these loci are rare.Notwithstanding, studies on these loci have provided insights into biological pathways required for maintenance of glomerular function.

FSGS1: Kaplan and colleagues identified mutations in the *ACTN4* gene encoding α-actinin-4 in three families with autosomal dominant focal glomerulosclerosis.[372] Kidney disease in affected family members was marked by incomplete penetrance, detection of proteinuria during adolescence or adulthood, slow progression of kidney disease and variable progression to ESRD.[372,373] Biopsy findings of focal glomerulosclerosis established the diagnosis in several probands from each of the families. Disease-causing *ACTN4* mutations have since been reported in additional families but not definitively—and not widely—in screening studies of patients with sporadically occurring focal glomerulosclerosis.[328,374,375]

Alpha-actinin-4 is one of four α-actinin family members implicated in filamentous F-actin-binding, cytoskeletal organization and other diverse cellular functions.[376] α-actinins-1 and -4 are expressed primarily in non-muscle cells, and α-actininis-2 and -3 in muscle cells.Identified originally by expression cloning, the *ACTN4* gene on chromosome 19q13 encodes a 3893-base pair transcript and 911-amino acid protein, 86% identical to the cardinal α-actinin-1 family member.[377] Each α-actinin family member contains an amino-terminal head composed of two calponin-homology domains constituting the actin-binding domain, a central rod domain composed of four spectrin repeats, and a carboxy-terminal calcium-binding calmodulin-like domain. The α-actinins homo-dimerize, forming anti-parallel "dumbbells" that bridge F-actin fibers. In recent years, it has become clear that spectrin repeats within the rod domain confer strength and elasticity on α-actinin-mediated cross-links. Moreover, the spectrin repeats can bind a myriad of proteins, both within F-actin filaments and within specialized cellular domains that can include intercellular junctional complexes, focal adhesions at sites of cell-matrix interactions, and cellular processes and protrusions. The body of evidence indicates that the α-actinins are multifunctional, participating in the regulation of diverse cellular behaviors including cell adhesion and motility.

Alpha-actinin-4 but not -1 is present within the kidney glomerulus; its expression and distribution are subject to regulation in experimental glomerular disease.[372,378] Among the small number of disease-causing *ACTN4* mutations reported to date, most are missense mutations within exon 8, altering the actin-binding domain and thus the binding properties of the mutant protein.[372,375,379] Disease-associated α-actinin-4 mutants bind F-actin with higher affinity than the wild-type form, a gain of function offering a tenable explanation for autosomal dominant inheritance.[372,380] Follow-up studies of α-actinin-4 mutants suggest that cellular disease mechanisms are more complicated. In kidney biopsies from FSGS1 patients, and in a variety of model systems, α-actinin-4 mutants aggregate abnormally, undergo rapid degradation and/or fail to traffic to the sites of F-actin filaments, implying that loss-of-function mechanisms distinct from altered actin binding may prevail.[381–384] Homozygous mice rendered deficient in α-actinin-4 by targeted mutagenesis die prematurely with severe glomerular disease, a process mediated at least in part by defects in α-actinin reinforcement of integrin-mediated podocye attachments, further emphasizing the likelihood of loss of function mechanisms.[385,386] Given these multifunctional roles of the α-actinins, it is likely that the effects of *ACTN4* mutations ramify widely through the glomerulus, by mechanisms still incompletely understood.

FSGS2*:* Winn and colleagues described a large New Zealand family with kidney disease segregating in an autosomal dominant pattern.[387,388] Affected individuals presented at a mean age of 33 years with proteinuria and elevation of serum creatinine; more than ten family members evaluated by kidney biopsy demonstrated focal glomerulosclerosis. Extrarenal manifestations of genetic disease were not described. Mapped to chromosome 11q21–q22, the disease gene was eventually identified as *TRPC6* encoding the transient receptor potential C6 ion channel.[389] Reiser et al. simultaneously reported *TRPC6* mutations in five families with autosomal dominant FSGS.[292] Mutations have since been reported in additional families with adult-[390] or childhood-[391] onset of disease, and in sporadic cases from a large Spanish cohort.[392]

TRPC6 is a member of the transient receptor potential (TRP) superfamily of ion channels, and specifically the "canonical" subgroup comprised of seven channels (C1-7) in mammals that share sequence homology with each other and Drosophila orthologues.[393] TRPC6 contains six transmembrane domains within which the fifth and sixth domain putatively form the channel

pore. Both the amino-terminal domain containing ankyrin repeats, and the carboxy-terminal containing a proline-rich region, are intracellular, and offer regulatory sites for channel activity and turnover. TRPC6 forms homo-oligomers and—with other TRPC subgroup members—hetero-oligomers, constituting Ca^{2+}-permeable, non-selective cation channels effecting localized changes in intracellular Ca^{2+}, and thus a variety of cellular processes including cytoskeletal remodeling[394–396] and secondary ion channel activation.[397] TRPC6 is widely expressed.In kidney, it is expressed in glomeruli and tubules and—within glomeruli—in endothelial cells, mesangial cells and the cell body, and primary and foot processes of podocytes.[292,389] TRP channels including TRPC6 are widely recognized as cellular sensors.Like other TRPC subgroup members, TRPC6 is activated by phospholipase C-coupled receptor signaling pathways originating from G protein-coupled receptors and receptor tyrosine kinases.[398] TRPC6 may also be mechanosensitive,[336,399,400] of potential importance to its functions in the glomerulus under conditions of pressurization and mechanical stress. TRPC6 interacts directly with nephrin and podocin in heterologous systems suggesting a specific role(s) in the slit diaphragm.[292]

Disease-causing TRPC6 mutants investigated in heterologous systems operate by gain of function, amplifying Ca^{2+} signals. All but one ("K874X") of seven described to date are missense mutations in the amino- or carboxy-terminus. Mutations variably cause increases in agonist-induced, channel-mediated whole-cell currents[292,389] or Ca^{2+} transients,[390] or delays in wild-type patterns of voltage-dependent channel inactivation.[391] The P112Q mutation within the amino-terminal-most ankyrin repeat increases surface expression of the channel.[389] The mechanisms by which TRPC6 mutants modify cellular processes so as to contribute to disease progression are likely complex and otherwise at an early stage of elucidation.

FSGS3: The importance of the adaptor protein CD2-associated protein (CD2AP) in glomerular function was first demonstrated in a targeted mouse mutant.[401] Homozygous mice with complete CD2AP deficiency developed proteinuria and died prematurely of kidney failure, with histological findings of mesangial hypercellularity, abnormal extracellular matrix accumulation, immunoglobulin deposition, and podocyte foot process effacement. Heterozygotes demonstrated similar findings over a prolonged time course.[402] Since report of the CD2AP mutant mouse strain, additional evidence has implicated CD2AP in human glomerular disease. A heterozygous splicing mutation in the CD2AP gene was identified in two of 45 patients with idiopathic focal glomerulosclerosis.[402] A homozygous truncating mutation was identified in a 10-month-old child with collapsing glomerulopathy.[403] Three heterozygous mutations with functional consequences were identified in an Italian cohort of patients with sporadic idiopathic FSGS.[404]

CD2AP was first identified as an adaptor protein for CD2, a lymphocyte membrane protein that promotes attachment to antigen-presenting cells.[405] A Src homology 3 (Sh3) domain-containing protein, CD2AP is widely expressed and interacts with nephrin and podocin, co-localizing with nephrin at sites of slit diaphragm insertion into podocyte foot processes, and thus implying roles in slit diaphragm development, maintenance and/or signaling.[289,401,406–409] Kim and colleagues have raised the possibility of roles for CDAP in endocytic and protein degradation pathways within glomerular cells, required for protein turnover and maintenance of glomerular architecture;[402] indeed, at least one CD2AP mutation is associated with decreased expression of nephrin and podocin.[404] The action(s) of CD2AP may be mediated in part through actin binding, which is altered by at least one disease-causing mutation.[410,403]

FSGS4: Brown et al. have described pathogenic mutations in the *INF2* gene encoding inverted formin 2, in nine families with autosomal dominant FSGS presenting in adolescence or young adulthood.[411] Kidney biopsy findings in FSGS4 are generally typical of secondary FSGS. One additional family has been reported, in which the proband was a 9 year-old boy presenting with proteinuria.[412]

Inverted formin 2 (INF2) is a member of the formin family, consisting of 15 members in mammals and involved centrally in cytoskeletal remodeling.[413] Like that of other formins, the modular structure of INF2 consists of a diaphanous inhibitory domain (DID), formin homology 1 (FH1) and 2 (FH2) domains that underpin actin filament nucleation and polymerization/depolymerization processes, and a diaphanous autoregulatory domain (DAD) that regulates formin activity largely through inhibtory interactions with the upstream DID. Extrapolating from other formins, INF2 operates as a dimer in which FH2 domains are paired head-to-tail, forming a doughnut structure.Perhaps uniquely among the formins, INF2 severs actin filaments, an activity regulated by DID-DAD interactions.[414,415] INF2 may also be unique among the formins in its endoplasmic reticulum localization[415] and roles in vesicular trafficking.[416]

INF2 is widely expressed and, in the kidney glomerulus, appears to be expressed primarily within podocytes.[411] Disease-causing *INF2* mutations described to date are missense mutations within the DID. In heterologous systems, these mutations alter cellular INF2 distribution from a perinuclear pattern typical of the wild-type protein to a more diffuse pattern. The effects of

these mutations on a multitude of cellular processes including cytoskeletal remodeling and vesicular trafficking are likely manifold and await further investigation.

MYH9-Related Disorders (Epstein and Fechtner Syndromes)

Epstein and Fechtner syndromes are autosomal dominant disorders that share some features with Alport syndrome, including hematuria, progression to ESRD and sensorineural deafness. In addition, patients with these conditions have thrombocytopenia and giant platelets, and Fechtner patients exhibit granulocyte cytoplasmic inclusions known as Döhle-like bodies.[417,418] At least some of these patients have ultrastructural GBM changes that resemble those of Alport syndrome.[419,420] Epstein and Fechtner syndromes are transmitted as autosomal dominant conditions.[418–425]

Until recently Epstein and Fechtner syndromes were considered variants of Alport syndrome. However, recent molecular studies have demonstrated that these disorders have a distinct pathogenesis. First, both disease loci were mapped to chromosome 22q11-13.[427,428] This led directly to the finding that Epstein and Fechtner syndromes, along with two other genetic conditions featuring giant platelets, Sebastian syndrome and May-Hegglin anomaly, and nonsyndromic hereditary deafness DFNA17, result from heterozygous mutations in the gene *MYH9*, which encodes nonmuscle myosin heavy chain IIA (NMMHC-IIA).[429–432]

Clinical Features

Kidney disease is a defining feature of Epstein and Fechtner syndromes but occurs in fewer than 50% of patients with *MYH9* mutations.[431,433–435] It is characterized by variable hematuria, proteinuria and chronic kidney disease, from mild to progressive and leading to ESRD by late adolescence.[424,435–437] Intra-familial differences in kidney disease have been described.[438] Hematological abnormalities are nearly universal in *MYH9*-related disorders and always accompany kidney disease; their clinical features have been reviewed.[439] Sensorineural hearing loss is more frequent than kidney disease and may occur in the absence of other disease manifestations.[429,431,433] Cataracts are a further manifestation of *MYH9*-related disorders.[433,435]

Pathology

Light microscopic findings in Epstein and Fechtner syndromes are non-specific and include glomerulosclerosis and tubulointerstitial fibrosis. Glomerular basement membrane changes seen by electron microscopy have been likened to those in Alport syndrome, with variable thickening, thinning and lamination,[419,420,440–442] but findings of normal-appearing glomerular basement membrane have also been reported.[438,441]

Genetics and Pathophysiology

Three non-muscle myosin class II isoforms are expressed in human tissues, NMMHC-IIA, IIB and IIC.[443] While platelets and granulocytes express the IIA isoform exclusively, the kidney, eye and ear express the IIA isoform as well as at least one additional isoform, an arrangement that likely influences the clinical phenotype of *MYH9*-related diseases.[444] NMMHC-IIA consists of an amino-terminal motor domain that catalyzes the hydrolysis of ATP and binds to actin, and a tail domain that participates in dimer formation.[445] The basic functional unit of NMMHC-IIA is a hexamer in which the dimer is complexed with one pair of essential light chains and one pair of regulatory light chains.[446] Enzymatic activity of NMMHC-IIA is regulated by phosphorylation of regulatory light chain, a target of Rho signaling pathways.[447,448] NMMHC-IIA units assemble at the tail domain as filaments, i.e. bundles, in which motor domains extend outward giving a characteristic "bipolar" array,[449] suited to isometric contraction or net movement of bound actin bundles, and thus constituting major components of the actomyosin motor complex within non-muscle cells. Assembly/disassembly and functions of the actomyosin motor complex are highly regulated, with α-actinin playing an especially important role as an actin cross-linker, alternating with myosin filaments to form a pseudo-sarcomeric unit.[450,451] In contrast to NMMHC-IIB, NMMHC-IIA appears to spend little time bound strongly to actin during its contraction cycle; it has been postulated that this property confers a means of rapid cytoskeletal adaptation to mechanical stress.[452,453]

The mechanisms by which *MYH9* mutations result in glomerular disease are unknown.NMMHC-IIA is expressed in the podocytes of adult kidneys suggesting that absent or defective NMMHC-IIA could adversely affect podocyte function, but the protein is also expressed in mesangial and endothelial cells.[454,455] Extrapolating from work in model cell lines, it is possible to postulate effects on cytoskeletal function, cell-matrix interactions and/or cell-cell interactions.[456–459] Non-muscle myosin is also implicated in extracellular matrix turnover.[460] Within podocytes, NMMHC-IIA function is almost certainly connected to the highly specialized localization and configuration of actomyosin complexes within foot processes.[461,462] To what degree the roles of NMMHC-IIA in kidney overlap

with those in blood cells—themselves at an early stage of elucidation[463]—remains to be determined.

Over 100 mutations in the *MYH9* have been described but not all are independent having arisen spontaneously in different families. Mutations occur in well-described hotspots primarily in the tail domain; most but not all are missense mutations.[433,464,435] Motor domain mutations impair NMMHC-IIA's capacity to move actin,[465] while tail domain mutations compromise filament assembly.[466] Mutations affecting the motor domain of NMMHC-IIA result in severe thrombocytopenia, greater numbers of neutrophil inclusions and development of nephropathy and deafness before age 40, while tail domain mutations are associated with milder degrees of thrombocytopenia, fewer neutrophil inclusions and less severe renal and cochlear involvement.[435] The basis for genotype-phenotype correlations are unknown with possibilities including tolerance for tail mutation effects in kidney and/or overlapping functions of NMMHC-IIB present in kidney but not bood cells.Dominant negative effects of mutant NMMHC-IIA proteins have been recapitulated *in vitro*.[466]

Diagnosis and Treatment

Epstein and Fechtner syndrome are diagnosed primarily on clinical grounds. They are distinguished from Alport syndrome by the accompanying hematologic abnormalities and, in informative families, demonstration of autosomal dominant inheritance. Diagnostic considerations in *MYH9*-related disease presenting chiefly as a blood disorder are reviewed elsewhere.[433] Characteristic patterns of NMMHC-IIA staining in blood cells may be a useful adjunct in diagnosis.[467] *MYH9* gene testing is commercially available.

There are no proven treatments in Epstein and Fechtner syndrome. A study of four patients demonstrated the anti-proteinuric effects of renin-angiotensin inhibitors.[435] Owing to platelet abnormalities, patients with Epstein and Fechtner syndrome may be at increased risk of peri-operative bleeding requiring specialty management.[468]

DISORDERS OF PODOCYTE GENE REGULATION

Denys-Drash Syndrome (DDS) and Frasier Syndromes

Clinical Features

DDS is a constellation of disorders that includes Wilms' tumor, XY gonadal dysgenesis with ambiguous genitalia, and a nephropathy that typically presents as infantile-onset nephrotic syndrome, with rapid progression to renal failure. The association of these disorders was first described by Denys in 1967 and subsequently by Drash in 1971.[469,470] Children with DDS may exhibit the complete constellation of abnormalities, or may exhibit nephropathy and genital abnormalities without Wilms' tumor, or nephropathy and Wilms' tumor without genital abnormalities.[471] Thus the common feature of DDS patients is the nephropathy. Proteinuria is usually documented during infancy and is frequently of nephrotic range. Microhematuria and hypertension are not uncommon. Most patients progress to ESRD by three years of age.

In those patients with a 46XY karyotype, abnormalities of the external genitalia vary from hypospadias with cryptorchidism to clitoral enlargement with labial fusion. External genitalia usually appear normal in those whose karyotype is 46XX. Anomalies of the internal reproductive organs, including atrophy of the vagina and uterus, streak ovaries or dysgenetic testes, may occur with either karyotype. The abnormal gonads of 46XY patients may evolve into gonadoblastoma.

Children with DDS are significantly more likely to have bilateral Wilms' tumor, and are considerably younger when their tumors are identified, than children with sporadic Wilms' tumor.[472] However the histology and behavior of Wilms' tumors associated with DDS are similar to those of sporadic Wilms' tumor.

Pathology

Although a variety of renal histologic abnormalities has been reported in patients with DDS, Habib and her colleagues demonstrated that the common glomerular alteration in these patients is diffuse mesangial sclerosis, or DMS.[473] The glomerular changes of DDS-associated DMS are somewhat variable, depending on the cortical depth of the glomerulus, and therefore its degree of maturation, and the timing of the biopsy or nephrectomy. Juxtamedullary glomeruli show podocyte hypertrophy and mesangial matrix increase without mesangial proliferation. Middle cortical glomeruli show mesangial expansion with obliteration of the capillaries, so that the tuft appears to be a "solidified mass," in Habib's words,[473] covered by a corona of hypertrophied podocytes. Bowman's space is patent and sometimes appears enlarged, although crescents may be present. Finally, glomeruli in the subcapsular zone appear extremely immature, with small tufts containing a few capillary loops, surrounded by podocytes.With time, juxtamedullary glomeruli acquire the appearance of middle cortical glomeruli. This evolution suggests that the formation of glomeruli is initiated more or less normally, but effective maturation is not sustained.

Genetics and Pathophysiology

DDS arises from mutations in WT1, the gene encoding a transcription factor known as the Wilms' tumor

suppressor. The *WT1* gene was identified in 1990, and found to be homozygously deleted in a subset of sporadic Wilms' tumors.[474,475] In 1991, Pelletier and colleagues first reported missense mutations in the WT1 gene in DDS patients.[476]

The *WT1* gene consists of 10 exons. The WT1 protein has four zinc finger domains and a predicted molecular weight of 47 to 49 kDa, according to the presence or absence of two alternatively spliced exons.[477] WT1-expressing cells can generate four *WT1* transcripts, carrying both, one or none of the alternative exons.The first splice consists of a separate exon (exon 5) that encodes a 17-amino acid sequence inserted between the proline-rich amino-terminal domain and the carboxy-terminal zinc finger domains. The second splice results in the insertion of three amino acids—lysine (K), threonine (T) and serine (S)—between zinc fingers 3 and 4. WT1 products containing this second insertion are termed WT1 + KTS, while those lacking it are designated WT1 − KTS. The predominant *WT1* transcript contains both alternative exons, while the least prevalent transcript lacks both exons.

The WT1 protein contains at least two functional domains. The proline-rich amino-terminal domain is essential for transcriptional regulation and also mediates self-association of WT1.[478,479] The carboxy-terminal domain consists of four Cys_2-His_2 zinc finger motifs that mediate binding of WT1 protein to DNA. Zinc fingers 2, 3 and 4 of WT1 exhibit strong homology to the three zinc fingers of the early growth response gene-1 protein product, EGR1,[480,481] and WT1-KTS binds to the consensus binding site for EGR1 (5′-GCG (G/T)GGGCG-3′).[480] However, WT1 binds with 20- to 30-fold greater affinity to a slightly different motif, 5′-GCGTGGGAGT-3′, termed WTE.[482] WT1 + KTS and WT1 − KTS appear to have somewhat different DNA binding specificities,[483] suggesting that alternative splicing of WT1 may be functionally important.

In contrast to EGR1, a potent transcriptional activator, the WT1 protein represses transcription of most of the genes to which it binds.[484] *In vitro* studies have demonstrated WT1-mediated transcriptional repression of the genes encoding IGF-II,[485] IGF-I receptor,[486] PDGF-A chain,[487,488] EGR1,[489] TGF-β1[490] and the EGF-receptor.[491] Transcriptional repression by WT1 may be modulated by other proteins. For example, the ability of WT1 to repress, rather than activate, transcription by binding to the EGR1 consensus site appears to depend upon the presence of the ubiquitously expressed tumor suppressor p53.[492] WT1 is also capable of binding to RNA, and may regulate gene expression by post-transcriptional as well as transcriptional mechanisms.[493]

Introduction of wild-type WT1 into embryonal tumors such as Wilms' tumor and osteosarcoma induces programmed cell death. WT1-induced apoptosis is characterized by repression of EGF-receptor mRNA and protein, and by induction of the cyclin-dependent kinase inhibitor p21, associated with G1 phase arrest.[491,494,495]

WT1 mRNA is expressed during nephrogenesis in the condensed mesenchyme, renal vesicle and podocytes.[496,497] Podocytes of adult kidneys continue to express *WT1* mRNA, but at a reduced level compared to the developing organ.[496,497] In the induced mesenchyme, expression of *WT1* mRNA is preceded by increased expression of the paired-box transcription factors PAX2 and PAX8; the PAX2 and PAX8 proteins have been shown to bind and activate the promoter of the *WT1* gene, and to stimulate expression of endogenous WT1.[498,499] The temporal and spatial pattern of *WT1* mRNA expression is consistent with a role for WT1 in mediating differentiation of nephrogenic mesenchyme to glomerular epithelium, and in maintaining the epithelial phenotype of the podocyte.[484] In this scheme, loss of WT1 function can lead to uncontrolled growth of metanephric blastema cells, resulting in Wilms tumor, as well as aberrant podocyte differentiation. *WT1* mRNA is also expressed in primordial tissue of the gonadal ridge, in ovarian follicular granulosa cells, and in Sertoli cells of the testis.[496,497] Normal maturation of the gonads may also depend upon the functional integrity of WT1. For example, WT1 acts synergistically with the testis-determining factor SRY to activate transcription from promoters containing binding sites for SRY.[500] XY mice lacking KTS + isoforms exhibit reduced expression of *Sry* in the urogenital ridge and a female phenotype.[501]

Most patients with DDS have a mutation in exon 9 of the *WT1* gene affecting the third zinc finger.[502] The predominant abnormality is a missense mutation R394W that abolishes the DNA-binding activity of WT1, as do the less prevalent missense mutations D396B and R366H.[503,504,476] Almost all of these mutations appear to have arised *de novo*, but inheritance of *WT1* mutations has been described.[471]

Wilms' tumors in DDS patients are hemizygous for the mutant *WT1* allele,[476] indicating that the tumors develop through a recessive mechanism. The persistence of nephrogenic rests (undifferentiated mesenchyme) in DDS kidneys[505] likely results from the germline *WT1* mutation. A Wilms' tumor will then result if a somatic mutation ("second hit") of the normal *WT1* allele occurs within a nephrogenic rest, resulting in unrestrained cell proliferation.

In contrast to Wilms' tumor, DMS and gonadal dysgenesis in DDS do not occur by a recessive mechanism, since DDS patients are heterozygous for their WT1 mutations. The dominant effect of DDS mutations could reflect a gain of function by the mutant protein,

but there is no evidence that any of the reported DDS mutations impart new functions to WT1. Rather, it appears that the DDS mutations behave in a dominant-negative fashion, i.e., the mutant protein interferes with the function of the product of the wild-type allele. *WT1* proteins can self-associate *in vitro* and *in vivo*, mediated by domains in the amino-terminal region of the protein.[505,479] The association of mutant and wild-type proteins antagonizes WT1-mediated transcriptional repression.[505,479] The dominant-negative effect of DDS *WT1* mutations helps explain why renal and genital abnormalities are more severe in DDS than in patients with WAGR (*W*ilms-*A*niridia-*G*enital-*R*enal) syndrome, who have one wild-type *WT1* allele, while the other is a null allele due to a deletion or frameshift mutation.

Individuals with typical DDS *WT1* mutations but without the DDS phenotype have been reported. For example, Coppes et al found the R394W mutation in a boy with DDS and in his father, who was phenotypically normal.[471] Another child with this mutation had Wilms' tumor, but normal renal function and histology at age seven.[506] Such cases suggest that there are other factors that influence the penetration or effects of *WT1* mutations Phenotypic variation has been described with other *WT1* mutations as well.[507]

Frasier syndrome is another rare disorder characterized by male pseudohermaphroditism and renal failure.[508] These patients have normal female genitalia and an XY karyotype. Proteinuria appears during childhood, progressing to nephrotic syndrome and chronic renal failure by adolescence or early adulthood. Renal pathologic changes consist of focal and segmental glomerulosclerosis, rather than DMS. Development of Wilms' tumor in patients with Frasier syndrome is rare but has been reported.[509] These patients may not be recognized until they undergo evaluation for primary amenorrhea, and gonadoblastoma is a frequent complication. Screening of exons 8 and 9 of the *WT1* gene in a cohort of Frasier patients showed that they did not carry typical DDS mutations.[510] However, further studies of the *WT1* gene in Frasier patients by Barbaux and colleagues identified mutations in the donor splice site in intron 9, which would be predicted to result in the loss of the WT1 + KTS isoform.[511] The differences between DDS and Frasier syndrome suggest several implications: (1) The WT1 + KTS isoform is particularly important in the testicular differentiation program. (2) Loss of the WT1 + KTS isoform does not prevent nephrogenic mesenchyme from differentiating to the point beyond which evolution into Wilms' tumor is no longer possible. (3) The WT1 − KTS isoforms support podocyte differentiation and function, at least to some extent, resulting in relatively mild renal abnormalities, in comparison to DDS. Intron 9 splice site mutations have been described in male FSGS patients.[512,513] However, *WT1* splice-site mutations appear to be only rarely associated with primary steroid-resistant FSGS, in the absence of genital abnormalities.[512]

Diagnosis and Treatment

DDS should be suspected in children with proteinuria in association with Wilms' tumor and/or ambiguous genitalia, and confirmed by renal biopsy and karyotype analysis. In turn, the presence of DMS in a kidney biopsy should prompt suspicion of DDS. Screening of the *WT1* gene for mutations is as yet available only in research laboratories. Evaluation of DDS patients should include imaging of the internal reproductive organs and, at some point, examination of gonadal histology.

Because of the high risk for development of Wilms' tumor, any remaining renal tissue should clearly be removed once the child develops ESRD (some will have had previous unilateral nephrectomy for Wilms' tumor).[514] Some clinicians favor prophylactic bilateral nephrectomy, or removal of the remaining kidney after excision of a unilateral Wilms, once the diagnosis of DDS has been made, and then proceeding to transplant.[515] Other clinicians prefer to monitor such patients for development of Wilms' tumor in any remaining renal tissue by frequent ultrasound examination, moving to nephrectomy and transplant when ESRD supervenes. Gonadal tissue should be excised in DDS patients with an XY karyotype, because of the frequent occurrence of gonadoblastoma. Gonadectomy is not necessary in those with an XX karyotype. In our experience, children who have been free of Wilms' tumor and off chemotherapy for one year, and who have their gonads removed when indicated, exhibit patient and graft survival rates comparable to our general pediatric renal transplant population.

Nail-Patella Syndrome

Nail-patella syndrome (NPS) is an autosomal dominant disorder consisting of hypoplasia or absence of the patellae, dystrophic nails, dysplasia of the elbows and iliac horns, and renal disease.[516,517]

Clinical Features

Renal Findings: clinically apparent renal disease occurs in less than half of NPS patients.[518,519] The nephropathy is usually benign, with about a 10% risk of progression to ESRD. The clinical signs of NPS nephropathy include microhematuria and mild proteinuria and appear in adolescence or young adulthood. Some patients develop nephrotic syndrome and mild hypertension. The course of the nephropathy may differ substantially in related individuals.

Skeletal Defects: Absence or hypoplasia of the patellae occurs in over 90% of NPS patients[520] and may be associated with effusions and osteoarthritis of the knees. About 80% of patients exhibit osseous processes projecting posteriorly from the iliac wings (iliac horns), which are pathognomonic. Abnormalities of the elbows include aplasia, hypoplasia, and posterior processes at the distal ends of the humeri, and occur in over 90% of patients.[520]

Nails: Nail abnormalities occur inmore than 90% of patients, and tend to be bilateral and symmetric.[520] Fingernails are more commonly affected than toenails. The nails may be absent or dystrophic with discoloration, koilonychia, longitudinal ridges, or triangular lunulae. The latter finding is pathognomonic for NPS.[520]

Pathology

There are no specific light or immunofluorescence microscopic features of the NPS renal lesion. By electron microscopy the GBM, and on occasion the mesangium, exhibits multiple irregular lucencies, producing a "moth-eaten" appearance.[521–524] These lucent areas sometimes appear to contain cross-banded collagen fibrils, which are better seen after staining with phosphotungstic acid. The fibrils tend to be arranged in clusters, with thickening of the adjacent GBM. These fibrils may be observed in the kidneys in the absence of clinically evident renal disease, but they have not been found in extraglomerular basement membranes.

Cross-banded fibrils of type III collagen have been seen in GBM of patients with glomerular disease who lack nail or skeletal abnormalities, sometimes as a familial condition with autosomal recessive inheritance (collagen type III glomerulopathy).[525] Although collagen type III glomerulopathy and NPS appear to be distinct diseases, a recent study identified the collagen fibrils of NPS as type III collagen, suggesting a possible pathogenetic relationship between these disorders.[526]

Pathogenesis

The etiology of NPS was unknown until recently. Targeted disruption in mice of the LIM homeodomain transcription factor gene *Lmx1b* resulted in skeletal defects (hypoplastic nails and absent patellae) as well as renal dysplasia.[527] *LMX1B*, the human homolog of *Lmx1b*, was found to map to chromosome 9q34, where the NPS gene is located, and heterozygous mutations in *LMX1B* were identified in patients with NPS.[528] A variety of mutations in *LMX1B* have been found in NPS patients, including missense, splicing, insertion/deletion and nonsense alterations.[528–530] These findings, along with the results of *in vitro* studies of the transcriptional effects of mixing wild-type and mutant *LMX1B*, suggest that haploinsufficiency of *LMX1B*, rather than a dominant-negative effect, is the cause of NPS.[531,529]

While *LMX1B* appears to be important for normal limb and kidney development, the precise mechanisms for the renal effects of *LMX1B* mutations remain under investigation. LMX1B binds to an enhancer sequence in intron 1 of the mouse and human *COL4A4* genes and stimulates reporter constructs containing this sequence.[532] *Lmx1b*$^{-/-}$ mice exhibit markedly reduced GBM expression of the α3 and α4 chains of type IV collagen.[532] LMX1B binding sites have also been found in the putative regulatory regions of the genes encoding the slit diaphragm proteins podocin and CD2AP, and these genes are down-regulated in *Lmx1b*$^{-/-}$ mice.[533,534] However, Heidet and colleagues were unable to identify any abnormalities in the expression of type IV collagen chains, podocin or CD2AP in the kidneys of NPS patients, although they were able to identify the fibrillar material in NPS GBM as type III collagen.[526]

Treatment

There is no specific therapy for the nephropathy of NPS. Renal transplantation has been performed successfully, without apparent recurrence of the disease in the transplanted kidney. Since NPS is an autosomal dominant disorder, careful evaluation of potential living related kidney donors for features of the disease is essential.

INTRODUCTION

Nephrotoxins produce acute or chronic kidney failure or functional injury, usually as a result of specific injury to tubular epithelial cells. While these toxins usually produce localized and specific injury to target cells in the kidney by specific mechanisms, many of the final common pathways of cytotoxic injury are shared with ischemia-reperfusion injury. As the latter have been studied more extensively, these are included as part of this review. The common cellular pathways involved lead to cellular adaptation, sublethal or lethal injury, and pathways for regeneration and repair. These events are not confined to the target cells but also involve other cells in the kidney, which may not necessarily reveal apparent injury but which invoke a stress response and/or inflammatory and vascular responses. The role of direct and indirect injury in mediating the phenotypic response to injury is illustrated schematically in Figure 85.1. The parallel response in the cells that are not directly targeted, such as cytokine or growth factor release or release of inflammatory mediators and recruitment of further inflammation together with the response of target cells, are factors that determine the final outcome of toxic injury. The accompanying vascular response may well be pivotal. Thus, the pathophysiology of acute kidney injury includes a complex interplay among specific cellular injury, inflammation, and altered renal hemodynamics. This review will trace the general mechanisms of renal cell injury before focusing on selected specific nephrotoxins that demonstrate these principles of injury. Potentially, all of the cellular events involved in injury leave molecular footprints, which can be used as biomarkers in urine or plasma, Although such biomarkers have been used largely for diagnostic and predicitive purposes, it is through these biomarkers that we may be able to map such events non-invasively. Event specific biomarkers may allow mapping the time course of injury and the recruitment of secondary injury pathways. We will review the development and use of biomarkers in the detection of nephrotoxic injury.

LOCALIZATION OF INJURY

Cellular Susceptibility: General Principles

Renal susceptibility to toxic injury emanates from a combination of nonspecific and specific factors. The major nonspecific factor is high blood flow with the kidney receiving 20–25% of the cardiac output, thus ensuring high delivery rates of circulating toxins. The general principles governing the susceptibility of a particular nephron segment to nephrotoxic or ischemic injury include segmental transport functions, metabolic activity, metabolic reserve, filtered load, and local blood and substrate supply including oxygen. The concentration of a drug or its metabolites will contribute to toxicity, and this will be modified by local tubular reabsorption, secretion, and metabolism, as well as by the local reabsorption of water. Intracellular activating mechanisms and organelle distribution will contribute

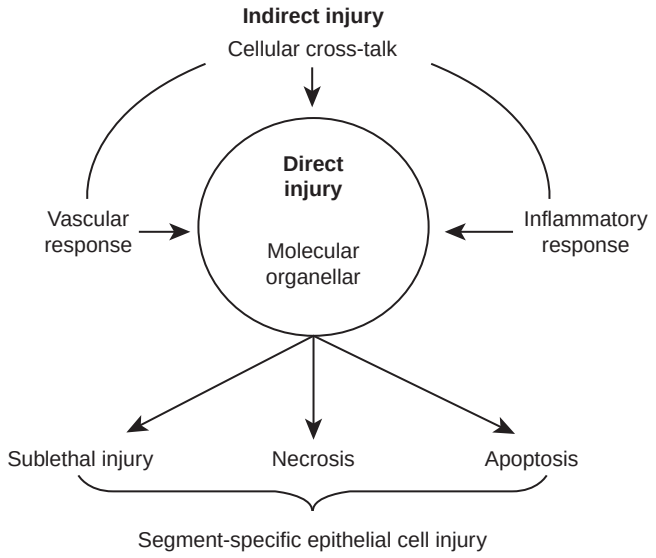

FIGURE 85.1 Determinants of injury outcome. The influence of indirect injury to adjacent structures and of the subsequent vascular and inflammatory response to injury on primary cellular targets of nephrotoxic injury is shown schematically. The phenotypic response to toxic injury is the sum of these responses.

further to toxicity. Because of the heterogeneity of these factors along the nephron, it is not surprising that the pattern of injury differs among nephrotoxins. Toxin delivery to a target site is a sine qua non for toxicity. Protein binding of the potential nephrotoxin will dictate whether the molecule is freely filtered at the glomerulus, dictating early exposure to the luminal aspect of proximal tubular cells or, if highly protein bound, to basolateral transport systems anywhere along the nephron. Thus, there is good correlation between the morphological and functional attributes of each nephron segment and the potential development of nephrotoxicity, especially in the proximal tubule where the greater proportion of specific drug toxicity occurs. Survival after toxicant exposure is also affected by the cycle status of the cell and the extent to which activation of pro- versus anti-apoptotic pathways and pro- versus anti-inflammatory pathways occurs; these factors collectively represent the "stress response" of the cells and are affected by the metabolic state of the cell. The anti-apoptotic and -inflammatory factors may be considered as a type of functional cytoprotective reserve (akin to antioxidant status in the face of oxidant stress), which might account for the differential susceptibility of particular tubular cells.

Renal Blood Flow and Cell Susceptibility

Heterogeneity of renal blood flow (RBF) defines the vascular limits of substrate and toxin delivery. The outer cortex receives 80% of the total RBF, the inner cortex and outer medulla only 15%, the inner medulla 5%, and the papillary region 2%.[38] Renal oxygenation is modified by diffusional shunting of oxygen from arterial to venous vessels running in close approximation. This is most apparent in the vasa recta, so that oxygen tension also falls off sharply at the corticomedullary junction, thereby producing the characteristic low oxygen tensions found in the renal medulla averaging approximately 10 mm Hg.[261] However, preglomerular shunting of oxygen also contributes and reduces cortical oxygenation to below renal vein values.[431] This arrangement is essential for maintenance of the medullary interstitial osmotic gradient generated by the countercurrent multiplier system that allows modulation of water reabsorption for the generation of concentrated or dilute urine. In a teleological sense, the arrangement also provides a selection advantage by creating a zone of borderline oxygenation in the kidney that may be ideal for sensing hypoxia by erythropoietin-producing interstitial cells in cortex. The disadvantage is that any significant reduction in RBF—for example, in shock—can easily lead to hypoxic damage, at least in outer medullary tissues, including "medullary rays" situated in the cortex and containing the S3 proximal tubule and TAL segments arising from glomeruli in the outer and mid-cortical layers.[40] Although both proximal tubular S3 cells and medullary thick ascending limb cells are exposed to a similar risk of hypoxia, only proximal tubular cells undergo early cell death following equivalent hypoxic insults *in vivo*.[119,147,275] This suggests that there are differences in susceptibility to injury between these segments, which may reflect differences in segmental cytoprotective mechanisms as discussed below.

Regulation of regional blood flow may be critical to localization of hypoxic and toxic injury. Autoregulation of cortical blood flow is highly efficient, whereas the extent of autoregulation of medullary blood flow remains controversial. Some studies indicate that medullary blood flow is not efficiently autoregulated, especially during volume expansion.[262,309] Other studies show efficient autoregulation of medullary blood flow under other conditions.[127,183,294] Such disparate observations may arise from different methods of estimating medullary blood flow.[125] Modulation of cortical and medullary blood flow may be critical to the actions of several nephrotoxins, such as iodinated contrast and nonsteroidal anti-inflammatory drugs. Heterogeneity of nitric oxide synthase (NOS) distribution within the kidney influences these regional differences in renal perfusion, and contributes to cytotoxic injury. All three isoforms of NOS are present in the kidney.[457,512] NO from eNOS is involved in regulation and maintenance of blood flow, and NO synthesized by nNOS in the

macula densa is important in the modulation of tubuloglomerular feedback (TGF) and regulation of glomerular filtration rate (GFR).[450] iNOS is present in the tubules of normal rat kidney, predominantly in the medullary thick ascending limb, but its involvement in regulation of kidney function under normal physiological conditions is unclear. Quantitative studies of NOS activity[523] and NO production[550] suggest that the renal medulla is the principal site for basal NO synthesis in the kidney, suggesting an important role of NO in regulation of medullary circulation.[75,76,309]

There is increasing interest in the role of the endothelium in ischemia-reperfusion injury, which may provide some insights into the effects of nephrotoxic injury on the renal vasculature. Endothelial dysfunction and vasoconstrictor hypersensitivity are well-recognized sequelae of ischemic acute renal failure (ARF).[150,151,152,219,278] After ischemia-reperfusion injury loss of GFR arises from a combination of a reduced transcapillary hydraulic pressure gradient (ΔP) during delayed graft function and back leak of the glomerular filtrate presumed secondary to both epithelial injury and tubular obstruction.[3,400] The decrease in ΔP may arise from two mechanisms.[400] The first is a reduction in perfusion pressure secondary to an increase in afferent arteriolar tone as a result of some combination of vasoconstrictor hypersensitivity, endothelial dysfunction impairing the generation of vasodilators, and increased TGF. The afferent arteriole provides the highest contribution to renal vascular resistance and is the key modulatory site for renal autoregulation.[234] The second mechanism is a rise in intratubular pressure arising from actual or functional tubular obstruction. Recent studies[161] confirming the continuing presence of TGF activity after ischemia-reperfusion injury support the postulated contribution from enhanced TGF secondary to reduced sodium and water reabsorption.[306,473] Structural obstruction of the nephron is recognized in ischemic ARF,[414] and functional (high-flow) obstruction causing intratubular pressure increases sufficient to stop filtration have been observed in toxic ARF after p-aminophenol.[190] Endothelial cell dehiscence and microvascular obstruction may also contribute a significant component of this reduction in renal blood flow, as recent studies have observed not only endothelial cell dehiscence, microvascular aggregation, and obstruction, but even reversal of flow.[41,463,528] These observations coupled with evidence of endothelial ICAM1 adhesion molecule upregulation[1] and leukocyte adhesion in the vasa recta[89,91] explain the outer medullary vascular congestion observed consistently after ischemic injury,[307] usually described as the "no-reflow" phenomenon.[257,459]

Iodinated contrast agents may be injurious through modulation of regional blood flow. One of the two principal explanations for genesis of acute renal failure by contrast is induction of vasoconstriction, either directly by high osmolar-contrast agents or by release of endothelin or adenosine or both. Medullary blood flow may be critical, since the potential for regional hypoxia described above predisposes to ischemic injury when both nitric oxide and vasodilator prostaglandin synthesis are blocked.[193] Iodinated contrast reduces NO synthesis in primary cultures of renal artery smooth muscle cells.[412] Injection of radiocontrast results in an immediate decrease in renal blood flow that is counteracted by an increase in renal prostaglandin formation. When prostaglandin synthesis is inhibited by cyclooxygenase inhibitors, prolonged endothelin-mediated renal vasoconstriction is observed.[57] Endothelin antagonists have not been successful in preventing contrast nephropathy.[506] However, the only clinical trial using endothelin antagonists utilized a nonselective endothelin antagonist that promoted both an increase in circulating endothelin of longer duration than the duration of antagonism[185,507] and antagonism of ET-B receptors, which would have suppressed NO production. Subsequent experimental studies have demonstrated protection by ET-A selective antagonists, but it is uncertain whether this protection was hemodynamically mediated.[282]

Modulation of NO also contributes to calcineurin-inhibitor and cisplatin toxicity. Acute dose-dependent vasoconstriction of the renal microcirculation by cyclosporine and tacrolimus is NOS dependent[113,114,509] and reversed by supplementation with l-arginine.[114] Chronic cyclosporine involves downregulation of eNOS, which can be reversed by administration of l-arginine[6,530] or pravastatin.[264] Inhibition of NOS (by 2-amino-4-methylpyridine aggravates experimental cisplatin-induced nephrotoxicity with exaggeration of both histological and metabolic features of cisplatin toxicity including reduction in glutathione[2] -peroxidase activity and elevation of platinum accumulation, but prevents the typical reduction in GSH and increase in malondialdehyde.[418]

Both vasodilator and vasoconstrictor prostaglandins generated by COX from arachidonic acid are critical in the regulation of vascular tone and sodium and water homeostasis in the kidney. Endogenous prostaglandins have been found to modulate the regulatory status of the perfused kidney and there is growing evidence to indicate that COX-2 is involved in the modulation of afferent arteriolar autoregulatory responses.[182,198] The interplay between endogenous vasodilators and vasoconstrictors—for instance, prostaglandins and endothelin—and the increase in vasoconstrictor production when vasodilators are stimulated or vice versa, highlights the important homeostatic effects of local

autoregulation. This is critical in determining regional blood flow and toxicity, but can make interpretation difficult.

CELLULAR TARGETS

Cellular Targets: General

Significant exposure of the kidney to toxicants typically results in ARF. The primary target for most nephrotoxin and ischemic injury are epithelial cells of the proximal tubule.[33,101,274,411] Other renal target cells include endothelial cells—for example, in response to Shiga toxin-2[549] or ischemia.[332] Endothelial cells can also be modified by cytotoxins to sensitize them to other forms of injury. For example, incubation of endothelial cells with calcineurin inhibitors has been shown to increase subsequent adhesion by dendritic cells.[427] Vascular smooth muscle cells can be indirect or direct targets. For instance, impaired vasorelaxation through impaired NO formation characterizes cyclosporine, contrast, and myoglobin toxicity as described. Severe ischemia may injure smooth muscle cells directly.[74] Podocyte injury is critical in the development of several forms of glomerular disease, and is induced experimentally by the nephrotoxin puromycin.[496] Tubular interstitial cells may be targeted by drugs with resultant tubulointerstitial nephritis, glomerular cells to cause proteinuria, and distal tubular cells to cause functional injury manifested as inhibition of transport (e.g., lithium and demeclocycline cause diabetes insipidus, and cotrimoxazole causes hyperkalemia) or structural damage (e.g., with fibrosis induced by lithium or other drugs). Secondary parenchymal injury may result from activation of inflammatory chemokines resulting in an inflammatory response with leukocyte activation and infiltration. This is a critical component of ischemia-reperfusion injury,[33,47,534] but has been inadequately explored in nephrotoxic injury.

Proximal Tubular Characteristics

Most nephrotoxic and ischemic injury involves proximal tubular cells.[32] Proximal tubule dysfunction is primarily responsible for activation of several of the main pathophysiological mechanisms, which leads to loss of GFR in acute renal failure as discussed earlier. The S3 segment of the proximal tubule and the medullary thick ascending limb (MTAL) of the loop of Henle traverse the outer stripe of the outer medulla and medullary rays in close proximity. These are regions of the kidney that are marginally oxygenated because of diffusional shunting of oxygen,[432] and where blood flow is reduced in the setting of ischemic and some toxic injuries.[120,187,307,534] Although both nephron segments have high transport activity and concomitant high metabolic activity, only proximal tubular cells are susceptible to injury causing cell death in most animal models.[119,275] This greater susceptibility probably arises because proximal tubular cells rely principally on fatty acid oxidation for energy,[406,519,520] and have low glycolytic capacity compared with MTAL cells under conditions of oxygen deprivation.[14,417] Thus, the higher glycolytic capacity of MTAL cells allows continued generation of ATP in the setting of rapid ATP depletion resulting from impaired oxidative phosphorylation.[32] There may also be greater cytoprotective reserve in MTAL cells in contrast to proximal tubule cells against early apoptotic injury through early and differential upregulation of anti-apoptotic Bcl-2 family members,[146] and of the protective mitogen-activated kinases (MAP kinase) pathway regulated by extracellular signal kinase (ERK),[96] as will be discussed further below. However, while ATP availability may make distal nephron cells less vulnerable to immediate cell death by necrosis, MTAL cells do undergo sublethal changes and produce various chemokines, cytokines, and growth factors that may have autocrine and/or paracrine effects on the injury and regeneration process of the kidney post-ischemia; MTAL cells may also undergo apoptotic cell death pathways under severe stress conditions.[146,270,271,272]

Transport-Based Selectivity

In the S1 and S2 segments, the proximal tubular cells have well-developed brush borders, a well-developed phagolysosomal system, a large endocytic apparatus with numerous apical vesicles, and mitochondria associated with the basolateral membrane.[477] Functionally, this region is associated with bulk isosmotic solute and fluid reabsorption coupled to the gradient generated by active sodium transport across the basolateral membrane by sodium ATPase and the tubular uptake and metabolism of protein by the endocytic and phagolysosomal systems.[477] The final (S3) segment of the proximal tubule is located in the outer stripe of the outer medulla. The cells are characterized by less well-developed phagolysosomal and endocytic systems, but contain a much greater proportion of smooth endoplasmic reticulum (ER) and peroxisomes.[477] S3 segment cells are the predominant location of the renal mixed-function oxidases, which contribute to both metabolic activation and toxicity of some compounds.

The greater diversity of transport functions in proximal tubule contributes to localization of injury because of preferential accumulation of many toxicants in this segment. For example, halogenated hydrocarbons are

common environmental chemicals present in solvents and pesticides that produce toxicity and ARF after enzymatic conversion to reactive intermediates and cysteine S-conjugates, which are particularly injurious to the S3 segment of proximal tubule,[64,115,116] since the S3 segment has the highest γ-glutamyl transpeptidase and cysteinylglycinase transport activity.[416] Similarly, nephrotoxic heavy metals—including mercury, cadmium, gold, lead, nickel, and chromium—induce injury targeted to the proximal tubule as a result of active transport systems. For example, mercuric chloride conjugates with glutathione[2] and cysteine in the liver and plasma, but accumulates in and is toxic to the S3 segment[456] where the Hg-GSH conjugates are converted into Hg-cysteine conjugates by γ-glutamyl transpeptidase, and then transported intracellularly by the Na-dependent L-alanine, L-serine, and L-cysteine (ASC) systems, and the Na-independent L-system.[538]

The relationship between transport proteins and protection is complex, as illustrated by cadmium-induced injury. Cadmium, a ubiquitous environmental toxin, is absorbed by inhalation or ingestion, and accumulates to produce proximal tubular injury. Cadmium induces the cysteinyl-rich metal-binding protein, metallothionein (MT), an important protective mechanism against many heavy metals.[487] However, MT contributes to cadmium injury since MT-knockout mice are protected against Cd toxicity.[231] Paradoxically, the MT complex facilitates uptake and accumulation by proximal tubular cells, with free cadmium and Cd-MT targeting different subsegments (S3 and S1/S2 segments, respectively) of the proximal tubule *in vivo*.[420] Cd-MT complexes formed in the liver are freely filtered and taken up into proximal tubular cells by endocytosis.[63,420] After endocytosed Cd-MT is degraded by lysosomes, free cadmium is released intracellularly and binds to subcellular targets to produce toxic injury characterized by proteinuria, phosphaturia, glucosuria, aminoaciduria, and polyuria.[419,539] Some protection against cadmium is afforded by pretreatment with cyproterone acetate, which appears to increase transport out of the proximal tubular cells by upregulation of a ZnT-1 transporter gene that encodes for a membrane protein associated with zinc efflux.[468]

Thus, transport systems, including endocytosis, are important in localizing toxicity. Gentamicin localizes to proximal tubule because of selective uptake. Megalin (also known as LRP-2), is a giant multiligand endocytic receptor, abundantly expressed in the apical membrane of proximal tubular epithelial cells, and is known to mediate uptake of β2-microglobulin. Megalin-knockout mice accumulate very little gentamicin compared with wildtype mice, suggesting that megalin-mediated endocytosis is the main mechanism of gentamicin accumulation in proximal tubules.[178,344,428] Even more compelling evidence indicates that megalin mediates MT−heavy metal complexes including MT-Cd.[232] Surface plasmon resonance and flow cytometry studies using overlapping MT peptides and recombinant MT fragments identified the hinge region of MT as a critical site for megalin binding, and suggest that disruption of the hinge motif (SCKKSCC) can inhibit proximal tubular MT uptake and eliminate much of the renal accumulation and toxicity of heavy metals such as cadmium, gold, copper, and also of cisplatinum, which is also transported bound to metallothionin.[232]

Distal tubular cells are also targeted through selective transport mechanisms. Lithium toxicity localizes to the distal nephron because lithium ions enter the cells via the amiloride-sensitive Na channel[16,139] to cause nephrogenic diabetes insipidus by markedly downregulating expressions of AQP2[299,505] and Na,K-ATPase.[256] Through understanding this transport selective toxicity, it was shown that polyuria can be ameliorated by amiloride in patients receiving long-term lithium therapy.[20,24] Similarly, the side effect of closure of luminal apical sodium channels in distal tubular cells—for example, by the antibiotics trimethoprim[492] and pentamidine[235] or by the diuretics triamterine and amiloride—is functional dose-dependent hyperkalemia, as blockade of Na transport reduces the transepithelial voltage and inhibits potassium secretion.

CELL INJURY PATHWAYS

Sublethal Injury

Nephrotoxic or ischemic injury not severe enough to cause cell death can nevertheless produce sublethal injury with significant pathophysiological consequences.[31] Some nephrotoxins produce changes in solute reabsorption as highlighted above for lithium and trimethoprim. Similarly, cadmium and maleic acid toxicity can produce proximal renal tubular acidosis with aminoaciduria, and glycosuria,[16] while amphotericin B can induce a distal renal tubular acidosis with hypomagnesemia and hypokalemia.[102] The factors defining whether sublethal injury produces a higher risk of further injury leading ultimately to cell death or is protective through pre-conditioning (e.g., by upregulation of heme-oxygenase-1) remain of considerable interest in ischemia-reperfusion injury.

Sublethal injury associated with ATP depletion in proximal tubular cells results in impairment of epithelial permeability, loss of functional integrity of tight junctions (zona occludens), loss of cell polarity, and altered localization of cell adhesion molecules and polarized membrane proteins.[31] Proximal tubular cell injury after acute chemical or ischemic insult is

characterized by ATP depletion, mitochondrial and peroxisome dysfunction, impaired solute and ion transport, loss of cell polarity, and cytoskeletal dysfunction. Oxidative damage and ionic and pH changes also contribute to cell injury, but ischemic and chemically induced ATP depletion have been more extensively studied than other mediators of injury.[275,276] The cellular and molecular lesions induced by ATP depletion are duration dependent and have been reviewed recently.[52] The lesions include misfolding and aggregation of membrane and secreted proteins;[248] disruption of the actin-based cytoskeleton;[12,13,331] disturbances in apical–basolateral protein polarization;[134] mislocalization and degradation of protein components of the intercellular junctions;[53,480] upregulation of many genes, including molecular chaperones,[51,248] growth factors and their receptors,[360] and regenerative proteins;[95,199,202] perturbation of integrin-mediated cell adhesion;[151,237,273,553] and induction of cell death by apoptosis or necrosis.[373]

Many of these changes occur very rapidly after the onset of ATP depletion, particularly changes involving the cytoskeleton. The apical microvillar region of proximal tubular cells is particularly sensitive because of the rapid rate of actin polymerization, so that severe but repairable damage occurs within five minutes of ischemia.[330] These changes are not confined to tubular epithelial cells. Rather, renal ischemia rapidly produces characteristic and duration-dependent effects on the actin cytoskeleton of numerous renal cell types, including endothelial[41] and smooth muscle cells, suggesting that the alterations are independent of cell type.[330] Microvascular injury resulting from changes in the endothelial cell actin cytoskeleton—including cell swelling, altered cell–cell attachment and reduced endothelial cell–basement membrane attachment—may play a central role in reduced blood flow to affected microvascular beds secondary to altered vascular reactivity, in increased leukocyte adherence and extravasation, in altered coagulation after endothelial dysfunction, and in increased interstitial edema secondary to increased endothelial permeability.[188] Injury to the vascular endothelium may also contribute to progressive loss of the microvasculature and perhaps via chronic hypoxia through glomerulosclerosis and tubulointerstitial fibrosis to progressive renal disease.[222] Chronic hypoxia induced in part by angiotensin II–mediated vasoconstriction may similarly contribute to chronic cyclosporine nephrotoxicity.[389]

Cell Death: Apoptosis and Necrosis

The responses of renal tubular cells to severe injury include cell death, de-differentiation of viable cells, proliferation, and re-differentiation and restitution of normal epithelium.[442,449,464,470] Cell death pathways are initiated by the same stressors, that initiate adaptive responses, including toxins and ischemia. Where these stressors are of sufficient initial magnitude or there is failure of the adaptive response mechanisms to rescue the cell, cell death is initiated by either apoptosis or necrosis. These responses are intimately related to cell cycle events leading to recovery or cell death (Figure 85.2). Heterogeneity of response in the kidney can result in concurrent apoptosis and necrosis within the same nephron segments following a single injurious influence.[147] The distinction between these modes of death is important in defining therapeutic strategies.[7] A clear distinction between modes of death follows the seminal study by Kerr, Wyllie, and Currie[230] in which they coined the term "apoptosis," and distinguished necrosis and apoptosis using morphological criteria. In necrosis, there is swelling of cell organelles including the mitochondrial matrix, chromatin flocculation, loss of plasma membrane integrity, and rupture of the cell contents into the extracellular space, which invokes an inflammatory response.[228] The mitochondria undergo inner membrane swelling, cristeolysis, and disintegration.[250] Polyribosomes disintegrate and disperse throughout the cytoplasm, and the cisterns of rough ER and Golgi apparatus are dilated and fragmented.[478] In apoptosis, the nuclei undergo chromatin condensation, pyknosis, and karyorrhexis, with the chromatin forming crescents along the periphery of the nuclear membrane.[230,526] The cells then shrink, lose microvillae and cell junctions, and fragment into a series of plasma membrane–bound condensed apoptotic bodies containing small masses of condensed cytoplasm, chromatin, and occasional organelles. Phosphatidylserine residues, normally located on the inner cell membrane surface, are exteriorized prior to cell fragmentation; these signal adjacent viable cells to

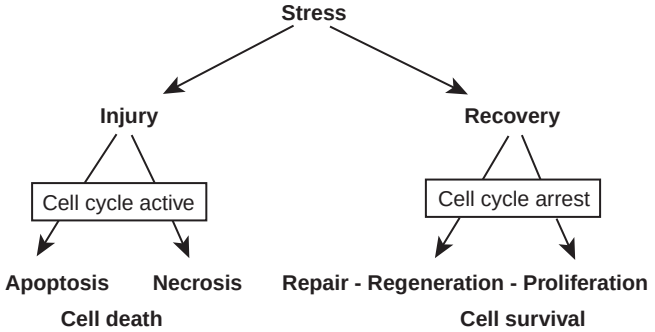

FIGURE 85.2 Injury response and cell cycle activity. The role of cell cycle activity in determining injury outcome is cell-type, toxin, and tissue dependent; the response for the general case is illustrated schematically.

phagocytose the apoptotic bodies without inducing an inflammatory response.[311,454]

To emphasize the distinctions between the catastrophic nature of necrosis in contrast to the orderly, genetically driven process of apoptosis, these are sometimes referred to respectively as "accidental cell death" and "programmed cell death." Despite these distinctions, there is considerable overlap between the cellular pathways involved in apoptosis and necrosis. For example, if a fragmented cell is not phagocytosed—for instance, in *in vitro* culture systems where macrophages are absent, and *in vivo* where phagocytosis is impaired, as in autoimmune disorders[522]—the apoptotic bodies eventually swell and lyse, a process known as secondary necrosis.[229] Consequently, the same insult may produce apoptosis or necrosis depending on severity.[272,274] Studies in animal models which demonstrated that apoptosis is a "normal" feature of ischemia-reperfusion injury *in vivo*,[18,67,82,145,146,362,430,447,448,482,537] have been confirmed in clinical biopsies of transplanted cadaveric kidneys, which are recognized as the best-defined model of human ischemia-reperfusion injury.[49,60,366] These studies have stimulated interest in downregulating apoptosis as a means of ameliorating or preventing acute renal injury,[30,271] a proposal that has now proven successful in experimental ischemia-reperfusion injury with the use of caspase inhibitors[110] and erythropoietin.[439,494]

Adaptive and cell regulatory pathways are initiated simultaneously with cell death pathways at the time of initial cell injury (Fig. 85.2). Thus, injury and recovery are postulated to be part of the same response[177] and involve engagement of the cell cycle.[397] Recovery after injury requires an orderly progression through the cell cycle (reviewed by Price et al.,[397]) which is regulated inter alia by the phosphorylation of substrates by interacting proteins called cyclins and cyclin-dependent kinases (cdk). Transition through so-called regulatory checkpoints G1 (gap-1) and S (DNA synthesis) and G2 and M (mitosis) cannot occur before each phase is completed. Natural inhibitors of cdk's such as p21, the 21-kd protein that inhibits cyclin-dependent kinase 2 (cdk2) activity are increased naturally during G1 to prevent further cycle progression or by the p53 transcription factor after DNA damage[50,88] or by p53-independent mechanisms after acute renal injury.[315] In p21(-/-) mice, both cisplatin and ischemic injury produce more rapid and severe acute renal failure with morphologic damage including necrosis and apoptosis throughout the renal cortex, whereas damage is restricted to the S3 segment of the proximal tubule in wildtype p21(+/+) mice.[313,314] In association with the increase in cell death there is an increase in cell cycle activity in p21(-/-) mice.[312] The corollary to these changes is that increases in p21 expression are associated with suppression of apoptosis after injury, and in preventing p53-induced apoptosis in a variety of cancer types, while reduction of p21 may induce apoptosis in such transformed cells.[157,391] These findings emphasize the importance of coordinated cell cycle control to recovery from acute renal injury with the final outcome dependent on both the severity of injury and the net balance of the cellular responses.[397]

Lethal Injury: Apoptosis

Since apoptosis of renal tubular cells predictably accompanies necrosis[433,434] and mechanisms of necrotic injury, such as ATP depletion and hypoxia, also induce apoptosis in cell culture models,[4,130,167–169,225,274] inhibition of apoptosis may be therapeutic[87] in ameliorating injury after ischemia-reperfusion injury including renal transplantation.[272,482] Intensive investigation of the molecular pathways involved in apoptosis have demonstrated that aspects of necrosis are also actively mediated, and that cytotoxic injury also leads to apoptosis through similar or identical pathways affirming the concept of a continuum of cell injury and death.

Caspases are the molecular executioners of apoptosis.[138,472] The molecular mechanisms of caspase-induced cell death were first elucidated in the nematode *Caenorhabditis elegans*.[489] Caspases are a family of at least 14 highly specific cysteine proteases synthesized as proenzymes (procaspases). They all possess a catalytic cysteine in the active site, require a tetrapeptide recognition sequence with a C-terminus aspartate, cleave target proteins after an aspartate residue, and are hence stylized "c(asp)ases." Procaspases are activated by proteolytic cleavage, usually at caspase substrate sites, which allows autolytic cleavage (e.g., adapter-facilitated self-cleavage by proximity) in a caspase cascade.[471] Caspases are either pro-inflammatory (caspases 1, 4, 5, 11, 13) and involved in maturation of cytokines, such as both interleukin (IL)-1 and IL-18 in the case of caspase-1, or pro-apoptotic.[471] The pro-apoptotic caspases can be divided into initiator caspases (caspases 2, 8, 9, 12) and effector caspases (caspases 3, 6, 7). Initiator caspases are activated by pro-apoptotic stimuli that induce adapter-facilitated self-cleavage. In turn, initiator caspases activate effector caspases that are responsible for cleavage of various physiological substrates including nuclear lamins, cytoskeletal proteins fodrin and gelsolin, actin-signaling protein, p21-activated kinase-2 (PAK2),[42,239,259,303] and caspase-activated DNAase (CAD).[118]

Target cleavage leads to the characteristic molecular and morphological patterns of apoptotic cell death. Lamins are intermediate filament proteins forming the

nuclear lamina underlying the nuclear membrane and responsible for chromatin organization: caspase-induced cleavage leads to collapse and characteristic condensation of nuclear chromatin. Similarly, caspase-induced cleavage of fodrin and gelsolin leads to cell blebbing, while PAK2 cleavage leads to cytoplasmic and nuclear condensation, cellular detachment, and to phosphatidylserine externalization,[302] which is critical for macrophage activation and phagocytosis. CAD activation, through proteolysis of ICAD (inhibitor of caspase-activated DNase), is one of the pathways of endonuclease activation.[118] Endonuclease activation is the final common execution of both apoptotic and necrotic cell death pathways after ischemia-reperfusion injury and results in the generation of unrepairable strand breaks in double-stranded DNA.[482,524] Random digestion of DNA in necrosis produces a smear pattern. Since internucleosomal DNA cleavage is nonrandom, producing DNA fragments that are multiples of ~180 base pairs and characteristic DNA laddering, these strand breaks have long been regarded as an indicator of apoptosis.[525] However, other studies have shown that both apoptosis and necrosis can occur in the absence or in the presence of DNA fragmentation,[73,100,413,483] so it is critical that apoptosis is defined by morphological as well as biochemical criteria. Caspase-independent (CAD-independent) DNA fragmentation occurs via endonuclease G, an endonuclease released from the mitochondrial intermembrane space and responsible mainly for single-strand fragmentation.[265,381] Apoptosis-inducing factor[4] also released from the mitochondrial intermembrane space and induces DNA fragmentation with high molecular weight fragments compared with the smaller fragments generated by caspase-induced deoxyribonuclease.[214,462]

Caspases are activated by mitochondrial or ER-mediated intrinsic pathways or following activation of cell surface receptors, the extrinsic pathway.[223] The extrinsic pathway is activated by triggering of cell death receptors, such as TNF and Fas, cell surface molecules that possess a common piece within their cytoplasmic tails called the death domain (DD).[11,488] Binding of ligands such as FasL to these receptors (e.g., Fas) induces receptor trimerization and formation of a death receptor−ligand complex. Adapter molecules, such as Fas-associated death domain protein or TRADD in the case of TNF, possess both DD and the death sector domain (DED). The death receptor−ligand complex recruits FADD by binding to the DD. FADD in turn recruits procaspase-8 modules through DED interaction and forms the death-inducing signaling complex (DISC) that facilitates activation of caspase-8.[340] Caspase-8 causes autocatalytic activation of further caspase-8 molecules through induced proximity. These translocate to the cytoplasm and directly activate downstream caspases, such as caspase-3, -6, and -7. Alternatively, caspase-8 catalyses the cleavage of cytoplasmic Bid,[256] a death-promoting member of the Bcl-2 superfamily. Truncated Bid (tBid) translocates to the mitochondria, integrates into the outer membrane, and interacts with other Bcl-2 family members to promote release of cytochrome C and other pro-apoptotic factors from the mitochondria, thereby activating caspases of the mitochondrial-dependent pathway.[159] Extrinsic pathway activation is regulated by Fas-associated death domain inhibitory proteins, like cytosolic FLIP (the FADD like IL-1β−converting enzyme inhibitory protein) and cowpox virus protein crm A, which inhibits caspase-8 and downstream caspases.[201,242,243,438,488]

The mitochondria-dependent intrinsic pathway (Figure 85.3) is responsible for most apoptosis, and leads to mitochondrial release of pro-apoptotic factors, including cytochrome C, AIF, and endonuclease G.[213,214,241,461] Intrinsic pathway-activating signals include DNA damage, heat shock, radiation, oxidative stress, glucocorticoids, perturbations in redox balance, ceramide activation of tumor suppressor proteins such as p53, and oncogenes such as c-myc, growth factor withdrawal, and some nephrotoxins.[373] During ischemia-reperfusion and after cisplatin, respiratory chain dysfunction impairs ATP generation. While severe ATP depletion causes necrosis, sustained milder degrees of ATP depletion can trigger apoptosis. One reason for the selective activation of apoptosis with milder degrees of ATP depletion appears to be the relatively greater reduction in the smaller intracellular pool of guanosine triphosphate (GTP), which is in tight equilibrium with ATP.[84] While the GTP: GDP ratio regulates various signaling GTPases such as Ras and Rho, which are regulators of cell proliferation and apoptosis,[174] GTP depletion also triggers an increase in p53, which translocates to the mitochondria and triggers mitochondria-dependent apoptosis.[83,226] In addition to functional changes in mitochondrial energy generation, ischemia produces two structural abnormalities in mitochondria. First, it triggers collapse of the mitochondrial membrane potential ($\Delta\Psi\mu$) following opening of the mitochondrial transition pore in the inner mitochondrial membrane, producing high amplitude swelling and impairing ATP generation early in reflow.[171,172] Second, it triggers leakage of cytochrome c leakage from the inner membrane space into the cytoplasm.[241] Dislocation to the cytoplasm of cytochrome c, an electron shuttle protein, both impairs respiration and facilitates binding of deoxyadenosine triphosphate to the adapter protein apaf-1-cytochrome C-complex, inducing oligomerization to form the high-molecular-weight caspase-activating complex, the apoptosome.[266,551] The apoptosome recruits procaspase-9, which autocatalytically activates and then

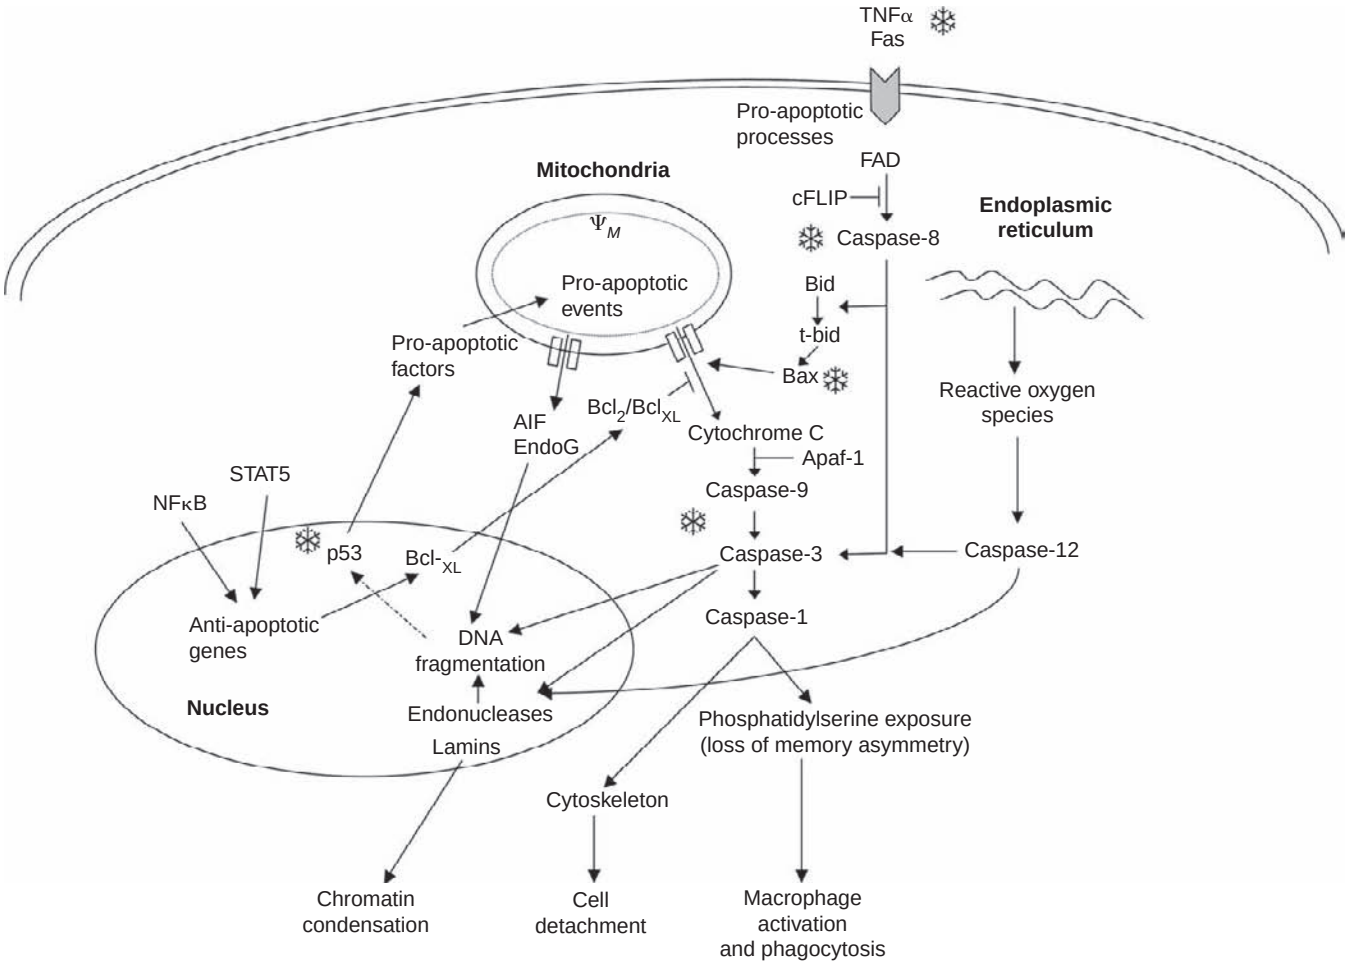

FIGURE 85.3 Extrinsic and intrinsic pathways of apoptosis in nephrotoxic injury. Caspase-dependent fragmentation of DNA follows activation of executioner caspase-3 via either the intrinsic (mitochondrial and endoplasmic reticulum) or extrinsic (Fas/TNF) pathways as shown in schematic form. Caspase-independent fragmentation of DNA follows mitochondrial release of AIF and EndoG and also leads to cell death by apoptosis. Several sites of interaction between the extrinsic and intrinsic pathways are illustrated. Sites of reported activation by cisplatin are marked by the symbol. See text for definitions and detailed explanations.

proteolytically activates caspase-3, triggering execution of apoptosis.[552]

The intrinsic mitochondrial signaling pathway is regulated by members of the Bcl-2 family.[1,87] Mammals possess a large family of Bcl-2 proteins that includes pro-apoptotic as well as anti-apoptotic members. Anti-apoptotic members include the prototype Bcl-2,[491] Bcl-xL, Bcl-w, and Mcl-1. Pro-apoptotic members include Bax, Bak, and Bok. A third class of molecules sharing homology with the Bcl-2 homology-3 (BH3) domain can activate pro-apoptotic members or inactivate antiapoptotic members and include Bin, Bid, Bad, and Bik. The ratio of anti- to pro-apoptotic molecules such as Bcl-2 to Bax is a measure of susceptibility to apoptosis via the intrinsic pathway, perhaps because pro- and anti-apoptotic members of the Bcl-2 family heterodimerize with each other.[1] The precise mechanism by which mitochondrial intermembrane space proteins are released by the actions of Bax and Bak is uncertain. Translocation to the mitochondrion, oligomerization, and insertion of Bax into the outer mitochondrial membrane to form pores or channels, which allow release of intermembrane space proteins, has been proposed.[448] Alternatively, Bax may mediate opening of the mitochondrial permeability transition pore, which then somehow modulates permeability of the outer mitochondrial membrane, perhaps after swelling and rupture.[189] Nevertheless, although there is evidence for these alternatives (see Danial and Korsmeyer[87]), the precise mechanisms remain uncertain. It is clear, however, that anti-apoptotic Bcl-2 family members (such as Bcl-2 and Bcl-xL) block apoptosis-induced release of these intermembrane space proteins, perhaps by stabilizing and preventing opening of the mitochondrial

permeability transition pore.[1,87] Translocation of both pro- and anti-apoptotic Bcl-2 proteins to the mitochondria appears critical: for example, protection against apoptosis in distal tubular cells after oxidative injury was associated with translocation of Bcl-xL to mitochondria within the surviving distal cells, whereas proximal tubular cells showed reduced survival coupled with decreased expression of Bcl-xL, which did not translocate to the mitochondria.[79] After ischemia-reperfusion *in vivo*, rat proximal tubules show a marked increase in Bax expression and apoptosis as well as an expected increase in necrosis.[146] The relevance of these and similar[18] experimental rat studies is clear from similar observations in human kidneys after cadaveric renal transplantation, where increases in apoptosis with ischemia time were associated with increased Bax expression and of cytoplasmic cytochrome C, confirming mitochondrial pathway involvement in the observed apoptosis.[60]

Impairment of mitochondrial outer-membrane integrity allows numerous other proteins normally sequestered in the inner membrane space to enter the cytoplasm.[410] These include caspase-independent death effectors such as the apoptosis-inducing factor (4), mitochondrial pools of co-caspases (such as caspases-2, -3, and -9), the second mitochondrial activator of caspases (Smac),[104] the direct inhibitor of apoptosis proteins (IAPs) binding with low pI (Diablo),[493] and serine protease HtrA2/Omi.[490] AIF translocates to the nucleus triggering chromatin collapse and digestion of DNA as described earlier. IAPs regulate caspase activity by acting as pseudosubstrates. By binding IAPs that inhibit caspases-3, -7, and -9 directly, Smac/Diablo frees these caspases to promote cell death.[410,444]

As shown in Fig. 85.3, there are three potential levels of interaction between the extrinsic and intrinsic apoptotic pathways. Initial activation of caspase-8 via Fas can induce mitochondrial translocation of Bid with resultant cytochrome C release.[292] Second, the transcription factor p53 activates pro-apoptotic Bcl-2 family members and also Fas-dependent apoptosis.[50] Third, the extrinsic and intrinsic pathways converge at caspase-3 activation, the beginning of the execution phase.[472]

Pro-inflammatory caspases are also involved in ischemic renal injury, reflecting our increasing awareness that even apparently purely ischemic renal injury involves significant inflammation.[33] Caspase-1 (previously known as ICE, interleukin-converting enzyme) proteolytically cleaves the precursor forms of both pro-inflammatory cytokines IL-1β, and IL-18.[128] These are increased after ischemia-reperfusion injury, although from a combination of knockout and protection studies, it appears that only the increase in IL-18 plays a significant[317,318] but uncertain[80] role. Cisplatin-induced apoptosis does not involve caspase-1 activation.[224]

Nephrotoxic injury is associated with caspase activation and apoptosis. Cisplatin-induced apoptosis is associated with translocation of Bax to mitochondria, release of cytochrome c, and activation of caspase-9 and -3,[224,253,277,378] while inhibition of these caspases provided partial protection[223] confirming a role for mitochondrial pathway activation. Cisplatin also induces increased expression of TNF-α and Fas and with activation of caspase-8, suggesting a significant contribution to apoptosis from extrinsic pathway activation.[436,481] Similarly, caspase-2 release from human fibroblast mitochondria is associated with cisplatin, etoposide, and UV light−induced apoptosis, which can be prevented by small interfering RNA (SiRNA)-mediated silencing of caspase-2 expression.[252] Since p53 inhibition provides partial protection against cisplatin-induced apoptosis,[78] a role for p53 in cisplatin-induced cell death seems likely.

The ER−specific caspase, caspase-12, appears to be involved in apoptosis following ER stress.[345,408] The ER contains high concentrations of cytochrome P-450 enzymes, which can lead to generation of reactive oxygen metabolites. Microsomal CYP2E1 is the source of reactive oxygen species generation in cisplatin-induced apoptosis.[284] This oxidative stress and mobilization of ER calcium stores precedes procaspase-12 activation, which then leads to apoptosis of LLC-PK1 cells, directly by bypassing caspase-9 and -3, but also partly mediated by caspase-3 activation, perhaps after oxidant injury to the mitochondria and resultant cytochrome C release.[245,285]

Necrosis. While there have been considerable advances over the last decade in our understanding of apoptosis, our understanding of molecular pathways in necrosis has been more selective, beginning with the concept that necrosis is a largely "passive" process secondary to acute ATP depletion. Direct consequences of ATP depletion include impairment of ATP-dependent ion channel transport, disruption of ion gradients, actin cytoskeleton disruption, cell swelling, membrane blebbing, and cell disruption (see recent review by Padanilam[373]). There is now evidence that both forms of cell death include actively mediated steps. Since both necrosis and apoptosis are frequently found together in the same tissue, distinguishing these death modalities may sometimes be difficult.

Classically ischemic, hypoxic or chemical ATP depletion leads to cell death associated with an increase in cell volume, so called "oncosis,"[295] and was presumed to occur because of sodium and water influx and initial potassium ion efflux associated with increased plasma membrane permeability. This general pattern was confirmed using 23Na, 31P, and 87Rb magnetic resonance spectroscopy of intact kidneys.[5,77,409] While the initial sodium influx is balanced

by potassium efflux, increased intracellular sodium will further dissipate ATP by activating Na^+,K^+-ATPase, and severe ATP depletion will lead to failure of pump-leak balance, further sodium influx, and cell swelling.

Further evidence indicates that whether a lethally injured mammalian cell undergoes necrosis or apoptosis may be determined by early activation of cell membrane ion channels. Most cells can regulate their volume by mechanisms called regulatory volume decrease or increase, after osmotic swelling or shrinkage. In contrast, a major hallmark of apoptosis is "normotonic" shrinkage of cells.[293] Apoptotic volume decrease requires active K^+ and Cl^- efflux.[293,367] Necrotic volume increase is initiated by uptake of osmolytes, such as Na^+, Cl^-, and lactate after injury, hypoxia, ischemia, acidosis, or lactacidosis through membrane carriers and through stress-activated nonselective cation channels.[17] Persistence of necrotic volume increase is caused by dysfunction of the regulatory volume decrease mechanism due to impairment of volume-sensitive Cl^- channels under conditions of ATP deficiency or lactacidosis. The role of these ion fluxes in the death phenotype is highlighted by the observation that both lactacidosis-induced dysfunction of regulatory volume decrease and necrotic cell death are prevented by pretreatment of cells with the vacuolating cytotoxin-A (VacA) protein purified from *Helicobacter pylori*, which forms a lactacidosis-resistant anion channel.[367] Similarly, blocking the increase in K^+ and Cl^- conductances following stimulation of either extrinsic or intrinsic pro-apoptotic pathways prevented the biochemical and morphological changes of apoptotic cell death, whereas inhibiting apoptosis by broad-spectrum caspase inhibition did not prevent apoptotic volume decrease.[293]

Stress-activated nonselective cation channels of the transient receptor potential, melastatin-like (TRP) family, such as melastatin-like TRPM2, also known as long transient receptor potential channel-2 (LTRPC2), are dormant in viable cells, but become activated and contribute to necrosis after binding ADP-ribose, or reactive oxygen or nitrogen species.[17,180,310,386,387] LTRPC2 is permeable to both Ca^{2+} and Na^+ after activation, and contributes to Na^+ and Ca^{2+} overload. Since hypoxic and ischemic injury results in oxygen-derived free radical generation,[216,217] such channels explain the earlier observation, that the rate of Na accumulation in the hypoxic kidney was reduced by free radical scavengers.[77] Sodium overload coupled with severe ATP depletion leads to a necrotic outcome. Increased cytosolic calcium further increases ATP depletion by activating Ca^{2+}-ATPase and by producing mitochondrial depolarization (see previous discussion). Even mild oxidative stress can increase cytosolic Ca^{2+} by stimulating release of calcium from intracellular binding sites such as the ER.[527] The role of these TRP channels in nephrotoxic injury is unknown, although the common features of oxidative and mitochondrial injury in cisplatin nephrotoxicity[1] suggest mechanisms likely to activate calcium influx and promote further injury.

Additional molecular events promoting necrosis triggered by ischemia include activation of proteases, phospholipases, endonucleases, poly(ADP-ribose)polymerase (PARP), iNOS, and the protein kinase (PK) family, including PKC and the mitogen-activated protein kinases (MAPK) and the generation of reactive oxygen species.[372] The activated proteases include calpain[181,287,288] and meprin (metallopeptidase from renal tissue),[58,192] both of which mediate further injury. Phospholipases (PL) are activated by phospholipolysis following ischemia. PLA_2 has various isoforms that vary in their dependence on Ca^{2+} for activation. Activation leads to membrane phospholipid breakdown, with potential loss of membrane integrity, generation of inflammatory mediators, and cytotoxicity from lysophospholipids and free fatty acids.[31,394] Separate mention must be made of fatty acids, since β-oxidation of fatty acids is a major energy source in renal cortex.[406,520] Renal peroxisomes and mitochondria utilize identical pathways for β-oxidation of fatty acids, except that peroxisomes, which are single-membrane–bound organelles, do not use carnitine for entry of fatty acids (in contrast to mitochondria where these are involved in transport into the mitochondrial inner matrix).[393] Peroxisome proliferator–activated receptors (PPARs) are members of the nuclear hormone receptor superfamily of ligand-dependent transcription factors. PPARα is expressed predominantly in proximal tubule and medullary thick ascending limb in the kidney and agonists, including fatty acids, eicosanoids, and fibrate drugs, act as ligands and induce fatty acid oxidation.[393] Peroxisomal as well as mitochondrial fatty acid oxidation are inhibited after ischemia-reperfusion and cisplatin injury to the kidney, while administration of PPARα ligands prior to injury was protective.[393,395] Cisplatin attenuates PPARα signaling by reducing the expression of a tissue-specific coactivator of PPARα called PPARγ-coactivator-1 (PGC1) which is also a transcriptional coactivator for other transcription factors including nuclear respiratory factor, which are important in the regulation of oxidative metabolism, cellular respiration, and adaptive thermogenesis.[144] Survival of renal tubular epithelial cells after cisplatin appears to depend on intact PGC-1/PPARα function. PPARα agonists appear to have therapeutic potential for cisplatin-induced ARF. Use of PPARα ligands prevented acute tubular necrosis by ameliorating cisplatin-induced inhibition of mitochondrial medium-chain, acyl-CoA dehydrogenase–mediated fatty acid

oxidation and pyruvate dehydrogenase complex activity.[268] PPARα ligand also protects against cisplatin-induced renal injury by reducing the expression and enzyme activity of proximal tubule endonuclease G.[267]

The PKC family comprises serine-threonine kinases, with 12 isozymes activated by Ca^{2+}, phosphatidyl serines, and diacylglycerol.[372] Activation of PKCs leads to signal transduction via activation of G protein–coupled receptors, tyrosine kinase receptors, and nonreceptor tyrosine kinases.[361] As a result of controlling 70% of the phosphorylating activity in the proximal tubule, PKC regulates numerous physiological functions of the renal epithelium including Na^+,K^+-ATPase activity, gluconeogenesis, and transport of amino acids, glucose, sodium, potassium, chloride, water, organic anions, and cations.[94] PKC isozymes also play a crucial role in the regulation of other major cellular functions, including proliferation and differentiation.[94] After ischemia, the increased Ca^{2+} and phospholipids hydrolysis products induce PKC isoenzymes and activated C-kinase receptor in kidney.[373] PKC induction appears to be protective. Induced PKCα, -βII, and -ζ protect cultured renal cells from oxidant injury and subsequent necrosis.[373] PKC is involved in ischemic preconditioning[258] and heat shock–induced protection.[316]

PKC isoenzymes directly influence mitochondrial function, and are therefore involved in recovery from both ischemic and apoptotic injury to renal cells. For example, while initiation of apoptosis by many agents is preceded by mitochondrial dysfunction and depolarization of the mitochondrial inner membrane, Nowak[365] demonstrated that, in renal proximal tubular cells, cisplatin induces mitochondrial dysfunction associated with hyperpolarization of the mitochondrial membrane, and that these events are mediated by protein kinase C (PKC)-α and extracellular-regulated protein kinase (ERK)1/2. Nowak also demonstrated that PKC-α and ERK1/2 mediate activation of caspase-3 by acting downstream of cytochrome c release from mitochondria, and that ERK1/2 activation by cisplatin occurred through a PKC-α–independent pathway. Nowak subsequently observed[364] that PKC inhibition decreases recovery of physiological function, recovery of PKC activity precedes the return of physiological functions after oxidant injury, and that activation promotes recovery of mitochondrial function and active Na^+ transport. Since oxidant injury–induced *tert*-butylhydroperoxide was associated with recovery of total PKC activity, while that associated with the nephrotoxic cysteine-S conjugate, S-(1,2-dichlorovinyl)-L-cysteine (DCVC), was not, Nowak concluded that the repair of renal function is mediated through PKC-dependent mechanisms, and that cysteine conjugates inhibit renal repair, partly through inhibition of PKC signaling.[364] Subsequently, Nowak observed that serine but not threonine phosphorylation of the beta-subunit of F^1F^1-ATPase was increased during late recovery following DCVC. Inhibition of PKC-α activation decreased this phosphorylation, confirming that PKC-α regulation of repair of mitochondrial function involves phosphorylation of the catalytic subunit of F^1F^1-ATPase.[286]

Repair and regeneration of renal cells after injury is less well studied than the initiation of injury but is known to involve proliferation and migration as well as repair of injured proximal tubular cells, and thus involves growth factors, integrins, and extracellular matrix protein interactions.[146,363] Growth factors administered pre- or post-ischemia–reperfusion injury ameliorate injury and enhance regeneration through their anti-apoptotic, proliferative, and pro-angiogenic actions.[175,176] Insulin-like growth factor (IGF-1) and hepatocyte growth factor may also enhance GFR after injury by increasing NO production, increasing local blood flow and vasodilating renal microvessels.[109,476] However, the utility of growth factors in ARF therapy remains uncertain.[194]

MAP kinases are serine/threonine kinases ubiquitously expressed in mammalian cells and known to be modulated in response to ischemic and toxic stress.[32] MAPK activation is important in determining whether cellular stress leads to proliferation, differentiation, or apoptosis. Three MAPK cascades have been identified, the ERK, JNK, and p38 pathways. Cellular stress, such as toxic injury, induces generation of growth factors and inflammatory cytokines. The ERK pathway is activated by growth factors, vasoactive peptides, and nephrotoxins, including aminoglycosides and cephaloridine[32] via a cytoplasmic-activating protein, MEK1. After activation, ERK proteins translocate to the nucleus, and phosphorylate and activate several Ets-domain transcription factors including Elk-1, SAP1, Ets-1, and Ets-1.[136] ERK activation is involved in cell proliferation and differentiation and appears to be protective in the preconditioned post-ischemic kidney[378] and in distal tubule cells.[8,96] The JNK (c-Jun N-terminal kinase) pathway, also designated as stress-activated protein kinases (SAPK), are activated by genotoxic and osmolar stress, mechanical stretch, shear stress, and the inflammatory cytokines TNFα and IL-1β.[32] They are also activated by ischemia-reperfusion.[392] The p38 pathway is activated by many of the same stimuli that activate JNK/SAPK, but is independently regulated and plays a significant role in inflammatory cytokine production.[32] Activation of the JNK/SAPK and p38 pathways is antiproliferative and can lead to cell death. While the effect of toxins on JNK activation in the kidney is unknown, JNK activation and subsequent apoptosis of hair cells have been implicated in gentamicin

ototoxicity.[531] Activation of ERK in distal tubule cells relative to JNK may contribute to the differential survival of these cells in contrast to proximal tubular cells after ischemia-reperfusion injury[96] and with the renal protection associated with preconditioning.[378]

PARP is a nuclear enzyme that adds ADP-ribose to various proteins including PARP itself after activation by DNA strand breaks. PARP is involved in both DNA repair and gene transcription and acts to open up the condensed structure of chromatin.[308] After injury, activation of PARP leads to consumption of its substrate β-NAD^+. Resynthesis of β-NAD^+ consumes further ATP.[161,301] Whether the cell proceeds to apoptotic or necrotic cell death varies, possibly depending on the degree of initial ATP depletion or on PARP cleavage. While fibroblasts from PARP(-/-) mice are protected from necrosis, TNF-α can still induce death by apoptosis.[163] However, in fibrosarcoma cells, TNF-α can activate PARP and induce death by necrosis.[291] It appears that NAD^+ depletion induced by PARP activation may act as a trigger for AIF translocation from mitochondria to cytoplasm and nucleus to induce chromatin fragmentation.[535] Moderate oxidative stress activates PARP, but it is then inactivated by caspase cleavage, which prevents further ATP depletion and enhances apoptosis.[192]

The inflammatory cascade is initiated by ATP depletion and exacerbated by reperfusion.[369] Endothelial, epithelial, and infiltrating inflammatory cells all participate in and mediate the inflammatory process after ischemia-reperfusion.[443] Endothelial cells express adhesion molecules including ICAM-1, VCAM, P and E selectins, and β2-integrins. ICAM-1 binds to LFA-1 (CD11α/CD18) and Mac-1 (CD11β/CD18) receptors on leucocytes producing recruitment and activation.[398] Involvement of adhesion molecules has been confirmed by blockade of ICAM-1[227] and selectin.[466] Adherent leukocytes release reactive oxygen species, proteases, and other enzymes, and, together with the activated endothelial cells, release inflammatory cytokines such as IL-1, IL-6, IL-8, IL18, TNF-α, chemokines, and MCP-1.[318,465,470] The relative importance of neutrophils, macrophages, and T and B lymphocytes as critical leukocytes in postischemic inflammatory events remains unclear.[33,45,46,48,90,91,233,279,318,534] However, inhibition of various inflammatory pathways, including the CD28-B-7 costimulatory pathway by selectin blockade,[465,466] the melanocortin-stimulated inflammatory gene stimulatory pathway by α-melanocyte−stimulating hormone, α-MSH,[65,66] IL18 cytokine depletion in neutrophil-depleted mice,[318] and of multiple pathways including cell infiltration, ICAM-1 and iNOS upregulation, matrix molecule expression, MAP kinase ERK1/2 activation, and transcription factor activation by cerivastatin,[162] all ameliorate ischemia-reperfusion injury, thus supporting a critical role for inflammation in both necrotic and apoptotic injury.

Overlaps Between Necrosis and Apoptosis

While this review has delineated distinct molecular pathways that are triggered by pro-necrotic or pro-apoptotic events, it is important to emphasize that there is considerable opportunity for intersection and overlap between these pathways after both ischemic and nephrotoxic injury. Mitochondrial and peroxisomal involvement in both pathways appears likely. PARP activation may be crucial as highlighted above. Inflammatory mediators are involved in necrosis, but the observation that inhibition of apoptosis can ameliorate both inflammation and necrosis, for example, by pan-caspase inhibition after ischemia-reperfusion,[81] emphasizes that apoptosis is frequently if not always a normal component of injury previously regarded as pure necrosis. Recruitment of stress-activated pathways and cell cycle proteins may be critical in determining the final outcome after injury. These overlaps highlight new therapeutic opportunities that may be available in the treatment and prevention of nephrotoxic injury.

BIOMARKERS OF NEPHROTOXIC INJURY

While serum creatinine and urea (BUN) have been used routinely to detect and monitor AKI, these conventional biomarkers of renal function only increase beyond the normal range when nearly half of the functional reserve of the kidney has been compromised. Thus, they detect kidney injury only after it is far advanced.[441] They are also slow to respond to change in renal function. Since extrapolations to GFR from serum creatinine require that creatinine is in steady state equilibrium, this requires three to five half lives before such extrapolations are valid. The half-life of creatinine is four hours when GFR is normal[68] and this increases in proportion to any decline in GFR. Thus after the one third decline in GFR required to be diagnosed as having AKI by the corrected RIFLE criteria,[390] creatinine will only reach a steady-state after 12 to 20 hours or longer if the decline is greater. The implication is that at least 12 and, more likely 24 to 48 hours, must elapse before a new creatinine value is a reliable index of changed renal function. This creates an unavoidable delay in diagnosis of and intervention in AKI. In nephrotoxic injury, these delays may be greater since accumulation of drug or injury or both may be needed to induce measurable changes in renal function. In addition, drug-induced kidney injury in

nonclinical animal models is a major cause of elimination of compounds during drug development; these compounds are eliminated from the development process even when it is unclear whether the toxicity would translate to humans. More sensitive biomarkers are needed to enable more reliable diagnosis of nephrotoxin-induced AKI in both clinical and preclinical studies and to facilitate earlier intervention and monitoring.

A biomarker is any parameter that can be objectively measured and evaluated, which acts as an indicator of a normal or pathological process, or of a response to intervention. The identification of biomarkers of renal cellular injury along with the re-discovery and quantitation of the predictive relationship between enzymuria and renal injury[517] have re-kindled widespread interest in the nephrology and diagnostic communities, since these new tools offer the possibility of a paradigm shift in diagnosis of AKI and open the door to early intervention.[121,122,123] These biomarkers are present in urine, plasma and sometimes both. Since plasma or serum biomarkers have many potential sources, urinary biomarkers generally have higher renal specificity and are easily acquired in non-oliguric AKI. Consequently, urinary biomarkers have been the main focus of recent studies. The urinary biomarkers fall into at least five categories: filtered biomarkers where glomerular permeability has increased, filtered biomarkers where renal reabsorption is impaired as a result of tubular injury, pre-formed cellular biomarkers released following injury, upregulated biomarkers, and inflammatory biomarkers released into the urine following recruitment of inflammatory cells.[124] An alternative way of classifying these is as as inflammatory, excreted tubular proteins and surrogate markers of tubular injury, with different mechanisms for increase and significance.[516] At present, the most studied biomarkers are the tubular enzymes GGT, GST and N-acetyl-beta-glucosaminidase (NAG), and the novel induced biomarkers, kidney injury molecule-1, (KIM-1), interleukin 18 (IL-18) and neutrophil gelatinase associated lipocalin (NGAL).[179,322,377] New biomarkers are appearing regularly in the literature, for example, Trefoil factor 3,[536] Clusterin,[98] Netrin-1[508] and Aprotinin.[354] Albumin may have a specific role as a biomarker in AKI since proximal tubular receptor-mediated uptake may be impaired.[347,348,536]

Because nephrotoxic potential is critical in the both safety and commercial decisions regarding the continuation or abandonment of the development of candidate drugs, tubular enzymuria, particularly NAG, GGT, alanine-aminopeptidase, lactate-dehydrogenase and alkaline phosphatase have been widely used by the pharmaceutical industry to assess nephrotoxicity during drug development. However this process has not been regulated until recently. The United States Food and Drug Administration (FDA) and the European Medicines Evaluation Agency (EMEA) have taken an active role together with the pharmaceutical industry in developing a process for context-dependent qualification of biomarkers to improve the drug development and regulatory review process.[154–157] The FDA and the EMEA have also expanded the context in which qualification for biomarkers is determined, and an expedient biomarker-qualification process is currently in place.[98,154,155,156] The Critical Path Institute (C-Path) created the Predictive Safety Testing Consortium (PSTC) as a neutral ground where scientists from 16 pharmaceutical companies and academia could share and test new methods that are more reliable predictors of human safety. The PSTC developed the legal framework needed to share the cost of qualification and to protect intellectual property associated with biomarker qualification and it submits the data to the FDA and EMEA to support the biomarker certification process.[154–156] The first FDA and EMEA review of biomarker qualification data involved biomarkers of renal injury and qualified seven biomarkers as supplemental data for evaluation of nephrotoxicity in nonclinical safety studies.[154] These new biomarkers qualified for specific contexts of use are the urinary concentrations of KIM-1, albumin, total protein, β2-microglobulin, cystatin C, clusterin, and trefoil factor-3. The PSTC submitted data supported claims that three of these urinary biomarkers—total protein, β2-microglobulin, and cystatin C concentrations—could outperform levels of BUN and serum creatinine in detecting and monitoring drug-induced glomerular injury, while four urinary biomarkers—levels of KIM-1, albumin, clusterin, and trefoil factor-3—could either outperform or add value to levels of BUN and serum creatinine in detecting and monitoring certain drug-induced tubular injuries.[154] More recently, renal papillary antigen-1 RPA-1 was qualified as marker of site-specific injury in the collecting duct and clusterin was requalified as a voluntary biomarker for use in detecting drug-induced tubular injury, particularly when signs of regeneration are present. These biomarkers were qualified for use as adjuncts in detecting nephrotoxic injury on a voluntary basis in pre-clinical rat studies while other biomarkers remain "exploratory." The qualification process and need for more data on nephrotoxins and also on reversibility has encouraged much further study, e.g.[98,370,415,536]

From both drug development and safety viewpoints, better biomarkers could enable safer and easier-to-monitor therapies by reducing the margin between efficacy and safety needed for clinical and preclinical applications. Much of the current work involves comparing biomarker performance in preclinical or clinical

contexts. The sensitivity, specificity and time course of biomarkers are critical factors in determining utility in a particular disease. The favored metric for assessing biomarker performance is currently the receiver operator characteristic (ROC) curve analysis. When sensitivity is graphed against (1-specificity), the area under the ROC curve (AUC) (± the confidence interval) defines performance. The AUC for a perfect biomarker is 1.0, for a non-performing biomarker it is 0.50; clinical utility requires a minimum AUC of 0.70, although, realistically, much higher values are needed for clinical utility. Comparison of individual predictors and multivariable models is usually undertaken following the method of DeLong.[92] The prognostic benefit of adding a biomarker to a baseline clinical model is calculated from the net reclassification improvement (NRI) and integrated discrimination Improvement (IDI) indices.[382]

Thus in the detection of histological injury in one study of rat kidney injury induced by ten different nephrotoxins, urinary total protein (ROC AUC 0.86), cystatin C (0.92) and β2-microglobulin (0.89) showed a better diagnostic performance than BUN (0.80) and SCr (0.53) for detecting glomerular injury, while urinary clusterin (ROC AUC 0.88), outperformed BUN (0.79) and SCr (0.73) for detecting proximal tubular injury.[98] Similarly, urinary KIM-1, outperformed the traditional biomarkers SCr, BUN and urinary NAG for the diagnosis of proximal tubular damage, using both using both exclusion and inclusion analysis approaches.[484] For all observed histopathology grades following eight different nephrotoxicants, KIM-1 had the highest AUCs (exclusion analysis, 0.91; inclusion analysis, 0.88), whether compared to SCr (exclusion analysis, 0.73; inclusion analysis, 0.72), BUN (exclusion analysis, 0.79; inclusion analysis, 0.75) or urinary NAG (exclusion analysis, 0.82; inclusion analysis, 0.76). A total of tubular nephrotoxicants, including gentamicin, cisplatin and cyclosporine, and ischaemia-reperfusion injury were examined in that study. Regardless of whether the kidney injury was induced by well-established kidney toxicants or ischemia, urinary KIM-1 outperformed the conventional markers, BUN, SCr and urinary NAG. In addition, the very high ROC-AUC values of 0.91 to 0.99 for urinary Kim-1 demonstrated that urinary KIM-1 measurements were sensitive, specific and accurate in diagnosing either drug-induced or ischaemic kidney injury of various histological types as well as regenerative basophilia when lesions were either subtle with little organ involvement, or very severe with disturbed renal function.[485] KIM-1 was subsequently qualified by the FDA as an early diagnostic biomarker of drug-induced acute kidney tubular alterations in rat toxicology studies, for regulatory decision making as a biomarker used by sponsors on a voluntary basis to demonstrate that drug-induced acute kidney tubular alterations are monitorable in good laboratory practice rat studies (used to support the safe conduct of clinical trials).[485] Urinary KIM-1 was also considered qualified for regulatory decision making as a clinical bridging biomarker for use by sponsors on a voluntary basis in phase 1 and 2 clinical trials for monitoring kidney safety when animal toxicology findings generated a concern for tubular injury.[485]

Using the same approach, the comparative performance, temporal profiles and recovery after gentamicin injury have been published for several candidate urinary biomarkers for kidney injury, including KIM-1, NGAL, osteopontin, glutathione-s transferases, RPA-1, albumin and clusterin.[415] During the evolution of injury, KIM-1, RPA-1, and clusterin best mirrored the histopathologic lesions, while during injury resolution, KIM-1, osteopontin, and BUN best reflected recovery. Based on histopathology, necrosis, or apoptosis scoring, KIM-1 was the best biomarker of overall renal injury.[415] RPA-1 outperformed the other biomarkers using regeneration scores.[415] Clinical studies of KIM-1 have also yielded promising results. FDA/EMEA qualification of KIM-1 as a biomarker for clinical applications will involve a systematic evaluation of diagnostic performance in well-controlled observational and/or interventional clinical protocols using both standard-of-care agents with known nephrotoxic properties and/or exploratory agents with renal safety concerns. As pointed out by the authors, "the opportunity to use the same translational marker, such as Kim-1, for both the preclinical and clinical setting facilitates clinical monitoring of toxicity that has been demonstrated at higher doses in preclinical development or in a single test species when human relevance is suspected.[485]"

An additional potential role of biomarkers reflects their unique role in specific metabolic pathways of cell injury. Detected in serum or urine, their presence should flag recruitment of these specific pathways. Since many recently discovered biomarkers were uncovered by genomic or proteomic strategies, understanding their role in injury can be viewed as linking empirical outcomes to mechanisms. Three examples of novel biomarkers reflecting different injury pathways in AKI are IL-18, KIM-1 and NGAL.

IL-18 is produced in the kidney predominantly by recruited inflammatory cells, probably macrophages[521] but also by activated injured renal parenchymal cells and has a significant role in AKI.[319] Mice deficient in Caspase-1 or IL-18 or wild-type mice treated by IL-18-binding protein are protected from AKI induced by IL-18 injection.[521] KIM-1 is a transmembrane protein express highly expressed in de-differentiated proximal tubular cells in response to injury. It has multiple roles including a role as a phosphatidylserine receptor that

confers a phagocytic phenotype on epithelial cells. This allows these cells to recognize apoptosis cell surface-specific epitopes and thereby enables injured tubular cells to contribute to the clearance of apoptotic cells after AKI.[200] The simultaneous detection of urinary KIM-1 and IL-18 could be regarded as good evidence of significant proximal tubular cell injury leading to cell death and de-differentiation. KIM-1 was the best performing biomarker by histopathology score in models of nephrotoxic injury using cisplatin[475] and gentamicin.[415]

The most highly upregulated biomarker after ischemia-reperfusion injury is NGAL, an acute-phase protein initially found in activated neutrophils but also expressed by a wide range of tissues in response to injury.[460] NGAL participates in host innate immune defence by binding bacterial siderophores to limit bacterial iron acquisition.[135] NGAL forms a complex with iron binding siderophores, which is renoprotective in murine ischemia-reperfusion injury.[335] In the kidney NGAL mRNA expression is only detectable in the distal tubule, including the thick ascending limb of Henle's loop and collecting duct,[376] but the protein is freely filtered and reabsorbed by megalin-mediated transport in the proximal tubule.[197] After ischemia and after cisplatin-induced toxic injury NGAL is detected in a punctate pattern corresponding to endosomes and predominantly in proliferating cell nuclear antigen-positive proximal tubular cells.[321,323] This suggests that proximal tubular NGAL accumulates after injury but that the primary source is the distal tubule belonging to the injured nephrons.[376] Urinary NGAL was recognized immediately as an important biomarker of acute kidney injury,[322] with presence in urine suggesting renal specificity despite the possibility of alternative systemic sources. However, it was confirmed only recently, using cross-transplants between NGAL knockout ($NGAL^{-/-}$) and wild-type C57BL/6 mice ($NGAL^{+/+}$) followed by renal artery clamping, that urinary NGAL definitely originates from the kidney.[376] While urinary NGAL was increased in mice after cisplatin,[323,376] it inexplicably did not appear to increase in some studies in the rat.[475] Interestingly, urinary NGAL had a perfect score (ROC-AUC 1.0) after PAN, a nephrotoxicant that causes marked proteinuria and glomerular morphological changes in rats, similar to those seen in human minimal change nephropathy.[251] Given the potential for albumin and protein to compete with NGAL (and other low molecular weight protein biomarkers) for megalin-mediated transport,[348] the explanation for increased urinary NGAL following PAN may simply be that the proximal reabsorption of NGAL is inhibited.[348] Urinary NGAL has not (yet) been qualified as a nephrotoxicity biomarker, although there is little doubt that both urinary and plasma NGAL have already proven to be a useful as a clinical biomarker of AKI, at least after ischemic injury where it clearly outperforms serum creatinine and blood urea nitrogen.[164–166] Recent clinical studies have demonstrated that in high risk patients screened with urine or serum NGAL and serum creatinine, that creatinine negative but NGAL positive patients were at higher risk of both dialysis and had higher mortality that creatinine negative NGAL negative patients.[164] This also highlights the described delay inherent in using creatinine to make a diagnosis of AKI and suggests that injury biomarkers should be included in the definition of AKI.

In addition to illustrating potential as markers of nephrotoxicity in drug development or in clinical studies, these three biomarkers illustrate the potential for injury biomarkers to provide useful information about timing, location and mechanisms of renal injury in disease. Since NGAL and KIM-1 are produced in different parts of the nephron, the performance of these biomarkers in urine samples should be different as these studies highlight. Recent clinical studies suggest that other factors also modify biomarker performance, including duration of injury and baseline renal function.[122] Further refinements may allow biomarkers to differentiate the specific drug causing renal injury when the patient has been exposed to several potential nephrotoxins. For example urinary levels of regenerating islet-derived protein III beta and gelsolin were increased following gentamicin but not by cisplatin.[132]

Large volumes of data are now needed. Well-designed preclinical and clinical studies that allow biomarker profiles to be followed after different types of AKI, including combinations of as well as individual nephrotoxins and in the presence of various comorbidities that may themselves contribute to biomarker generation or modify biomarker performance.

To illustrate the concepts of drug-induced nephrotoxicity, a number of important drugs with well-defined pathways of injury are discussed in depth.

CYCLOSPORIN A

Since the introduction of cyclosporin A into clinical transplantation in 1978[56] it perhaps more than any other agent, has expanded our understanding of the mechanisms involved in drug-induced nephrotoxicity. Cyclosporin has been shown to modify many different aspects of cellular function, from hormone-receptor activation, second messenger pathways, transcription and translation of mRNA, alterations in protein synthesis and formation, changes in cellular metabolism, cellular repair mechanisms and cell death, the expression of various cytokines and growth factors, and changes

in renal haemodynamics, all of which contribute to the final expression of nephrotoxicity.

Cyclosporin-induced renal functional impairment occurs in all forms of solid organ transplantation, bone marrow transplantation as well as in autoimmune disorders.[173,341] The clinical manifestations of cyclosporin A nephrotoxicity can be classified into two groups, that are not necessarily exclusive. Cyclosporin A induces a marked increase in renal vascular resistance associated with a fall in renal blood flow and a decrease in glomerular filtration rate. These changes are often associated with the development of *de novo* hypertension.[173,341] Cyclosporin A has been shown to modify renal tubular function with impaired distal tubular excretion of potassium and hydrogen ions consistent with a voltage dependent distal renal tubular acidosis,[15,341,344] increased proximal tubular sodium reabsorption with decreased delivery of solute to the distal tubule,[97] and impairment of urinary concentrating ability.[325,342,344]

The clinical presentation of cyclosporin A nephrotoxicity may occur in three different time frames.[218,342] Primary non-function of renal grafts, usually associated with kidneys that have been subjected to prolonged warm ischemia, donor and/or recipient hypotension, or concurrent drug nephrotoxicity.[173,342] Cyclosporin-induced acute alterations in renal haemodynamics augment the damage already sustained by the kidney.[173,342] The acute toxicity is not necessarily associated with an adverse outcome of long-term graft function[173] although this is debated.

At a cellular level the changes in renal haemodynamics are mediated through a variety of hormone-receptor activated pathways, and subsequent intracellular signalling. Cyclosporin A has been shown to enhance the transmembrane Ca^{2+} flux and increase intracellular Ca^{2+} stores in response to agonist stimulation in vascular smooth muscle cells and mesangial cells which leads to enhanced contractility.[320,388] Cyclosporin A has been demonstrated to inhibit activation of protein kinase C (an important component of the second messenger pathway) *in vitro*[500] which also requires Ca^{2+} for its activity. More recent studies have suggested that cyclosporin A inhibits phospholipase A2 directly.[148,453] On this basis it is reasonable to assume that cyclosporin A modulates the hormone receptor activated pathway at several different points with subsequent impairment of cellular function.[499] These alterations in transmembrane signal transduction induced by cyclosporin A have lead Skorecki and colleagues[453] to propose that acute cyclosporin nephrotoxicity is a prototype for a renal membrane signalling disorder.

The acute administration of cyclosporin A causes a dose-dependent increase in renal vascular resistance and a reduction in RBF and GFR in experimental animal and human studies.[338,339] These early changes are functional, with no structural damage evident and are reversible on withdrawl of the drug.[339] In the renal microcirculation, similar reductions were observed.

Baxter et al.[21] have shown that cyclosporin A activates the renin angiotensin system *in vivo* and *in vitro*,.[21,246] Similarly, cyclosporin A has been shown to stimulate and enhance the release of renin from juxtaglomerular cells in culture.[246] Stimulation of mesangial cells by cyclosporin A alone does not modify the release of the vasodilatory prostaglandins or increase in the vasoconstricting prostaglandin thromboxane A_2 (TXA_2). However, cyclosporin A inhibits angiotensin II (AII) stimulated prostaglandin release from mesangial cells,[502] as well as in vascular smooth muscle cells in culture.[247] Exaggerated glomerular thromboxane synthesis has been suggested as a potential mechanism in producing the cyclosporin A induced reductions in GFR. Perico and colleagues[384,395] have shown, *in vivo*, that glomerular synthesis and urinary excretion of thromboxane progressively increase with cyclosporin A therapy. Other studies have demonstrated that the increase in urinary thromboxane excretion is a consequence of intrarenal platelet and macrophage activation probably triggered by cyclosporin induced endothelial damage[27] rather than arising from glomerular mesangial cells.[27,502] The increased release of the vasoconstricting thromboxane from these nonrenal sources could potentate the reduction in glomerular filtration rate associated with cyclosporin A.

Alterations in nitric oxide (NO) and endothelin (ET) have been implicated in cyclosporin-mediated changes in vascular haemodynamics.[28,368] Cyclosporin enhanced release of ET has been implicated as a significant mechanism contributing to cyclosporin-induced vasoconstriction.[385] Cyclosporin has been demonstrated to inhibit NO production by inhibition of inducible nitric oxide synthetase (iNOS) activity, possibly by inhibition of transcription factors in mesangial and vascular smooth muscle cells[305] A number of studies have demonstrated that NO blockade enhances acute cyclosporin nephrotoxicity.[140]

Chan et al.[62] examined endothelial−dependent and independent vascular reactivity in ex vivo studies using aortic rings from rats treated with cyclosporin (5 mg/kg/day) for 7−21 days. They failed to demonstrate impaired endothelial−dependent vasorelaxation but reported enhanced responsiveness to vasoconstricting agents. Therefore, it would seem probable that cyclosporin A induces a decrease in vaso-relaxant mediators (NO, PGI_2, PGE_2) associated with an enhanced response to vasoconstricting agents (AII, ET) which would allow mesangial cell and vascular smooth muscle cell contraction to predominate.[499,502] Subacute

nephrotoxicity frequently occurs in the first six months post transplant,[218,342,343] and it is associated with a slow rise in plasma creatinine or a persistently elevated plasma creatinine compared to azathioprine treated control patients with or without other signs of cyclosporin-induced alterations in renal function.[218,342,344] A significant proportion of patients will have sufficient damage due to interstitial fibrosis that results in irreversible renal impairment.[173,218,342,344] Renal histological changes include an arteriopathy with the development of constrictive intimal proliferation with mucoid thickening and arteriolar hyalinosis, and injury to the proximal tubule with foci of tubular dilatation, epithelial cell degeneration, fine reticulin deposition in the interstitium and giant mitochondria.[129,399] In addition, a significant infiltration of macrophages into the interstitium, associated with an increase in interstitial and tubular cell proliferation has been demonstrated following chronic cyclosporin exposure.[495,533] Activated infiltrating macrophages will amplify the inflammatory and profibrotic response by stimulating fibroblast proliferation and migration as well as increased collagen synthesis. Endothelial cell injury associated with the vascular changes may also be associated with a haemolytic-uremic like syndrome.[342]

Prolonged administration of cyclosporin A, particularly at higher concentrations, has led to the development of chronic nephrotoxicity associated with hypertension, significantly elevated renal vascular resistance and deteriorating renal function that may progress to end stage renal failure.[344] Histopathological changes associated with chronic cyclosporin nephrotoxicity are diffuse interstitial fibrosis or striped interstitial fibrosis with tubular atrophy, an obliterative arteriolopathy and ischaemic changes in some glomeruli.[129,342,346,399]

Lesions characteristic of cyclosporin nephrotoxicity seen in human kidneys have been reproduced in sodium depleted rats treated with cyclosporin.[117] Jackson et al. found that cyclosporin-induced focal areas of tubular atrophy and interstitial fibrosis in the outer cortex and an increase in cell proliferation, the majority of which were located in the interstitium and not the renal tubules.[203] Chronic cyclosporin A administration (12.5 mg/kg/day for 10 weeks) to rats was shown to produce histological injury to the inner stripe of the outer medulla and medullary rays of the kidney[203] similar to that seen in the striped interstitial fibrosis associated with chronic cyclosporin A administration in humans.[346] It is significant that these changes were demonstrated in nephron segments particularly sensitive to limited oxygen availability. Thus hypoxia secondary to cyclosporin-induced vasoconstriction may further potentiate cellular injury. This may also play an important role in the subsequent development of interstitial fibrosis as discussed below in Figure 85.4.

Cyclosporin A has a high lipid solubility and is extensively distributed to extravascular tissues, with the highest concentrations found in fat, liver, and kidney. Metabolism of cyclosporin A is via the cytochrome P-450 dependent mixed function oxidases. Experimentally, cyclosporin A has been shown to significantly inhibit hepatic mixed function oxidases by uncompetitive inhibition.[333] The renal cortex contains similar cytochrome P-450 dependent mixed function oxidases located predominantly in the S3 segment of the proximal tubules which is the main site of histological injury produced by cyclosporin A. Walker et al.[501] have demonstrated that cyclosporin A produces a significant uncompetitive inhibition of renal cortical NADPH cytochrome C reductase, an essential component of the mixed function oxidase enzyme complex.. The combined effect of lower enzyme activity, a greater degree of uncompetitive inhibition and lower enzyme concentrations acting as a rate limiting step, may in part explain the increased propensity for renal tubular damage as compared to hepatocellular damage despite similar tissue concentrations of cyclosporin A in the liver and kidney.[501] Ischaemic damage to the kidney associated with transplantation, coupled with cyclosporin A induced reduction in renal blood flow, would alter oxygen availability and metabolic requirements in

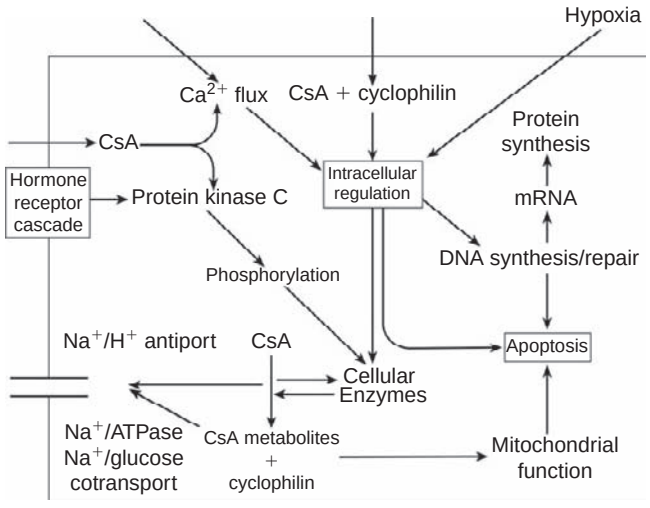

FIGURE 85.4 Potential pathways for the development of cyclosporin-induced interstitial fibrosis. Cyclosporin has been shown to influence the release of a number of cytokines and growth factors within renal vessels, renal tubular epithelial cells, and renal interstitial fibroblasts. With or without cellular injury from other mechanisms (hypoxia and rejection), this can lead to the development of interstitial fibrosis. *(With permission, modified from Walker RJ. Cellular mechanisms of drug nephrotoxicity. In: Seldin DW, Giebisch G, eds. The Kidney: Physiology and Pathophysiology. 3rd ed. New York: Raven Press, 2000:2835–2860.)*

the S3 segment of the nephron. This reduced oxygen gradient would further limit the activity of the renal mixed function oxidases already compromised by the inhibitory effects of cyclosporin.

Cyclosporin A has been shown to reduce renal glutathione content and produce an increase in lipid peroxidation, *in vitro*, in renal cortical microsomes, mitochondria and membrane fractions.[469,501] Cyclosporin A has been shown to generate superoxide through an as-yet-unclarified alteration in cytochrome P450 dependent mixed function oxidase.[435] A reduced availability of glutathione could impair the ability of glutathione peroxidases to metabolise fatty acid peroxides generated by lipid peroxidation. The net effect could be an increase in oxidant injury to renal tubular cells exposed to a hypoxic environment.[499] The hypoxic environment may also impair cellular mechanisms essential for maintaining cell integrity (see below).

Cyclosporin A has been demonstrated to alter cellular macromolecular synthesis in various cell lines in culture[126,500–504] within two hours of exposure to cyclosporin, suggesting that cyclosporin might be altering the normal regulatory mechanisms that control the cellular enzyme systems.[503] At a cellular level cyclosporin has also been shown to modify the intracellular assembly of the renal tubular Na^+ D-glucose cotransporter with subsequent intracellular accumulation of the transporter components.[548] Similarly cyclosporin has been demonstrated to selectively reduce the gluconeogenic capacity of rat proximal tubules via a decrease in phosphoenolpyruvate carboxykinase (PEPCK) activity.[336] This is due to a selective inhibition of renal PEPCK gene transcription and a corresponding reduction in renal PEPCK mRNA. Protein kinase C, a ubiquitous enzyme important in regulating a variety of intracellular functions, can be inhibited by cyclosporin A both *in vivo*, and *in vitro*.[503] These results would suggest a selective inhibition of the activity of a transcription factor(s) required for the expression of specific genes in renal tubules may play a role in cyclosporin-induced nephrotoxicity.[336] The net effect of direct inhibition of various intracellular enzymes or inhibition of gene transcription–translation controlling the synthesis of these enzymes, would be to impair the ability of renal cells to maintain their function and integrity in response to the toxic insult. Histological evidence of cellular damage either apoptosis or necrosis will only be apparent if the toxic injury exceeds the capacity of the cellular mechanisms to respond to the damage or alternatively if the cellular reparative mechanisms are modified by changes in intracellular regulation[499] (Fig. 85.4).

Buss et al.[54] have demonstrated that exposure to cyclosporin directly interferes with renal microsomal protein translation or the regulation of translation. Subsequent studies have shown that cyclosporin binds to cyclophilin A (the intracellular cyclosporin binding protein),[133,467] which is a microsomal peptidyl prolyl cis-trans isomerase, that facilitates protein folding and maturation.[458] Inhibition of cyclophilin A results in an accumulation of unfolded protein which in turns contributes to endoplasmic reticulum stress that further contributes to cellular injury.[374]

Within cells almost all soluble and membrane proteins of the cell are processed or degraded by the endoplasmic reticulum (ER). Proteins enter the ER in an unfolded state as linear polypeptides. In any situation in which an increased burden of unfolded proteins exceeds the ER's ability to deal with them results in a state of ER stress.[32] Pallet and colleagues have provided further evidence supporting the role of cyclophilin A inhibition and ER stress in contributing to tubular injury.[374] If the ER's capability to deal with the increased load of protein via resident enzymes and/or chaperone proteins is exceeded, this may then lead to cellular injury, transformation to a more profibrotic phenotype[374] and cellular death via apoptosis.[32,296]

Cyclosporin has been demonstrated to induce apoptosis in a number of models of cyclosporin toxicity via increased expression of pro-apoptotic mediators. The induction of apoptosis was associated with increased TGFβ synthesis[260] which will further favor the development of interstitial fibrosis. Cyclosporin has been shown to upregulate Fas and Fas ligand expression, p53 expression, alter the ratio of Bax and Bcl-2, and upregulate ICE and caspase 3 activity. This favours the induction of apoptosis leading to tubular cell drop-out and impaired ability to remodel after cyclosporin-induced injury.[186,445,446,529] More recently Justo and colleagues have demonstrated that cyclosporin-induced apoptosis was associated with Bax translocation to the mitochondria and release of cytochrome c that was caspase-independent as well as a caspase-mediated alteration in mitochondrial membrane potential.[215]

Activation of anti-apoptotic pathways offers a possible therapeutic option. Erythropoietin binding to its receptor activates a number of intracellular pathways including the phosphatidyl-inositol 3 phosphate kinase/Akt axis which is a key regulator of cell proliferation and survival. Pallet and colleagues have demonstrated the recombinant human erythropoietin protects against acute cyclosporine nephrotoxicity in part through Akt signaling and inhibition of caspase 3 activation.[375] This would be consistent with other experimental studies that have demonstrated a protective role for EPO in acute kidney injury.[210]

A number of studies have demonstrated a dissociation between cyclosporine–induced changes in GFR and progressive interstitial fibrosis. Angiotensin II has been shown to be an important renal growth factor

independent of its vascular actions. Chronic exogenous AII exposure produces significant renal interstitial proliferation and fibrosis.[211] In addition, renal type I interstitial fibroblasts contain a high density of AII receptors.[547] Experimentally, blockade of the renin - angiotensin system with either AII receptor antagonists or angiotensin converting enzyme inhibitors prevented cyclosporin induced interstitial fibrosis without modification of renal functional parameters.[43,44]

Angiotensin II has been shown to stimulate the release of TGFβ in vascular smooth muscle cells. Furthermore, interactions between TGFβ and PDGF determine the nature of the growth response of cells to AII *in vitro*.[142] Both PDGF and TGFβ are potent fibrogenic growth factors that stimulate fibroblast proliferation, collagen synthesis and alterations in extracellular matrix synthesis. Enhanced renal expression of both PDGF and TGFβ during cyclosporin administration has been demonstrated both experimentally and clinically.[208,209,440] Insulin-like growth factor 1 (IGF1) has also been implicated as a mediator of cyclosporin-induced renal tubular interstitial fibrosis.[208,209]

More recently, the active non-hypercalcemic vitamin D analog, paricalcitriol has been shown to attenuate cyclosporin A induced renal tubular acidosis and fibrosis in an experimental rat model of nephrotoxicity.[379] Park and colleagues propose that the renoprotective effects are due to down regulation of nuclear factor−kappa B (NF-κB) and nitric oxide signalling with subsequent down regulation of TGF β1 signalling pathways.[379] However the role of paricalcitrol on other recognised pathways for CSA-induced nephrotoxicity also need to be explored.

The transmembrane efflux pump P-glycoprotein has been linked to the development of chronic cyclosporin nephrotoxicity. P-glycoprotein is associated with cyclosporin elimination by proximal tubular epithelial cells. Reduced renal expression of tubular P-glycoprotein has been shown to be related a greater degree of cyclosporin nephrotoxicity.[93,240] Recently clinical studies have demonstrated that low levels of renal P-glycoprotein, in the donor kidney leads to decreased cyclosporin clearance and subsequent cyclosporin accumulation and toxicity.[184]

The chronic interstitial fibrosis associated with cyclosporin therapy appears to be related to a complex interplay between cellular regulatory pathways controlling cell death or survival, various cytokines and growth factors whose expression will also be modified degree of cellular injury, as well as by the relative ischemia associated with cyclosporin-induced alterations in renal perfusion as outlined in Figure 85.5.

Thus cyclosporin appears to affect many facets of renal function, from changes in whole-kidney function *in vivo*, to alterations at a subcellular level demonstrated in cell culture models. Despite the large number

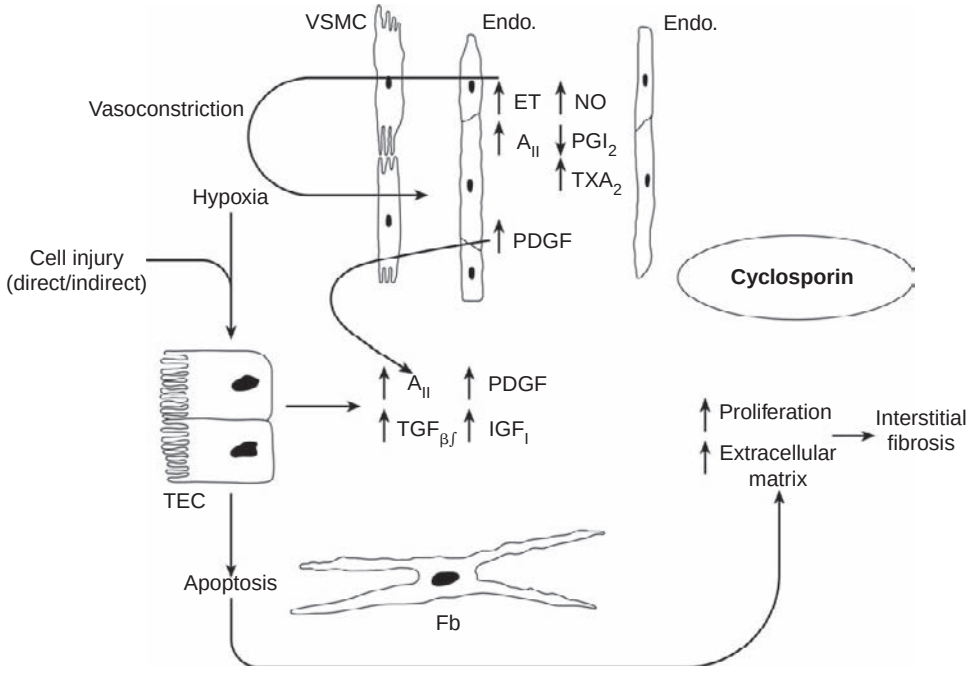

FIGURE 85.5 Diagramatic representation of the interaction of cyclosporin with components of cellular function including hormone receptor cascade and second messenger pathways; transcription, translation, and translocation pathways; apoptotic pathways; and cellular metabolism. *(With permission, modified from Walker RJ, Fawcett JP. Drug nephrotoxicity—cellular mechanisms. In: Jucker E, ed. Progress in Drug Research. Vol. 41. Basel, Birkhauser Verlag AG, 199341:3−45.[499])*

of studies investigating cyclosporin nephrotoxicity, there are still many unanswered questions as to how this unique agent produces the various changes that are manifested in the development of nephrotoxicity.

CISPLATIN

Cisplatin is an antineoplastic agent which acts by inhibiting DNA synthesis.[283] It has been used success fully in solid organ tumours, particularly in testicular germ cell tumours. The clinical use of cisplatin is limited by the development of nephrotoxicity which are manifest clinically as renal tubular defects in potassium, calcium, magnesium and hydrogen ion handling, inability to concentrate the urine and with more severe toxicity, changes in RBF and GFR. The extent of nephrotoxicity has been reduced significantly by the use of appropriate hydration schedules with normal saline.

The high renal concentrations of cisplatin, and subsequent development of nephrotoxicity, are a consequence of renal tubular cell handling predominantly via peritubular uptake and metabolism of cisplatin.[85,86,421,422] Renal clearance of platinum is very efficient, with high clearances at low plasma levels of the drug, due to net tubular secretion in addition to filtration of platinum.[61] Filtration of cisplatin does not appear to be a prerequisite for the initiation of nephrotoxicity; rather, the tubular uptake of cisplatin and metabolites including the basolateral transport of cisplatin and/or metabolites may be important in the generation of nephrotoxicity.[85,325] The kidney specific organic cation transporter 2 (SLC22A) mediates the basolateral uptake of cisplatin and thus its subsequent toxicity. Cisplatin excretion from the cell is via the multidrug and toxin extrusion 1 transporter (MATE1), but the extent to which this may or may not influence intracellular concentrations of cisplatin is less clear.[532]

The current concept of cisplatin nephrotoxicity is that cisplatin uptake by tubular epithelial cells activates complex intracellular signalling pathways including DNA damage response pathways, caspase activation (extrinsic, intrinsic and ER stress pathways), induction of free oxygen radicals along with inactivation of anti-oxidant systems, leading to cell apoptosis and necrosis. This is associated with an intense inflammatory response with TNFα a major mediator further exacerbating tubular cell injury (Figure 85.6).[371]

Morphological studies have shown that cisplatin induces focal damage to the proximal tubules, predominantly confined to the S3 segment located in the outer stripe of the outer medulla.[99,212] The earliest changes of nucleolar segregation, microsomal dispersion and aggregation of smooth endoplasmic reticulum are evident within six hours of cisplatin administration. These

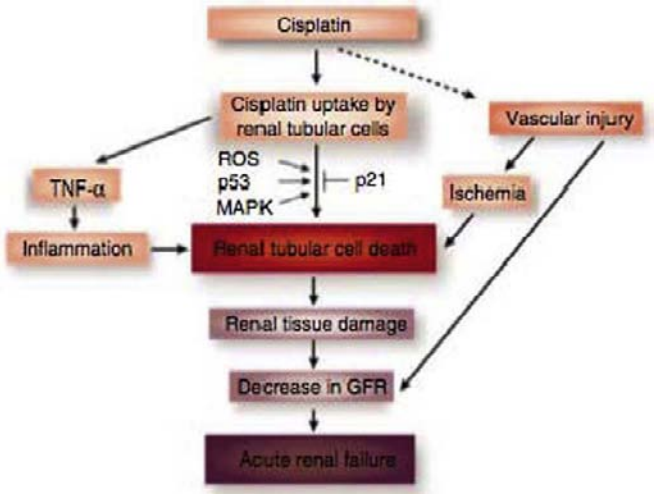

FIGURE 85.6 Overview of the pathophysiological events in cisplatin nephrotoxicity. *(Used with permission from the Nature Publishing Company (Pablo & Dong).*[371])

early changes are consistent with apoptotic changes.[147] Functional changes leading to depression of glomerular filtration rate (GFR) are not apparent until 48 hours post administration, by which stage there is focal loss of the tubular epithelial cells' brush border, cellular swelling, and focal areas of necrosis.[99,212] With established renal failure and maximal nephrotoxicity, there is widespread tubular necrosis, predominantly involving the S3 segment and to a lesser extent, the S1, and S2 segments of the proximal tubule.[99,212]

It has been demonstrated that the cis isomer of the platinum complex is necessary for tumoricidal actions and is also responsible for the development of nephrotoxicity.[85] Unlike other heavy metal-induced nephrotoxicity, the onset of cisplatin toxicity is delayed, with functional changes not readily apparent until 48–72 hours.[149] This suggests that toxicity is not due directly to the effects of the platinum ion but rather to the biotransformation of cisplatin to various platinum metabolites and subsequent binding to intracellular components. The cisplatin metabolites, especially the hydrolysis product $[Pt(NH_2)\ (OH_2)^{2+}]$, when infused into rats at equivalent concentrations to cisplatin, generate greater nephrotoxicity.[85,86]

Within the kidney, cisplatin and metabolites are preferentially localised to the juxtamedullary cortical regions[69,99,324] with a greater degree of injury seen in the S3 segments of the proximal tubules. Cellular concentrations are high in the nuclear and microsomal fractions,[69] with quantitatively the greatest concentrations of cisplatin in the protein fraction of the cytosol associated with the sulfhydryl rich metallothioneins.[263] Levi et al.[263] demonstrated that following cisplatin administration *in vivo* there was a marked fall in

protein bound sulfhydryl groups. The binding to sulfhydryl groups suggests that glutathione dependent transferases may be important in the modulation and/or mediation of cisplatin nephrotoxicity. It has been suggested that either an active platinum metabolite binds to the sulfhydryl group, or alternatively the platinum metabolite(s) inhibits oxidative metabolism, preventing regeneration of reducing equivalents necessary to maintain the reduced sulfhydryl groups.[263] Exogenous reduced glutathione, at a high dose, has been shown to reduce cisplatin-induced nephrotoxicity,[554] further supporting the role of binding to sulfhydryl groups as well as the generation of free oxygen radicals is important in mediating toxicity. Depletion of mitochondrial GSH has been shown to be an early and critical step in cisplatin-induced cell injury which results from oxidative stress to the mitochondria.[544] Kruidering and colleagues[244] using porcine proximal tubular cells, have demonstrated that cisplatin specifically affected mitochondrial function by inhibition of the enzymatic complexes I to IV of the respiratory chain with decreased intracellular ATP levels as a consequence. GSH reductase activity was also impaired leading to reduced intracellular GSH levels.[244] Alterations in mitochondrial function will also lead to increased oxidative stress.

Thus the formation of reactive oxygen species may be one of the early signals that contribute to the activation of various intra-cellular signalling pathways leading to cellular injury. A number of experimental models (*in vitro* and *in vivo*) have demonstrated renoprotective effects for a number of different antioxidants including vitamin E, N-acetyl cysteine, and dimethylthiourea (DMTU).[207,371]

Recent studies have demonstrated several pathways by which cisplatin-induced apoptosis occurs (Figure 85.7)[78,371] that include the extrinsic pathway mediated by death receptors such as Fas and TNFα, the intrinsic pathway via mitochondrial-dependent pathways[10,224,380] and the endoplasmic reticulum (ER) stress pathway.[371] In the extrinsic pathway, the binding of ligands to the major death receptors Fas and TNFα receptors leads to activation of caspase 8 and subsequent downstream pathways leading to apoptosis. It has been shown that cisplatin upregulates the expression of Fas and Fas ligand in both lymphocytes and proximal tubular epithelial cells.[280] TNFα plays a major role in the inflammatory response associated with cisplatin injury, which may be the major route of subsequent injury rather than the activation of the extrinsic pathway.

Experimental evidence suggests that the intrinsic pathway via mitochondrial injury is the major pro-apoptotic pathway in cisplatin injury. Bax activation,

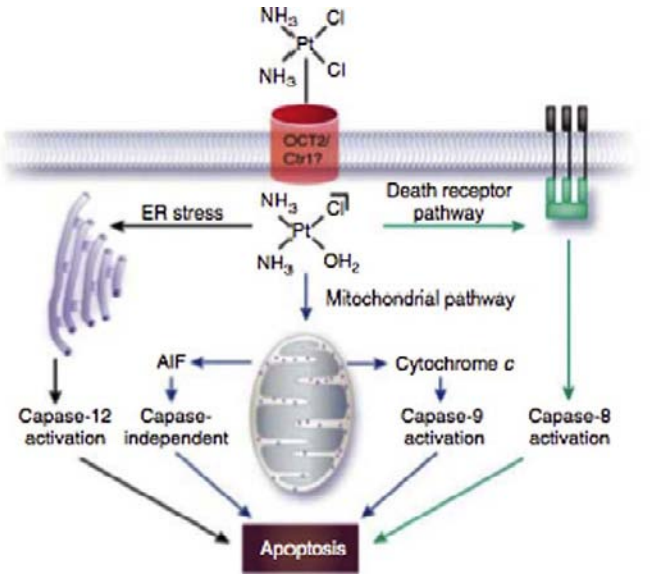

FIGURE 85.7 Apoptotic pathways activated by cisplatin in renal tubular epithelial cells. *(Used with permission from the Nature Publishing Company (Pablo & Dong).*[371])

mitochondrial release of cytochrome c and activation of caspase 9 are key steps in the pathway.[371]

The third pathway is via endoplasmic reticulum stress with activation of caspase 12[285] and more recently a role for COX-2 and membrane bound prostaglandin E synthase 1 in mediating cisplatin nephrotoxicity has been demonstrated.[205] In addition cisplatin may induce reactive oxygen species in microsomes via cytochrome P450 activation.[285]

Renal cells mount a cytoprotective response to oxidative stress. In an hypoxic setting, up-regulation of hypoxic–inducible factor 1α (HIF-1α) plays an important protective role against injury. Cisplatin has been shown to suppress HIF-1α in cell culture models. Downstream mediators of HIF-1α actions include heme-oxygenase 1, vascular endothelial growth factor and erythropoietin, all of which have been demonstrated to provide a degree of protection against cisplatin-induced nephrotoxicity.[424,511] Therefore HIF-1α is a potential target for protection against cisplatin nephrotoxicity.

DNA fragmentation has been observed in both apoptotic and necrotic pathways related to cisplatin injury, suggesting a common link at the level of cell death endonucleases. Basnakian and colleagues, using a deoxyribonuclease 1 (DNase 1) knock out mouse model, recently demonstrated that DNase 1 is important in mediating cisplatin-induced DNA fragmentation, tubular necrosis and possibly tubular necrosis.[19] They demonstrated that the inactivation of DNase 1 was protective against cisplatin-induced DNA

fragmentation. Another important step in the cellular response to DNA damage is activation of p53. A number of studies have demonstrated that p53 is rapidly phosphorylated and induced prior to tubular cell apoptosis. It is thought that activated p53 mediates its action through increased transcription of target genes. Studies have shown that p53 activation co-localises with apoptosis and nephrotoxicity can be ameliorated in p53 deficient mice.[206,510] Interventions that reduce cisplatin-induced nephrotoxicity have been shown to reduce apoptosis and decrease p53 activation.[206,207]

In cisplatin-induced nephrotoxicity, there is an intense inflammatory response to injury and experimental studies have demonstrated that TNFα is a key regulator of the inflammatory response. Inhibition of TNFα results in a marked amelioration of cisplatin injury. Of interest, is recent evidence that renal tubular cells contribute significantly to TNFα production during cisplatin nephrotoxicity.[543] This in conjunction with the studies by Linkerman[280] who demonstrated a close crosstalk between proximal tubular epithelial cells and distal tubular epithelial cell, suggest that the local production of TNFα by renal cells plays an important role in regulating cellular response to injury including apoptosis or necrosis pathways, referred to as fratricide.[423]

Cisplatin nephrotoxicity appears to be dependent on renal tubular uptake and probable conversion to more toxic intermediates. Nephrotoxicity is probably secondary to alterations in cellular mitochondrial function, generation of reactive oxygen species and the balance between the activation of cell death pathways and cell survival signals and inflammation.[224,371]

ACETAMINOPHEN NEPHROTOXICITY

Acetaminophen (paracetamol) is an antipyretic and analgesic agent that is freely available as a proprietary medicine and is the most widely used analgesic in the United States. Acetaminophen is the major metabolite of phenacetin, which has been used in compound analgesics. Both agents, either alone or in combination with other analgesics, have been implicated in the pathogenesis of analgesic nephropathy.[425] In addition, Sandler et al.[425] demonstrated a significant association between excessive acetaminophen intake and the subsequent development of chronic renal failure. The renal handling of phenacetin and acetaminophen exemplifies the heterogeneity of renal anatomical, biochemical, and physiological characteristics that influence the development of acute and chronic nephrotoxicity.[499] Phenacetin is metabolised extensively to acetaminophen by the liver and gut. Only very low concentrations of the parent compound enter the systemic circulation. Phenacetin is filtered at the glomerulus and undergoes passive reabsorption along the nephron at a rate equivalent to water, related to the lipid solubility of the drug.[105–107] Acetaminophen is moderately lipid soluble and it is filtered at the glomerulus with passive diffusion of the non-ionic form. Clearance is independent of plasma concentrations or tubular reabsorption. Reabsorption is not localised to a particular nephron segment.[105–107] Acetaminophen clearance is related to the rate and the concentration gradient generated between intracellular/interstitial compartments and the tubular fluid. Under conditions of antidiuresis, acetaminophen increases in concentration in the inner medulla, conversely diuresis results in a diminution of the concentration gradient, with the concentration of acetaminophen being the same as that of the cortex. The clearance of phenacetin is increased by changes in urine flow rate directly proportional to the increase in urinary flow.[105–107] The accumulation of acetaminophen in the medulla is important in the subsequent development of chronic nephrotoxicity. Renal metabolism of acetaminophen is essential in the development of nephrotoxicity[337,349–351] and is linked to the proportional conversion of acetaminophen to its non toxic and toxic metabolites. The generation of non-toxic conjugated metabolites is potentially rate limited and increases in renal concentrations of acetaminophen will favour the formation of toxic metabolites. The distribution of the enzymes involved in the metabolism of acetaminophen is important in the development and localisation of the renal injury in acute and chronic nephrotoxicity.[327] The predominant pathways for acetaminophen metabolism involve the $NADPH^+$-dependent cytochrome P-450 mixed function oxidases located in the renal cortex and the $NADPH^+$-independent prostaglandin H synthase (prostaglandin endoperoxidase synthetase system), consisting of a fatty acid cyclooxygenase and prostaglandin hydroperoxidase, localised predominantly in the inner medulla.[327]

Acute Nephrotoxicity

This occurs clinically in the context of an acute overdose of acetaminophen but is not always associated with acute hepatic toxicity.[108] The concentration of acetaminophen in the kidney is important in the development of acute nephrotoxicity.[106] Acute toxicity is dependent on metabolic activation of acetaminophen to reactive metabolites. This has been shown to be a prerequisite for the development of acute tubular necrosis which is confined predominantly to the renal cortex.[349,353] Following an acute overdose, there is insufficient GSH generated to bind all the metabolites generated by cytochrome P450 mixed function oxidases and intracellular reduced glutathione stores become

depleted. Reactive metabolites bind covalently to intracellular constituents, as well as causing depletion of cellular GSH and lipid peroxidation, producing cell damage and eventual cell death.[108] In the renal cortex, acetaminophen may be deacetylated to p-aminophenol, which is five to 10 times more nephrotoxic.[59,349,351] Deacetylase activity is predominantly located in the renal cortex and is significantly more active than in the liver.[59,108] Cytochrome P-450, prostaglandin H synthase, and possibly other peroxidases can convert acetaminophen and p-aminophenol into reactive intermediates through peroxidative reactions with the formation of semiquinoneimines [N-acetyl-p-benzoquinoneimine (NAPQI)], quinoneimines, or p-benzoquineimines (PQI).[108,326,337] In the absence of GSH and other reducing equivalents, acetaminophen and p-aminophenol may undergo catalytic conversion mediated by mixed function oxidases, peroxidation by cytochrome P-450 or prostaglandin H synthase, as well as auto oxidation of p-aminophenol to reactive arylating intermediates.[108] Cytochrome P-450 mediated peroxidative activation of both acetaminophen and p-aminophenol can continue to occur despite the depletion of cellular GSH and $NADPH^+$.[486] The arylation of renal macromolecules and subsequent cellular damage has been postulated as the initiating event in acetaminophen-induced acute nephrotoxicity.[352] The toxicity of acetaminophen occurs only after the depletion of cellular GSH. GSH protects against toxicity induced by acetaminophen metabolites by several potential mechanisms. GSH may form a glutathione conjugate with NAPQI, which will then be excreted.[350,396] GSH can react with NAPQI to reform acetaminophen.[350,396] GSH may protect against lipid peroxidation due to further reactions of NAPQI. Recent evidence also suggests a possible nephrotoxic role of p-aminophenol glutathione S-conjugates and other hepatic metabolites.[236,479] These S-conjugates after γ-glutamyl transpeptidase dependant cleavage are translocated into renal tubular epithelial cells where p-aminophenol derived S-conjugates accumulate as has been demonstrated for toxic S-conjugates from other xenobiotics.[429]

GSH is a prerequisite for the activity of glutathione peroxidases, which protect the cell from peroxidative injury. Depletion of GSH by acetaminophen and p-aminophenol reactive intermediates would prevent glutathione peroxidase activity, increase lipid peroxidation, and enhance cytochrome P-450 mediated peroxidase activation of acetaminophen and p-aminophenol.[108] Acute acetaminophen nephrotoxicity involves the metabolic activation by cytochrome P-450, mixed function oxidases, deacetylase, and prostaglandin H synthase with the generation of reactive intermediates. When the cellular protective mechanisms, predominantly GSH and GSH-related enzymes, cannot detoxify the reactive intermediates, tissue damage and subsequent acute tubular necrosis occur.

Chronic Nephrotoxicity

With chronic administration, acetaminophen achieves a higher concentration in the cells of the renal inner medulla compared to the renal cortex and plasma.[106] This relatively higher concentration is important in the subsequent development of chronic nephrotoxicity. The prostaglandin H synthase enzyme complex, which appears to be the main mediator of chronic nephrotoxicity, is predominantly located in the inner medulla.[540,541] The hydroperoxidase component reduces the hydroperoxy group of PGG_2 to the alcohol producing the endoperoxide PGH_2, with the oxidation of a suitable electron donor.[540,541] Acetaminophen has shown to act as a suitable substrate in this enzyme reaction.[35,326–328,543] Mohandas et al.[327,328] have demonstrated *in vitro*, using rabbit renal cortical and medullary microsomes, that the prostaglandin synthesis is enhanced by acetaminophen at low concentrations, comparable to those that would be achieved during chronic ingestion (up to O.5 mM), and inhibited at higher concentrations (as would be seen in acute overdose situations). More recently, similar results were demonstrated using human renal cortical, outer and inner medullary microsomes.[153] The prostaglandin hydroperoxidase component of the enzyme complex converts acetaminophen to its reactive metabolite probably by a one electron oxidation reaction and hydrogen abstraction to form the phenoxy radical of acetaminophen, which then undergoes further oxidation to the more reactive intermediate NAPQI.[329] This metabolite reacts rapidly with GSH with the regeneration of acetaminophen or the formation of a stable conjugate. The sharing of the conversion of PGG_2 to PGH_2 by both glutathione peroxidase and prostaglandin hydroperoxidase would influence the extent of co-oxidative activation of acetaminophen, since depletion of GSH by binding to NAPQI would decrease glutathione peroxidase participation in this reaction as opposed to prostaglandin hydroperoxidase which does not require GSH as a substrate. The increased prostaglandin hydroperoxidase activity would increase the co-oxidation of acetaminophen and formation of active metabolites.[329] The cellular concentration of GSH is critical in preventing damage initiated by the reactive acetaminophen metabolites. The metabolite NAPQI may form a conjugate or is reduced back to acetaminophen with the production of oxidised glutathione (GSSG).[328] GSSG is reduced by glutathione reductase requiring $NADPH^+$. Thus, depletion of cellular GSH may occur due to decreased availability of $NADPH^+$, low activity of

glutathione reductase in the renal medulla, or the movement of excess GSSG out of the cell, in addition to conjugation with metabolites.[328] In addition, extracellular GSSG is not readily available to the renal inner medulla cells due to very low levels of gamma glutamyl transpeptidases on the cell membranes as opposed to high enzyme concentrations in renal cells in the cortex.[328]

More recently, it has been demonstrated that acetaminophen may cause direct toxicity to renal inner medullary cells. Cai and colleagues[55] using passage 1 rat inner medullary collecting duct (p1rIMCD) cells maintained in a osmotic environment that represents the osmolality of the inner medulla *in vivo*, demonstrated a toxic effect of acetaminophen and caffeine. Acetaminophen (0.5−2.0 mM), either alone or in combination with caffeine or salicylic acid induced proliferation of p1rICD cells when they were confluent. This was in contrast to an inhibitory effect of acetaminophen on cell growth if the cells were subconfluent. Normally there is little proliferation of inner medullary cells *in vivo* and proliferating inner medullary cells have a reduced tolerance for hyperosmolality.[55] Thus it would appear that acetaminophen-induced proliferation appears to sensitize the cells to toxicity, which was demonstrated by evidence of DNA damage and apoptosis. Other workers have also suggested that acetaminophen induced renal cell injury may be mediated via an apoptotic process.

Lorz and colleagues[290] demonstrated that acetaminophen can induce apoptosis in murine tubular cells that was not mediated via the Fas Fas-ligand pathway or mitochondrial injury. Rather, apoptosis was associated with a decrease in antiapoptotic Bcl-xL protein levels and evidence of increased endoplasmic reticulum stress.[290]

Compound analgesics containing aspirin, caffeine and phenacetin (or its major metabolite, acetaminophen) have a synergistic effect in the development of chronic nephrotoxicity. Aspirin inhibits the action of cyclooxygenase but not prostaglandin hydroperoxidase in the prostaglandin synthase complex.[542] Clinically little or no aspirin reaches the kidney[141] as aspirin is deacetylated to salicylate. Salicylate, as well as depleting renal glutathione levels increasing the potential for oxidative injury, potentiates acetaminophen effects on renal inner medullary cell proliferation and susceptibility to hyperosmotic injury.[55] Likewise caffeine can potentiate acetaminophen induced cellular injury.[55] Caffeine influences a number of pathways involved in cellular response to DNA damage. Caffeine also blocks p53 activation in response to DNA damage as well as blocking DNA repair.[55,546]

Clearly, acetaminophen, either alone or in combination with other agents can have significant effects on renal cellular function leading to nephrotoxicity. These may be mediated via intracellular metabolic pathways producing reactive metabolites and/or by direct effects on cell survival.

AMINOGLYCOSIDES

Aminoglycosides are an important group of antibiotics that are widely prescribed in the treatment of life-threatening gram-negative infections. Nephrotoxicity remains the major limitation to their clinical use. Aminoglycosides consist of two or more amino sugars joined in glycoside linkage to a hexose nucleus, usually in a central position. At physiologic pH, they are polycations with a high degree of polarity and water solubility and have no significant binding to plasma proteins. Autoradiographic studies have demonstrated rapid proximal tubular uptake within six hours of administration of tritiated gentamicin.[451] Only a small percentage of the filtered aminoglycoside (about 5%) is taken up by the proximal tubular cells, yet the renal cortical concentrations exceed the plasma or tissue concentrations by two to five fold. The majority of renal aminoglycoside accumulation occurs by active transport into the proximal tubular cells following binding to the luminal membranes.[518] A smaller proportion is taken up across the basolateral membrane,[220,221] but this may be more important in the mediation of cellular toxicity, as it allows for drug exposure to intracellular organelles such as mitochondria and microsomes. Aminoglycosides have been demonstrated to cause multiple structural, functional, and metabolic alterations within renal proximal tubular epithelial cells. These alterations are evident within 90 minutes following the single administration of an aminoglycoside. It is probable that nephrotoxicity is the combined result of these insults which compromise cellular structural and functional integrity (Figure 85.8).[220,221,289]

The cationic aminoglycosides bind to the anionic phospholipids, predominantly the phosphoinositols, in the brush border membrane.[426] The drug-receptor complex is pinocytosed with subsequent translocation to intracellular lysosomes.[131] The more acidic pH of the lysosomes increases the binding affinity of the aminoglycosides to the phospholipids. The aminoglycosides have been shown to inhibit the action of phospholipases both *in vitro* and *in vivo*, preventing the degradation of the phospholipids and release of inositol triphosphate.[131,254,255,281,297,401]

Aminoglycosides have also been demonstrated to inhibit renal protein kinase C activity.[170] Inhibition of protein kinase C activity may be due to decreased substrate availability due to inhibition of phosphoinositol metabolism or a direct effect on the activation of the

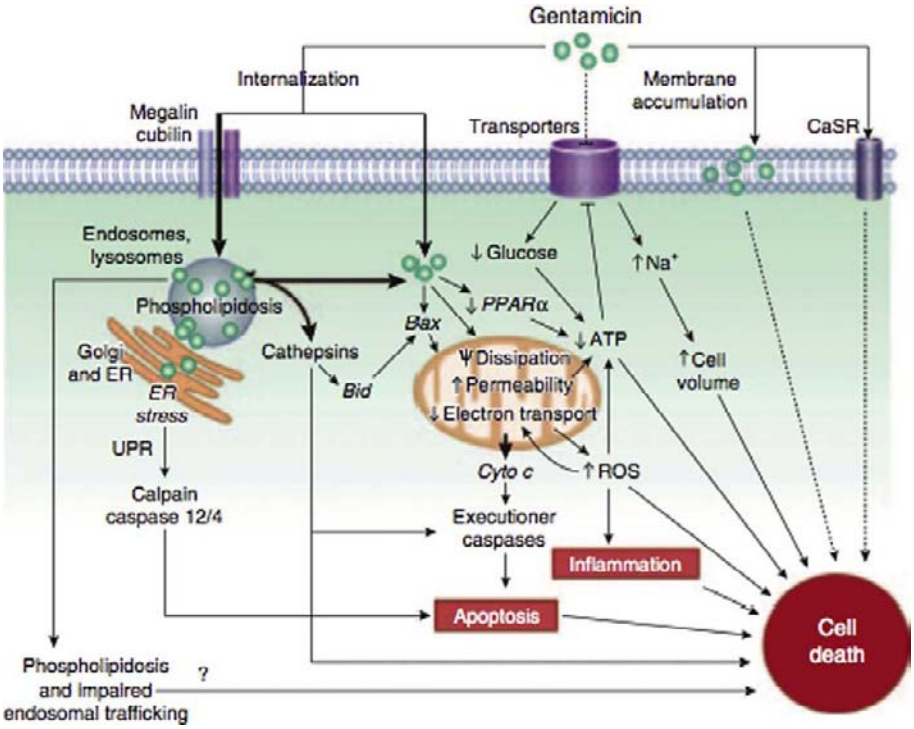

FIGURE 85.8 Mechanisms and cell signaling pathways underlying the cytotoxic effect of gentamicin. *(Used with permission from the Nature Publishing Company. Lopez-Novoa et al.*[289])

protein kinase C complex. Aminoglycoside-induced inhibition of phospholipid metabolism has been shown to occur not only within lysosomes but also involves other cellular constituents.[221,401,402] The net effect would be the impairment of the phosphoinositol cascade and second messenger pathway which may be an early event in aminoglycoside nephrotoxicity.[402]

The degree of aminoglycoside binding to the phospholipids, particularly in relationship to the ester bond split by the phospholipases, is postulated to be critical in the inhibition of phospholipid metabolism.[36,37] Alterations in membrane phospholipids probably result in the modification of both apical and basolateral membrane transport functions including decreased calcium transport, organic acid and base transport, decreased sodium/potassium ATPase and adenyl cyclase activity, ultimately impairing the control of cellular integrity.[196,220,221,297,515]

Gentamicin interacts with megalin (a giant multiligand endocytic receptor, localised to the apical membrane of proximal tubular epithelial cells) to gain entry into the cells, but can inhibit early endosomal fusion which may in part explain the toxic vacuolation in tubular cells that occurs with aminoglycoside toxicity.[178] Of interest, is the observation that megalin-knockout mice accumulate very little gentamicin compared to wild-type mice, further supporting a role for megalin-mediated endocytosis as the main mechanism of gentamicin accumulation in proximal tubular epithelium.[428] Megalin receptor-mediated endocytosis requires functional GTP-binding proteins that in turn require prenylation by isoprenoid products. Antione and colleagues have demonstrated that statins by inhibiting the formation of isoprenoids provide protection against aminoglycoside-induced accumulation and cytotoxicity in proximal tubule cells in culture.[9] This possible pleiotrophic action of statins in reducing megalin-mediated uptake of nephrotoxins and hence reducing proximal tubule cell injury needs to be explored with well-constructed clinical trials.

Aminoglycosides may access the intracellular cytosol via endosomal degradation or disruption. Aminoglycosides have been shown to bind to mitochondrial membranes and inhibit oxidative phosphorylation in renal cortical mitochondria *in vivo* and *in vitro*.[515] This is probably mediated by alterations in mitochondrial membrane permeability and mitochondrial calcium transport, which would produce alterations in mitochondrial respiration[452,513–515] and increased release of cytochrome c.[334] Increases in cytosolic cytochrome c concentrations will stimulate pro-apoptotic pathways with subsequent cell death. Several investigators have demonstrated increased markers of apoptosis in various animal models of aminoglycoside nephrotoxicity which was also associated with an increase in tubular and peritubular proliferation.[111,112,131]

Alterations in intracellular calcium transport, ATP synthesis, and mitochondrial permeability, are associated with endoplasmic reticulum stress and the

production of reactive oxygen species. *In vitro*, gentamicin has been demonstrated to enhance the generation of hydrogen peroxide by mitochondria[497] with the probable generation of other reactive oxygen species. Free oxygen radicals interact with numerous intracellular processes including peroxidation of membrane phospholipids, which has been demonstrated in aminoglycoside nephrotoxicity. Hydroxyl radical scavengers and iron chelators are protective against gentamicin induced acute renal failure.[497] However, the use of antioxidants (vitamin E and diphenyl-phenylenediamine) prevented gentamicin-induced lipid peroxidation but did not prevent the development of acute renal failure.[404,405] This suggests that lipid peroxidation is a consequence of toxicity[405] but does not exclude the interaction of hydroxyl radicals with other intracellular constituents in initiating cellular damage.

More recently Morales and colleagues have demonstrated that metformin (administered before gentamicin) substantially reduces gentamicin-induced mitochondrial respiratory chain dysfunction, in particular, reducing the changes in mitochondrial permeability transition, decreasing the release of cytochrome c and formation of reactive oxygen species, despite high tissue concentrations of gentamicin.[334] Co-administration of polyaspartic acid can also reduce aminoglycoside (gentamicin) nephrotoxicity despite higher intracellular concentrations of gentamicin.[143,195,403] This suggests that binding and intracellular uptake of aminoglycosides alone is not sufficient to produce cell damage.[143] Bennett et al. have demonstrated that aminoglycoside-induced inhibition of microsomal protein synthesis may be important in the generation of renal cell toxicity and a critical mechanism in determining the cellular ability to recover from the nephrotoxic insult.[29]

Tubular injury alone is probably insufficient to explain the significant reduction in GFR that occurs with aminoglycoside nephrotoxicity. There is good experimental evidence that aminoglycosides have direct effects on glomerular and vascular function with alterations in mesangial and endothelial cell contractility leading to a reduction in GFR as well as constriction of vascular smooth muscle cells leading to a reduction in renal blood flow.[289,304] In addition, the local cellular responses will enhance an inflammatory response which will produce an amplification of tubular, glomerular and vascular injury further exacerbating the renal injury.[289]

Chronic administration, for six months, of low-dose gentamicin has been shown to produce a mild chronic tubulointerstitial nephritis with progressive renal failure in rats.[195] Following cessation of the drug, interstitial inflammation intensified with a further decline in renal function, suggesting that gentamicin was inhibiting the reparative response (DNA and protein synthesis) of the tubular epithelium.[195] Alternatively, the chronic exposure to gentamicin can lead to enhanced proximal tubular cell apoptosis, and an ongoing inflammatory response resulting in chronic interstitial fibrosis. This raises the possibility that nephrotoxicity from aminoglycosides is inevitable and only in severe cases, where there has been marked renal cell injury, will the changes be observed clinically by the current rather insensitive clinical indices of renal function.

With the advent of sensitive urinary biomarkers of tubular injury as discussed above, it is to be hoped that monitoring of the urinary biomarkers will detect aminoglycoside toxicity earlier and minimise the risk of long-term injury.

LITHIUM

Lithium is a therapeutic agent used to treat patients with bipolar (manic depressive) illness and successfully alleviates both manic and depressive symptoms in 70−80% of patients. In fact, Timmer and Sands[474] estimate that about 1 in 1000 Americans are prescribed lithium at some time. However, chronic lithium administration has also been associated for many years with several different forms of renal injury. An analysis of several studies published from 1979 to 1986, comprising some 1172 patients,[34] revealed that the most prevalent renal effect of lithium reported was impairment of renal concentrating ability, which was estimated to be present in at least 54% of 1105 unselected patients on chronic lithium therapy. This defect translated into overt polyuria and polydipsia in up to 20% of cases.[34] Initially the decrease in urinary concentrating ability, which is resistant to the action of arginine vasopressin (AVP), is usually reversible following cessation of lithium administration. Of greater concern is the development of a progressive impairment of urinary concentrating ability in patients on long-term maintenance lithium therapy.[26] Markowitz et al.[298] reviewed the clinical features of 24 patients with biopsy-proven lithium toxicity, resulting from long-term treatment for bipolar disorder. This functional lesion is not usually readily reversible, is associated with a chronic focal interstitial fibrosis on renal biopsy, and may ultimately lead to renal failure.[298]

Complex mechanisms may be involved in lithium-induced changes in tubular cell water permeability, but the proximate cause is a loss of the ability to modulate the permeability, to water, of the apical cell membranes of the renal cortical and medullary collecting tubules. As a consequence of the loss of collecting duct permeability a hypo-osmotic urine is delivered to the medullary collecting tubule whose capacity to reabsorb water

(5% of the filtered water load) is limited. Thus voluminous dilute urine is produced which is manifest clinically as polyuria.

Rats given lithium therapy for up to 35 days became polyuric, losing weight and producing a large volume of dilute urine, a condition which was only partially reversed by water deprivation or by sustained treatment with AVP.[299] Semi-quantitative immunoblotting and studies by immunofluorescence and immunogold labelling revealed a massive reduction in aquaporin 2 (AQP2) expression in the lithium-treated animals. Water deprivation led to a small upregulation of AQP2, mainly in intracellular vesicles, while AVP infusion led to an accumulation of AQP2 largely in the apical membranes of collecting duct cells.[299] Chronic lithium therapy in the rat was associated with a reduction of AQP2 gene expression and product[249] along with altered cellular organization in collecting ducts characterized by a reduced fraction of principal cells, and increased number of intercalated cells.[71,72] These effects are likely to be important in lithium-induced nephrogenic diabetes insipidus.

Walker and colleagues recently demonstrated a reduction in urinary concentrating ability, associated with a decrease in urinary AQP2 excretion and urinary cAMP excretion, following lithium ingestion for four weeks in healthy human volunteers.[505] These changes are consistent with results obtained from animal models of lithium induced nephrogenic diabetes insipidus. In addition, in another study, they demonstrated a reduction in AQP2 expression in the cortical collecting tubules of human renal biopsies obtained from patients with lithium induced nephropathy.[22]

Lithium can readily substitute for sodium on several transport proteins that normally transport sodium, thus providing for lithium entry into tubular cells.[158,437] Lithium is a poor substitute for Na^+/K^+ ATPase thus allowing lithium to accumulate intracellularly. The amiloride-sensitive epithelial sodium channel (ENaC), co-expressed with AQP2 in the collecting duct, is critically involved in sodium homeostasis. Chronic lithium treatment is associated with a concomitant increase in urinary sodium excretion, and studies examining the expression of a number of sodium transporters in the rat kidney demonstrated a highly segment-specific down regulation of βENaC and γENaC in the cortical and outer medullary collecting ducts[355] but ENaC in the distal convoluted tubule, connecting tubule and inner medullary collecting duct are not modified by lithium.[72,355] Likewise there is no down regulation of the more proximal sodium transporters (NHE3, Na-K-ATPase, Na-K-2Cl cotransporter).[249] More recent studies by Christensen and colleagues using a specific cortical collecting duct ENaC knock out mouse model demonstrated that these mice did not develop lithium-induced NDI.[72] Of interest was the fact the ENaC expression, allowing lithium uptake, was still present in the adjacent cortical connecting tubular cells in these knock out mice. The exact mechanism of how segment-specific lithium uptake mediates NDI still needs greater clarification.

Earlier studies had shown that lithium inhibits the action of vasopressin at steps both proximal and distal to the intracellular formation of cAMP.[103,137] Within the cell, the principal action of lithium is thought to inhibit cAMP transduction pathways by competing with Mg for activation of G proteins which inhibit the activation of vasopressin-sensitive adenyl cyclase.[249] It has also been suggested that lithium may alter the balance between the formation of diacyl glycerol, with subsequent activation of protein kinase C, and the release of inositol triphosphate with subsequent mobilisation of intracellular calcium.[2] The phosphorylating activity of protein kinase C could in turn regulate the activation of adenyl cyclase and membrane transport function.[2] Bisphosphate nucleotidase activity which removes the 3′-phosphate from 3′−5′ bisphosphate nucleosides has a role in regulating salt tolerance. The presence of high levels of bisphosphate nucleotidase in the kidney and its role in sodium trafficking suggest a potential role also in lithium handling. It has been proposed that inhibition of human bisphosphate nucleotidase may contribute to lithium-induced nephrotoxicity.[455]

Alterations in adenyl cyclase activity and cAMP formation will impact on AVP receptor-stimulated regulation of aquaporin translocation and possibly (long term) aquaporin expression. cAMP activates protein kinase A by phosphorylation which in turn phosphorylates AQP2. It has recently been elegantly demonstrated that this is essential for the trafficking of AQP2 to the apical membrane.[2,299,300,356,358] Phosphorylation of AQP2 by other kinases in particular glycogen synthase kinase 3β (GSK3β), may also participate in the regulation of AQP2 trafficking. These effects are shown in a cartoon (Figure 85.9) adapted from Nielsen et al., and Grunfeld and Rossier.[160,357]

AQP2 gene expression is in part regulated via a cAMP response element in the 5′ flanking region of the AQP2 gene. Longer term, lithium via inhibition of adenylyl cyclase activity leads to the down regulation of cAMP-response element binding protein (CREB) which in turn down-regulates AQP2 gene expression via the cAMP response element.[269,299,300]

However a more recent study has demonstrated that the down regulation of AQP2 mRNA is by decreased gene transcription but it is independent of adenylate cyclase activity and it is proposed that glycogen synthase kinase 3β (GSK3β) (a serine/threonine protein kinase) may play a critical role.[269] GSK3β has been

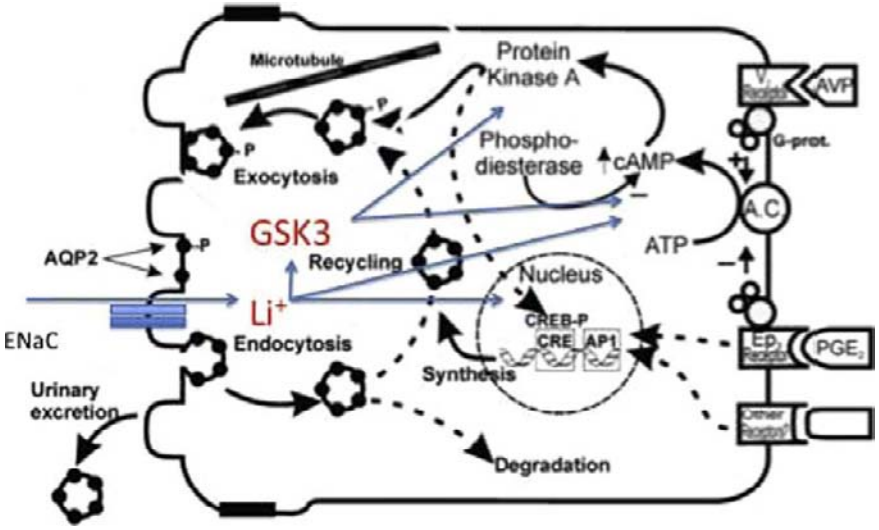

FIGURE 85.9 Pathways by which lithium modulates aquaporin 2 synthesis, phosphorylation and translocation to apical membrane in the principal cell in the collecting duct. Lithium (Blue lines) either directly modulates adenylyl cyclase activity or lithium inhibits GSK3β[160] which in turn modulates adenylyl cyclase pathways. *(Adapted from Nielsen et al.[357] with permission American Physiology Society.)*

demonstrated to mediate the renal response to vasopressin by modulating adenylate cyclase activity and cAMP generation.[407] Lithium at concentrations (10−25 mM) that can be achieved within collecting duct cells has been demonstrated to increase the amount of phosphorylated GSK3β (inactivated form) but not modifying the total amount of GSK3β.[238] Inactivation of GSK3β by lithium is associated with subsequent down-regulation of AQP2 expression.[238]

Battle and colleagues first demonstrated that amiloride can attenuate the polyuria associated with lithium-induced nephrogenic diabetes insipidus.[20] Amiloride blocks ENaC reducing lithium absorption in the distal convoluted tubule. Experimental animal studies[23,238,249,359] confirm that amiloride reduces transcellular lithium transport, and intracellular accumulation of lithium. This is associated with reduced phosphorylation and inactivation of GSK3β (238) along with increased AQP2 expression.[23,238] In addition to the direct effects in the distal convoluting tubule, amiloride largely restores the medullary concentrating gradient which is associated with upregulation of not only AQP2, but urea transporters (UT-A1 and UT-B) along with repletion of the medullary osmolytes critical for regulating the medullary osmotic gradient.[23] Presumably this is associated with restoring the cellular responsiveness to AVP, which regulates not only AQP2 expression but also regulates urea transporter expression. At a clinical level, amiloride has been demonstrated to significantly improve urinary concentrating ability in patients who had well established nephrogenic diabetes insipidus consistent with an improvement in the medullary concentration gradient.[24]

In patients on long-term lithium treatment for bipolar disorder, with biopsy-proven lithium toxicity, the histology demonstrates a chronic focal interstitial fibrosis, which may ultimately lead to renal failure.[298] The loss of nephrons and tubular damage with lithium induced nephropathy, is associated with a reduction in AQP2 expression in the cortical collecting tubules of human renal biopsies.[22] Electron microscopy has demonstrated that the cellular damage consists of swollen cells with increased numbers of mitochondria, swollen and damaged endoplasmic reticulum and vacuolation of the apical membranes with prominent accumulation of glycogen granules in the cytoplasm. The accumulation of glycogen correlated with the lithium-induced inhibition of AVP mediated activation of adenyl cyclase and alterations in glycogen synthesis. These lesions were associated with areas of fibrosis, dilated tubules and desquamation of tubular cells.

Earlier studies were not able to delineate the role of lithium-induced apoptosis compared to lithium-induced necrosis in mediating cell death and subsequent fibrosis. Controversy exists as to whether or not these lesions predispose to the development of a chronic focal interstitial nephritis as a consequence of long-term lithium therapy.[204] Lithium, at high concentrations (20 mmol/l), has been shown to produce apoptosis in neural tissue and other types of cell cultures[238,545] but there have been no studies in renal cell culture models. More recently, Walker and colleagues have established a long-term chronic model of lithium-induced interstitial fibrosis.[25] Preliminary studies demonstrate the TGFβ expression is markedly upregulated, especially in the medullary region but there is no associated inflammatory infiltrate. It is tempting to speculate that with active cellular update of lithium via sodium transport pathways that high intra-cellular concentrations can be achieved in both proximal and distal tubular epithelial cells, which in turn could

initiate cell to cell cross talk regulating apoptosis and a proinflammatory response as has recently been demonstrated for cisplatin nephrotoxicity.[280,423]

The link between lithium, sodium transport in the cortical collecting cells and subsequent lithium-induced nephrogenic diabetes insipidus is now well established.[70,72,238,249] However, the pathogenesis of the lithium-induced chronic interstitial nephritis still remains to be clearly elucidated.

Conclusion

This chapter has highlighted the importance of the kidney's unique functional organization, from a subcellular level to tissue level, in the development of drug nephrotoxicity. The heterogeneity of renal-tubular epithelial cell function and metabolism is the initial determinant in the development of nephrotoxicity. While these toxicants produce localized and specific injury to target cells in the kidney by specific mechanisms, many if not all of the final common pathways of toxicant injury are shared with ischemia-reperfusion injury.

The concentration of the drug and/or its metabolites within the tubular epithelial cells plays a critical role in the generation of toxicity. This may be modified by the tubular secretion and/or reabsorption of the drug, the intrarenal distribution of specific enzyme systems important in drug metabolism, and the potential generation of toxic metabolites. The final expression of nephrotoxicity will be dependent on the availability of intracellular mechanisms essential for maintaining cellular integrity and the cellular reparative response to injury. Thus, the pathophysiology of acute toxicant-induced kidney injury includes a complex interplay among specific cellular injury, inflammation, and altered renal hemodynamics.

CHAPTER

86

Role of Glomerular Mechanical Stress in the Pathogenesis of Chronic Kidney Disease

Clarice Kazue Fujihara and Roberto Zatz

Renal Division, Department of Clinical Medicine, Faculty of Medicine of the University of São Paulo, Brazil

DETERMINANTS OF GLOMERULAR ULTRAFILTRATION AND HOW THEY ARE INFLUENCED BY THE GLOMERULAR ARTERIOLES

The notion that derangements of glomerular dynamics may exert a deleterious effect and play a role in the pathogenesis of chronic kidney disease (CKD) is relatively recent, having been first postulated in a coherent way in the early 1980s.[1,2] This formulation was made possible after the determinants of glomerular ultrafiltration were directly measured in micropuncture experiments, and theoretically analyzed by Brenner, Deen and co-workers in the late 1960s and early 1970s.[3,4]

The ultrafiltration process at each glomerulus is governed by four independent physical determinants:[4] the first and most important of them is the glomerular transcapillary hydraulic pressure difference, ΔP, defined by the expression, $\Delta P = P_{GC} - P_{BS}$, where P_{GC} represents the glomerular intracapillary hydraulic pressure and P_{BS} denotes the hydraulic pressure in Bowman's space. The second determinant is the plasma protein concentration at the afferent arteriole (C_A), which is nearly identical to the systemic plasma protein concentration and determines the oncotic force that opposes filtration. The third determinant is the initial glomerular plasma flow (Q_A); and the fourth determinant is the glomerular hydraulic conductance coefficient (K_f). Variations of ΔP and Q_A cause changes in the same direction in SNGFR, whereas the relationship between SNGFR and K_f is more complex: although a decrease of K_f below normal lowers SNGFR, an increase of K_f has limited effect on ultrafiltration. A more detailed description of these determinants, of their individual effects, and of the relationship between them is given in Chapter 21.

Two of the determinants of ultrafiltration, ΔP and Q_A, are directly affected by variations of the afferent (R_A) and efferent (R_E) arteriolar resistances, as well as by changes in systemic blood pressure. The deep influence of these vessels on the dynamics of ultrafiltration derives from the unusual arrangement of the glomerular microcirculation, with the capillary loops interposed between the afferent and efferent arteriolar resistors (Fig. 86.1). If we assume the hydraulic pressure at the end of the efferent arteriole (P_E) to be much lower than the mean arterial pressure (MAP), and neglect the effect of fluid escape from the glomerular capillaries through ultrafiltration, the glomerular intracapillary hydraulic pressure (P_{GC}) can be approximated by:

$$P_{GC} = MAP \times R_E / (R_A + R_E) \qquad (86.1)$$

It becomes clear from this ultra-simplified equation that P_{GC}, and therefore ΔP, varies simultaneously with MAP and with the ratio between R_E and the total glomerular arteriolar resistance. An arterial pressure elevation, with R_A and R_E kept constant, would be accompanied, still in accordance with Equation 86.1, by a proportional elevation of P_{GC}. Such situation is seldom observed, because autoregulatory mechanisms make R_A change in the same direction as the change of MAP or, more specifically, of the renal perfusion

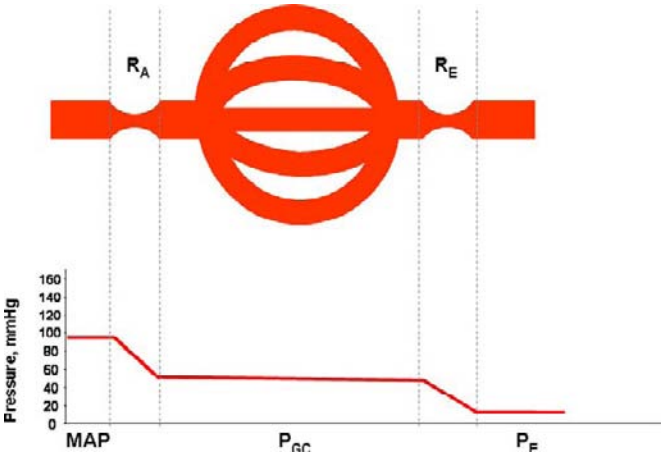

FIGURE. 86.1 Schematic representation of the glomerular microcirculation. MAP, mean arterial pressure; R_A, afferent arteriolar resistance; R_E, efferent arteriolar resistance; P_{GC}, glomerular hydraulic pressure; P_E, hydraulic pressure at the end of the efferent arteriole.

pressure (Chapters 21 and 24). On the other hand, changes in the glomerular arteriolar resistances can deeply influence SNGFR and its determinants. A decrease in R_A, with MAP kept constant, will elevate P_{GC}, still as predicted by Equation 86.1, whereas the opposite will occur if R_A increases. The consequences of changing the preglomerular resistance are not limited to the P_{GC}, since in a hydraulic system consisting of series resistors, such as the glomerular microcirculation, variations of one of the resistances will always promote reciprocal variations of flow. Specifically, Q_A can be approximated by the expression:

$$Q_A = MAP/(R_A + R_E) \times (1 - Ht) \qquad (86.2)$$

where Ht denotes the arterial hematocrit. Thus, a decrease of R_A will augment Q_A, while the reverse will occur if R_A increases. Since as noted above an analogous relationship exists between R_A and P_{GC}, and since SNGFR is a direct function of both Q_A and ΔP,[4] it follows that variations of R_A always promote changes of SNGFR in the opposite direction.

The effect of R_E on SNGFR is more complex than that of R_A, because of the peculiar location of the efferent resistor. An increase of R_E tends to increase P_{GC} (and ΔP), approaching its value to that of MAP, as predicted by Equation 86.1. Conversely, a decrease of R_E tends to bring P_{GC} close to zero, or more precisely, to the low pressure of the postglomerular microcirculation. On the other hand, an increase of R_E, as in the case of R_A, tends to diminish Q_A, as predicted by Equation 86.2, while the opposite will be seen with a decrease in R_E. Thus changes of R_E promote opposite effects in P_{GC} (and ΔP) and Q_A. If R_E is brought to very low values, ΔP may fall to critical levels (close to the plasma oncotic pressure), reducing SNGFR to values that approach zero, regardless of the value of Q_A. As R_E increases above these critically low values, SNGFR rises very steeply, since the positive effect on P_{GC} (and ΔP) largely compensates its initially small negative effect on Q_A. This effect reaches a maximum at R_E values that are within the normal range, since further efferent vasoconstriction will promote no additional increase of SNGFR and may even diminish it, because Q_A will be reduced in such a way as to offset the elevation of P_{GC}.

In view of the above considerations, it becomes clear that the pre and postglomerular resistors exert quite different functions. The monotonic inverse relationship between R_A and the SNGFR renders the afferent resistance ideally suited to function as a regulator of the glomerular microcirculation. Indeed, variations of R_A can entirely account for renal *autoregulation*, which keeps GFR, renal plasma flow and ΔP within narrow ranges in the face of wide variation of systemic blood pressure.[5] Although variations of R_E appear unsuited to intervene in the process of regulation of the glomerular microcirculation, the efferent arteriole is essential for the glomerular ultrafiltration process to occur. The mere existence of the efferent arteriole, acting as a "postcapillary sphincter," allows the glomerular capillaries to maintain much higher hydraulic pressures than in other microcirculatory territories, which is a physical requirement for high-grade ultrafiltration to occur. If R_E is decreased to critically low values, which may happen for instance in patients with bilateral renal artery stenosis treated with inhibitors of the renin-angiotensin system or angiotensin II receptor blockers, a catastrophic fall of SNGFR occurs, and acute renal failure can ensue.[6]

The GFR is Fairly Constant Under Physiologic Conditions—But There are Exceptions

Under physiologic conditions, there is little need for the GFR to vary very much, since the balance of water and solutes such as sodium, chloride and potassium is achieved by the action of the tubules, especially at the final portions of the nephron. In fact, GFR is tightly controlled by autoregulatory mechanisms, which involve mostly variations of the afferent arteriolar resistance, more suitable to this task, as pointed out earlier. These variations of R_A are thought to be achieved by local myogenic reflexes and by signals generated at the macula densa.[5,7]

In states of decreased effective arterial volemia such as in dehydration, the GFR can be brought to very low values, even in the absence of kidney injury, as part of the organism's effort to conserve salt and water. Such an effect is accomplished by arteriolar vasoconstriction and mesangial cell contraction, with consequent reduction of K_f.[8,9]

In contrast with the promptness with which GFR can be reduced whenever necessary, there is usually little need to promote a substantial *increase* of the GFR. However, there are a few notable exceptions to this rule. Expansion of the extracellular volume, besides promoting tubular rejection of fluid and electrolytes, can increase GFR through the action of atrial natriuretic peptides.[10,11] Ingestion of a single protein-rich meal can acutely increase the GFR by 30–50% in humans and in laboratory animals,[12,13] an effect that can be replicated by intravenous infusion of amino acids in rats,[14–16] and that is thought to represent an adaptation to the need to excrete the protein catabolites more readily.[1,17] A sustained increase of GFR, of similar magnitude as in the acute experiments, can be obtained by chronic feeding of a high-protein diet.[18–20] This change in GFR involves approximately proportional dilatation of both the afferent and efferent arterioles and consequent augmentation of Q_A, without elevation of P_{GC} and ΔP, as predicted by Equation 86.1.[20,21] Normal pregnancy is another physiologic situation characterized by augmented GFR.[22–24] As with high-protein feeding, the GFR increase observed during pregnancy is due to commensurate decreases of R_A an R_E, resulting in increased Q_A without elevation of ΔP.[23,24] These changes are entirely reversible, but will recur with every subsequent pregnancy in the same individual, with no cumulative effect.[25]

Single Nephron Hyperfiltration is a Prominent Feature of Chronic Kidney Disease

From the original description of chronic kidney disease (CKD) by Richard Bright in the XIXth century until the 1950s, it was generally believed that the kidneys affected by chronic disease simply ceased to function as a whole, thereafter becoming essentially unable to maintain homeostasis or to adapt to that unfavorable condition. In 1952, Robert Platt proposed that the functional disturbances encountered in renal disease result from progressive reduction in the number of functioning nephrons rather than from the separate impairment of glomerular or tubular functions of all nephrons.[26] He suggested that, as the number of nephrons diminishes, the remaining units undergo functional hypertrophy, in such a way that impairment of renal function is easily overlooked initially, becoming apparent only at relatively advanced stages of the disease. Bricker and colleagues[27,28] carried this concept a step further by showing that, in an experimental model of CKD, glomerular and tubular functions decreased in parallel, but function per nephron was increased, suggesting that whole nephrons were indeed disappearing as functional units, forcing the surviving nephrons to undergo vicarious hypertrophy. Bricker and coworkers coined the expression *intact nephron hypothesis* to define this concept, which has survived, with some modifications, up to the present day.

In the 1920s and 1930s, Addis had already postulated that increased "workload" to the kidneys, originating from excess protein intake and/or unilateral kidney removal, led to compensatory functional and structural hypertrophy of the remaining renal tissue.[29] The nephron hypertrophy implied by the intact nephron hypothesis was in keeping with this notion of compensatory whole kidney hypertrophy. However, it was not until the early 1980s that a detailed physiologic basis was constructed to explain the mechanisms by which this nephron adaptation might take place. In 1981, Hostetter, Rennke and Brenner[30] demonstrated that five-sixths renal ablation (by removal of the right kidney and infarction of two thirds of the contralateral one), standardized a few years earlier by Shimamura[31] as a model of progressive glomerulopathy, promoted a striking increase of SNGFR, confirming the earlier predictions of compensatory nephron hyperfiltration upon loss of renal parenchyma. These investigators went on to demonstrate that hyperfiltration was due to the combination of systemic hypertension with a pronounced dilatation of the glomerular microvessels, especially the afferent arteriole. As a consequence of this predominant decrease of R_A, and in keeping with Equations 86.1 and 86.2, there were marked increases of Q_A, P_{GC} and ΔP, leading to a corresponding increase of SNGFR, partially offset by a mild reduction of K_f. Similar results were later reported by the same group in a different model of glomerular injury, the DOC-salt model, in which uninephrectomy is associated with dietary salt overload and mineralocorticoid excess.[32]

Glomerular Hyperfiltration in Diabetes Mellitus

Renal mass reduction is not the only pathologic instance in which SNGFR is chronically increased. In type 1 diabetic patients not yet afflicted by the long-term complications of the disease, but in which metabolic control is poor, GFR tends to increase by 30 to 40% compared to the normal population, an abnormality that is accompanied by a proportional increase in kidney size.[33–35] Renal hypertrophy involves mostly the enlargement of glomeruli, whose size may double, although tubular hypertrophy is also prominent in these subjects. Although the mechanisms responsible for the renal hypertrophy in diabetes are presently unknown, a physiological basis for hyperfiltration in this setting is well established. In 1981, Hostetter and coworkers[36] showed that in rats made diabetic with streptozotocin there is vasodilatation of both the

afferent and efferent arterioles, with ample predominance of the former, in a similar manner as in compensatory single nephron hyperfiltration. As a consequence, both Q_A and ΔP are increased, thus promoting hyperfiltration even in the absence of systemic hypertension. These findings were later confirmed in the same laboratory[37,38] and elsewhere.[39–41] In diabetic patients, hyperfiltration and hyperperfusion can be easily demonstrated, but direct determination of P_{GC} is not possible. However, indirect estimates obtained from measurement of filtration fraction suggest that glomerular hypertension does accompany human diabetes as well.[42,43]

A large body of evidence indicates that glomerular hyperfiltration also occurs in patients with type 2 diabetes mellitus;[44–46] although its prevalence is lower than among type 1 diabetic patients,[47] and its very existence was questioned in some earlier reports.[48,49] Hyperfiltration has also been shown in experimental models of type 2 diabetes.[50,51] It must be noted that analysis of renal hemodynamics in these patients is clouded by the concomitant occurrence of cardiovascular abnormalities, which tend to compromise large arteries, including the renal arteries and their branches, along with the cardiac function. In addition, the exact time of onset of type 2 diabetes is often uncertain, allowing diabetic and/or ischemic nephropathy to develop, and GFR to decline substantially from initially elevated levels.

THE "HYPERFILTRATION HYPOTHESIS" AND THE PROGRESSIVE NATURE OF CHRONIC KIDNEY DISEASE

The consistent finding that nephron hyperfiltration antecedes, and even predicts, the development of renal injury in clinical and experimental CKD prompted the hypothesis, formulated by Brenner and coworkers, that a causal relationship existed between abnormal glomerular hemodynamics and the development of progressive glomerular damage. In the original version of this *hyperfiltration hypothesis*,[1] it was postulated that the presence of heightened flows *and* pressures at the glomerular capillaries would promote mechanical aggression to the fragile capillary walls, triggering a process of progressive injury of the glomerular tuft that would eventually result in its complete destruction. In addition, the concept of compensatory nephron hyperfunction implied that glomerular dropout would impose an ever-increasing burden on the remaining units, aggravating the existing mechanical stress and closing a vicious circle that would perpetuate the process of renal parenchymal destruction.

Besides offering a plausible explanation for the well-known progressive behavior of CKD, the hyperfiltration hypothesis formulated in the early 1980s fitted well with a series of findings reported elsewhere. A few years earlier, Steffes and coworkers[52] had demonstrated that the severity of diabetic nephropathy was aggravated in rats also subjected to uninephrectomy, presumably through exacerbation of hyperfiltration in the remaining kidney. In a prior study of the same laboratory, it had been shown that in diabetic rats subjected to unilateral renal artery clipping, diabetic nephropathy was prevented in the clipped side, and aggravated in the contralateral kidney.[53] Accordingly, ipsilateral protection from diabetic nephropathy in patients with unilateral renal artery stenosis has been reported.[54,55]

The practical implications of the hyperfiltration hypothesis were evident, since it opened the tangible possibility that chronic damage to the renal parenchyma by diabetes or progressive nephron loss could be treated by maneuvers aimed at lessening the associated abnormalities of glomerular dynamics. A few seminal studies developed by Brenner and associates showed that this goal was indeed attainable. Hostetter et al.[30] showed that the early structural abnormalities associated with 5/6 nephrectomy in rats were abrogated by administration of a low-protein diet, a maneuver that normalized SNGFR, Q_A and ΔP. Zatz and associates[20] obtained similar amelioration of glomerular dynamics, and equal renoprotection, in diabetic rats that received a low-protein diet for one year. These observations appeared to confirm the hyperfiltration hypothesis and, at the same time, the possibility of changing the natural course of CKD by measures distinct from treatment of hypertension or the metabolic disturbance of diabetes, then the only therapeutic resources available.

Glomerular Hypertension is the Relevant Pathogenic Factor Linking Hyperfiltration to Glomerular Damage

Although the hyperfiltration hypothesis initially seemed to explain convincingly the clinical and experimental findings obtained theretofore, it was soon challenged by a series of apparently inconsistent observations. The predictive value of GFR in relation to diabetic nephropathy was not confirmed in a number of clinical studies.[56,57] In addition, long-term observations in subjects that had undergone uninephrectomy showed only mild and non-progressive proteinuria and arterial hypertension,[58,59] or even no abnormality at all,[60] compared with the general population. Likewise, no renal injury was associated even with

multiple successive pregnancies in rats, in which GFR is expectedly increased,[25] a finding in keeping with clinical observations in multiparous women.[61] Other studies showed that it was possible to ameliorate glomerular injury in the 5/6 renal ablation model without reducing GFR.[62] Other attempts at preventing the progression of CKD, though successful, were not entirely consistent with the hyperfiltration hypothesis. In rats subjected to five-sixths nephrectomy and treated with the then brand new ACE inhibitor, enalapril, the associated glomerulosclerosis was largely prevented. However, enalapril failed to normalize GFR or Q_A, although it did normalize glomerular pressure.[63,64] Similar results were subsequently reported in the streptozotocin-diabetes model,[37–38] and confirmed elsewhere. In view of these results, it was no longer possible to bundle together glomerular hyperfiltration, hyperperfusion and hypertension as a pathogenic mechanism of chronic glomerular injury. It became necessary to modify the hyperfiltration hypothesis to reconcile it with the evidence that glomerular hypertension, rather than the hypertension/hyperperfusion/hypertension trio, represented the actual physical mechanism promoting long-term glomerular capillary injury. The designation "Hyperfiltration hypothesis," though still widely employed, should therefore be replaced by more precise expressions such as "Hemodynamic hypothesis," or "Hemodynamic theory."

THE IMPORTANCE OF GLOMERULAR HYPERTROPHY AND THE CONCEPT OF MECHANICAL AGGRESSION

During the second half of the 1980s, a series of clinical and experimental observations showed that enlargement of the glomerular tuft, a "nonhemodynamic" abnormality, was consistently associated with the development of progressive glomerular injury.[65–69] Several of these studies suggested that the development of glomerulosclerosis was more closely associated with glomerular hypertrophy than with glomerular hypertension. A study in proteinuric pediatric patients showed that glomerular size predicted the development of focal and segmental glomerulosclerosis,[70] while several experimental observations showed either the development of glomerulosclerosis without glomerular hypertension or the converse.[66–69] These observations gave rise to a "hypertrophy theory," which was initially regarded by many as a better alternative to the hemodynamic theory. However, evidence obtained during subsequent years failed to lend support to this "hypertrophy theory." Some of these studies corroborated the earlier observations of a tight association between glomerular hypertension and glomerular injury.[37,39,71] In others, the relationship between glomerular hypertrophy and glomerular injury was rather inconsistent.[72–74] However, it became clear, in the years that ensued, that the hypertrophy and hemodynamic theories were not at all irreconcilable, and that the two mechanisms must act in concert, rather than separately, to promote glomerular injury. The physical basis for such interaction becomes apparent when we consider the local forces that act on the glomerular filtration surface, shown in simplified form in Fig. 86.2. The presence of a transcapillary hydraulic pressure difference, ΔP, imposes a continuous mechanical stretch to the glomerular wall. According to Laplace's law,[65] the wall tension, T, equals the product of the pressure gradient, ΔP, and the capillary radius, R. An elevation of ΔP will promote a proportional increase of T and, therefore, of the mechanical stretch to which the components of the glomerular wall are subjected.[65] On the other hand, enlargement of the glomerular tuft will increase the capillary radius, R, augmenting T in exactly the same way as would an elevation of ΔP. Thus, while glomerular hypertension can conceivably promote capillary damage in the absence of tuft hypertrophy, mechanical injury to the glomerular capillary wall can in principle occur without elevation of ΔP. Accordingly, it is hardly surprising that the association of the two abnormalities can accelerate glomerular injury.[75,76]

Cellular Mechanisms by Which Mechanical Stretch Can Injure the Glomerular Wall

Stretching of the glomerular capillary wall by intracapillary hypertension or tuft hypertrophy would be expected to promote only localized, non-progressive injury if the resulting physical forces were the only factors at operation. However, the glomerular tuft is not constituted solely by inert elements such as collagen fibers: injury to endothelial cells, mesangial cells and podocytes trigger a series of events that together conspire to extend and amplify the initial mechanical aggression, as will be discussed in the paragraphs that follow.

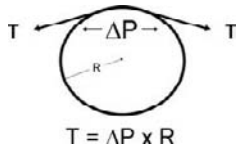

FIGURE. 86.2 Schematic and simplified representation of the wall tension, T, generated by the glomerular transcapillary pressure difference (ΔP) at the walls of a cylindrical capillary with radius R. According to Laplace's law, T is directly proportional to both parameters.

Endothelial cells are sensitive to mechanical strain, undergoing changes of shape and increasing their rate of proliferation when exposed to axial stretch *in vitro*.[77] Subjecting these cells to prolonged strain *in vivo* may result in severe damage,[78] which can even promote disintegration or detachment, leading to local denudation of the glomerular basement membrane, with consequent exposure of extracellular matrix constituents to the circulatory stream. The resulting activation/aggregation of platelets, with fibrin accumulation, may favor the formation of intracapillary microthrombi, leading to luminal obliteration.[72] With subsequent organization of this material, the glomerular tuft can become partially or totally fibrotic.[72] Microaneurysms, which have been reported in several experimental models characterized by severe glomerular hypertension, may undergo a similar process of organization.[32,79,80]

The *mesangial cells* possess a complex cytoskeleton[81] that may be affected by mechanical stretch transmitted from the capillary filtration surface.[82] A number of *in vitro* experiments have brought evidence that, when subjected to such strain, cultured mesangial cells undergo a series of phenotype changes, increasing their proliferative activity and synthesizing a number of molecules involved in inflammatory phenomena—cytokines, growth factors, adhesion molecules and cyclooxygenase products.[83–87] In addition, mechanical stretch stimulates the production of collagen fibers,[87] thus favoring the development of fibrosis and contributing to the progressive destruction of the glomerular tuft. Heightened intracapillary pressure can promote additional mesangial injury by driving circulating macromolecules, including immunoglobulins and complement components, into the mesangial region, where they may accumulate, thus contributing to irritate the mesangial cells and to maintain an inflammatory environment at a local level.[88] Such movement is facilitated by the fact that the mesangial region is not covered by glomerular basement membrane, being separated from the circulatory stream only by the fenestrated endothelial layer.[82]

Among the native glomerular cells, the *podocytes* are perhaps the most likely to suffer phenotypic changes upon exposure to mechanical strain. These cells lie amidst a very complex molecular setup, with a myriad of intricate connections between cytoskeleton constituents, such as actin, myosin and α-actinin, and those of the slit membrane, such as nephrin and p-cadherin.[82,89,90] Conceivably, any disturbance of such a delicate arrangement can disrupt this complicated structure, leading to simplification of the foot processes, rupture of the slit membrane, and impairment of the glomerular barrier function, with ensuing proteinuria.[91,92] Because podocytes are terminally differentiated cells, they possess limited proliferative capacity, being unable to adapt to the increased capillary dimensions imposed by glomerular hypertension and/or hypertrophy.[93–95] Thus, the inevitable mechanical strain associated with these conditions can promote podocyte rupture, death by apoptosis or necrosis, and detachment from the basement membrane, resulting in denudation of its outermost aspect.[96–98] The latter is likely to favor the fixation of the glomerular tuft to the parietal layer of Bowman's capsule, leading to the formation of synechiae, from which a local process of sclerosis may arise and spread to a glomerular segment, to the whole tuft, and/or to the adjacent interstitium.[93–95,99] Additional damage can result from leakage to the interstitium, through this adhesion spot, of plasma ultrafiltrate, with limited hindrance to the passage of proteins, given the local absence of foot processes or slit membranes. This "misdirected filtration" (Fig. 86.3)[100,101] may lead to accumulation of fluid relatively rich in protein at the vicinity of the glomerulus or, if abundant enough, around extensive parts of the respective tubular segments. Inflammation and

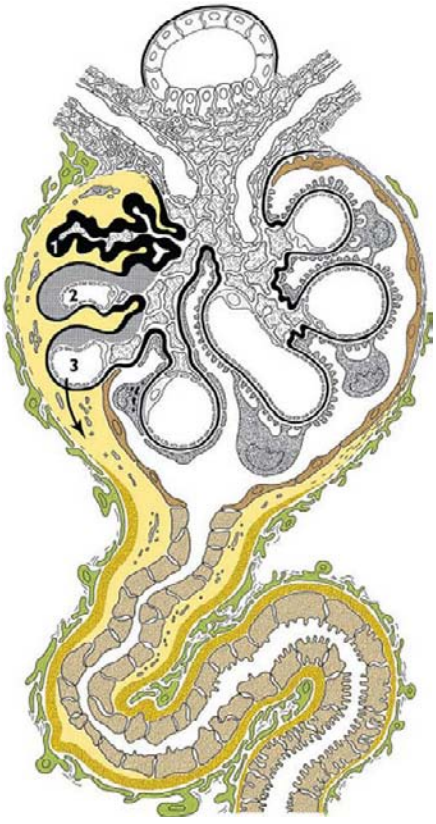

FIGURE. 86.3 Schematic illustration of the consequences of localized podocyte loss, with capillary loops adhering to Bowman's capsule and becoming hyalinized, while fluid leaking through the damaged glomerular walls infiltrates between the nephron (glomerular tuft and tubule) and the adjacent interstitium. Organization of this material may lead to progressive destruction of the nephron. (*Reproduced with permission from ref. [100].*)

subsequent organization of this initially amorphous layer may lead to ensheathing of substantial parts of that particular nephron, which can eventually be sectioned by the fibrotic process, and even disintegrate.[99,100]

As mentioned earlier, mechanical strain of the podocyte layer may lead to disruption of the glomerular filtration barrier, with the passage of large amounts of protein to the urinary space and the appearance of proteinuria, a well-known hallmark of glomerular injury. As a consequence, the protein reabsorption rate of the proximal tubular cells increases markedly, in an attempt at recovering the filtered protein, thus limiting the urinary protein loss. To perform this task, cells must digest the reabsorbed protein, intensifying the formation of endosomes and the synthesis of proteolytic enzymes. Several investigators believe that prolonged exposure of proximal tubular cells to this situation can trigger a process of interstitial fibrosis, which contributes strongly to accelerate the progression of the nephropathy. A number of clinical studies[102–104] support this hypothesis by showing a direct relationship between the proportion of patients with glomerulopathies that progress to end-stage renal disease and the level of proteinuria at the time of diagnosis.

Although other investigators note that these findings could merely reflect a natural association between the intensity of proteinuria and the severity of the underlying glomerular disease,[105] numerous experimental studies have provided more direct evidence that abnormal passage of proteins to the urinary space can indeed favor interstitial inflammation and fibrosis. When cultured in albumin-rich medium, proximal tubular cells produce significant amounts of cytokines and chemokines.[106–109] Accordingly, interstitial fibrosis, inflammation, and markers of oxidative stress were found in association with heavy proteinuria in congenital nephrotic syndrome.[110] Together, these findings indicate that glomerular injury with impairment of the filtration barrier can be indirectly propagated to the interstitium, amplifying the resulting renal damage. However, there is evidence that this mechanism may be of limited importance or may become active only at advanced stages of CKD. In two experimental models of proteinuric CKD, Kriz[99] showed that chronic injury was confined to individual nephrons, rather than being disseminated, as would be expected if increased glomerular passage of proteins were a major pathogenic factor in this setting. In addition, Theilig and coworkers[111] studied mutant mice in which proximal reabsorption of protein was severely limited due to deficient expression of megalin, an essential element for protein endocytosis to work properly. Although the presence of inflammatory markers did associate with protein uptake, tubulointerstitial injury correlated with glomerular damage to the parental glomerular tuft, rather than to the local inflammatory activity. Thus, despite evidence favoring the inflammatory effect of filtered protein, the role of impairment of the glomerular barrier in the pathogenesis of interstitial fibrosis in CKD remains open to question.

From Stretch-Induced Injury to Progressive Nephropathy: the Role of Inflammation

As remarked earlier, progressive nephron loss promotes or aggravates mechanical strain in the remaining units, thus contributing to the establishment of a vicious cycle that leads to further nephron destruction. An additional crucial factor for CKD perpetuation is the presence of inflammatory events, a common denominator to all cellular mechanisms discussed in the preceding paragraphs. The participation of inflammatory phenomena in the pathogenesis of nephropathies of *immunologic* injury has been known for decades.[112] Tissue infiltration by macrophages and fibroblasts has been regarded as a natural follow-up of such events as activation of T-lymphocytes and of the complement cascade.[113] Evidence obtained since the late 1980s in human nephropathies and, especially, in experimental models of CKD, showed that these phenomena are also important as promoters of chronic renal injury not mediated by immune mechanisms, especially those induced by mechanical strain. The presence of inflammatory cells has been described in several models of progressive renal injury, such as streptozotocin-induced diabetes mellitus,[114–116] aging nephropathy,[117–119] chronic NO inhibition,[120–122] experimental nonimmune nephrotic syndrome[123] and protein-overload proteinuria.[124]

Floege and coworkers[125–127] reported that, in rats with 5/6 renal ablation, by far the most widely utilized CKD model, renal interstitial lymphocyte infiltration, activated by unknown mechanisms, can be observed a few days after renal mass removal, when sclerosing glomerular lesions are still scarce. In the following days, the renal interstitium is progressively invaded by macrophages, while the intensity of the lymphocyte infiltration decreases. These findings were subsequently corroborated in other laboratories.[128–131] In addition, a surge of cell proliferation, mostly located at the tubulointerstitial compartment, is noted in these rats a few days after renal ablation, decreasing after two weeks, but persisting for at least two months.[128,127] The identity of these cells is uncertain, although it is conceivable that part of this proliferative activity may be related to the generation of myofibroblasts from either interstitial fibroblasts or tubular cells, the latter through epithelial-to-mesenchymal transdifferentiation.[132–134]

The recruitment of inflammatory cells into the renal parenchyma, and the proliferation of resident glomerular and tubular cells are crucially dependent on the production of inflammatory mediators. The presence in the renal parenchyma of a number of cytokines, chemokines and growth factors, such as interleukin-1, RANTES, fractalkine, TGF-β, MCP-1, TNF-α, and adhesion molecules, among many others, have been associated with several clinical conditions and experimental models of CKD,[107,114,135–139] along with evidence of activation of the intricate and often redundant intracellular pathways involved in the synthesis of these molecules.[132,140–143] An extensive analysis of the participation of these systems in the pathogenesis of CKD would transcend the scope of this chapter. Additional discussion of this subject can be found in Chapters 82, 87 and 90.

The importance of inflammatory phenomena in the pathogenesis of CKD is further highlighted by the protective effect exerted by anti-inflammatory agents. Fujihara and coworkers[128] reported that concomitant administration of mycophenolate mofetil (MMF), a specific inhibitor of lymphocyte proliferation, strongly attenuated renal inflammation and prevented glomerular and interstitial injury in the remnant kidney model, a finding also reported, almost simultaneously, by Romero and coworkers.[131] Renal protection by MMF monotherapy was also described in streptozotocin-induced diabetic rats[41] and in the chronic NO inhibition model,[120] and was strongly enhanced by association with a depressor of the renin-angiotensin system.[129,144–149] Interestingly, administration of non-steroidal anti-inflammatories exerted a protective effect in the remnant kidney model[130,150–152] and in experimental diabetes mellitus.[153] However, this class of drug is contraindicated in CKD due to the risk of precipitating a catastrophic fall of GFR (see below).

THE IMMENSE PATHOGENIC IMPORTANCE OF ANGIOTENSIN II IN CKD

As detailed in Chapter 15, Ang II is a potent vasoconstrictor agent, which binds to the AT-1 receptor, abundant in smooth muscle and mesangial cells.[154] By virtue of its vascular effects, Ang II contributes to the maintenance of blood pressure, especially in states of dehydration. This effect is strongly reinforced by the action of Ang II on sodium conservation, as a result of its effects on both the nephron itself, enhancing sodium reabsorption, and the adrenals, stimulating the release of aldosterone. At the glomerular microcirculation, Ang II constricts both the afferent and efferent arterioles.[154] However, this vasoconstrictor effect was shown to be disproportionally intense at the efferent arteriole,[155,156] a finding confirmed by *in vitro* studies of isolated afferent and efferent arterioles.[157,158] The reasons for this asymmetry are unclear, and may be related to the finding that Ang II stimulates vasoconstriction of the afferent arterioles through activation of voltage-gated (L-type) calcium channels, whereas Ang II–mediated vasoconstriction of the efferent arteriole depends mainly on mobilization of calcium from intracellular stores.[159–161] Ang II also promotes contraction of the mesangial cells,[9,162] with a consequent reduction of the glomerular K_f. The predominant efferent vasoconstriction leads to an elevation of P_{GC}. However, since K_f decreases, and since Q_A is depressed due to the arteriolar vasoconstriction, the SNGFR remains relatively constant during Ang II infusions,[163,155] with consequent increase of the filtration fraction (FF). Recent evidence has shown that the renin-angiotensin system is much more complex than originally thought, and that novel components of this system may have physiologic importance. Angiotensin 1–7, a heptapeptide generated by the action of angiotensin I converting enzyme 2 (ACE2), exerts a vasodilatory effect and may modulate the action of Ang II.[164] Likewise, activation of the AT2 receptor by Ang II can initiate a series of events that culminate in vasodilatation and natriuresis, thus antagonizing the vasoconstrictor/antinatriuretic effects elicited by Ang II binding to the AT1 receptor.[164] However, the exact physiologic role of angiotensin 1–7, the AT2 receptor and other, less known components of the renin-angiotensin system is presently unclear.

Chronic nephron loss tends to promote extracellular expansion due to a natural limitation to sodium excretion.[165,166] In this setting, there is a trend toward renal vasodilatation, while the circulating levels of renin and angiotensin II tend to be depressed, reflecting inhibition of renal renin release to the circulation.[165] On the other hand, abundant evidence has been amassed in the past two decades that a large number of organs and tissues, including the kidneys, possess all the components of the renin-angiotensin system, being able to produce Ang II locally in an independent fashion.[167–169] The combination of renal arteriolar vasodilatation with local production of Ang II, which as noted above acts preferentially on R_E, may result in disproportionate decrease of R_A, leading to simultaneous increases of Q_A and ΔP and, as a result, to single nephron hyperfiltration.

In diabetes mellitus, the circulating levels of renin and angiotensin II tend to be reduced,[37,170] which might favor hyperperfusion and hyperfiltration in these individuals. On the other hand, there is evidence that the renin-angiotensin system may be activated at the intrarenal level in early experimental diabetes,[171,172]

which may help to explain the relatively modest fall in R_E observed in this condition, which favors, as we have seen, the elevation of P_{GC}, hence glomerular injury. The reasons for the local and systemic derangement of the renin-angiotensin system in diabetes mellitus are yet to be elucidated.

The intrinsic action of Ang II on glomerular hemodynamics in CKD and in early diabetes mellitus is unveiled by the striking effect of treatment with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor type 1 blockers (ARBs), which promote dilatation of afferent and efferent arterioles, as well as normalization of glomerular pressure,[37–39,63,64,173,174] without significant changes of SNGFR. Thus it is beyond doubt that Ang II exerts a pathogenic effect on the glomerulus, which may favor the installation of tuft injury by the mechanisms discussed above. However, the scope of action of Ang II is now known to largely transcend the hemodynamic sphere, characterizing this octapeptide as a potent proinflammatory cytokine.[175,176] Chronic systemic Ang II infusion in rats was shown to promote not only arterial hypertension, but also glomerular and interstitial infiltration by mononuclear cells and severe renal fibrosis.[177,178] Ang II was subsequently shown to influence cell proliferation,[179,180,181] and the synthesis of a number of cytokines, chemokines, growth factors and adhesion molecules, all of which exert an obvious pathogenic impact on the progression of CKD, such as RANTES,[182] MCP-1,[176,183] osteopontin,[184] tumor necrosis factor-α (TNF-α),[178] CTGF[185] and PDGF,[186] among others. These actions are largely mediated by Ang II binding to the AT1 receptor,[179,187,188] which stimulates several intracellular pathways linked to inflammation, especially the NF-κB cascade[176,189] and the MAPK and Stat/Jnk pathways.[143,187] One of the main proinflammatory effects of Ang II is mediated by its strong stimulation of TGF-β, a well-known promoter of fibrosis in the renal tissue, as well as in other territories.[190,191] Furthermore, *in vitro* exposure of mesangial cells to Ang II can increase the production of superoxide anions and induce oxidative stress, a well-known promoter of inflammation.[192] Likewise, *in vivo* Ang II infusion enhances the production of oxidation markers such as thiobarbituric acid–reactive substances and protein carbonyl,[193] as well as 8-iso prostaglandin F2α.[194] Ang II can further contribute to CKD by one of its classical nonhemodynamic actions, the production of aldosterone by the adrenals. Aldosterone has been shown to increase collagen IV synthesis by mesangial cells,[195] and to facilitate the progression of CKD in the renal and myocardial tissue, independent of Ang II.[196,197] Plasma aldosterone concentrations are strikingly elevated in partially nephrectomized rats.[196,198] Conversely, mineralocorticoid receptor blockade, alone or associated with ACE inhibitors or Ang II receptor blockers, reduces glomerulosclerosis and proteinuria in several CKD models, further suggesting a pathogenic role for the stimulation of the mineralocorticoid receptor.[199,200] Ang II can provide additional contribution to renal damage by increasing glomerular permeability,[201–203] thus promoting tubulointerstitial damage through the mechanisms discussed earlier. An important evidence of the pathogenic role of Ang II is the demonstration, by immunohistochemistry and/or by immunofluorescence, that Ang II associates with infiltrating cells at inflamed areas of the renal interstitium in several models of CKD,[128,130,131,204] as well as in biopsy material obtained from CKD patients.[205,206] In these studies, the intensity of tissue infiltration by Ang II-positive cells correlated directly with the extent and severity of interstitial inflammation. A more direct link between Ang II and glomerular mechanical strain was unraveled by the finding that, when subjected to cyclical stretching, mesangial cells upregulate components of the renin-angiotensin system.[207–209] Thus, the glomerular action of Ang II may lead to a vicious cycle, in that Ang II elevates P_{GC}, which promotes mechanical stress, stimulating further Ang II production and setting in motion its many pro-inflammatory actions.

Given the plethora of hemodynamic and nonhemodynamic actions of Ang II, it is far from surprising that treatment with ACE inhibitors or Ang II receptor blockers prevents or attenuates renal injury in several forms of clinical and experimental CKD.[37,63,64,80,174,210–212] Although several promising novel therapeutic strategies have been proposed in the past two decades, administration of depressors of the renin-angiotensin system remains a mainstay of the therapy of CKD, along with diuretics, other antihypertensives and glycemic control in diabetics. However, CKD patients who receive these drugs still progress to ESRD, albeit at a slower rate,[210–212] particularly when treatment is initiated at advanced stages of the disease. The reasons why the protection offered by these drugs is incomplete are obscure. It is likely that several of the complex and interrelated intracellular pathways that culminate in the synthesis of inflammatory mediators are activated by physical and chemical events distinct from the Ang II-AT1 interaction, such as oxidative stress and the binding of a number of cytokines and growth factors to specific receptors. Of particular interest is the recent discovery that prorenin, once regarded as an inert precursor of renin, binds to a specific receptor, undergoing a nonproteolytic conformational change that enables prorenin to cleave angiotensinogen to angiotensin I.[213,214] In addition, binding of prorenin to this receptor activates several intracellular proinflammatory pathways.[215,216] This receptor can also be activated by renin through the binding of an epitope

shared with prorenin. For this reason, this receptor became known as the (pro)renin receptor.[214,217] Recent evidence suggests that blockade of this receptor with a specific antagonist prevents the progression of experimental diabetic nephropathy,[218] suggesting that this may become a new strategy in the management of CKD.

THE ROLE OF OTHER VASOACTIVE COMPOUNDS IN GLOMERULAR MECHANICAL STRAIN

Circulating Catecholamines and Renal Sympathetic Innervation

As with Ang II, the glomerular microcirculation is exquisitely sensitive to the vasoconstrictor activity of the sympathetic system and of its circulating mediators. Different from Ang II, however, norepinephrine induces vasoconstriction of both afferent and efferent arterioles,[156,157,219] an effect thought to be mediated by α-adrenergic receptors[219] and to depend at least in part on variations of intracellular calcium, especially at the efferent arterioles.[161] Acute catecholamine action results in systemic hypertension and, given the proportionate increases in pre- and postglomerular resistances, a corresponding elevation of glomerular pressure. Because the overall resistance of the glomerular microcirculation increases, glomerular blood flow is diminished. The net result of these changes is, as observed with Ang II, maintenance of GFR at relatively constant levels.[156] In addition to its direct effect on the glomerular vessels, the renal sympathetic inflow has been long known to stimulate renin exocytosis from the juxtaglomerular cells through activation of β1-adrenergic receptors, an effect that enhances the sympathetic action on blood pressure, sodium reabsorption, and the glomerular microcirculation,[220] and can contribute to cause glomerular injury through the mechanisms discussed above. Recent studies indicate that sympathetic activity and, in particular, the sympathetic inflow to the kidneys, are enhanced in CKD.[221] Increased renal sympathetic stimulation has been implicated in the pathogenesis of hypertension in CKD[222] and in the remnant kidney model,[223] while renal denervation has been shown to lower systemic blood pressure in murine hypertension, underlining the important influence exerted by the sympathetic innervation on the renal vasculature and on sodium reabsorption.[220,224] Additional complexity derives from the finding of two types of sympathetic nerve fibers in the kidney,[225] with differential innervation of the afferent and efferent arterioles.

Nitric Oxide

Nitric oxide (NO) was originally identified about a quarter century ago as a powerful endogenous vasodilator produced from L-arginine by endothelial cells, under the action of NO synthases (NOS), and soon proven to be responsible for the vasodilator effect of compounds such as acetylcholine, histamine and bradykinin.[226,227] Besides being a potent vasodilator, NO inhibits cell proliferation and platelet aggregation, which helps to preserve the endothelial integrity.[228,229] Although NO was originally described as a product of the endothelial cells, it became soon clear that it can be synthesized by mesangial cells, smooth muscle cells, tubular cells and leukocytes, among other cell types.[230–232] Because NO is very diffusible and highly reactive, it quickly combines with other free radicals or is taken away by hemoglobin.[233] In view of these characteristics, which are shared by other reactive species such as superoxide, NO has a short-lived effect, confined to the immediate surroundings of the cells in which it is produced, and must be generated uninterruptedly if it is to play any significant physiologic role.

A number of experimental studies suggest that continuous NO production is fundamental for the circulatory system to function properly. Acute intravenous administration of unselective NOS inhibitors promotes a quick and marked elevation of systemic blood pressure, in addition to a pronounced constriction of renal microvessels,[234–236] while P_{GC} rises and Q_A and K_f are decreased. As a result of these opposing changes, the SNGFR is little affected. These findings are strongly reminiscent of the effect of acute Ang II infusions,[155,156] and suggest that NO may be needed as a modulator of the effect of Ang II and other vasoconstrictors.[237] The individual role of the main isoforms of NOS is unclear. Acute selective inhibition of neuronal NOS (nNOS), which is strongly expressed at the macula densa,[238,239] lowers GFR without affecting blood pressure or renal blood flow.[240] Parallel results were obtained after perfusion of the macula densa with a NO synthase inhibitor.[241] These findings suggest a regulatory role for nNOS. However, chronic nNOS inhibition was reported to raise blood pressure without changing GFR.[242] Inhibition of the inducible isoform of NO synthase (iNOS) has not been reported to promote consistent changes of renal or systemic hemodynamics under physiologic conditions,[243,244] being more closely related to the operation of the innate immunity and of inflammatory mechanisms.[243,245,246] The current evidence suggests that the endothelial NOS isoform (eNOS) accounts for most of the modulation of renal and systemic hemodynamics ascribed to NO.[247]

Chronic inhibition of NO production promotes abnormalities of glomerular hemodynamics that are

qualitatively similar to those elicited by acute NO inhibition,[80,248] with the development of severe and progressive systemic and glomerular hypertension, besides intense renal vasoconstriction. After a few weeks of treatment, these rats exhibit glomerular ischemic and sclerotic injury, renal interstitial inflammation and vascular damage suggestive of malignant hypertension. Together, these findings indicate that NO exerts an indispensable tonic vasodilatation on renal and systemic microvessels, and that its absence may lead to severe cardiovascular and renal injury.

Evidence obtained in several studies suggests that changes in NO production can participate in the pathogenesis of deranged glomerular dynamics in CKD. Administration of inhibitors of NO synthase limits the hyperfiltration observed in experimental diabetes mellitus, suggesting that excessive renal production NO may be one of the mediators of the associated renal hemodynamic derangement.[249–251] In subnephrectomized rats, 24-hour urinary excretion of nitrites and nitrates, taken as a surrogate marker of NO production, is significantly decreased.[252,253] Similarly, in humans with chronic kidney disease (CKD), Schmidt and Baylis showed that urinary nitrites/nitrates excretion is diminished.[254] These observations suggest that CKD is a state of NO deficiency. One of the possible causes of impaired NO synthesis in CKD is the abnormal production in the circulation of a potent endogenous competitive inhibitor of NOS, asymmetric dimethyl-L-arginine (ADMA). The presence of this compound was demonstrated in animal models of CKD,[255,256] as well as in CKD patients.[254,257–259] The finding of elevated ADMA levels at early phases of CKD suggests that subtle degrees of NO deficiency may be one of the primary factors causing glomerular hemodynamic dysfunction and leading to progression of renal injury. On the other hand, inhibition of NO aggravates kidney injury in subnephrectomized rats,[79,260] in association with glomerular and peritubular endothelial cell loss,[260] with consequent development of microthrombosis and glomerulosclerosis.[79] Conversely, in partially nephrectomized rats, administration of the substrate for NO synthesis, L-arginine, prevented the decrease of GFR and renal blood flow, and reduced the severity of glomerulosclerosis.[261] These observations suggest that endogenous NO still exerts a protective role even after the development of CKD, and point to a potential therapeutic use of NO-releasing drugs,[262] although solid evidence in favor of this concept is lacking.

Prostanoids

Prostanoids are 20-carbon compounds derived from arachidonic acid through the action of two cyclooxygenase (COx) isoforms, COx-1, said to be "constitutive," and COx-2, initially considered as being "inducible." Subsequent research showed that both isoforms are active in normal subjects and should be considered "constitutive".[263–265] Although acute administration of vasodilator prostanoids such as prostacyclins and PGE2 can induce the synthesis of cyclic AMP and exert a pronounced effect on glomerular circulation and on sodium excretion,[8,266] acute inhibition of prostaglandin synthesis in normal rats does not affect GFR or glomerular hemodynamics,[267,268] indicating little tonic activity of these compounds.[269] Likewise, the use of COx inhibitors as anti-inflammatories or painkillers usually promotes little or no change of renal function in most individuals,[270] although adverse cardiovascular and renal effects such as sodium retention, hypertension and vascular injury may occur in a minority of patients treated chronically with these compounds.[271]

Although the effects of COx inhibitors in normal subjects are relatively mild, the vasodilator prostanoids exert an important physiologic role by modulating the action of the renal sympathetic innervation and of circulating vasoconstrictors such as catecholamines and Ang II.[8,163,272] For this reason, the use of COx inhibitors in situations in which there is exacerbation of vasoconstrictor activity, such as in states of volume depletion or contraction of the effective arterial volume, may promote exaggerated vasoconstriction and even the development of acute kidney injury.[271,272]

The thromboxanes, the main representative of which is Thromboxane A2, are potent renal vasoconstrictors, which act through activation of phospholipase C and elevation of the intracellular calcium levels, antagonizing the effects of the vasodilator prostanoids. The thromboxanes also have an important function in hemostasis through platelet activation. Despite the intensity of their vascular effects, the thromboxanes, as in the case of vasodilator prostanoids, exert little effect on renal hemodynamics under physiologic conditions.[273]

A number of observations suggest that vasodilator prostanoids may participate in the pathogenesis of CKD and early diabetic nephropathy by mediating at least part of the attending hemodynamic changes. The renal expression of COx-2 is increased in experimental diabetes mellitus,[153] and may contribute to the renal vasodilatation observed in this condition.[274] Likewise, renal mass ablation increases fractional urinary excretion of both vasodilator and vasoconstrictor prostaglandins in rodents.[267,268,275,276] In partially nephrectomized rats, indomethacin lowers both SNGFR and renal blood flow.[267,268] Together, these observations suggest that increased activity of cyclooxygenase derivatives may contribute to maintain the glomerular hemodynamic

changes encountered in CKD models. However, a different picture emerges when the synthesis of prostanoids is blocked on a chronic basis in rats with renal ablation. Chronic treatment of subnephrectomized rats with either an unselective or a COx-2 selective cyclooxygenase inhibitor, starting on the day following renal mass removal, led to a mild fall in glomerular pressure,[150,151] without change of GFR. Two months after renal ablation, renal injury was markedly attenuated in rats treated with the COx inhibitors. These observations suggest that prostanoids can act as mediators of progressive kidney injury through nonhemodynamic mechanisms, possibly related to inhibition of renal inflammatory mechanisms. These findings are difficult to translate into clinical practice, however, because, as just noted, increased prostanoid synthesis may be one of the mediators of single nephron hyperfiltration in CKD patients. Therefore, COx inhibition may abrogate this adaptive mechanism, leading to a sudden and dangerous fall of GFR in a substantial proportion of these subjects,[272] a finding that is paralleled in experimental models of CKD.[275] Thus, the use of COx inhibitors is better avoided in CKD.

Endothelin

Endothelin (ET), synthesized mostly, but not exclusively, by endothelial cells, is the most potent known vasoconstrictor. Experimental evidence indicates that ET constricts the afferent and efferent arterioles in proportion, without a clear predominance of one or another.[277–279] As a result, Q_A falls, while P_{GC} remains approximately constant, although higher doses may raise glomerular pressure.[280] Despite its vasoconstrictor potency, the physiologic role of ET in the regulation of the renal microcirculation is uncertain, because acute or chronic administration of ET inhibitors has little effect on glomerular microcirculation and renal function.[281] Equally unclear is the participation of ET in CKD. In rats subjected to partial nephrectomy, Benigni and coworkers reported an increase in the urinary excretion of the best-known ET isoform, ET-1,[282] and in the expression of the ET-1 gene.[283] Moreover, thrombin stimulated ET-1 secretion in glomeruli isolated from remnant kidneys, an effect that was absent in glomeruli isolated from intact kidneys,[282] raising the possibility that endothelins are involved in the alterations of glomerular hemodynamics seen after nephron loss. These investigators also showed that treatment with an ET inhibitor was renoprotective in the remnant kidney model, although a hemodynamic mechanism for this effect was not demonstrated.[284] In streptozotocin diabetic rats, chronic ET receptor blockade caused glomerular vasodilatation and limited hyperfiltration, despite a simultaneous increase of renal plasma flow, suggesting that glomerular pressure was reduced, although direct measurement of this parameter was not performed. In the long run, diabetic nephropathy was largely prevented in treated rats.[285]

Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) is released mostly from the atrial wall, usually in response to extracellular volume expansion. As a result, the kidneys excrete a large amount of sodium, which tends to bring the hemodynamic status back to normal. This potent natriuretic effect stems from hemodynamic and nonhemodynamic renal actions. ANP promotes dilatation of the afferent arteriole and constriction of the efferent arteriole,[10,11] a unique effect among vasoactive substances, with resulting elevation of P_{GC} despite a concomitant fall of arterial pressure, which reflects systemic vasodilatation. Since Q_A is also increased due to the predominance of the afferent dilatation, SNGFR increases, augmenting the amount of sodium that reaches the tubules.[10] ANP may also inhibit renal sodium reabsorption by direct action and/or by promoting disproportionate medullary hyperperfusion[286–288] thus amplifying the natriuretic effect of glomerular hyperfiltration.

The participation of ANP in the pathogenesis of the glomerular hemodynamic changes associated with CKD and diabetes is unclear. The plasma concentration of atrial natriuretic peptide (ANP) is elevated in partially nephrectomized rats on high-salt, but not on low-salt diets,[289] suggesting a potential role of ANP in the adaptive increase of single-nephron sodium excretion in this model of chronic kidney injury. In experimental diabetes, the plasma levels of atrial natriuretic peptide are elevated, and may contribute to the attending renal hemodynamic abnormalities.[290,291]

The Metabolic Derangement Itself May Promote Hyperfiltration in Diabetes Mellitus

Besides the possible role of prostaglandins and nitric oxide, discussed above, the glomerular hemodynamic abnormalities observed in early diabetes may be influenced by factors more directly related to the attending metabolic derangement. Acute glucose infusions have been reported to increase GFR in normal men,[292] and in diabetic subjects,[293] raising the possibility that hyperglycemia itself may promote hyperfiltration in diabetes. Other contributing factors may be the excessive production of some hormones that deeply influence carbohydrate metabolism, such as growth hormone[294] and glucagon.[274]

GENETIC AND ENVIRONMENTAL FACTORS CAUSING GLOMERULAR INJURY THROUGH MECHANICAL STRAIN

Nephron Number at Birth

The rate of progression of CKD shows enormous variability among individuals. In some patients GFR declines at over 10 mL/min/1,73 m^2/year, leading to the need for renal replacement therapy in a few years; other patients lose renal function at a rate that barely exceeds that expected from normal aging, while in others still CKD does not progress at all.[295] Apart from differences in the genetic background, one of the reasons for such variability may be that the number of nephrons at birth differs widely among individuals, ranging from 210,000 to 1,825,000 per kidney, with an average of 600,000–800,000.[296–298] Brenner and colleagues postulated that the fraction of the population possessing few nephrons at birth is predisposed to hypertension and renal damage in adult life compared with those with a normal or increased nephron endowment.[299,300] Several lines of evidence have provided support for this hypothesis. In a recent autopsy study, Keller et al. found a 50% reduction in the number of nephrons in hypertensive subjects, compared with matched normotensives, all of whom had died in accidents.[301] Of note, little signs of glomerular obsolescence were found in hypertensive subjects, ruling out the hypothesis that nephron deficiency was caused by hypertension, rather than causing it. In addition, glomerular volume was twice as high in hypertensive as in normotensive subjects, indicating compensatory growth. Expectedly, less subtle nephron number reduction at birth is also associated with renal injury in adulthood. Subjects with unilateral renal agenesis develop proteinuria and focal segmental sclerosis is often encountered in the solitary kidney.[59,302] In oligomeganephronia, a congenital disorder characterized by developmental arrest of the metanephric renal blastema, the total nephron number at birth is reduced to 20–25% of normal. These subjects develop proteinuria and glomerulosclerosis, reaching end-stage CKD during adolescence.[303,304]

The association of congenital reduction of the nephron number with progressive renal injury in adults is also observed in rodents, although genetic factors may modify this relationship.[305,306] Several investigators demonstrated that Ang II is essential for proper nephrogenesis, and that administration of ACE inhibitors or AT-1 receptor blockers to rat pups during the first three weeks after birth, before nephron formation is completed, led to severe reduction of the nephron number at weaning, followed by progressive CKD during adult life.[307–309] These findings were later extended by Machado and coworkers,[310] who showed that these rats developed glomerular enlargement and intracapillary hypertension at three months of age, as well as systemic hypertension, severe glomerulosclerosis and extensive interstitial inflammation at 10 months of age. Arterial hypertension and/or CKD are also associated with spontaneous congenital limitation of nephron number. In the rat model of male hypogonadism (hgn/hgn) with bilaterally hypoplastic kidneys, an 80% reduction of nephron number is associated with glomerular hypertension, hyperfiltration, proteinuria, glomerulosclerosis and progressive renal insufficiency.[311] Spontaneously hypertensive rats (SHR), Dahl salt-sensitive rats, Milan hypertensive rats and Munich Wistar Fromter rats have fewer nephrons than their respective normotensive counterparts, Wistar Kyoto rats, Dahl salt-resistant rats, Milan normotensive rats and Wistar rats.[312–315] Conversely, PVG/c rats exhibit a higher number of nephrons and develop no renal disease compared to Wistar rats.[316,317]

Although the concept that nephron number reduction at birth predisposes to CKD appears well founded, the relationship between nephron loss during adult life and the subsequent development of renal injury appears to be less clear-cut. Extensive nephrectomy—for example, in cases of renal tumors—does associate with proteinuria, progressive renal injury, and eventual need for renal replacement therapy.[318–320] However, as noted earlier in this chapter, lower grade renal mass reduction is not consistently associated with the development of CKD. Veterans who had lost a kidney due to trauma during the Second World War failed to show an increased prevalence of renal disease and progression of proteinuria 45 years later.[321] Moreover, individuals who donate a kidney for transplantation show no serious long-term renal problems apart from mild proteinuria.[58,322,323] This apparent incongruence between the consequences of congenital and acquired nephron loss is echoed in experimental studies. Ikoma and coworkers found that in rats that underwent renal ablation during maturational growth renal injury is more severe than in adult animals subjected to identical procedure.[324] Similar results were obtained by Okuda et al.[325] The reason for the striking influence of the time when nephrons are lost is unclear, and may relate to a complex relationship between nephron number and the ability to remodel the extracellular matrix.[326]

Obesity

Morbid obesity is associated with focal segmental glomerulosclerosis, an association known as obesity-related glomerulopathy (ORG).[327–329] This disease

seems to be both histologically and clinically distinct from idiopathic focal segmental glomerulosclerosis (FSGS). In ORG, a lower percentage of glomeruli is affected by segmental sclerosis, the degree of foot process effacement is less severe, glomerulomegaly is always present,[327] and edema is absent despite nephrotic-range proteinuria.[330] As in other conditions that may cause CKD, ORG is associated with a state of hyperfiltration and renal hyperperfusion,[331,332] although ΔP has not been determined in these subjects. In severely obese patients without overt kidney disease, Chagnac and coworkers found that renal blood flow and GFR decreased following gastroplasty and a decrease of BMI from 48 to 32.1 kg/m^2.[333,334] In addition to the increased risk of *de novo* development of CKD, excessive body weight is also a risk factor for CKD in patients with kidney mass reduction, such as after uninephrectomy,[335] kidney transplantation[336,337] or severe renal mass reduction,[338] suggesting that the effects of massive weight increase add to other insults to promote renal injury.

The renal impact of obesity has also been studied in animal models. Henegar and colleagues studied dogs with obesity induced by a high-fat diet, a model that mimics the neurohormonal changes in the early stages of human obesity.[339] Renal plasma flow and GFR were increased in these animals, an abnormality that was accompanied by glomerular hypertrophy, increased mesangial matrix, and thickening of glomerular basement membrane.[339] In another animal model, the Zucker obese rat, an initial increase of GFR was noted, followed by normalization and subsequent decrease of GFR, in association with progressive albuminuria and glomerulosclerosis.[340] In other studies of obese Zucker rats, GFR at 26 weeks of age was significantly higher than in lean Zucker rats, underlining once again the relationship between obesity and hyperfiltration. Of note, ΔP, which as noted earlier is the most important hemodynamic factor of glomerular damage, was also elevated in these rats.[341,342] These differences disappeared when obese Zucker rats were fed the same food amount as given to the lean controls.[343] Thus, massive obesity can initiate or aggravate glomerular disease, at least in part, by promoting alterations in glomerular hemodynamics and glomerular size. The mechanisms by which these abnormalities take place are currently unknown.

Tobacco

According to the MRFIT study, which included over 300,000 men, smoking increases the risk of end-stage renal kidney disease (ESRD) in the general male population. Compared to nonsmokers, the relative risk was 1.69 in heavy smokers.[344] In a longitudinal study over 18.5 years of over 2500 healthy subjects, the risk of ESRD was elevated in smokers (odds ratio [OR] 1.42).[345] The importance of smoking in the development of renal diseases is further illustrated by the observation in a large cross-sectional population study that current cigarette smoking was associated with a hazard ratio for CKD of 2.4 in men and 2.9 in women.[346] Smoking also increases the risk of nephropathy in diabetic[347] and nondiabetic patients.[348,349]

The mechanisms by which smoking could promote renal damage have not been fully clarified. Acute smoking as compared to sham smoking causes sympathetic activation[350,351] with a rise of blood pressure and heart rate, which, as discussed earlier, may have been transmitted to the glomerular microcirculation and stimulated the production of renin. Recent evidence suggests that a hemodynamic basis for the deleterious effect of tobacco on the kidneys may indeed exist. Acute smoking has been recently reported to relax renal arteries.[352] Hyperfiltration was more prevalent in current smokers than in former smokers or nonsmokers in a cohort of healthy subjects.[353] Similar findings were reported in over 7000 healthy Japanese men.[354] These results were reproduced in db/db mice, in which nicotine intake was associated with glomerular hypertrophy.[355] Thus, mechanical strain to the glomerular tuft may contribute to the glomerular damage caused by tobacco smoking.

Protein Intake

As discussed earlier, increased protein intake promotes glomerular hyperfiltration and hyperperfusion in healthy rats, without elevating P_{GC}.[21,20] In the long run, high-protein diet promotes only mild glomerular injury in healthy rats.[20] However, high-protein diets tend to augment P_{GC} and glomerular size, and may accelerate the progression of renal injury, in experimental models of CKD.[20,356] Thus, excess protein may predispose to renal damage, and become especially deleterious in the setting of established renal disease. On the other hand, as noted above, dietary protein restriction has been shown to limit or prevent both glomerular hemodynamic abnormalities and chronic renal injury in a variety of experimental models of CKD.[20,30,357,358]

The mechanisms by which the dietary protein content interferes with the glomerular microcirculation remain unclear, and may involve the action of vasoactive agents such as kinins,[359] vasodilatory prostanoids[360] and nitric oxide.[361] Recently, a transcriptional regulator, the Kruppel-like factor 15 (KLF-15) has been shown to inhibit the development of renal fibrosis, and

to be downregulated by high-protein intake.[362] Thus protein intake may influence the development of CKD by a double mechanism: (1) by interfering with glomerular hemodynamics through the mediation of vasoactive compounds; (2) by modulating cell mechanisms that conduce to the development of renal fibrosis. Additional benefit of low-protein diets may result from the phosphorus restriction that inevitably accompanies such regimens.[363]

Despite these consistent experimental data, it remains uncertain whether dietary protein can initiate or aggravate human renal disease,[364–367] although some clinical studies indicate that protein excess does increase GFR.[360,368] On the other hand, a series of clinical studies tested the use of low-protein diets as a possible therapeutic measure in the management of CKD. However, although several of these studies showed a protective effect of dietary protein restriction in patients with CKD,[369–372] large randomized trials, such as the Modification of Diet in Renal Disease (MDRD) study, failed to unequivocally demonstrate that the administration of a low-protein diet improve renal survival in this setting.[373–375] In fact, protein restriction in CKD may pose a therapeutic dilemma, since it is necessary to carefully balance the possible beneficial effects of this maneuver against the risk of promoting protein malnutrition,[376,377] which is a matter of considerable concern in view of the high mortality associated with reduced body weight in dialysis patients. Thus the current evidence does not favor protein restriction as a therapeutic maneuver to slow the progression of CKD, nor does it emphatically prohibit protein-rich diets, although dietary protein excess is generally avoided.

Pregnancy

As pointed out earlier, pregnancy is associated with glomerular hyperfiltration and hyperperfusion, but not hypertension, a finding in keeping with the lack of association between repetitive pregnancies and the development of CKD. However, the rate of decline of renal function associated with CKD may be hastened in gravid women in whom GFR is already compromised at the onset of pregnancy.[378,379] The mechanisms underlying this pathogenic interaction between pregnancy and CKD are unknown. It is conceivable that the renal vasodilatation associated with pregnancy aggravates the glomerular hypertension that may be associated with CKD, although data on renal and glomerular hemodynamics under these conditions are lacking. The reader is referred to Chapter 81 for a more detailed discussion on the complex relationship between pregnancy and renal disease.

PREVENTING THE PROGRESSION OF CKD BY TREATMENT OF THE GLOMERULAR HEMODYNAMIC DERANGEMENT

Based on the above considerations, it is only natural that several therapeutic measures intended to prevent or detain the progression of CKD target the mechanisms of glomerular mechanical aggression discussed in the preceding paragraphs. The most obvious of these is the treatment of arterial hypertension. In most glomeruli of most subjects with essential hypertension, afferent arteriolar contraction, mediated by myogenic reflexes and/or by signals originated from the macula densa, protects the glomeruli from transmission of the elevated blood pressure, thus preventing mechanical strain and keeping SNGFR constant.[380,381] This mechanism may fail in a fraction of the glomeruli, which may undergo sclerosis,[382] while other units may become ischemic due to arteriolar injury,[383] leading to the development of "benign" nephrosclerosis in a fortunately small proportion of these patients. Autoregulation is deficient in CKD and in diabetes mellitus, as shown in a number of experimental studies, thus contributing to accelerate the progression of renal injury.[384–386] Accordingly, lowering blood pressure in CKD patients is expected to promote a proportional decrease in glomerular pressure, thus contributing to attenuate the progression of the disease.

As discussed above, inhibition of the RAS by ACEI or ARB became one of the current cornerstones of the pharmacological treatment of CKD, in view of both its hemodynamic and nonhemodynamic effects. For this reason, therapy with these drugs is said to exert renoprotection that is independent of their antihypertensive action. A similar consideration holds for sympatholytic agents, which may exert significant renoprotection even at doses that do not lower blood pressure.[387,388]

Since a large proportion of CKD patients still progress to ESRD despite being treated with inhibitors of the RAS, the use of higher doses of these compounds, or varying combinations between an ARB, an ACE inhibitor and, more recently, a renin inhibitor, have been proposed.[389–392] An alternative measure, supported by clinical and experimental evidence, is to associate a mineralocorticoid receptor antagonist, such as spironolactone or eplerenone, to an ARB or ACE inhibitor.[200,393] However, whether any of these regimens offers real advantages over the conventional therapeutic schemes is currently undetermined.[392,394]

Because a more extensive review of the therapeutics of CKD would be beyond the scope of this chapter, the reader is referred to clinically focused textbooks,

reviews and websites for more detailed analysis of the current clinical guidelines for the management of CKD patients, and of the most relevant clinical trials that provide the scientific support for these strategies.

MECHANICAL STRETCH IN THE PATHOGENESIS OF IMMUNE-MEDIATED GLOMERULONEPHRITIS

As pointed out earlier, hemodynamic stress of the glomerular capillary walls can trigger a sequence of inflammatory events that are in many respects indistinguishable from those evoked by immune-mediated glomerulonephritides. Several observations suggest that, on the other hand, the latter can promote glomerular hypertension, thus increasing the severity of the aggression to the renal parenchyma. Maddox and associates[395] showed that both glomerular plasma flow and glomerular intracapillary pressure were augmented in the early autologous phase of rat nephrotoxic serum nephritis, an experimental model for Goodpasture's syndrome. Similar findings were reported in the same model by Sakai et al.[396] Yoshioka and coworkers[397] observed elevated glomerular pressure in rats with passive Heymann's nephritis, an experimental model for membranous glomerulonephritis, showing in addition that proteinuria was acutely increased by maneuvers that aggravated glomerular hypertension. In patients with IgA nephropathy, Konichi et al.[398] showed that the estimated glomerular pressure correlated directly with the degree of glomerulosclerosis. Indirect evidence also supports the existence of glomerular hypertension in immune-mediated renal disease. Woo et al.[399] showed less severe renal injury in patients with the II ACE genotype than in those with the ID or DD genotypes, in all likelihood due to less renal ACE activity and, possibly, less severe glomerular hypertension, along with lesser manifestations of the nonhemodynamic effects of AII discussed earlier. Accordingly, treatment with inhibitors of the renin-angiotensin system ameliorated proteinuria and renal injury in clinical[400] and experimental[401] glomerulonephritis, prompting the recommendation, by several investigators, that ACE inhibitors or AII receptor blockers be used in this setting.[400–403]

GLOMERULAR HEMODYNAMICS AND THE CLINICAL TRANSLATION OF EXPERIMENTAL DATA: A WORD OF CAUTION

Knowledge about the vast majority of the mechanisms discussed in this chapter was obtained through animal studies. A large portion of these mechanisms is indeed shared by humans and animals, particularly rodents, largely justifying the widespread use of experimental models of CKD to mimic human disease. However, important differences exist that may preclude direct application of data generated by experimental work to the clinical context. For instance, unilateral nephrectomy is known to cause substantial proteinuria in rodents, being used as an experimental model of CKD,[88,95] whereas removal of one kidney in humans, as noted earlier in this chapter, leads to only mild abnormalities.[58,322,323] Another example of the disparity between human and animal disease is given by the differing responses to RAS inhibition, discussed earlier: whereas treatment reduces spectacularly proteinuria and glomerular injury in rats with renal mass removal or diabetic nephropathy,[38,64] the human response is frequently incomplete and, all too often, complicated by hyperkalemia and/or GFR decline, forcing the cessation of treatment.[404] Despite the enthusiasm that bench data may evoke, generation of clinical evidence remains mandatory before information thus obtained can be effectively applied.

SUMMARY AND CONCLUSIONS

The mechanisms discussed in this chapter are represented in a simplified manner in Fig. 86.4. Mechanical strain to the glomerular walls can be caused by intracapillary hypertension and/or tuft hypertrophy, both of which are associated with several instances of progressive renal disease. Capillary stretch can damage endothelial cells, mesangial cells and podocytes, setting off a chain of events that culminate in the development of glomerulosclerosis and interstitial fibrosis. Inflammatory events, such as leukocyte infiltration and local production of cytokines, chemokines and growth factors, play a crucial role in the translation of stretch-induced cell injury to progressive scarring of the renal tissue. Activation of the renin-angiotensin system plays a crucial role in this process, favoring both mechanical strain and inflammatory phenomena. Genetic and environmental factors, such as nephron number at birth, obesity, use of tobacco and protein intake can worsen the mechanical stretch to the glomeruli, contributing to an acceleration of the progression of the disease. Nephron dropout resulting from the combined action of all these factors aggravates the compensatory functional and anatomical hypertrophy of the remaining units, leading to further mechanical strain and establishing a positive feedback loop that perpetuates and intensifies the destruction of the renal parenchyma. Although a number of potential therapeutic targets has been uncovered in the past two decades, lowering of

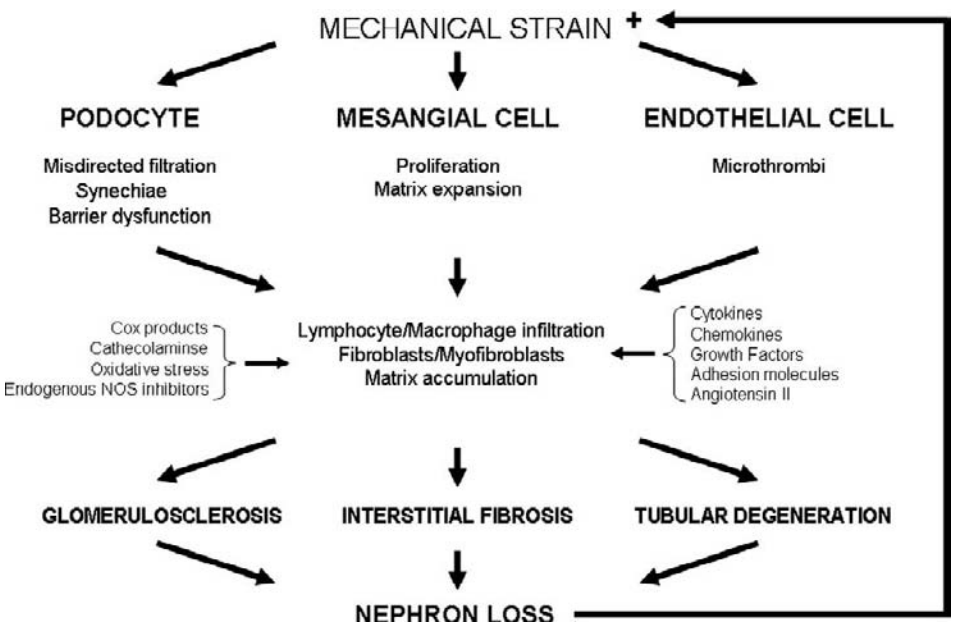

FIGURE. 86.4 Simplified schematic of the factors involved in progressive renal injury initiated by glomerular mechanical strain.

blood pressure, inhibition of the renin-angiotensin system and, in diabetic patients, strict metabolic control remain the best options in the effort to halt mechanical strain to the glomerulus and/or the development and propagation of its deleterious effects.

INTRODUCTION

Chronic progressive nephropathies, independent of the type of the initial insult, have in common persistently high levels of urinary protein excretion, chronic tubulointerstitial lesions, and glomerular sclerosis. It has become clear that in otherwise comparable groups of patients, those with higher levels of proteinuria are at a greater risk of progression. It has been long known that the severity of tubular interstitial damage is highly correlated to the degree of deterioration of renal failure, even better than the glomerular lesions do. The recognition that proteinuria is an independent predictor and a possible contributor of progression rather than just a marker of the severity of glomerular damage represents a major change in our concepts of progressive kidney disease. Proteinuria is enlisted among modifiable risk factors of progressive renal insufficiency, and antiproteinuric treatments are consistently renoprotective. Proteinuria reduction must therefore be considered as a target of therapeutic intervention in managing the patient with a chronic proteinuric nephropathy.

Among the cellular mechanisms that may contribute to determine progression, proteins that gain access to the glomerular filtrate as a consequence of altered glomerular permeability reach the Bowman's space and the tubular lumen and act as trigger of interstitial inflammatory and fibrotic reactions through the tubular synthesis of bioactive mediators. *In vitro* studies using polarized proximal tubular epithelial cells as a model system to mimic the effects of prolonged exposure to proteins have highlighted specific mechanisms underlying renal cell activation and renal interstitial injury.

The main focus of this chapter is on pathways of interstitial inflammation and fibrosis activated by ultrafiltered proteins that play major roles in the multifactorial process ultimately responsible for kidney scarring and loss of function (Figure 87.1).

Historical Perspective

A relentless decline in glomerular filtration rate can follow initial insults to the kidney through a process termed as 'renal disease progression' by nephrologists since 1982.[1] Studies in the early 19th and 20th centuries[2,3] contributed to link a disparate body of knowledge about patients with albuminuria and pathological evidence of diseased kidneys. By summarizing his concept in term of renal 'osmotic work', Addis calculated how this work would vary with the amount of proteins in the diet and suggested that dietary protein restriction could possibly help patients with renal impairment.[4]

When glomerular permeability is altered, as occurs in many glomerular diseases, considerable quantities of circulating proteins are abnormally filtered in the urinary space. Volhard and Fahr[5] and subsequently Mollendorf and Stohr[6] provided the early descriptions of hyalin droplets in the cytoplasm of proximal tubular cells and suggested that they reflected renal damage related to severe proteinuria. It was then proposed that such changes could represent the initial phase of activation of cellular pathways leading to cell necrosis.[7] The appearance of droplets was also

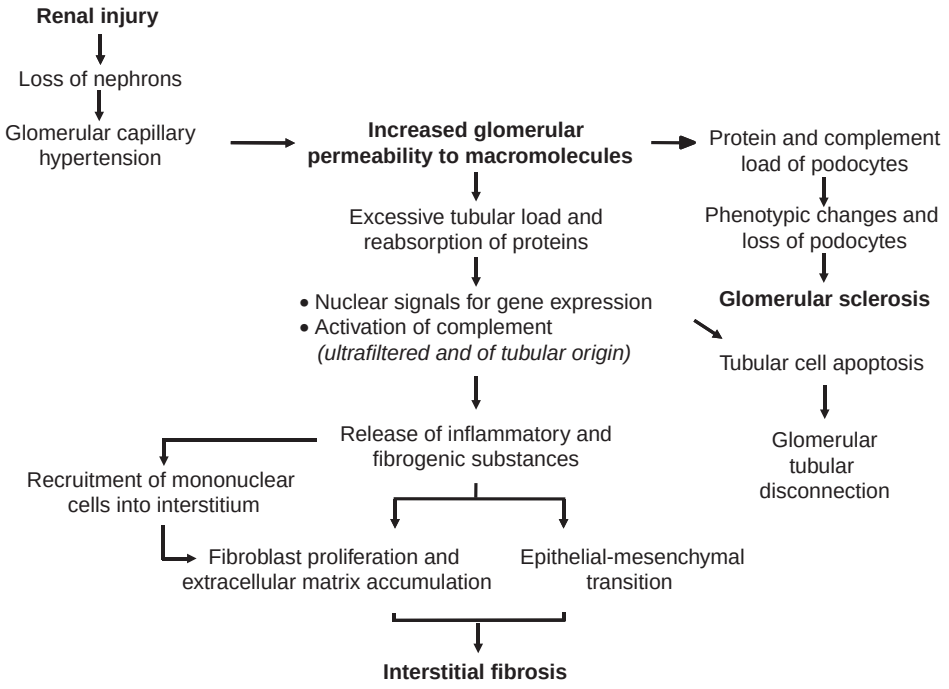

FIGURE 87.1 Schematic representation of the events that lead to chronic tubulointerstitial damage and glomerular sclerosis in proteinuric nephropathy.

suggested to be associated with impairment of normal reabsorbption and degradation of plasma proteins by proximal tubular cells.[8]

Hints about a possible association between proteinuria and renal function impairment formally emerged in the late 1970s. Cameron and colleagues showed that among patients with focal and segmental glomerulosclerosis those with nephrotic syndrome progressed more rapidly than those who had never been nephrotics.[9] This was also true for mesangiocapillary glomerulonephritis[9] and membranous nephropathy.[10] Their speculation was that during the course of prolonged nephrotic syndrome intracapillary platelet thrombi induced segmental sclerosis, or that these glomerular lesions were a consequence of proteinuria. These observations were in agreement with previous findings that none of patients with focal and segmental glomerulosclerosis who responded to corticosteroid treatment with reduction of proteinuria developed renal failure.[11]

In 1981 Brenner and associates introduced the concept that glomerular hemodynamic changes (glomerular hyperfiltration) ensuing as compensatory adaptation to nephron loss can cause progressive deterioration of remaining nephrons. Instrumental in clarifying the pathophysiology of renal adaptation to nephron loss was the model of renal ablation in the rat.[12] After removal of a critical portion of renal mass, remnant nephrons undergo sudden hypertrophy with concomitant lowering of arteriolar resistance and increased glomerular plasma flow. Since the vascular tone drops more in afferent arterioles than in the efferent ones, glomerular capillary hydraulic pressure rises and more filtrate is formed per nephron. While such changes serve to enhance the filtration capacity of remaining nephron units, thus minimizing the functional consequences of nephron loss, they are ultimately detrimental. Therapies that attenuate such adaptive changes limit GFR decline and structural damage. In harmony with the data obtained in animal studies, clinical studies showed markedly reduced rates of GFR decline in patients with diabetes receiving antihypertensive agents.[13,14] Elevated intraglomerular capillary pressure was suggested to act as a noxious stimulus to glomerular cells.[15] Studies of mathematical models of the glomerular filtering membrane documented that the high glomerular capillary pressure acted to enlarge the radii of the pores perforating the glomerular membrane by a mechanism at least partly mediated by angiotensin II.[16] This impairs the size-selective function of the barrier resulting in protein ultrafiltration. The association of protein ultrafiltration and progression of renal disease was underscored by Mathiesen and coworkers[17] who reported that in diabetic patients the higher the microalbuminuria the faster the rate of GFR decline.

In 1986, it was suggested for the first time that proteins abnormally filtered through the glomerular capillary might have intrinsic renal toxicity that is relevant to the progression of renal damage.[18] In the kidneys of proteinuric rats with adriamycin nephrosis, the accumulation of filtered proteins in the cytoplasm of proximal tubular cells and in luminal casts was associated with focal breaking of the tubular basement membrane

and extravasation of the tubular content into the renal interstitium. Aging is associated with progressive proteinuria and glomerulosclerosis, which lead to the renal insufficiency of certain strains of rats. The severity of proteinuria predicted the development of glomerulosclerosis and tubulointerstitial changes.[19] Implications of these studies were that the enhanced protein uptake may activate proximal tubular epithelial cells to promote the accumulation of inflammatory cells into the interstitium, in turn responsible for renal scarring.[20] Studies using animal models and pharmacologic manipulations found that the dysfunction of the glomerular capillary barrier to proteins can precede the onset of structural lesions in the absence of glomerular hemodynamic changes, consistent with the possibility that—at least in certain settings—protein load of the nephron may contribute independently to progressive renal damage before maladaptive hemodynamic changes can take place or be measurable within the glomerulus.[21,22]

Cause-and-effect relationships between enhanced transtubular protein passage and interstitial inflammation were investigated by Eddy in a rat model of protein overload.[23] Repeated injections of albumin increased the permeability of the glomerular barrier leading to proteinuria and tubular changes, including the accumulation of injected albumin in intracellular droplets of tubular cells. These changes occurred in advance of heavy infiltration of macrophages and T lymphocytes into the renal interstitium. Excessive proteinuria was also induced in rats by transplanting a pituitary tumor (MtT SA5) that causes liver hyperplasia with both overproduction and abnormally high urinary excretion of albumin, followed by tubular damage and interstitial inflammation.[24] Models of protein overload contributed to suggest that the pathogenic potential of ultrafiltered plasma proteins is not confined to pathways underlying tubular and interstitial damage. The availability of cultured cells with features of differentiated podocytes revived investigation on the effects of plasma proteins on the function of glomerular epithelial cells,[25,26] currently recognized to play a key role in the progression of lesions toward glomerular sclerosis. Plasma proteins that are filtered accumulate as protein droplets within podocytes from the early stages of non-immunologically-induced glomerular damage. At the same stage, podocytes show signs of dedifferentiation and injury.[25] These abnormalities are likely to play role in the development of glomerular sclerotic lesions. They will be discussed in the light of findings indicating another important pathway, i.e., the activation of complement upon excess protein ultrafiltration.

Tubular Handling of Proteins

Proteins that reach the tubular lumen are reabsorbed in the proximal segments by receptor-mediated endocytosis, via two multiligand-binding receptors, megalin and cubilin.[27] Megalin, a 600-kDa transmembrane glycoprotein belonging to the low density-lipoprotein receptor family, represents the most abundant endocytic receptor in the proximal tubule, being concentrated in clathrin-coated pits (CCPs) and vesicles in the brush border region.[28,29] It binds different ligands including albumin, hormones such as insulin, angiotensin II and prolactin, and vitamin-binding proteins. Megalin's endocytic function is regulated by the G protein–mediated signaling pathway that includes Gαi3, GAIP and GIPC, the latter interacting with the cytoplasmic tail of megalin[30] (Figure 87.2). This portion contains recognition motifs for intracellular adaptor proteins and protein kinases involved in endocytosis, apical sorting of receptor, and signaling.[27]

Among adaptor proteins, Disabled protein 2 (Dab2) colocalizes with megalin in CCPs and vesicles of renal proximal tubules where it binds the second endocytic motif of megalin, and, by interacting with the motor protein nonmuscle myosin heavy chain IIA, regulates trafficking of megalin through the endocytic/recycling pathway[31] (Figure 87.2). Suboptimal trafficking of megalin in Dab2 knockout mice leads to decreased megalin levels, possibly due to increased protein shedding and degradation, and impaired endocytosis as documented by urinary loss of megalin ligand.[32] Association of motor proteins with adaptor proteins is now emerging to be instrumental for renal proximal tubular endocytosis. Myosin VI (Myo6) is highly expressed in the brush border where it associates with the CCP via its tail domain binding to Dab2 (Figure 87.2). Myo6 functional null mice show increased urinary albumin excretion, similar to megalin- and cubilin-deficient animals, and reduced and delayed endocytic uptake and trafficking of horseradish peroxidase consistent with impaired endocytosis.[33] This defect is associated with structural and phenotypic changes of tubular cells and fibrosis.

The expression and subcellular distribution of megalin is controlled by the chaperone receptor-associated protein RAP that prevents ligand–induced endoplasmic reticulum (ER) retention and degradation of the receptor and is possibly involved in its proper folding[27] (Figure 87.2). RAP knockout mice are characterized by both reduced expression of megalin and its preferential subcellular distribution to the ER. RAP deficiency is also associated with leakage of proteins in urines due to impaired megalin-dependent tubular reabsorption. Pro-inflammatory and pro-fibrotic mediators such as transforming growth factor beta (TGF-β) and angiotensin II[34,35] as well as nephrotoxicants[36] also down-regulate megalin expression in proximal tubular cells.

Cubilin or intrinsic-factor B12 receptor, is a 460-kDa peripheral membrane protein that binds albumin,

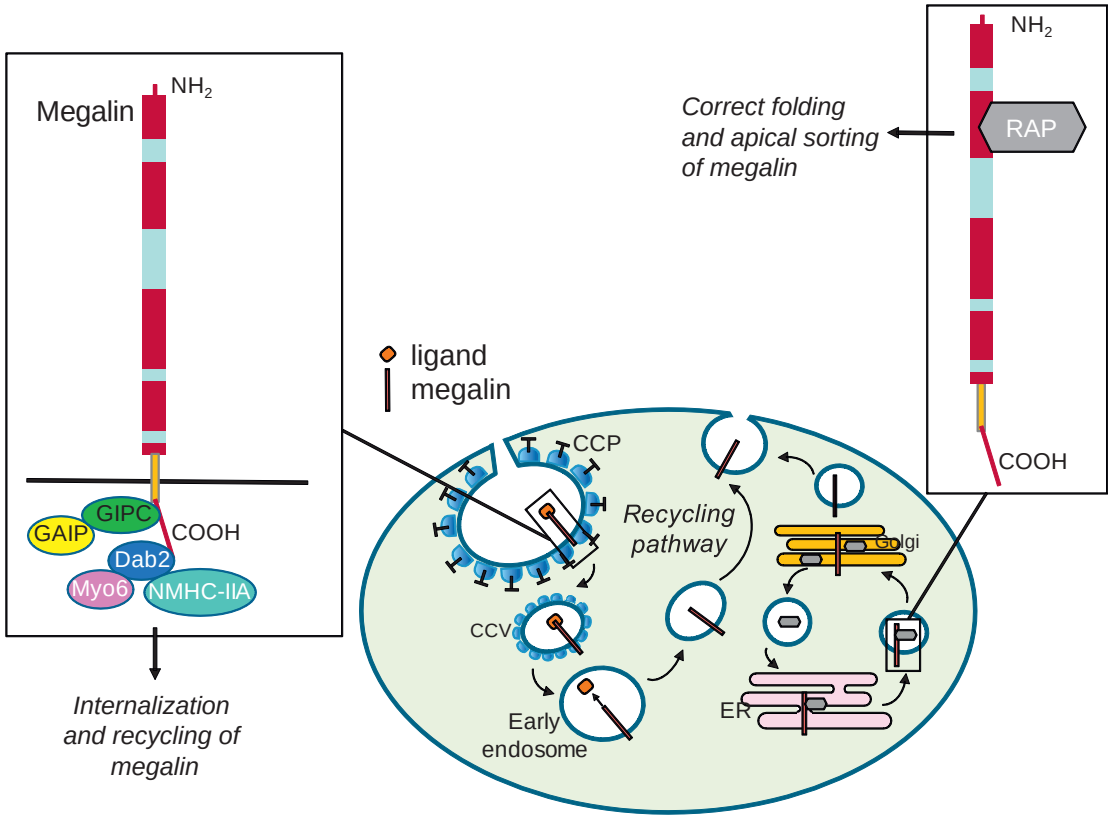

FIGURE 87.2 Regulation of trafficking and apical sorting of megalin. Megalin is associated with CCPs in the brush border of the renal proximal tubular cell. Through its cytoplasmic tail it interacts with the G protein GIPC and the adaptor protein Dab2, both regulating the endocytic/recycling pathway of the receptor. GIPC interacts with GAIP, and Dab2 binds the motor proteins NMHC-IIA and Myo6, which contribute to megalin's endocytic function. RAP binds megalin within the extracellular domain with the effect of regulating the receptor processing by proper folding, and prevents its retention in the ER due to early binding of ligands. This leads to correct transport of megalin through the Golgi and subsequent apical sorting to the brush border. Abbreviations: CCPs, clathrin-coated pits; CCV, clathrin-coated vesicle; Dab2, Disabled protein 2; ER, endoplasmic reticulum; GAIP, Gα interacting protein; GIPC, GAIP interacting protein, C terminus; Myo6, myosin 6; NMHC-IIA, nonmuscle myosin heavy chain IIA; RAP, receptor-associated protein.

transferrin, IgG light chains and RAP, but lacks the sites for interaction with adaptor proteins or other mediators of clathrin-dependent endocytosis.[28,29] Since megalin binds cubilin with high affinity, it has been hypothesized that megalin mediates endocytosis and intracellular trafficking of cubilin.[37] *In vitro*, the uptake of the cubilin-specific ligands, including transferrin, was inhibited both by anti-megalin antibodies and by megalin anti-sense oligonucleotides.[38–40] Furthermore, in megalin-deficient mice transferrin accumulates on the luminal membrane of the proximal tubule without being internalized.[38] Cubilin binds amnionless (AMN), a 50-kD transmembrane protein that is required for membrane targeting and may permit internalization of cubilin.[27] Patients with Imerslund-Grasbesk syndrome (IGS), a rare autosomal recessive disease caused by inheritable cubilin or AMN gene defect, show reduced protein reabsorption and proteinuria. Consistently, inappropriate apical membrane insertion of cubilin in the proximal tubule leads to proteinuria in a model of IGS in dogs with a mutation of the AMN gene. Kidney specific AMN knockout mice also show increased urinary excretion of transferrin.[41]

The generation of mice with the genetic ablation of cubilin, with or without ablation of megalin, disclosed a mutual dependency of cubilin and AMN to form a functional membrane receptor complex.[42] Cubilin is indispensable for albumin reabsorption in renal proximal tubule under physiological conditions, whereas megalin drives the internalization of cubilin-albumin complexes.[42]

Megalin undergoes regulated intramembrane proteolysis with protease-mediated ectodomain shedding, producing a membrane–associated C-terminal fragment, which is in turn the substrate for the γ-secretase activity of a multimolecular complex of proteins, including the so-called presenilins, that release the C-terminal soluble cytosolic domain predicted to target the nucleus. In the rat kidney, the brush border exhibits both γ-secretase activity and presenilin-1 expression.[43]

In a cell line derived from opossum proximal tubule (OK cells), metalloprotease activity sheds the ectodomain of megalin, producing a membrane-bound megalin COOH-terminal fragment with the same size as a major fragment of megalin found in the kidney.[43] This fragment is further cleaved by γ-secretase into a soluble intracellular domain leading to down-regulation of megalin and Na^+/H^+ exchanger 3 (NHE-3) transcripts.[44] This domain does not affect megalin expression and endocytic function *in vivo* at least under physiological conditions, although a regulatory effect on renal gene transcription under stress cannot be excluded.[45]

Reduced expression of megalin is a common feature to settings of proteinuria and defective tubular uptake of filtered proteins, such as early stages of experimental diabetes or polycystic kidney disease, Fanconi syndrome and Dent's disease in humans.[41] Dent's disease is caused by a mutation of the gene CLCN5 encoding the 2 chloride (Cl^-)/proton (H^+) exchanger ClC-5. Inactivating mutations of ClC-5 in Dent's disease and the deletion of CLCN5 in knockout mice lead to low-molecular-weight proteinuria due to reduced endocytic uptake of filtered proteins in the proximal tubule. This defect was initially attributed to impaired acidification of apical endosomes in these cells,[46–48] but subsequent data indicate selective loss of expression of megalin and cubilin at the brush border as a major cause of defective protein endocytosis in this disease.[49] Along this line, reduced megalin and cubilin levels have been found in tubules with the uncoupling E211A (unc) mutation that converts CLC-5 into a pure Cl^- conductor. Despite maintaining active endosomal acidification, $ClCN5^{unc}$ mice show impaired proximal tubular endocytosis and resultant low-molecular-weight proteinuria as found in CLC-5 knockout mice and in patients with Dent's disease.[50] These results indicate that endosomal chloride-proton exchange rather than chloride conductance is crucial for tubular endocytosis (Figure 87.3).

During receptor-mediated endocytosis, ligand-receptor complexes are internalized and transported via clathrin-coated vesicles to early endosomes where they dissociate. The receptor is sorted to the plasma membrane (recycling pathway) and the endocytosed proteins are transported further into the degradative pathway. The endocytic pathway is regulated by a protein network. The inositol 5′-phosphatase OCRL -whose mutations are responsible for *OculoCerebroRenal Syndrome of Lowe*, an X-linked disorder characterized by cataract, mental retardation, and renal Fanconi syndrome- is present throughout the early endocytic pathway including CCPs and interacts with adaptor molecules involved in the early endocytic traffic of receptors in brain and kidney.[51] On peripheral early endosomes OCRL binds the Rab5 effector APPL1, an adaptor/signaling protein that binds several transmembrane receptors and also the adaptor protein GIPC (Figure 87.3). Since GIPC directly binds megalin (see above), loss of the interaction of OCRL with APPL1 due to disease mutation may have a causal role in the reabsorptive defect of kidney resulting in low-molecular-weight proteinuria in Lowe syndrome patients and in a subset of Dent's disease patients.

Another protein, the transporter NHE-3 contributes to the early phase of the apical endocytic pathway at least in part due to its involvement in endocytic vesicle fusion.[52] NHE-3 is associated with megalin and dipeptidyl IV in proximal tubule endosomes where it also participates in the acidification process[48] (Figure 87.3). Acidification of endosomal compartment is crucial not only for ligand-receptor dissociation and receptor recycling, but also for a correct protein endocytic trafficking from early to late endosomes, and finally lysosomes. The acidification of proximal tubule endosomes is driven by the vacuolar H^+-ATPase (V-ATPase), an electrogenic pump that translocates protons from the cytoplasm to the endosomal lumen and in conjunction with a parallel chloride conductance generates the acidic milieu of the endosomal compartment[53] (Figure 87.3). V-ATPase acts as an endosomal pH sensor that recruits the small GTPase Arf6 (ADP-ribosylation factor) and its cognate GDP/GTP exchange factor ARNO (ADP-ribosylation factor nucleotide site opener) from the cytosol to the endosomal membranes by direct binding these proteins upon vesicle acidification (Figure 87.3). Interaction of both Arf6 and ARNO with V-ATPase allows correct vesicular trafficking from early to late endosomes. By contrast, inhibition of V-ATPase or uncoupling of endosomal acidification impairs V-ATPase/ARNO/Arf6 interaction leading to accumulation of endocytosed proteins in early endosomes, and ultimately, to inhibition of endocytosis.[53] An intact actin cytoskeleton is important for correct assembly and function of the V-ATPase.[53] The disorganization of the actin cytoskeleton induced by statins through reduced prenylation of the small GTP-binding proteins results in a defect of albumin endocytosis in proximal tubular cells.[54,55]

Protein Overload Activates Phenotypic Changes in Cultured Proximal Tubular Cells

Insights into mechanisms linking the excess traffic of plasma proteins and interstitial injury have come from *in vitro* studies using polarized proximal tubular cells as a model to assess effects of apical exposure to proteins (Figure 87.4). Challenge of cultured proximal tubular cells with high concentrations of proteins

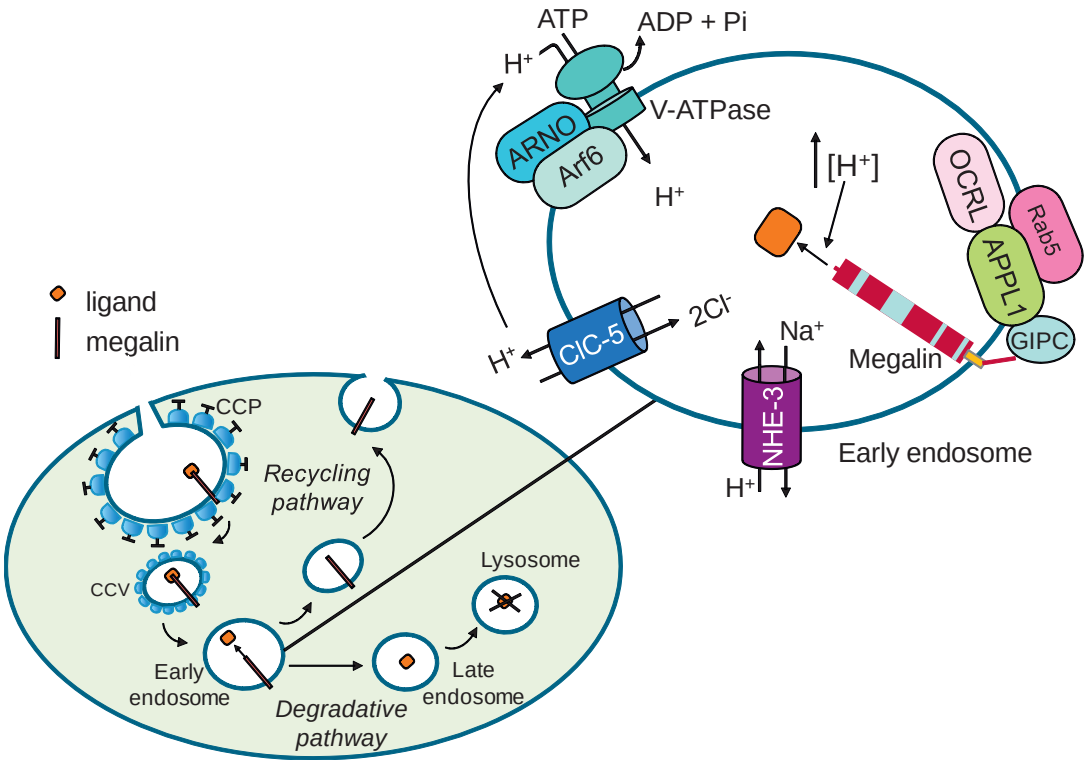

FIGURE 87.3 Regulation of endocytic pathway in the renal proximal tubular cell. Upon binding of ligand (i.e., albumin) to megalin in CCPs, ligand-receptor complexes are internalized and transported via clathrin-coated vesicles to early endosomes where they dissociate. Megalin is sorted to the plasma membrane (recycling pathway) and the endocytosed proteins are transported further into the degradative pathway. Acidification of intracellular lumen of the early endosome involves NHE-3 and V-ATPase with counter ion being provided by CLC-5. Upon acidification, Arf6 and ARNO are recruited to the endosomal membrane and both interact with V-ATPase driving the vesicular trafficking of endocytosed proteins from early to late endosomes. Interaction of the inositol 5′-phosphatase OCRL with the rab5 effector APPL1, which binds GIPC regulates the early steps of the endocytic traffic of megalin. Abbreviations: Arf6, ADP-ribosylation factor; APPL1, Adaptor Protein containing pleckstrin homology domain, PTB domain and Leucine zipper motif 1; ARNO, ADP-ribosylation factor nucleotide site opener; CCPs, clathrin-coated pits; CCV, clathrin-coated vesicle; CLC-5, 2 chloride (Cl^-)/proton (H^+) exchanger; NHE-3, Na^+/H^+ exchanger 3; OCRL, oculocerebrorenal syndrome of Lowe; V-ATPase, vacuolar H^+-ATPase.

(delipidated or lipid-enriched albumin, IgG and transferrin) induced the synthesis of the vasoconstrictor peptide endothelin-1,[56] a mediator of progressive renal injury due to its ability to stimulate renal cell proliferation and extracellular matrix production and to attract monocytes. Monocyte chemoattractant protein-1 (MCP-1 or CCL2) and Regulated upon Activation, Normal T cell Expressed and Secreted (RANTES or CCL5), potent chemoattractants for monocytes/macrophages and T-lymphocytes, were upregulated in proximal tubular cells challenged with albumin and other plasma proteins.[57,58] Albumin overload also induced tubular gene expression and production of the C-X-C chemokine interleukin-8 (IL-8), a potent chemoattractant for neutrophils and lymphocytes.[59] Endothelin-1 and chemokines induced by plasma proteins were released mainly toward the basolateral compartment of the cell, which is indicative of a directional secretion potentially responsible for the tubulointerstitial inflammatory reaction as found in proteinuric nephropathies. Co-culture systems of proximal tubular epithelial cells and monocytes/T cells proved useful to document that the release of MCP-1 and RANTES upon apical exposure of tubular cells to albumin was further increased in the presence of monocytes or T cells, either through a cell-to-cell contact mechanism or mediated by soluble factors such as interleukin-1 and tumor necrosis factor.[60] Moreover, the conditioned medium of tubular cells activated by albumin induced distinct patterns of chemokine receptor expression on T cells or monocytes, thereby implying that different arrays of chemokines may mediate the chemotactic activity of leukocytes in the tubulointerstitium during the proteinuric state.

Protein overload promotes the tubular expression of fractalkine/CX3CL1, a cell-membrane anchored chemokine that serves as an adhesive molecule to promote firm adhesion of mononuclear cells expressing the specific receptor CX3CR1, in addition to functioning in its cleaved soluble form as a chemoattractant. Upregulation of fractalkine mRNA and increased

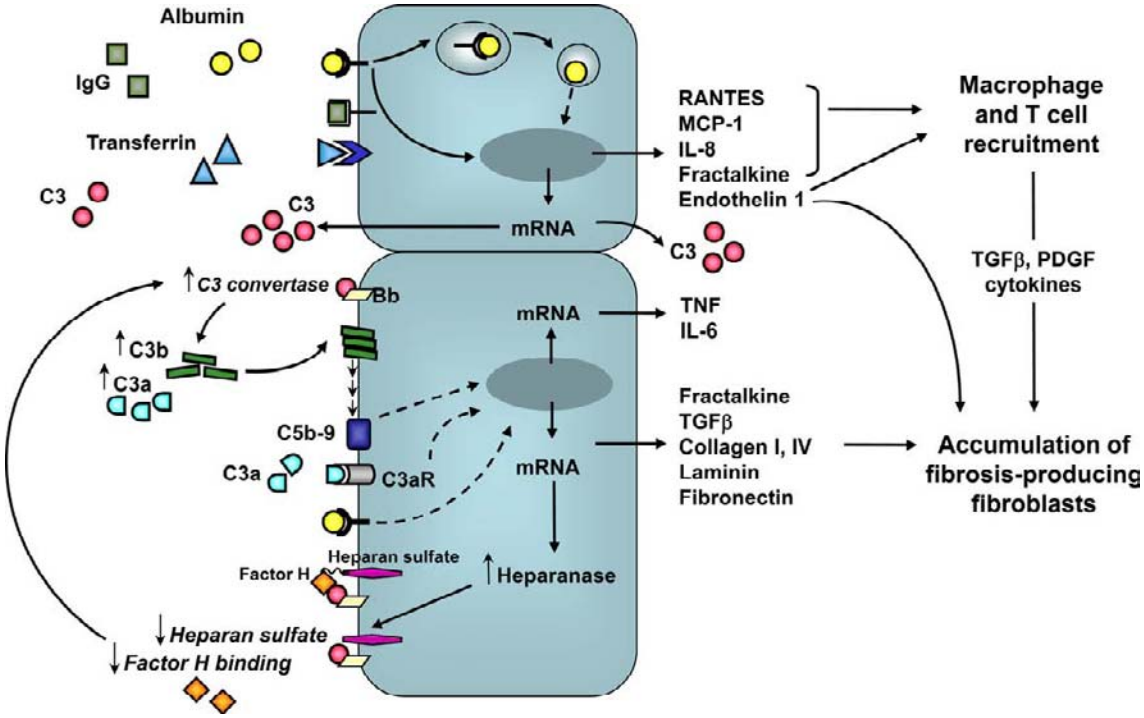

FIGURE 87.4 Cellular mechanisms of injury underlying the activation of inflammatory and fibrogenic pathways by proximal tubular cells in response to excess load of filtered plasma proteins that occurs in chronic proteinuric nephropathies.

synthesis of both membrane-bound and soluble forms of the protein occurred upon stimulation of human proximal tubular cells with albumin.[61] In a murine model of protein overload proteinuria, fractalkine mRNA was overexpressed in the kidney, and fractalkine staining was detected in tubular epithelial cells in a focal distribution.[61] Treatment of mice with an antibody against CX3CR1 limited the accumulation of monocytes/macrophages in the renal interstitium. These data suggest that in proteinuric conditions, fractalkine overproduction might contribute to direct mononuclear cells into the peritubular interstitium and possibly enhance their adhesive property.

TGFβ is a profibrogenic cytokine capable of directly stimulating the proliferation of fibroblasts and the synthesis of matrix proteins, in addition to exerting indirect stimulatory effects via inflammatory infiltrating cells. TGFβ acts as a key stimulus for epithelial-to-mesenchymal transition (EMT), by which tubular cells acquire features of fibroblasts.[62] High concentrations of albumin induced in cultured proximal tubular cells the transcription of the TGFβ gene resulting in the enhanced release of the cytokine in the cell supernatant.[63,64] Albumin upregulated TGFβ receptor type II expression in proximal tubular cells, which became more susceptible to the matrix-stimulatory actions of TGFβ.[65] Albumin stimulated the accumulation of extracellular collagen type IV, laminin, and fibronectin by proximal tubular cells through a post-transcriptional mechanism.[66] A reduced degradation could be responsible for the increased accumulation of extracellular matrix protein components, as indicated by induction of tissue inhibitors of metalloproteinases (TIMP)-1 and TIMP-2, in response to albumin.[66]

Advances have been made in clarifying the mechanisms of albumin-induced TGFβ production in proximal tubular cells. *In vitro*, albumin-induced secretion of TGFβ1 by proximal tubular cells could occur in the absence of albumin endocytosis.[67] Thus two cell lines, opossum kidney (OK) proximal tubular cells and HKC-8 proximal tubular cells, which display different degrees of endocytosis, produced an equivalent amount of TGFβ1 when exposed to albumin. Moreover, inhibiting albumin endocytosis in OK cells with two agents with different mechanisms of action as EIPA (a sodium/hydrogen exchanger-3 inhibitor) or simvastatin (a 3-hydroxy-3-methylglutaryl CoA reductase inhibitor) did not reduce albumin-induced TGF-β1 secretion. On the other hand, RAP, a known inhibitor of binding of albumin to megalin, inhibited albumin endocytosis but it did not affect TGFβ1 production, suggesting that albumin-induced secretion of TGFβ1 is not via megalin signaling.[67] Along this line, further studies showed that primary cultures of mouse proximal tubular cells exhibited substantial albumin endocytosis that could be similarly inhibited by both statins

and thiazolinediones, but only statins had the ability to limit albumin-stimulated MCP-1 production.[68] It was concluded that inhibition of albumin endocytosis alone was insufficient to attenuate chemokine production and therefore to protect proximal tubular cells from the toxic effects of albumin.[69]

The contact between tubular cells and interstitial matrix is operated by specialized adhesion molecules, the integrins. They are α/β transmembrane heterodimers that mediate adhesion of the basal surface of cells to the underlying substratum by recognizing extracellular matrix components and by interacting with different cytoskeletal molecules. *In vitro* these molecules are clustered in specialized structures, called focal contacts. In tubular cells the expression of integrins can be regulated by cytokines, including TGFβ, that either directly influence mRNA transcription of integrins or modulate the synthesis of interstitial matrix and the consequent rearrangement of integrins at focal contacts.[70] On the other hand, matrix proteins can modulate integrin expression and via integrin-generated signals, regulate the synthesis, degradation and organization of the matrix itself. Therefore, alterations in the expression and/or functional status of tubular cell integrins may play roles in the events leading to tubulointerstitial fibrosis. In cultured tubular cells the addition of albumin increased membrane expression of αvβ5 integrin which became organized in typical focal contacts dose-fashion related.[71]

The Role of Proteinuria in Tubular Apoptosis

Protein overload is a stimulus for apoptosis. A dose- and time-dependent induction of apoptosis by albumin was demonstrated in cultured proximal tubular cells as revealed by internucleosomal DNA fragmentation, morphological changes including cell shrinkage and nuclear condensation, and plasma membrane alterations.[72] Apoptosis in this setting was associated with activation of Fas-FADD-caspase 8 pathway, suggesting activation via the extrinsic pathway of apoptosis. Peroxisome proliferator activated receptor (PPAR)-γ[73] is also implicated in molecular mechanisms underlying albumin-induced apoptosis. **A**lbumin-bound fatty acids stimulated PPAR-γ in primary cultures of human proximal tubular cells and caused apoptosis that could be blocked by PPAR response element decoy oligonucleotides. Moreover, transfection experiments revealed that the transient overexpression of PPAR-γ in tubular cells resulted in enhanced apoptosis.[73] In HKC-8 human proximal tubular cells, albumin-induced apoptosis was mainly mediated by the intrinsic pathway of apoptosis, characterized by Bax translocation to mitochondria and cytochrome *c* release from the organelles.[74] This pathway was recently confirmed in rat proximal tubular cells by inhibition with Bcl-2 transfection and was found to be mediated by protein kinase C-delta (PKC-δ), a novel subfamily member of PKC serine/threonine protein kinases.[75]

Albumin-dependent signaling and albumin endocytosis appear to act as interrelated processes regulating the fate of proximal tubular cells *in vitro*. Megalin may behave as a sensor molecule that determines whether the cells will be protected from or injured by albumin, pending on the protein concentration. On one hand, low concentrations of albumin lead to activation of serine/threonine kinase PKB and phosphorylation of Bad protein, which inhibits apoptosis.[76] On the other hand, albumin overload decreased the expression of megalin on the plasma membrane that was associated with a reduction of PKB activity and Bad phosphorylation, favoring apoptosis.[77] As well as albumin load of tubular cells, a balance has also been suggested between the induction of a NF-kB dependent, Bcl-xL mediated anti-apoptotic pathway and the induction of AP-1 mediated clusterin overexpression that instead, by inhibiting the pathway, would favor a switch from inflammatory phenotype to apoptotic injury.[78]

Multiple pathways of apoptosis can be activated in renal tubular cells during proteinuric kidney diseases. Apoptotic responses to protein load were documented in the rat model of albumin overload proteinuria, showing increased numbers of terminal dUTP nick-end labeling positive apoptotic cells both in the tubulointerstitial compartment and in glomeruli.[79] In tubuli, most of the positive cells were found in profiles expressing angiotensin II type 2 (AT2) receptor. Findings of reduced phosphorylation of ERK and Bcl-2 were suggested to reflect an AT2 receptor-mediated mechanism underlying tubular cell apoptosis.[79] Proximal tubular cell apoptosis may contribute to glomerular-tubule disconnection and atrophy in response to proteinuria in rats with accelerated passive Heymann nephritis.[80] Another study, in agreement with results obtained using cultured proximal tubular cells, showed PKC-δ overexpression and tubular apoptosis in kidneys of mice upon albumin overload, whereas PKC-δ knockout mice were protected.[75] Levels of proteinuria remained comparable, indicating lower susceptibility to apoptosis rather than differences in protein exposure. Mechanistically, PKC-δ could promote apoptosis by activation of apoptotic genes, phosphorylation of caspases, interaction with apoptotic regulators, remodeling of cell membranes, or interference with mitochondrial function possibly including ER-mitochondrial crosstalk during ER-stress-induced apoptosis. ER stress has been demonstrated both in proximal tubular cells *in vitro* and in kidneys of rats with albumin-overload or puromycin aminonucleoside-nephrosis.[81]

Apoptotic cells were also detected both in proximal and distal tubular profiles in biopsy specimens of patients with primary focal segmental glomerulosclerosis. A positive correlation was found between proteinuria and incidence of tubular cell apoptosis, which was identified as a strong predictor of outcome in these patients.[82] Albumin exposure caused the activation of the Fas pathway and apoptosis in cultured Madin-Darby canine kidney epithelial (distal/collecting) cells, hence extending to the distal nephron the pro-apoptotic potential of enhanced protein load.[82] Besides promoting tubulo-glomerular disconnection at proximal level, tubular apoptosis could create and sustain a local proinflammatory microenvironment via release of molecules that serve as danger signals by dying cells. Danger-associated molecular patterns (DAMPs) trigger inflammation by engaging Toll-like receptors (TLR) and nucleotides-binding domains, leucin-rich, repeat-containing proteins (NLRs). Engaged NLR form complexes with apoptosis-associated proteins to produce macromolecular complexes termed inflammasomes that cleave proinflammatory cytokines to their mature forms.[83] A role for inflammasomes in progressive renal disease has been recently shown in NLRP3 $^{-/-}$ mice that were protected from injury and fibrosis of unilateral ureteral obstruction. Increased expression of NLRP3 was also detected in kidney biopsy specimens of patients with progressive kidney diseases.[84]

Intracellular Signaling of Protein Overload

In vitro studies have documented that protein overload activates signal transduction cascades in proximal tubular cells resulting in transcriptional upregulation of proinflammatory and fibrogenic molecules.[85]

Molecular mechanisms leading to chemokine gene induction as a consequence of enhanced protein uptake have been identified. Nuclear transcription factors such as NF-kB have attracted attention as candidate pathways and are seen as a potential target of therapeutic intervention against proteinuria-induced tubulointerstitial injury. The NF-kB/Rel family includes homodimeric or heterodimeric complexes designated as p50, p52, p65, c-rRel and RelB.[86,87] The prototype NF-kB is composed of p50-p65 subunits. NF-kB proteins normally exist in the cytoplasm bound to the inhibitory protein IkBα. Upon cell activation by different stimuli, such as cytokines, viruses and oxidants, IkBα is phosphorylated by the IkB kinase (IKK) complex, ubiquitinated and degraded, allowing NF-kB translocation into the nucleus for binding to DNA motifs in gene promoters. In cultured proximal tubular cells albumin dose-dependently enhanced NF-kB activity resulting in upregulation of RANTES, MCP-1 and IL-8.[58,59,88] The role of NF-kB activation in chemokine mRNA induction by protein overload was supported by experiments showing that adenovirus-mediated gene transfer of IkBα or the dominant negative mutant of IkB kinase-2 (IKK-2) which fails to phosphorylate IkBα, reduced upregulation of fractalkine mRNA in proximal tubular cells exposed to albumin.[61] Reactive oxygen species (ROS) served as second messengers in protein overload-induced NF-kB activation.[89] Albumin and IgG caused a rapid and sustained generation of hydrogen peroxide (H_2O_2) in human proximal tubular cells, and antioxidants while preventing hydrogen peroxide production, almost abolished the enhanced NF-kB activity induced by both proteins.[89] Oxidant generation is upstream regulated by protein kinase C (PKC) which, once activated, translocates from the cytoplasm to cell membrane to mediate ROS production and NF-kB activation. Inhibitors of PKC prevented hydrogen peroxide generation, NF-kB activation,[89] and MCP-1 and IL-8 gene upregulation induced by albumin, suggesting a cascade of signals from PKC-dependent oxygen radical generation to nuclear translocation of NF-kB and consequent gene upregulation.[89,90]

NF-kB transcriptional activity also depends on mitogen-activated protein kinase (MAPK) cascade pathways that transduce external stress stimuli into intracellular responses.[91] In human proximal tubular cells albumin caused rapid phosphorylation of p38 MAPK.[61] Treatment with a specific p38 inhibitor resulted in inhibition of the transcription of NF-kB promoter/luciferase reporter gene construct, consistent with a role of p38 as regulator in this pathway. The p38 blockade limited the overexpression of fractalkine mRNA and protein induced by albumin.[61] Moreover, activation of the MAPK signaling pathway was involved in albumin-stimulated TGFβ-1 gene expression and protein secretion in rat proximal tubular cells.[64] Strong and rapid activation of p44/42 MAPK was detected following cell exposure to albumin. A specific MAPK inhibitor abolished the increase of TGFβ-1 mRNA induced by albumin.

There is evidence in mouse proximal tubular cells that albumin activated extracellular signal-regulated kinase (ERK) and that blockade of ERK activation by a specific inhibitor of the mitogen-activated protein kinase kinase (MEK), the immediate upstream regulator of ERK, partially reduced albumin-induced MCP-1 expression, inhibited the increase in AP-1 and NF-kB DNA-binding activity, and prevented the degradation of IkB in albumin treated cells.[92] It has been shown that in a proximal tubular epithelial cell line engineered to constitutively express heme oxygenase-1 (HO-1) MCP-1 production in response to albumin was

reduced and that this inhibitory effect involved mechanisms that are distal to the activation of ERK and are associated with a suppressive effect on NF-kB activation.[93] Another study showed that high concentrations of albumin stimulated ERK via an EGF-receptor-dependent pathway.[94] The mechanism underlying albumin-induced stimulation of EGF-R is undefined. Based on the observations that EGF-like activators of EGF-R exist as transmembrane precursors that must undergo ectodomain cleavage to release the soluble EGF-activating fragment, and that the extracellular domain of megalin has 17 EGF-type repeats, it has been suggested that abnormal EGF activation could result from ectodomain shedding of megalin occurring from proximal tubular cells in the pathological setting of proteinuria.[69] In addition, it has also been proposed that transactivation of EGF-R by G-protein-coupled receptors could in part be regulated by PKC and c-Src, that activate ERK and are stimulated by albumin.[69] Moreover, in primary cultured proximal tubular cells albumin stimulated DNA synthesis by Ca^{2+}/PKC as well as the EGFR-dependent p44/42 MAPK and NK-kB signal pathways.[95]

The activation of the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway is an important mechanism converting cytokine and growth factor signals into gene expression programs that regulate cell proliferation and survival.[96] The evidence that albumin activated JAK/STAT in murine proximal tubular cells[97] led to the suggestion that albumin may stimulate proximal tubular cells in the manner of a cytokine.[98] The activation of STAT was also observed after treatment of the cells with apotransferrin, one of the major components of plasma proteins consisting of transferrin not saturated with iron. Findings that albumin and apotransferrin induced in tubular cells the upregulation of intracellular ROS generation and that antioxidants prevented albumin-induced phosphorylation of STAT suggested that STAT activation could occur by way of the ROS generating system.[97]

Among genes differentially regulated by excess proteins in proximal tubular cells of mice with protein overload proteinuria, glia maturation factor-B (GMF-B), a 17-kD intracellular protein originally purified from the brain, that regulates the life/death signaling by activating p38 was identified.[99] Proximal tubular cells engineered to overexpress GMF-B acquired susceptibility to cell death under sustained oxidative stress through p38 pathway activation. H_2O_2 stimulation persisted in GMF-B overexpressing cells in which the H_2O_2-generating enzyme, CuZn-SOD, was upregulated, and the H_2O_2-reducing enzymes glutathione peroxidase and catalase were down-regulated.

In Vivo *Evidence for Proinflammatory and Profibrogenic Signaling in Tubular Cells Activated by Proteinuria*

Proinflammatory signals. Studies of experimental models of kidney disease or injury, followed by further investigation in human nephropathies, have shown that activation of transcription factors and overexpression of chemokines can indeed be elicited by the proteinuric condition contributing to the development of progressive renal damage. In rats with protein-overload proteinuria the upregulation of MCP-1 and osteopontin in tubular epithelial cells was closely associated with an interstitial inflammatory reaction.[100] In this model, enhanced renal NF-kB activity was localized preferentially to tubular epithelial cells.[101] In rats with 5/6 nephrectomy, the increased urinary protein excretion over time was attended by a remarkable increase in NF-kB activity in the remnant kidney.[102] Strong nuclear staining for the p50 NF-kB subunit was visualized in proximal tubular cells and in sparse cells within the renal interstitium. A progressive increase in renal expression of MCP-1 gene occurred over time concomitant to the activation of NF-kB. Tubular MCP-1 mRNA upregulation became detectable at stages that preceded the accumulation of monocytes/macrophages and T lymphocytes in the remnant kidney interstitium, suggesting MCP-1 dependent recruitment of the cells. In other animal models of proteinuric nephropathies, renal MCP-1 overexpression preceded or coincided with the interstitial infiltration of mononuclear cells.[90,100] The administration of a neutralizing anti-MCP-1 antibody to rats with tubulointerstitial nephritis significantly decreased macrophage infiltration, strenghtening the possibility that MCP-1 is functionally important in eliciting an interstitial inflammatory response.[90] The possibility that excess protein load and reabsorption by proximal tubular cells could indeed play a role in the development of interstitial inflammation and fibrosis was supported by results of analysis of time course and sites of protein accumulation and interstitial infiltration by macrophages and MHC-II-positive cells in the rat models of 5/6 nephrectomy[103,104] and passive Heymann nephritis.[103] A link was also observed between excess plasma protein reabsorption by proximal tubuli and the expression of osteopontin, a cytokine responsible for the attraction of mononuclear cells. Osteopontin was detected in cells of proximal tubuli congested with ultrafiltered proteins, and the sites of colocalization revealed a strict relationship with adjacent infiltrates.[103] If the interstitial inflammatory reaction ensued as a consequence of excessive ultrafiltration and proximal tubular reabsorption of proteins that also promoted NF-kB activation and chemokine synthesis, limiting the enhanced

protein traffic should also limit the biological effect of excessive tubular protein reabsorption and should slow renal disease progression. The best strategy to reduce protein traffic both in experimental animals and humans relies on ACE inhibitors effectively employed to slow the pace of progression of renal disease.[105,106] ACE inhibitor given to rats with a remnant kidney reduced urinary protein excretion and at the same time almost suppressed NF-kB DNA-binding activity and reduced MCP-1 mRNA expression and interstitial inflammatory cell infiltrates.[102] Similar effects were observed in the immune model of passive Heymann nephritis.[102] The decrease of NF-kB activation was associated with down-regulation of MCP-1 expression and reduction of interstitial inflammation.

In line with the possibility that NF-kB activation has a role in tubulointerstitial injury in proteinuric rats, there are data showing that in rats with adriamycin-induced nephropathy, chronic treatment with the putative NF-kB inhibitor pyrrolidine dithiocarbamate (PDTC), initiated at the time of overt proteinuria, suppressed cortical NF-kB activation and markedly reduced interstitial monocyte infiltration.[107] Chronic inhibition of NF-kB with PDTC also attenuated renal inflammation and injury in rats with 5/6 nephrectomy.[108] The mechanism by which PDTC inhibits NF-kB is unclear. It can directly impede the degradation of IkB or it may act through its antioxidant properties to inhibit the stimulatory effect of oxidative stress on NF-kB system. Although in the above models no major side effects were observed, studies on the clinical toxicity and safety of PDTC and other NF-kB inhibitors are needed before considering their potential use against renal disease progression. Systemic inhibition of NF-kB might have unwanted effects on the induction of genes critically regulating inflammatory and immunologic responses. Several conventional therapies in clinical use, including ACE inhibitors, AT1 receptor antagonists, glucocorticoids and hydroxymethyl glutaryl-CoA reductase inhibitors, are able to modulate NF-kB activation, but data on specific NF-kB inhibition in human disease are still lacking.[109]

To more specifically inhibit NF-kB activation, a recombinant adenovirus vector expressing the truncated form of IkBα that lacks the phosphorylation sites essential for the activation of NF-kB, was injected into renal arteries of rats with protein overload proteinuria.[110] This maneuver prevented NF-kB activation in tubular cells and attenuated the interstitial infiltration of mononuclear cells, interstitial edema, and fibrosis. These data suggest the possibility of using gene therapy targeting NF-kB as a means of interrupting the process of tubulointerstitial injury.

Specific blockade of the MCP-1/CCR2 signaling pathways attenuated interstitial nephritis induced by protein overload proteinuria. A hydrodynamic-based gene transfer technique was used to introduce naked plasmid encoding 7ND (a MCP-1 antagonist) into the left kidney of rats subsequently given repeated injections of bovine serum albumin.[111] Anti-MCP-1 gene therapy reduced interstitial inflammation and fibrosis and tubular damage, and limited the number of apoptotic cells in the treated kidney but not in the contralateral one. Finding that 7ND acted locally would envision a potential therapeutic application for this strategy against tubulointerstitial injury in the clinical setting.

Analysis of renal biopsy specimens from patients with severe proteinuria revealed NF-kB activation in tubular epithelial cells, which significantly correlated with the magnitude of proteinuria. There was a concomitant upregulation of proinflammatory chemokines, MCP-1, RANTES and osteopontin, found mainly in tubular epithelial cells, with the strongest expression in patients with progressive nephropathy.[109,112,113] NF-kB activation and MCP-1 upregulation in proximal tubular cells were also shown in patients with diabetic nephropathy.[114] A relationship between proteinuria and MCP-1 mediated interstitial damage was documented in a prospective study of patients who underwent renal biopsy for chronic kidney disease.[115] Furthermore, transcriptome analysis by complementary DNA microarray of renal proximal tubular epithelial cells isolated by laser capture microdissection from patients with proteinuric nephropathies revealed more than 160 differentially expressed genes, including those encoding for signal transduction, cell cycle control, intracellular transport and metabolism.[116]

Profibrogenic signal. Interstitial fibrosis represents the final common pathway of any form of progressive renal disease.[117] There is general consensus that fibroblasts within fibrotic tubulointerstitium proliferate[118,119] and that fibrosis-generating myofibroblasts – i.e, activated matrix secreting cells with features and gene patterns of smooth muscle cells – are an hallmark of the process.[119–121] In proteinuric settings, protein load and reabsorption by proximal tubular cells initiate or enhance fibrogenesis by at least two mechanisms. First, proximal tubular epithelial cells have the potential to interact directly with the adjacent interstitial fibroblasts via paracrine mechanisms. Indeed, proximal tubular cells by their ability to synthesize platelet derived growth factor (PDGF) and TGFβ1 stimulated renal cortical fibroblasts in coculture to grow and synthesize collagen.[122] On the other hand, the proinflammatory activation of tubular cells fosters local recruitment of macrophages and lymphocytes that by releasing TGFβ, PDGF and other cytokines[123] stimulate interstitial cells to produce excess matrix. That both the tubular paracrine

pathway and the inflammatory cell-mediated pathway are activated after the onset of proteinuria was suggested by findings that in remnant kidneys of rats, cells expressing the myofibroblast-associated marker α-smooth muscle actin (α-SMA) were first detectable in the interstitial areas and colocalized with macrophages surrounding proximal tubular cells that were engaged in excess protein reabsorption.[104] TGFβ mRNA was upregulated in proximal tubular cells in parallel with the nearby accumulation of inflammatory cells and α-SMA positive cells. Treatment of rats with remnant kidney with an ACE inhibitor limited excess protein accumulation and interstitial inflammatory cell infiltration and also abrogated abnormal TGFβ1 gene expression in tubular cells, and myofibroblast formation.[104]

In addition to the activation of interstitial cells, the fibrogenic reaction involved a phenotypic reversal of tubular epithelial cells termed as EMT.[119] The epithelial cells can be induced by several stimuli to become α-SMA expressing myofibroblasts. A huge number of studies have documented the abnormal expression of α-SMA and other myofibroblast markers in the renal tubule both in human and experimental nephropathies (for review, see [124]). Urinary proteins from nephrotic patients with focal segmental sclerosis, or to a lesser extent from patients with minimal change disease, induced cultured proximal tubular cells to express EMT-related patterns including α-SMA and vimentin via ERK1/2 and p38 pathway.[125] In remnant kidneys, α-SMA expression was also found in focal areas both in the context of the tubular epithelium and in peritubular microvascular cells with features of endothelium following the onset of proteinuria and TGFβ overexpression.[104] However, the primary source(s) of activated fibroblasts or myofibroblasts even in experimental settings are not clear.[119] Evidence was provided both for EMT in tubular epithelium[126,127] and endothelial-mesenchymal-transition.[128] Complete EMT appears difficult to detect as compared to intermediate phenotypic EMT stages.[119] Fate-tracing studies of epithelial cells in non-proteinuric mouse models failed to identify myofibroblasts originating from the epithelium.[129–131] A more predominant role is emerging for mesenchyme-derived stromal cells of the developing kidney that mature into perivascular pericytes in the adult kidney.[129]

TGFβ remains the most important cytokine for renal fibrogenesis. It has also been identified as the best characterized stimulus for EMT in renal tubular cells. Studies have focused on the signaling pathways which are activated during TGFβ-induced EMT. TGFβ caused Smad2 phosphorylation in a tubular epithelial cell line, and overexpression of the inhibitory Smad protein, Smad7, inhibited TGFβ − induced Smad2 activation, thereby preventing EMT and collagen synthesis.[132,133] An endogenous antagonist of TGFβ1−induced EMT has been identified as bone morphogenic protein-7 (BMP-7), a member of TGFβ superfamily whose genetic deletion in mice leads to severe impairment of kidney development.[134] BMP-7 reversed TGFβ1−induced EMT through a Smad-dependent reinduction of E-cadherin, an adhesive junction protein serving to maintain the structural integrity and polarity of epithelial cells.[135] Systemic administration of recombinant BMP-7 repaired severely damaged renal tubular epithelial cells and reversed renal injury in mice with nephrotoxic serum nephritis.[135] Investigation of a candidate mechanism downstream of BMP-7 suggested a role for *TRPS1* (whose mutations cause tricho-rhino-pharyngeal syndrome) acting as an essential regulator of nephron development.[136] Trps1 was found in proximal tubular epithelial cells of mice and its expression was reduced by ureteral obstruction. Trps haploinsufficiency promoted interstitial fibrosis via increased phosphorylation of Smad3 and decreased Smad7 protein. *In vitro* studies using proximal tubular cells suggested that the mechanisms underlying both TGFβ1−induced EMT and fibrosis were related to reduction of amount of Smad7 protein through ubiquitin-mediated degradation.[136] Other mediators that may critically contribute to fibrogenesis include PDGF[137] and endothelin-1[138] able to activate α-SMA gene expression in renal fibroblasts and vascular smooth muscle cells, respectively. IL18[139] and parathyroid hormone-related protein[140] were found to promote EMT *in vitro* and to contribute to interstitial fibrosis in murine models of ureteral obstruction.

Growth factors in the ultrafiltrate, such as hepatocyte growth factor (HGF) and TGFβ1 itself, may contribute to the induction of fibrosis *in vivo*.[141] In rats with glomerular proteinuria due to diabetic nephropathy, HGF and TGFβ were both detected in proximal tubular fluid and their receptors were upregulated in apical tubular membranes. In cultured proximal tubular cells, the exposure to ultrafiltrate rich in HGF and TGFβ induced the expression of fibronectin and PDGF as well as the basolateral secretion of MCP-1 and RANTES. The latter by interacting with macrophages in the renal interstitium caused them to secrete TGFβ which in turn, stimulated the expression of collagen type I and II, and fibronectin by interstitial myofibroblasts. Proximal tubular fluid from proteinuric, diabetic rats also increased the expression of connective tissue growth factor (CTGF) in tubular cells.[142] Interestingly, CTGF induces moderate pro-fibrogenic activity and raises the expression of fibronectin in proximal tubular cells as well as extracellular matrix proteins in renal fibroblasts.

Thus, a multitude of profibrotic cytokines are generated as a consequence of glomerular inflammation and are conveyed with proteins into the tubular urine to amplify interstitial injury. Evidence indicates that glomerular proinflammatory cytokines combined with massive proteinuria are major determinants of subsequent tubulo-interstitial injury and progressive kidney failure in experimental and human glomerulonephritis. An elegant experiment, however, yielded data to dissect the role of glomerular inflammation from that of protein toxicity. Besides closed nephrons the kidney of a primitive amphibium, the axolotl, contains nephrons with ciliated peritoneal funnels (nephrostomes) that have free access to the peritoneal fluid.[143] Injection of albumin into the peritoneal cavity caused selective uptake of proteins in tubular epithelial cells of nephrons with nephrostomes. As a consequence, protein and lipid droplets massively accumulated in the tubular cells. Furthermore, tubular lumen dilatation occurred and progressive focal accumulation of fibrous tissue was noted around protein-storing tubules, with the presence of fibronectin and TGFβ both in the tubular epithelial cells and in interstitial cells. Thus, protein loading *in vivo* directly induces tubulointerstitial activation and interstitial fibrosis, in the absence of glomerular inflammatory lesions. In this respect, myosin 1e (myo1e) knockout mice are a novel interesting model of glomerular disease, due to the disruption of a podocyte associated molecular motor protein that evolves to progressive tubulointerstitial injury.[144] Early ultrastructural glomerular changes consisting of increased thickness of glomerular basement membrane and effacement of podocyte foot processes were detected in 1−3 week old mice and were followed by albuminuria, formation of protein droplets, and accumulation of immunoglobulin and C3 in proximal tubular cells. Tubular changes were associated with excess deposition of collagen V and fibronectin in the periglomerular and peritubular interstitium, that could be related to proteinuria-associated signaling, in the absence of any evidence of immune or inflammatory glomerular disease.[144] Another report basing on an albumin-tracing analysis on serial sections of kidneys of OVE26 diabetic mice showed significant internephron heterogeneicity with sharp localization of albumin-staining to proximal tubuli showing various degrees of injury from minimal protein droplet formation to ultrastructural damage and dilatation. Similar findings were obtained in biopsy samples of proteinuric patients. The intensity of positive staining was dependent on the level of albuminuria and immunoglobulin and C3 stained in albumin positive tubules. Connections were visualized between albumin-leaking glomeruli and tubuli accumulating albumin, either prior to or in association with the onset of fibrosis. Collectively these findings favor the possibility that both progressive injury within individual nephrons and consequent scarring were directly related to worsening of proteinuria of glomerular origin.[145]

The Pathogenic Role of the Complement System in Renal Disease Progression

Intrarenal activation of complement. In physiologic states with an intact glomerular filtration barrier, the epithelial cells of the adult nephron are exposed to tightly regulated amounts of serum-derived complement proteins. C3 is an essential factor of both the classical and alternative pathways of complement activation that lead to the formation of C5b-9 membrane attack complex. Renal tubular epithelial cells appear most susceptible to effects of C5b-9 formation because of a relative lack of membrane-bound complement regulators such as membrane cofactor protein (CD46), decay-accelerating factor or CD55 and CD59 on apical surface.[146,147] *In vitro*, proximal tubular cells activated exogenous complement via alternative pathway leading to fixation of C5b-9 on cell surface[148] followed disruption of the network of actin stress fibers, and cytolysis. Increased production of superoxide anion, H_2O_2, and proinflammatory cytokines such as IL-6 and TNFβ was also observed.[149]

Deposition and intracellular accumulation of complement in proximal tubular cells was seen both in experimental models, such as protein overload proteinuria,[23] renal mass ablation[150,151] and aminonucleoside nephrosis,[152] and in patients with nonselective proteinuria. C5b-9 is a mediator of interstitial inflammation and fibrosis in experimental animals. Thus, in rats with severe nephrotic syndrome induced by aminonucleoside of puromycin the congenital absence of C6 markedly attenuated both complement dependent interstitial inflammation and renal dysfunction.[153] In C6-deficient rats with 5/6 nephrectomy a marked improvement of tubulointerstitial injury and function in respect with normocomplementemic rats was demonstrated.[154] Complement deposition greatly augments interstitial inflammation and fibrosis in the context of enhanced proximal tubular uptake of proteins. In the rat remnant kidney,[151] the intracellular C3 staining colocalized with IgG in proximal tubules in a stage closely preceding the appearance of inflammation. Protein accumulation in proximal tubular cells was followed by local recruitment of infiltrating mononuclear cells as well as by peritubular accumulation of myofibroblasts.[104] The amidation of C3 by ammonia in the presence of high protein catabolism was suggested to contribute to luminal formation of C5b-9[155] and generation of a monocyte-activating factor (amidated

C3).[150,156] Treatment with ACE inhibitor prevented proteinuria and, at the same time, limited both the tubular accumulation of C3 and IgG and interstitial inflammation.[151] The pivotal role of complement as a mediator of progressive tubulointerstitial damage seems to require an environment of protein-enriched ultrafiltrate. In the absence of proteinuria C5b-9 alone did not modify the evolution of tubulointerstitial disease[157] that showed similar degrees of severity among three distinct models of non-proteinuric disease regardless of whether the animals were from breeding pairs with normal complement activity or C6-deficiency.[157]

The presence of C3 in the tubular ultrafiltrate is recognized as a major promoter of injury in proteinuric nephropathies. C3 deficient mice were significantly protected against protein overload-induced renal injury.[158] This protective effect was explained by the absence of circulating C3, as indicated by kidney transplant studies showing that C3 deficient mice recipients of a wild-type kidney developed only mild proteinuria and tubulointerstitial injury upon protein load. Moreover, the treatment of wild-type mice with ACE inhibitor therapy in this model limited the amount of plasma proteins and C3 filtered, the accumulation of C3 by proximal tubular cells, and the degree of renal inflammation. The interaction between complement and other proteins in the ultrafiltrate and its functional consequences on tubular cells have been analyzed *in vitro* (Figure 87.4). Plasma protein overload of human proximal tubular cells (HK-2) renders the cells prone to activate complement. Addition of albumin or transferrin to HK-2 cells caused increased apical deposition of exogenous serum-derived C3, and, if added together, they additively increased fractalkine and TGFβ mRNA expression.[159] Enhanced C3 deposition was blocked by incubation with the wide-range inhibitor of complement activation, soluble complement receptor-1 (sCR1), but not by inhibitors of classic or lectin pathways, consistent with a disruptive interference by plasma proteins on the regulation of alternative pathway C3 convertase. The main regulator of this pathway is factor H, a 150-KDa soluble protein that binds to heparan sulfate on cell surface. The density of heparan sulfate was reduced by protein load via stimulation of heparanase synthesis, thereby reducing factor H binding and enhancing the serum-dependent complement activation potential of the cells.[159] The impact of factor H binding on renal tubule function is difficult to establish *in vivo*, particularly in human disease. Evidence in mice lacking other important complement regulators including either factor D or CD59 is in support of a role of alternative pathway in accelerating tubulointerstitial injury of adriamycin nephropathy.[160] Collectively these data provide links between proteinuria, uncontrolled activation of complement, and phenotypic changes of tubular cells that may underlie renal inflammatory cell infiltration and fibrosis.

Renal parenchymal tissues express a limited repertoire of receptors, including CR1, CR3, CD88, that may directly bind complement proteins present in the ultrafiltrate. The receptor for the complement anaphylotoxin C3a is highly expressed both by normal murine and human kidney epithelial cells. Among target genes, TGFβ[161] and collagen I[162] were upregulated by activated C3a, suggesting the induction of pathways underlying inflammation and fibrosis. In kidneys of proteinuric mice with adriamycin nephrosis a topographic relationship was found between the deposition of C3 and the enhanced expression of collagen type IV and its intracellular chaperone heat shock protein 47 at sites of tubulointerstitial damage.[163] The gene expression of collagen and heat shock protein 47 was also upregulated in primary cultures of mouse proximal tubular epithelial cells stimulated with C5b-9, further suggesting that complement activation on tubular cells can act directly to stimulate the profibrotic process associated with tubulointerstitial damage.[163] Other genes, such as pyrin (a gene responsible for familial Mediterranean fever) and Gulp were negatively regulated in tubular cells exposed to C3a, possibly reflecting modulatory effects on the inflammatory response and, respectively, on the clearance of apoptotic bodies.[162] Tubular epithelial cells exposed to either serum proteins or C3a also adopt phenotypic and functional characteristics of mesenchymal cells, with decreased expression of E-cadherin and increased expression of both α-SMA protein and collagen I mRNA.[164] These effects were prevented by cell treatment with a C3a receptor antagonist. Importantly, C3a receptor deficient mice were less susceptible to develop interstitial collagen I and α-SMA overexpression and kidney dysfunction, and to die, when subjected to adriamycin-induced proteinuria, in respect to wild-type mice.[164] A C5a receptor dependent, TGFβ1 mediated pathway has been shown to play major role in the pathogenesis of interstitial fibrosis induced in mice by unilateral ureteral ligation.[165]

Complement Activation and Proteinuria-Associated Progressive Glomerular Injury

Experimental models have been instrumental to identifying the role of complement in the progression of glomerular lesions in proteinuric disease. Abnormal fixation of C3 by immunohistology was detected in podocytes and glomerular epithelial cell areas in early stage of proteinuric disease in the remnant kidney in rats[25] and in the protein overload model in mice.[158] C3 colocalized with other plasma proteins that were filtered

as a consequence of their abnormal passage across the glomerular capillary wall. Podocytes showed signs of dedifferentiation and injury with loss of synaptopodin and *de novo* expression of desmin, followed by glomerular TGFβ overexpression and development of sclerotic lesions. The antiproteinuric treatment with ACE inhibitor mitigated all these changes.[25] Moreover, the exposure of cultured podocytes to protein overload also caused synaptopodin loss, actin rearrangement, and TGFβ overexpression. The conditioned medium of albumin-stimulated podocytes was able to induce a myofibroblast-like phenotypic change of cultured mesangial cells to express α-SMA. The role of C3 in the presence of other excess plasma proteins to enhance glomerular epithelial cell injury of proteinuric disease was further addressed directly in the protein overload model. C3 deficient mice were protected from podocyte injury and sclerosis, largely because of the lack of systemically-derived C3, as confirmed by transplantation experiments using wild-type donor kidneys.[158]

Other recent studies have consistently shown the importance of C3[160] and C3a[164] in the pathogenesis of glomerulosclerosis in experimental animals. The mechanisms by which complement can become activated and mediate the progression of glomerular injury in the above models are yet unknown. Because podocytes normally express complement inhibitory molecules such as complement receptor 1 or its mouse analogue factor H,[166] perturbed complement regulation can be pivotal. Indeed, the lack of either the alternative pathway regulator, factor D, or the membrane-bound regulator of membrane attack complex, CD59, was associated with worse glomerular injury in mice with adriamycin nephrosis,[160] whereas the lack of the alternative pathway factor B was associated with less severe albuminuria in the early stage of injury.[167] Future studies in this field will be important in view of potential therapeutic implications. Antibodies capable of blocking complement activation, including an anti-C5 antibody, are approved for use in humans. Given the role of permselective dysfunction in allowing both access of complement proteins to the glomerular and tubular ultrafiltrate and the activation of complement in the renal tubular and interstitial compartment, an antiproteinuric treatment might be most beneficial if combined with inhibitors of circulating and/or serum-derived complement. The consideration of alternative cellular sources of C3, such as the tubular cell itself, will be important for determining additional pharmacologic and molecular targets. Small molecule receptor inhibitors under development for human use may better block the actions of the C3a and C5a cleavage products and their unwanted consequences on the renal parenchyma.

Role of locally synthesized complement. In addition to activating exogenous complement, proximal tubular epithelial cells can synthesize a number of complement components including C3, C4, factor B, and C5.[168] The exposure of cultured tubular epithelial cells to total serum proteins at the apical surface upregulated C3 mRNA expression and protein biosynthesis.[169] The enhanced secretion of the protein was predominantly at the basolateral site. Serum fractionation experiments identified the substance(s) responsible for such effects in the molecular size range of 30 to 100 kD. This fraction contains proteins that pass across the glomerular barrier during proteinuric states, including albumin and transferrin. However, the addition of albumin alone did not reproduce the effects observed with whole serum, whereas after incubation with apical transferrin, C3 mRNA was overexpressed and both apical and basolateral C3 secretion increased.[170] A similar degree of C3 upregulation was obtained using iron-poor transferrin, or apotransferrin as stimuli, indicating that the synthesis of C3 in proximal tubular cells is upregulated by the protein rather than the iron moiety accounting for observed effects. Despite the documented role of C3 of non-renal cell origin as demonstrated in mice with protein overload proteinuria, the additional finding of marked C3 mRNA upregulation in tubular cells in the same model would reflect the functional engagement of C3 synthesis also contributing to tubulointerstitial injury.[158] Studies in nonproteinuric settings of ischemia-reperfusion or allograft injury strongly support this possibility. In this respect, complement activation may directly regulate the immunologic response. Of important note, the local synthesis of C3 may stimulate transmigration of T cells across tubular epithelial cells.[171] This pathway involves direct action of tissue C3 with infiltrating T cells expressing C3 receptors and is a candidate target of lymphocyte inhibitory agents, such as mofetil mycophenolate, shown to be effective if combined with antiproteinuric therapy against primary non-immune disease characterized by tubular deposition of complement.[151,172] Intrarenal effects of local complement activation have been recently reviewed.[173] Whether similar mechanisms may be recruited within glomeruli is not known. Incidentally, cyclosporine A, another immunosuppressant drug, showed the peculiar action of blocking calcineurin-mediated dephosphorylation of synaptopodin to preserve podocyte function, possibly accounting for its ability to induce remission of proteinuria in patients with proteinuric glomerulopathies.[174] Novel drugs more safely combining antiproteinuric and lymphocyte inhibitory actions might represent a valid tool to simultaneously protect both the glomerular epithelium and the tubular interstitial compartment from the deleterious effects of both plasma protein/C3 load and local activation of complement in the long-term.

Proteinuria Triggers Immune Response

The accumulation of immune-competent cells such as T lymphocytes and dendritic cells (DC) in the renal parenchyma is a common finding of proteinuric nephropathies even in the absence of an immune insult.[172,175] As antigen presenting cells, DC can initiate immune response or tolerance. The outcome depends on context. The current view is that immunity is controlled by internal communication between the tissue, where DC are resident, and the immune-competent cells, so that tolerance is maintained by the healthy organ, whereas immunity can be stimulated by a distressed organ.[176] In proteinuric nephropathies abnormal filtration of proteins that causes distress of renal proximal tubular cells ensues an inflammatory environment that might enable DC, in close contact with the tubular epithelium, to become immunogenic towards normally ignored self-antigens. It has been documented that through the concerted action of renal proximal tubular cells and DC, albumin is processed into antigenic peptides, thus triggering an immune response[177] (Figure 87.5). Proteolysis of excess autologous albumin by proximal tubular cells *in vitro* generated N terminal fragments, the most abundant being albumin 1 to 24 aminoacids (Alb1-24). This peptide was then taken up by DC and further processed, by a proteasome-dependent pathway, into antigenic peptides that bore binding motifs for MHC class I and activated syngeneic $CD8^+$ T cells. Studies in a rat model of proteinuria secondary to renal mass reduction confirmed the functional role of Alb1-24 processing by renal DC in inducing immune response. Dendritic cells were found to accumulate in the renal parenchyma of proteinuric rats one week after surgery. At four weeks a decrease in the percentage of DC in the kidney was paralleled by an enhancement of these cells in the renal draining lymph nodes, suggesting migration of DC from the renal interstitium. The $CD8^+$ T cells isolated from renal lymph nodes from renal mass reduction rats were already activated at the first encounter, when incubated with Alb1-24-pulsed DC, suggesting that they were pre-sensitized to the albumin peptide *in vivo* during the course of the disease. By contrast, the *in vivo* treatment with the proteasome inhibitor bortezomib, that prevents the formation of peptides for recognition by $CD8^+$ T cells, made these cells resistant to activation by Alb1-24-pulsed DC either in a primary or secondary culture. These findings provide a link among proteinuria, autoimmunity, and renal disease progression.[177]

Role of Protein-Bound Lipids

Beside proteins themselves, fatty acids carried by filtered albumin have been advocated as trigger of

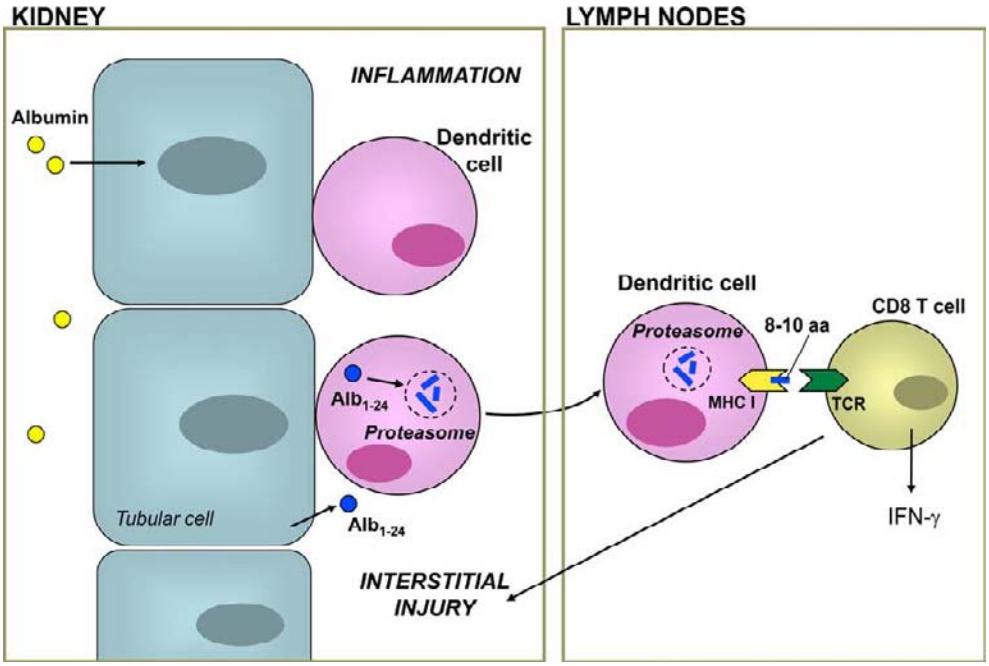

FIGURE 87.5 Proteasomal processing of albumin fragment by renal dendritic cells generates antigenic peptides. The inflammatory environment caused by distressed renal tubuli exposed to protein load favors dendritic cell (DC) accumulation and activation in the peritubular interstitium. Albumin is cleaved by proximal tubular cells into Alb1-24 that is taken up by DC and processed into 8 to 10 aminoacid peptides with a size compatible with MHC-I binding. DC migrate to the renal lymph node and present antigenic peptides within MHC-I to naive $CD8^+$ T cells leading to their activation. Activated T cells then reenter the kidney where they propagate renal damage (Ref. 177).

tubulointerstitial injury. In rats with overload proteinuria a potent chemotactic lipid was isolated from the urine, which attracted monocytes but not neutrophils.[178] Consistently, incubation of isolated proximal tubuli with albumin caused the release of a lipid factor chromatographically indistinguishable from that isolated from proteinuric urine.[179] This inflammatory lipid was not released after exposure of proximal tubuli to delipidated albumin, indicating that the synthesis of chemoattractant lipid is a consequence of tubular metabolism of fatty acid-bearing albumin. Rats injected with fatty acid-carrying BSA developed macrophage infiltration and apoptosis to a greater extent than those receiving fatty acid-depleted albumin.[180] Similar results were obtained in mice transgenic for human liver-type fatty acid binding protein, that in human proximal tubular cells was shown to bind free fatty acids in the cytoplasm and to carry them to mitochondria or peroxisomes for metabolism by beta-oxidation.[181] These mice developed less macrophage infiltration and a tendency to reduced tubulointerstitial damage than the wild-type control, possibly suggesting that intracellular accumulation of overloaded free-fatty acids can be regulated so as to modulate cell activation.

Studies in cultured proximal tubular cells have contributed to differentiate the effects of individual fatty acids (palmitate, stearate, oleate, and linoleate) on cell toxicity and fibronectin production. Oleate and linoleate were identified as the most profibrogenic and tubulotoxic fatty acids.[182]

By comparing effects of BSA alone or loaded with oleic acid, it has been shown that fatty acids accentuated albumin-induced oxidative stress and inflammatory cytokine expression in proximal tubular cells by increasing mitochondrial ROS and impairing protective antioxidant responses.[183] In human proximal tubular cells albumin repleted with fatty acids (rBSA) and defatted albumin complexed with linoleic acid (LA/dBSA) induced more apoptosis than defatted albumin alone.[184] Interestingly, fatty acid-bound BSA increased the number of lipid droplets (LDs)-organelles that store esterified fatty acids and the LD-associated proteins adipocyte differentiation-related protein and TIP47, that favor LD formation. Knockdown of adipocyte differentiation-related protein or TIP47 by RNA interference enhanced the induction of apoptosis by both rBSA and LA/dBSA, leading to suggestions that LDs and LD-associated proteins could protect tubular cells from fatty acid-induced apoptosis by sequestering free fatty acids.[184]

An additional pathogenic pathway has been linked to a form of low density lipoprotein modified by hypochlorous acid (HOCL), found to accumulate in tubular epithelial cells in settings of injury.[185] Hypochlorous acid/hypochlorite is a major oxidant generated from H_2O_2 by myeloperoxidase during oxydative burst. In the HK-2 proximal tubular cell line, hypochlorite-modified low density lipoprotein caused a rapid increase in the expression of several genes encoding for proteins engaged in control of cell proliferation and apoptosis (Gadd153), ROS metabolism (HO-1, cytochrome b5 reductase), tissue remodeling and inflammation (CTGF, VCAM1, IL-1β, MMP7, VEGF).[185]

SUMMARY

Experimental studies have established that a loss of selectivity of the glomerular filtration barrier causes excess transglomerular and tubular passage of plasma proteins which are potentially toxic to renal epithelial cells. This knowledge was derived by studies of models of progressive kidney disease including protein overload proteinuria, immune-mediated PHN and renal mass reduction in rats that leads to increased glomerular capillary hydraulic pressure and perfusion pressure resulting in capillary stretching and enhanced passage of proteins in the urine. Protein overload and reabsorption by proximal tubular cells can activate intracellular signaling pathways underlying the release of mediators into the interstitium. Chemokines attract mononuclear cells which together with activated tubular epithelial cells initiate fibrosis via TGFβ/growth factor mediated proliferation of fibroblasts and deposition of excess extracellular matrix. Complement activation is a stimulus for inflammation and fibrosis in experimental models of proteinuric nephropathies. Proteinuria acts both as a source of filtered complement and as a likely permissive factor by favoring both local synthesis and uncontrolled activation of complement via alternative pathway. A mechanism of interstitial injury in proteinuric diseases is mediated by immune cell activation through the interaction of renal proximal tubular cells and dendritic cells processing albumin into antigenic peptides. The glomerular epithelium is an important target of toxicity by filtered proteins and complement possibly fueling a vicious cycle of abnormal permeability, capillary injury, adhesion of tuft to Bowman's capsule, and sclerosis. ACE inhibitors/angiotensin II receptor blocking agents exert beneficial effects acting upstream at glomerular level to ameliorate the integrity of the glomerular barrier. A large body of clinical data is available from the past two decades to support the concept that proteinuria is both a marker of renal disease and a risk factor for human renal disease progression.[186–189] Clinical trials have suggested a tight link between the specific antiproteinuric action of ACE inhibitors/angiotensin II receptor blocking agents and their superior ability to limit GFR decline as compared to other

antihypertensive drugs, despite similar effect on blood pressure.[190] Therapeutic approaches have been devised on top of angiotensin II blockers based on experimental data demonstrating that combinations of therapies targeted to reduce proteinuria may retard renal disease progression more efficiently than single drugs.[191] Thus, the "Remission Clinic Program" uses all available pharmacological tools and lifestyle rules to reduce urinary proteins in patients with chronic kidney disease and heavy proteinuria despite ACE inhibitor therapy.[192] Advances in these areas will hopefully improve current protocols to prevent both proteinuria and its consequences on the renal parenchyma and kidney dysfunction in the long term.

CHAPTER

88

The Inflammatory Response to Ischemic Acute Renal Injury

Christopher Y. Lu

Division of Nephrology, Department of Internal Medicine, University of Texas, Southwestern Medical Center, Dallas, Texas, USA

INTRODUCTION

Acute ischemia reperfusion injury (IRI) is a major cause of acute kidney injury (AKI).[1] A major conceptual insight is that the total amount of renal injury is the result of not only the initial ischemic insult, by the ensuing responses. This simple insight has profound clinical implications: it suggests that therapy after the initial insult has already occurred may ameliorate the course of AKI (see Figure 88.1). Some of these responses are maladaptive. Examples include inappropriate intrarenal hemodynamics, altered mitochondrial and other metabolic functions,[2–4] endothelial dysfunction,[5,6] and tubular obstruction and back-leak.[7] Other responses are reparative. Examples include the production of growth factors such as Wnt7.[8]

In addition to the above, IRI elicits an inflammatory response. Some components of this inflammatory response exacerbate injury, other components mediate repair. In either case, inflammation is a major determinant of the ultimate outcome of ischemic AKI. A complete understanding of the inflammatory response to IRI—the composition and functions of the leukocytes, the stimuli that elicit inflammation, and the regulation of inflammation—remain a fundamental unsolved problem in renal disease. The goal of this chapter to provide a perspective on our rapidly growing insights into the inflammatory response to IRI.

In addition to its importance for injury of the native kidney, the inflammatory response to IRI is important for transplantation. Ischemic injury to the allograft inevitably accompanies organ harvesting, the cold storage, and the warm ischemia during the surgical creation of the vascular anastomoses between allograft and recipient. In addition, for brain dead donors, the donor kidneys are damaged by the hemodynamic instability resulting from the trauma that causes brain death. The leukocytes recruited to the allograft by ischemia exacerbate rejection. This is predicted by the "danger" theory of immunology where injury elicits inflammation, the leukocytes detect non-self at the site of injury (infectious pathogens or the allograft), and then develop an immune response against the non-self.[9–13] The relation of this "injury response" to rejection has previously been reviewed.[14–23]

An inflammatory response is also elicited by chronic injuries in common human diseases such as progressive renal failure from diabetes and hypertension.[24–26] Understanding the inflammatory response to the "single hit" model of acute ischemia may aid our understanding of the more complicated chronic diseases. The goal of this chapter is to review our current understanding of this rapidly evolving field. Although complement and gene activation by hypoxia/reactive oxygen species are important, our focus will be on the nature of the inflammation and its regulation by injured and dying cells.

Most studies of the inflammatory response to renal ischemia have involved rodents. The potential difficulties in extrapolating such studies to the clinical setting have been discussed previously.[27–29] Although inflammation is not a prominent feature of human ischemic acute renal failure, leukocytes are present.[30] The susceptibility of patients to acute renal failure may correlate with polymorphisms of pro- and anti-inflammatory genes;[31] and this further supports a role of inflammation in the pathogenesis of human disease. Biopsy studies during ischemic acute renal failure of native human kidneys are limited, but post-anastomosis

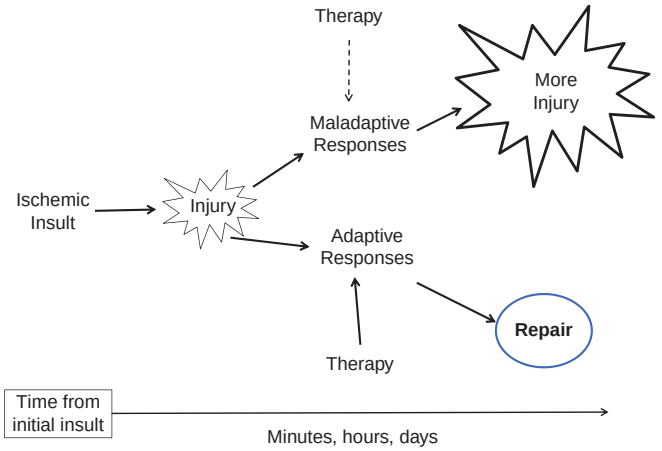

FIGURE 88.1 Injury after ischemic AKI is the sum result of the initial insult, subsequent maladaptive, and adaptive responses. Original figure.

biopsies of renal allografts are increasingly common. Most such biopsies indicate inflammation, particularly in deceased, compared to living, donors.[32–36] Furthermore, intraoperative biopsies have also indicated expression of pro-inflammatory genes.[37–40] Such inflammation may be a response to ischemic injury to the allograft due to the hypotension associated with the trauma that caused brain death, due to the cold storage, and due to the warm ischemia during creation of the vascular anastomoses. In addition, inflammation in the cadaver kidneys was also caused by neurohormonal effects of brain death.[41] Inflammation during these intraoperative biopsies are not due to rejection because there is no time for immune recognition of the transplant. Furthermore, biopsies of kidneys between identical twins, where there is no allo-recognition, also shows inflammation that must be due to ischemic injury occurring during the transplant process.[42]

Some argued that injury and damage to kidney is not the major contributor to most cases of human ischemic AKI.[43] Instead the major factor is abnormal renal microvascular function and use of oxygen.[2] Indeed, in those rare cases where the kidney is biopsied, the morphologic injury by conventional staining techniques are minimal. However, the longterm maladaptive effects of ischemic AKI suggests that injury does occur and the kidney never completely recovers from this injury. Indeed, recurrent episodes of ischemic AKI may be a major contributor to the current epidemic of CKD.[44,45]

The medullary thick ascending limb and the S3 straight proximal tubule in the outer medulla are the tubules most vulnerable to ischemic injury in both rodents and humans.[29,46–50] This is the area with the greatest inflammation.[51,52] Although the outer medulla is the injured earliest and after the least ischemia, longer periods of ischemia result in the injury of the cortex also.[43] Because different structures in the kidney may be injured depending on the intensity of ischemia, and because these structures produce different cytokines, chemokines, and other regulatory molecules in response to IRI, renal IRI may be a family of diseases rather than a single entity. Thus, the length of ischemia time, or the temporature of ischemia may modify the inflammatory response to IRI.[53]

The inflammatory response to acute ischemia of the heart, and brain have been more intensively studied than ischemic acute renal failure because of the greater clinical incidence of coronary artery disease and stroke. Where renal studies are not available, we will review studies from these and other non-renal organs. Although the general principles may be the same in these various organs, the particular mechanisms of the inflammatory response to ischemic injury may be different in different organs. For example, blocking the pro-inflammatory cytokine interleukin 1α and β ameliorates ischemic injury of the rodent brain[54] and heart,[55] but has no effect on ischemic acute renal failure.[56]

LEUKOCYTES IN INJURED, ISCHEMIC TISSUES: FRIEND, AND FOE.

Over a decade ago, anti-inflammatory agents were shown to ameliorate ischemic acute renal failure.[57,58] These studies demonstrated the maladaptive effects of the inflammatory response to injury. Recent studies elucidate greater detail about which leukocytes are involved and how they regulate renal IRI.

Mononuclear phagocytes—monocytes, macrophages and dendritic cells: The relationship of the various members of the mononuclear phagocyte family—monoctye, macrophages, and dendritics, and there various subsets—is complex.[59–63] Various mononuclear phagocytes participate in ischemic AKI. Some exacerbate injury. Others facilitate repair.

These leukocytes exacerbate the early phases of ischemic injury.[52,64,65] Macrophages appear within hours after ischemic injury in both mice and rats; these macrophages are located adjacent to the vasa rectae of the outer medulla.[52,66] This is the region of the rodent kidney that is most vulnerable to ischemic injury,[29,67,68] and where there is endothelial injury[69] and expression of both B7 and adhesion molecules.[51,52]

Elimination of this early macrophage infiltrate prevented the increased interleukin 6[64,70] that occurs after renal ischemia.[71,72] The former exacerbate ischemic renal injury because its elimination by transgenic knockout, or anti-interleukin-6 antibodies[66,73] ameliorates renal injury. *In situ* hybridization shows that interleukin 6 is produced by macrophages in the

ischemic kidneys; the construction of bone marrow chimeras where renal parenchymal cells or macrophages have their IL6 gene knocked out showed that the greatest injury occurred when macrophages were capable of making interleukin 6.[66] Macrophages are also capable of producing a number of other molecules that might exacerbate ischemic acute renal failure. However, as discussed below, what cytokines are produced by which renal cells, and which cytokines have harmful versus helpful effects remain to be clearly delineated.

In these studies, there was an early infiltration of macrophages in the absence of neutrophils. This sequence of macrophages then neutrophils contradicts the classical paradigm which proposes that neutrophils infiltrate first, and produce molecules that recruit monocytes subsequently.[74] However, recent data indicate that monocytes can infiltrate tissues early and, in some cases, in the absence of neutrophils.[75] In the lung[76,77] and liver,[78] macrophage inflammation may precede neutrophilic inflammation. This may also occur in ischemic acute renal failure. Furthermore, the nature of renal cell death during ischemic AKI may regulate the type of inflammation. Apoptosis generally recruit macrophages, but necrosis recruits neutrophils. We discuss the various types of cell death and their effects in inflammation later in this chapter.

In addition to this early infiltrate, there is also a late infiltrate of macrophages and related dendritic cells during the first weeks after acute ischemic injury.[79–82] Large numbers of these leukocytes are still present after the recovery of glomerular filtration has already occurred. The contribution of these leukocytes to renal injury and repair is not known. On the one hand, they may contribute to chronic injury. On the other hand, some macrophage subpopulations participate in tissue repair, perhaps through the secretion of growth factors such as Wnt7b or anti-inflammatory cytokines such as interleukin 10.[8,83–92] These macrophages have many attributes of "M2" macrophages present late after infections.[93]

Macrophage infiltration into the outer medulla is regulated by endothelia. Endothelia are the border between the vasculature and the renal interstitium. Thus, the quantity and composition of leukocyte traffic from blood into the renal interstitial spaces is regulated by proinflammatory genes expressed by endothelia.[94–97] Ischemic endothelia in the outer medulla do increase their expression of pro-inflammatory ICAM-1 (CD54) and B7. 1 (CD80).[51,52,98,99] In addition, endothelial expression of P-selectin (CD62P) and VCAM-1 (CD106) also contribute to the inflammatory response to renal ischemia,[100–103] but the precise anatomical location is not known. Inactivation of ICAM-1 and selectins via antibodies, antisense oligonucleotides, or transgenic knockout ameliorates inflammation and injury after acute ischemia.[98,103–107]

Furthermore, macrophage infiltration into the ischemic kidney is regulated by MCP 1, a chemokine that attracts macrophages are expressed by the ischemic kidneys.[108] Transgenic knockout of the receptor for MCP 1 (CCR2)[109] or administration of a truncated, inhibitory form of MCP 1[110] both ameliorate ischemic injury and inflammation.

In addition, macrophages may be recruited by molecules released by necrotic or apoptotic cells. This will be discussed in later sections of this chapter. Finally, blocking B7 on ischemic endothelia decreases macrophage infiltration and ischemic renal injury.[111,112] CD28, the ligand for B7, is not known to be expressed by macrophages, but is expressed by T cells. This suggests a role for T cells in ischemic acute renal failure (see below).

Neutrophils: In contrast to the early infiltration of macrophages, some studies report that there is a later infiltrate of neutrophils.[100,113] The role of these neutrophils is not clear. Early reports[98,114] suggested that elimination of these neutrophils with antibodies ameliorated ischemic injury. But this may have reflected the use of polyclonal antibodies that actually recognized both neutrophils and macrophages.[115] Recent data using monoclonal antibodies for neutrophils are controversial. Some,[116] but not others,[117,118] find that deleting neutrophils ameliorated ischemic injury. One difficulty in these studies is the use of the monoclonal antibody for Ly6C/G (Gr1). Although Ly6C/G is highly expressed on neutrophils, it is also expressed, albeit weakly, on some subsets of monocyte/ macrophages.[119]

Renal parenchymal cells produce the neutrophil chemokines KC and MIP 2,[108,116] the murine analogs for human interleukin 8, as well G-CSF that would stimulate neutrophil production by the bone marrow.[113] In one study, antibody to the neutrophil chemokines KC and MIP 2[116] decreased neutrophilic infiltration and also ameliorated ischemic injury. However, antibody to the receptor for these chemokines CXCR2 unexpectedly exacerbated injury.[120] These results need to be reconciled. One possibility is that these chemokines have both maladaptive and adaptive functions; in addition to regulating neutrophilic inflammation, KC and MIP 2 may also regulate the differentiation of renal tubular cells during the repair process after injury.[121,122]

Those advocating a role for neutrophils point out that, in addition to releasing toxic molecules that might injure the kidney, neutrophils are now known to produce cytokines, chemokines, and other regulatory molecules.[123] By producing these molecules, neutrophils may regulate any subsequent inflammation and repair.[124] Those, who find no role for neutrophils in renal injury, might argue that the presence of neutrophils in tissue does not necessary indicate that these

neutrophils are activated. Thus, ectopic gene expression of the neutrophil chemokine KC results in a neutrophilic infiltrate but no tissue damage, presumably because the neutrophils are not activated to produce toxic molecules.[125] This neutrophil infiltration may be regulated by NK T cells.[126,127]

Lymphocytes: Small numbers of T cells are found in kidneys after renal ischemia.[52,128] The role of these T cells is not understood. On the one hand, elimination of T cells via the foxn1 mutation (nude mice) ameliorated injury. FTY720, an immunosuppressive drug that traps lymphocytes in lymph nodes, inhibits ischemic acute renal injury.[129] But, on the other hand, elimination of all classical T cells via mutation of the TCRα chain[128] or via mutation of the rag gene (scid mice)[130] did not inhibit. There is further controversy when elimination of specific subsets of T cells was examined. On the one hand, eliminating CD4 T cells with monoclonal antibodies[128,131] did not ameliorate injury, but elimination with transgenic knockout[101] did. Similar controversy surrounds the role of CD8 T cells. On the one hand, transgenic knockout of CD8 did not ameliorate ischemic injury;[101] however, anti-CD8 antibodies used in combination with anti-CD4 antibodies did.[131] B-lymphocytes may also contribute to ischemic AKI.[132] This is discussed further in the section on complement and "natural" antibodies.

The role of lymphocytes in ischemic injury is further complicated by observations suggesting that T cells ameliorate injury in some models. These studies fall into three groups: those involving CD4 T cells, those involving interferon gamma, and those involving "unconventional" $\gamma\delta$ T cells.

Some CD4 T cells may ameliorate injury. CD4 knockout results in decreased HGF production and increased tubular apoptosis after ureteral obstruction.[133,134] Nude mice with no classical T cells have increased injury after optic nerve injury, and injection of such T cells improves repair.[135] CD4 T cells play a dual role of exacerbating and inhibiting inflammation after ischemic hepatic injury.[136]

Interferon gamma may play a dual function. Interferon gamma is a cytokine associated with ischemic injury, and produced in quantity by T cells. Interferon gamma exacerbates ischemic acute renal failure in some models.[101,137] However, there are interferon gamma dependent pathways of tissue repair.[138,139] Whether or not there are such pathways in the kidney is not known.

Recent data suggest that unconventional T cells recognize injured tissues. Thus, some T cells with $\gamma\delta$ T cell receptors recognized stressed epithelia and release keratinocyte growth factors that facilitate repair.[140] Whether or not such T cells are present in the ischemic kidney is not known. NK T cells also participate in ischemic AKI[126,127] and some NKT cell regulate inflammation during AKI.[141–143]

THE PROINFLAMMATORY EFFECTS OF INJURY—DAMPS, STERILE INFLAMMATION, AND THE "DANGER/ DAMAGE" HYPOTHESIS

Although the above shows that the inflammatory response to ischemia may an important determinant of the extent of injury and repair, how ischemic injury is translated into inflammation is a major outstanding question. Approaches to addressing this question are reviewed in the remainder of this chapter. Several concepts and terms need to be defined before beginning our discussion. A major recent concept is that injury itself is proinflammatory. The proinflammatory signals are generated in several ways. Molecules, normally residing within cells, elicit inflammation when they are released into the extracellular space or are expressed on cell surfaces. In addition, enzymes released by injured cells or leukocytes convert extracellular matrix molecules into proinflammatory signals. Finally, intracellular stress may generate proinflammatory signals. Altogether these proinflammatory molecules have been called "danger (or damage)-associated molecular pattern" molecules (DAMPS) or Alarmins. This inflammatory response to injury has been called the "danger" response or "sterile" inflammation to differentiate it from the inflammatory response to infections.[144–150]

The biology of DAMPS, their receptors, and their regulation of injury, of the inflammatory response to injury, and of repair remain to be completely elucidated. The biology is complex because the receptors are promiscuous and interact with numerous DAMPS, because each DAMP interacts with multiple receptors, because DAMPS interact with each other, and because the cellular response to a DAMP is unique to the cell and its microenvironment. We review our current understanding of this rapidly evolving field with the humble realization that this understanding will certainly change in the future.

TLR4 AND HMGB1

During ischemic AKI, the best characterized receptor for DAMPS is TLR4. TLR4 is best known as the receptor for endotoxin produced by gram negative bacteria, and mediates the inflammatory response against these bacteria.[151,152] It is one member of a family of "pattern recognition receptors" that recognize molecules produced by pathogens. In addition to endotoxin, these molecules include viral DNA, viral RNA, and sugar molecules

unique to yeast. The TLR's are present on most leukocytes of the "innate" immune response—macrophages and neutrophils.[153–155] They are critical for the immediate inflammatory response against infections.[13]

A major discovery was the insight that TLR4 not only recognizes endotoxin, but also recognizes DAMPS.[148,156–163] These molecules are called "endogenous" because they are produced by mammalian cells and to differentiate them from endotoxin, the "exogenous" TLR4 ligand that is produced by gram negative bacteria.

Striking confirmation for the importance of TLR4 in ischemic disease were experiments comparing inflammation and injury in wildtype mice versus TLR4 deficient mutant mice after ischemia to the heart,[164,165] liver,[166–168] lung,[169] and kidney.[170–175] In all of these studies, mutant mice with non-functional TLR4 are protected from ischemic injury. Furthermore, human mutations that inactivate TLR4 ameliorate post-transplant ischemic AKI.[173]

HMGB1 is released from injured cells and is the best documented DAMP ligand for TLR4 during ischemic AKI. The HMGB1-TLR4 interaction is one of the few DAMP-TLR4 interactions that have been confirmed by biophysical studies.[176] Furthermore, HMGB1 has a proven role in ischemic AKI. Its expression increases in both murine ischemic AKI,[170,177] and biopsies of human renal transplant grafts that had ischemic AKI during the transplant process.[173] Antibodies that inactivate HMGB1 ameliorate murine ischemic AKI.[177,178] Altogether this data show HMGB1 has maladaptive functions during ischemic AKI.

Within four hours reperfusion, reactive oxygen species produced during ischemia reperfusion[179–181] increase endothelial expression of TLR4. HMGB1 released from injured renal tubulesbind the endothelial TLR4, and cause increased adhesion molecule expression.[150] These adhesion molecules facilitate the immigration of leukocytes into the injured outer medulla.[98,104,182–184] HMGB1 binds to TLR4 on these leukocytes, including macrophages, and stimulates the production of maladaptive interleukin 6.[174] In addition, the HMGB1 also stimulates TLR4 on tubules and stimulates the production of maladaptive chemokines and cytokines.[178] See review[185] and Figure 88.2.

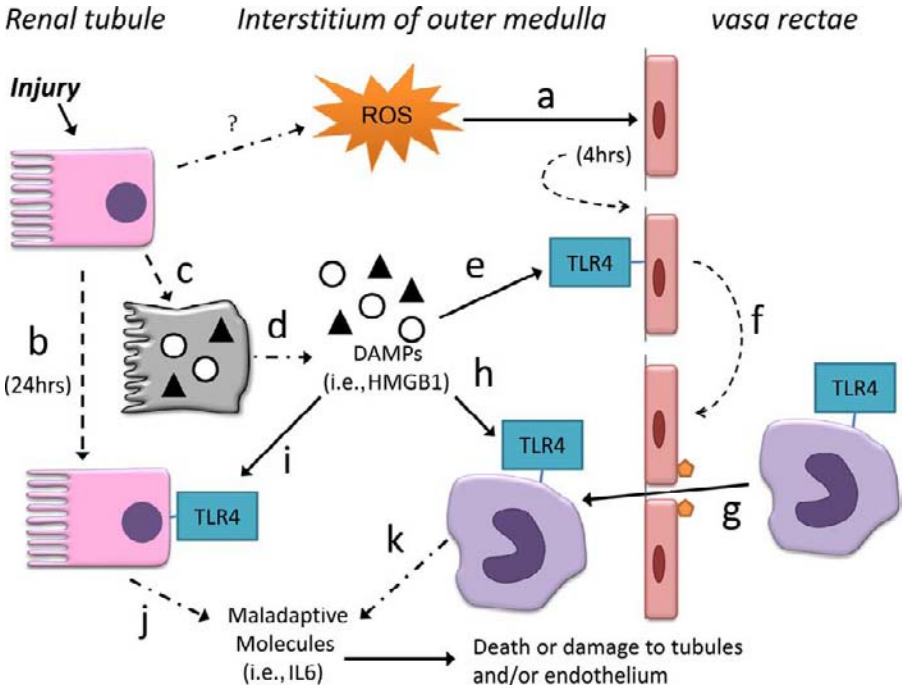

FIGURE 88.2 The structure of HMGB1. TLR4-HMGB1 in Ischemic AKI. In response to reactive oxygen species (ROS) released during ischemia/ reperfusion, endothelia of the vasa rectae express TLR4 within four hours after reperfusion (a). Renal tubules also express TLR4, but only after 24 hours following reperfusion; renal tubular TLR4 expression is a response to interferon gamma and TNFα (b). Injury also increases renal tubular production of endogenous TLR4 ligands such as HMGB1 (b), and severely injured cells release these ligands into the extracellular space (d). These extracellular TLR4-ligands trigger maladaptive responses. They activate TLR4 on endothelial cells (e) which in turn, express adhesion molecules (f) that facilitate diapedesis of monocytes (macrophages) from blood into the renal interstitial space (g). The endogenous TLR4-ligands (HMGB1) then activate TLR4 on macrophages (h), and tubules (i). The activated macrophages and tubules release maladaptive molecules such as interleukin 6 (j & k) that exacerbate injury. From Lu CY, Winterberg PD, Chen J, Hartono JR. Acute kidney injury: a conspiracy of toll-like receptor 4 on endothelia, leukocytes, and tubules. *Pediatr Nephrol 2011*. http://www.ncbi.nlm.nih.gov/pubmed/22033798.

The Complex Biology of HMGB1 and TLR4—Promiscous Molecules with Promiscous Partners and Multiple Biologic Effects

Although the HMGB1−TLR4 interaction in ischemic AKI is well documented in the above experiments, much remains to be learned.

The biology of HMGB1 is complex. HMGB1 is expressed by all eukaryotic cells and is highly conserved through evolution. It was originally described as a nuclear protein that enables interactions between DNA and nuclear proteins that regulate transcription. However, in the late 1990's a search for mediators of shock revealed that HMGB1 elicited lethal inflammation.[186] Antibodies against HMGB1 prevented shock. Subsequent experiments showed that HMGB1 was released by necrotic cells, and actively secreted by leukocytes of the innate immune response. The little inflammation seen after apoptosis, as opposed to necrosis, may result from sequestration of HMGB1 within the nucleus of apoptotic cells. The various protein domains HMGB1 have unique functions as shown in Figure 88.3. The A and B boxes bind to DNA, and the C box is negatively charged. The proinflammatory effect of HMGB1 may be reproduced by recombinant B box. Recombinant A box peptide is a specific antagonist of the proinflammatory effects. Thus, there is therapeutic potential in using these genetically engineered peptides to either increase or decrease inflammation.[187]

HMGB1 is post-translationally modified both enzymatically and by reactive oxygen species. It also binds endotoxin and nucleic acids. These may change its biological activity.[187−189]

HMGB1 has seven known receptors in addition to TLR4.[176] In addition to TLR4, only one other receptor, RAGE,[190,191] has been studied in ischemic AKI. RAGE is thought not to participate in ischemic AKI in mice because its transgenic knockout does not affect disease.[192]

The biology of TLR4 is also complex. In addition to HMGB1 it binds to other DAMPS. These include oxidation products resulting from reactive oxygen species produced during ischemia reperfusion,[193,194] extracellular matrix components and heat shock proteins as discussed below.

After tissue injury, the extracellular matrix is degraded into low molecular weight fragments. Two of these fragments, heparan sulfate and hyaluronan, activate TLR4,[162,163,195,196] and may participate in ischemic AKI. Low molecular weight heparan sulfates are

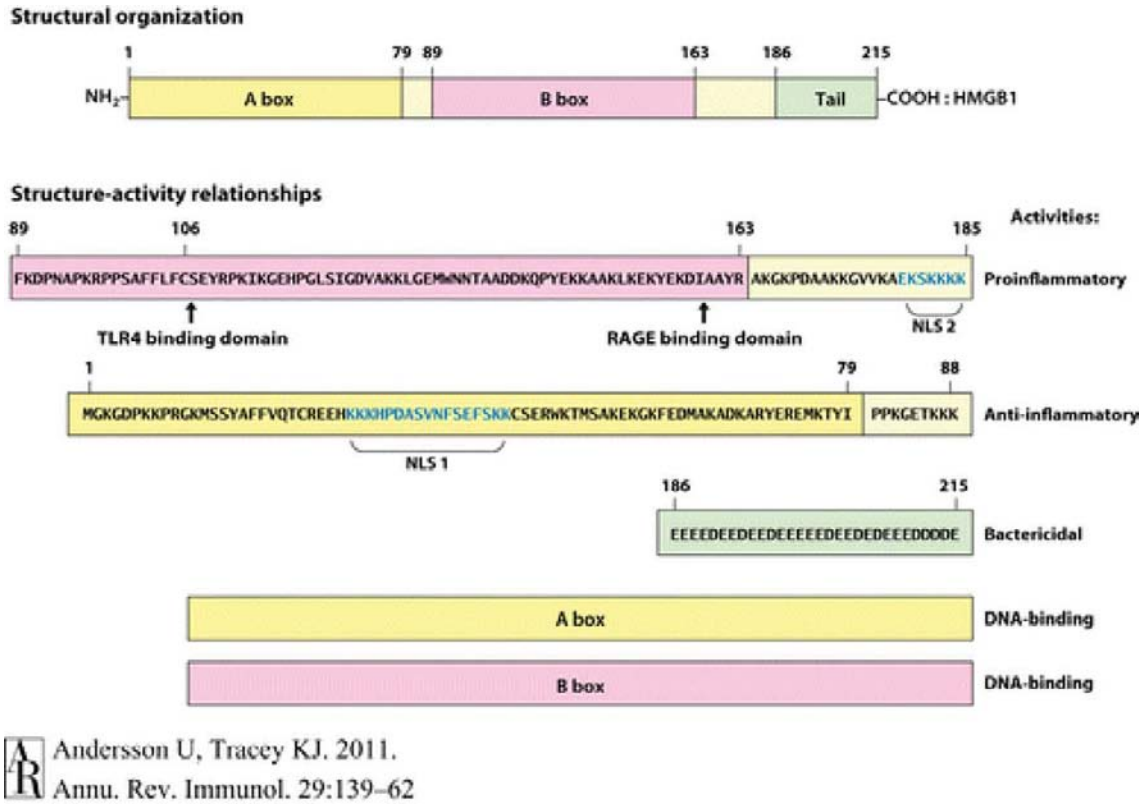

FIGURE 88.3 Structure function of HMGB1. From article cited in text.

released when neutrophil elastase degrades heparan sulfate proteoglycans in the extracellular matrix (see review[197]). Inhibition of neutrophil elastase ameliorated ischemic acute renal failure in rodents, possibly by inhibiting the production of heparan sulfate fragments.[198] Hyaluronan increases in the ischemic kidney.[199] Low molecular weight hyaluronans are released when hyaluronidases from tubules and leukocyes degrade the extracellular matrix. Small hyaluronans stimulate renal tubular cells to produce MCP-1 (a macrophage chemokine), and TNFα (a proinflammatory cytokine) *in vitro*.[200] Biglycan is another extracellular matrix component that may stimulate TLR4 after tissue injury.[201]

Heat shock proteins (Hsp's) are major candidates for being the TLR4 ligands during ischemic AKI: different intracellular and extracellular functions during ischemic AKI?

Hsp70. 1 and Hsp70. 3 are two members of the murine heat-shock-70 family. They are over 95% identical to each other.[202–207] Gp96 is the heat shock protein of the endoplasmic reticulum.[207,208] The murine and human Hsp's are highly homologous.

Although these Hsp's have well known intracellular cytoprotective effects, they also have extracellular functions as cytokines, and particularly as TLR4-ligands.[148,156–161] Indeed, Hsp's have been used as adjuvants in an attempt to immunize experimental subjects against cancer.[209]

Intracellular Heat Shock Proteins are Cytoprotective

Hsp's70. 1 and 70. 3 expressions in the nucleus and cytoplasm is increased after cell stress. Gp96 expression is increased as well.[207,208] These proteins have also been implicated in renal ischemic injury. Within one hour of renal ischemia, Hsp's70. 1 and 70.3 increase by 5x in the S3 segment of the proximal tubule,[210–213] and gp96 increases in both the S3 segment and the loop of Henle.[213] Therefore, increased intracellular Hsp's70. 1 & 3 and gp96 may be part of a cytoprotective mechanism during ischemic ARF (for example[214] and see reviews [215–218]).

Extracellular heat shock proteins may be endogenous TLR4-ligands that recruit inflammatory responses during ischemic ARF.

There is also mounting evidence that extracellular Hsp's act as cytokines, and the term "chaperokine" was coined to highlight their dual functions.[219] Most importantly, extracellular Hsp's activate TLR4 to recruit an inflammatory response.[10–12,158,220] The possibility that extracellular Hsp's may have a harmful proinflammatory role in ARF was proposed in a theoretical paper.[221]

Source of Extracellular Hsp's

Since Hsp's are normally intracellular proteins, the question of how Hsp's are released into the extracellular space during injury needs to be addressed. There are several possibilities.

Firstly, leakage from cells *with* morphologically evident injury (necrosis). Hsp's may be released from severely injured and therefore leaky cells. Since Hsp's are abundant proteins, and their cytokine functions are likely to require very low extracellular concentrations, a small amount of leakage may trigger the self-amplifying inflammatory mechanisms that induce further injury during the "extension" phase of ischemic ARF. Such necrosis would result in the release of intracellular heat shock proteins into the extracellular space where they could activate the endothelium and leukocytes.

Secondly, release from cells *without* evident morphologic injury. Several such mechanisms have been proposed: One is the secretion of Hsp's by stressed cells[156,157] or cells activated by cytokines. A second mechanism is the release of "exosomes." Exosomes are formed by a process of "reverse" endocytosis. These small particles contain Hsp's and they activate macrophages and dendritic cells (see review[209,222–224]). A third mechanism is the expression of membrane bound Hsp's. Although Hsp's normally reside in the cytoplasm, endoplasmic reticulum, or mitochondria, they may redistribute to the cell surface after stress.[225–227] Such cell surface Hsp's activate leukocytes.[228] Altogether there is ample evidence to support the possibility that Hsp's from injured renal tubular cells could stimulate TLR4 in the absence of morphologic features of cell death that are detectable by light microscopy.

Other endogenous molecules also interact with TLR4, but they are less well studied than HMGB1, Hsp's and extracellular matrix components discussed above. Fibronectin IIIA is a variant fibronectin that is produced by stressed cells,[229] and is increased during ischemic ARF.[230] β-defensin is found in kidneys stressed by infection,[231] but β-defensin production during ischemic ARF has not previously been examined. Hsp60 is not known to increase after renal ischemia, but might still be released during ischemic ARF and stimulate TLR4.[161] Tamm Horsfall protein may also be a TLR4 ligand.[232,233] See review.[234] Not only does TLR4 bind to numerous ligands, each ligand may trigger unique biological effects.

Thus, endotoxin and the endogenous TLR4-ligands have different interactions with the TLR4 receptor. Endotoxin interacts with TLR4 in two ways: first, soluble endotoxin may bind the TLR4-MD2 heterodimer.[235] Second, endotoxin may form lipid micelles that

intercalate into cell membrane and then bind TLR4.[236–239] In contrast, all of the endogenous TLR4 ligands identified so far are soluble molecules. Although the hydrophobicity of these ligands may be important,[9] they are unlikely to directly intercalate into the membrane bilayer. Furthermore, some endogenous TLR4 ligands also bind other cell surface receptors in addition to activating TLR4. For example: Hsp's 70. 1 & 3 and gp96 bind cell surface CD40[240] and CD91.[241]

Because endotoxin and the endogenous TLR4-ligands have different modes of interaction with the TLR4 receptor, it is not surprising that they elicit different responses *in vitro*[242] and in a model of autoimmunity *in vivo*.[243]

Of particular importance for this discussion is the different effect of endotoxin and ischemia on the kidney. Both injure the kidney, but in different ways. When care is taken to prevent hypotension, endotoxin decreases GFR by over 70% in the absence of apoptosis, inflammation, and other morphological changes; this injury is not affected by transgenic knockout of inducible nitric oxide synthase (iNOS).[244] In contrast, murine ischemic ARF, which is accompanied by the release of endogenous TLR4-ligands, is characterized by profound morphologic injury and inflammation (see for example review[245]). Unlike normotensive endotoxin ARF, ischemic ARF is ameliorated by transgenic knockout of iNOS.[246,247]

When hypotension is not controlled, endotoxin causes glomerular, in addition to tubular, injury. In contrast, ischemic ARF with release of endogenous ligands, injures tubules, but not glomeruli.[248] Other data shows that systemic endotoxin injures the kidney by increasing the production of extrarenal TNFα.[249]

Note that ARF induced by endotoxin differs from ischemic ARF in another fundamental way: endotoxin is injected systemically and induces massive cytokine production in many organs; on the other hand, during ischemia the postulated TLR4 ligands are released locally in the kidney.

Another example of differences between endotoxin and endogenous TLR4 ligands is a model of autoimmune isletis where endotoxin alone induced diabetes, but Hsp's 70.1 and 70.3 (both endogenous TLR4 ligands) required additional activating anti-CD40 to induce diabetes.[243] Still another relevant example is the TLR4-dependent abilities of LPS to decrease, but HMGB1, another TLR4 ligand, to increase, the carcinogenicity of croton oil.[250]

In addition to differences between the response of TLR4 to endotoxin versus DAMPS, individual DAMPS may each elicit a unique response through TLR4.[251]

As discussed above, TLR4 recognizes both DAMPs and endotoxin produced by bacteria. Microbial products, such as endotoxin, have hydrophobic domains; these domains are also found on proteins denatured during cellular injury, and on DAMPs such as HMGB1 that are released into the extracellular space. Because DAMP receptors appeared early during evolution,[252,253] they may have evolved to recognize injury, organize repair, and then later acquired a host-defense role by recognizing microbes.[9] However, the responses to infection and repair have different goals. After recognizing microbes, TLR4 triggers an aggressive inflammatory response where elimination of the pathogen is the overwhelming priority, and collateral damage to self tissue by toxic microbicidal molecules is an acceptable price for survival of the organism; ultimately, repair occurs after cure of the infection. In contrast, sterile injury such as ischemia/ reperfusion, has tissue repair as the priority. The initial maladaptive inflammation may reflect the fact that tissue injury and infection often occur together, especially after trauma and disruption of the skin. A "shoot first, ask questions later" strategy may have evolved because an initial inflammatory response against the possibility of infection best served survival despite some collateral tissue damage. A fundamental question is how, after either infection or sterile injury, the mononuclear phagocytes change from aggressively proinflammatory (maladaptive for ischemic injury) to reparative.[254] This question may be answered, at least in part, by the presence of CD24-Siglec 10 on mammalian but not bacterial cel surfaces.[255,256] CD24/ Siglec 10 binds DAMPSand turns off the TLR4 response. Bacteria do not express CD24/ Siglec 10 and the TLR4 response would therefore not be inhibited. See Figure 88.4.

Less widely appreciated are recent studies showing that TLR4 participates in repair of non-infectious colitis.[257–265] Some types of non-infectious pulmonary injury,[196,266–269] skin wounding[270] and partial hepatectomy.[271] Whether TLR4 has similar repair functions in the kidney is not known.

Other Multi-Ligand Receptors for other Multi-Receptor DAMPS may Detect Ischemic Injury?

In addition to TLR4, a number of other receptors recognize DAMPS. These recognize injury by a number of pathways including the detection of reactive oxygen species, uric acid, glycolipids, and intracellular stress.[126,146,272,273] These receptors include

CD91: This is also a receptor for heat shock proteins[241,274,275] released by injured cells. It has been targeted as a means of increasing immunity against tumors. In addition to binding heat shock proteins, CD91 also binds α2-macroglobulin,[276,277] collectin and calreticulin,[278] and is known as LDL receptor related protein.[279] These recognize injury by a number of pathways including the detection of reactive oxygen

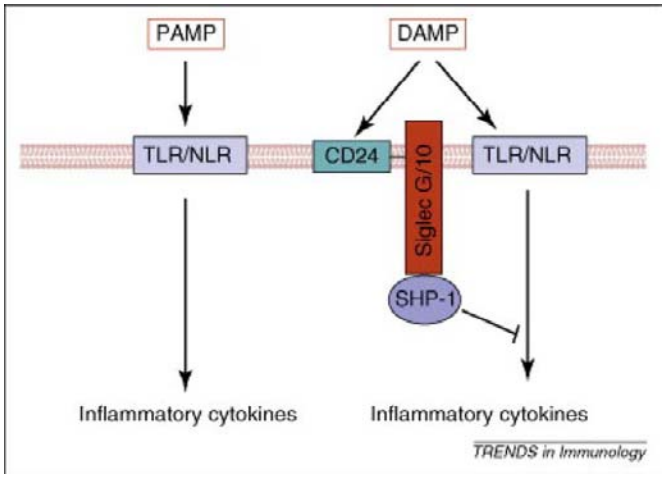

FIGURE 88.4 CD24/ Siglec 10 prevent excessive inflammation after stimulation of TLR4. Pathogen-associated molecular pattern molecules (PAMP), such as endotoxin associated with bacteria, elicits a vigorous response. In contrast, damage-associated molecular pattern molecules (DAMP), such as HMGB1, elicit a response which is inhibited by CD24/ Siglec/10 on the host cell. *(From Liu Y, Chen GY, Zheng P. CD24-Siglec G/10 discriminates danger- from pathogen-associated molecular patterns. Trends Immunol 2009; 30: 557-561. http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?cmd=Retrieve&db=PubMed&dopt=Citation&list_uids=19786366 PMCID 2788100.)*

species, uric acid, glycolipids, and intracellular stress.[126,146,272,273]

TLR2: TLR2 is related to TLR4 and may also recognize Hsp's.[152,280,281] Mice with non-functional TLR2 are protected from ischemic renal failure.[272,273,282] Renal tubules express both TLR2 and TLR4 after severe ischemic injury.[283,284] TLR2 may also be important in ischemic injury to the liver[285] and heart.[286]

RAGE: Although RAGE is best known as the receptor for advanced glycation endproducts and for its contribution to the secondary complications of diabetes mellitus, including diabetic nephropathy,[287–290] RAGE also detects molecules released by injured cells, and triggers an inflammatory response.

Uric acid: Weibel Paladi bodies, NALP3, and Pyronecrosis. Uric acid is released from injured cells.[146] During ischemic AKI this may induce endothelia to release proinflammatory Weibel-Palade bodies.[291] Uric acid may also activate Nlrp3,[273] possibly by activating the inflammasome and triggering pyronecrosis.[292]

Complement: Renal IRI does activate complement. Tubular injury decreases expression of basolateral expression of Crry, the murine homolog of human MCP (membrane cofactor protein) and DAF (decay accelerating factor); Crry normally prevents amplification of the alternative complement pathway after "C3 tickover".[293] In the absence of basolateral Crry during renal IRI, alternative complement activation continues unrestrained and renal tubular injury results.[294,295]

Why there should be so many ways to detect molecules released by injured cells is not clear. Do all injured cells release the same molecules, are different molecules released after different types of death and injury, do different molecules and receptors elicit different inflammatory responses? In very broad strokes, we will discuss the different modes of programmed cell death and the different inflammation elicited by different types of death later in the chapter. However, a profound understanding of these questions remains to be elucidated by future research.

WHEN DEATH IS NO ACCIDENT: NECROSIS AS A PROGRAMMED EVENT

The above section shows that molecules released from necrotic cells elicit an inflammatory response. Necrosis is often considered accidental death. However, a growing body of data indicates that necrosis may also be a programmed event.[296–301] This suggests that when inflammation is desirable, a cell may be programmed to die a necrotic death, and thus release the pro-inflammatory molecules discussed above.

Poly (ADP-Ribose) Polymerase [PARP] and Programmed Necrosis

The PARP's are a family of 18 genes. PARP-1 regulates necrosis.[302–304] That an enzyme regulates necrosis indicates that death is no accident, but is programmed. Pharmacologic inhibition of PARP ameliorates ischemic acute renal injury in rodents.[305,306] Transgenic knockout of PARP-1 also decreases injury after acute renal ischemia.[307,308] Inhibition of PARP-1 also ameliorates ischemic injury of the brain and liver.

The best known function of PARP-1 is to repair DNA damage, such as occurs in response to oxidative stress during ischemic acute renal failure. Renal PARP-1 levels increase during ischemic acute renal failure.[305,309]

It is not intuitively obvious why such a repair enzyme should be required for necrosis. One possibility is that, in the face of massive DNA damage, PARP depletes intracellular NAD^+ and thus ATP stores. This leads to necrosis, especially in the setting of mitochondrial damage as discussed later in this section.[310–312] However, necrosis is not necessarily correlated with intracellular energy stores in all model systems. Another possibility is that PARP-1 enhances the activity of NFκB and other pro-inflammatory transcription factors. PARP may also increase mitochondrial release of AIF.

Some suggest that caspases degrade PARP and thus direct cell death down an apoptotic pathway.[313]

However, there is decreased ischemic acute renal injury in mice expressing a genetically engineered PRAP-1 that cannot be degraded by caspases.[314]

Cyclophilin D, Mitochondria, and Programmed Necrosis

Another argument that necrosis is regulated comes from studies of mice with transgenic knockout of cyclophilin D. Such mice have decreased necrosis during ischemic acute renal failure.[315–317] Cerebral ischemia was similarly ameliorated in these knockout animals.[318] These results extend data that cyclosporine, by inhibiting cyclophilin D, ameliorates ischemic injury in some tissues.[319,320]

Cyclophilin D regulates the mitochondrial permeability transition pore, and the subsequent release of mitochondrial molecules that regulate cell death. The above data suggest an important role for mitochondria in regulating necrosis.[319,321,322] Whether opening this pore results in necrosis or apoptosis may depend upon several factors. One is the length of time that the pore is open—transient opening might result in apoptosis; longer opening, necrosis.[323] In addition the availability of ATP may switch the mitochondrial signal from necrosis to apoptosis.[321] This is in line with data showing that lower, more prolonged decreases in ATP are associate with necrosis, while shorter and lesser ATP depletion result in necrosis in renal cells,[324] and that lesser oxidant injury also leads to apoptosis instead of necrosis.[325,326] Finally, intracellular pH also regulates. The return of the pH from acidic to more alkaline levels with reperfusion makes necrosis more likely.[321]

Additional Examples of Programmed Necrosis *in Vivo*

We will now review three additional striking examples of the importance of programmed necrosis *in vitro*.

One example is the host defense against murine vaccinia virus. This virus protects itself by preventing apoptotic programs within infected host cells. In mice with wild type TNFR2, infected cells die by programmed TNFα-mediated necrosis, and elicit a protective inflammatory response. Mice with TNFR2 knockout have a reduced programmed necrosis and thus reduced antiviral inflammatory response and decreased viral clearance.[327]

The second example is the difference between cerulean pancreatitis in rats versus mice. The worse outcome in the latter is due to greater programmed necrosis. Rats have high apoptosis and low necrosis and thus a better clinical outcome. Mice have low apoptosis and high necrosis and thus a worse outcome with more inflammation. This difference was due to different function of the X-linked inhibitor of caspases (XIAP) in these two species. There was less inhibition of caspases, and thus less inhibition of apoptosis, in the rat by XIAP.[328]

The third example is the exacerbation of shock when apoptosis is inhibited in mice given TNFα. In this case, switching programmed cell death from apoptosis to necrosis had fatal consequences.[329]

AFTER THE SUICIDE, DISPOSAL OF THE CORPSE: REGULATION OF INFLAMMATION BY MACROPHAGES AFTER THEY PHAGOCYTOSE APOPTOTIC CELLS

Apoptosis occurs during ischemic acute renal failure.[330–335] The goal of this discussion is not the regulation of this apoptosis but rather the effect of apoptosis on inflammation. In other words, we discuss phagocytic clearance of the apoptotic cells before their loss of membrane integrity and leakage of the proinflammatory molecules discussed in the previous section. Such clearance is regulated by "eat me," "don't eat me," "come get me" signals.

The surface of the apoptotic cell has "eat me" signals that trigger phagocytosis by macrophages. A major signal is phosphatidylserine that has somehow "flipped" from the intracellular leaflet to the extracellular leaflet of the plasma membrane where it is recognized by macrophage receptors including the phosphatidylserine receptor after bridging by Annexin I. Other less well understood interactions between apoptotic cell and macrophage also contribute to the "eat me" signal. These include sites also capable of binding collectins such as mannose binding protein, C1q, C3b/bi, oxidized LDL, and thrombospondin 1. In addition, the apoptotic cell surface has decreased "don't eat me" signals such as CD31. Furthermore, phosphatidylcholine on apoptotic cell surfaces is cleaved by phospholipase A2 to form lysophosphatidyl choline which is the best understood chemoattractant "come get me" signal issued by apoptotic cells to macrophages. [See review[336]].

Under many circumstances, macrophages, which have engulfed apoptotic cells, release anti-inflammatory molecules that prevent further inflammation (for example [337,338]). The phosphatidylserine receptor on macrophages may trigger the release of inhibitory cytokines, but this begs the question of why this receptor is not triggered when macrophage phagocytose necrotic debris, including phosphatidylserine on the intracellular side of cell membrane fragments.[339] In the absence of a receptor for phosphatidylserine, macrophages cannot ingest apoptotic cells, and the

lungs of such mice fill with cellular debris and inflammation.[340,341] This may reflect the consequences of overwhelming the phagocytotic system with too many apoptotic corpses as perhaps occurs during ischemic acute renal failure.[332] This situation may reflect "post-apoptotic necrosis" and the release of proinflammatory mediators.

However, there are a number of experimental circumstances where phagocytosis of apoptotic cells results in the release of pro-inflammatory molecules by macrophages, and where ingestion of necrotic debris results in the release of anti-inflammatory molecules. This may reflect the influence of cytokines in the microenvironment,[342] or the redox potential of the microenvironment that can oxidize phospholipids and turn them into macrophage activating signals.[343,344]

Efferocytosis is the phagocytosis of apoptotic cells and does not cause the release of proinflammatory cytokines. If efferocytosis cannot dispose of all the apoptotic cells, then some will degenerate and release DAMPS.[345–347] Increasing efferocytos by injections of MFG-E8 (milk fat globule-EGF factor 8/ lactadherin) ameliorates ischemic AKI in rodents;[348,349] MFG-E8 is a "bridging molecule" that links the apoptotic cells to phagocytes, and thus increases efferocytosis.[350]

SUMMARY

The ultimate amount of injury during ischemic AKI is the result, not only of the ischemic insult, but also of the resulting inflammation. In this chapter, we have summarized the current understanding of the major inflammatory processes during ischemic AKI.

INTRODUCTION

Despite advances in understanding the pathophysiology of acute kidney injury (AKI) and chronic kidney disease, treatment for kidney disease remains unsatisfactory. In this chapter, we briefly recount the importance of acute kidney injury and chronic kidney disease, then provide a brief description of labile iron, and, finally, summarize the role of labile iron in acute and chronic kidney disease. The availability of iron chelators provides new therapeutic tools to prevent and/or treat kidney disease.

Acute kidney injury is an independent risk factor for morbidity and mortality. A modest increase (0.3 mg/dL) in serum creatinine is associated with high in-hospital mortality,[1,2] and AKI is associated with post-hospital discharge mortality[3,4] and progression to end-stage kidney disease (ESKD).[5,6]

Chronic kidney disease (CKD) affects approximately 10-15% of the adult population worldwide,[7,8] is an independent risk factor for cardiovascular disease,[9] and carries a high economic cost.[10] There is a worldwide increase in the incidence and prevalence of diabetes, which is the most common cause of CKD. These observations, coupled with the increasing incidence of end-stage kidney disease despite the use of angiotensin receptor blockers (ARBs) and the multiplier effect of CKD on cardiovascular disease, indicate a major importance of CKD as a global public health problem. The failure of recent studies to halt diabetic nephropathy highlights an urgent need[11] for new therapeutic modalities to halt progression of kidney disease.

DEFINITION OF CATALYTIC (LABILE) IRON AND ITS IMPORTANCE IN TISSUE INJURY

Iron is the most abundant transitional metal in the body. The term "labile iron pool" was first used to denote a transient iron pool of low-molecular-weight, weakly chelated iron that passes through the cell.[12,13] Methodological approaches for detection of this pool of iron ions are based on the use of metal chelators.[14] Critical to iron's importance in biological processes is its ability to cycle reversibly between its ferrous and ferric oxidation states. This precise property, which is essential for its functions, also makes it very dangerous, because free iron can catalyze the formation of free radicals that can damage the cell. Thus, from a pathophysiological standpoint, the broadest definition of a labile iron pool is that it consists of chemical forms that can participate in redox cycling, and is therefore often referred to as catalytic iron.[15]

The catalytic iron pool[15,16] is estimated to be less than 100 mg compared to the total iron in the body, which is approximately 4 g. In most cells iron homeostasis consists of iron uptake, utilization, and storage. The process of iron uptake is carried out by a transferrin receptor (TFR) and a divalent metal transporter 1

DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00089-6

(DMT1, also called DCT1; NRAMP2), whereas ferritin is an intracellular, iron-sequestering protein. Studies are beginning to yield information on the pathways of iron transport, its export from the cell via the divalent iron ion exporter ferroportin 1,[17] and its regulatory mechanisms including hepcidin.[18] Since uptake and storage of iron is carried out by different proteins, the pool of accessible iron ions constitutes a crossroad of metabolic pathways of iron-containing compounds.

Studies using a variety of methods have begun to define intracellular distribution of labile iron (for reviews see Kruszewski[14] and Esposito[19]). Using several techniques including laser scanning microscopy, the concentration and distribution of chelatable iron has been estimated to be about 5.0 to 15 μM in the cytoplasm and subcellular organelles including mitochondria and nuclei.[20] *In vivo*, most of the iron is bound to heme or non-heme protein and does not directly catalyze the generation of hydroxyl radicals or a similar oxidant.[15] The bleomycin-detectable iron assay measures catalytic iron and is based on the observation that the anti-tumor antibiotic bleomycin, in the presence of catalytic iron, binds to and degrades DNA with the formation of a product that reacts with thiobarbituric acid to form a chromogen. Thus the assay detects iron complexes capable of catalyzing free-radical reactions in biological samples.[21,22] The binding of the bleomycin-iron complex to DNA makes the reaction site-specific and antioxidants rarely interfere. The bleomycin assay detects only "free" iron and not iron bound to specific transport proteins or to enzymes.

The ability of iron to participate in redox cycling makes it potentially hazardous by enabling it to participate in the generation of powerful oxidant species such as hydroxyl radical (metal-catalyzed Haber-Weiss reaction, below) and/or reactive iron-oxygen complexes such as ferryl or perferryl ion.[15] In several systems, the amount of free-radical generation is related to the amount of labile iron present[23] (Figure 89.1).

$$Fe^{3+} + O_2^{\bullet} \rightarrow Fe^{2+} + O_2$$
$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{-}OH + {}^{\bullet}OH$$
$$H_2O_2 + O_2^{\bullet} \xrightarrow{Fe^{3+}} {}^{-}OH + {}^{\bullet}OH + O_2$$

Iron also has a major role in lipid peroxidation, either directly or indirectly (through hydroxyl radicals or forming a perferryl ion) in which there is oxidative reaction of polyunsaturated lipids by removing hydrogen atoms from polyunsaturated fatty acids.[15]

A major advancement in understanding the important role of iron in the pathophysiology of tissue injury is the recognition that iron plays a role even in the absence of systemic iron overload. It is now known that specific defects in cellular iron metabolism and/or an increase in catalytic iron may be important in several disease processes not associated with iron overload.[17,24] In Friedreich's ataxia, there is an improper processing of iron because of the deficiency of the iron-chaperone protein frataxin, resulting in accumulation of iron in the mitochondria.[24] Deficiencies in pantothenate kinase, a key enzyme in coenzyme A synthesis, leads to iron depositions and brain damage.[24] In addition to these specific defects in cellular iron, there is now overwhelming evidence that increased catalytic iron from subcellular or other sources participates in tissue injury in a wide variety of common disease states. This has been demonstrated in many disease states including acute and chronic kidney disease, acute myocardial infarction, and neurodegenerative disorders.[25] In large part, the evidence consists of demonstrating an increase in catalytic iron and the ability of iron chelators to provide a protective effect, thus establishing a cause-effect relationship (Table 89.1).

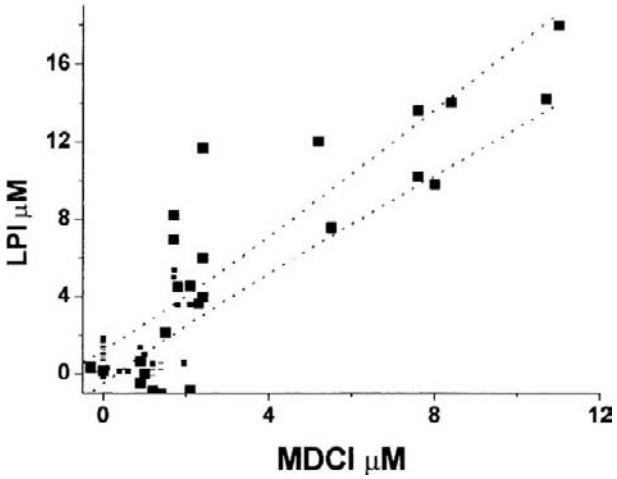

FIGURE 89.1 Labile plasma iron (LPI) in sera from thalassemic patients and its correlation with mobilizer-dependent chelatable iron (MDCI).

ROLE OF CATALYTIC IRON IN ACUTE KIDNEY INJURY

Catalytic Iron in Myoglobinuric Acute Kidney Injury

The first causative association of acute kidney injury with muscle injury (rhabdomyolysis) was described during the Battle of Britain.[26] We now recognize that the spectrum of etiologies for rhabdomyolysis, myoglobinuria, and renal failure has been expanded with the recognition of both traumatic and nontraumatic causes.[27] The most widely used model of myoglobinuric acute kidney injury is produced by subcutaneous or intramuscular injection of hypertonic glycerol.[28]

There are a number of studies that indicate a role for catalytic iron in rhabdomyolysis. There is a marked and specific increase in catalytic iron content in myoglobinuric acute kidney injury[29] (Figure 89.2). In addition, studies from different investigators have shown functional and histological protection in models of myoglobinuric acute kidney injury[12,30,31] (Fig. 89.2).

Because myoglobin is rich in heme iron, the prevailing dogma is that myoglobin from the muscle serves as an important source of iron in glycerol-induced acute kidney injury. However, several studies indicate that cytochrome P450 can also serve as a rich source of iron.[32] Cytochrome P450 is a heme-containing enzyme that can generate reactive oxygen metabolites. Baliga et al. have shown that cytochrome P450 is a significant source of catalytic iron in glycerol-induced acute renal failure, and inhibitors of cytochrome P450 provide significant protection.[29]

TABLE 89.1 Catalytic (Labile) Iron

What is catalytic iron?

- A transient iron pool of low-molecular-weight, weakly chelated iron that passes through the cell
- The broadest definition of labile iron pool (LIP) is that it consists of chemical forms that can participate in redox cycling (catalytic iron)
- LIP is less than 3% (70–90 mg) of total cellular iron (3–5 g)

Evidence for its participation in disease states:

- LIP (catalytic iron) is increased in disease states
- Iron chelators have a protective effect, establishing a cause-effect relationship

Catalytic iron is a common theme of cellular injury in disease states of:

- Acute and chronic kidney disease
- Acute myocardial infarction
- Neurodegenerative disorders

Catalytic Iron in Cisplatin-Induced Nephrotoxicity

The mechanism of cisplatin nephrotoxicity is not well known. Baliga et al. have shown that the exposure of LLC-PK$_1$ cells to cisplatin results in a significant increase in catalytic iron released into the medium (Figure 89.3). In addition, two iron chelators significantly protected against cisplatin-induced cytotoxicity (Fig. 89.3). In an *in vivo* study, rats treated with cisplatin have a marked increase in catalytic iron (Figure 89.4). An iron chelator provided marked functional (as measured by blood urea nitrogen and creatinine) (Fig. 89.4) and histological protection against cisplatin-induced acute kidney injury.[33]

Baliga et al. have also examined potential sources of catalytic iron in cisplatin-induced nephrotoxicity.[34] Using CYP2E1null (CYP2E1$^{-/-}$) mice, Liu and Baliga have demonstrated a pivotal role of CYP2E1 in cisplatin-induced nephrotoxicity (Figure 89.5, Table 89.2).[35] Incubation of CYP2E1$^{-/-}$ kidney slices with cisplatin results in a significant decrease in the generation of reactive oxygen metabolites and attenuation of cytotoxicity as compared to that of wild-type mice (CYP2E1$^{+/+}$). CYP2E1-null mice had marked functional and histological protection against cisplatin-induced renal injury, thus demonstrating the importance of cytochrome P450 2E1 in cisplatin nephrotoxicity. Taken together, these data support a critical role for iron in mediating tissue injury via hydroxyl radical (or a similar oxidant) in this model of nephrotoxicity.

Catalytic Iron in Gentamicin Nephrotoxicity

The mechanisms of gentamicin nephrotoxicity remain unknown.

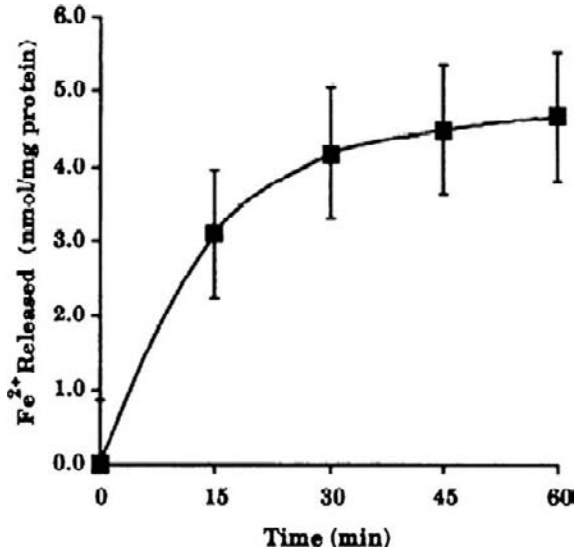

FIGURE 89.6 Time course of gentamicin-induced iron release from rat renal cortical mitochondria.

Gentamicin-Induced Mobilization of Iron from Renal Cortical Mitochondria

A source of iron not previously considered is iron-rich mitochondria, which contain heme as well as non-heme iron. Ueda et al. demonstrated that rat renal mitochondria incubated with gentamicin results in a time- and dose-dependent iron release as measured by the formation of the iron-bathophenanthroline complex FeII (BPS)3[36] (Figure 89.6). In addition, it was shown that gentamicin-induced iron mobilization from mitochondria is mediated by hydrogen peroxide. Direct addition of hydrogen peroxide to mitochondria results in release of iron. These results demonstrate that gentamicin induces the release of iron from mitochondria and that this is mediated through the generation of hydrogen peroxide. These results also indicate that mitochondria should be considered as a potential source of iron for the generation of other oxidant species or initiation of lipid peroxidation in other models of tissue injury.

Evidence Suggesting a Role for Iron in Gentamicin-Induced Acute Renal Failure in Rats

Superoxide and hydrogen peroxide may interact (with trace metals such as iron as the redox agent) to generate highly reactive and unstable oxidizing species including the hydroxyl radical. Several studies have in fact shown that agents that enhance the generation of hydrogen peroxide and superoxide anion by mitochondria also enhance generation of the hydroxyl radical. Walker et al. demonstrated that hydroxyl radical scavengers and iron chelators provide a marked protective effect on renal function in gentamicin-induced acute

renal failure in rats.[37] Data collected from several experiments are depicted in Figure 89.7. In addition, histological evidence of damage is markedly reduced by the interventional agents. Additional support for a role of iron-catalyzed free-radical generation has been provided by demonstrating that gentamicin-induced generation of hydroxyl radicals is reduced by iron chelators *in vitro*[38] and iron supplementation enhances gentamicin nephrotoxicity *in vivo*.[39,40] Taken together, it appears that reactive oxygen metabolites and catalytic iron play an important role in gentamicin nephrotoxicity.

Catalytic Iron in Contrast-Media-Associated Nephrotoxicity

Subjects undergoing either an intravenous pyelogram or a renal arteriogram have a marked increase in urinary catalytic iron accompanied by evidence of tubular injury, documented by an increase in urinary alkaline phosphatase and N-acetyl-β-glucosaminidase[13] (Figure 89.8). Since the effect of catalytic iron is to increase oxidative stress, unsurprisingly there is experimental evidence for the role of oxidants in contrast-induced acute kidney injury.[41–43] In human studies Efrati et al. reported an increase in urinary F2-isoprotane levels after coronary angiography,[44] and Drager et al. reported a several-fold increase in urinary isoprostane compared to the control group after cardiac catheterization.[45]

These human studies indicate an association between catalytic iron and oxidative stress with contrast-induced nephropathy, but they do not establish a cause-effect relationship. Although there do not appear to be any satisfactory animal models of contrast-induced acute kidney injury,[46] Vari et al., utilizing a multi-insult model,[47] examined the effect of an iron chelator on renal function. An infusion of contrast was associated with a significant decrease in creatinine clearance, which was prevented in rabbits pretreated with an iron chelator, suggesting an important role of catalytic iron in this model[48] (Table 89.3).

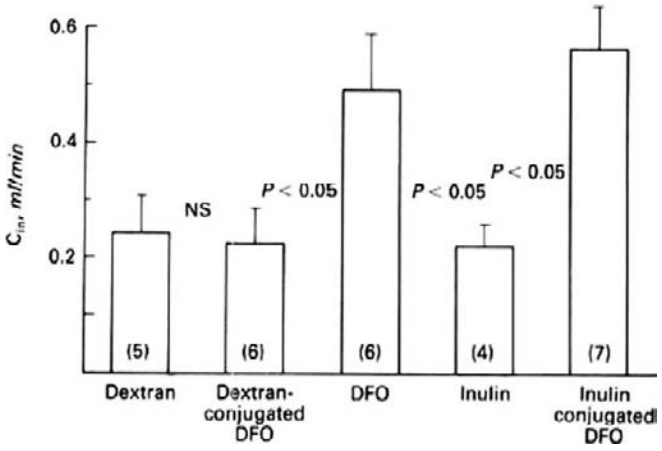

FIGURE 89.10 Effect of an iron chelator on renal function after ischemia.

Catalytic Iron in Ischemia-Reperfusion Injury

Ischemia-reperfusion is an important cause of acute kidney injury. In this section, evidence for the role of catalytic iron in this injury is reviewed. In addition, we briefly describe the role of catalytic iron in cardiac ischemia-reperfusion injury to provide supportive evidence for these mechanisms in cellular injury.

There is a marked increase in catalytic iron after ischemia-reperfusion injury[49] (Figure 89.9), and an iron chelator has been shown to be protective[50,51] (Figure 89.10). The amount of circulating redox-active iron has been shown to increase significantly in an experimental model of ischemia-reperfusion injury, and an infusion of apotransferrin (but not iron-saturated apotransferrin) results in a dose-dependent improvement in renal function following reperfusion.[52] In addition, studies related to neutrophil gelatinase-associated lipocalin (NGAL),[53,54] which is an important iron-transporting and -translocating compound, provide evidence for the importance of iron in acute kidney injury.[55] NGAL is one of the most upregulated genes and proteins in the kidney following ischemic insult,[55] and infusion of NGAL protein has been demonstrated to be protective of renal ischemia-reperfusion injury.[54]

There is a 30-fold increase in catalytic iron during experimental cardiac ischemic injury.[56] This increase in the cellular catalytic iron pool is associated with severe oxidative stress.[56–58] Two iron chelators, deferiprone and deferoxamine, have been demonstrated to protect against experimental cardiac ischemia-reperfusion injury,[59–61] and iron loading has been demonstrated to further increase cardiac ischemia-reperfusion injury.[59] It is of great therapeutic significance that deferoxamine has also been shown to improve outcomes in humans following coronary artery bypass graft surgery.[62] Taken together, the body of scientific and clinical data supporting the importance of the role of iron in the pathogenesis of ischemic injury is compelling.

CATALYTIC IRON IN CHRONIC KIDNEY DISEASE

Catalytic Iron in Experimental Glomerular Disease

Several studies have examined the role of iron in models of leukocyte-dependent and -independent glomerular disease. In an anti-glomerular basement membrane antibody model, a well-characterized model of complement- and neutrophil-dependent glomerular injury, Boyce et al. reported that an iron chelator

significantly attenuates proteinuria[63] (Figure 89.11). The ability of glomerular cells to generate oxidants suggests that they may act as important mediators of injury in glomerular diseases that lack infiltrating leukocytes. A single intravenous injection of puromycin aminonucleoside in rats results in an animal model of minimal change disease. Ueda et al. have shown that catalytic iron (measured as bleomycin-detectable iron) is markedly increased in glomeruli from nephrotic rats, and that an iron chelator prevents an increase in catalytic iron and provides complete protection against proteinuria[64,65] (Figure 89.12).

Cytochrome P450 appears to be a source of this catalytic iron, at least in part. Baliga et al. have demonstrated that cytochrome treatment of PAN results in a significant loss of glomerular cytochrome P-450 content accompanied by a marked increase in catalytic iron. The loss of CYP content can be prevented by CYP inhibitors, which also prevent the rise in catalytic iron. Administration of CYP inhibitors also resulted in a marked decrease in proteinuria.[66] In an *in vitro* study using glomerular epithelial cells (GEC), CYP inhibitors also markedly prevented a PAN-induced increase in catalytic iron (Figure 89.13) and hydroxyl radical formation accompanied by significant protection against PAN-induced cytotoxicity. Taken together these data indicate that CYP, a group of heme protein, may serve as a significant source of this catalytic iron. In addition, they have shown with *in vivo* and *in vitro* studies that cytochrome P450 2B1, an isozyme present in the glomerulus, is a source of catalytic iron that participates in glomerular injury in this model.[67,68]

Passive Heymann nephritis, induced by a single intravenous injection of anti-Fx1A, is a complement-dependent model of membranous nephropathy in humans. The role of iron in this model has been delineated by demonstration of an increase in catalytic iron, both *in vivo* and *in vitro*, and reduction in proteinuria by either an iron chelator or an iron-deficient diet[30,69] (Figure 89.14).

Role of Iron in Experimental Progressive Kidney Disease

A major determinant of the degree and rate of progression of renal failure is the severity of the tubular interstitial injury. Several lines of evidence support the role of iron in progressive renal disease. These include demonstration of increased iron in the kidney; enhanced oxidant generation, which provides a mechanism by which iron can be mobilized; and the beneficial effect of iron-deficient diets and iron chelators. Rats with proteinuria have increased iron content in proximal tubular cells, which is the only independent predictor of both functional and structural damage.[70] Similarly, in a remnant kidney model of progressive kidney disease, there is a substantial iron accumulation associated with increased evidence of lipid peroxidation. The sources of increased iron in the kidney have not been well-delineated, but Alfrey et al. have suggested that urinary transferrin provides a potential source of iron.[71,72]

Several studies have demonstrated an important role of iron in progressive kidney disease. An iron chelator significantly reduces iron accumulation and tubular damage in the rat remnant kidney, a model for progressive renal disease.[73] Remuzzi et al. have shown that rats fed an iron-deficient diet have a significant reduction in proteinuria and develop less glomerulosclerosis.[74] It was reported that an iron-deficient diet (Figure 89.15) or iron chelators prevent the development of tubulointerstitial disease and renal functional deterioration in nephrotoxic serum nephritis.[72,75]

Catalytic Iron in Human Disease

While there is substantial evidence for the role of oxidants and iron derived from models of glomerular disease as well as progressive renal failure, there is little information on the potential role of these mechanisms in human disease. There are many differences

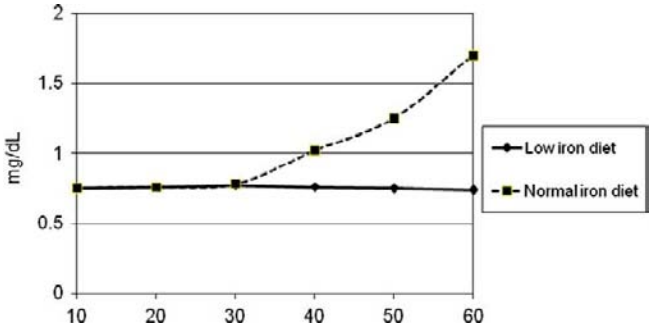

FIGURE 89.15 Effect of a low-iron diet in halting progression of kidney disease. Feeding a low-fat diet to rats with nephrotoxic serum nephritis prevented a rise in serum creatinine and provided histological protection.

between animal models and glomerular disease in humans. For example, the animal model of minimal change disease is a toxic model whereas the mechanism of minimal change disease in humans is not known. Similarly, the anti-Fx1A antibody, which is used for the animal model of membranous nephropathy, has been difficult to demonstrate in human membranous nephropathy. Indeed, the lessons from animal models of acute kidney injury have been disappointing when attempting to translate to human disease. However, although the information from human studies is limited, it does appear to support the notion that mechanisms observed in animal models may be applicable to human disease.

Catalytic Iron in Diabetic Nephropathy

Early in the course of diabetic kidney disease in humans there is an increase in urinary iron excretion.[76] Our data demonstrate that patients with overt diabetes have a marked increase in urinary catalytic iron (Figure 89.16A). Urinary catalytic iron is not merely a reflection of albuminuria, because patients with

% Reduction	47 ± 9		

FIGURE 89.16 Urinary catalytic iron in patients with diabetic nephropathy (Panel a) and the effect of the iron chelator deferiprone on proteinuria (Panel b).

microalbuminuria also have a marked and highly significant increase in urinary catalytic iron. Some patients in the diabetic control group who do not have microalbuminuria have high catalytic iron, leading us to postulate that urinary catalytic iron precedes the onset of microalbuminuria and may predict patients at risk for diabetic nephropathy.

Adult patients with a diagnosis of diabetes mellitus and significant abnormal albumin excretion but with serum creatinine levels <1.2 mg/dL were included in a single-center, single-arm, open-label, proof-of-concept study to evaluate the safety and efficacy of the oral iron chelator deferiprone in reducing albuminuria.[77] Patients received standard of care and enalapril, which was kept constant throughout the study. Deferiprone, an oral iron chelator, was administered in a daily dose of ~50 mg/kg in three divided doses for nine months. There were 37 patients (21 males and 16 females) enrolled in the study, with a mean age of 51.27 (± 1.67) years. Deferiprone did not affect the blood glucose control as measured by HbA1c.The administration of deferiprone resulted in a significant decrease in the albumin-to-creatinine ratio, as shown in Figure 89.16, Panel B. There was no significant effect on renal function as measured by serum creatinine. The calculated mean arterial blood pressure (MAP) declined from a baseline value of 100.78 ± 1.7 to 97 ± 0.6 at three months ($p = 0.2$), but remained relatively stable from then on to 6 months (96.24 ± 0.7; $p = 0.6$) and 9 months. Future randomized, double-blind trials, with careful monitoring of safety issues, may lead to use of a new class of agents for the treatment of diabetic nephropathy.

Catalytic Iron in Progression

Using the urinary catalytic iron assay described before, we have shown a marked increase in patients who have biopsy-proven glomerulonephritis (Figure 89.17A). In addition, Nankivell et al. have reported increased iron content in patients with chronic kidney disease.[78]

We conducted a single-center, prospective, single-arm, open-label, proof-of-concept study to evaluate the safety and efficacy of an oral iron chelator, deferiprone, in patients with biopsy-proven glomerulonephritis. We enrolled 15 patients with biopsy-proven idiopathic glomerulonephritis who had persistent proteinuria despite treatment with steroids and/or cyclophosphamides. Secondary glomerulonephritis was ruled out by appropriate serologic tests. Two patients complained of severe nausea and vomiting after administration of the first dose of the drug and did not participate in the study.

The thirteen patients who completed the study were considered for analysis. Of the remaining 13 subjects there were six males. The age at study entry was 26.76 ± 4 years; four were pediatric subjects. Among the 13 patients, four had membranous nephropathy, three had focal segmental glomerulosclerosis (FSGS), three had diffuse proliferative glomerulonephritis, two had mesangial proliferation, and one had chronic sclerosing glomerulonephritis. These patients had persistent proteinuria despite receiving steroids (seven subjects) or steroids and cyclophosphamides (six subjects).

All patients were monitored clinically and with laboratory evaluation for the evidence of development of adverse effects of deferiprone. Three patients noticed dark coloration of urine during administration of the medication. No patients developed arthritis. No patients developed agranulocytosis. Bilirubin and SGOT and SGPT were not significantly different from baseline at the end of the study. Deferiprone therapy reduced the proteinuria from 4.05 ± 0.46 g/day (range 1.2–6.5) to 2.21 ± 1.61 g/day by six months, an overall reduction of 47 ± 9% (Figure 89.1). Seven of 13 subjects had >50% improvement in proteinuria and three had <600 mg/day proteinuria after therapy. As shown in Figure 89.17, Panels B, C, and D, treatment with the iron chelator significantly decreased the amount of

total urinary protein in patients with glomerulonephritis.[79] Serum creatinine was 1.10 ± 0.15 before and 0.90 ± 0.10 (n = 11) at the end of the study period. Our data indicate an increase of catalytic iron in patients with glomerulonephritis and that treatment with an oral iron chelator leads to a reduction in proteinuria.

There is at least one published study in the literature in which the effect of a metal chelator on progressive kidney disease has been examined. Lin et al. have shown that chelation therapy with ethylenediaminetetraacetic acid (EDTA) in patients with chronic renal insufficiency results in a reduced rate of decline in the glomerular filtration rate[80] (Figure 89.18). The authors attribute the beneficial effect to the chelation of lead, which also participates in the Fenton reaction. However, given the affinity constants for iron and lead, the large experimental evidence for the role of iron in kidney disease, and the demonstrated efficacy of EDTA in enhancing excretion of urinary iron, we believe that the beneficial effects are more likely to be explained by the chelation of iron rather than lead.[81]

CONCLUDING COMMENTS

One has to be cautious in extrapolating results from animal studies to humans. The results from clinical trials in acute kidney injury based on animal models have not been encouraging. These studies to prevent or treat acute kidney injury using atrial natriuretic peptide,[82,83] insulin-like growth factor,[84,85] thyroxine,[86,87] and furosemide[88,89] have yielded negative results. Nonetheless, evidence that catalytic iron appears to be involved in a variety of models of acute kidney injury suggests that it may be a common mechanism of tissue injury (Table 89.4). Additionally, limited human data support the possibility of similar pathophysiological mechanisms in humans. Demonstration of an increase in catalytic iron in humans and the availability of iron chelators with a favorable side-effect profile for short-term use make them attractive for evaluating their efficacy and safety in preventing or treating acute kidney injury.

There are several points from animal and human studies related to halting progression with a metal

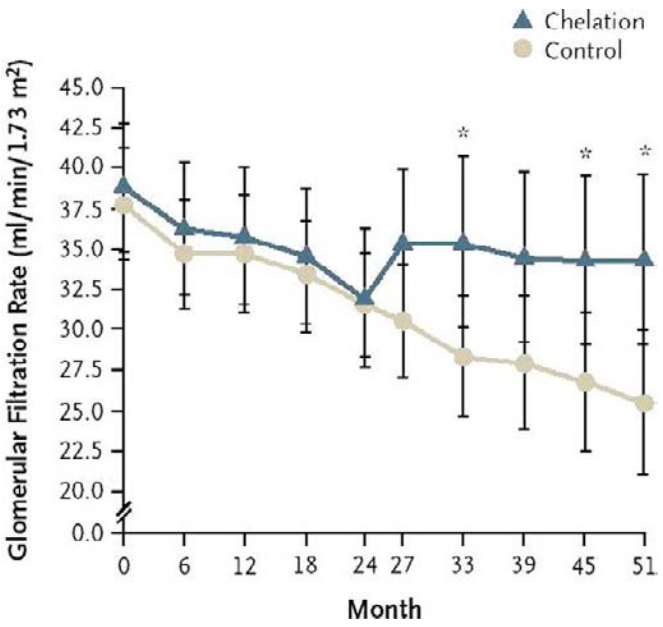

FIGURE 89.18 Estimated mean (±2 SE) glomerular filtration rate according to time in the EDTA chelation group (N = 31) and the control group (N = 30) during the observation and intervention periods.

chelator that are worth noting. Based on animal studies, it is conceivable that iron chelators may provide a beneficial effect, not only by reducing proteinuria but also by directly preserving the tubulointerstitial region, independent of its effect on proteinuria. Bicarbonate supplementation was shown to slow the rate of progression of renal failure to ESRD without reducing proteinuria.[90] In an open-label trial, pirfenidone was shown to slow the loss of kidney function in patients with focal segmental sclerosis with no reduction in proteinuria.[91] In a model of diabetic nephropathy, pirfenidone was shown to reduce generation of reactive oxidant species and significantly reduce mesangial matrix expansion without affecting albuminuria. In studies by Alfrey, an iron-deficient diet or iron chelator provided both functional and histological protection against progression in a model of nephrotoxic serum without affecting proteinuria.[71,75] Similarly, in a study by Lin et al., EDTA provided protection against progression without reducing urinary protein.[80] Thus, clinical studies targeted toward halting progression should focus not only on short-term studies on proteinuria, but they need be of sufficient duration to evaluate the effect on renal function.

The evidence reviewed suggests the possibility of using iron chelators to halt the progression of kidney disease. As a practical matter, the long-term use required for chronic kidney disease makes oral iron chelators more attractive than parenteral medications. Of the two oral iron chelators currently approved for human use in iron overload states, deferasirox has been shown to have some nephrotoxicity[92] but may nonetheless be potentially beneficial in patients with kidney disease. Deferiprone (1,2-dimethyl-3-hydroxypyridin-4-1) has been approved for treatment of iron overload states in Europe, India, and recently North America. In addition to its suitability for long-term treatment (because of oral administration), the high-membrane permeability of deferiprone is well documented, as shown by its capacity to access and deplete intracellular iron pools.[24] In addition, a recent study has demonstrated its ability to remove labile iron from nuclei, endosomes, and mitochondria.[24] The major adverse effect reported so far in several thousand patients receiving deferiprone for periods of up to 14 years is transient agranulocytosis in less than 1% of patients. Based on the collective evidence to date, randomized, controlled, double-blind trials may be warranted to evaluate the efficacy and safety of iron chelators to halt progression of chronic kidney disease.

Chronic Kidney Disease: Pathophysiology and the Influence of Dietary Protein

Biruh T. Workeneh and William E. Mitch

Department of Medicine (Division of Nephrology), Baylor College of Medicine, Houston, Texas, USA

INTRODUCTION

The concept of chronic kidney disease (CKD) continues to evolve from a common pathway initiated by unrelated diseases into a number of complications and adaptations that affect the function of virtually every organ. Key concepts are that these complications increase in severity as glomerular filtration rate (GFR) declines and their severity can be modified by modifying the diet and by treating each part of the syndrome of CKD. This concept of CKD allows for individual variations in the manifestations of the complications of CKD related to the primary kidney disease and/or an individual's genetic and environmental background. The increasing number of patients with CKD[1] and especially the growing number of elderly, diabetic, and minority populations, leads to morbidity and mortality concerns as well as the increasing costs of treating patients with end-stage renal disease (ESRD) when dialysis or transplantation are required to sustain life. Recent information underlines the necessity of employing established methods of treating CKD and preventing its complications. At least three groups of investigators have evaluated the hypothesis that "early dialysis" should be initiated in CKD patients.[2–7] Their analyses demonstrated that early dialysis does not improve survival, clinical outcomes or quality of life.

The flood of new information about the pathophysiology of CKD (e.g., hypertension, the renin-angiotensin system, renal hypertrophy, electrolyte disturbances, nephron adaptations, and mineral metabolism, among others) has created separate fields of study. There also has been identification of mechanisms associated with the complications of CKD such as the contribution of the gastrointestinal tract to the generation of uremic toxins, the influence of erythropoietin on morbidity and mortality, the abnormalities in protein metabolism and the potential role that acid accumulation plays in the progression of CKD. Epidemiologic reports have emphasized the risks of CKD patients for the development of cardiovascular diseases and a link with the impending world wide increase in diabetes. These reports also emphasize that new strategies for slowing progression of CKD and mitigating its complications (e.g., cardiovascular disease, death) must be developed since a randomized, clinical trial has confirmed earlier reports indicating that initiating dialysis "early" does not improve mortality expectations of CKD patients.[6] Our major focuses are the pathophysiology of progressive CKD and the role of the diet in counteracting CKD complications. The latter focus is relevant because successful implementation of dietary measures can blunt the severity of complications of CKD and recent findings show that this type of therapy is safe.

MEASUREMENT AND NATURAL HISTORY OF CKD

Assessment of Glomerular Filtration Rate

The "gold standard" for assessing the amount of residual kidney function and the rate of loss of kidney function is the GFR. The measurement of GFR is classically, the urinary clearance of inulin, a 5200 Da polysaccharide which is filtered by the glomerulus, is neither reabsorbed nor filtered and has no extrarenal clearance (i.e., no metabolism or elimination by other organs). Unfortunately, measuring inulin clearance is cumbersome and expensive: trained personnel are

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00090-2

required to infuse inulin in order to achieve a prolonged, steady-state plasma concentration and for obtaining precisely timed urine collection.[8,9] In addition, the measurement of inulin is difficult.[10] To minimize errors due to retained urine in the bladder, patients are given a water load and sonography can be used to confirm completeness of bladder emptying. To minimize changes in renal perfusion, patients should remain supine or be seated, standing only to void.[11–13] Despite these precautions, the coefficient of variation of inulin clearance ranges from 5–10 ml/min per 1.73 m^2 in subjects with nearly "normal" GFR values; the variability is higher in patients with CKD.[10] Sources of this error include variation in the steady-state concentration of inulin; since the common practice is to collect urine after two to three hours which may be insufficient time for complete distribution of inulin and hence, produces a degree of variability in the plasma inulin concentration. This is the reason that the inulin clearance calculated from the rate of inulin infusion (mg/min) divided by the plasma inulin concentration consistently exceeds inulin clearance calculated from the urinary excretion. The alternative explanation is that there is an extrarenal clearance of inulin and there is no concurrence why the two means of calculation differ.

To reduce the analytic error due to difficulties in measuring inulin in blood and urine, radiolabeled compounds that are cleared predominantly by glomerular filtration have been used. Generally, these compounds (e.g., 125I-iothalamate) are gamma-emitters so the error from variable quenching of beta-emitting compounds (e.g., 14C-inulin) is minimized. Fortunately, there is concordance between the clearances of inulin and 125I-iothalamate (or other radiolabeled compounds) over a wide range of GFR.[9,13] To avoid the error related to incomplete urine collections, GFR has also been calculated from the plasma disappearance of an injected compound (e.g., radiolabeled compounds or compounds like iothalamate which can be measured by spectrophotometry). This method is based on the assumption that the plasma and renal clearance will be insignificantly different because there is minimal extrarenal clearance of the compound. There are at least two other assumptions: (1) that the plasma clearance is constant when blood is sampled; and (2) the duration of blood sampling must be sufficiently prolonged to ensure that the terminal, steady-state period of monoexponential loss of plasma radioactivity with time is present. The latter requirement is especially important for patients with advanced CKD because hours may be required to reach a constant.[8] In patients with severe CKD, there also may be a small extrarenal clearance (e.g., intestinal secretion) which would not be detected while there can be a delay in distribution of the GFR marker in patients with ascites or edema.

The radionuclide agents most commonly used to assess GFR is Tc-99m-DTPA and ^{125}I-iothalamate in the U.S. and ^{51}Cr-EDTA in Europe. Overall, the correlation of these radionuclide markers and urinary inulin clearance is high ($r > 0.9$ in most published studies) as is the use of nonradioactive iodinated compounds, such as iohexol.[14] In addition, some have advocated estimating the entire plasma disappearance curve from a single plasma sample obtained after only a few hours following injection of a GFR marker. Unfortunately, this technique is decidedly less accurate compared to the multiple sampling techniques, especially when there is renal insufficiency.[8,14–18] Lastly, gamma cameras have been used to estimate GFR from the disappearance of labeled GFR markers but this technique has errors greater than plasma-based techniques (up to 20% error). An advantage of this technique is it can provide an estimate of GFR in individual kidneys.

SERUM CREATININE

A single value of serum creatinine (SCr) is an unreliable estimate of creatinine clearance (or GFR) because it is a function of creatinine production and its clearance by the kidney and extrarenal means. Creatinine production is emphasized because it is directly proportional to lean body mass and hence, a muscular individual will have a higher serum creatinine than one who has lost muscle mass, even though they have the same creatinine clearance (CCr).[19] Three other caveats are important in evaluating GFR from the serum creatinine. First, the rate of creatinine production is not constant, despite the fact that lean body mass does not vary (at least over short periods). In part, this occurs because creatine in meat is converted to creatinine by cooking extensively.[20] Secondly, the kidney not only filters but also secretes creatinine and hence consistently exceeds GFR by a variable amount.[21–23] Third, creatinine is degraded, presumably by bacteria in the gastrointestinal tract. This extrarenal clearance is small and averages 0.04 liters/kg/day. Consequently, it is difficult to detect until renal clearance is depressed. Specifically, creatinine removal by extrarenal creatinine clearance (i.e., a method of clearing the blood that does not depend on excretion by the kidney) affects estimates of creatinine production when SCr rises to ~6 mg/dL. At this level, the amount of creatinine degraded is significant and should be considered in interpretation of estimates of SCr in CKD patients. The amount of creatinine degraded in mg/kg/day can be calculated as 0.042 l/kg/d x serum creatinine in mg/L.[21]

The inaccuracies in estimating GFR from SCr can be compounded by practices in the Clinical Laboratory. If the SCr standards are 1, 4, and 10 mg/dl, the accuracy

TABLE 90.1 Most Commonly Used Creatinine-Based Approximations of GFR

Name of Equation	Formula
Cockcroft-Gault CCr[25]	Men: CCr = [(14-age) × weight (kg)]/ SCr × 72; Women: CCr = ([(14-age) × weight (kg)]/SCr × 72) × 0.85
MDRD Study Equation[26]	GFR (mL/min/1.73 m^2) = 186 × $(S_{cr})^{-1.154}$ × (Age)$^{-0.203}$ × (0.742 if female) × (1.212 if African-American)
IDMS-Traceable MDRD Study Equation[27]	GFR (mL/min/1.73 m^2) = 175 × $(S_{cr})^{-1.154}$ × (Age)$^{-0.203}$ × (0.742 if female) × (1.212 if African American)
CKD-Epidemiology group (CKD-EPI)[28]	GFR (mL/min/1.73 m^2) = 141 × min(Scr/k, 1)^a × max(Scr/k, 1)$^{-1.209}$ × 0.993^{Age} × 1.018 [if female] × 1.159 [if black]
Schwartz Equation[29]	GFR (mL/min/1.73 m^2) = k (Height in cm)/Serum creatinine; k = 0.33 in preemie infants; 0.45 in term infants to 1 year of age; 0.55 in children to 13 years of age and adolescent females; 0.70 in adolescent males

of measuring SCr in the normal range (typically less than 1.2 mg/dl) will be compounded.[24] Variability among clinical laboratories in the calibration of serum creatinine assays introduces another error in GFR estimates especially at high SCr levels. Efforts are underway to institute national standardization of creatinine using values determined by isotope-dilution mass spectrometry (IDMS). Selected equations used to estimate the GFR from SCr yield results that are satisfactory as long as the patient is in the steady state and the SCr exceeds 2 mg/dl[25–29] (Table 90.1; Fig. 90.1). Although it can be clinically useful, the practice of estimating GFR from SCr often introduces a significant degree of inaccuracy.

Performance of the modification of diet in renal disease and Cockcroft-Gault Equations in the estimation of GFR in health and in chronic kidney disease. J Am Soc Nephrol 2005;16:459–466).*

CREATININE CLEARANCE

Since creatinine is secreted by proximal tubule cells, the 24-hour endogenous CCr usually exceeds inulin clearance but with advanced CKD, values of CCr and GFR become numerically closer even though the percentage difference between CCr and GFR increases.[10,22,30,31] Using CCr as an estimate of GFR presents difficulties including the inconvenience of obtaining an accurate 24-hour urine collection. In addition, 24-hour CCr values have a high coefficient of variation: in one study of 119 healthy ambulatory subjects, the coefficient of variation was 26% and others reports that the variability varies from 6% to 22%.[21,22,32] One reason for this variability is the day-to-day differences in creatinine excretion;[20,23,32,33] among hospitalized patients, it varies by at least 10%.[19,25,34] These problems have prompted some investigators to recommend abandoning the 24-hour CCr as an index of CKD

severity.[35] The same caveats apply to calculating the average of the 24-hour creatinine and urea clearances to estimate GFR, even though this average value corresponds closely to inulin clearance.[30]

Another strategy is to measure CCr after giving cimetidine to inhibit creatinine secretion and hence, improve the estimate of GFR. Generally, 1.2 g of cimetidine completely suppresses creatinine secretion and lower doses yield incomplete blockade. Reportedly, with water loading and carefully timed urine collections, the cimetidine-adjusted CCr procedure yields values that have a coefficient of variation of approximately 8% in patients with GFR values ranging from 12 to 150 ml/min.[36] Although this technique avoids using radioactive markers, it does require trained personnel to improve the accuracy of urine and blood collections.

FORMULAS FOR ESTIMATNG GFR

Cockcroft-Gault Formula

Frustration with the variability of the 24-hour CCr has led to the widespread practice of estimating CCr from SCr. The equations rely on an estimated daily rate of creatinine production (and hence, excretion in the steady state). The widely used Cockcroft-Gault formula (Table 90.1) is based on a value of creatinine production form the age, weight, and gender of the patient. However, it was derived from results obtained in "normal, hospitalized" patients, and hence, may not be appropriate for patients with CKD.[25,37] It also does not include a value for extrarenal clearance (see above) although for SCr values below 6 mg/dL, this variable has a minimal impact on the estimates of creatinine production. Creatinine production in milligrams per kilograms per day has also been estimated as 28−0.2 A, and for women, as 23.8−0.17 A where A is the age of the subject in years.[25,37] Besides using these equations to estimate CCr and hence, GFR, some investigators have calculated creatinine production as a means of estimating loss of muscle mass. Since there are no independent means of evaluating muscle mass, the reliability of this method is unknown. Regardless, creatinine production in mg/kg/day in men can be predicted as $(28-0.2A)+(0.04\times SCr\times 10)$ and for women, as $(23.8-0.17\times SCr\times 10)$. Using these formulas, the measured 24-hour CCr of uremic adults with stable serum creatinine values above 8 mg/dl was estimated to within 1.5 ml/min.[37] It is important to recognize the assumptions underlying these estimates (and those accompanying the Cockcroft-Gault equation): they were derived from a homogenous cohort of predominantly Caucasian males without kidney disease and may not be appropriate for individuals of other races or groups. This shortcoming was uncovered when the MDRD formulas were studied in patients in China and Japan. Secondly, the Cockroft and Gault equation can systematically overestimate the GFR because of tubular secretion of creatinine.

MDRD Formula

The Modification of Diet in Renal Disease (MDRD) Study was a multicenter, randomized, controlled trial to evaluate the effectiveness of dietary protein restriction plus strict blood pressure control on the progression of renal insufficiency. The outcome was based on measurements of GFR estimated from urinary clearances of ^{125}I-iothalamate. Many other variables were collected (e.g., age, gender, weight, serum albumin, serum creatinine, etc.) and used to develop equations that predicted the measured ^{125}I-iothalamate clearance.[38] The initial MDRD equation was found to yield a correlation of $r^2 = 91\%$ (Table 90.1; Eq. 90.1). In this equation, SUN is serum urea nitrogen and UUN is urine urea nitrogen. A revised MDRD equation (Table 90.1; Eq. 90.2) is based on demographic assessments and serum variables only (yielding a maximal R2 of 90.3%). The most widely used modified MDRD equation was derived to avoid including serum values of albumin and urea nitrogen (Table 90.1; Eq. 90.3). The latter equation has almost the same predictive ability and its use is fully supported by the National Kidney Disease Education Program (NKDEP) of the National Institutes of Health (NIH), the National Kidney Foundation (NKF), and the American Society of Nephrology (ASN). In fact, it is widely used as a means of estimating the severity of kidney disease based on a conclusion that patients with an estimated GFR below 60 ml/min/1.73 m^2 have a high risk of progressive CKD and should be treated to postpone or avoid ESRD.

There are caveats associated with using the MDRD equation: firstly, the equations were derived from results of measurements in only two ethnic groups, Caucasian and African Americans. Subsequent reports indicate that the equation does not accurately estimate GFR in Chinese, Japanese and Brazilian patients.[39−42] In short, the ability of these equations to predict an individual's GFR from SCr, etc. in other races/ethnicities will introduce errors. Furthermore, a recent analysis uncovered that measurements of the urinary clearance of ^{125}I-iothalamate (the reference GFR in the MDRD Study) had stable average values, but substantial variability across visits.[43] Although it is known that GFR in individuals varies throughout the day and that repeated measures of GFR may better reflect an individual's true GFR, there is inherent variability in GFR

measured using iothalamate. This analysis points to another difficulty in interpreting GFR values and the severity of kidney disease based on SCr plus other factors present in an individual patient. An important factor is the age of the patient because those of >65−70 years comprised a small fraction of the MDRD study group and very few of ≥80 years were studied. It is critical to recognize that aged patients may have a depressed GFR even when SCr is within reference range. Regardless, the MDRD equation overestimates eGFR in the elderly. Besides the inaccuracies associated with different ethnic groups, there are serious deficiencies in the predictive value of these equations in people with obesity and normal kidney function.[39,44,476]

In a study of adults from the Netherlands, Vervoort et al. compared the inulin clearance of 46 controls and 46 uncomplicated diabetic patients with predicted GFRs based on the MDRD and Cockcroft-Gault equations.[45] The difference between predicted values and the measured GFR was significant (the Cockcroft-Gault formula had a 9.0 ml/min/1.73 m^2 difference while the MDRD equation had a 10.7 ml/min/1.73 m^2 difference from the measured inulin clearance). Secondly, Lin et al. found that the MDRD equation is decidedly less accurate in subjects without kidney disease when compared to GFR measured as 99mTc clearance; the MDRD equation systematically underestimated GFR while the Cockcroft-Gault formula overestimated the GFR. The Schwartz formula is commonly used to estimate GFR in children. Other equations used in estimating the GFR in CKD patients are listed in Table 90.1.

In summary, the GFR can be predicted from formulas that are based on SCr and characteristics of a patient with CKD.[24] The prediction equations exhibit errors and must be used with an understanding of the sources of variability, including the influence of obesity, race and age. Specifically, no single equation will reproducibly predict the GFR of an individual patient and this is especially true for subjects with minimal loss of kidney function or aged patients. Presumably, standardization of the measurement of creatinine and the use of a range of "standards" in a creatinine assay will be associated with improvements in the accuracy of the equations. But, it also is clear that GFR varies from hour to hour and is not constant day to day. These shortcomings do not invalidate the calculations because the estimation of GFR provides a means of identifying patients at risk for developing increasingly severe renal insufficiency and a method for detecting differences in rates of loss of kidney function (see below).

CKD-EPI Formula

The estimated GFR based on the MDRD equation has increased the awareness of CKD in both physicians and patients. There is, however, concern about assigning a CKD diagnosis if there is no kidney disease.[46] The concern has prompted The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) to derive another designed to improve the detection of CKD in adults with early/moderate kidney disease.[28] This new equation (Table 90.1) is based on a method of measuring creatinine that is traceable to standards established by isotope dilution mass spectroscopy (IDMS) and in patients with normal or mildly decreased GFR, it appears to yield a more accurate estimate of GFR compared to the MDRD Study equation. Importantly, when the CKD-EPI equation was used to analyze the NHANES database, it was concluded that the prevalence of CKD in U.S. adults was 11.5% compared to the estimate of 13.1% derived with the MDRD Study equation. Although this difference may seem small, the number of individuals predicted to have CKD would change from roughly 26 down to 23 million and thus may have significant public health implications.

Estimation of GFR from Cystatin C Concentration

Cystatin C is a low molecular-weight protein (13,000 Da) that is produced by all nucleated cells and acts to inhibit cysteine proteases. It has been used as an estimate of the severity of CKD because a high level of cystatin C is associated cardiovascular disease and may even be more closely associated than SCr.[47−49] As a marker of GFR, however, it has shortcomings. A factor that estimates glomerular filtration should be produced as a constant rate, should not be removed by organs other than the kidney, and should be measured by a reliable method. Cystatin C fulfills some but not all of these requirements. Reportedly, the production rate of cystatin C is unaffected by age, gender, and muscle mass, while creatinine production is affected by all three.[50] However, cystatin C production was not estimated using standard techniques but rather indirect estimates of production. Moreover, reports indicate that smoking, evidence of inflammation, and catabolic conditions affect cystatin C production.[50,51] Second, although cystatin C is filtered through the glomerulus and is reabsorbed and catabolized by the proximal tubule,[52] it is not known if other epithelial cells absorb and degrade cystatin C; it is evident that the extrarenal clearance of cystatin C is substantial.[50] Third, cystatin C measurements employ an antibody-based technique, and there is controversy concerning which method is "most accurate."[47] Conclusions about the impact of CKD as assessed by serum cystatin C in patients is principally based on the conclusion that measured GFR

has a higher correlation coefficient with serum cystatin C compared to GFR estimated from the reciprocal of serum creatinine.[47,48] For example, in adults over 65 years of age living in four different areas in the US, it was found that in a comparison with serum creatinine, a high serum cystatin C level was correlated more closely with the number of deaths and cardiovascular events (stroke, myocardial infarction and congestive heart failure) occurring seven years later.[53] Although it is known that CKD is associated with cardiovascular disease, the association between serum cystatin C and stroke, myocardial infarction and congestive heart failure, could be related to factors affecting cystatin C production and elimination that are independent of kidney function since there was no information about events and treatments occurring in the seven-year interval following the initial, baseline measurement. Thus, serum levels of cystatin C may be a harbinger of future adverse events but whether this can be attributed to CKD is unsettled. A related question is whether cystatin C accurately reflects the rate of loss of kidney function in patients with progressive renal insufficiency. Some have reported that serum cystatin C does reflect changes in GFR,[54] but others conclude that the reciprocal of serum cystatin C is inferior or that there is no statistical difference between the analysis of changes in reciprocal serum creatinine and serum cystatin C.[55] The association between serum cystatin C and GFR is more complex during pregnancy[56] and in infants and children.[55,57–59] It was proposed that serum cystatin C may have a higher sensitivity for detecting a low GFR compared to serum creatinine in patients with cirrhosis but in patients with chronic liver disease, neither serum cystatin C nor creatinine reliably predicts the GFR.[60] The role of cystatin C continues to evolve but to date, it lacks evidence for being a precise measure of kidney function.

Estimation of GFR from Other Substances

β-2-microglobulin is another endogenous protein that undergoes glomerular filtration plus reabsorption and metabolism by the proximal tubule. Like serum cystatin C, the serum β-2 microglobulin has been suggested to be more sensitive to an early decrease in GFR compared to serum creatinine.[61] However, the influence of extrarenal clearance and constant production are unsettled and tubule degradation of the protein rises when urine is acidic, so patients should be given sodium bicarbonate to raise the urine pH above 7 if β-2 microglobulin is used to monitor kidney function. Even less fully investigated markers include beta-trace protein[62] and tryptophan glycoconjugate[63] and additional experiments are needed before they can be recommended as a method of monitoring kidney function.

In conclusion, the most accurate estimate of kidney function is the measurement of GFR using inulin, radionucleotide-labelled compounds, or iodinated compounds like iodothalamate. Results of studies from large groups of patients indicate that the MDRD equation can be used but it is important to remember its limitations. They include variations that are associated with different ages, races, etc. as well as those associated with the measurement of serum creatinine. Other strategies for estimating the degree of dysfunction of the kidney include the CCr that has been estimated from predictions of creatinine production and serum cystatin C. The latter has been used to evaluate the risks of adverse outcomes of kidney disease, including cardiovascular disease. But, there are problems with using serum cystatin C as an estimate of kidney function since its production depends on several factors and there is the potential for extrarenal clearance of cystatin C. To screen populations or even individuals for the presence of CKD, the MDRD equation has been most widely evaluated and provides a reasonable approximation. During long-term followup evaluations, it should be remembered that serum creatinine is the major factor that changes with renal insufficiency so determining the rate of loss of estimated GFR with time is subject to the same influences as evaluating changes in the reciprocal of serum creatinine with time (see below). In diagnosing CKD, a combination of techniques along with sound judgment about the influence of variables such as age, gender, diet, etc. should be employed since CKD is a progressive disease associated with increased mortality.

EPIDEMIOLOGY OF CHRONIC KIDNEY DISEASE

End-Stage Renal Disease

The epidemiology of ESRD is based largely on information from the United States Renal Data System (USRDS), a geographically comprehensive, population-based ESRD registry that collects information from all Medicare-eligible patients (~90% of all incident U.S. patients) at the start of dialysis, and at death or transplantation. Despite the robust information contained in the USRDS, it should be remembered that there are legitimate concerns about the accuracy of the primary cause of kidney disease, comorbid conditions, and the causes of death present in the yearly report. The concerns arise because diagnoses are left to the judgment of the treating nephrologist who often does not have a tissue diagnosis. For example, few ESRD patients who

have hypertension listed as the cause of kidney failure have in fact, satisfied uniform diagnostic criteria for this diagnosis making it possible that other diseases led to ESRD. There are similar concerns about the accuracy of comorbid conditions[64] and causes of death.[65]

Undeniably, USRDS data indicate there has been substantial growth in the number of patients enrolled in the Medicare-supported ESRD program: there were roughly 10,000 beneficiaries in 1973 and over 86,000 a decade later but by 2009, the prevalence of ESRD in the US had grown to approximately 527,000. Moreover, in 1980, the incidence rate for ESRD compiled after adjustment for age, race/ethnicity and gender was 76 cases per million (18,000 patients). In 2002, the rate was 338 cases per million (102,000 patients) but by 2007, the rate was 361 cases per million (110,000 patients).[66] The seemingly relentless increase in the incidence of ESRD has declined from 8% per year in 1980 to below 1.5% per year in the years after 2000. This encouraging change may represent improvements in preventive care or some unidentified factors.

In the 2009 USRDS report, the primary cause of ESRD was diabetes, afflicting 54% of new patients, yielding an incidence rate of 155 per million population. In contrast, the incidence of ESRD from hypertension or other kidney diseases has not increased. The diabetes-associated incidence rate is 36% higher than a decade ago and it parallels the rising prevalence of diabetes in the general population: increasing from 5% in the 1988–1994 era to 7.6% during 2003–2006. The increase in diabetes and CKD is especially prevalent in African and Native American populations. Besides diabetes, other ESRD-associated epidemiologically relevant factors include aging of the dialysis patients. From 1999–2009, the prevalent ESRD population of 20–40 years of age has risen 9.7%. Among those 40–60 year of age, the prevalence had risen 54% and 61% for those beyond 70 years. Besides age, the incidence of ESRD is clearly racial-dependent; in 2007, the incident rates in African Americans and Native Americans were 3.7 and 1.8 times greater, respectively, than the rate in whites while the rate in the Hispanic population is 1.5 times higher than that of non-Hispanics. Among African Americans, the rate of new ESRD cases in 2007 reached 998 per million population or 3.7 times greater than the rate of 273 among whites. Likewise, in 2007, Hispanic patients had an incidence rate of 508 per million population (1.5 times greater than in non-Hispanic patients). Thus, the annual increase in incidence ESRD may be leveling but these racial factors may still increase the number of ESRD patients because of demographic trends; similar factors present in developing countries may also be active and increase the number of ESRD patients.[67]

Definition of CKD

Guidelines from the U.S. National Kidney Foundation (NKF) have led to a widely adopted framework for defining CKD.[68] CKD is a nonspecific term that does not indicate the cause of kidney disease but it is useful for improving communications with investigators, practitioners and the public. CKD is defined as kidney injury and/or impaired kidney function lasting 3 or more months.[69] Kidney injury is signified by the presence of microalbuminuria or proteinuria, abnormalities in the urinary sediment (RBC, RBC casts, WBC, WBC casts, tubular cells, cellular casts, granular casts, oval fat bodies, fatty casts, or free fat) and/or abnormal radiographic evidence and of course, evidence from kidney biopsies. CKD is categorized into five stages according to the level of the estimated GFR (see Table 90.2). All patients with CKD are increased cardiovascular risk, but those with an estimated GFR ≤ 60 ml/min/1.73 m^2 are also at higher risk for a progressive decline in kidney function and as GFR declines, pathophysiologic changes increase in complexity and management becomes more varied and increasingly specialized.[69] The NKF guidelines attempted to tie the stages of CKD to specific clinical abnormalities and suggested treatment goals. In Stages 1 and 2, efforts are needed to adjust dietary factors, control blood pressure and glycemia. It is also suggested that inhibitors of the renin-angiotensin-aldosterone system (RAAS) should be used to conserve kidney function and reduce the risk of death and cardiovascular disease. In Stage 3 CKD, efforts are increased to detect and manage anemia and renal bone disease while the diet is controlled to prevent the accumulation of unexcreted waste products. These products include the myriad of compounds associated with the metabolism of a high protein diet (e.g., guanidines, middle molecules, etc.) and ions (sodium, acid, phosphates, etc.) but moderate to severe kidney disease, dietary adjustments are needed because the damaged kidney does not eliminate these metabolites. In Stage 4 CKD, attention to the same

TABLE 90.2 National Kidney Foundation Staging of CKD

Stage	Description	GFR (ml/min)
1	Kidney damage (marked by proteinuria or abnormal urine sediment)	> = 90
2	Early kidney disease	60–89
3	Moderate kidney disease	30–59
4	Advanced kidney disease	15–29
5	Established renal failure	<15 or dialysis

topics is needed and the patient should be introduced to options for treating ESRD; if hemodialysis is chosen, the patient should be evaluated for placement of a vascular access. At this stage, it is especially important to adjust medication doses for the loss of kidney function. In Stage 5 CKD, the pathophysiologic and metabolic functions become more difficult to manage and the clinician will need special training and skills to maximize therapy. The importance of managing the complications of advanced CKD is emphasized because the alternative option of initiating dialysis "early" (i.e., before uremic symptoms are present) has been tested repeatedly and found to be wanting in terms of improving mortality/morbidity.[2,4–6]

Unfortunately, many patients are unaware of the presence of CKD and the factors needed to treat CKD appropriately. In one study, patient awareness of CKD was only 22% of patients in Stage 3 and 44.5% of those with Stage 4 CKD (these dismal percentages were independent of race/ethnicity, gender, or age.[70,71]) Undoubtedly, the lack of awareness contributes to the development of complications of CKD in those with advanced CKD including anemia, bone disease, loss of muscle mass, abnormalities in serum electrolytes, etc.[7,72] Similar shortcomings of managing CKD are present in primary care practices and Nephrology clinics.[73,74] Even when it is recognized that a therapy target has not been met, clinicians can fail to change management, a behavior present in other chronic conditions and known as "clinical inertia".[74]

Epidemiology of CKD

Population-based studies of epidemiologic factors and CKD are largely based on the National Health and Nutrition Survey (NHANES). This survey includes results from representative samples of the U.S. population that were collected by the National Center for Health Statistics of the Centers for Disease Control and Prevention.[75–77] For example, the prevalence of Stages 1 to 4 CKD estimated from the NHANES data that was collected between1999 to 2004 was found to be 13.1% (approximately, 26.3 million people) and varies according to the stage of CKD.[78] As expected from information about the epidemiology of patients with ESRD (see above), the prevalence of CKD is greater among diabetic subjects vs patients without diabetes (40.2% vs 15.4%). Data from the NHANES III survey of those in different stages of CKD also identify significant racial and gender discrepancies. Based on analyses of serum creatinine values, evidence from both diabetic and nondiabetic subjects reveal that a GFR below 60 ml/min/1.73 m^2 was present in 5% of non-Hispanic whites, 3.4% of non-Hispanic blacks, 1% of Mexican Americans, and 2.2% of other race/ethnic groups.[76] Among black and white NHANES III participants with a comparable prevalence of CKD, it was estimated that the risk of developing ESRD for African Americans was fivefold greater compared to other populations even when results were controlled for differences in age, gender, and the presence of diabetes. Analyses of this database revealed that the prevalence of proteinuria in the U.S. population aged 20 years and older was present in those without impaired kidney function.[76] In men of this age group, a random albumin/creatinine ratio of 17 to 250 mg/g (or 25 to 355 mg/g for women was) was present in 10.5% of the population; this was also present in 63.2% of the people on reexamination two months later. Overt proteinuria (an albumin/creatinine ratio >250 mg/g for men and 355 mg/g for women was found in 1.1% of the U.S. population, including 0.5% of individuals with an estimated GFR >90 ml/min/1.73 m^2, 1.2% of whom had an estimated GFR between 60 and 89 ml/min/1.73 m^2, and 7.2% of those with a GFR between 15 and 30 ml/min/1.73 m^2. Evaluation of the NHANES III data indicated that increasing age affected the prevalence of proteinuria (urine albumin/creatinine ratio) and diabetes was the most frequently associated diagnosis while hypertension was the second most common abnormality.[76] The staging of CKD also affected proteinuria since nonhypertensive, nondiabetic people with an estimated GFR between 30 and 60 ml/min/1.73 m^2 and aged 60 to 79 years had a prevalence of albuminuria of 20.6% compared to 14.1% among individuals with an estimated GFR >60 ml/min/1.73 m^2.

High-Risk Populations

Patients with hypertension, diabetes mellitus, and cardiovascular disease, and family members of patients with ESRD are at high risk of developing CKD (Fig. 90.2). Screening and health promotion can be cost-effective in such high-risk groups.[79]

Hypertension. From the NHANES III results, the serum creatinine increased as the severity of hypertension rose.[80–82] It is still not settled whether nonmalignant hypertension is a primary cause of ESRD or whether hypertension is caused by pre-existing kidney disease.[83]

Diabetes. The USRDS has identified diabetes as the most common cause of ESRD, accounting for nearly 54% of all new cases of ESRD (USRDS ADR 2009). In a population-based study of Rochester, Minnesota, the risk of developing diabetic nephropathy among individuals with type 2 diabetes mellitus but no kidney disease, the incidence was 133 per 100,000 person-years.[84] The cumulative incidence of diabetic nephropathy was similar for type 1 and type 2 diabetes mellitus: the 20-year cumulative risks were 27% for type 2 and 28% for type diabetes mellitus.[85] Although there seems to

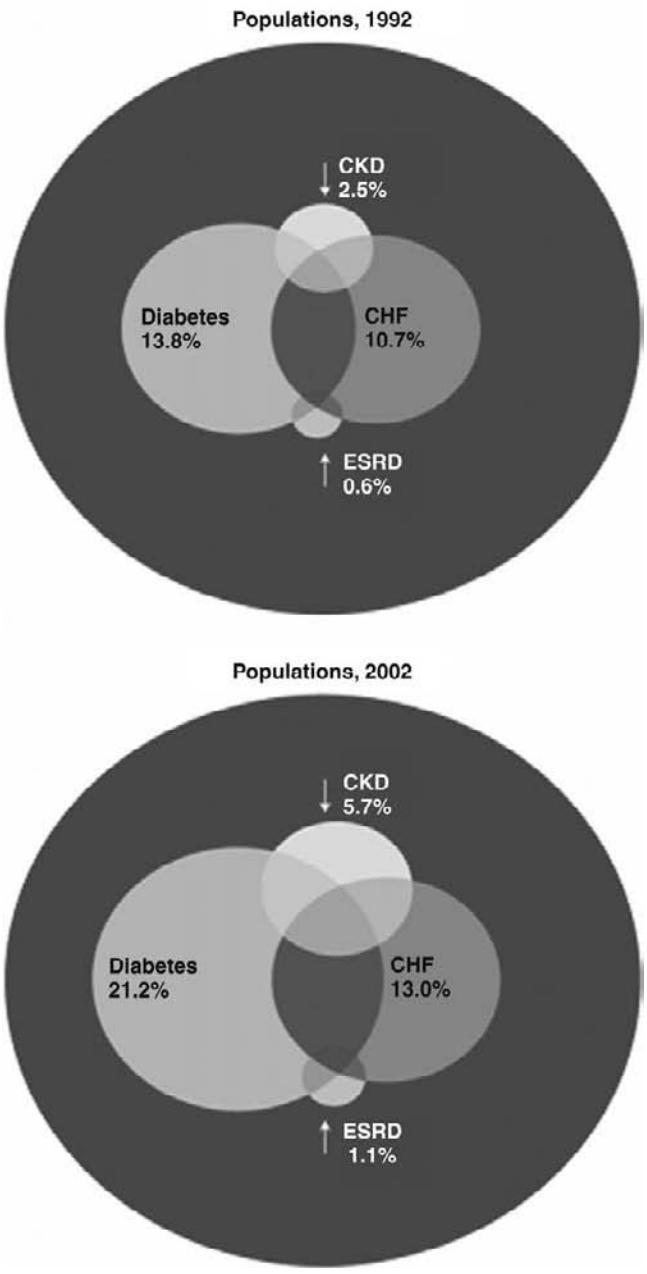

FIGURE 90.2 Distribution of patient counts in the CKD, CHF, DM, and ESRD populations. Populations were estimated from the 5% Medicare sample, and include patients surviving the entire cohort year (1992, 2002) with Medicare as the primary payor, plus period-prevalent end-stage renal disease (ESRD) patients for 1993 and 2003. Diagnoses were determined from claims in 1992 and 2002. Patients with ESRD in the 5% sample were excluded, as they are counted in the ESRD population. *(From United States Renal Data System. 2005 annual data report: atlas of end-stage renal disease in the United States. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2005.)*

be a declining incidence of diabetic nephropathy among individuals with type 1 diabetes mellitus (attributable to improved detection and care)[86,87] but not for those with type 2 diabetes.

Cardiovascular Disease. CKD is associated with an increased risk of cardiovascular disease and adverse outcomes from it.[88] Reports from more than 28 study populations reveal that cardiovascular disease patients had evidence of impaired kidney function; the average prevalence was 29.9%.[88] The Valsartan in Acute Myocardial Infarction Trial (VALIANT) trial of participants evaluated from 0.5 to 12 days following an acute myocardial infarction complicated by heart failure and/or left ventricular dysfunction revealed that 11.3% had an estimated GFR < 45 ml/min/1.73 m^2 and the overall prevalence of impaired kidney function was 33.5%.[89] The baseline characteristics of the 1,120,295 participants in the Kaiser Permanente Renal Registry in Northern California aged 20 years and older revealed that the prevalence of an estimated GFR below 60 ml/min/1.73 m^2 was 6.4% of subjects with a history of diabetes mellitus, 7.5% of those with hypertension, 10.5% of those with coronary heart disease, and 12.5% of those with cerebrovascular disease.[90] Other studies have essentially confirmed these associations.[91]

Family History of ESRD. Individuals with a family history of ESRD have an increased prevalence of hypertension, diabetes, and CKD. Bergman et al. screened the first-degree relatives of patients with hypertensive ESRD and found that 65% of those in participating families had evidence of kidney disease, including those with a serum creatinine of ≥ 1.4 mg/dL.[92] The same relationships occur in Canada.[93]

Clinical Outcomes of CKD

Mortality. An analysis of nearly 28,000 health plan members with CKD defined as estimated GFR values below 90 ml/min per 1.73 m^2 on two occasions separated by at least 90 days revealed that during the ensuing five years, the cumulative risk of ESRD for CKD Stages 2, 3, and 4 were, respectively, 1.1%, 1.3%, and 19.9%, and the risk of death was 19.5%, 24.3%, and 45.7%.[94] In another analysis of a large sample of patients, Go et al. found that the risk of all-cause mortality increased with decreasing GFR.[95] In those with an estimated GFR of ≥ 60 ml/min per 1.73 m^2 there were 0.76 deaths per 100 person-years but 4.76 deaths per 100 person-years when the estimated GFR was 30–44 ml/min per 1.73 m^2 and 11.36 deaths per 100 person-years for individuals with a GFR 15–29 ml/min per 1.73 m^2.

CVD Disease. Pre-existing cardiovascular disease in CKD patients increases the risk of morbidity and mortality.[96] In a screening of 185 publications involving more than 550,000 subjects, 96% concluded there is a positive relationship between the presence of cardiovascular disease and CKD.[97] Specifically, among

individuals with an estimated GFR of 15–60 ml/min per 1.73 m^2, the rate of myocardial infarction or fatal coronary heart disease was 13.9 per 1000 person-years vs 6.5 per 1000 person-years when the GFR was >60 ml/min per 1.73 m^2.[98]

Natural History of CKD

The most accurate measure of kidney function is a measured GFR but as discussed, this is cumbersome so various equations have been used to estimate the GFR and hence, evaluate the loss of GFR as indicative of lost kidney function. Besides kidney disease, one factor affecting GFR is the decline that occurs with advancing age in many but not all patients. This "renal senescence" was associated a 20–25% decrease in GFR after 60 years of age and as many as two-thirds of normal adults over age 40 years are predicted to have such a decrease in GFR despite the absence of obvious kidney disease;[99] in the remaining third of adults, GFR remains stable.[100] Histologically, aging yields interstitial expansion and glomerular sclerosis and reabsorption. Fortunately, this abnormality rarely progresses to ESRD. In contrast, kidney damage from various diseases leads to manifestations of CKD plus continued loss of function, commonly known as "progression." Notably, progression occurs even when the disease that initially damaged the kidneys is no longer active (e.g., obstructive uropathy or cortical necrosis following obstetric accidents.[101] The rate of progression varies widely as some CKD patients (including those with diabetic nephropathy) do not progress over periods as long as three years.[102,103] Since these reports indicated there was improved control of blood sugar and blood pressure, this could have accounted in part for the improvement in progression. Attention to such factors may have contributed to the lack of progression found in ~15% of patients who participated in the closely monitored Modification of Diet in Renal Disease Study [MDRD], despite having GFR values between 13 and 24 ml/min/1.73 m^2.[104]

Patient-specific characteristics that have been related to the occurrence and progression of kidney disease are shown in Table 90.3.[88,91,105–130] Some of these factors were uncovered in results from the MDRD Study and are expected (e.g., African American race/ethnicity, increased mean arterial blood pressure, baseline urine protein excretion, polycystic kidney disease) while others are not obvious (e.g., lower baseline levels of serum transferrin and HDL cholesterol). The utility of these factors is not obvious although they may serve as a stimulus for clinical trials. Two caveats should be remembered: first, the MDRD Study included a large number of patients with polycystic kidney disease but virtually none with diabetes making it difficult to extend the findings to other populations of CKD patients. Secondly, if risk factors do play an important role in determining the rate of loss of GFR, the implication is that the progression of CKD in individual patients is unpredictable. This is incorrect since the rate of loss of GFR in most patients, including those with diabetes is linear and hence, predictable.

TABLE 90.3 Risk Factors for Chronic Kidney Disease Progression

Older age[105]
Race and ethnicity[106,107]
Dietary protein intake[108,109]
Gender[110]
Lower birth weight[111]

Aldosterone[130]
Sympathetic nervous system activation[475]

Assessment of Rate of Progression of Renal Insufficiency

Before it was recognized that the course of CKD in most individual patients is predictable, the prognosis for CKD patients was estimated from analyses of the average time for patients with similar degrees of CKD to reach the stage requiring dialysis or to reach a predetermined degree of renal insufficiency.[131–133] The breakthrough in identifying that progression of CKD was not chaotic was based on the determination that

individual CKD patients experience a loss of renal function with time is linear, constant and predictable.[134,135] The recognition that individual patients have a characteristic rate of loss of kidney function arose from the finding that the reciprocal of serum creatinine (SCr^{-1}) declines linearly with time in most patients. For example, about 80% of the patients reported by Rutherford et al.[136] or by Coresh et al.[137] had linear slopes in plots of changes in SCr^{-1} with time. The implication of this finding was that GFR declines linearly with time and therefore that creatinine clearance will decline linearly with time. These conclusions were confirmed by Viberti and colleagues who measured GFR sequentially in studies of patients with diabetic nephropathy[138] and by Barsotti and colleagues who measured CCr sequentially in patients with different types of non-diabetic kidney disease.[139] Results from the MDRD Study of patients with non-diabetic kidney diseases confirmed that GFR is lost in a linear fashion with time in larger numbers of patients.[140] In a group of patients with progressive diabetic nephropathy, the SCr^{-1} declined linearly with time as renal insufficiency advanced but the rate varied almost 40-fold[102] ! The conclusion is that individual patients exhibit a specific rate of loss of kidney function and hence, the rate of loss must be determined individually; it can not be assumed that a particular kidney disease has a "characteristic" rate of loss of GFR or CCr or SCr^{-1} with time[22,134,140] (Fig. 90.3). Considering the complexity of CKD, it is not surprising that some patients will have periods in which there are deviations from linearity and a "break-point" in the SCr^{-1} plot with time was reported in as many as 32% of 77 patients.[141] The clinical relevance of finding such a breakpoint was not reported, but is likely associated with new insults or acute perturbations in kidney function. In contrast, Coresh et al. found significant breakpoints in only 19% of a series of 67 patients who had sequential measurements that were made until ESRD was required.[137] There have been few reports comparing the rates of progression by measuring GFR and SCr^{-1} in the same patient. In one such study, the rate of loss of GFR in 17 selected patients was compared to changes in their plots of SCr^{-1} with time, four had progressive loss of SCr^{-1} but stable GFR values.[142] But, two of these four patients had to begin dialysis and one actually experienced a sharp increase in GFR while SCr^{-1} remained stable. When rates of progression were evaluated during different treatment periods, 9 of 22 periods exhibited a statistical difference between the slopes of estimated SCr^{-1} and DTPA clearance. In two of these periods, GFR remained stable while changes in the SCr^{-1} values of clearance suggested progression and in two other periods, the estimated SCr^{-1} method suggested faster progression. These results are difficult

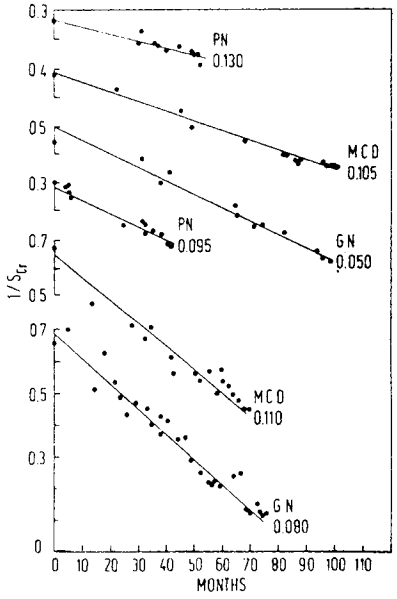

FIGURE 90.3 Rate of loss of residual renal function with time in patients with pyelonephritis (PN), medullary cystic disease (MCD), and glomerulonephritis (GN), estimated as changes in the reciprocal of serum creatinine concentration ($1/S_{cr}$). The unit divisions of the ordinate have been changed so that the curves can be displayed on the same plot numbers that refer to final measured value for $1/S_{cr}$. *(With permission from Mitch WE, Buffington GA, Lemann J, et al. A simple method of estimating progression of chronic renal failure.* Lancet *1976;2:1326–1328.)*

to interpret but as with any test, caution must be used when interpreting results since in 4 of 22 periods, the SCr^{-1} estimate yielded an inappropriate conclusion based on the measured GFR. A practical implication of these results would be that the physician caring for a CKD patients should investigate why the rate of loss of kidney function (GFR, CCr or SCr^{-1}) deviates from linearity.

In estimating the rate of progression, it is suggested that GFR should be measured at least four times over two or more years.[143] This can be cumbersome because of the costs and complexities of measuring GFR. To circumvent this difficulty in trials directed at evaluating the effectiveness of therapy, another outcome has been used, the time required for serum creatinine to double. Unless large numbers of patients are studied, this method can be misleading because the rate of loss of GFR varies so widely even in patients with the same disease.[102]

For clinical evaluations, the SCr^{-1} vs time plot is a simple alternative of obtaining repetitive GFR measurements. Alternatively, the modified MDRD equation (see above) is widely recommended as a means of monitoring the course of renal insufficiency; inspection of this equation reveals that it is essentially a plot of relatively constant values (ethnicity, age, gender)

multiplied by SCr^{-1}. The reasons for the popularity of these methods are first, the measurement of serum creatinine is being standardized in most clinical laboratories, prior values are widely available and the values are reproducible (the day-to-day coefficient of variation in CKD patients with relatively advanced CKD is only 6.5%[144]). Second, SCr^{-1} (like GFR and CCr) declines linearly with time in most patients with progressive CKD.[22,134,137] Another alternative is to monitor changes in serum cystatin C but there are interpretative problems with this approach.

Do changes in SCr^{-1} with time spontaneously slow as GFR falls to low levels? Analyses of small groups of patients have not settled this question. There have been reports of either acceleration or slowing of changes in SCr^{-1} in patients with advanced CKD.[145,146] Results from the AASK (African-American Study of Kidney Disease) trial suggested that patients with hypertensive nephrosclerosis had accelerated loss of GFR but the interpretation is complicated because the rapid loss of GFR was largely confined to those treated with ramipril but not in those treated with amlodipine or metoprolol.[147] Thus, certain treatments or possibly changes in processes causing nephrosclerosis may indeed, change the loss rate of loss of GFR so it is no longer constant. Besides these factors, results from the AASK trial also uncovered an accelerated loss of GFR in those patients assigned to a mean blood pressure goal of 102 mm Hg at least when compared to MDRD study patients who were enrolled with a similar blood pressure goal and no dietary restriction.[140] These variations in response seem to point to a difference characteristics of the patient population (e.g., possibly genetic) or in the pathophysiology of nephrosclerosis. For example, it was recently reported that the rate of loss of GFR in participants in the AASK trial was not improved by lowering the blood pressure to $\leq 140/80$.[148,149] The caveat is that patients with higher degrees of proteinuria might have a more beneficial response.

There are other reasons why creatinine-based methods (SCr^{-1}, estimated CCr, or MDRD GFR) could yield an inaccurate estimate of the rate of loss of residual renal function. First, it is well known that creatinine secretion accounts for differences between CCr and GFR and any method of estimating CCr method will not correct for secretion.[31,146] Second, as discussed earlier, creatinine production exceeds creatinine excretion because there is extrarenal elimination of creatinine (presumably degradation by gastrointestinal bacteria[150]). Fortunately, there is a method for correcting CCr for the creatinine extrarenal clearance because there is evidence that the extrarenal clearance is constant.[37,51] Using a constant value of 0.04 liters/kg/day for the extrarenal clearance, it can be shown that the linear decline in CCr of patients with CKD is compatible with a linear decline in the SCr^{-1}.[22,139] It should be pointed out, however, that it is not known whether extrarenal CCr is constant throughout the course of CKD. A more important confounder is the problem of dietary factors, especially variations in the amount of meat eaten. Meat, like other muscle, contains creatine, so varying meat in the diet varies the size of the creatine pool. Cooking meat converts a portion of the creatine to creatinine, so the larger creatine pool will increase the amount of creatinine that is excreted.[20] In contrast, an abrupt reduction in meat intake decreases the creatine and creatinine pools, and this will lower serum creatinine at least as long as CCr is constant. On the other hand, if GFR falls, then serum creatinine will rise. When the meat content of the diet is relatively constant, any change induced by varying dietary meat and hence, creatine intake, is at best short-lived because the conversion of creatine to creatinine in muscle (and other cells) is quite slow; the turnover of the endogenous creatine pool averages only 1.7% per day.[20,151,152] Thus, a new steady state of creatinine production after a sustained change in meat intake will occur in approximately four months.[22,37] In practical terms, if dietary protein is reduced to any extent, a change in serum creatinine should not be used as an indication that the loss of GFR has been identified until at least four months have passed. Finally, there is the problem that raising dietary protein acutely increases GFR and, hence, CCr.[153] This alone has virtually no effect on changes in SCr−1 but will affect GFR if the measurement occurs shortly after a meal.[154] On the other hand, results from the MDRD indicate that a prolonged decrease in dietary protein (or blood pressure) can be associated with a sustained fall in GFR that is due to hemodynamic factors. This decrease in GFR does not signify a loss of kidney function because GFR rises following resumption of a higher protein intake.[140] In summary, changes in serum creatinine alone should be discarded as a method of estimating the GFR, and hence, the degree of kidney damage. For an individual patient, however, changes in the slope of SCr^{-1} can be used to screen and detect patients who are progressing, or determine if there has been a sudden change in clinical status. Ideally, changes in SCr−1 should not be used to determine if a new therapy slows progression; changes in GFR should be measured more accurately.

The emphasis should be on evaluating the course of renal insufficiency in an individual patient. It is well known that variation of rates of progression among patients is high: Jones et al.[102] reported that patients with diabetic nephropathy had rates varying as much as 20-fold, and Walser[143] found that changes in 99mTc-DTPA clearance in 34 patients with different causes of CKD varied from −0.96 to +0.64 ml/min/month.

According to these results, about 15% of CKD patients may not show any progression (at least during the period of observation). These results emphasize why clinical trials with no attempt to initially screen patients to exclude those with no evidence of progressive loss of GFR will be at risk of studying an inadequate number of subjects and thereby leading to incorrect conclusions.

PATHOPHYSIOLOGY OF CKD

The pathophysiology of CKD is varied depending on underlying injury and the response to injury is complex involving interplay of hemodynamic and biochemical processes that affect the glomerular capillaries and tubulointerstitium. In this section we will focus largely on common pathways of renal injury and waste products of protein metabolism, which are among the most important determinants of progression and uremia. To retain the larger view of the pathophysiology generated by loss of renal function, we will discuss the role of other uremic toxins, including hormonal changes. We will touch briefly on other crucial factors such as sodium and 1,25 hydroxyvitamin D3 affecting the development of CKD; these are discussed in other chapters.

Hyperfiltration Theory

Thomas Addis was a pioneering nephrologist who came to Stanford University in the first half of the twentieth century. He introduced and developed the concept of osmotic work by progressively nephrectomizing rats to varying degrees, feeding them diets with varying amounts of protein. He used renal ablation (1 and 5/6 nephrectomy) as a model of kidney disease and showed that when he progressive reduced the kidney volume in rats, the kidney hypertrophied.[155] He observed that the more renal mass that was removed the greater the remnant kidney grew in relation. He hypothesized the kidneys hypertrophied because of the increased osmotic work that the remnant kidney had to undertake. His work led to speculation about the mechanism by which protein restriction preserved renal function and inspired further work in this field. The question reduced renal mass was revived by Brenner, Deen and others who found a way to study the hemodynamic changes that take place in animal models of CKD.[156] The discovery of Munich-Wistar rats, a unique breed that had superficial glomeruli that was accessible using micropuncture techniques, was especially useful in characterizing the pathophysiology of CKD. Investigators found that characteristic hemodynamic changes take place in the glomerular capillaries of nephrectomized rats, namely increased glomerular plasma flow and increased hydraulic pressure, which accounted for the observed rise in single nephron GFR (SNGFR). This increase in glomerular capillary hydraulic pressure (glomerular hypertension) causes injury, which results in progressive glomerulosclerosis. Investigators found that glomerular hypertension was result of renal adaptation of nephron loss (due to any cause) and that a final common pathway resulting in progressive nephron loss occurred once glomerular number was reduced below a critical threshold.[157,158] The hyperfiltration theory is generally accepted as the cause for progressive renal failure in CKD and therapies targeting glomerular hypertension (e.g., ACE inhibitors) as an intervention to retard progression have been pursued with success.

Hemodynamic Mechanisms of Progression

Systemic hypertension. Arterial hypertension arises in the course of most cases of chronic renal insufficiency, and generally increases as renal damage progresses. Most but not all clinical studies suggest that blood pressure control can sharply reduce the rate of loss of renal function and all studies demonstrate important reductions in cardiovascular mortality. The role of sodium intake on blood pressure and mechanisms of hypertension-related renal damage are discussed in detail elsewhere (Chapter 88), but it is important to recognize the primary role that sodium retention plays in the hypertension seen in CKD. While population studies strongly suggest increases in blood pressure when sodium intake is increased, healthy subjects do not invariably increase blood pressure and GFR.[159] However, an increase in salt intake not only raises blood pressure in humans with mild CKD but also increases GFR (see below). In addition to sodium, dietary influences on blood pressure include protein, calcium, potassium, and trace minerals, and the complex interaction of these factors explains the blood pressure reduction with the Dietary Approaches in Systolic Hypertension (DASH) diet.[160]

In experimental kidney disease, there is an association between an increase in dietary protein and a higher blood pressure, and lowering dietary protein has been effective in reducing systemic arterial pressure in mineralocorticoid-induced hypertension in rats.[161] In other forms of experimental hypertension, dietary protein restriction has not been so clearly associated with a reduced systemic pressure. The systemic hypertension that develops in rats following subtotal nephrectomy or in the two-kidney, one-clip renovascular hypertension model persists even when dietary

protein is severely restricted.[162] In several models of CKD, dietary protein restriction diminishes renal injury, but there has been no consistent decrease in blood pressure, indicating that the beneficial effects of protein restriction do not necessarily depend directly on reducing salt or eliminating some unidentified factor or compound that raises blood pressure.

Similarly, for humans with essential hypertension, there is no clear cause-effect relationship between protein intake and arterial pressure.[163] Notably, when adults with CKD and hypertension are examined, systemic blood pressure has not been consistently reduced by restriction of dietary protein intake, similar to the results found in rats with CKD from subtotal nephrectomy.[140,164–167] The caveat is that a high-protein diet is generally associated with a high salt intake, and this could certainly raise the blood pressure of hypertensive CKD patients. However, raising the vegetable and dairy protein content of a DASH diet does not impair the effect on blood pressure lowering.[168] The observation that the role of dietary protein on blood pressure in CKD appears to increase as GFR falls[169] suggests that either alterations in diseased nephrons create sensitivity to dietary protein or that other dietary-derived compounds accumulated in CKD (e.g., phosphorous, acid, uric acid, or other uremic toxins) cause hypertensive effects. Of these compounds, uric acid is most clearly associated with hypertension (see below). Recent reports emphasize that diets that are uncontrolled for phosphates or salt will negate the beneficial effects of angiotensin converting enzymes on the progression of CKD.[169a,169b] These reports emphasize the importance of the design of a diet for patients with CKD.

Other hemodynamic effects. The neurohumoral basis for the hemodynamic responses of normal and diseased nephrons to changes in dietary protein is unknown but there are several candidates. For example, infusion of amino acids causes vasodilatation; somatostatin blocks this response.[176,177] The changes induced by somatostatin could be secondary to many hormones, including glucagon, because plasma glucagon levels rise with oral protein feeding or intravenous amino acids while intravenous infusion of glucagon to achieve blood levels that are similar to those observed following an amino acid infusion does provoke a rise in GFR and renal blood flow in humans.[178] This response to glucagon, however, appears to depend at least in part on prostaglandin (PG) synthesis because the simultaneous administration of a cyclooxygenase inhibitor and either amino acids or glucagon blunts the expected increase in GFR and renal blood flow. Several cyclooxygenase-dependent products could be the mediator in these studies; at least urinary excretion of PGE and the prostacyclin metabolite, PGF1α, are quite variable following dietary protein loads, making it unlikely that these compounds are the sole mediators of renal vasodilatation. Another renal vasodilator system, the endothelium-derived relaxing factor or nitric oxide, could be involved since blocking of the synthesis of nitric oxide does cause renal vasoconstriction in the rat.[129,179] Moreover, the renal vasodilatation that occurs with amino acid infusion appears to be particularly susceptible to nitric oxide synthase blockade, suggesting that nitric oxide is a major factor affecting the renal hemodynamic response to dietary protein. In fact, a chronic increase in protein intake by normal rats increases both GFR and the excretion of metabolites of nitric oxide.[180] The stimulus for nitric oxide production is uncertain but some suggest that it is arginine, the substrate for nitric acid production.[181,182] However, infusion of amino acids other than arginine also causes renal vasodilatation, emphasizing the complexity of this response.

In rats with diseased kidneys, raising dietary protein increases GFR by raising renal blood flow, but also by increasing areteriolar tone.[165] The major mediator of the rise in efferent resistance is initiated by renin secretion activating the intrinsic, intrarenal angiotensin-converting enzyme activity. This raises angiotensin II to cause efferent arteriolar vasoconstriction. Notably, dietary protein stimulates renin and angiotensin-converting enzyme expression in the kidney.[165,183] The response is more complicated than prolonged stimulation of the efferent arteriole,[184,185] and may involve production of another intrarenal hemodynamic mediator such as endothelin.[165,186] When glomerular capillary pressure or the diameter of glomerular capillaries increases, the tension in the capillary walls will rise, and constriction of the efferent arteriole constriction will also augment the increase in wall tension. This increase in mechanical stress could cause or at least predispose to sclerosis.

Do similar events occur in other animal models of CKD? Similar events do occur, at least partially. Following subtotal nephrectomy, cats fed a high-protein diet (51.7% protein) develop more serious kidney injury than cats fed a more restricted diet (27.6% protein).[187] At least over the short term, the cats fed a high-protein diet do not have loss of GFR. Baboons subjected to a partial nephrectomy and fed 25% protein did lose GFR at a faster rate than animals fed 8% protein; the degree of histologic damage was not reported.[188]

Plasma aldosterone levels also increase with dietary protein and this could induce a fibrotic response in the kidney.[186,189] Hostetter and colleagues studied the subtotal nephrectomy CKD model in rats treated with aldosterone inhibitors and found that the treated rats had less kidney damage.[190] In recent studies, they have found that aldosterone treatment over only 3 days will

stimulate TGF-β expression independently of the degree of hypertension.[191] Thus, aldosterone should be added to the list of factors causing kidney damage in CKD.

Uric Acid

Another accumulated product that has toxic properties and is associated with a high-protein diet is uric acid. A 12-year population study of 47,150 previously normal men led to the conclusion that diets containing high levels of meat or seafood are associated with an increased risk of gout.[170] The mechanism for this effect was not identified. Besides gout, Johnson and colleagues have emphasized the toxicity of uric acid. They point out that the gene encoding urate oxidase was lost by primates millions of years ago leading to plasma uric acid levels that are substantially higher in humans compared to rodents, and other animals.[171] Johnson et al. also point out that hyperuricemia predisposes humans to hypertension, through sodium retention and possibly a renin-dependent mechanism. They showed that when rodents are given an inhibitor of uricase and/or allopurinol, there is an important association between the plasma level of uric acid and hypertension and the rate of loss of residual renal function.[172,173] Importantly, they found that serum uric acid levels in untreated, otherwise normal adolescents with hypertension are highly correlated with systolic blood pressure ($r^2 > 0.8$). In a randomized, controlled crossover trial of 30 hypertensive adolescents Feig et al. showed that patients treated with allopurinol treatment resulted in significant reduction in blood pressure by a mean systolic pressure reduction of −6.9 mmHg (95% CI −4.5 to −9.3 mmHg) and mean diastolic change of −5.1 mmHg (95%CI −2.5 to −7.8 mmHg).[174]

Identifying the impact of uric acid on progression of renal insufficiency is difficult because the serum uric acid level in these patients do not rise to the level that would be predicted from their degree of lost kidney function. This occurs because bacteria in the gastrointestinal tract extensively metabolize uric acid and hence, it is difficult to link the serum uric acid to dietary protein or to rates of loss of kidney function.[175] On the other hand, the plasma uric acid level of patients with CKD is above the concentration that has been shown to be associated with hypertension and possibly kidney damage.[171] For the same reason, the degree to which dietary protein restriction will reduce the level of serum uric acid in CKD patients has not been established. Potential mechanisms that cause the nephrotoxicity of uric acid have been explored. In rats given an inhibitor of urate oxidase, there is only a slight rise in serum uric acid (1−2 mg/dl) but this is associated with the development of a primary arteriolopathy which is independent of hypertension; this abnormality is largely corrected by allopurinol treatment.[173] Similarly prepared rats were found to have glomerular hyperfiltration, an abnormality that was prevented by allopurinol administration. Other mechanisms might involve impairment of nitric oxide. Both normal and CKD rats (subtotal nephrectomy) exhibit collagen deposition, macrophage infiltration, and an increase in juxtaglomerular renin content, but there also is a decrease in the macula densa expression of neuronal nitric oxide synthase. It is proposed that uric acid decreases nitric oxide synthesis in endothelial cells, possibly through peroxynitrite production and oxidative injury.[129,171] The scientific evidence suggests that uric acid could have a role in the development of hypertension and possibly kidney disease progression. At present, additional information is needed before we can recommend the use of uric acid to protect against progression of CKD. Certainly, acute or chronic gouty attacks should be treated.

Progression of Experimental Renal Damage and Dietary Protein

There is a body of evidence that suggests proteinuria is toxic to the kidney. This is relevant because high-protein diets potentiate proteinuria. For example, it has been proposed that filtration and subsequent reabsorption of albumin by proximal tubule cells can excite inflammatory responses, including expression of NF-κB, a transcription factor that is heavily involved in mediating inflammatory responses.[192,193] Clinical support for this formulation comes from results of a multicenter trial (RENAAL): when proteinuria was successfully suppressed, there was a decrease in the risk of both kidney failure and major cardiovascular events such as stroke, congestive heart failure, and death.[194,195] The relevance to the amount of protein eaten is that dietary protein restriction suppresses proteinuria and will add to the effectiveness of the antiproteinuric response to ACEIs.[196−198]

The beneficial effects of dietary therapy in order to limit renal injury in experimental models of CKD have been recognized for more than 65 years (Table 90.4).[199]

TABLE 90.4 Experimental Models of Renal Diseases Improved by Dietary Protein Restriction

Subtotal nephrectomy
Nephrotoxic serum nephritis
Doxorubicin nephrosis
Deoxycorticosterone acetate (DOCA)-salt hypertension
Spontaneous hypertension with reduced renal mass
Salt-sensitive hypertension with glomerulonephritis
Diabetes mellitus
Spontaneous glomerular sclerosis of aging
Antitubular basement membrane nephritis

Identification of the mechanisms responsible for the effectiveness of dietary therapy requires integrating the separate contributions of dietary protein, phosphates, salt, and/or unexcreted metabolic waste products that cause ongoing kidney damage. This identification would be useful not only to understand how diet affects the kidney, but also because it could lead to more specific therapies that would act to preserve kidney function. The mechanisms by which components of the diet affect kidney function are probably not mutually exclusive. We will focus on the dietary protein derived largely from meat as is typical in a Western diet. There are some intriguing data suggesting that diets of different protein sources might be less nephrotoxic in early CKD, but there is insufficient human evidence to judge this question at this time.[109] Later in CKD, the high phosphorous content of vegetable and dairy protein sources makes these diets poorly tolerated.[169]

Nephrotoxic Compounds Derived from Dietary Protein

When speaking to patients and the lay public, we often explain the manifestations of kidney disease in terms of poisons that accumulate in bodily fluids as renal function (GFR) falls. The appealing simplicity of this concept is based on the role of the kidney as the principal clearance mechanism for water-soluble waste. In this concept, the symptoms progress with declining GFR because of the decreased clearance of substances (often called "uremic toxins") that cause specific signs or symptoms of CKD.[200] In 1905, Folin pointed out that the principal metabolic response to an increase or a decrease in dietary protein content is a parallel change in urea excretion.[201] Using somewhat more sophisticated techniques, the same relationship between protein intake and urea production has been demonstrated repeatedly in normal adults and patients with CKD.[202–204] This occurs because protein ingested is metabolized in the gastrointestinal tract to peptides and amino acids. These peptides and amino acids are further degraded in the gastrointestinal tract or liver, yielding an enormous number of nitrogen-containing products that must be excreted by the kidney in addition to the newly synthesized proteins. Thus, if kidney function is impaired, it follows that the products arising from the metabolism of dietary protein will accumulate in patients in direct proportion to the amount of protein eaten and in inverse proportion to the degree of kidney failure. Accumulation of unexcreted compounds not only causes metabolic abnormalities but also can damage the injured kidney. A more categorical discussion of protein-derived uremic toxins follows in the next section.

Progression of renal disease can similarly be seen to be caused by accumulation of these toxins. While it is theoretically possible that there is one toxin that explains progression of renal disease or certain signs and symptoms, the interaction of many toxins is thought to be required in most circumstances. For example, a combination of waste products of protein metabolism (urea, magnesium, acetoin, 2, 3-butylene-glycol, sulfate, creatinine, p-cresol, and guanidine) impair oxidative metabolism in slices of cerebral cortex, but when studied separately at the same concentration, each agent has no effect.[205] Certain signs or symptoms that do not increase progressively as GFR fails can be explained by a threshold model. Furthermore, if a threshold can be identified, the threshold concentrations can define criteria for adequacy of renal replacement therapy. While simple in theory, the large number of potential uremic toxins makes such calculations difficult. In 2003, the European Uremic Toxin Work Group (Eutox) published a structured review of the literature identifying 90 known compounds that are accumulated in CKD that have toxic potential. Since then 25 additional retention solutes have been identified, thus suggesting the uremic syndrome is produced by complex biochemical interactions of a number of retained solutes.[206]

Bergstrom has proposed definitive criteria for determining if a proposed chemical (organic or inorganic) compound is a uremic toxin: (1) the chemical identity of the compound should be known; (2) the concentration should be higher in tissue or plasma from uremic patients than in that from normal subjects; (3) the concentration should correlate with specific uremic signs or symptoms and be improved by the removal of substance; and (4) the toxicity of the compound in tissue, cells, or a test system should be demonstrated at the concentration found in tissue or fluids from uremic patients.[207] Given the complex nature of renal excretion, few compounds have been found that meet all criteria.

Urea

The possibility that urea itself might be toxic has been tested, albeit with some challenges, since the half-life of urea is short with normal kidney function is difficult to test the toxicity of urea.[200] Nephrectomized dogs, treated with peritoneal dialysis and a dialysate supplemented with urea, achieved BUN values between 173 and 224 mg/dl and developed weakness, anorexia, and decreased attentiveness.[208] Continued therapy was followed by vomiting, hemorrhagic diarrhea, hypothermia, and death. In humans, no apparent toxicity was seen when chronic dialysis patients were dialyzed against urea-supplemented dialysate.[209] However, when the urea concentration was gradually

increased in the dialysate of stable long-term hemodialysis patients to obtain a steady state BUN between 140 and 200 mg/dl for several weeks, most patients experienced malaise, weakness, lethargy, and a bleeding diathesis.[210] Thus, some symptoms of uremia, such as nausea, vomiting, malaise, and bleeding, may be due to urea intoxication; other uremic symptoms cannot be provoked by even high urea concentrations. Thus, urea seems to be clinically important only at very high concentrations. Consistent with this idea, there is little direct effect of high urea on cellular function. Urea suppresses inducible nitric oxide synthesis in mouse macrophages and stimulates macrophage proliferation in a dose-dependent fashion.[211] This response could be relevant to the proliferation of macrophages within atherosclerotic lesions.

One possible explanation for this high degree of tolerance to urea is that its decomposition may be required for direct toxicity. Urea can also be spontaneously decomposed to form ammonia or cyanate adducts. Cyanate can condense with NH_2-terminal amino and amide lysine groups on proteins to alter the tertiary structure of proteins; enzyme activity can change. This explains why CKD is associated with carbamylation of many proteins. The consequences of this process are not settled; protein carbamylation has been reported to aggravate the uremic syndrome and may decrease the activity of insulin.[212] As discussed below, carbamylation may enhance oxidation and formation of advanced glycosylation end products. A variety of lipids may also be carbamylated to form toxins.[200] For example, 3-carboxy-4-methyl-5-propyl-2-furaproprionic (CMPF) acid has been demonstrated to be a major cause of altered drug protein binding in uremia.[213] Finally, urea is converted to ammonia and carbon dioxide, principally by bacterial urease. Systemic blood ammonia levels are minimally elevated in uremia, largely because the resulting ammonia diffuses across intestinal epithelia to portal blood and is reconverted to urea in the liver.[214,215] Thus, at high concentrations urea is toxic, but is insufficient to completely account for the uremic syndrome.

Other Toxic Metabolites of Protein

A major difficulty in identifying uremic toxins occurs because most compounds produce toxic effects in concert with other compounds or after secondary modification.[200] Widespread and variable secondary modification of organic molecules by carbamylation, glycosylation, and oxidization in uremia often influences their toxicity.[212,216] Rather than trying to identify individual toxins, the toxins should be considered in broader categories. The most important group is the products of protein metabolism. These include not only nitrogen containing compounds, but also metabolic acidosis and phosphorous.[169] However, any substance with decreased clearance can meet these criteria including bacterial products, electrolytes (e.g., sodium), cytokines, and hormones.[200]

Not all manifestations of chronic kidney disease are caused by water-soluble toxins easily cleared by hemodialysis or peritoneal dialysis.[206] Inadequate removal of toxins can lead to complications even with seemingly adequate dialysis: the inability to clear sufficient sodium in conventional hemodialysis leads to extracellular volume expansion, cardiac dilatation, sympathetic nervous system activation, and inflammatory cytokine production. But even with ideal dialysis therapy, there is increasing evidence that other aspects of renal function may still drive complications of CKD. The best examples of this are the hormones erythropoietin (EPO) and 1,25 hydroxyvitamin D3, where the kidney acts as a major source of production. Larger molecules (both so-called middle molecules (0.5−3.0 kD) and larger polypeptides) including many hormones and cytokines, are destroyed by the kidney and their levels rise as GFR declines. The kidney is metabolically active playing a secondary role in glucose production, lactic acid metabolism, and arginine metabolism. These metabolic functions of the kidney may not be crucial in the normal, resting state, but may regulate major adaptations in liver disease, oxidative stress, and regional ischemia.

The principal example of metabolic disorders is the accumulation of unexcreted acid arising from the metabolism of certain amino acids (e.g., sulfur-containing amino acids and others). Metabolic acidosis leads to several metabolic abnormalities including an increase in the breakdown of protein and essential amino acids, insulin resistance, and abnormalities in endocrine function and bone metabolism.[217−221] An example of a toxin accumulated by CKD patients is indoxyl sulfate, which arises from the breakdown of tryptophan.[222] When given to rodents that serve as models of glomerular sclerosis, indoxyl sulfate (or indole compounds) accelerates the degree of kidney damage.[223,224] The mechanism underlying this toxic effect is complex and may involve expression of TGF-β in the kidney, but how TGF-β is stimulated and whether other toxic mechanisms are involved is unknown.[225] The link to dietary protein is that accumulation of indoxyl sulfate in uremic rats and CKD patients can be reduced by restricting dietary protein.[226] This should not be surprising because the amino acid, tryptophan, is the precursor of indoxyl sulfate. Another means of lowering indoxyl sulfate is by ingestion of a sorbent to increase its extrarenal clearance, and there are clinical trials assessing if this strategy as a means of preventing uremic toxicity.[226,227]

Besides these compounds, other potentially toxic metabolites of dietary protein can affect kidney

function indirectly. For example, excess dietary protein will increase the accumulation of phenylalanine metabolites in patients with renal insufficiency, and at least in dialysis patients, phenylacetic acid accumulates and inhibits the expression of inducible nitric oxide synthase.[228] This inhibitory effect could increase atherosclerosis, one of the major problems caused by kidney failure. The metabolism of amino acid derivatives, like the metabolism of creatinine, is complex in patients with renal insufficiency.[51,175] Metabolism of these (and other) compounds makes it difficult to predict how the serum/plasma level of these compounds will change or how abnormalities caused by accumulation of the metabolites will respond to dietary protein restriction. Regardless, it is clear that dietary protein restriction will decrease the accumulation of any of these products.

Guanidino-Containing Compounds

Guanidino compounds are strong organic bases that bear the amidino group; these compounds accumulate in the sera and tissues of uremic patients.[200,229,230] Dietary protein is the ultimate source of the nitrogen in guanidino compounds, and their excretion rises with increased protein intake.[231,232] However, urinary excretion of guanidine compounds in CKD patients is higher than that of control subjects even when protein intake is the same. Because the extrarenal clearance of these compounds is negligible, it follows that CKD increases the production of guanidino compounds. The biochemical pathways in which guanidino compounds are synthesized are largely unknown. Arginine can be converted into amidino groups *in vivo*, and urinary excretion of both methylguanidine and guanidinosuccinic acid rise when dietary protein is increased, but whether this is attributable to an increase in arginine accumulation is unknown. Besides arginine levels, there are other factors regulating their production. Kopple et al.[231] reported that three CKD patients with a constant protein intake had increased excretion of guanidinosuccinic acid with an intercurrent illness. Most synthesis of guanidine-containing compounds from arginine is likely to occur in the liver, because there is a high activity of glycine transamidinase and a low rate of arginine export by hepatocytes.[233] Arginine turnover in normal adults includes a relatively large nonexchangeable pool in the liver that could serve as a source of guanidino compounds, and perfusion of rat liver with L-[guanidino-14 C] arginine yields a progressive increase of 14 C-guanidinosuccinic acid.[234] Ingestion of L-[guanidino-15 N] arginine by uremic patients yielded 15N-methylguanidine at levels that initially exceeded that present in creatinine, consistent with (methylguanidine) being a precursor of creatinine.[235] This result supports the hypothesis that arginine may be degraded to form methylguanidine and a-aminobutyric acid. High concentrations of creatinine or its immediate precursor, guanidinoacetic acid decreases utilization of arginine to form guanidinoacetic acid. The increased availability of arginine may lead to donation of its amidino group to form other compounds, such as guanidinosuccinic acid, methylguanidine, γ-guanidinobutyric acid, and guanidinopropionic acid.[236] Regardless of the mechanism, the concentration of guanidino compounds in tissue and plasma increases as renal function declines, and their concentrations are best correlated with the amount of protein eaten.

Difficulty measuring plasma and tissue concentrations of guanidino compounds has caused much of the controversy surrounding the importance of candidate uremic toxins.[200] Because there is great variation among species in levels of guanidino compounds, human studies will be considered here.[237] Plasma levels as high as 8 to 10 mM can occur in uremic patients, but corresponding tissue levels have not been extensively studied, so it is difficult to verify toxicity. Methylguanidine has been detected in the cerebrospinal fluid of uremic patients, but not in normal subjects or experimental animal models of renal failure.[238] *In vitro*, high doses of methylguanidine cause autohemolysis, defects in erythrocyte metabolism, and inhibit salivary and exocrine pancreatic secretion.[239] Likewise, guanidinopropionic acid, guanidinoacetic acid, or γ-guanidinobutyric acid can cause autohemolysis of red blood cells, possibly related to inhibition of glucose-6-phosphate dehydrogenase.[240] Clinically, plasma levels of these compounds in uremic patients can be shown to be inversely correlated with the erythrocyte glutathione concentration, suggesting they induce a loss of the protective effect of glutathione against hemolysis. Other guanidino compounds may have neurotoxic effects: guanidine and methylguanidine have been related to peripheral neuropathy, and γ-guanidinobutyric acid, taurocyamine, homoarginine, and α-keto-δ-guanidinovaleric acid lower the seizure threshold of experimental animals.[241] The concentrations of guanidine compounds in serum, urine, and cerebrospinal fluid of nondialyzed patients with renal insufficiency were as much as 100-fold higher in the cerebrospinal fluid of uremic patients, and these compounds can induce experimental convulsions at concentrations found in uremic brain.[242,243] Based on biochemical and electrophysiologic measurements *in vitro*, the central nervous system excitatory effects of uremic guanidino compounds could be explained by inhibition of γ-aminobutyric acid (GABA) receptors, selective activation of N-methyl-D-aspartate (NMDA)

receptors by guanidinosuccinic acid, and an intrinsic depolarizing response.[244]

ADMA and Other Arginine Derivatives

Related compounds derived from arginine can inhibit NO synthase: asymmetric dimethylarginine (ADMA) inhibits this enzyme and some, but not all, investigators feel that ADMA accumulates in patients with impaired renal excretion.[245,246] Interpretation is difficult because plasma concentrations of ADMA are higher in patients with vascular disease and even asymptomatic hypercholesterolemia.[247,248] A recent report found a GFR-dependent increase in the serum concentration of ADMA and related compounds in CKD patients, but also found that patients with both CKD and cardiovascular disease had even higher levels.[246] Clearance of ADMA by hemodialysis is lower than expected for its molecular weight, suggesting that there is binding to plasma proteins. For example, two groups found only a 20% reduction in ADMA concentrations during dialysis.[245]

In experimental animals, accumulation of ADMA is associated with a concentration-dependent pressor and bradycardic response and vasoconstriction in mesenteric and hindquarter vessels.[249] In CKD patients, loss of the vasodilating properties of NO (e.g., because of a high ADMA level) could aggravate hypertension and accelerate the progression of renal failure.[250] A positive correlation between plasma levels of ADMA and mean arterial blood pressure has been noted and possibly an inverse relationship between progression of CKD and nitrate excretion.[251] Despite the suggestive higher levels in cardiovascular disease patients and the appropriate physiologic responses, there are no studies showing whether ADMA causes cardiovascular disease or cardiovascular disease increases ADMA.[246] Besides changing hemodynamic responses, NO depletion may cause anorexia in hemodialysis patients as administration of N-nitro-L-arginine, an inhibitor of NO synthesis, reduced the food intake of rats. Another possibility is that it raised the ornithine concentration because ornithine can inhibit protein ingestion in a dose-dependent manner.[252]

Products of Bacterial Metabolism

Uremic toxins can be synthesized by gut bacteria and absorption of bacterial products could be high because of increased permeability of the gastrointestinal mucosa.[200,253] The gut (mainly colon) has come forth as a major source of the generation of various metabolic wastes.[254,255] Nutrients that escape digestion/absorption in the small bowel become substrates for bacterial metabolism—there are more bacterial cells in the colon than there are cells in the whole human body. Moreover, there is bacterial overgrowth in the gastrointestinal tracts of uremic patients so it is possible that these bacteria contribute to the accumulation of "uremic toxins.[257]" Bacteria use the nutrients for their own metabolism, as well as generating short chain fatty acids, which are absorbed and used as energy. This constitutes about 3% of our total energy source, which is not a vital source of calories in modern societies, but in evolutionary terms or when food is scarce, this extra energy may be essential. Intestinal bacteria generate nitrogenous wastes and aromatic compounds (e.g., phenols, indoles, aliphatic amines) from protein metabolism and are cleared mainly by the kidneys. Bacteria derived uremic toxins include indoxyl sulfate, hippuric acid, p-cresol, and 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid.[256] The evidence that bacterial products contribute to altered mental status in uremia is indirect: administration of nonabsorbable antibiotics to two patients with uremic encephalopathy resulted in a marked improvement in asterixis, myoclonus, mental alertness, and electroencephalographic abnormalities, coinciding with a decline in serum amine levels.[257] Some of these bacterial products are directly derived from amino acids; others are derived from compounds rich in muscle, such as creatinine, lecithin, and choline.

Aromatic amines. Tryptophan has been suggested as one of the major precursors of this class of uremic toxins.[200] Tryptophan undergoes deamination and decarboxylation by gut bacteria, yielding a variety of metabolites that include indole, indoxyl, skatole, skatoxyl, indican, and indoleacetic acid. Aromatic amines also result from bacterial metabolism of tyrosine, phenylalanine, or tryptophan.[258,259] Several indole compounds are high in the plasma of uremic subjects and can inhibit oxidative metabolism in brain slices.[260] Moreover, patients with uremic encephalopathy have high concentrations of tryptophan, 5-hydroxyindoleacetic acid, and homovanillic acid in their cerebrospinal fluid.[261,262] The pathogenic significance of this association is unclear, but 5-hydroxyindoleacetic acid is a precursor of the neurotransmitter serotonin, as well as indoxyl sulfate.[261,262] The potential nephrotoxicity of indol sulfate was discussed above. Uremic rats fed a proprietary resin that absorbs such compounds were found to have greatly reduced plasma and urinary levels of indoxyl sulfate, but more interestingly, there were improvements in several metabolic pathways, even though the degree of azotemia was unchanged.[222] The administration of this resin was associated with increased food intake, leading to the suggestion that other toxins causing anorexia were removed. Indoxyl sulfate can inhibit the deiodination of T4 to T3 in cultured hepatocytes.[263] Most if not all of the breakdown products of the aromatic amino acids, including

tryptophan, have been shown to interfere with the binding of drugs to serum proteins.

Aromatic amines could contribute to uremic encephalopathy by serving as false neurotransmitters.[258,259] Infusion of phenol or p-cresol into dogs results in a variety of neurologic symptoms, and conjugated phenols can inhibit ATPases and ion transport systems, leading to changes in intracellular ionic composition and abnormal cellular metabolism.[264] It is known that p-cresol can inactivate β-hydroxylase, a key enzyme in the transformation of dopamine to norepinephrine.[265] P-cresol is also associated with decreased bactericidal free-radical formation by activated macrophages[266] and reduces vascular endothelial function.[267]

Aliphatic amines. Aliphatic amines come from different sources: monomethylamine is thought to be derived from the metabolism of creatinine through sarcosine, whereas bacterial metabolism of choline and lecithin produce tertiary methylamines, which are absorbed and oxidized or demethylated to form secondary methylamines.[200,257,268] These compounds can be absorbed by the gut and taken up by the muscle of the animal and finally eaten by humans. For example, trimethylamine-N-oxide (TMAO) is readily absorbed from dietary fish, and is promptly excreted by normal adults, but accumulates in CKD patients.[269]

Secondary methylamines are high in blood, cerebrospinal fluid, and brain tissue, as well as in duodenal aspirates.[257,270] This may reflect the greater density of bacteria in the small intestines of uremic patients or the higher choline levels in the plasma of uremic patients Niwa has identified high levels of derivatives of hydroxyphenolic acids, including p-hydroxybenzoic acid and p-hydroxyphenylacetic acid and precursors of phenol and p-cresol, in the sera of hemodialysis patients; the levels were proportional to dietary protein intake.[222]

Toxins not derived from dietary protein. Finally, not all bacterial products that are potential uremic toxins are synthesized from amino acids or other substances in meat. Low-molecular-weight polyamines necessary for the synthesis of nucleic acid and cell growth include putrescine, spermidine, and spermine. These factors can be synthesized in mammalian tissues, and cadaverine and putrescine are formed by intestinal bacteria in a reaction that decarboxylates lysine and ornithine.[271] *In vitro* experiments indicate that spermine can inhibit erythropoiesis, whereas in hemodialysis patients, the serum spermine levels vary inversely with the hematocrit.

Evidence for Protein Restriction in CKD

For more than 100 years, it has been known that dietary protein restriction decreases the BUN and the severity of uremic symptoms.[200,272] Dietary manipulations in the form of protein restriction were the standard of care to alleviate the symptoms of uremia prior to the widespread availability of dialysis. Presumably this maneuver lowered the generation rates of nitrogenous waste solutes. When dialysis became readily available to treat advanced uremia, efforts to reduce uremic solute production by restricting the diet were largely abandoned. However, studies that manipulated dietary intake of protein provide important insight into the uremic syndrome. Cotton and Knochel demonstrated the toxic consequences of excess dietary protein by measuring abnormalities in the resting membrane potential of skeletal muscle fibers in patients with advanced uremia.[273] After six weeks of intensive dialysis, uremic symptoms improved, and the skeletal muscle resting membrane potentials returned to normal.[274,275] When the investigators reduced the frequency of their dialysis treatments, anorexia, nausea, and vomiting developed in four of six patients, and the muscle membrane potential fell. On the same reduced dialysis schedule, the diet was switched from 1 g of protein per kilogram per day to 0.5 g/kg/day plus a supplement of essential amino acids. With the reduced amount of dietary protein, five of six patients had normal membrane potential values in skeletal muscle (the remaining patient did not comply with the dietary restriction) and in all patients, uremic symptoms resolved.[273] We have discussed some of these protein-derived toxins in the section on progression of renal disease, especially uric acid. We will not discuss acidosis separately here, because it influences a variety of systems and will be discussed in detail in the section on endocrine abnormalities.

Besides reducing nitrogen intake, a low-protein diet is generally associated with a reduction in phosphorus and sodium intake. The potential benefit of lowering salt intake in hypertensive CKD patients is obvious, but benefits of dietary phosphate restriction are less obvious. A low-phosphate diet can mitigate the progressive renal disease that occurs after subtotal nephrectomy or experimental glomerulonephritis in the rat,[276] but interpreting these results is complicated because there are studies in which dietary protein but not phosphorus was varied, and it was concluded that dietary protein restriction without phosphate restriction can be beneficial.[277] On the other hand, dietary phosphate restriction without simultaneous protein restriction is capable of reducing progressive experimental renal disease. The mechanism whereby phosphate restriction reduces renal injury is uncertain. Four possibilities have been suggested. First, dietary phosphate restriction can reduce GFR so that its effect could occur by diminishing hyperperfusion in residual nephrons. Second, severe dietary phosphate restriction leads to defects in inflammatory responses and

dysfunction of leukocytes, which could reduce damage. However, the degree of phosphate restriction for this response is too severe to be used clinically. Third, intrarenal deposition of calcium phosphate crystals could be reduced by dietary restriction of phosphates as demonstrated histologically in 1937.[278] Fourth, phosphate restriction could minimize renal hypermetabolism (i.e., oxygen and glucose consumption).[279] Clearly, these mechanisms are not mutually exclusive, and all may contribute to the beneficial effects of phosphate restriction.

In summary, while there is confusion surrounding the identity of uremic toxins derived from animal protein, there is no shortage of candidate molecules. It is likely that many toxins contribute to any given pathophysiologic response. It is clear that the degree of uremic toxicity is roughly related to protein intake; the most severe symptoms occur in the patients with the highest protein intake; and most symptoms decline in severity when dietary protein intake is reduced or are removed through dialysis. However, there are pathophysiologic responses that do not respond to these maneuvers, suggesting that restricting dietary protein by itself is not sufficient for conservative management of uremia.

Larger Uremic Toxins

It is clear that not all compounds accumulated in CKD are small molecules derived from metabolism of dietary precursors for which urea is a surrogate marker.[200] For example, uremic neuropathy has been linked to accumulation of so-called "middle molecules" weighing between 500 and 3000 Daltons (0.5−3 kD).[280] Just like the smaller toxins, much of the controversy about the clinical importance of accumulating middle molecules stems from difficulties in identifying compounds present at low concentrations in fluid that is as chemically complex as plasma. It is also clear that the 3-kD cut-off for defining middle molecules is arbitrary, and larger protein molecules may cause uremic toxicity by similar mechanisms.

Middle Molecules

Most of the data on middle molecules derives from studies on fractions of uremic plasma. When the plasma ultrafiltrates from uremic patients or urine from normal adults were injected intraperitoneally into rats, their appetites fell sharply, whereas injections of normal saline or ultrafiltrates of plasma from normal adults did not alter feeding behavior.[281] It was concluded that one or more factors eliminated by the kidney accumulate in the body fluids of patients with renal failure and suppress appetite. Ultrafiltrate subfractions with molecular weights of 1−5 kD and 5−10 kD obtained from uremic patients were also shown to inhibit the hunger for carbohydrates and proteins in a dose-dependent manner.[282] Similar results occurred after direct injection of the middle molecule fractions into the lateral brain ventricles of rats, suggesting that specific brain receptors or neurotransmitters control feeding.[280] These results were site- and route-specific because intravenous injection of the same uremic ultrafiltrate subfractions had no effect on feeding behavior nor was the sexual behavior of the rats altered.[283] The authors concluded that middle molecules contained in plasma from uremic patients or from urine of normal adults act in both the brain and the splanchnic region to inhibit food intake.

Similar studies have implicated middle molecules in the impairment of immune responses and abnormalities in lipoprotein metabolism associated with uremia. Middle molecule fractions of uremic serum inhibited lymphocyte proliferation by 50% and decreased production of interleukin-2, a cytokine that stimulates T-lymphocyte proliferation.[284] Middle molecules also cause polymorphonuclear leukocyte dysfunction in uremia. Serum samples containing middle molecules can inhibit chemotaxis, oxidative metabolism, intracellular bacterial killing, and other polymorphonuclear leukocyte functions.[285−287] Middle molecule fractions from serum of uremic patients directly inhibit apolipoprotein A-I (apo A-I) production in hepatoma cells.[288] Since apo A-I is the structural protein for HDL, this mechanism could contribute to the lower HDL levels seen in CKD and ESRD patients.

What is the chemical identity of these molecules? Specific toxic responses to molecules identified thus far are unknown, although β2-microglobulin, which accumulates in the plasma of patients with renal failure, is the major constituent of amyloid-like deposits that accumulate in dialysis-related secondary amyloidosis.[289] Small polypeptides accumulate in the plasma of uremic patients; at least 38 ninhydrin-positive (i.e., amines or amino-containing peptides) have been isolated from dialysate, while peptide-bound, N-substituted amino acids are present in excess amounts in the plasma of uremic patients.[290] Abiko and associates isolated four peptides from the plasma of patients with severe uremia that were characterized as peptide fragments of plasma proteins that are eliminated or metabolized by the normal kidney.[291,292] Similarly, Chu and colleagues identified six middle molecules weighing between 800 and 2015 Daltons that accumulate in the serum of uremic patients but are excreted by healthy subjects.[293]

A number of these substances may be circulating hormones or cytokines accumulating in uremic patients—and we will discuss hormonal changes in a

separate section—but one class of possible middle molecule uremic toxins is inflammatory cytokines. The half-lives of circulating cytokines are elevated due to decreased glomerular filtration and proximal tubular uptake and destruction. How clinically relevant decreased destruction of small inflammatory cytokines is in CKD is unknown, and most well-studied cytokines are above the 3 kDa used by some to describe middle molecules. For example, elevated TNF-α and IL-6 plasma levels have been noted in CKD and ESRD.[49] However, cytokines often act in a paracrine fashion, so that circulating levels may not correlate with tissue action. In one study monocyte levels had a much smaller increase than in plasma.[294] Inflammation and oxidative stress clearly play a major role in increasing the production of these cytokines, accounting for the marked variability seen among patients and studies. Some cytokines do have important circulating responses. For example, reports suggest that IL-6 has important circulating effects to promote inflammation.[49] On multivariate analysis, serum creatinine was the sole determinant of IL-6 levels in a group of CKD patients.[295] The IL-6 circulating receptor, a binding protein that increases plasma half-life, also increased with declining GFR. However, these results suggest, but do not prove, that decreased renal clearance may increase plasma levels of this circulating cytokine.

The relative importance of larger versus smaller uremic toxins is not entirely known. Dialysis efficiently corrects the uremic syndrome, suggesting that low-molecular-weight solutes are most important. However, the high mortality of dialysis patients suggests that major abnormalities remain. A carefully performed study did not show a survival advantage (except in the subgroup of the patients who had been on dialysis the longest) of a larger hemodialyzer-membrane pore size (high flux dialysis) designed to clear some middle molecules.[296] Caution should be used in the interpretation of dialysis studies to determine the importance of small versus middle molecules, because of the distinction between dialyzability and elimination. For instance, inorganic phosphorous is readily cleared through dialysis membranes, but is removed poorly because of its large volume of distribution and slow release from its intracellular stores. Larger molecular weight fractions of plasma are also cleared efficiently by the kidney, but not with dialysis, even when high-flux membranes are used. Suggestions have been made that continuous dialysis or bioartificial kidneys may remove these molecules more successfully, but data remain limited. Overall, the data suggest that larger uremic toxins have the potential for enhancing morbidity associated with the uremic syndrome, but it is not clear what approach may be best for their removal.

Advanced Carbamylation, Oxidation, and Glycosylation Products

In the discussion on urea, we pointed out that modification of peptide and protein substrates by carbamylation probably accounted for some of the toxic effects of this molecule. Modification of protein substrates by carbamylation is a possible mechanism for formation of middle molecule and larger uremic toxins related to dietary protein intake. While proteins can be directly modified by oxidation and glycosylation, carbamylated proteins can have enhanced reactivity with oxygen and glucose accelerating formation of these products.

Oxidation

While carbamylation, glycosylation, oxidation, and nitrosolation of proteins are all probably important mechanisms for generating toxins, oxidant and glucose modification has a high correlation with cardiovascular disease. Generation of oxidant species is a normal enzymatic process example, xanthine oxidase, NAD(P)H oxidase, endothelial nitric oxide synthase (NOS), as well as by transition metals, such as iron.[297] Activated leukocytes and other phagocytic cells generate reactive oxidation species such as hydrogen peroxide or hydroxyl radicals. Antioxidant defenses include superoxide dismutase, catalase, glutathione peroxidase, trace metal scavengers and nonenzymatic substances such as melatonin, tocopherol, ascorbic acid, carotenoids, and flavonoids. The structure of proteins is altered by oxidation of specific amino acid residues such as tyrosine resulting in cross-linking, aggregation, or fragmentation of proteins following reactions with reactive oxygen species including advanced oxidation protein products.[216,298] An imbalance between reactive oxygen radical production and antioxidant defense occurs in uremia, although the mechanisms are not entirely clear.[297] Possible causes include changes in diet to reduce the intake of antioxidant compounds in fruits and vegetables, retention of circulating oxidant molecules, and intercurrent inflammatory illnesses. Dietary protein intake does not appear to influence oxidative stress.[299]

Advanced oxidation products can be found even in the early stages of renal insufficiency, but increase sharply with progressive loss of renal function. These products are at high concentrations in dialysis patients, forming protein aggregates, and there is a positive correlation between the levels of oxidation products and inflammatory markers such as TNF-α and its soluble receptor.[298] Because these compounds have been linked to the development of atherosclerosis,[283] formation of these products could be linked to cardiovascular disease.

Glycosylation. Advanced glycosylation end products (AGE) form from glucose modification of proteins, and are associated with toxicity in diabetes mellitus. While insulin resistance and reduced removal of small proteins are thought to contribute to AGE formation in CKD, they are not believed to be the only mechanisms.[300] Glucose can interact with proteins that have been modified by carbamylation to form AGEs. The toxic properties of AGEs have been well studied in the diabetes literature.[301] Needless to say, they may contribute to similar end-organ dysfunction in patients with CKD, including increased progression of renal disease. The role of AGEs may explain, in part, the synergistic effects of decreased GFR and diabetes on uremic signs, symptoms, and end-organ damage. Furthermore, the potential that this modification could interact with protein carbamylation and oxidation products to additively impair protein function must be considered.

Homocysteine and cysteine-homocysteine.One interaction between amino acids and oxidative stress is the formation of homocysteine derivatives. Homocysteine, a sulfur-containing amino acid derived from the metabolism of methionine or cysteine, is rapidly oxidized creating a special class of uremic toxins.[200] Homocysteine is found in the plasma and in erythrocytes and cells of the liver and other organs.[302–304] In plasma from CKD patients, the levels of sulfur-containing amino acids, including homocysteine, are high; the mechanism for these abnormalities is unknown. Accumulation of homocysteine is a potentially severe complication because of the association between homocysteine levels and cardiovascular disease. By convention, plasma or serum total homocysteine refers to the sum of homocysteine and its disulfide derivatives whether they exist in the bound or the free-state. Studies in rats and humans suggest that the kidney eliminates about 70% of the daily homocysteine burden and this indicates why homocysteinemia levels are high in predialysis as well as renal transplant patients[305,306] It is postulated that homocysteine plays a role in the excessive cardiovascular risk associated with CKD.[307] Homocysteine is metabolized by reactions that include transsulfuration or remethylation. In transsulfuration, homocysteine is degraded to cystathione and then to cysteine and other sulfur-containing compounds, including glutathione, taurine, hydrogen sulfide, and sulfate. In remethylation, homocysteine is methylated through the action of methylenetetrahydrofolate reductase. Folic acid is the major cofactor for this enzyme and a deficiency of folic acid leads to increases in homocysteine. Vitamin B6 is a cofactor involved in transsulfuration and vitamin B12 is involved in remethylation. Treatment of homocysteine excess with folic acid has shown some value in subjects with normal renal function, but was not proven effective in a clinical trial in dialysis and pre-dialysis patients.[308,309] This result has led to speculation about a folate-independent pathway for the hyperhomocysteinemia seen in ESRD.

Alterations in Endocrine Function

Many characteristic features of uremia result from the extensive disruption of endocrine systems. Clearly, hormones predominately produced by the kidney, such as EPO and 1,25-$(OH)_2D_3$, are found in progressively reduced concentrations as CKD worsens.[69] However, more subtle disruption occurs in endocrine systems that have no renal production. Accumulation of nitrogenous waste, phosphate and other inorganic acids, and the effect of other hormonal systems affect endocrine systems, which is addressed in Chapter 91. In the discussion below we will limit our focus to endocrine abnormalities that affect nutritional status and protein turnover.

Insulin

Patients with CKD exhibit significant abnormalities of glycemic control. These include an alteration of peripheral glucose utilization, a subnormal response to insulin, and elevated plasma insulin.[310] The increase in insulin levels is generally attributed to the decreased insulin catabolism secondary to renal dysfunction. Insulin requirements decline in diabetic subjects with advancing CKD, because most insulin catabolism is mediated by the kidneys. The plasma *t1/2* of insulin increases significantly when the creatinine clearance decreases to less than 30 ml/min.[311] Plasma levels of both C-peptide and proinsulin are increased in individuals with CKD. Although serum insulin levels also are increased, clinically significant hypoglycemia is not observed except with the use of endogenous hypoglycemia agents.[310] Glucose tolerance tests in uremic individuals are marked by elevated glucose levels and hyperinsulinemia, even if diabetes mellitus is not present. In addition, there is decreased insulin-mediated glucose uptake by forearm tissues, and patients with renal failure metabolize less glucose in response to infused insulin than normal subjects. In euglycemic or hyperglycemic clamp studies, the late responses to glucose and insulin are quite characteristic of peripheral insulin resistance.[312] Hepatic glycogenolysis appears to occur at normal or increased rates, but it is less sensitive to insulin than that in nonuremic subjects.[313]

The defect in insulin responsiveness appears to reside primarily in skeletal muscle, which represents the vast bulk of glucose-dependent metabolic tissue.

This peripheral unresponsiveness to insulin in uremia has been examined in detail. The number of insulin receptors appears to be normal or increased, and the binding affinity for insulin of the receptors is not affected in uremia.[314] However, the degradation of the hormone-receptor complexes occurs at slower rates than normal.[315] The findings together define the insulin resistance to be a post-receptor event. Thus, uremia-associated resistance to the action of insulin in muscle has been linked to abnormalities in insulin signaling, but it is not known which step(s) in the signaling pathway is abnormal.[316] In normal cells, activation of the insulin receptor following insulin binding induces auto phosphorylation of the β-subunit to stimulate the activity of a tyrosine kinase that subsequently phosphorylates other substrates.[317] The major substrates are the insulin-receptor substrates (IRS-1 and IRS-2), which after phosphorylation acts as a scaffold to bring together enzymes critical for subsequent insulin events, including phosphatidylinositol- 3-kinase (PI3-K).[318] The PI3-K complex is a heterodimer composed of an 86-kD (p85) regulatory subunit and a 110-kD (p110) catalytic subunit. The p85 regulatory subunit can form stable high-affinity complexes with the p110 catalytic subunit, but the amount of these cellular complexes and the amounts of the subunits are differentially regulated by stimuli like glucocorticoids.[319] For example, Giorgino and coworkers reported that stimulation of expression of the p85 subunit of PI3-K following glucocorticoid treatment was associated with reduced IRS-1−associated PI3-K activity.[320] They speculated that the excess of p85 competed with the p85-p110 complex for binding to phosphorylated IRS-1. The reduced amount of IRS-1 associated p110 catalytic subunit resulted in decreased PI3-K activity. This would partially explain the insulin resistance associated with glucocorticoid administration. Since glucocorticoids are increased in uremia, insulin resistance may occur via a similar mechanism. Just as with glucocorticoid treatment, the quantity of p85 was substantially increased in muscle of chronically uremic rats.[200]

Acidosis also has the potential induce insulin resistance. Acidosis does not alter islet cell secretion of insulin, but does induce resistance to insulin action in peripheral tissues; reversal of acidosis improves the sensitivity of glucose metabolism to insulin.[321] One possible mechanism of acidosis is to increase glucocorticoids. Bailey and colleagues also found that correction of acidosis with sodium bicarbonate improved insulin stimulated PI3-K activation in rats.[322] In muscle cell culture models without elevated glucocorticoids, acidosis by itself causes decreases in insulin stimulated PI3-K, without the typical glucocorticoid-mediated changes in the quantity of p85 subunits.[323] This suggests that in uremia acidosis induces insulin resistance at the level of PI3-K by glucocorticoid-dependent and -independent pathways. It is not clear if these same mechanisms may be important earlier in CKD where frank acidosis is not present, but the transient acid loads increase amino-acid mobilization from muscle.

Several other factors have been found to be at least partially responsible for the decreased insulin sensitivity. As discussed above, PTH excess impairs the response to insulin.[324] Suppression of PTH levels by the administration of 1,25-$(OH)_2D_3$ improves glucose metabolism.[325] Additional factors associated with uremia that could aggravate insulin resistance include angiotensin II, TNF-α, and chronic insulin stimulation.[326,327] The relative contributions of these factors are unknown.

In uremia, the counter-regulatory hormones of carbohydrate metabolism are also affected. Plasma glucagons levels are elevated.[328] Both active hormone and inactive precursors and metabolites are found in greater than normal concentrations. In contrast to insulin, the cellular response to glucagons is normal or only slightly depressed. On the other hand, glucagon binding by receptors and the post-receptor cyclic adenosine monophosphate (cAMP) response to glucagon are both subnormal in uremia.[329]

Growth Hormone/IGF-1

Growth hormone levels increase in renal failure.[330] Renal failure does not decrease the clearance of growth hormone so the production of growth hormone must be greater than normal. Thus, the high serum levels result from abnormally increased growth hormone secretion. Despite excess growth hormone, growth retardation is nearly universal in children with renal failure, beginning by the time the GFR decreases to about 50 ml/min/1.73 m^2. Resistance to the action of IGF-1 is thought to be, in part, due to the accumulation of circulating binding proteins that reduce the free fraction (i.e., the active fraction) of the hormone.[331,332] In the case of growth hormone, there are circulating proteins that bind growth hormone, and receptor density is reduced, especially in acidotic patients.[332a]

The administration of exogenous growth hormone may stimulate growth; even though increased hormone levels are already present.[333] These data suggest that there is resistance to growth hormone action. Based on these results, Schaefer and colleagues investigated whether a post-receptor defect in growth hormone signaling caused of growth hormone resistance in uremic rats.[334] There was a marked reduction in phosphorylation of the JAK/STAT signal transduction pathway in liver tissue isolated from uremic rats and an increase in the corresponding suppressor protein. Thus, they

found impairment in the intracellular signal transduction pathway of growth hormone that could contribute to the growth hormone resistance found in patients with CKD.

Acidosis reduces growth hormone release from the pituitary and this leads to lower levels of IGF-1 production.[335] The response to an infusion of physiological concentrations of growth hormone may be very mildly impaired in acidosis, but larger concentrations completely reverse the effects of acidosis. Two factors appear to blunt the response to administered growth hormone: first, the density of IGF-1 receptors in muscle is lowered by acidemia; and secondly there is a defect in the signaling that results from the binding of IGF-1.[335] Since insulin and IGF signal through the same IRS proteins, the mechanisms that impair insulin signaling should also impair IGF-1 signaling. With correction of acidosis IGF-1 in uremic subjects, IGF-1 resistance does not improve to the same extent as insulin resistance, suggesting that separate mechanisms also play a role.[336,337]

It has recently been shown that administration of super-physiological doses of growth hormone reduces renal nitrogen loss. As discussed in the section on nitrogen metabolism in uremia, IGF-1 and insulin are major determinants of amino acid release from the muscle. Abnormalities in insulin and IGF-1 play an important role in the growth suppression seen in children with uremia and acidosis.[338] Despite normal levels of circulating growth hormone and IGF-1, growth retardation is common in uremic children.[339]

Leptin and Other Energy-Related Hormones

Plasma levels of leptin, a 16-kDa protein hormone that regulates appetite and energy expenditure, rise during CKD. Leptin is produced in adipose cells and in skeletal muscle.[340] When fat stores are large, the level of leptin is high and acts to suppress appetite but changes in serum leptin levels can occur within hours of fasting and are out of proportion to corresponding changes in body fat.[341] Leptin production is increased by hormones that have altered metabolism in CKD including glucocorticoids and proinflammatory cytokines (e.g., IL-1 and TNF-α).[340] Thus, inflammation would ordinarily be expected to stimulate leptin production, but this relationship may not hold in uremia.[342] CRP levels actually show an inverse correlation with leptin in ESRD. Leptin levels also increase markedly in conditions of insulin resistance.[343] Because leptin is a small peptide, it is partly cleared by the kidney, and with kidney damage, leptin clearance is reduced. Transplantation reduces leptin to control levels.[344] Some results suggest mechanisms besides clearance may also increase leptin levels in uremia. Clearly, leptin levels in patients with advanced renal failure increase up to fourfold in plasma when compared with controls of similar body composition.[345] In addition, uremic patients have decreased protein binding of leptin and nearly all their circulating leptin is in the free, biologically active form.

While human mutations as well as animal studies make it clear that absence of leptin activity can result in obesity,[341,346] the role of elevated leptin levels in driving anorexia or in regulating body mass is less clear, especially in CKD. Leptin binds its receptor in the hypothalamus, especially in the areas most associated with regulation of appetite and body weight.[340] Leptin suppresses neural pathways associated with hunger including neurons that produce neuropeptide Y and agouti related peptide.[347] For example, a decline in leptin levels yields a reciprocal increase in the production of by the hypothalamus which stimulates appetite. Thus, increased leptin should bias the system toward anorexia and weight loss. However, other peripheral energy-related hormones also influence similar signaling. Ghrelin is released an empty stomach, stimulates neuropeptide Y release from hypothalamic neurons and appetite while, PYY_{3-36} released from a full intestine, has the opposite effect. Plasma ghrelin levels also rise with CKD possibly partly offsetting leptin-induced hypothalamic signaling.[348] Insulin and neural inputs also have complicated regulation of this system. Leptin levels correlate very well with insulin resistance in many populations including ESRD. Clinical studies confirm that regulation of this system is complex in ESRD.[349] While there are high levels in ESRD, both leptin and ghrelin plasma levels seem to modulate appropriately with food intake and do seem to correlate appropriately with body mass and composition in ESRD patients. Even though regulation of leptin may be occurring, the extent to which this system is responsible for anorexia and weight loss in uremia remains to be determined.

Mechanism(s) in animal models of CKD with poor appetite had abnormal signaling processes in the third ventricular region of the hypothalamus.[347] Their appetite improved when the agouti-related peptide were injected into this area because this peptide blocks the anorexia-producing receptor, melanocortin receptor-4. It has been proposed that anorexia was caused by high levels of the negative regulator of appetite, leptin, because they found that CKD-associated anorexia was eliminated in db/db mice that do not express the leptin receptor. There are complementary possibilities. For example, Mamoun and colleagues reported that a circulating factor with a molecular weight of 1−5 kDa could be isolated from the plasma of dialysis patients and would cause anorexia when injected into rats.[283]

This is of interest because another anorexiogenic hormone produced by the intestine, PYY_{3-36}, has an estimated molecular weight of 3.9 kDa, raising the possibility that accumulation of PYY_{3-36} could contribute to the anorexia of uremia.[350] In fact, injection of PYY_{3-36} into animals or patients produces anorexia. Finally, the report by Cheung et al.[347] is of interest because the events they found to occur in mice with CKD also occur in animal models of cancer and sepsis.[350] This provides additional results for a common pathway leading to loss of protein stores in uremia and other catabolic conditions (see below).

Leptin can act directly on T cells to stimulate inflammatory responses[351] and is required for full cell-mediated immunity in mice.[340] Hyperleptinemia correlates with some inflammatory markers (e.g., IL-6) in ESRD patients, but inversely correlates with CRP.[342] Immunodepletion of leptin in uremic serum restored normal neutrophil chemotaxis in an *in vitro* study, but addition of leptin to normal serum did not hamper chemotaxis.[352] Once again it appears that leptin's effects are being modulated by other factors in uremic serum. Leptin stimulates glomerular endothelial and mesangial cell proliferation.[353] Because leptin increases extracellular matrix production in both cell types, it is interesting to note that infusion of leptin into normal rats for three weeks fostered the development of focal glomerulosclerosis and resulted in proteinuria. Thus, leptin may influence sympathetic activity, bone mineralization, inflammation, and glomerular disease, but the clinical importance of these findings remains to be determined.

INFLUENCE OF DIETARY THERAPY IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Uremia and Anorexia

It was reported as early as 1869 that dietary manipulation can improve uremic symptoms and, at least in some patients, dietary protein restriction can change the course of renal insufficiency at least in some patients.[272,354–356] It seems curious, therefore, that this strategy is not more widely used. Perhaps, its use would increase if there were not the concern that dietary protein restriction will increase the risk of developing malnutrition and hence, compromise the patient's prognosis after dialysis therapy is initiated. The intakes of protein, calories and other nutrients that are required to prevent malnutrition in CKD are known[357] and compliance with the diet can be monitored by 24 hour urine collections for urea nitrogen measurements.[202,203] Therefore, it has been possible to evaluate the risk of loosing protein stores with low-protein diets in CKD patients. The National Institutes of Health Modification of Diet in Renal Disease Study (MDRD) was a multicenter study of the impact of low-protein diets in CKD patients.[140] Throughout this study, patients were examined for evidence of malnutrition. Despite reports that some patients spontaneously reduce their dietary protein with progressive CKD, malnutrition is rare when a properly monitored diet is used to treat patients even when GFR is below 10 ml/min.[358–360] This point is emphasized because of the suggestion that a decrease in protein in the diet of a CKD patient is a signal to start dialysis.[2] It is axiomatic that if little or no attention is given to the diet severe metabolic disturbances will develop, including metabolic acidosis, hyperphosphatemia, low values of serum proteins, and so on.[3] With proper attention, these problems do not occur: CKD patients (average GFR 18 ml/min) were given a restrictive diet plus a supplement of essential amino acid analogues and followed for one year.[361] The patients were found to be in neutral nitrogen balance, had no acidosis, and normal values of serum phosphorus and albumin. Walser et al. evaluated 76 patients with GFR values $\leq$15 ml/min and followed them for a median of 1 year while they ate a low-protein diet.[358] Weight did not decline and average serum biochemistry values were: HCO_3^-, 22 mM; phosphorus, 5.6 mg/dl; and albumin, 4.1 g/dl. Aparicio and colleagues reported similar outcomes in 239 CKD patients followed for an average of 29.6 months.[359] There was no decline in weight or body mass index and average values of serum HCO_3^- and albumin were 24 mM and 3.9 g/dl respectively. A few reports indicate that prolonged use of low-protein diets by CKD patients does not impair their survival after beginning dialysis.[137,362] MDRD patients assigned to different diets were examined repeatedly for the presence of malnutrition during an average of 2.2 years.[363] The average values of "nutritional indices" (including weight and serum proteins) of those given low-protein diets remained within the normal range. There were small, statistically significant decreases in certain parameters in each of the groups eating protein-restricted diets but only two patients had to withdraw from the MDRD because of abnormalities in nutritional status values. Finally, Aparicio and colleagues examined the outcomes of dietary protein restriction in 203 CKD patients treated for an average duration of 33.1 months.[6] The number of patients is comparable to that participating in the MDRD Study. The outcome of these patients after they began treatment with dialysis or kidney transplantation was superior to that of CKD patients who were not treated by dietary restriction. This is of interest considering the report of Menon et. al.[364] They examined the outcome of CKD patients

treated in the MDRD study and concluded that treatment with ketoacids increased the risk of death in these patients. There are numerous problems with this report: (1) the therapies, complications, etc. of patients during the ~7 years from the end of the MDRD study until death were not evaluated; (2) ketoacid therapy was stopped at the end of the MDRD study nor was the outcome of those patients who complied with the ketoacid therapy during the two year trial. (3) This outcome was the opposite of that published by Chauveau et al.[6]

We emphasize these results because they document the safety of dietary therapy in terms of nutritional measurements. They also underscore the need to use strategies to delay the need for dialysis.[365] This is necessary because dialysis it will not be possible to offer dialysis therapy for all the patients who will develop kidney failure throughout the world. Most importantly, the survival of CKD patients is not improved by instituting dialysis at higher levels of renal insufficiency.[4–6] This points out why strategies must be developed to avoid or delay the development of end-stage renal disease.

Since there is evidence that low-protein diets do not compromise nutritional status if the diets are properly designed and if compliance is monitored,[202,355] we will address factors that could adversely affect nutritional status. One such factor is the mechanisms that decrease appetite of CKD and dialysis patients. This is a problem because there are reports that the protein and calorie intakes of CKD patients decreases as renal insufficiency becomes more severe and many dialysis patients will have decreased appetite.[366,367] Concern about this type of report plus the constellation of hypoalbuminemia, loss of weight and anthropometric evidence for loss of lean body mass has been ascribed to malnutrition or "uremic malnutrition." The specter of this syndrome has even prompted the suggestion that dialysis should be initiated "early" (e.g., creatinine clearance 20 ml/min) in order to avoid the development of malnutrition.[2] This diagnosis is incorrect because malnutrition is defined as abnormalities that arise from an inadequate amount of food or an abnormal composition of the diet. In CKD, however, there are several other mechanisms that can cause these abnormalities and they provide persuasive reasons why there is loss of weight, hypoalbuminemia, and so on.[368–370] Identifying mechanisms for a loss of protein stores is not simply pedantic or formalistic because a diagnosis of malnutrition implies that simply eating more protein can correct the abnormalities.[368,370] On the contrary, it has been known for over 130 years that eating too much protein will aggravate the symptoms of CKD leading to the constellation of findings that is termed "uremia.[272]" The critical questions are whether

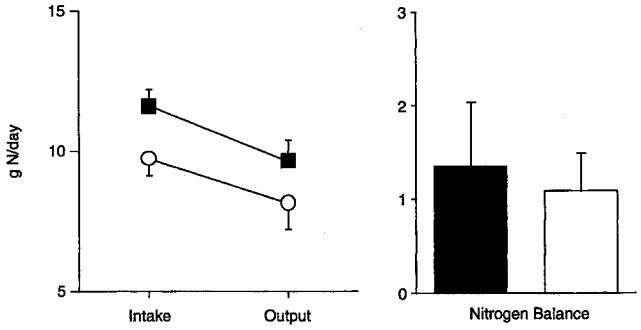

FIGURE 90.4 Nitrogen balance results in control subjects (*open symbols*) and nephrotic patients (*closed symbols*) fed 0.8 g of protein per kilogram per day plus 1 g per gram of proteinuria. The intake and output values of nitrogen were not different and nitrogen balance was mildly positive in both groups. *(With permission from Maroni BJ, Staffeld C, Young VR, et al. Mechanisms permitting patients with the nephrotic syndrome achieve nitrogen equilibrium with a protein-restricted diet. J Clin Invest 1997;99:2479–2487.)*

long-term therapy with low-protein diets leads to loss of protein stores, and at what point dialytic therapies improve survival compared to adequate conservative therapy. We will address the first question in detail, but the latter question still requires adequate controlled trials in diverse populations.

It has been repeatedly demonstrated that protein-restricted diets will maintain nutritional status: early studies demonstrated that neutral nitrogen balance was achieved during long-term therapy with low-protein diets; normal values of serum albumin were also present.[361,371–373] There is a report that a regimen of 0.3 g protein/kg/day plus a supplement of ketoacids increased the serum albumin level in CKD patients who had hypoalbuminemia.[374] Even for nephrotic patients, there is evidence that protein restricted diets are safe and that they improve the metabolic consequences of CKD[375–377] (Fig. 90.4). What then causes the loss of lean body mass and low values of serum proteins in CKD patients?

Abnormalities in Protein Turnover in Uremia

Body weights of dialysis patients are often low for the patient's height and are coupled with anthropometric evidence for loss of muscle mass plus low values of serum proteins.[207,378,379] Lack of attention to the diet does cause serious problems in patients with moderate CKD: Hakim and Lazarus reported biochemical measurements in 911 outpatients who were treated for up to seven years with received minimal attention to their diets.[380] When serum creatinine exceeded 5 mg/dl, one-third of patients had serum bicarbonate levels below 15 mM, hyperphosphatemia (values >7 mg/dl) and severe azotemia (BUN >120 mg/dl). These values

are rare even when CKD is advanced if patients are instructed about the design of diets and progress with this intervention is monitored.[358,359,361,373,381–384]

To what extent is excess dietary protein responsible for abnormal protein stores found in some CKD patients? In young rats with CKD, feeding a high-protein diet stunted linear growth and weight gain and led to very high levels of serum urea nitrogen (BUN).[385] CKD rats fed lower amounts of protein exhibited improved utilization of dietary protein to promote growth and decreased the BUN. Since acid is generated from the metabolism of sulfur-containing amino acids, phosphoproteins and phospholipids, a high protein diet would not only raise the BUN but also reduce serum bicarbonate. This is relevant because studies of rats as well as CKD patients have demonstrated that acidosis stimulates the catabolism of protein and amino acids and these reports led Bergstrom to conclude that acidosis is the only demonstrable uremic toxin.[207,221,386–388]

CKD is commonly associated with evidence of inflammation identified by the presence of increased levels of circulating cytokines.[49] In addition, high circulating levels of acute phase reactant proteins not only indicate the presence of inflammation but also are closely linked to subnormal levels of serum albumin in hemodialysis patients.[389,390] Experimental studies have demonstrated that injection of TNF-α or IL-6 can cause muscle protein wasting but the mechanism for this effect only recently was identified. Zhang et al. infused angiotensin II into mice and found increased production of both IL-6 and serum amyloid A, an acute phase reactant protein.[391] These events were accompanied by an increase in muscle protein breakdown and muscle atrophy. Their investigations showed that the inflammatory increase in IL-6 and serum amyloid A levels acted synergistically to impair IGF-1 signaling in muscle. The result was stimulation of muscle protein breakdown. These results not only show how inflammation can cause muscle atrophy but also demonstrate that some acute phase reactant proteins actually impair muscle metabolism. What is the mechanism by which metabolic acidosis and/or inflammatory cytokines cause a loss of protein stores? The answer involves understanding two metabolic principles: (1) the daily turnover rate of protein is quite large; and (2) metabolic responses are activated to prevent loss of protein stores when dietary protein is restricted. For example, in a 70 kg adult eating 1 g protein/kg/day, protein turnover is approximately 280 g of protein each day (i.e., four times the protein intake of 1 g per kilogram per day).[51,392] Therefore, even a small but sustained decrease in protein synthesis or increase in protein degradation will cause a major loss of lean body mass.

Mechanisms that Regulate Body Protein Stores

An increase or decrease in protein intake activates robust metabolic responses to maintain lean body mass: rates of amino acid and protein synthesis and degradation are adjusted rapidly and precisely to prevent loss of body protein stores. A major metabolic response is the rapid suppression of essential amino acids (EAA) degradation to ensure that an adequate supply of EAA is available for protein synthesis. When EAA degradation is suppressed to its minimum level, another mechanism is activated which suppresses protein degradation and increases protein synthesis (a less robust response).[393] These changes are detectable when the quantity of dietary protein is just adequate for achieving nitrogen balance; the World Health Organization (WHO) has determined that this amount of dietary protein is the minimum daily requirement or $\sim$0.6 g of protein per kilogram of ideal body weight per day.[394] These changes in EAA and protein metabolism are demonstrable in normal adults and in CKD patients as long as there are no complicating illnesses such as acidosis.[361,382,395] The same adaptive responses occur in patients with the nephrotic syndrome treated with 0.8 g protein/kg/day but the responses are keyed to a "net intake of protein" (the difference between actual intake and urinary losses).[375] Fortunately, the responses are not only precise, but they also occur rapidly and hence, are able to prevent changes in body protein stores when dietary protein changes. In CKD patients with metabolic acidosis or increased cytokine production, these metabolic responses are impaired and dietary protein restriction leads to loss of lean body mass.[396]

There is abundant evidence that metabolic acidosis causes amino acid and protein catabolism in infants, children, normal adults and CKD patients (Table 90.5).[221,386,387,397–404] The fate of essential amino acids is difficult to measure with the exception of the, branched-chain amino acids (BCAA), which are measured from the decarboxylation of the carbonyl group. In addition, BCAA are important components of muscle protein and the correction of acidosis raises their levels in plasma and muscle. In a rat model of CKD, Hara et al. identified the mechanism for the accelerated breakdown of BCAA in muscle.[220] They found that the mechanism reducing the levels of valine, leucine, and isoleucine was an increase in the activity of branched-chain ketoacid dehydrogenase (BCKAD), the rate-limiting enzyme that irreversibly oxidizes BCAA. They also showed that the low levels of BCAAs were corrected simply by adding sodium bicarbonate to the diet. The increase in BCKAD activity was found to result from an increase in the fraction of the enzyme in the dephosphorylated—and hence, its activated form.[405] There also are increased levels of the

TABLE 90.5 Metabolic Acidosis Induces Protein and Amino Acid Catabolism in Infants, Children and Adults

Subjects Investigated	Measurements	Outcome of Trial
Infants[397]	Low-birth-weight, acidotic infants were given $NaHCO_3$ or NaCl	$NaHCO_3$ supplement improved growth
Children with chronic kidney disease[398]	Children with CKD had protein degradation measured	Protein loss was approximately twofold higher with serum HCO_3 <16 mM vs 22 mM
Normal adults[399]	Acidosis induced and amino acid and protein metabolism measured	Acidosis increased amino acid and protein degradation
Normal adults[400]	IAcidosis induced and nitrogen balance and albumin synthesis measured	Acidosis induced negative nitrogen balance and suppressed albumin synthesis
Chronic kidney disease[401]	Nitrogen balance before and after acidosis treatment	$NaHCO_3$ improved nitrogen balance
Chronic kidney disease[221]	Essential amino acid and protein degradation before and after acidosis treatment	$NaHCO_3$ suppressed amio acid and protein degradation
Chronic kidney disease[402]	Muscle protein degradation and degree of acidosis	Proteolysis was proportional to acidosis and blood cortisol
Hemodialysis[387]	Protein degradation before and after acidosis treatment	$NaHCO_3$ decreased protein degradation
Hemodialysis[403]	Serum albumin before and after acidosis treatment	$NaHCO_3$ increased serum albumin
Continuous ambulatory Peritoneal dialysis[386]	Protein degradation before and after acidosis treatment	$NaHCO_3$ decreased protein degradation
Continuous ambulatory peritoneal dialysis[404]	Weight and muscle mass before and after acidosis treatment	Raising dialysis buffer increased weight and muscle mass

messenger RNAs (mRNAs) encoding E1a, E1b, and E2 subunits of the enzyme, implying that the expression of BCKAD is increased in response to acidosis. The biochemical triggers for these responses of BCKAD are complex because the expression and activation of BCKAD depend on both acidification and glucocorticoids.[388,406]

In humans as well, metabolic acidosis stimulates BCAA degradation: normal adults fed NH4Cl to induce acidosis raised their levels of leucine oxidation by 25%.[399] Likewise, when CKD patients were given sodium bicarbonate to raise their serum bicarbonate levels from16 to 21 mM, the rates of leucine oxidation decreased by 29%.[221] These changes are significant because muscle biopsies of hemodialysis patients revealed low free levels of BCAA and the levels increased to normal when the patients were given sodium bicarbonate.[407] Likewise, Mochizuki[408] reported that low levels of BCAAs in the plasma of acidotic CKD patients increased substantially when acidosis was treated. Acute uremia that is not complicated by acidosis is also associated with increased BCAA catabolism in muscle by unknown mechanisms.[409] Thus, acidosis stimulates the breakdown of essential amino acids and this in turn could reduce protein synthesis in muscle and potentially other organs.

Metabolic acidosis also stimulates protein degradation in muscle and hence, will block the second adaptive response to dietary protein restriction, the ability to suppress protein degradation when protein intake is restricted to minimal levels.[410] May et al.[411] studied acidotic, CKD rats and found their nitrogen excretion was 22% higher than in sham-operated, pair-fed rats. The mechanism causing the nitrogen losses was a 90% increase in the rate of muscle protein degradation. The critical experiment showed that correcting acidosis with dietary sodium bicarbonate eliminated the increase in muscle protein degradation.

Mechanisms that Degrade Muscle Protein

In muscle cells, a low pH activates the ATP-ubiquitin-proteasome system (UPS) to degrade protein.[51,323] The UPS initially acts to conjugate a chain of ubiquitins to proteins that are destined for degradation; these protein are then degraded in a very large structure, the 26S proteasome which consists of many subunits.[412] ATP is also required to remove the ubiquitins and to unfold the substrate protein and inject it into the central tunnel of the proteasome where it is degraded. Ubiquitin is present in the cytoplasm and nuclei of all cells and is a member of the heat-shock family of proteins. Degradation of proteins in the 26S proteasome yields peptides that are split to form amino acids by cytoplasmic peptidases or the peptides are used in the process of antigen recognition.[412] The UPS is responsible for degrading the bulk of proteins in all cells and hence, its activity is highly regulated. This regulation principally occurs by the availability and action of specific E3 ubiquitin conjugating enzymes. There about 1000 of these enzymes which are able to recognize specific proteins that are destined for degradation and transfer the activated ubiquitin to the

substrate protein. In the case of muscle, the specific E3 enzymes are atrogin-1 or MAFbx and MuRF1 and their expression rises sharply in conditions associated with accelerated muscle protein degradation. When the atrogin-1/MAFbx gene was knocked out in mice, the increase in protein degradation stimulated by muscle denervation was reduced by ~50%.[413] Notably, the expression of atrogin-1/MAFbx and a number of other genes in muscle of rats with various catabolic conditions, including uremia, starvation, cancer, or insulin deficiency rises sharply.[414] These reports suggest that catabolic conditions, including CKD, activate a catabolic program of gene expression leading to muscle atrophy. In fact, experiments in rats with CKD have demonstrated that there is increased transcription of the genes encoding components of the UPS, including ubiquitin and subunits of the 26S proteasome.[217]

Experimental models of metabolic acidosis as well as CKD with associated metabolic acidosis have demonstrated that the UPS plays the critical role in the production of muscle atrophy in these conditions.[217,415] These results are reminiscent of the increase in the mRNAs that encode subunits of branched chain ketoacid dehydrogenase in muscle of acidotic rats.[405] Because the UPS is responsible for the breakdown of the bulk of proteins in all cells and the regulation of the half lives of so proteins that influence transcription and biochemical reactions, its mechanisms have been extensively studied and its discoverers Hershko, Ciechanover and Rose were awarded the 2005 Nobel Prize in Chemistry.

Activation of the UPS is responsible for the excessive protein degradation that occurs in response to diabetes, starvation, denervation, burns, sepsis, and cancer as well as metabolic acidosis.[51] Because the UPS is the key to the loss of muscle mass that occurs in all of these catabolic conditions, triggers to its activation have been sought. It has been speculated that the development of muscle wasting in CKD is initiated by inflammation.[49] As noted above, there is evidence that inflammation can activate muscle protein degradation but this process is complicated and does not depend on a direct influence of inflammatory markers. Instead, the activation of the UPS and protein degradation occurs when insulin- or IGF-1-induced cellular signaling is impaired.[391] In fact, the influence of NF-κB, the transcription factor that is activated by inflammatory cytokines, is not to stimulate expression of proteasome subunits in muscle cells but rather to suppress transcription of proteasome subunit genes by a mechanism that involves glucocorticoids.[416] In contrast, the transcription of the ubiquitin gene is stimulated by activation of the Sp1 transcription factor.[417] In short, the increase in expression of genes encoding components of the ubiquitin-proteasome system in catabolic conditions such as uremia cannot be explained by activation of a single transcription factor.

Other proteases besides the UPS participate when muscle proteins are being degraded. This was uncovered when it was shown that the UPS rapidly degrades actin or myosin but degrades actomyosin or myofibrils only slowly. This means that the complex structure of muscle is first cleaved yielding substrates for the UPS. This initial cleavage is performed by caspase-3.[396,418] In the process of cleaving actomyosin or myofibrils, caspase-3 leaves a characteristic "footprint" in muscle, a 14-kDa actin fragment in muscle that can be recognized by Western blotting. As with activation of the UPS, impaired insulin or IGF-1 cell signaling stimulates caspase-3 activity; in muscle of insulin-deficient rats, the 14-kDa actin fragment accumulates and protein degradation is accelerated.[419] Another demonstration of the integration of mechanisms that degrade muscle protein is the influence of caspase-3 on activity of the UPS. It was found that caspase-3 increases proteolytic activity of the 26S proteasome by altering subunits of the proteasome.[420]

The cell signaling mechanism activating caspase-3 and the UPS depends on the presence of defects in downstream signaling of the insulin/IGF-1 pathway. Whent there is suppression of the activity of phosphatidylinositol 3-kinase (PI3K) and Akt[419] there is reduced phosphorylation of the Forkhead transcription factor, FOXO. This factor can then enter the nucleus to increase the expression of the key E3 conjugating enzyme, atrogin-1/MAFbx. This response is responsible for stimulating muscle protein degradation. There are still important responses and processes that regulate muscle protein turnover, but these steps are relevant to patients with CKD. First, it was shown that correction of the metabolic acidosis of patient being treated by chronic ambulatory peritoneal dialysis resulted in an increase in body weight and evidence for suppression of the UPS.[256] Second, it was demonstrated that the 14 kD actin fragment in muscle biopsies was proportional to the rate of protein degradation measured in patients who had muscle wasting from severe osteoarthritis.[421] In addition, the density of the 14 kD actin fragment decreased in muscle biopsies of hemodialysis patients when they were trained in endurance exercise (i.e., bicycle pedaling); this beneficial response was not present in control patients or those trained in resistance exercise.

There is abundant clinical evidence that acidosis causes protein losses in uremic patients (Table 90.5). Papadoyannakis et al.[401] showed that treating CKD patients with sodium bicarbonate improved their nitrogen balance. Williams and colleagues[422] studied acidotic CKD patients who were eating a high-protein diet and reported that the rate of protein degradation

did not decrease appropriately when the patients were switched to a low-protein diet. This response was attributed to interference with adaptive responses to decreasing dietary protein and was corrected by giving sodium bicarbonate. Using a similar strategy, Reaich et al.[221] found that the rate of protein degradation was high in acidotic, CKD patients. When the patients were given sodium bicarbonate, partial correction of acidosis decreased protein degradation by 28% but when given an equimolar amount of sodium as sodium chloride, proteolysis increased again. The presence of metabolic acidosis in CAPD or hemodialysis patients increases protein breakdown and correction of acidosis significantly reduces the rate of protein breakdown.[386,387,423,424] Similar responses can be detected in subjects with normal kidney function. Induction of metabolic acidosis in otherwise normal adults increases protein breakdown and causes negative nitrogen.[399,400] Moreover, if premature infants, children with renal tubular acidosis, or elderly women are treated to correct acidosis, their growth in the first two cases or the estimate of nitrogen balance improves in the last case.[397,425,426] This benefit extends to increasing serum albumin. Ballmer et al.[400] reported that creating metabolic acidosis in normal adults reduced their rate of albumin synthesis and Movelli et al.[403] reported that correcting metabolic acidosis in hemodialysis patients increase the concentration of serum albumin.

Acidosis also causes important changes in hormone responses. For example, Krapf and colleagues have reported that induction of metabolic acidosis in otherwise normal adults will impair the function of growth hormone and thyroid hormone and the conversion of vitamin D to its most active form, 1,25 $(OH)_2$ cholecalciferol.[337,427] Consequently, acidosis could interact to impair the ability of CKD patients to maintain protein stores by indirect mechanisms. One of the most well documented abnormalities in hormones is insulin resistance. It can occur in CKD patients who have serum creatinine values as low as 2.4 mg/dL.[428] The presence of insulin resistance is a trigger of muscle protein breakdown because it stimulates the activity of both casapase-3 and the UPS.[418,429,430] Fortunately, there is evidence that restricting dietary protein can improve the insulin sensitivity of CKD patients.[431,432]

Despite these well-documented reports of acidosis-induced catabolism in animals and humans, results from a cross sectional analysis of dialysis patients led the authors to conclude that acidosis is benign.[433] There are several problems with this conclusion. First, a cause-effect relationship cannot be established by results from cross-sectional studies.[434] Second, a single serum bicarbonate measurement is insufficient evidence of acidosis. This occurs because there can be loss of CO_2 during processing of the blood sample giving a falsely low HCO_3 level.[435] We recommend that even mild degrees of acidosis should be corrected to prevent interruption of the critical adaptive responses to changes in the diet. Otherwise, the patients will be at risk of loosing protein stores, including albumin.

In summary, uremic patients can lose protein stores if the adaptive metabolic responses that are required to maintain lean body mass are blocked when dietary protein is restricted. This has been demonstrated in normal subjects and CKD patients with acidosis. Another cause of lost body stores is the presence of inflammation or insulin resistance. Whether uremic toxins besides acid induce muscle wasting is unknown. Fortunately, acidosis and insulin insensitivity are improved by a low-protein diet and this may explain why eating a low-protein diet will improve the nutritional state of CKD patients.[358,359,377]

Assessment of Dietary Compliance

Since adequate but not excessive protein intake is required for optimal patient outcomes, monitoring dietary compliance is essential. The classic report by Folin[201] showed that a change in urea excretion is the principal response that occurs when the amount of protein in the diet is raised or lowered. This relationship has been repeatedly confirmed and provides the basis for methods directed at assessing compliance with low-protein diets.[202,203,371,372,436] In short, a change in the steady-state rate of urea excretion indicates that the amount of protein in the diet has changed. Methods devised to estimate dietary protein intake can be used repeatedly to evaluate how the diet affects the symptoms of kidney disease as well as assessing compliance with a dietary prescription.[202,203,363] The accuracy of the method is based on two facts. First, urea production is directly proportional to protein intake. Second, the half-life of urea in normal adults is approximately seven hours, so virtually all the urea that is synthesized following a change in the amount of protein in the diet is excreted within a day. To utilize the method optimally, it is important to emphasize that steady-state conditions must be present. Specifically, if kidney function is increasing or decreasing this introduces an error because the amount of urea excreted will depend not only on changes in the amount of protein eaten but also on the change in urea clearance. Fortunately, it is possible to determine if steady-state conditions are present, it is only necessary to measure body weight and the serum urea nitrogen (SUN). If both are stable, then the patient is in the steady state. Even if weight and/or SUN are not constant, the method can be used to estimate the change in the body pool of urea nitrogen as will be explained.

It is important to define certain elements of urea turnover in order to understand the basis for this

method of estimating dietary protein. First, the rate of urea production actually exceeds the steady-state rate of urea excretion in both normal and uremic subjects.[437] This occurs because there is an extrarenal clearance of urea that is due to urea degradation by bacterial ureases present in the gastrointestinal tract.[437–440] Fortunately, the amount of urea degraded does not cause a net decrease in urea excreted or accumulated in body fluids because the urea degraded is simply recycled and used to synthesize more urea.[437] Physiologically, this is important because it demonstrates there is no benefit to urea recycling. Previously, it was believed that the ammonia nitrogen arising from the degradation of urea can contribute substantially to the synthesis of amino acids in the liver, ultimately, providing a source of amino acids that could be used to synthesize proteins with an improvement in the nutritional status of uremic patients.[441] However, it was shown that ammonia nitrogen arising from urea breakdown is simply used to synthesize more urea and hence does not improve protein synthesis or nitrogen balance.[437,440] Because recycling of urea nitrogen does not change the rate of net urea production, this net urea production closely parallels dietary nitrogen.[202,371,442] Fortunately, net urea production is easily calculated even when weight and SUN are changing because the concentration of urea is equal throughout body water.[189,437] Since water represents ~60% of body weight in nonedematous patients, changes in the urea nitrogen pool can be calculated by multiplying 60% of body weight (in kilograms) by the serum urea nitrogen concentration (in grams per liter). The net production of urea, generally termed the urea appearance rate (UNA), is calculated as the change in the urea nitrogen pool (positive or negative) plus the amount of urea nitrogen excreted in the urine. Clearly, when serum urea nitrogen and weight are stable, there is no urea nitrogen accumulation and the urea appearance rate equals the urea nitrogen excretion rate (Table 90.6).

TABLE 90.6 Estimating Dietary Compliance Using Urea metabolism

1. A 70-year-old man with a urea clearance of 10 ml/min weighs 70 kg (CKD stage 5). He is prescribed a diet containing 0.8 g of protein per kilogram per day, which meets the daily allowance of protein recommended by the World Health Organization. Since protein is 16% nitrogen, he is eating 9 g nitrogen daily. His nonurea nitrogen excretion is 70 kg. His serum urea nitrogen (SUN) and weight are unchanging. A 24-hour urine collection contains 6.5 g of urea nitrogen. His non-urea nitrogen excretion is 0.031 g nitrogen per kilogram per day or 2.17 g nitrogen per day. His total nitrogen excretion is 8.7 nitrogen per day indicating he is compliant with the prescribed diet ($8.7 \times 6.25 = 54$ g protein per day (1 gram nitrogen equals 6.25 g protein).
2. cA 60-year-old woman with stage 5 chronic kidney disease is admitted to the hospital for plastic surgery. She weighs 60 kg and is eating a diet of 40 g per day (the minimum daily protein requirement (equivalent to 6.4 g nitrogen/day since protein is 16% nitrogen). She is excreting 4.5 g of urea nitrogen per day and her non-urea nitrogen is 1.9 gN/day ($60 \text{ kg} \times 0.031$ gN/Kg). Therefore, her total daily nitrogen excretion is 4.5 g urea nitrogen + 1.9 non-urea nitrogen ~6.4 gN per day. Subsequently, her SUN rose from 50 to 60 mg/dl. This represents an additional increase in nitrogen production ($10 \text{ mg/dL} \times 36$ L of body water or an excess of 3.6 gN above the pre-surgery value (this would not be rapidly excreted by patients with advanced or stage 5 CKD). Because her nitrogen excretion exceeds her protein nitrogen intake, her diet should be reviewed and a stool sample for blood should be collected (to exclude GI bleeding).

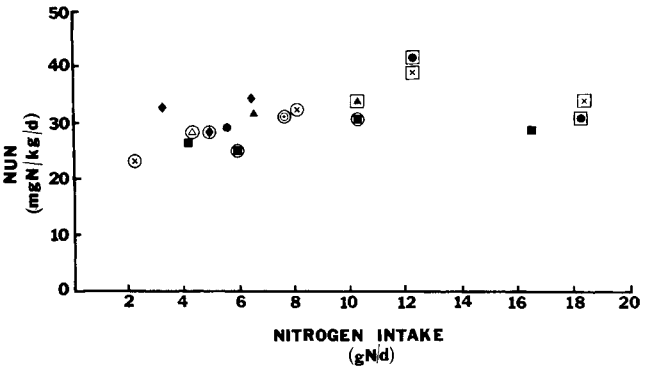

FIGURE 90.5 Calculated values of total non-urea nitrogen excretion (NUN) in normal subjects (*solid symbols*) and patients with chronic renal failure. The average value for patients not being treated by dialysis is 0.031 g of nitrogen per kilogram per day. *(With permission from Maroni BJ, Steinman T, Mitch WE. A method for estimating nitrogen intake of patients with chronic renal failure. Kidney Int 1985;27:58–65).*

Non-Urea Nitrogen

Fortunately, the contribution of non-urea nitrogen excretion (i.e., the nitrogen that is excreted in feces and in urinary uric acid, creatinine, peptides, and unmeasured nitrogenous products) can be estimated even more easily than urea nitrogen. The non-urea nitrogen varies minimally over a large range of dietary protein and averages 0.031 g of nitrogen per kilogram ideal body weight per day (Fig. 90.5).[202–204] This average value was based on results from CKD patients who had 5 g/day or less of proteinuria (if proteinuria exceeds 5 g per day, an additional amount of nitrogen equivalent to the urinary loss of protein nitrogen should be added to non-urea nitrogen excretion). To assess the accuracy of this equation for estimating dietary protein intake, we examined results from more than 70 nitrogen-balance measurements of CKD patients and found no significant correlation between dietary nitrogen and either fecal nitrogen or the sum of all forms of non-urea nitrogen excretion. Thus, compliance with a prescribed amount of dietary protein is evaluated by converting the prescribed amount to its nitrogen equivalent by multiplying it by 0.16 (protein is 16% nitrogen). If nitrogen balance is assumed to be

zero, then nitrogen intake will be equal to nitrogen excretion and the latter can be calculated as the sum of the urea appearance rate plus 0.031 g of nitrogen per kilogram per day.[202] If the total amount of waste nitrogen produced is the same as the amount of protein in the prescribed diet, then the patient is compliant with the diet. But, if waste nitrogen production is greater or lesser than the amount of nitrogen in the prescribed diet, the patient should meet with a skilled dietician to uncover why the patient is not being compliant with the prescribed diet. The caveat to using method is that it is unreliable in patients who are receiving total parenteral nutrition or eating completely digestible foods (e.g., astronauts). In these cases, non-urea nitrogen excretion will be less than 0.031 g of nitrogen per kilogram per day.[443] The method could also be inaccurate when assessing patients with severe catabolic illnesses or for those being treated with glucocorticoids or medicines that affect protein turnover in the body (e.g., anticancer drugs or growth hormone, and so on). This is important because patients being treated with glucocorticoids, or those with severe catabolic conditions will break down body protein stores to increase nitrogen excretion more than that derived from dietary protein.

In summary, the amount of nitrogen-containing waste products produced each day can be calculated from changes in body weight and SUN plus the 24-hour excretion of urea nitrogen and 0.031 g of nitrogen per kilogram per day. This is valuable because the amount of waste nitrogen produced is equal to nitrogen intake in stable patients. Since protein is 16% nitrogen, the prescribed nitrogen intake can be compared to the amount of nitrogen excreted and if the values differ by more than 20%, then reasons for noncompliance or reasons for nitrogen balance to be negative should be investigated.[354]

These calculations can also be used to evaluate calorie intake. Although this calculation is not as accurate as that of dietary protein, the principle is similar. Specifically, a skilled dietician can determine the percentage of calories that are derived from dietary protein so the calorie intake can be estimated from the calculated protein intake based on urea excretion. It is important to monitor calorie intake regularly for two reasons: first, an insufficient intake of calories will reduce the utilization of dietary protein, increasing the risk of losing protein stores. Second, there is evidence that CKD patients frequently "under-report" their calorie intake.[444–446] It is important to make these calculations so that the adequacy of a patient's actual intake can be evaluated. Moreover, advising a patient about his/her degree of compliance will help them participate in their therapy.

Other methods of assessing protein intake including dietary histories have been exhaustively reviewed:[447] dietary interviews not only provide less accurate estimates of actual intake but their reliability is questionable when interviews are used repeatedly (patients quickly learn to give the expected responses about dietary habits). At least two groups have compared estimates of energy intake obtained from food records with those based on anthropometric and oxygen consumption measurements.[444,445] The evaluations indicated that the intakes of calories based on dietary records are gross underestimates of actual energy intake. For these reasons, we recommend that dietary compliance be evaluated from measurements of urea nitrogen production plus an estimate of non-urea nitrogen excretion.

DIETARY PROTEIN RESTRICTION AND PROGRESSION OF RENAL INSUFFICIENCY

Clinical trials have been used to examine whether reducing dietary protein can influence the nutritional status and the loss of kidney function in CKD patients. Some of the published studies are of low methodological quality because they were based on a retrospective analysis, enrolled only a small number of patients or had serious design flaws. Overall, we examined more than eighty trials and identified ten randomized controlled trials[140,164,422,448–454] and five meta-analyses that were studied to assess if dietary protein restriction would slow the progression of CKD.[455–459] We also reviewed recent studies to assess whether dietary protein restriction (as part of an integrated treatment program for CKD patients) is nutritionally sound and does not jeopardize survival following a kidney transplant or initiation of dialysis therapy.[460] Generally, the trials were based on estimating changes in serum creatinine or the degree of proteinuria. The problems with this strategy are that several factors can modify creatinine metabolism and/or influence the degree of proteinuria (see discussions of creatinine metabolism and proteinuria). Second, restricting protein intake to treat the complications of CKD can change the rate of loss of kidney function by mechanisms not directly related to protein metabolism. For example, a low protein diet will also limit dietary salt intake to reduce the severity of hypertension and slow the progression of CKD. Alternatively, reducing protein intake could limit the accumulation and hence the toxicity of metabolic products such as indoxyl sulfate.

Efficacy of Protein Restriction in Non-Diabetic Kidney Disease

There are clinical trials which satisfy requirements for a high quality report.[458] The Northern Italian

Cooperative Study Group analyzed 456 patients who were designated as NKF-defined Stage CKD patients.[450] Patients were randomly prescribed 0.6 g/kg/day (LPD) or 1 g/kg/day (control group) plus at least 30 kcal/kg/day and followed for at least two years. Based on urea nitrogen excretion, the amount of protein eaten can be estimated: the control group ate an average of 0.90 g protein/kg/day while the low protein group ingested an average of 0.78 g protein/kg/day and there was substantial overlap in the protein ingested by the two patient groups.[202] The primary outcome, "renal survival," was defined as the start of dialysis or the doubling of serum creatinine and there was only a borderline difference between control and LPD groups; slightly fewer of the LPD patients group reached the endpoint ($p = 0.059$). Because the difference in protein intake was so small, it can not be concluded that the trial tested the hypothesis that "eating a low protein diet will slow the loss of kidney function."

The Modification of Diet in Renal Disease Study (MDRD) examined in a 2×2 design how different levels of protein intake and two levels of blood pressure control influenced changes in GFR measured using urinary collections of injected ^{125}I-iothalamate.[140] In Study A (Stages 3 CKD) 585 patients were randomly assigned to a standard diet of >1 g protein/kg/day or a diet containing 0.6 g protein/kg/day; targeted mean blood pressures were 105 or 92 mmHg. In Study B, 255 CKD patients (Stage 4 CKD) were randomly assigned diets of 0.6 g protein/kg/day or 0.3 g protein/kg/day supplemented with a ketoacid/essential amino acid mixture; blood pressure goals were the same as in Study A. There were no control patients eating an unrestricted diet. The actual protein intakes in Study A averaged 1.11 or 0.73 g protein/kg/day and in Study B, they averaged 0.69 or 0.46 g protein/kg/day plus the ketoacids/amino acids mixture.[202] After analyzing the results, it was concluded that in Study A, the loss of GFR in the two groups was not different. In Study B, the rate of GFR loss was somewhat higher in the group ingesting 0.69 g protein/kg/day compared to the rate in patients assigned to the 0.46 g protein/kg/day plus ketoacids/amino acids diet ($p = 0.07$). While these conclusions were consistent with a negative outcome, there are caveats. First, patients assigned to the restricted diet in Study A had an initial decrease in GFR during the first four months. This was assigned to the lower protein intake producing a hemodynamic reduction in glomeruli.[154] Subsequently, these patients had a slower loss of GFR than those assigned to the unrestricted diet. If the initial physiologic response is ignored (because it did not arise from kidney damage), then the low protein diet led to a significantly slower loss of GFR; there also was a significant improvement in "kidney survival" ($p = 0.009$). Secondly, the rate of loss of GFR in the unrestricted dietary protein group was lower than predicted and hence an additional three month follow-up should have been added before determining whether decreasing dietary protein influences the progression of CKD. For example, there was no protective effect of intensive insulin treatment in the U. S. NIH-sponsored Diabetes Control and Complications Trial (DCCT) on the protective effect of strict blood glucose control on the progression of kidney disease initially. After two years of observation, however, a benefit of glucose control was established and after four years of therapy, the development of microalbuminuria or macroalbuminuria/proteinuria was significantly reduced. In fact, secondary analyses of results of the MDRD trial, although less robust did identify slowing of progression during the trial.[461] For example, when the hypothesis that *eating a low-protein diet* slowed the loss of kidney function was tested, the reduced protein intake measured in Study B patients was associated with significant ($P = 0.011$) slowing of the loss of kidney function.[462] There also was reduced frequency of renal death (death or initiation of dialysis; $p = 0.001$). Indeed, for every reduction of 0.2 g /kg/d of protein intake there was a 1.15 mL/min/yr reduction in the rate of loss of GFR and there was a 49% reduction in the frequency of renal deaths. Notably, the benefit from eating a low-protein diet seemed to be linearly related to slowing of progression; stated another way, a progressive reduction in the amount of protein in the diet protects the kidney to a greater degree suggesting that there is no single level of dietary protein which will that provide benefits for all patients. Third, there was no apparent benefit of restricting dietary protein or controlling blood pressure in patients with polycystic kidney disease. This caveat is relevant because patients with polycystic kidney disease constituted ~25 percent of all patients in the MDRD Study and the presence of this group would prevent documentation of slowed progression in a trial lasting only 2.2 years. In short, inclusion of patients with CKD could have obscured beneficial responses of the diet in patients with other types of kidney disease.[140] Despite these caveats, the intention-to-treat analysis of the MDRD study results showed no statistically significant benefit of dietary protein restriction on the rate of decline in GFR.

In a smaller study lasting only 18 months, Williams et al. analyzed the effects of three dietary interventions in 95 patients with stage 4-5 CKD.[422] Patients were randomly to diets containing 0.6 g protein/kg/day and 800 mg phosphate, 1000 mg phosphate/day plus phosphate binders or to an unrestricted intake of protein and phosphates. Dietary compliance was estimated from diet records and urea excretion, yielding average levels of 0.7, 1.02 and 1.14 g protein/kg/day and 815,

1000 and 1400 mg phosphorus per day, respectively. Although there was a minor loss of weight in the low protein and low phosphate groups (−1.3 and −1.6 kg respectively) there were no differences in the decrease in repeated measures of creatinine clearance over time. There also were no differences in the numbers of patients who died or began dialysis therapy. Shortcomings of the study included a limited number of patients and the problems of detecting differences in creatinine clearances assessed over a relatively short period. For these reasons, no conclusions about the influence of the diets on progression of kidney disease can be reliably made.

Cianciaruso et al. studied patients with stage 4-5 CKD when they were randomly assigned to protein intakes of 0.55 or 0.80 g/kg/day.[453] The study lasted 18 months and included 212 CKD patients assigned to the lower protein intake and 211 who were prescribed the higher level of dietary protein. In the two groups, there was a significant ($p < 0.05$) difference in urea nitrogen production and hence, the average protein intakes. The protein-restricted group ate 0.72 while those assigned to the higher protein diet ate 0.92 g protein/kg/day ($p < 0.05$) but serum phosphorus, parathyroid hormone and bicarbonate levels were not different. In contrast, values of urinary excretion of urea, sodium and phosphate were all reduced in the low-protein diet patients yet the authors found no differences in body composition or nutritional indices (principally, serum albumin) between the two groups. Notably, if the results were analyzed on an intention-to-treat basis, 13 patients assigned to the 0.8 g protein/kg/day diet vs 9 assigned to 0.55 g protein/kg/day died or had to begin dialysis.

Di Iorio et al. evaluated 20 patients assigned to a very low protein intake supplemented with ketoacids and assessed whether the diet would affect the efficiency of erythropoietin therapy during two years.[452] Actual protein intakes of the two groups were 0.49 g/kg/day plus a supplement of ketoacids compared to 0.79 g/kg/day. Interestingly, only two patients assigned to the very low protein plus ketoacid regimen began dialysis compared to seven such outcomes in those assigned to the higher dietary protein ($p < 0.05$). Erythropoietin responsiveness was also improved in the low protein diet subjects and the improvement was inversely related to the serum parathyroid hormone and the decrease in serum phosphorus.[452]

Ihle and colleagues, studied 72 Australian patients with stage 4-5 CKD over 18 months.[164] They were randomly assigned to a unlimited protein diet or to 0.4 g protein/kg/day and actual protein intakes based on urea excretion values were 0.6 g/kg/day vs 0.8 g protein/kg/day.[202] The GFR (^{51}Cr-EDTA clearance) was measured every 6 months; it progressively declined only in subjects assigned to the higher protein intake. This adverse outcome was confirmed by a higher number of patients who had to begin dialysis ($p < 0.05$). The authors reported that patients in the protein-restricted group lost weight but there were no differences in other anthropometric measures or serum albumin. There was no analysis of differences in energy intake as a reason for weight loss.

Jungers et al. reported the outcomes of dietary protein manipulation in only 19 stage 5 CKD patients.[449] Ten patients were randomly assigned to a very low protein diet (0.4 g protein/kg/day) supplemented with ketoacids while 9 were assigned to a conventional low protein diet of 0.6 g protein/kg/day. The actual amount of dietary protein, however, differed by only 0.2 g/kg/day. Seven of the 9 patients assigned to the 0.6 g protein/kg/day had to begin dialysis vs 5 of 10 patients assigned to the ketoacid regimen ($p = 0.20$). The small number of patients limits conclusions from this report.

Malvy et al. studied 50 stage 4-5) randomly assigned patients prescribed a very low protein diet (0.3 g protein/kg/day) supplemented with ketoanalogues (Ketosteril®, 0.17 g/kg/day) or a diet containing 0.65 g protein/kg/day diet.[451] The outcome tested depended on differences between the diets in terms of the time until creatinine clearance decreased below 5 ml/min/1.73 m^2 or until a patient began dialysis. There was no significant difference in this measure of "renal survival" but the study was underpowered to test the hypothesis adequately. Patients in the very low protein/ketoacid group but not in the higher protein diet lost 2.7 kg of both fatty tissue and lean body mass during the three year study. Interestingly, the time for patients to reach a GFR of ≤ 15 ml/min/1.73 m^2 was different: for the 0.65 g protein/kg/day group it yielded a "half-life" before renal death of 9 months compared to 21 months for those assigned to the more restricted diet/ketoacid regimen. Although delaying the need for dialysis is undoubtedly a beneficial response, it is difficult to interpret the results because there was no control group assigned to an unrestricted diet.

Mircescu et al. evaluated the clinical course of 53 stage 4-5 CKD patients over 60 weeks.[454] They randomly assigned 26 patients to a diet of 0.6 g protein/kg/day and 27 to a 0.3 g protein/kg/day diet supplemented with ketoacids. Actual protein intakes were estimated to be 0.59 ± 0.08 and 0.32 ± 0.07 g protein/kg/day respectively. There were no deaths but 7 of the 26 patients assigned to the 0.6 g protein/kg/d diet required dialysis compared to only 1 of 27 in the very low protein/ketoacid group ($p = 0.06$). The more restrictive diet decreased serum phosphorus values ($p < 0.05$) but no differences in nutritional status and no significant difference in the loss of GFR estimated from serum creatinine. Again, the number of patients studied was too few to determine if dietary protein restriction slowed progression of CKD (in fact, the authors estimated that approximately 100 patients per

group would be required to identify if the diets produced a significant difference in progression of CKD).

Rosman et al. evaluated the influence of dietary protein restriction in 247 stage 3–5 CKD patients after two or four years.[166,448] There was a control group assigned to an unrestricted diet yielding stage 3 CKD patients eating 0.90–0.95 g/kg/day and stage 4–5 CKD patients eating 0.70–0.80 g/kg/day. After two years, there was significant slowing of progression of kidney failure but only in male patients (again, patients with polycystic kidney disease had no benefit). After four years, patients assigned to the protein-restricted diet had beneficial responses calculated as kidney survival and/or the percentage of patients who did not require dialysis (60% vs 30%, $p < 0.025$).[448] It is not clear whether patients prescribed the unrestricted diet had to begin dialysis because of increasing uremic symptoms. Regardless, the beneficial effect of low protein diet on the decline in GFR of patients prescribed the low protein diet was evident. Notably, there were no signs of malnutrition and the authors concluded that compliance was reasonable.

Brunori et al. examined 56 elderly IFtalian patients with Stage 5 CKD when they were treated with a protein-restricted diet or dialysis.[463] The patients were randomly assigned to begin dialysis therapy or treatment with a very low protein diet (0.3 g protein/kg/day) supplemented with ketoacids. After one year, the survival rates were comparable (83.7% in the dialysis group and 87.3% in the low protein diet; $p = 0.6$). When the results were evaluated by an intention-to-treat analysis (including those in the diet-restricted group who were switched to dialysis), there was a continuous benefit of the protein-restricted diet over time. Specifically, patients assigned to dialysis had a 50% higher degree of hospitalization. It was concluded that the low protein diet plus ketoacids did not impair survival compared to maintenance dialysis (Fig. 90.6).

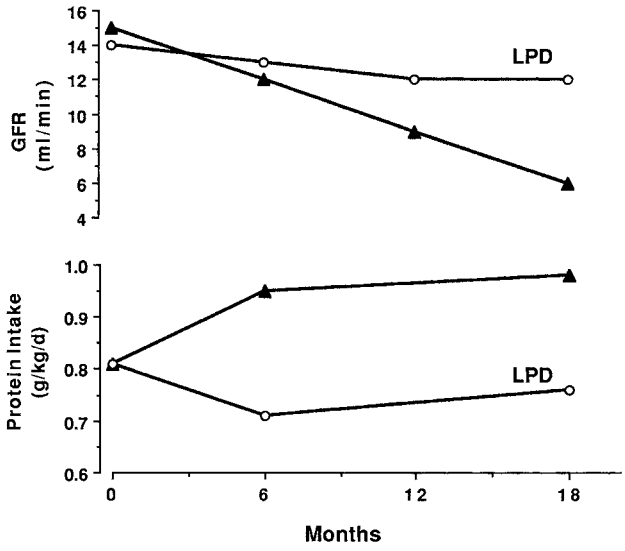

FIGURE 90.6 Changes in glomerular filtration rate (GFR) measured as the plasma clearance of 51Cr-EDTA in patients prescribed a protein-restricted diet (open circles) or an unrestricted diet (open triangles). The calculated level of dietary protein based on urea excretion is also shown. The low-protein regimen significantly reduced the decline in GFR. LPD, low-protein diet. *(Figure based on results from Ihle et al.[164] and is reproduced with permission from Mitch WE, Klahr S, eds, Nutrition and the Kidney. Second ed. Boston: Little, Brown; 1993:254.)*

Efficacy of Protein Restriction in Diabetic Kidney Disease

In diabetic, CKD patients, the benefits from dietary protein restriction have been tested but generally, only over brief periods of time. Consequently, surrogate analyses have been based to examine if there is efficacy of protein-restricted diets in terms of progression of CKD or changes in nutritional factors. The surrogate outcomes include changes in the degree of microalbuminuria or proteinuria and/or changes in creatinine clearance or serum creatinine (converted into an estimate of GFR). Besides the brief treatment periods, ACE inhibitor use was not distributed equally yielding important differences in the control of blood pressure.

Zeller et al. compared a diet containing 1 g protein/kg/d or 0.6 g protein/kg/d in 36 type 1 diabetic, CKD patients treated for an average of 35 months.[167] Changes in creatinine clearance and iothalamate clearance were measured and protein intakes were monitored from urea excretion: they averaged 1.08 vs 0.72 g protein/kg/day. The low-protein diet led to a significant ($p < 0.02$) reduction in the loss of GFR compared to results with the control diet. There was no indication that nutritional status was compromised by the low-protein diet.

The longest randomized trial of dietary responses in patients with Type 1 diabetes and CKD was reported by Hansen et al.[464] Patients were prescribed their usual diet or assigned to one containing 0.6 g protein/kg/day (actual protein intakes were 1.02 and 0.89 g/kg/day) over a four year trial. The degree of proteinuria was not different with the two diets but the frequency of renal death (i.e., end-stage renal disease) was 36% lower in patients consuming the protein-restricted diet and after adjustment for cardiovascular disease, the benefits in terms of renal deaths were even more significant ($p = 0.01$) for the low-protein diets.

Meta-Analyses of Reports Concerning CKD Progression and Low-Protein Diets

Meta-analysis is an alternative approach that to clinical research because it is a means of artificially raising

the number of subjects studied if the clinical trials are methodologically acceptable and address a common question. Meta-analyses can help to identify responses found in each original study that exhibit a tendency towards resolving a question but are insufficiently powered to determine if there is a statistically significant response when the outcomes are combined. Results and conclusions from large, randomized trials are considered to yield "level one" evidence while evidence from meta-analyses is considered to be equal to outcomes from smaller randomized trials. Meta-analyses are generally based on a so-called systematic review of the scientific literature, ensuring the most exhaustive collection of trials; they include searches of international databases as well. As noted, the most rigorous criteria for selecting or rejecting a report for analysis is to include only randomized, controlled trials because they are generally believed to produce more reliable results than those arising from non-randomized controlled trials.[457] Based on the identified problems with the planning and interpretations of the MDRD study results (see above), several meta-analyses have addressed the question of whether low-protein diets slow the loss of kidney function. The most frequent outcome in the analyzed trials is 'renal death' defined as a patient's death or the need to start dialysis;[455,456,465] alternatively, the rate of decline in kidney function[457] or changes in the degree of proteinuria[459] have been used.

In one of these meta-analyses, Kasiske et al. analyzed published results of clinical trials addressing whether low-protein diets reduced the loss of estimated GFR; they included a total of more than 1900 patients. It was concluded that these diets were positive since they prevented a loss of 0.53 ml/min GFR per year ($p < 0.05$).[457] This degree of protection was less than the amount reported by Fouque and colleagues.[458]

Meta-analyses of this question in diabetic patients have produced opposing views. Pedrini et al. found that low-protein diets reduced the risk of developing combined criteria of microalbuminuria and declining renal function by 44% ($p < 0.001$).[456] A more recent meta-analysis was based on eight randomized trials with a total of 519 patients, 253 in the low-protein diet group and 266 in the control group.[459] When analyzed by changes in GFR or creatinine clearance, no difinitive outcome was noted concerning differences in death or need for dialysis. Proteinuria did decrease significantly ($p = 0.003$), glycosylated hemoglobin improved (mean reduction, 0.31%, $p = 0.005$) and there was evidence for improved insulin sensitivity. However, the difference in protein intake between the control and experimental diets was small, 1.27 *vs* 0.91 g protein/kg/day ($p = 0.04$) and in six of the eight studies evaluated, the average estimated GFR values were above 69 ml/min. There are limits to this report: both type I and II diabetic patients were evaluated with some studies addressing only patients with early renal impairement (e.g., isolated microalbuminuria and no renal insufficiency (i.e., CKD stages 1 or 2) while another report consisted only patients with macroalbuminuria. The duration of trials only ≤ 12 months in four trials and the total number of patients might have been too small to assess all the measures tested.

Fouque and Laville performed their meta-analysis using results of ten randomized, controlled trials of the influence of low protein diets in slowing the loss of kidney function in non-diabetic CKD patients.[458] The outcome criterion was renal death. In their analysis, the genders of patients and their kidney diseases were equally distributed between control and diet-restricted patient groups, thereby avoiding the need to evaluate independent causes for more rapid losses of kidney function. The outcomes of 1002 patients assigned to dietary protein restriction were compared to the outcomes of 998 patients who were assigned to higher protein intakes (Fig. 90.7). Overall, 113 "renal deaths" occurred in the low-protein diet group compared to 168 patients with renal death in the control group. These outcomes reveal a 0.68 odds ratio for renal death in the low protein group compared to the control group (95% confidence interval, 0.55−0.84; $p = 0.0002$). The authors concluded that eating low protein diets can result in a 32% reduction in patient death or the need to start dialysis therapy when compared to unrestricted diets. Another method of expressing the results is to calculate the number of patients "needed to treat" or NNT in order to compare the outcomes of a treatment in different studies; this method tends to homogenize the results when absolute event risks are quite different between studies.[466] The NNT is the number of patients that would have to be treated for one year in order to spare one major event (e.g., death, kidney failure, or even hospitalization). Fouque and Laville concluded that the NNT with a low protein diet varied from 2 to 56 for each study.[458] Notably, the variability in the NNT mainly depends on the risk for renal death present at inclusion of the study and the degree of impairment in renal function; this follows because the absolute risk of renal death will be greater in subjects with more impaired kidney function.[449,451] Thus, the 2−56 NNT values are acceptable for evaluating primary and secondary prevention for a treatment, especially since the costs of therapy with a low protein diet is far below that of dialysis or transplant therapy. To illustrate the difference, consider that the reduction in mortality associated with prescribing a statin uncovered in the 4S trial (NNT = 30) or in the WOSCOPS study (NNT = 111) is in the range of that found with the low-protein diet.[467]

Protein restriction for diabetic renal disease (Cochrane Database Syst Rev. 2007 Issue 4 CD002181).)*

Thus, the meta-analysis technique, by increasing the number of observations, can reduce the incidence of renal death or increasing the time until dialysis is required. The conclusion stands in sharp contrast to the suggestion that dialysis be "started early".[2,3] As noted, results from controlled trials of early start dialysis have demonstrated that this practice does not offer patients any survival benefit.[4–6,137,460] It is worth noting that only two evaluations of the influence of the diet on the loss of kidney function were actually based on GFR measurements in patients with more advanced CKD: the report of Ihle et al. showed a protective effect and results from the MDRD study yielded a benefit that was nearly significant benefit ($p = 0.07$).[140,164] In contrast to outcomes with this precise measure of kidney function, there is abundant evidence that these diets can reduce the accumulation of unexcreted, metabolic products while maintaining nutritional status and consequently, can delay the need to begin dialysis therapy.

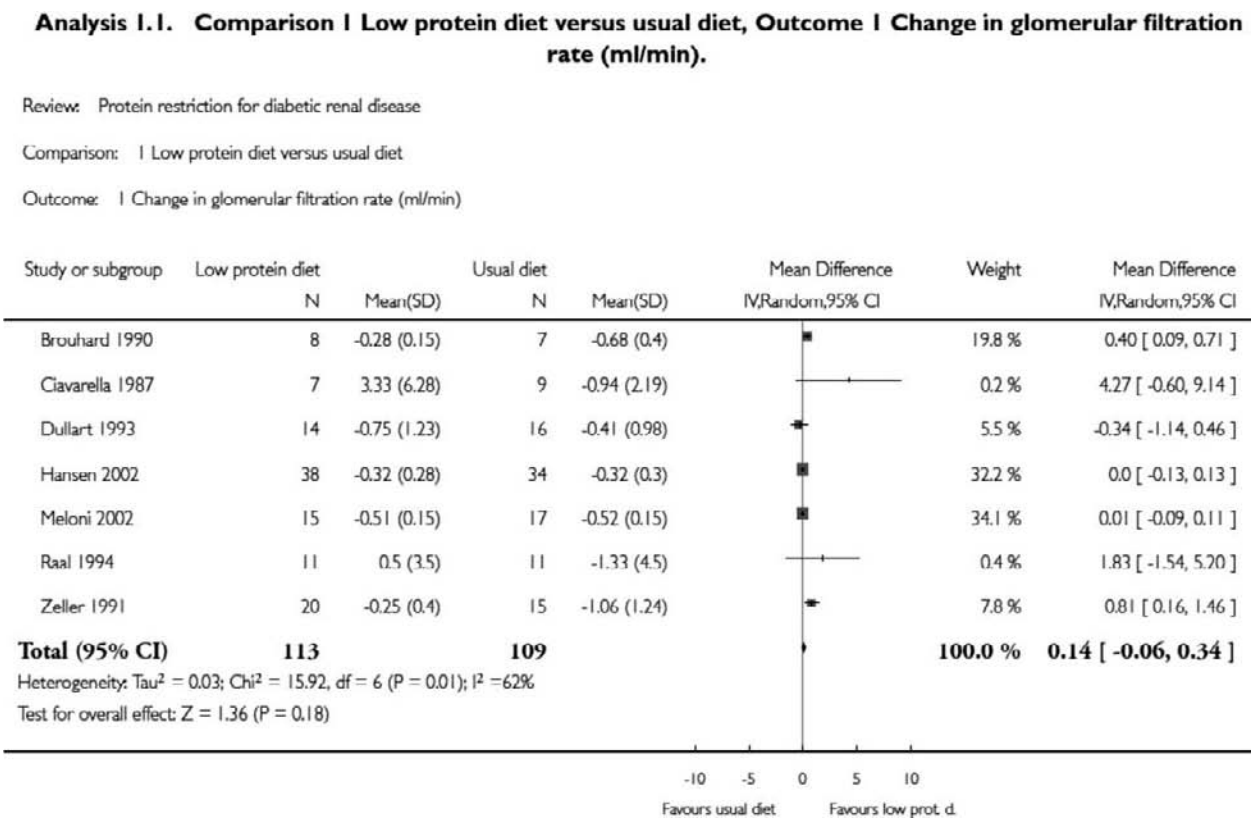

FIGURE 90.7 (Continued)

Our discussion of the pathophysiology and treatment of patients with CKD is based on a seemingly simple concept, namely that the cause of the morbidity and mortality occurring in CKD patients results from a reduced ability to excrete nitrogenous, non-nitrogen-containing metabolites and ions. It follows that restricting the precursor of treatment reduces signs and symptoms of CKD and is nutritionally safe as long as there is no complicating factor such as acidosis, infection, and so on (Fig. 90.7). Thus, dietary manipulation in a treatment program that includes monitoring protein and calorie intake in consultation with a dietician[202,468] should be a mainstay of therapy for all patients. The observation that protein intake voluntarily decreases as renal insufficiency progresses is not a signal for increasing in dietary protein because high-protein diets will simply increase the degree of uremia (including hyperphosphatemia, aggravate hypertension, etc.) and it will not raise serum proteins.[377,385] On the contrary, a well-designed protein-restricted diet usually increases serum albumin.[469] Regardless of an effect on progression, a low-protein diet could delay the need for dialysis by ameliorating uremic symptoms while maintaining nutritional status. Two publications provide strong evidence for the long-term safety of this approach.[358] Patients in these studies were followed for an average of 1.5–2 years after GFR had decreased to 10–13 ml/min. Nutritional status was well maintained while they ate protein-restricted diets and dialysis was not required. Clearly, successful implementation of dietary therapy requires the motivation of both the patient and the physician. The principal, if not the only disadvantage of such therapy (assuming that it is successful in eliminating uremic symptoms), is the dietary restriction that it entails, but it is reasonable to expect that dialysis therapy will be significantly delayed.

Metabolic Acidosis and Progression

The kidneys are responsible for clearing fixed acids that are generated from protein intake and metabolic acidosis is a common complication seen in progressive kidney disease.[470] There have been a number of studies that have suggested that correction of acidosis can modify the course of CKD. Shah et al. studied 5422 patients with a baseline eGFR <60 mL/min/1.73 for at least four years.[471] Kidney progression was defined as a 30% decrease in eGFR or a doubling of serum creatinine. Kidney failure developed in a significantly higher rate in those patients with serum bicarbonate <22 mM

compared to those with serum bicarbonate of 25 mM. Kovesdy et al. found that serum bicarbonate was related to all-cause mortality in patients with moderate to advanced CKD.[472] In a randomized, controlled trial, 134 Stage 4 CKD patients (CrCl 15–30 ml/min per 1.73 m^2) and serum bicarbonate 16–20 mM were assigned to receive oral bicarbonate or a placebo.[473] Over two years, fewer patients in the bicarbonate group developed rapid progression and ESRD developed less frequently ($p < 0.001$). Recently, Majahan and colleagues reported results from a randomized, placebo-controlled trial in which CKD patients were given sodium citrate[474] and showed that there was significantly reduced loss of estimated GFR.

CONCLUSIONS

Based on the pathophysiology of CKD, it is clear that multiple, adverse effects products of protein metabolism can be minimized by careful dietary planning to reduce protein intake. A clinician ignores dietary therapy at his or her patient's peril because the consequences in terms of the generation of symptoms and acceleration of the rate of loss of kidney function are predictable. It is also clear that treatment with an optimal amount of dietary protein is only part of conservative management. As we have discussed and has been covered elsewhere in this textbook, preventing acidosis, limiting the accumulation of phosphates and sodium, controlling blood pressure, repleting EPO and vitamin D, and inhibiting the activation of the sympathetic nervous system and renin-angiotensin-aldosterone systems have the potential to improve outcomes both in conjunction with and independent of optimal dietary protein intake. While there are differences of opinion in how best to implement these measures, they form the basis of the National Kidney Foundation's clinical practice guidelines on the conservative management of CKD. The epidemiology of CKD reminds us not only of the societal importance of addressing this issue, but also of the many comorbid conditions that complicate management. In short, the conservative management of CKD must take into account other comorbidities. For example, inflammation from infection, cardiac failure, malignancy, or poorly controlled diabetes can change requirements for dietary protein. Still, the safety of conservative therapy, and the availability of reliable methods for judging compliance and its effects combined with its potential for ameliorating many symptoms of CKD indicate that conservative therapy should be offered to all patients unless a transplant will be immediately available or there are complications that require initiation of dialysis therapy.

CHAPTER

91

Management of Calcium and Bone Disease in Renal Patients

L. Darryl Quarles

Division of Nephrology, Department of Medicine, Associate Dean for Research, College of Medicine, Memphis, Tennessee, USA

INTRODUCTION

We have made significant advances in understanding of the pathogenesis and treatment of secondary hyperparathyroidism in chronic kidney disease (CKD). These include: (1) the discovery of the calcium-sensing receptor CaSR and the development of calcimimetics to target this receptor to suppress PTH secretion and production;[1] (2) the recognition that metabolic derangements in calcium and phosphate have a significant impact on morbidity and mortality,[1] possibly through effects on vascular calcification; (3) the discovery of the FGF23-bone kidney axis, where FGF23 produced by osteoblasts/osteocytes suppresses $1,25(OH)_2D$ production as an early adaptive response to the loss of kidney function,[2] (4) the finding that elevated serum FGF23 concentration is an important predictor of mortality and progression of kidney disease;[3] (5) the development of less hypercalcemic and hyperphosphatemic vitamin D analogs with the potential of reduced toxicity;[4] (6) the recognition of the possible importance of nutritional vitamin D deficiency on innate immune function; and (7) the availability of non-calcium containing phosphate binders.[5] The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI™) and more recently KDIQGO have also provided guidelines for earlier interventions and management of mineral metabolism disorders in CKD.[6,7] These new pharmacological agents and treatment paradigms offers the potential to more effectively and safely manage disordered mineral metabolism in patients with CKD.

Parathyroid Gland Disease versus Mineral Metabolism Disorders in CKD

Secondary hyperparathyroidism is an adaptive response to the loss of kidney function. Progressive parathyroid gland disease (i.e., hypertrophy and hyperplasia) and pathological consequences of elevated serum PTH levels have dominated the clinical focus of disordered mineral metabolism in CKD. PTH actions are mediated through PTH receptor (PTH1R) in the kidney, whose activation inhibits renal Pi reabsorption, decreases renal tubular calcium excretion and increases $1,25(OH)_2D_3$ production. Activation of PTH1R in osteoblasts in bone stimulates bone formation and osteoclastic bone resorption.[8] Chronic elevation of PTH in SHPT leads to increased bone remodeling which plays crucial role in mineral homeostasis by providing access to the stores in bones Ca and Pi. Thus, PTH is a calcemic hormone that maintains serum calcium levels by stimulating $1,25(OH)_2D$ production, renal calcium conservation and bone calcium efflux. The phosphaturic actions of PTH permit excretion of phosphate that accompanies the gastrointestinal absorption and bone efflux of calcium.

It is clinically important to prevent and treat secondary hyperparathyroidism, since increments in PTH (typically levels that exceed the 400–600 pg/ml range) are associated with increased mortality in CKD.[1,9,10] In addition, elevated PTH is associated with progressive parathyroid disease leading to tertiary hyperparathyroidism that may require parathryoidectomy[11] and high cortical bone remodeling leading to an increase in the risk of bone fractures.[12]

In spite of the importance of PTH, the recognition that hyperphosphatemia, vascular calcifications and

different treatment strategies may have a greater impact upon survival of patients with CKD has lead to a broadening of our conceptualization of hyperparathyroidism and "renal osteodystrophy" to include other metabolic abnormalities, termed, Chronic Kidney Disease—Mineral and Bone Disorder (CKD-MBD).[7] CKD-MBD describes a clinical syndrome that includes multiple metabolic/endocrine abnormalities, parathyroid gland dysfunction, bone disease, and unique CKD associated cardiovascular risk factors as well as other adverse clinical outcomes, such as fractures, vascular and soft tissue calcifications.

Because of the integration and interdependence of the calcium, phosphate, vitamin D and PTH axis, it is difficult to elucidate the primary or proximate causes of secondary hyperparathyroidism in CKD. Hyperphosphatemia, $1,25(OH)_2D_3$ and hypocalemia, acting through distinct molecular mechanisms, act in concert to cause secondary hyperparathyroidism in CKD. However, elevations of FGF23 and secondary suppression of $1,25(OH)_2D$ production may the initial abnormality in CKD that leads to increments in PTH, which may further stimulate FGF23 levels.[2,13] Nevertheless, suppression of PTH, while minimizing hyperphosphatemia, providing adequate vitamin D replacement, and maintaining bone health, remains the major goal of therapy. Different strategies to achieve this are based on different molecular targets for the available therapies that include, phosphate binders, vitamin D analogues and calcimimetics.

Molecular Targets for Suppressing Parathyroid Gland Function in CKD

Role of Hyperphosphatemia

A decline in GFR and reduced renal phosphate excretion is associated with increased PTH secretion by the parathyroid glands in CKD. In patients on maintenance hemodialysis, increased levels of serum phosphate strongly predict the degree of serum PTH elevation.[14] The importance of phosphate is also supported by the observation that phosphate restriction can attenuate the development of secondary hyperparathyroidism in CKD.[15] The stimuli linking hyperphosphatemia and increments in PTH are likely to be both direct and indirect. The molecular mechanism mediating the direct effects of phosphate on the parathyroid gland, however, are poorly understood.[16] Increments in media phosphate concentrations increases PTH synthesis in parathyroid cell cultures,[17–19] regulates PTH message stability,[16] and dietary restriction of phosphorus retards the development of hyperparathyroidism.[20] Phosphorus also modulates parathyroid growth and hypertrophy through activation of MAPK (mitogen activated protein kinases), TGF-alpha, and cyclin dependent kinases.[21] To date, no specific receptors, transporters or other molecular targets have been identified that mediate direct effects of phosphate on the parathyroid gland function.

Indirect effects of hyperphosphatemia on parathyroid gland function have greater experimental support, and are potentially mediated via FGF23, $1,25(OH)_2D_3$, and calcium, acting on their respective receptors in the parathyroid gland. Phosphate loading can also decrease $1,25(OH)_2D_3$ production by the kidney,[22] which in turn can decrease dietary absorption of calcium, thereby regulating parathyroid gland function indirectly through both the calcium sensing receptor and the vitamin D receptor.[23]

Vitamin D Receptor and the Role of 1, 25$(OH)_2D_3$ Deficiency

Decrements in both 25(OH)D and $1,25(OH)_2D$ occur early in the course of CKD-MBD. Low levels of vitamin D are associated with increased mortality in CKD and treatment in vitamin D analogs are believed to have a survival benefit.[24] ($1,25(OH)_2$) acts on the vitamin D receptor (VDR) in the parathyroid gland to suppress PTH transcription, but not PTH secretion, whereas calcitriol acts on the small intestines to increase active transport of both calcium and phosphate. Reductions in serum $1,25(OH)_2D$ levels play a central role in the pathogenesis of secondary hyperparathyroidism. Cross sectional studies of patients with CKD show that serum 1, 25(OH) $_2D_3$ levels decline as a function of the severity of renal impairment. Increments in PTH are inversely correlated with serum 1, 25 $(OH)_2D_3$ levels below GFRs of 60 ml/min/m^2. Low levels of 1,25 $(OH)_2D$ stimulate PTH though both loss of direct effects of $1,25(OH)_2D_3$ on vitamin D receptors (VDR) in the parathyroid glands and due to reductions in gastrointestinal absorption of calcium, which leads inhibition of the calcium sensing receptor (CaSR) in the parathyroid gland.

Nutritional deficiency of vitamin D as measured by low circulating $25(OH)D_3$ levels, is also common in patients with CKD, likely due to poor nutritional status, inadequate exposure to sunlight and chronic illness.[25] The negative correlation between serum PTH concentrations and 25(OH) vitamin D, the precursor to $1,25(OH)_2D_3$, is well established in the general population,[26] and may also contribute to secondary hyperparathyroidism in stage 3 and 4 CKD.

Role of the Calcium Sensing Receptor (CaSR) and Hypocalcemia

Calcium acting through CaSR is the major regulator of PTH transcription, secretion, and parathyroid gland

hyperplasia. From a biological standpoint, calcium and CaSR are more important that phosphate and 1,25 $(OH)_2D_3$ acting through the vitamin D receptor (VDR) in regulating parathyroid gland function. This conclusion is supported by mouse genetic approaches that have evaluated the phenotype in CaR, VDR, and 1 α-hydroxylase deficient mice has overlapping functions with CaR.[27–31] For example, secondary hyperparathyroidism and bone abnormalities in VDR-deficient mice can be corrected by normalizing serum calcium concentrations, whereas increased 1,25 $(OH)_2D_3$ levels is not sufficient to normalize PTH secretion and parathyroid gland growth in the absence of CaR. These mouse genetic studies are potentially important in setting the theoretical basis for selecting therapeutic strategies that target CaR as the dominant target in the parathyroid gland function, compared to VDR and phosphate.

Role of the FGF23-FGF Receptor/Klotho Signaling Network

FGF23, is a novel phosphaturic hormone produced by bone[32] is important in regulating phosphate homeostasis. Elevations in circulating FGF23 levels are one of the earliest abnormalities in CKD-MBD and are strongly associated with increased all-cause mortality.[33–34] Elevations of FGF23 inversely correlate with GFR.[35–38] Patients with end-stage renal disease (ESRD) have markedly elevated levels of FGF23 that parallels with degree of hyperphosphatemia[39] and SHPT.[40,41] FGF23 interacts with FGF receptors (FGFR) in the presence of the members of Klotho family of proteins.[42–43] The mechanism of increased FGF23 in CKD is poorly understood. The increase in serum FGF23 is not explained by reduced FGF23 clearance; and the proximate stimulus in early CKD that leads to increments in FGF23 are not clear. Nevertheless, FGF23 production is likely increased to counteract Pi retention due to reduced nephron mass by promoting urinary Pi excretion.[2] Elevations in FGF23 precede increments in PTH in CKD[44] and animal studies show that blockade of FGF23 by neutralizing antibodies lead to normalization of 1,25$(OH)_2D_3$ and PTH levels in models of CKD.[45] The effects of FGF23 on parathyroid gland function, however, are controversial. While some studies suggest that FGF23 promotes parathyroid gland hyperplasia,[46] other studies indicate that FGF23 directly suppresses PTH secretion via activation of FGF receptor/klotho complexes located in the parathyroid gland,[47] thereby explaining the apparent paradox between elevated FGF23 in patients with CKD and hyperparathyroidism. Additional studies will be needed to understand the direct effects of FGF23 in the pathogenesis secondary hyperparathyroidism.

Clinical Manifestations of Disordered Mineral Metabolism in CKD

The major abnormalities in CKD-MBD that require treatment are parathyroid gland dysfunction (i.e., increase PTH secretion and parathyroid gland hyperplasia), metabolic bone disease, and vascular calcifications/non-traditional cardiovascular risk.

Parathyroid Gland Abnormalities

Parathyroid disease in CKD is a progressive disorder characterized by increased PTH secretion as well as by an increase in the number of the PTH-secreting chief cells (hyperplasia). Disease progress correlates with hypocalcemia, hyperphosphatemia and duration of renal failure.[14,48] Unless adequately treated, secondary hyperparathyroidism inexorably progresses, with the frequency of parathyroidectomy proportional to the number of years of renal replacement therapy. The difficulty in treating hyperparathyroidism is due in part to massive hyperplasia and adenomatous transformation of the parathyroid gland that occur as a result of the chronic stimulation of PTH production in CKD. As the hyperplastic parathyroid glands enlarge, increments in basal, calcium-independent PTH secretion contributes to the elevated circulating PTH levels, although the glands retain responsiveness to calcium-mediated PTH suppression, i.e., normal set point.[49] With further progress there is adenomatous transformation along with reductions in CaR and VDR,[50] resulting in a right-ward shift in the set point typically associated with marked elevations of PTH and spontaneous hypercalcemia.

Renal Osteodystrophies

Bone disease in CKD is classically defined by bone histological analysis that assesses bone formation and resorption (rate of turnover or remodeling) and the presence or absence of a superimposed mineralization defect (osteomalacia). The major classifications include osteitis fibrosa (high turnover due to PTH stimulation of osteoblasts that are coupled to osteoclastic mediated bone resorption), osteomalacia (defective mineralization), and adynamic bone disease (low turnover due to low PTH and/or excessive treatment with vitamin D).[51] Symptomatic musculoskeletal disease, particularly tendon rupture, bone pain, muscle pain and weakness, and periarticular pain have decreased because of the success in suppressing PTH and the use of purer water to generate dialysate. Nevertheless, hip fractures occur 4-times more often in stage 5 CKD patients compared to the general population.[52] Attempts to link the type of histological bone disease or a specific level of PTH to increased fracture risk have been inconclusive. The utility of bone mineral density measurements to measure fracture risk have not been validated in CKD. Bone

biopsy after tetracycline labeling remains the standard for diagnosing bone disease in CKD. The use of bone biopsies, however, is diminishing because of cost and its invasiveness. Recent analysis of a cross section of patients with CKD found racial differences in the type of bone disease in CKD.[53] In this regard, whites exhibit low turnover whereas blacks have a greater prevalence of high turnover bone disease. A greater reliance is being placed on assessment of PTH and serum markers of bone turnover, which provide imprecise measures of bone disease.

The pathogenesis of the different forms of renal osteodystrophy is complex and not completely understood. PTH is the predominant factor controlling bone remodeling in CKD. In addition, the presence of C-terminal PTH fragments, which constitute 80% of circulating PTH, could potentially compete with PTH for type I PTH/PTHrP receptor or activate a novel C-PTH receptor with biological effects opposite to those of human PTH(1−84).[54] Whether the assessment of the PTH-(1−84)/C-PTH fragment ratio adds to the prediction of the underlying bone disease remains to be determined.[55] Active vitamin analogues also target osteoblasts and chondrocytes in vitro, but it has been difficult to separate the direct effects of vitamin D on bone and growth plate from that of PTH and calcium. Mouse genetic approaches to delete the VDR and 1α-hydroxylase suggest an independent role of Vitamin D in the growth plate and action in concert with calcium and PTH to activate osteoblasts and osteoclasts.[31,56]

The type of bone disease can influence serum calcium and phosphate levels. High bone turnover states contribute to elevated serum calcium and phosphate levels through increased release from bone, whereas low turnover states can also make patients more susceptible to developing hypercalcemia after dietary loads or vitamin D therapy, due to the diminished buffering capacity for calcium resulting from the diminished bone remodeling.[57] Adynamic bone disease may increase the risk of vascular and soft tissue calcifications, possibly due to limited calcium buffering capacity or to a calcium surfeit state.[58] An inverse relationship between vascular calcification and bone density is also found in stage 5 CKD.[59] Other examples of the impact of bone turnover on serum calcium and phosphate in ESRD are hungry bone syndrome following parathyroidectomy, hyercalcemina observed with immobilization, and hypocalcemia following treatment with anti-resorptive therapies.

Vascular Calcifications, Disordered Mineral Metabolism and Cardiovascular Disease/Morbidity and Mortality

Disordered bone and mineral metabolism in CKD contributes to calcification of soft tissues, particularly vessels, heart valves and skin. Vascular calcifications are very prevalent in CKD[60] and cardiovascular disease accounts for approximately half of all deaths in dialysis patients.[61] Several types of vascular calcification have been described in patients in CKD,[62,63] including intimal/atherosclerotic/fibrotic calcification, medial calcification, heart valve calcification, and calciphylaxis/calcific uremic arteriolopathy. First, intimal calcification occurs as focal calcification associated with lipid-laden foam cells seen in atherosclerotic plaques. Atherosclerotic/fibrotic calcification can have components of endochondral bone formation in the vessel wall. These calcifications may increase plaque fragility and risk for plaque rupture, or alternatively might stabilize the plaque, or merely represent an epiphenomena of atherosclerotic disease. Second, medial calcification is diffuse calcification that is not associated with atherosclerotic plaques and occurs in the media of vessels. Medial calcification, also called "Monckeberg's sclerosis," is seen with aging, diabetes, and with progressive renal failure. Valvular calcification represents the third major type of vascular calcification. This is a dystrophic calcification that is also associated with atherosclerotic disease.[64,65] There is a strong association between cardiac valve calcifications and vascular calcifications.

Calciphylaxis/calcific uremic arteriolopathy is the fourth type of calcification that results from amorphous calcium phosphate deposition in the vessel lumen leading to occlusion and tissue necrosis. The pathogenesis of calciphylaxis is not clear, but is associated with obesity, older age, female gender, diabetes mellitus, warfarin use, recent trauma, and calcium ingestion. Recently, studies in mice lacking fetuin, a calcium phosphate binding protein, have provided potential insights into the pathogenesis of this disorder. Fetuin binds to calcium phosphate to facilitate the clearing of this complex from the circulation. The absence of fetuin results in soft tissue calcification in mouse models. Low fetuin levels, which can be caused by inflammation, have been identified in dialysis patients with vascular calcifications and increased cardiovascular mortality.[66−68] Treatment of calciphylaxis with phosphate binders and parathyroidectomy typically are ineffective. Case reports suggest that sodium thiosulfate treatment can improve calciphylaxis-calcific uremic arteriolopathy.[69]

Coronary artery and vascular calcifications increase as a function of the number of years on renal replacement therapy and successful renal transplantation can lead to significant reductions in coronary artery calcifications by six months.[70] There is debate regarding whether the intimal calcification, which has predictive power in diagnosing coronary artery disease in non-uremic population, has the same significance in end stage renal disease. Traditional "non-uremic" factors,

such as hypertension, diabetes, and hyperlipidemia, may account for the increase in risk of cardiovascular disease. Interestingly, a multicenter, randomized, double-blind, prospective study of atorvastatin in type 2 diabetes mellitus CKD 5 showed that a 42% reduction in low-density lipoprotein cholesterol was not associated with a reduction in composite of death from cardiac causes, nonfatal myocardial infarction, and stroke.[71] Treatments to reduce cardiovascular mortality in non-dialysis patients may not be as effective in stage V CDK patients. Unique factors associated with renal failure may have a greater importance. Epidemiological data implicate hyperphosphatemia and elevated Ca X P product as being risk factors for increased mortality.[1]

Medial calcification of blood vessels had been thought to be of little clinical significance for many years, but its effect to increase blood vessel stiffness and reduce vascular compliance resulting in a widened pulse pressure, increased afterload, and left ventricular hypertrophy are potential mechanisms whereby vascular calcification could contribute to cardiovascular morbidity. In addition, retrospective analysis indicates that the presence of intimal and medial calcification are both associated with increased all-cause mortality and cardiovascular mortality in patients with ESRD.[72]

While hyperphosphatemia is believed to be the major the major cause of vascular calcification, it has not been proven that strategies to prevent hyperphosphatemia or efforts to maintain neutral phosphate homeostasis will prevent vascular calcifications in CKD.

Treatment Goals: K/DOQI™ Guidelines for Mineral Metabolism in CKD

Clinical practice guidelines for bone metabolism and disease in stage 3, 4, and 5 CKD have been developed by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI™) (Table 91.1).[6] The K/DOQI recommendations are influenced by the compelling evidence that elevated serum phosphorus and calcium x phosphorus product contribute to increased mortality[73] and the belief that excessive calcium loading may increase the risk of cardiovascular calcification.[5] The K/DOQI guidelines recommend attaining serum calcium, phosphorus, Ca X P product and PTH levels in a range that permits control of metabolic bone disease while limiting the potential toxicity of increased Ca X P product. The respective upper limit for serum phosphate in stage 5 CKD is 5.5 mg/dl, the corrected serum calcium is 9.5 mg/dL (corrected serum calcium = 0.8 x (4 − g/dL of serum albumin), and the Ca X P product <55 and intact PTH 300 pg/ml).

Retrospective data provide support for these recommendations. Most recently, analysis of the DOPPS database found that all-cause mortality and cardiovascular mortality were significantly and independently associated with serum concentrations of phosphorus, calcium, calcium-phosphorus product, and PTH.[74] Cardiovascular mortality was significantly associated with the serum concentrations of phosphorus, calcium (RR 1.14, P <0.0001), calcium-phosphorus product (RR 1.05, P <0.0001), and PTH (RR 1.02, P = 0.03). It is worth noting, however, that prospective studies demonstrating the benefit of attaining the recommended biochemical parameters or the adverse effects on mortality of excessive calcium exposure have not been performed or have not fully validated the K/DOQI recommendations. For example, the DCOR study, which enrolled 2103 adult hemodialysis patients who were randomly assigned to either sevelamer or calcium-based phosphate binders, found a 9 percent reduction in the risk of death from all causes in the sevelamer group compared to patients using calcium-based phosphate binders, but the result was not statistically significant (p = 0.30). Ganesh et al also did not find serum calcium or calcium based binders to be associated with higher cardiovascular mortality.[75]

In spite of wide adoption of these Kidney Disease Outcomes Quality Initiative (KDOQI)[76] guidelines in the United States, it is difficult to achieve the KDOQI guidelines. In a survey of hemodialysis facilities (N = 307) and patients (N = 17,236) participating in the Dialysis Outcomes and Practice Patterns Study (DOPPS) in the United States, Europe, and Japan from 1996 to 2001, 8% of patients were below lower target range and 52% were above upper target range for serum phosphorus; 9% were below and 50% were above for albumin-corrected calcium; 44% were above and 51% were below for calcium-phosphorus product; and 27% were above for intact PTH.[74] Because of this and other considerations, differing views of what represents adequate control of PTH and alternative clinical practice guidelines have been proposed, such as Kidney Disease: Improving Global Outcomes (KDIGO),[77] and Japanese Society of Dialysis Therapy (JSDT).[78] KDOQI PTH targets between 150 and 300 pg/ml is based on the estimated levels of PTH to maintain normal bone remodeling, with the higher than normal range reflecting the resistance to PTH actions and assessment of circulating inactive PTH fragments in dialysis patients.[79] The emphasis of changes in PTH and higher (i.e., >600 pg/ml) threshold PTH concentrations in the KDIGO recommendations reflects the variability in existing PTH assays in measuring bioactive PTH and the recognitions that only high PTH values are associated with increased mortality. In contrast, JSTA uses PTH concentrations in the normal range for the general population in CKD, which emphasizes the prevention of progressive parathyroid gland hyperplasia.[80] Other differences in these guidelines include more stringent control of serum phosphate and increasing the upper limit for serum calcium from 9.5 to 10 mg/dL in the KDIGO recommendations.

The guidelines for the lower phosphate, higher calcium and lower PTH values recommended for stage 3 and 4 CKD are largely best estimates that were available at the time the guidelines were formulation. Recent retrospective observations also suggest that hyperphosphatemia is a risk factor for mortality in predialysis patients as well.[81] Several studies support the fact that declining GFR is independently associated with the development of atherosclerotic cardiovascular disease independent of other risk factors.[82–84]

Treatment Strategies

The goals of treatment are to adequately control biochemistries (i.e., Ca, P, Ca x P, and PTH as recommended by the K/DOQI), prevent parathyroid gland hyperplasia, normalize bone remodeling, and prevent soft-tissues and vascular calcifications. To achieve these goals combinations therapy is needed, including phosphate binders, calcium supplementation, active vitamin D analogues, and calcimimetics. There are two major treatment paradigms using various drugs in different combinations. One approach uses titration of active vitamin D analogues (i.e., calcitriol paracalcitol, doxercalciferol) to achieve suppression of PTH. The other strategy uses titration of calcimimetics to suppress PTH. Both strategies require phosphate binders to control serum phosphate. The calcimimetic strategy does not require use of active vitamin D treatment, but is typically used in combination with a fixed low dose active vitamin D analog.

There have been numerous clinical trials comparing use of vitamin D analogous alone and in combination with calcimimetics both in incident and prevalent dialysis patients.[85,86] Several generalizations can be made from these studies. First, incident HD patients are more responsive to either strategy than prevalent patients with more severe hyperparathyroidism. In the groups with milder degree of hyperparathyroidism, cinacalcet HCl HCl tends to oversuppress PTH.[87,88] Second, cinacalcet HCl HCl based treatments are superior in suppressing PTH than treatment strategies using phosphate binders and vitamin D analogs in prevalent hemodialysis patients. Third, treatment strategies using active vitamin D analogs increase serum calcium and phosphate levels, whereas strategies that use cinacalcet HCl HCl in combination with low fixed doses of vitamin D results in lowering of both serum calcium and phosphate levels,[89] making it easier to achieve KDOQI targets.[90] Fourth, vitamin D treatment increases, whereas use of cinacalcet HCl-based strategies has no effect on or may lower serum FGF23 concentrations.[91] Fifth, there is indirect evidence, based on the persistently high rate of parathyroidectomies in patients treated with active vitamin D analog compared to the reduction in parathryoidectomies associated with calcimimetic treatment, that activation of CaSR is more effective than activation of VDR in preventing the progression of hyperparathryoidism. Sixth, the persistently high rate of vascular calcification and mortality in ESRD patients also suggest that the current use of phosphate binders in combination with vitamin D analogs is not adequately addressing these complications. Although animal studies indicate an effect of cinacalcet HCl HCl to reduce vascular calcifications, clinical trials failed to observe a significant difference between strategies using active vitamin D analogues compared to cinacalcet HCl HCl.[92] Seventh, cinacalcet HCl HCl based treatment regimens are associated with reduced fractures in retrospective analysis of phase three trials.[93] Finally, whether different treatment strategies affect mortality remains unknown, although initial studies favor an effect of cinacalcet

TABLE 91.2 Effects of Dialysis Modality, Phosphate Binders and Vitamin D on Estimated Phosphorus Balance in Stage V CKD

Subject/Treatment	Intake (g/wk)[a]	Absorption (g/wk)[c]	Bound (g/wk)[b]	Output (g/wk)[d]	Approximate Balance (g/wk)

[a] *Assumes dietary phosphorus of 800–900 mg/day*
[b] *Assumes two calcium carbonate tablets (1250 mg; 1000 mg elemental calcium) three times each day or three calcium acetate tablets (667 mg; 507 mg elemental calcium) three times each day with meals for all patients*
[c] *Assumes 60% absorption in ESRD patients and 80% absorption in normal subjects and calcitriol treated ESRD patients*
[d] *Assumes no residual renal function in ESRD patients.*
ESRD (end stage renal disease), HD (hemodialysis 3 times per week), PD (peritoneal dialysis), SNHD (slow nocturnal hemodialysis 6 nights per week).

HCl HCl to improve all-cause mortality.[94] There is an ongoing prospective clinical trial to address this question.[95]

Management of Hyperphosphatemia

Hyperphosphatemia develops in CKD when compensatory increments in PTH and FGF23 fail to offset the reduction in phosphate excretion due to diminished GRF. While dietary sources of phosphate is the major contributing factor to hyperphosphatemia in patients with ESRD, treatment with active vitamin D analogues further increases the gastrointestinal absorption of phosphate and calcium leading to elevated serum phosphate and calcium levels[96] (Table 91.2). Early in the disease process, CKD 3 and 4, initial management with dietary phosphate restriction can be effective. During these early stages, there is still capacity for renal excretion of phosphate, and a neutral phosphorus balance can be achieved if the diet is adequately restricted. However, frequently by late CKD 4 and certainly by CKD 5, dietary restriction is inadequate, and other methods for achieving phosphorus balance are necessary. Hemodialysis and peritoneal dialysis have a limited capacity for phosphorus removal (Table 91.2), and this net removal is usually not enough with thrice weekly dialysis to maintain a neutral phosphorus balance, especially when vitamin D is needed (Table 91.2). Therefore, use of phosphate binders with limited doses or less hyperphosphatemic vitamin D analogs are required to achieve neutral phosphate balance.

Dietary phosphate restriction, while theoretically attractive based on results of limiting phosphate intake in animal models of CKD, it is difficult to achieve in clinical practice due to the high amounts of phosphate in processed foods and the risk of inadequate dietary protein with phosphate restricted diets. Therefore, phosphate binders are required to control serum phosphate levels. Phosphate binders are the first line in medical management of hyperphosphatemia in CKD 5. Phosphate binders may need to be started in earlier stages of CKD before serum phosphate is elevated; the efficacy of early use of phosphate binder to limit a positive phosphate balance on serm PTH and FGF23 elevations have produced inconclusive results.[97] Three categories of phosphate binders exist, trivalent cations, divalent cations, and synthetic resin polyallylamine hydrochloride (sevelamer).

Trivalent cations, such as aluminum and lanthanum carbonate, are the most potent phosphate binder on a per weight basis.[98] Aluminum use as a phosphate binder, however, has been discontinued because of potential bone and CNS toxicity. Lanthanium carbonate has been shown to be an effective phosphate binder in clinical trials,[99] and has been recently approved for use as a phosphate binder. Current safety data look encouraging (e.g., no evidence of bone and CNS toxicity), but there is some systemic absorption of lanthanum, and studies are needed that evaluate potential long-term safety.[100] Calcium based products, calcium carbonate and calcium acetate, are the mainstay of treatment, but high calcium loads and risk of vascular calcifications lead to the K/DOQI recommendation to limit the total calcium intake to 2 grams per day. Recently, the risk of calcium loading has been reevaluated,[101] and greater amounts of oral calcium may be tolerated, especially in the absence of high dose vitamin D therapy. The CARE study, which is the only

prospective trial to directly compare the efficacy of calcium acetate with sevelamer showed that the calcium based binder was more effect in controlling serum phosphorus and CaxP product than sevelamer, although calcium acetate treatment resulted in higher calcium levels.[101] Poly-allylamine (sevelamer) is a non-metal and non-calcium based phosphorus binder that is a less potent than trivalent and divalent cations. However, sevelamer has been shown to reduce the development of vascular calcifications.[5] The Treat-to-Goal study demonstrated slower development of coronary and aortic calcification with sevelamer compared to calcium based binders, and the D-COR study, showed marginal survival benefit in subgroup analysis (i.e., patient over 65 years of age and treatment greater than two years, but no survival advantage in the entire sevelamer group). Poly-allylamines also lower LDL, which is probably due to its ability to bind bile acids akin to cholestyramine.[5,101,102]

It is common to use combinations of calcium and non-calcium phosphate binders to achieve control of serum phosphate in stage V CKD. Also, phosphate binders containing magnesium and iron are also under development. In addition efforts to block the active transport of phosphate across the intestinal epithelium might also reduce phosphate absorption. Therapies that target Npt2b, the sodium-phosphate contrasporter in the intestines are under development. Two other approaches may reduce active phosphate transport, including reduction of dose of active vitamin D and its analogs and treatment with niacin. Since use of active vitamin D analogs increases gastrointestinal calcium and phosphate absorption, the use of lower doses of active vitamin D analogs may lead to lower Pi absorption by the GI tract, and lower serum Pi. Niacin is converted into niacinamide during its metabolism and reduces intestinal transport of Pi via inhibition of Npt2b. Both, niacin and niacinamide are available, but niacinamide may be better tolerated since it does not cause vasodilatation or flushing. Niacinamide has been shown in small clinical trials effectively reduce serum Pi levels in hemodialysis patients,[103,104] as well as peritoneal dialysis patients.[105]

Use of phosphate binders alone is not sufficient to treat secondary hyperparathyroidism in stage V CKD, and therapy with vitamin D and/or calcimimetics are needed.

Role of Vitamin D Analogs

Treatment with 1,25-dihydroxyvitamin D_3 (calcitriol) or an active vitamin D analog (calcitriol, paricalcitol, doxercalciferol, and alfacalcidol) have been the major intervention to treat secondary hyperparathyroidism in CKD stage V. There is no uniform agreement regarding the route, dose, and type of active vitamin D analog that should be given, with oral vitamin D predominating in Europe and Asia and intravenous vitamin D administration the mainstay in the U.S. Available vitamin D_2 analogs, such as paricalcitol, may cause less hypercalcemia and hyperphosphatemia than calcitriol, although the mechanisms for this effect are not clear. In preclinical studies, *paricalcitol* induced less hypercalcemia than calcitriol in vitamin D–deficient rats, in spite of having similar intestinal and bone-mediated calcimimetic actions.[4] Some studies, however, have failed to observe major differences in the propensity of paricalcitol and calcitriol to induce hypercalcemia and hyperphosphatemia, indicating that all forms of currently available vitamin D analogs retain the side effect of increasing the Ca X P product, if given in sufficient dosages.[106,107] Moreover, activate vitamin D analogs elevate FGF23 levels,[2] which is a strong biomarker for mortality in CKD.[33] There have been no prospective, long-term trials comparing the efficacy and safety of the various vitamin D analogs. Alphacalcidol is a 1-alpha hydroxylated "low affinity" analogue that is hydroxylated by the liver to become the active drug that targets the vitamin D receptor. In spite of the effects of active vitamin D analogs to worsen hyperphosphatemia and stimulate FGF23, there is also data suggesting that treatment with active vitamin D may offer a survival benefit and paricalcitol may offer a survival advantage over calcitriol.[108] The survival effects of active vitamin D therapy may be dose dependent, with the survival advantage occurring with low dose and possible untoward effects associated with higher doses. Finally the potential of vitamin D to promote vascular calcifications in animal models has not been fully explored in the clinical setting. In a uremic rat model, calcitriol resulted in an increase in Ca X P production and aortic calcification.[109]

Until the institution of bundled payments in ESRD, the major factors influencing the use of vitamin D analogues were reimbursement. There have been no prospective studies that compare different vitamin D analogues or which attempt to determine the optimal dose of these agents. Since treatment with vitamin D analogues in CKD stage V make it difficult to achieving K/DOQI guidelines[110] and do not appear to eliminate the progression of parathyroid gland hyperplasia and rates of parathyroidectomy rates.[111] Significant parathyroid disease often persists following successful renal transplantation who have been managed with vitamin D based regimens, as evidenced by the frequent need for parathyroidectomy in this patient population.[112]

Use of vitamin D therapy in earlier stages of renal failure is controversial, in spite of the evidence of decreased 1, 25$(OH)_2D_3$ occurs early, in CKD stage 3 and 4, since calcium supplementation and phosphate binders can be effective in this setting. In addition,

elevations of FGF23 occur early in CKD and appear to suppress $1,25(OH)_2D$ synthesis, suggesting that reductions of $1,25(OH)_2D$ in early CKD is an adaptive response. This observation, along with the related observation that treatment with activate vitamin D analogues increases serum FGF23, raises concerns about use of active vitamin D analogs in early CKD.

On the other hand, vitamin D deficiency (defined by a serum 25(OH)D <20 ng/ml) is common in CKD.[113] Treatment with ergocalciferol or cholecalciferol to correct the deficiency of vitamin D along with phosphate binders to offset the loss of renal phosphate excretion may provide the most rational approach to manage patients with CKD 3 and 4. The standard of care is to treat individuals with serum 25 (OH)D concentrations <20 ng/mL (50 nmol/L) with 50,000 international units (units) of vitamin D_2 or D_3 orally once per week for six to eight weeks, followed by 800 units of vitamin D daily to maintain the target 25 (OH)D level.[114] Patients with CKD may be resistant to standard treatment with vitamin D_2 and D_3, requiring high doses to achieve 25(0H)D levels above 30 ng/ml.[115] Cholecalciferol treatment has been shown to regulate vitamin D receptor response in circulating monocytes in ESRD.[116] Treatment with Active vitamin D analogues, such as calcitriol, alfacalcidol, doxercalciferol, and paricalcitrol, can be reserved for patients who do not respond to phosphate binders and nutritional vitamin D supplementation.

Role of Calcimimetics

Calcimimetics offers an alternative approach to treating secondary hyperparathyroidism without raising calcium or using active vitamin D analogs. Calcimimetics are calcium-receptor sensing agonists that act on the parathyroid gland's CaSR by allosterically increasing the sensitivity of the receptor to calcium. Cinacalcet HCl HCl or (αR)-(−)-α -methyl-*N*-[3-[3-[trifluoromethylphenyl]propyl]-1-napthalenemethanamine hydrochloride has been approved for the treatment of secondary hyperparathyroidism in stage 5 CKD[117] as well as for primary hyperparathyroidism. In addition to directly suppressing PTH secretion and gene transcription through CaSR activation, calcimimetics have been shown to attenuate parathyroid gland hyperplasia in animal models of secondary hyperparathyroidism,[118] substantiating the role of CaSR in regulating parathyroid cell proliferation.

Results from several large clinical trials indicate that treatment with cinacalcet HCl hydrochloride (Sensipar®/Mimpara®) effectively lowers plasma PTH levels in hemodialysis patients with inadequately controlled secondary hyperparathyroidism despite previous management with vitamin D sterols and phosphate-binding agents.[85,86,95,119] Treatment with cinacalcet HCl HCl caused significant decreases in PTH without elevating serum calcium or phosphorus. In fact, there was a modest reduction in serum calcium and phosphate in protocols using calcimimetics in conjunction with standard therapy. The reduction in calcium and phosphate may be due to alterations in bone flux of these ions. The use of cinacalcet HCl HCl allowed more patients (approximately 41%) to attain the PTH and Ca X P values recommended by the KDOQI™ guidelines compared to less than 10% treated with phosphate binders and vitamin D analogues alone.[119] Treatment with cinacalcet HCl HCl also permits a reduction in doses of active vitamin D sterols while maintaining control of serum PTH. Calcimimetics are potent suppressors of PTH, and as a result use of cinacalcet HCl HCl can result in oversuppression of PTH and well as symptomatic hypocalcemia. In addition, cinacalcet HCl HCl is associated with increased nausea and vomiting, which limits its use in some patients. Only oral forms of cinacalcet HCl HCl are currently available, therefore, cinacalcet HCl HCl is currently outside of the bundled reimbursement for ESRD.

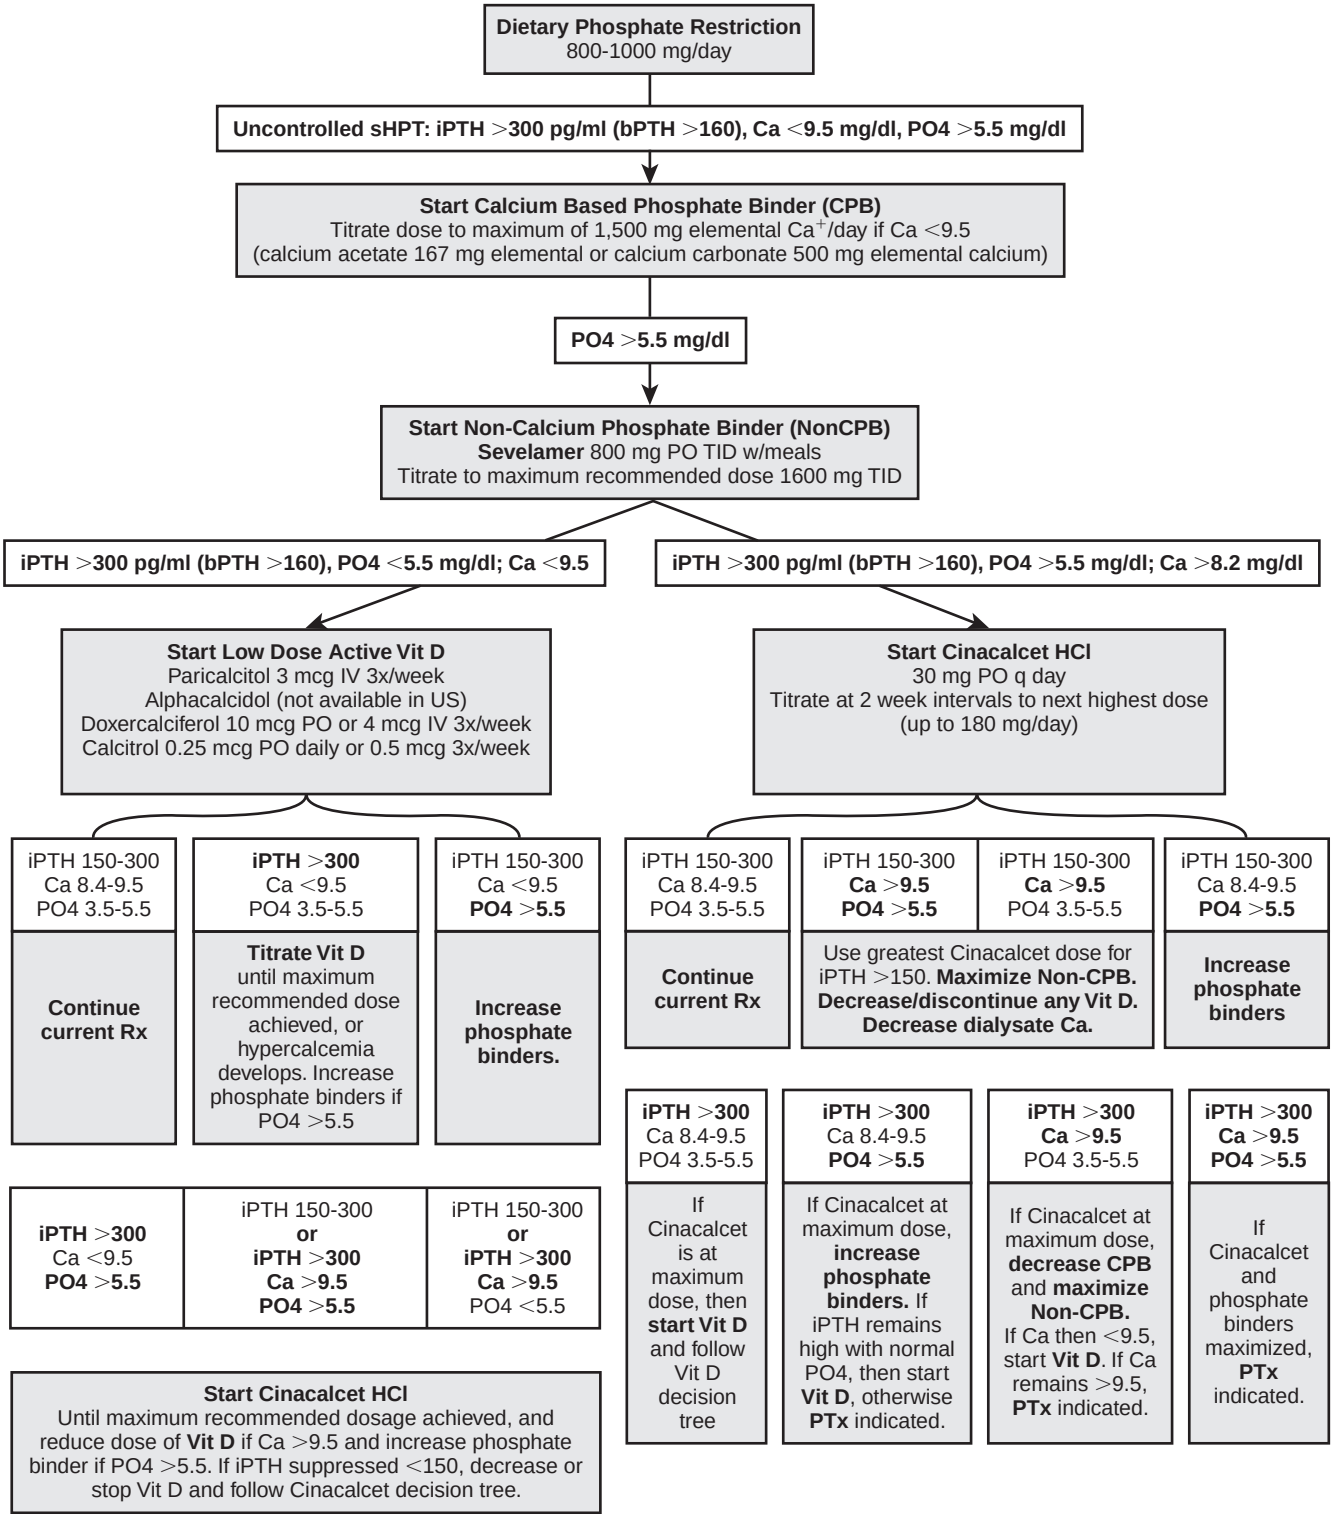
Calcimimetics also are effective in reducing PTH in CKD, but are associated with increased serum phosphate due to the loss of the phosphaturic effects of PTH and the lack of effects of cinacalect to stimulate FGF23.[120]

Specific Recommendations for Treatment

A possible algorithm is shown in Table 91.3 that takes into consideration advantages and disadvantages of calcium and non-calcium based phosphate binders, active vitamin D analogs, and calcimimetics.

Step 1: After measuring serum calcium, albumin, phosphate and intact PTH, begin therapy in all patients with phosphate of >5.5 mg/dl a phosphate binder. Calcium-based phosphate binder, either calcium carbonate or calcium acetate versus non-calcium containing phosphate binder. Calcium-based phosphate binders can be taken with meals at doses up to 1500 mg elemental calcium per day. Calcium carbonate has 500 mg of elemental calcium in a 1250 mg tablet; calcium acetate has 169 mg of elemental calcium in one 667 mg tablet. If serum phosphate remains greater than 5.2 mg/dl on maximal doses of calcium binders, then a non-calcium phosphate binder can be added. If there are vascular calcifications and unusual risk of cardiovascular disease in older patients, sevelamer, might be the treatment of choice, based on the treat to goal and D-Cor studies. In addition, concomitant use of active vitamin analogs favors use on non-calcium based binders, whereas the use of cinacalcet HCl HCl favors the use of calcium binders. Thus, the algorithm limits calcium exposure in patient receiving concomitant high

TABLE 91.3 Treatment Algorithm for Secondary Hyperparathyroidism in stage 5D CKD



dose therapy with vitamin D, but liberalizes calcium intake in hypocalemic patients treated with cinacalcet HCl HCl.

Step 2: Assess 25(OH)D levels. Treatment of vitamin D insufficiency should be considered if 25(OH)D levels are less than 20 ng/ml. Ergocalciferol or cholecalciferol should be administered to increase serum 25(OH)D levels to the 30 and 50 ng/ml (50−125 nM/L), regardless of serum PTH levels. If active vitamin D analogs are to be used to suppress PTH, correction of 25(OH)D levels may be superfluous, since active vitamin D analogs stimulate the innate immune responses similar to normalizing serum 25(OH)D.[116]

Step 3: Assess PTH levels. If PTH is greater than 300 pg/ml in the setting of phosphate binder therapy, then initiation of low dose, physiological replacement doses of active vitamin D analogs in doses equivalent to ~0.5 ug of calcitriol is recommended. If hyperphosphatemia develops after starting or increasing vitamin D, increments in the dose of phosphate binders, reductions in active vitamin D or institution of cinacalcet HCl HCl should be considered.

Step 4: If PTH values are greater than 300 pg/ml and serum calcium concentrations are above 8.2 mg/dl, on phosphate binders and low-dose active vitamin D therapy, cinacalcet HCl should be started at a dose of 30 mg/day and titrated upwards to suppress PTH in to the range of 150−300 pg/ml. Alternatively, active vitamin D analog doses can be titrated upward to achieve suppression of PTH if serum calcium and phosphate are respectively less than 9.5 mg/dL and 5 mg/dL.

Current clinical trials support the use of the cinacalcet HCl algorithm for patients with more severe hyperparathyroidism and elevated serum phosphate levels. This approach suppresses PTH without raising serum calcium and phosphate, whereas titration of active vitamin D tends to increase both calcium and phosphate (especially at high doses), making it difficult to achieve the K/DOQI endpoints. Cinacalcet HCl HCl should also be considered if hypercalcemia develops with treatment with Vitamin D. Calcium based phosphate binder may be preferred when using cinacalcet HCl HCl, since serum calcium levels are lower by calcimimetics. If hypocalcemia persists, consideration should be given to titrating upward the active vitamin D therapy. Patients with persistent hyperparathyroidism, in spite of maximal doses of cinacalcet HCl HCl and vitamin D should undergo parathyroidectomy. An open labeled trial comparing cinacalcet HCl HCl titration versus an active vitamin D titration,[85] similar to the proposed treatment paradigm, found that use of cinacalcet HCl HCl resulted in better control of serum PTH and phosphate concentrations than vitamin D titration. On the other hand, patients with milder forms of hyperparathyroidism, either a cinacalcet HCl or active vitamin D analog titration can reduce PTH levels to the 150 to 300 pg/ml range.[88] The ultimate choice between the initial use of cinacalcet HCl HCl versus active vitamin D analog titration involves patient compliance, ability to tolerate the gastrointestinal side effects of cinacalcet HCl, relative greater efficacy in optimizing serum calcium, phosphate and PTH with cinacalcet HCl, the differential costs of medications and reimbursement, and pending data on the effects on these different approaches to reduce mortality and morbidity in ESRD.

INTRODUCTION

During ontogeny, hematopoiesis—comprising erythropoiesis, granulocytopoiesis, and thrombopoiesis—is initiated in the blood islands of the yolk sac before the development of the kidneys. Later during gestation, at a time when hematopoiesis is fully established in the bone marrow, the kidney starts to play an important role in the control of erythro- and thrombopoiesis. This control is achieved through renal production of the hematopoietic growth factors erythropoietin and thrombopoietin. Thus, in addition to its role in waste excretion and water and electrolyte homeostasis, the kidney is also important in tissue oxygenation and coagulation.

With the exception of the growth period, the circulating red blood cell (RBC) mass, and hence the oxygen-carrying capacity of the blood, is normally fairly constant. Since the erythron is a continuously regenerating organ, a daily production of 20 ml of red blood cells is required in human adults to compensate for the physiologic demise of 120-day-old erythrocytes. In addition, when increased blood loss occurs or the oxygen saturation of hemoglobin falls, the bone marrow is capable of increasing this normal production rate of red blood cells three- to five-fold within a few days, and even up to seven-fold under chronic conditions. Similarly, the number of circulating platelets is kept constant (although in a wider range than red blood cells), and any decrease of platelet number results in activation of thrombocytopoiesis.

The predominant and essential regulators of red cell and platelet formation, erythropoietin and thrombopoietin are true hormones that are produced outside the bone marrow, and mainly in the kidney and in the liver.

This chapter is designed to summarize current knowledge about the specific role of the kidney in the humoral control of hematopoiesis both under physiologic and pathophysiologic conditions.

ERYTHROPOIESIS

Erythropoietin

Background

More than hundred years ago after the relationship between high altitude and inadequate tissue oxygenation was realized, it was postulated that hypoxia accounts for the adaptive increase in red cell mass that occurs during altitude exposure. While it was primarily believed that low oxygen pressure directly stimulates the bone marrow, the existence of a plasma factor regulating erythropoiesis was inferred from experiments in the early twentieth century,[1] and the term "erythropoietin" was coined to describe this putative factor.[2] However, it took another 50 years until convincing evidence was obtained for humoral oxygen-dependent control of erythropoiesis. At that time, Erslev[3] was able to stimulate erythropoiesis in rabbits temporarily through the injection of plasma from anemic donor animals, and Reissman[4] observed increased red cell formation in parabiotic rats kept at normal levels of oxygen when their partners were maintained in a hypoxic atmosphere. Surprisingly, it was found that—in addition to insufficient oxygen supply—the transition metal cobalt is also capable of inducing erythropoietin formation *in vivo*.[5] Systemic organ ablation analysis then revealed that the capability of the organism to

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00092-6

elaborate erythropoietin in response to anemia or to cobalt is markedly attenuated in bilaterally nephrectomized rats.[6] This was the starting point to consider a direct regulatory role of the kidney for erythropoiesis and a complement to the observation made much earlier that patients with kidney disease are usually anemic.[7] Nevertheless, the knowledge about erythropoietin remained rather limited, and erythropoietin was considered as an "elusive" hormone. This becomes understandable because the plasma concentration in healthy mammals is around a few femtomoles per milliliter. Continuous efforts to purify erythropoietin from the plasma of anemic animals have therefore not been successful, but provided very helpful information about the physicochemical properties of erythropoietin. Using the information that erythropoietin is a heat-stable acidic glycoprotein, Miyake et al.[8] then succeeded to purify human erythropoietin to apparent homogeneity from about 2500 liters of urine of patients suffering from severe aplastic anemia and obtained a few milligrams of the hormone. These small amounts allowed them to determine critical amino acid sequences, and with the help of recombinant DNA techniques, two groups independently succeeded to clone the human erythropoietin gene in 1985.[9,10] The knowledge of the genomic and complementary DNA sequence of erythropoietin and the availability of pure recombinant erythropoietin initiated a burst of activity leading to a greatly improved knowledge base about erythropoietin itself—action, regulation, and clinical use—and overall this work confirmed the important role of the kidneys as the primary site of erythropoietin production.

Structure of Erythropoietin

To the present, evidence for the existence of erythropoietin has been obtained for mammals. Whether *erythropoietin* also exists in lower organisms or in all vertebrates is not yet known. Evidence for erythropoietin genes was also reported for teleosts including fugu, zebra fish and trout.[11] Interestingly, this gene was found to be mainly expressed in the kidney, which is also an erythropoietic organ in these teleost fish.[12] Recently also erythropoietin of Xenopous laevis has been characterized.[13] The amino acid sequences of erythropoietin in mammals show a high degree of interspecies similarity. First, erythropoietin is generally synthesized as pre-erythropoietin that contains a typical endoplasmatic leader sequence of 25–27 amino acid residues that is cleaved off during intracellular processing. Second, the size of native erythropoietin is similar if not identical among species and comprises 165–167 amino acids. It was shown that the carboxy-terminal arginine of human erythropoietin is deleted from the molecule,[14] so that the 165 amino acids may be the species-independent length of circulating erythropoietin. Third, the overall structure of the molecule is highly conserved.[15,16] For example, out of 15 amino acid replacements between human and monkey and 41 replacements between human and mouse, roughly 50% are conservative. The high sequence conservation also explains the interspecies cross-reactivity of erythropoietin. From bioassays for erythropoietin, it is known that human, rat, monkey, dog, and rabbit erythropoietin are active in the mouse, and human erythropoietin also stimulates erythropoiesis in ewes, cats, and dogs. In keeping with the high degree of conservation, erythropoietin also shows no homology with other known proteins,[9,10] with the exception only of thrombopoietin.

Erythropoietin has a four-helical bundle structure with two disulfide bonds[17] (Fig. 92.1). One disulfide bridge between cys 7 and cys 161 links the N-terminus and the carboxy-terminus of the molecule together, generating a long loop. This disulfide bridge is fully conserved in mammals[16] and it appears therefore as if

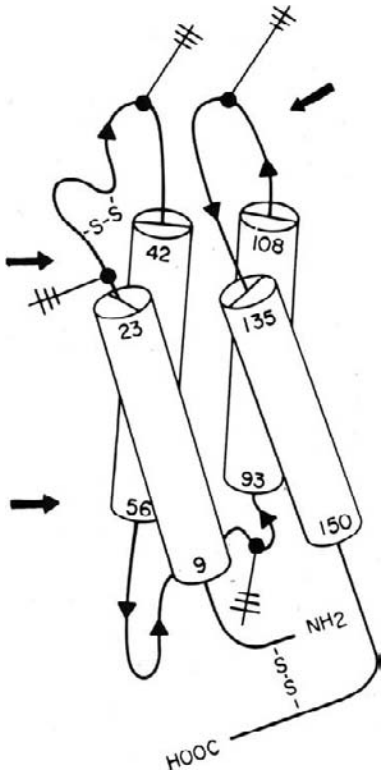

FIGURE 92.1 Predicted three-dimensional structure of the human erythropoietin molecule. The molecule appears as a four-helix structure, with four antennas of sugar side chains and two intramolecular loops formed by disulfide bridges. *(From Goldwasser E. The structure-function relationship of erythropoietin. In: Erslev AJ, Adamson JW, Eschbach JW, Winearls CG, eds, Erythropoietin: Molecular, Cellular, and Clinical Biology. Baltimore: Johns Hopkins University Press; 1991: pp. 41–52.)*

formation of the long loop is essential for the biologic activity of erythropoietin.

Erythropoietin is heavily glycosylated and different carbohydrate chains attached to the molecule contribute more than 40% to the total molecular weight of 30,400 Daltons. The protein backbone contains three highly conserved sites of N-glycosylation, to which sugar side chains are attached (Asn 24, 38, 83).[16,18] In addition, human but not mouse erythropoietin also contains a serine (Ser 126) as a possible O-linked glycosylation site, which bears a small oligosaccharide chain.

The oligosaccharide structures of recombinant human and native urinary erythropoietin have been determined[19,20] and were found to be rather similar. On average, one molecule of recombinant human erythropoietin contains 3 fructose, 10 mannose, 13 galactose, 16 N-acetylglucose, and 13 sialic acid molecules. The major component of the O-linked sugar is a disialyl chain.[21] The N-linked side chains are predominantly organized as tetra-antennaries (about 80%) and to a minor extent only as tri- (15%) or bi-antennaries (1–6%).[20,22] All of these saccharides are sialylated, although to a different extent. The distribution of different sugar chains varies at each glycosylation site. Chains at position Asn-38 are more heavily sialylated and less frequently of biantennary structure than those at Asn-24. Oligosaccharides at position Asn-83 are relatively homogenous tetra-antennary chains without polylactosaminyl repeats.[19] The glycosylation of erythropoietin results in slight heterogeneity of erythropoietin molecules. Interestingly, clear differences were found in the distribution of oligosaccharide components of urinary erythropoietin among individuals.[22]

The carbohydrates appear to be of considerable importance for the biologic activity of the hormone. Removal of the terminal sialic acids also increases the biologic activity of erythropoietin *in vitro* about two- to three-fold.[23] The carbohydrate moieties of erythropoietin therefore appear not to be essential for binding of erythropoietin to its receptor or the subsequent cellular signaling and may even inhibit both steps. However, *in vivo* the carbohydrate moiety is essential for the availability of erythropoietin for its target structures. Full deglycosylation abolishes the *in vivo* activity of erythropoietin, and removal of terminal sialic acids inactivates the hormone by shortening its biologic half-life in the circulation from about six hours to a few minutes.[23,24] The liver contains asialo-glycoprotein receptors that clear glycoproteins with free galactosyl residues from the circulation, and clearance through these receptors presumably causes the dramatic shortening of the biologic half-life of asialo-erythropoietin *in vivo*.[23,24] How and where this modified erythropoietin and the fully deglycosylated erythropoietin are cleared from the circulation is not yet known.

Biologic Effects of Erythropoietin

Hematopoiesis: Erythropoietin is absolutely necessary for erythropoiesis, particularly for the later stages of erythroid differentiation, and therefore is essential for life. Mice with disrupted erythropoietin or erythropoietin receptor genes[25–27] die from anemia at an embryonic stage of 12–13 days after fertilization because they cannot develop definitive erythropoiesis.

Erythropoiesis appears as a hierarchy of cell divisions and cell differentiations starting from the pluripotent stem and ending with the erythrocyte as a highly differentiated and specialized cell (Fig. 92.2). The pluripotent stem cell, which has the capability for self-renewal, feeds into three hematopoietic lineages, namely the megakaryocytic pathway, the granulocyte-macrophage pathway, and the erythroid pathway. For the erythroid lineage cells can be identified morphologically by specific markers at the state of the proerythroblast, which develops into the basophilic erythroblast and begins to produce hemoglobin. Downstream of the erythroblast stages, the erythroid lineage is not regulated significantly by erythropoietin, nor does the commitment of pluripotent stem cells into the erythroid lineage require erythropoietin.[28] The self-renewal of committed early erythroid progenitors is induced by the receptor tyrosine kinase c-ErbB,[29] whereas the downstream initiation of the erythroid differentiation program is then regulated by c-Kit and erythropoietin receptors. Thus, the main action

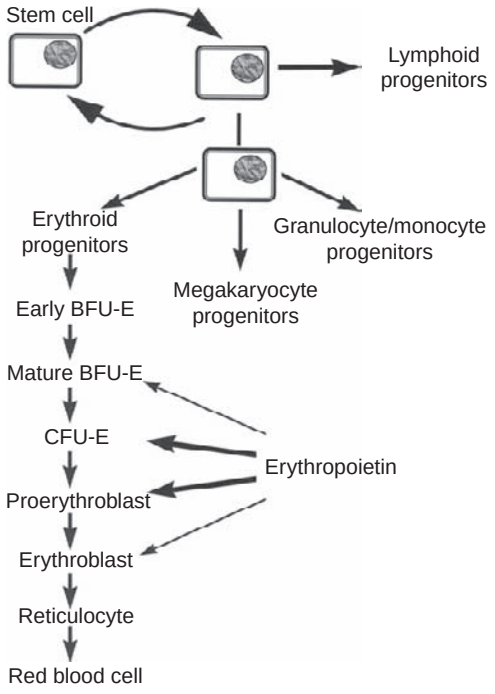

FIGURE 92.2 Schematic demonstration of differentiation steps of erythropoiesis and the action sites of erythropoietin.

of erythropoietin for erythropoiesis occurs on erythroid progenitors at stages between early committed erythroid precursors on the one side and the proerythroblasts on the other. Information about growth and differentiation of these cells has predominantly been obtained with cell cultures of hemopoietic cells. From those experiments, the existence of a rather early erythroid progenitor was inferred that was termed burst-forming unit erythroid (BFU-E), which has an abundance of about 0.01% among the nucleated cells of the bone marrow. Within 1 week of cell culture, a burst containing multiple subcolonies in clusters with up to 104 cells develops from one BFU-E. Hypertransfusion and acute erythropoietic stress have only a transient effect on BFU-E, suggesting that this progenitor cell is not dependent on ambient levels of erythropoietin for maintenance of its numbers. *In vitro*, the early divisions of this progenitor and the development of erythroid bursts essentially require interleukins, in particular IL-3, but are independent on erythropoietin. Final maturation and hemoglobinization of the cells of the burst are erythropoietin dependent. Hemoglobin synthesis begins at the stage of the proerythroblast and the cell population at this stage is considered as the main target for erythropoietin. *In vitro*, these cells are reflected by the colony-forming unit erythroid (CFU-E). In the normal bone marrow, about 0.1−0.2% of nucleated cells are CFU-E. The cells have limited proliferative potential, probably not more than six or seven cell divisions. Thus, CFU-E-derived colonies generally contain 60 to 120 hemoglobinized cells. Colony formation *in vitro* is essentially dependent on erythropoietin, and is positively modulated by insulin-like growth factor I.[30] CFU-E has the highest density of erythropoietin receptors within the normal erythroid precursor population, and is very sensitive toward erythropoietin. *In vivo*, the abundance of CFU-E is dependent on erythropoietin, such that the number of CFU-E increases during bleeding or hemolytic anemia and also in response to erythropoietin injection, whereas hypertransfusion-induced polycythemia results in a 70−80% reduction in the number of CFU-E in marrow and spleen. In summary, erythropoietin acts on erythropoiesis mainly by regulating the pool size of CFU-E, which then undergoes terminal differentiation into erythrocytes.

Expansion and maturation of the CFU-E pool implies three major effects of erythropoietin. First, erythropoietin increases the survival rate of erythroid progenitors and in line with this assumption evidence has been elaborated that erythropoietin prevents apoptosis in erythroid precursors.[31] Second, erythropoietin actively induces mitosis in erythroid precursors[32] with a preceding stimulation of RNA polymerase activity and subsequent DNA synthesis[33] and cell division. Third, erythropoietin initiates differentiating events such as the expression of globin chains, hemoglobin synthesis, transferrin receptor synthesis, and the synthesis of integral erythrocyte membrane proteins.[34] After induction by erythropoietin hemoglobin synthesis persists and becomes independent of the presence of erythropoietin. High doses of erythropoietin also stimulate platelet formation[35,36] and erythropoietin binding sites have been reported on megakaryocytes.[37] In view of the structural similarity between erythropoietin and thrombopoietin, one could imagine that this effect is at least in part due to cross-activation of the thrombopoietin receptor by erythropoietin.

Effects of erythropoietin unrelated to hematopoiesis: A steadily increasing number of reports clearly indicates that erythropoietin is involved in a number of effects outside the hemopoietic tissues, such as on the vasculature, the brain, the myocardium and else. There it may stimulate proliferation and inhibit apoptosis. For more detailed information, the reader is referred to recent reviews on this topic.[38−42]

Erythropoietin Receptor

Distribution: The biologic effect of erythropoietin is mediated by specific binding sites at the surface of its target cells. Erythropoietin binding sites have been identified on erythroid precursors, on megakaryocytes,[37] endothelial cells,[43−45] in distinct areas of the brain,[46] cultured neurons,[47] and placenta.[48]

The expression of the erythropoietin receptor is crucial for definitive erythropoiesis *in vivo*, since disruption of erythropoietin receptor gene leads to death around embryonic day 13. Primitive erythropoiesis in the yolk sac, however, proceeds in the absence of erythropoietin receptors. Erythropoietin receptors are also not required for erythroid lineage commitment nor for the proliferation and differentiation of BFU-E to CFU-E, but they are crucial *in vivo* for the proliferation and survival of CFU-E progenitors and their irreversible terminal differentiation. In line with this functional dependence, erythropoietin receptors are mainly found on erythroid precursors of the CFU-E stage. Nonetheless, compared with other cell surface receptors, CFU-E express a comparatively small number of erythropoietin receptors with 800−1200 binding sites per cell. The binding sites appear to occur with two distinct affinities, a high-affinity one with a dissociation constant below 100 pmol/liter and a low-affinity one with a dissociation constant higher than 300 pmol/liter. Binding sites with both affinities can be found on the same cell, and it is thought that the erythropoietic activity is mainly mediated via the high affinity binding site, because cells lacking these binding sites fail to differentiate in response to erythropoietin.

Erythropoietin receptor gene and protein: Erythropoietin binds and activates a high-affinity receptor (EpoR) present on the surface of immature erythroid cells,[49,50] exerting four known effects on erythroid progenitors, namely maintenance of viability, promotion of cell division, increase of hemoglobin synthesis, and fostering of morphological maturation. No other cytokine receptors can replace the erythropoietin receptor, because mice homozygous for deletions of the EPO or EPO receptor genes die at embryonic day 12.5 owing to severe anemia.[28] In these mice, erythropoiesis progresses through the BFU-E stage, but terminates at the colony forming unit-erythroid (CFU-E) and erythrocytes are not formed, demonstrating an absolute requirement of the EPO receptor for later stages of red blood cell development.[28] The EPO receptor belongs to the cytokine receptor superfamily.[51,52] Cytokine receptor signal transduction is mediated by cytoplasmic protein tyrosine kinases of the JAK family, found associated with individual receptor subunits (Fig. 92.3).[53]

The erythropoietin receptor genes exist as single copies and encompass eight exons.[50,54–56] In all species the cDNA encode with a high degree of interspecies homology a 507–amino acid protein of 55 kDa, which is modified by glycosylation and phosphorylation to 72–78 kDa.[57]

The EPO receptor does not have an intrinsic enzymatic activity; however, numerous signaling proteins

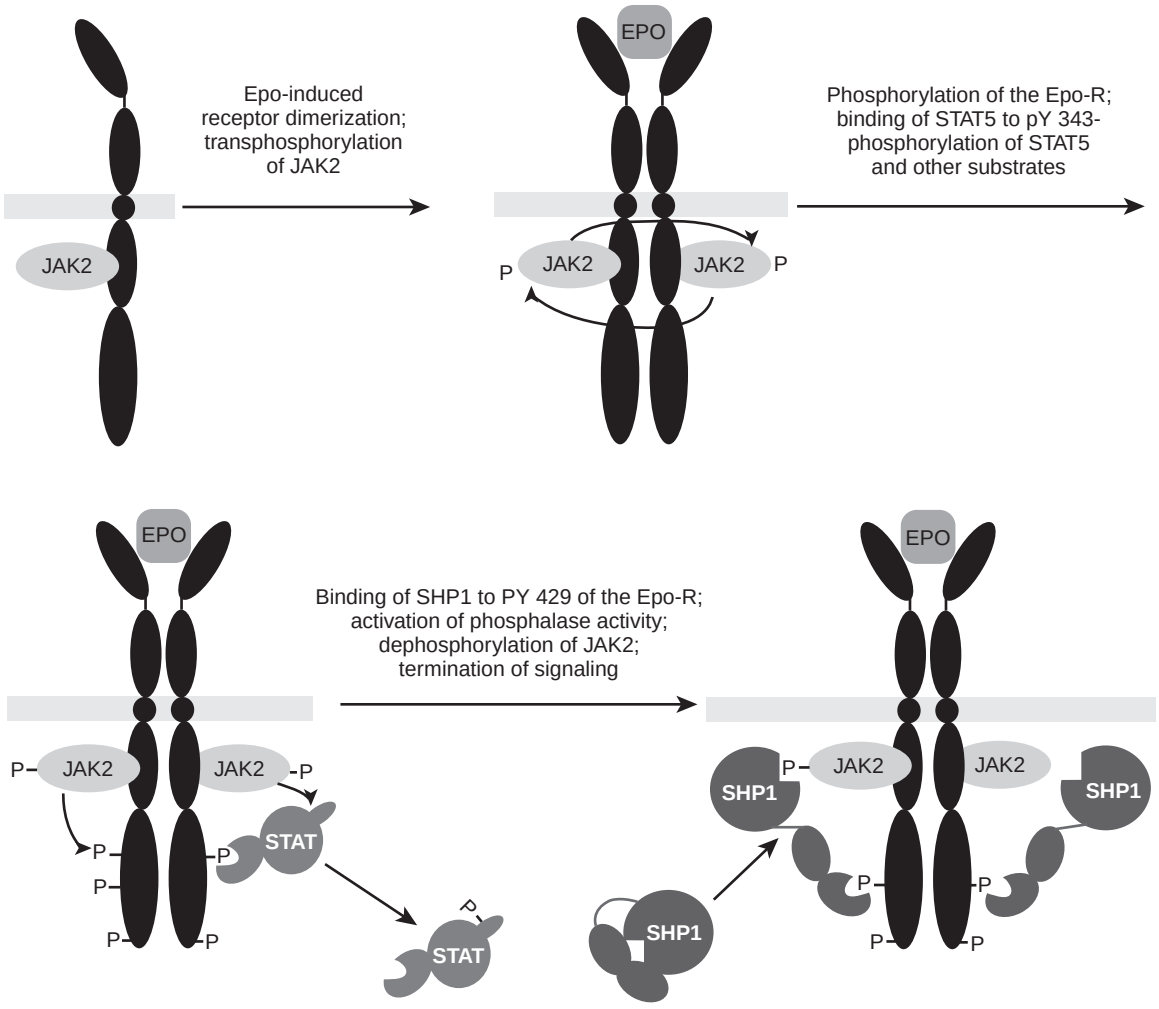

FIGURE 92.3 Model for activation and inactivation of the erythropoietin receptor. Binding of EPO induces receptor dimerization and auto- or trans-phosphorylation of the Janus family kinase, JAK2. JAK2 or another kinase then phosphorylates several tyrosine residues in the EpoR, creating docking sites for the SH2 domains of several signal transduction proteins, including STAT5. Once bound to the EpoR, STAT5 and other signaling proteins become phosphorylated and activated; phosphorylated STAT5 dissociates from the receptor, dimerizes, moves to the nucleus, and activates gene expression. The protein tyrosine phosphatase, SHP1, binds to a segment of the EPO receptor containing phosphotyrosine 429. Binding induces activation of the phosphatase, removal of the activating phosphate from JAK2, and termination of signal transduction. *(With permission from Stefan N, Constantinescu SN, Ghaffari S, Lodish HF. The erythropoietin receptor: structure, activation and intracellular signal transduction. Trends Endocrinol Metab 1999;10:18–23.)*

and the receptor itself are phosphorylated as a result of EPO stimulation. Like other members of the cytokine receptor family, such as receptors for growth hormone, prolactin, granulocyte colony-stimulating factor (G-CSF) and thrombopoietin, EpoR forms ligand-induced homodimers. EPO binding results in homodimerization of EpoR chains, which is critical for Jak2 (associated with the EpoR cytoplasmic tail) activation and the initiation of intracellular signaling.[58] JAK2 is rapidly phosphorylated in response to EPO stimulation. JAK2 is the primary kinase responsible for phosphorylation of the EPO receptor[58,59] and is essential for erythropoiesis.[60,61]

Erythropoietin receptor modifications: Mutations in the extracellular domain of the EpoR within the dimer interface renders the receptor constitutively active[62] as a result of the formation of an intermolecular disulfide bond.[58] The carboxyterminal end of the erythropoietin receptor appears to contain an inhibitory signaling element.[62] A hereditary truncation of the erythropoietin receptor at the COOH end has been discovered that is associated with increased affinity of the receptor and with erythrocytosis.[63,64] Similar to other members of the hematopoietin receptor family such as interleukins or thrombopoietin,[65] a naturally occurring soluble form of the membrane-bound receptor for erythropoietin has been found in the serum.[66] It has a molecular mass of 34 kD, is related to the extracellular domain of the erythropoietin receptor, and increased concentrations are found with enhanced erythropoiesis.[66] The physiological role of these soluble receptors and potential modes of action, however, are not yet understood.

Regulation of Erythropoietin Production

Sites of erythropoietin production: During fetal life the liver appears to be the predominant site of erythropoietin production. This has been shown for sheep and rats,[67,68] and the relevance of the liver for erythropoietin formation in the human fetus may be assumed from the fact that the cDNA for human erythropoietin has been cloned from human fetal liver.[9] Investigations in fetal sheep[69] revealed that the kidneys are also significant production sites for erythropoietin, particularly during the first half of gestation. In sheep and rat, a predominance of hepatic erythropoietin formation was found to last beyond birth,[68,70–72] whereas in mice the majority of erythropoietin mRNA has been observed in the kidneys from mid-gestation on.[73] An analysis performed in rats revealed that the kidney steadily increases its capacity for erythropoietin mRNA expression from birth on until adulthood, whereas the hepatic erythropoietin mRNA concentration changes less dramatically postpartum and even decreases when adulthood has been reached.[71]

The kidney overtakes hepatic erythropoietin mRNA three weeks after birth. Although species differences in the timing of the switch and the degree of contribution of the liver to total body EPO mRNA content exist,[69] the switch is undoubtedly found in humans as well.[74]

The reasons for the postnatal increase of renal erythropoietin formation may be related to the fact that in some species the kidney is not fully mature at birth. Once the kidney has gained its full function for waste excretion and salt and water homeostasis, the maximal capacity for erythropoietin has been reached. Apparently changes of organ oxygenation are not a major trigger for the switch from liver to kidney.[75] Based on experiments in anephric animals, the adult liver was generally assumed to contribute no more than about 15% to erythropoietin production.[6,67,68] However, this experimental approach may underestimate the hepatic contribution in intact organisms, because hepatic erythropoietin mRNA accumulation was found to be reduced after bilateral nephrectomy.[71] In intact adult rats erythropoietin mRNA amounts to about 30−40% of the total under conditions of severe hypoxic stimulation.[71,76] However, the hepatic contribution depends on the severity of the stimulus applied and is less significant, that is, below 20% of the total under mild hypoxia. This suggests that the liver is less sensitive in terms of hypoxia-induced erythropoietin formation than the kidneys, and it might help to explain why the liver, despite its large potential for erythropoietin mRNA expression, does not compensate for failure of the renal production site.

Cellular production sites in the kidney: In contrast to a number of other hormones, erythropoietin does not appear to be stored in the cells producing it. Consequently, almost no erythropoietin can be extracted from the liver and kidney of normoxic animals.[77–79] Attempts to localize erythropoietin by means of immunohistochemistry in normoxic and hypoxic animals have revealed inconclusive results. In situ hybridization studies localized erythropoietin mRNA to peritubular cells in the renal cortex.[80–82] Likely, peritubular interstitial fibroblasts are production sites for erythropoietin.[80] In this context colocalization was demonstrated for erythropoietin mRNA and the enzyme 5′-ectonucleotidase,[83] which is expressed on peritubular fibroblasts, but not on endothelial cells[84] (Fig. 92.4). The same conclusion about the peritubular fibroblast as production site for erythropoietin has been reached in an elegant approach of marker gene expression in mice bearing a transgene of erythropoietin/SV-40 T. In response to anemia or hypoxia the expression of the EPO-TAg gene was induced, and SV-40 T antigen accumulated in nuclei of peritubular cortical fibroblasts expressing 5′-nucleotidase, but not in other peritubular cell types.[85] Erythropoietin gene expression has been demonstrated in interstitial,

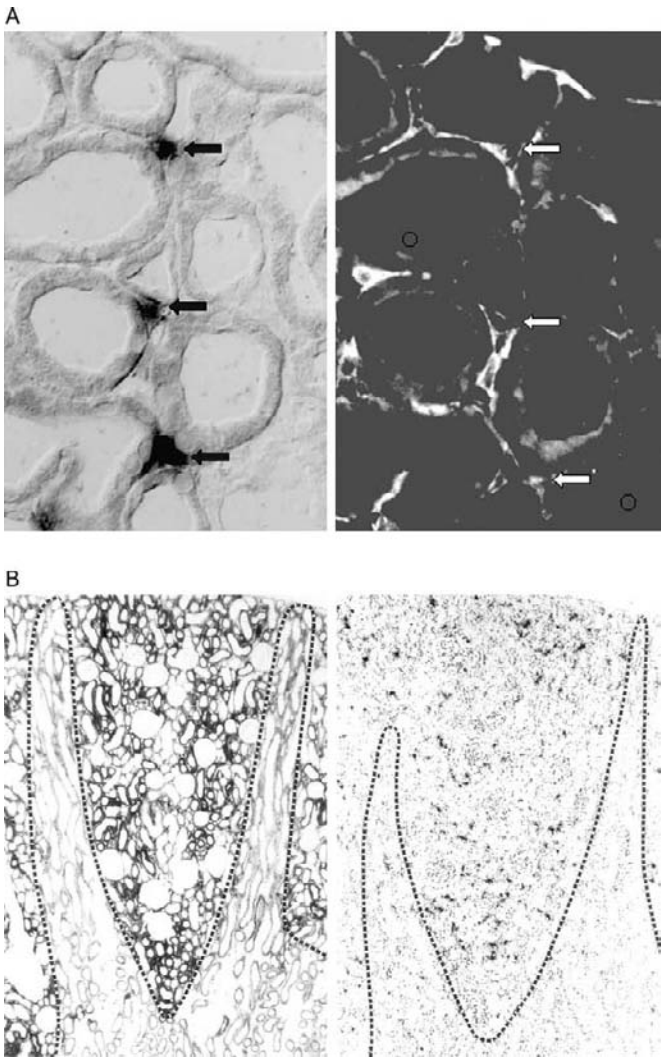

FIGURE 92.4 A: Detailed localization of erythropoietin-producing cells in the kidney. Combined in situ hybridization and immunohistochemistry on the same tissue section taken from anemic rat renal cortex. Left: Demonstration of erythropoietin mRNA. Right: Double-labeling on the same tissue section with antibody to 5′-ectonucleotidase. Cells positively stained with either technique are indicated by arrowheads. Only a minor proportion of 5′-ectonucleotidase-positive interstitial cells reveal erythropoietin mRNA expression. Double-labeled cells typically lie in angles between adjacent tubules, or between vessels and tubules. (Magnification × 800.) (*Courtesy of S. Bachmann, Berlin.*) B: Topography of the production of erythropoietin in the rat kidney. Left: The cortical labyrinth is well visualized using an enzyme histochemical technique for 5′-nucleotidase, with the strong reaction seen as black deposits in the proximal convoluted tubule and in the fibroblasts. Right: In situ hybridization of erythropoietin-mRNA in the kidney of an anemic rat. The comparison of the two micrographs shows that hybridization took place in the cortical labyrinth (delimited with a dotted line), but not in the medullary rays or in the outer medulla. (Magnification: A ~ ×62, B ~ ×95.) *(With permission from LeHir M, Eckardt KU, Kaissling B, Koury ST, Kurtz A. Structure–function correlations in erythropoietin formation and oxygen sensing in the kidney. KlinWochenschr 1991;69:567–575.)*

nonendothelial cells in normal human kidneys,[86] as well as in the walls of renal cysts of patients with polycystic kidney disease.[87] Similarly, renal erythropoietin has been localized in cortical interstitial cells in monkey[88] and sheep.[89] Although fibroblasts are widely distributed in the kidney both in the cortex and in the medulla, erythropoietin production appears to be confined to a special subset of fibroblasts in particular locations. Thus, cells expressing erythropoietin mRNA are generally not found in the inner renal medulla.[80,82,90] At least in rats, they are not present in the outer medulla, and within the renal cortex they have almost exclusively been found in the cortical labyrinths created by the convoluted tubules, and not in the medullary rays.[90] Even under severe hypoxia, however, only a minority of interstitial fibroblasts in the peritubular cortical labyrinth express erythropoietin mRNA.[83,91]

In addition, there are reports about enhanced expression of erythropoietin mRNA in human hypernephromas, and in one tumor, erythropoietin mRNA was clearly localized to epithelial tumor cells,[92] indicating that tubular cells may acquire the ability to produce erythropoietin with malignant transformation.

Cellular production sites in the liver: Within the liver at least two different cell types can express the erythropoietin gene. In situ hybridization in anemic rats demonstrated erythropoietin mRNA in hepatocytes, as well as in an interstitial cell type.[93] Similarly, in severely anemic mice transfected with the human erythropoietin gene, human erythropoietin mRNA was mainly localized to hepatocytes and to a lesser extent to an interstitial cell type, while endogenous mouse erythropoietin mRNA was not demonstrable in these animals.[94] That hepatocytes are a site of erythropoietin production was further confirmed by mRNA analysis in cells isolated from hypoxic rat livers, and the observation that in freshly isolated hepatocytes from normoxic animals erythropoietin mRNA expression can be stimulated by hypoxia *in vitro*.[95]

In contrast, the abovementioned mice bearing a erythropoietin SV-40 T gene construct were found to express the T40 antigen in Ito cells of the liver following stimulation by hypoxia or anemia,[96] indicating that these perisinusoidal cells represent the nonparenchymal cell population that produces erythropoietin in the liver. Moreover, in isolated Ito cells in culture, erythropoietin mRNA expression can be induced by hypoxia.[97] Interestingly, the Ito cells of the liver share similarities with the renal peritubular cells expressing the erythropoietin gene. In particular, the Ito cells, like the peritubular fibroblasts in the renal cortex, express 5′-ectonucleotidase.[98]

Other cellular production sites: Apart from liver and kidneys, small amounts of erythropoietin mRNA have also been observed in other organs such as the

lung, spleen, heart, and bone marrow.[99] In these organs, erythropoietin mRNA expression is stimulated by anemia or hypoxia and thus apparently regulated like in the kidney and the liver (see below). The physiological relevance of erythropoietin formation in organs other than liver and kidney is probably a para/autocrine one such as in the bone marrow. For the heart, EPO appears to be necessary for proper cardiac morphogenesis,[27] and might protect the myocardium from ischemia reperfusion injury.[70]

EPO expression in the reproductive tract[100–103] and in the brain[99,102,104–106] has been extensively considered. EPO is expressed in the central nervous system in the human fetus early in gestation,[104,107] suggesting a central role for normal brain development.[108] In addition, EPO has been found to be neuroprotective, particularly in situations of insufficient oxygen supply to the brain.[109–111] For the female reproductive tract, regulated expression of EPO in the uterus[103] and the oviduct of the mouse[101] has been found. The human endometrium expresses EPO throughout the menstrual cycle, with higher levels in the secretory than in the proliferative phase.[112] Along the same lines, estrogens stimulate EPO expression in the mouse oviduct and uterus,[101,103] but neither in the brain nor in the kidney.[113] Functionally, EPO appears to play an important role for endometrial angiogenesis and thus reproductive function.[103] EPO mRNA expression has been found in the human, murine, and ovine placenta, as well as on both the maternal and the fetal sides.[73,114–116] In addition, EPO exerts a trophic effect on the fetal gastrointestinal tract when taken up enterally from the amniotic fluid.[117]

Physiological determinants regulating erythropoietin production: Numerous experimental and clinical studies have developed the concept that circulating erythropoietin levels in turn are related to a balance of tissue oxygen supply and oxygen need. As a consequence, erythropoietin appears to carefully adapt red blood cell formation to meet the oxygen requirements of the organism. Comparing the role of both oxygen supply and demand for erythropoietin concentrations, the influence of oxygen supply appears to be of major importance. It has been established that reductions of oxygen supply either by anemia or by a fall of the arterial oxygen tension are by far the most powerful stimuli for elevations of the circulating erythropoietin concentration. Apart from these classic stimuli, it was recognized early on that the pharmacological application of certain transition metals, in particular cobalt[5] induces significant and reproducible elevations of circulating erythropoietin levels.

Effect of arterial oxygen tension: Both hypobaric normobaric hypoxia stimulate erythropoietin levels to a similar extent indicating that, it is a decline in alveolar oxygen tension and consequently a fall in arteriolar oxygen tension that stimulate erythropoietin levels.[118] Following a sudden fall of inspiratory, and subsequently, arterial oxygen tension plasma, erythropoietin levels start to rise after 60–90 minutes and then increase approximately linearly. The slope of this increase is dependent on the severity of hypoxia, a maximum value is reached between 12 and 24 hours in rodents[119–123] and within 48 hours in humans;[119,124] thereafter, erythropoietin declines to a steady-state level that is well below peak concentration, but still elevated above baseline and inversely related to the severity of hypoxia (Fig. 92.5A). Since the decline of plasma erythropoietin levels, which occurs long before an increase in red cell mass, proceeds in parallel with decreases in renal and hepatic erythropoietin mRNA levels,[123] it is reasonable to assume that the production of erythropoietin is downregulated during prolonged hypoxia. It has been excluded in this context that the downregulation of erythropoietin production is causally related to erythropoietin itself in the sense of a negative feedback,[123] and it is likely therefore that a desensitization of the cellular oxygen sensing mechanism occurs during continuous hypoxia (see below). Once plasma erythropoietin concentrations have moved out of the normal range, they are inversely related to the alveolar or arterial oxygen tension at any time after onset of hypoxia.[123,125]

The influence of oxygen tension on plasma erythropoietin concentrations is quite characteristic in the way that a lowering of the oxygen tension to about half of the normal value only exerts a rather small effect on circulating erythropoietin levels. A fall of inspiratory oxygen tensions below this threshold then induces an almost exponential increase of plasma erythropoietin concentration in humans and in laboratory animals.[123,125] The arterial oxygen tension, however, does not appear to directly influence erythropoietin levels, since the stimulation of plasma erythropoietin by inspiratory hypoxia is attenuated by polycythemia.[118,126] In conclusion, it appears therefore that the effect of the oxygen tension on erythropoietin concentrations is indirectly mediated by a process essentially involving the number of red blood cells.

Effect of blood oxygen-carrying capacity: The relevance of the red cell count for the plasma erythropoietin concentration is known based on numerous observations that anemias of various etiology (with the exception of renal anemia) are associated with elevated plasma erythropoietin levels, while states of primary polycythemia move in parallel with subnormal erythropoietin concentrations.[127,128] In principle, anemia could lead to an elevation of plasma erythropoietin levels by reduction of the oxygen-carrying capacity of the blood, as well as by the fall of the number of circulating red blood cells per se. This latter possibility is not trivial

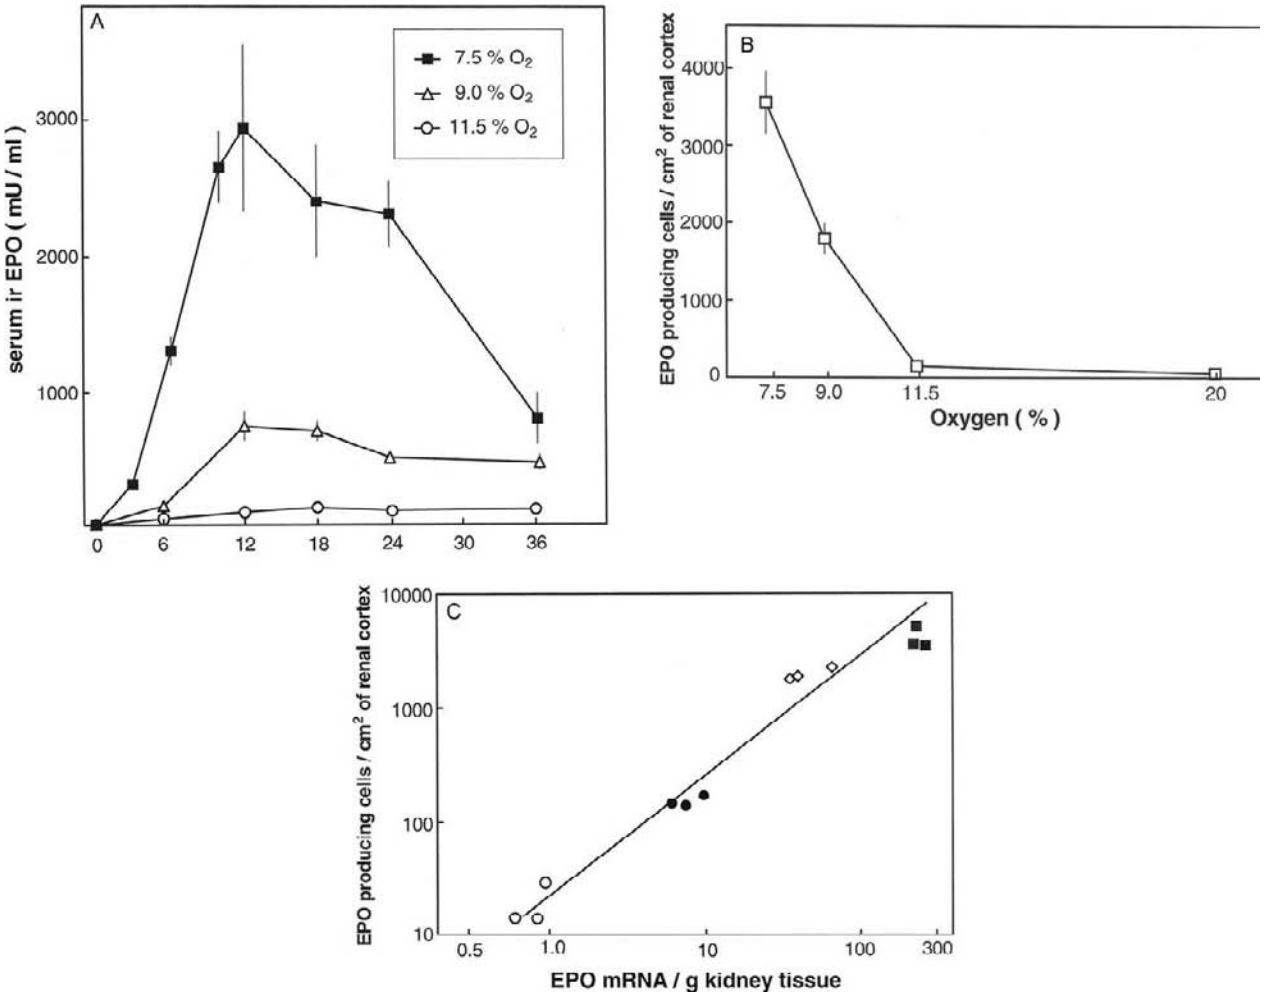

FIGURE 92.5 A: Influence of the oxygen tension on serum erythropoietin levels in rats. Time-dependent change in serum immunoreactive erythropoietin in rats exposed to different oxygen concentrations in a normobaric atmosphere. Total gas pressure was kept constant by balance nitrogen. *(With permission from Eckardt KU, Dittmer J, Neumann R, et al. Decline of erythropoietin formation at continuous hypoxia is not due to feedback inhibition. Relationship between the number of erythropoietin-producing cells per square centimeter of renal cortex in one kidney and erythropoietin mRNA concentrations in the contralateral kidney in individual animals studied under normoxic conditions or after 8 hours exposure to hypoxia of various levels of severity. Hollow circles, 20% O_2; solid circles, 11.5% O_2; hollow squares, 9% O_2; solid squares, 7.5% O_2. The number of erythropoietin-producing cells correlated linearly with tissue concentrations of erythropoietin mRNA. *(With permission from Eckardt KU, Koury ST, Tan CC, et al. Distribution of erythropoietin producing cells in rat kidneys during hypoxic hypoxia. Kidney Int 1993;43:815–823.)*

since, for example, plasma thrombopoietin levels appear to be regulated by the number of circulating platelets (see below). Therefore, the demonstration that a reduction of the oxygen-carrying capacity of the blood in the presence of a normal red cell count—for example, by carbon monoxide inhalation[129]—stimulates erythropoietin levels to a similar extent as anemia was an important confirmation that anemia influences erythropoietin production mainly through changes of the oxygen-carrying capacity of the blood. Again, the efficacy of carbon monoxide to increase plasma erythropoietin levels is dependent on the hematocrit/hemoglobin concentration in a way that it is less effective during polycythemia and exaggerated during anemia.[118]

The time course of changes of plasma erythropoietin in response to an acute reduction of the oxygen-carrying capacity of the blood induced by blood loss or carbon monoxide inhalation is rather similar to that seen with acute arterial hypoxia.[118] Plasma erythropoietin concentrations start to rise after about 60–90 minutes, reach a

maximum value after about 20 hours, and then decline to a steady-state level.[130] As with the influence of the oxygen tension on plasma erythropoietin levels, the effect of the oxygen-carrying capacity of blood on erythropoietin is not a linear one. The sensitivity of changes erythropoietin levels toward changes in hematocrit/hemoglobin concentration greatly decreases with increasing hematocrit/hemoglobin concentration, which becomes apparent when considering the plasma erythropoietin–hematocrit/hemoglobin relationship during the steady-state phase of chronic anemias (Fig. 92.6). In humans and in laboratory animals, a fall of the hematocrit/hemoglobin concentration down to 70% of the normal value induces only a moderate increases erythropoietin levels. If the hemoglobin concentration decreases further, erythropoietin levels begin to increase exponentially.[131–133] Nonetheless, significant elevations of plasma erythropoietin concentrations are measurable when hematocrit/hemoglobin are only slightly reduced from normal, such as following the donation of one unit of red blood cells.[130,134] An increase in hemoglobin concentration above the normal value, such as during polycythemia rubra vera or hypertransfusion, significantly lowers serum erythropoietin levels, but does not fully suppress them.[127,135,136]

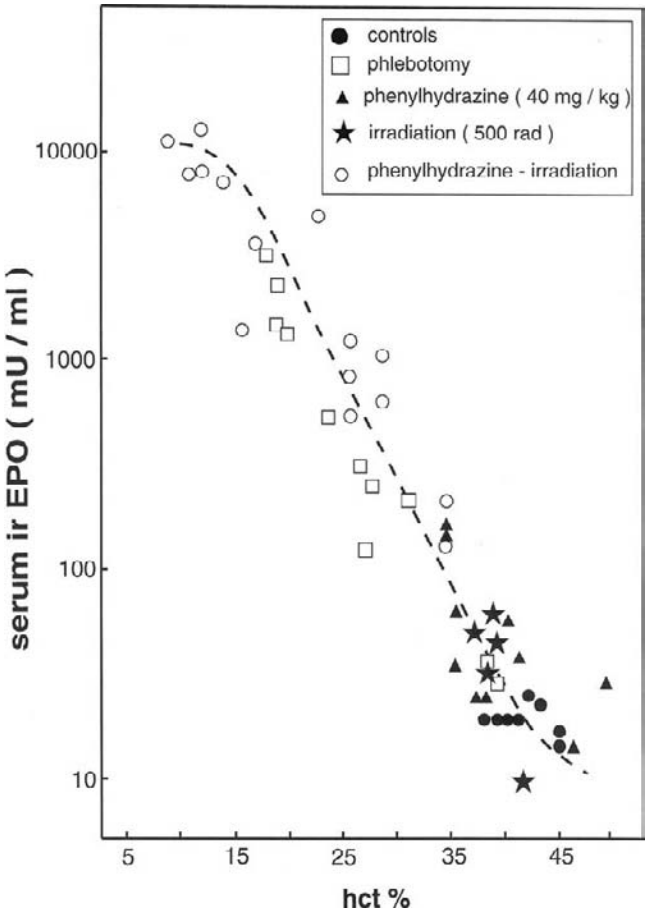

FIGURE 92.6 Relationship between hematocrit and plasma erythropoietin in rats. Anemia was induced by various maneuvers as indicated. *(With permission, from LeHir M, Eckardt KU, Kaissling B, Koury ST, Kurtz A. Structure–function correlations in erythropoietin formation and oxygen sensing in the kidney. Klin Wochenschr 1991;69:567–575.)*

Effect of hemoglobin oxygen affinity: Another parameter relevant for plasma erythropoietin levels that is linked to hemoglobin function is the oxygen affinity of the hemoglobin, which primarily determines oxygen release in the tissues. It has been observed that an increase of the hemoglobin oxygen affinity which impairs oxygen release to the tissues increases erythropoietin levels, while a decrease of the oxygen affinity attenuates the rise of erythropoietin levels in response to hypoxia.[137]

All of the findings mentioned above converge to the oxygen availability to the tissues as common denominator governing circulating erythropoietin levels, because this value depends on the concentration of hemoglobin molecules available for oxygen transport, on the arterial oxygen tension determining the degree of oxygen saturation of hemoglobin, and on the oxygen affinity of the hemoglobin which finally determines the oxygen release from the hemoglobin. The fact that erythropoietin levels are only weakly affected by reductions of the arterial oxygen tension or hemoglobin concentration down to 50–70% of the normal values but then increase exponentially may be explained by the characteristic dissociation of oxygen from the heterotetrameric hemoglobin, which allows sufficient oxygen supply to the tissues down to a significant reduction of the oxygen content of the arterial blood. The observations that maneuvers interfering with oxygen delivery to the tissues and administration of transition metals such as cobalt and nickel increase plasma erythropoietin levels remained without sufficient explanation for a long time. In contrast to the effects of hypoxia and of carbon monoxide is the stimulatory effect of cobalt, which is not dependent on the hematocrit/hemoglobin concentration,[118] suggesting that the effect of cobalt is not mediated by changes of the oxygen availability to the tissues. As outlined in detail below, a hypothesis has been developed that links the effects of cobalt and of hypoxia in a common model of oxygen sensing.

Additional physiological determinants involved in oxygen-dependent epo production?: Using a transgenic mouse model to modify keratinocytes, Johnson and coworkers suggested that the skin might be involved in systemic oxygen sensing by hypoxia induced vasodilation and redirection of the blood flow towards the skin, leading to renal hypoperfusion and increased Epo production.[138] This putative mechanism is difficult to reconcile with the fact that other modalities leading to increased perfusion of the skin, such as heat exposure,

must not alter renal Epo production and erythropoiesis. Subsequent to this study, it has been hypothesized that hair follicles in the skin itself could be a relevant source of circulating Epo.[139] However, in studies with human volunteers no difference in the hypoxic increase in circulating Epo could be observed between subjects exposed to either systemic hypobaric hypoxia or inspiratory normobaric hypoxia of identical oxygen partial pressures, suggesting that extracutaneous hypoxia does not cause a physiologically relevant change in circulating Epo (C. Lundby, Zürich, Switzerland, personal communication). It has also been suggested that the brain releases an as yet unidentified factor upon hypoxia that triggers renal Epo production.[140]

Astrocytes have been reported to represent another cell type responding to hypoxia with increased Epo synthesis in the human brain.[105] While it was believed that Epo cannot cross the blood-brain-barrier, it was reported that astrocyte-derived Epo accounts for up to 50% of circulating Epo in mice following acute hypoxic exposure.[141] This conclusion was derived from astrocyte-specific deletion of oxygen sensing which resulted in a 50% reduction of hypoxic Epo levels compared to wild-type mice.[141] However, when human subjects were exposed to normobaric hypoxia, increases in blood Epo levels were similar in *arteria brachialis* and *vena jugularis*, suggesting that the brain does not substantially contribute to total circulating Epo (C. Lundby, Zürich, Switzerland, personal communication).

Linkage between erythropoietin secretion and rate of erythropoietin gene transcription: Hypoxia, anemia, and cobalt increase erythropoietin mRNA abundance, and changes of plasma erythropoietin levels correlate closely with the amount of erythropoietin mRNA in kidney and liver.[90,91,142–145] Several lines of evidence suggest that erythropoietin producing cells do not develop stores of the hormone that can be rapidly released upon challenge. Thus, almost no erythropoietin can be extracted from the liver and kidney of normoxic animals.[77–79] It takes a delay of at least 1 hour between an acute stimulation of erythropoietin and the first measurable rise of erythropoietin in the plasma.[118,146] Several attempts to localize erythropoietin in the kidneys of normoxic animals failed to produce specific results. It is rather likely therefore that erythropoietin secretion into the bloodstream is directly triggered by the rate of de novo synthesis of the protein. Thus far, no evidence has been elaborated on how erythropoietin synthesis could be regulated on the ribosomal level; it is assumed now that erythropoietin synthesis is primarily determined by the number of mRNA copies available for translation. Steady-state mRNA levels in general result from a balance of gene transcription rate and the rate of mRNA degradation. Although there is some information that erythropoietin mRNA stability may be enhanced during hypoxia[147] and an erythropoietin mRNA-binding protein has been identified,[148] it is more or less accepted that cellular erythropoietin mRNA levels are mainly determined by the transcriptional activity of the erythropoietin gene. In summary, the erythropoietin secretion rate into the circulation is likely determined by the rate of erythropoietin gene transcription.

Survival of erythropoietin in the circulation: Considerable differences among species of the biologic half-life of erythropoietin in the circulation have been observed. In rats erythropoietin half-life is around two hours,[123,149,150] in dogs,[150] in sheep around nine hours,[151] and around eight hours in rabbits.[152] In humans the survival of erythropoietin is rather variable, and for human recombinant erythropoietin a number of studies have reported averaged half-lives at 4–11 hours. The mean half-life of endogenous erythropoietin in healthy humans was determined to be 5–6 hours.[125] There is no information about a physiologically relevant regulation of erythropoietin survival in the circulation; in particular, hypoxia does not appear to affect the plasma clearance of erythropoietin.[123] Even kidney function appears not to influence the half-life of erythropoietin in the plasma significantly,[149,151,153] although a small proportion of the hormone appears each day in the urine. It is furthermore conceivable that the target cells of EPO contribute to its plasma half-life, since receptor-bound EPO is internalized and degraded. Supportive of this idea are observations that at a given hematocrit, plasma levels of EPO are lower in hyper-regenerative than in hyporegenerative anemias, and that for hyper-regenerative anemias such as sickle-cell anemia, half-life times for erythropoietin appears to be rather short.

Taken together, the survival rate of erythropoietin displays a rather high degree if intra- and inter-species variability, but appears not to be regulated in states of elevated or suppressed plasma erythropoietin concentrations.

Recruitment of erythropoietin-expressing kidney cells: Under normoxic conditions, renal (and also hepatic) erythropoietin mRNA abundance is low. After acute onset of hypoxia or anemia, erythropoietin mRNA levels start to increase within 30–60 minutes, and after termination of hypoxia, erythropoietin mRNA levels decline with a half-life time of around 1–2 hours.[145] The rise of erythropoietin mRNA levels precedes and parallels the increase of erythropoietin plasma levels.[118,145] The increase of whole-organ erythropoietin mRNA abundance could in principle result from an acceleration of erythropoietin gene transcription in a fixed number of cells, recruitment of erythropoietin expression cells, or a combination of both. For the kidney, good evidence has been elaborated for the latter possibility. Thus, the number of erythropoietin-

expressing peritubular cells increases strikingly during anemia[91] and hypoxia[90] (Fig. 92.5B). In the kidneys of normoxic animals, only a few erythropoietin mRNA-expressing cells are found, preferentially in the deep cortex at the cortico-medullary junction. With increasing severity of hypoxic or anemic stress, an almost exponential increase occurs in the number or erythropoietin-expressing peritubular fibroblasts cells, which are recruited in direction to the superficial cortex.[90,91] By that the number of erythropoietin-expressing cells increases several hundred-fold in response to hypoxia or anemia. Considering the ratio of whole-organ erythropoietin mRNA and number of erythropoietin-expressing cells reveals that there is a certain regulation of erythropoietin mRNA per cell, but that the increase of the number of cells that start to express erythropoietin is by far the more relevant mechanism to account for the rise of whole-kidney erythropoietin mRNA, and consequently, plasma erythropoietin levels (Fig. 92.5B).[90,91] Therefore, regulation of erythropoietin production in the kidney appears mainly as an "on-off" switch of erythropoietin gene transcription by renal peritubular fibroblasts. In addition, cobalt administration increases the number of erythropoietin-expressing cells in the kidney.[90] In contrast to the effects seen during hypoxia or anemia, is the recruitment induced by cobalt, which is zonally less organized.

In the liver it appears as if it is an up- and down-regulation of erythropoietin gene expression in certain hepatocytes, rather than a recruitment of erythropoietin-expressing cells, that accounts for the increase of hepatic erythropoietin mRNA in response to anemia.[94] A gradual upregulation of erythropoietin mRNA in hepatocytes would also be supported by *in vitro* findings with primary cultures of hepatocytes or hepatoma cells (Fig. 92.7).

Evidence for local oxygen sensing in control of erythropoietin production: Oxygen-sensitive chemoreceptors are well known in the carotid body, and they are responsible for hemodynamic and respiratory adaptations to hypoxia. The regulation of erythropoietin appears to be independent of these systemic oxygen sensors; instead, it appears to be regulated by local oxygen sensing in liver and kidneys. Thus, ablation of the arterial chemoreceptors does not significantly alter erythropoietin production in response to hypoxia.[154] Moreover, with respect to the renal production of erythropoietin, renal denervation has been found not to influence the expression of erythropoietin in response to hypoxia or anemia.[155,156] On the other hand, there is consistent evidence that in isolated perfused kidneys taken from normoxic animals, erythropoietin gene expression[157] and erythropoietin protein secretion[158,159] can be induced by lowering the oxygen

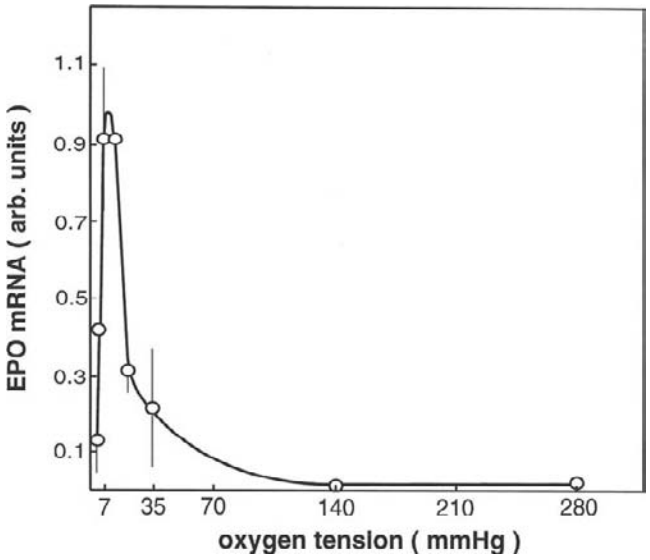

FIGURE 92.7 Oxygen dependency of erythropoietin mRNA in primary cultured rat hepatocytes. Freshly isolated rat hepatocytes were plated on gas permeable culture supports and were exposed to different oxygen concentration in a normobaric atmosphere for 3 hours as described in Eckardt et al.[104] Erythropoietin mRNA levels were standardized to β-actin mRNA levels and are given as arbitrary units.

tension of the perfusate, with rather similar characteristics of the *in vivo* situation. Thus, it appears that the essential events by which systemic hypoxia or anemia stimulate peritubular erythropoietin gene transcription occur within the kidneys itself. This does not rule out the possibility that renal erythropoietin production may in addition be modulated by extrarenal factors (see below).

Because erythropoietin production is stimulated in a similar fashion by a fall of the arterial oxygen tension, by a reduction of the oxygen-carrying capacity of the blood, and by an impairment of oxygen delivery from the hemoglobin, it is likely that the common denominator for these effects is a reduction of the oxygen availability to the peritubular tissue. A measurable parameter that results from the oxygen availability in conjunction with the local oxygen consumption is the local oxygen tension. In addition to oxygen availability, oxygen consumption is of relevance for erythropoietin production. This may be derived from observations that hormonal modulation of the metabolic rate exerts a major role in erythropoietin production. Thus, even upon hypoxic exposure, erythropoietin production in hypophysectomized animals may be as low as in nephrectomized animals.[160,161] Similarly, starvation also attenuates erythropoietin production.[122] On the other hand, hormones stimulating energy turnover such as growth hormone,[162] insulin-like growth factor I,[163] thyroid hormone,[164,165] and androgens[166,167]

enhance hypoxia-induced erythropoietin formation. Indeed, the renal cortical fibroblasts expressing erythropoietin are in close anatomical contact with proximal tubular cells,[83] which have a high metabolic rate. Since circumstantial evidence suggests that the oxygen regulation of erythropoietin production in the kidneys is dependent on transport activity of the proximal tubule,[168] it is conceivable that proximal tubule cells generate a sink of the oxygen tension around the neighbored fibroblasts.

Attempts to isolate erythropoietin-expressing fibroblasts and to study the regulation of erythropoietin gene regulation in these cells *in vitro*, however, have not been successful thus far. In mice bearing an erythropoietin SV-40T antigen construct transgene, renal fibroblasts expressing the T antigen could be isolated and cultured. In contrast to the *in vivo* situation, however, the cells did not increase their erythropoietin mRNA or T-antigen expression in response to hypoxia.[85]

In principle, the pericellular oxygen tension can directly trigger erythropoietin gene expression. Thus, in cultures of hepatoma cells,[169] hepatocytes,[95] astrocytes,[106] and liver Ito cells,[97] a prominent effect of the pericellular oxygen tension on erythropoietin gene expression can be demonstrated, in a fashion rather similar to that expected from *in vivo* data (Fig. 92.7).

Oxygen Supply to Kidney and Oxygen Sensor Function of Renal Cortex

At first glance, the location of an oxygen (tension) sensor in the kidney appears somewhat surprising, since the volume of oxygen transported to the kidney cortex is rather large compared to its oxygen consumption. Considering the comparatively low oxygen extraction rate of 8-10%, one might conclude that the kidney cortex generally is luxuriously supplied with oxygen. On the other hand, not only does the oxygen sensor governing erythropoietin gene transcription appear to reside within the kidney, but clinical experience also teaches that the kidney is an organ rather susceptible to hypoxic injury. The explanation for both these putative discrepancies probably resides in the unique architecture of intrarenal vessels. Since arterial and venous vessels run counter-currently over long distances in close association, it is assumed that a shunt diffusion of oxygen occurs between arterial and venous vessels, which lowers arterial oxygen pressure. While shunt diffusion of oxygen in postglomerular vessels is thought to be responsible for the high vulnerability of the thick ascending limb to ischemia,[170,171] shunt diffusion in preglomerular vessels, in particular interlobular vessels, might explain the oxygen sensitivity of cortical structures relevant for erythropoietin production. Support for this concept comes from measurements of oxygen tension in the renal cortex well below the venous PO_2 of the kidney.[172,173] Moreover, it has been demonstrated that preglomerular oxygen tensions at the kidney surface are much lower than those in the systemic circulation, this difference increasing greatly with rising oxygen tension and decreasing hemoglobin concentrations.[174] It should be noted that assuming major oxygen shunting along interlobular vessels would predict an oxygen gradient from the corticomedullary junction to the subcapsular cortex, while the distribution of erythropoietin-expressing cells displays just the opposite direction, with the majority of signals in situ hybridizations being located in the inner part of the cortex.[90,91] Thus, additional parameters are required to explain the particular distribution of erythropoietin-expressing cells. In particular, in the lower cortex the peritubular tissue frequently receives blood returning from the medulla or cortical medullary rays. Since these structures already extract a substantial amount of oxygen, oxygen delivery to the inner part of the cortex may be lower than in other cortical areas. Similarly, oxygen delivery to the midcortical peritubular cells may be somewhat reduced, because it also receives blood returning from the medullary rays, while in the superficial cortex postglomerular blood directly reaches the peritubular tissue. Another factor that has to be taken into account is that shunt diffusion is not limited to oxygen; it also (in the opposite direction) affects carbon dioxide, thereby trapping it in the outermost subcapsular zone.[175,176] Since carbon dioxide attenuates erythropoietin production by a pH-related mechanism,[121] an accumulation of carbon dioxide might at least partially counterbalance the effect of low oxygen tensions in the outer cortex. Consideration of all of these issues suggests that the main physiologic role of oxygen shunting occurring in the cortex could be an amplifying mechanism for the stimulation of erythropoietin production, which operates predominantly during states of anemia and less during arterial hypoxia. Assuming that the renocortical oxygen consumption is more or less unaltered during anemia, the oxygen tension in the primary capillary effluate leaving the parenchyma will be decreased in comparison with the nonanemic state. This decrease in venous oxygen tension will increase the driving force for oxygen shunting between interlobular arteries and veins, and in consequence further lowers the arterial oxygen tension of the blood entering the renocortical parenchyma.

In any case, the high oxygen sensitivity of the renocortical peritubular tissue is also substantiated by the observation that apart from erythropoietin expression, other events occur in the peritubular region of the renal cortex. Thus, within 1 week following the onset of anemia, a marked hypertrophy of peritubular fibroblasts in the cortical labyrinth of rat kidneys was found, with

an increased activity of 5′-ectonucleotidase on the surface of these cells.[84]

CELLULAR OXYGEN SENSING REGULATING ERYTHROPOIETIN GENE TRANSCRIPTION

Erythropoietin Gene

Gene promoter: There is only a single copy of the erythropoietin gene, and no evidence exists for an erythropoietin gene family or any pseudogenes. The human erythropoietin gene has been mapped to the long arm of chromosome 7,[177] and the mouse gene has been mapped to chromosome 5.[178]

The basic organization of the erythropoietin genes in different species is similar and consists of five exons and four introns.[9,10,179] The most conserved region between the genes has a high sequence homology, and is located directly upstream from putative transcriptional start sites. The first intron also shows interspecies homologies. In contrast, the size and sequence of the second, third, and fourth introns are highly divergent among species.

There is evidence for multiple start sites for erythropoietin gene transcription.[180] Within the putative promoter region for the human erythropoietin gene, apart from steroid hormone response elements,[181] none of the classical sequences has been identified. Two complementary approaches have been undertaken to localize cis-acting DNA sequences responsible for tissue- and stimulus-specific regulation of erythropoietin gene expression. First, the generation of transgenic mice carrying erythropoietin gene constructs of different length, and second, the expression of gene constructs incorporating different sections of the erythropoietin gene and its flanking sequence in cell lines. It turned out, that the regulation of the erythropoietin gene by the same parameters requires different gene sequences for liver and kidney, in a way that the physiologic regulation of the erythropoietin gene is managed within −0.4 kb of the 5′-sequence and 0.7 kb of the 3′region, while an essential regulator element for the renal expression of erythropoietin resides between −12 and −8 kb in the 5′-region[180,182] (Fig. 92.8).

Gene enhancer: The minimal erythropoietin (EPO) promoter encompasses 117 bp 5′ to the transcription start site and has no oxygen-regulated element. Proteins interacting with a 17 bp (nt −61 to −45) sequence synergize with transcription factors (HAF) binding to the 3′ enhancer of the EPO gene.[183] HAF is the murine homologue of Sart-1, a 125-kDa human protein recognized by cytotoxic T lymphocytes. HAF likely acts in conjunction with other transcription factors to modulate O_2-dependent EPO expression.[183] Some negative cis-acting elements exist in the promoter that also repress EPO expression. Two GATA sites have been extensively studied with respect to oxygen sensitivity, tissue specificity, and also their potential role during ontogeny.[184,185] Increased expression and binding of GATA-2 were found at high oxygen tensions and overexpression of GATA-2 and -3 suppressed EPO expression.[185]

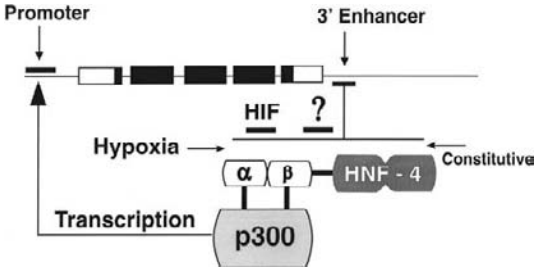

FIGURE 92.8 Organization of the erythropoietin gene. The erythropoietin gene is schematically illustrated with five exons (rectangles) and the coding regions (black). During hypoxia the HIF-1 heterodimer is stabilized and binds to a site on the 3′-enhancer. Downstream of this site, the nuclear receptor HNF-4 binds constitutively to the direct repeat (DR-2) site and also to the β-subunit of HIF-2. Both HIF-subunits bind to the transcriptional activator p300, providing a mechanism for triggering the erythropoietin gene promoter to transcribe the mRNA. Between the HIF-2 and HNF-4 binding sites, an essential sequence with an as yet unknown mechanism of operation is located. *(Modified with permission from Huang LE, H V, Arany Z, Kranic D, Galson D, Tendler D, Livingston DM, Bunn HF. Erythropoietin gene regulation depnds on heme-dependent oxygen sensing and assembly of interacting transcription factors. Kidney Int 1997;51:548−552.)*

The EPO 5′-promoter is only a weak promoter. However, it shows hypoxic inducibility and acts synergistically in concert with a 3′-enhancer[31] to achieve a 1000-fold stimulation *in vivo*. A 50-bp hypoxia response element (HRE) has been identified in the human gene within the untranslated 3′-sequence, 116 bp downstream of the erythropoietin RNA polyadenylation site. This sequence conveys oxygen-regulated expression on a variety of heterologous promoters *in vitro*[186−188] and acts in a position- and orientation-independent way, and thus fulfills the criteria of a classical eukaryotic enhancer. A similar enhancer, with highly conserved sequences, has been located at an equivalent position in the mouse gene. Within this EPO enhancer, three defined sites are important for the response to hypoxia. At the 5′ end, the sequence CACGTGCT was the first to be identified as a "hypoxia inducible factor" (HIF) binding site (HBS). Two protein complexes were identified, one bound constitutively and the other (HIF) was present only in hypoxic cells.[189] Components of the constitutive complex are ATF-1 and CREB-1, but the role for hypoxia-regulated EPO expression has not yet been settled for these

factors.[189] In contrast, intact HBS and HIF bindings are indispensable for hypoxia-induced EPO expression.

The second essential area within the erythropoietin HRE located downstream of the HBS encompasses the core sequence 5′-CACAG-3′. Mutation of this site abrogates hypoxia-inducible activity of the enhancer, but so far no protein bound to this repeat has been identified.

A third and more distal area in the EPO enhancer is a direct repeat of two steroid receptor half-sites separated by two base pairs (DR-2 site).[181] This DR-2 site is also absolutely required for hypoxic regulation of the EPO gene.[190] DR-2 sites bind nuclear receptors for hormones, but none of the known ligands such as thyroxine and vitamin D significantly influence EPO expression through this site.[181] However, screening for orphan receptors revealed specific binding of hepatocyte nuclear factor-4 (HNF4) that significantly enhances EPO gene expression in response to hypoxia.[190] It was further hypothesized that HNF4 may play an important role for tissue-specific expression of EPO.

Hypoxia-inducible transcription factor: The critical hypoxia-inducible protein binding at the most proximal 9 bp area (5′-TACGTGCT-3′) of this enhancer was initially termed hypoxia-inducible factor-1 (HIF-1),[189] and is a heterodimeric protein consisting of a HIF-1α and a HIF-1β subunit.[191,192] The HIF-1 binding motif is also found in other genes activated by hypoxia, such as, for example, vascular endothelial growth factor (VEGF) or enzymes of the glycolytic pathway—enolase, pyruvate kinase, and lactate dehydrogenase —indicating a widespread oxygen-sensitive system.[193,194]

HIF-β (120 kD) is the aryl hydrocarbon receptor nuclear translocator (ARNT),[191] and HIF-1α (91−94 kD)[192] is a member of the group of basic-helix-loop-helix proteins containing a PAS domain. Assembly of an active HIF complex is a multistep process involving regulated synthesis, processing, and stabilization of HIF-1, nuclear localization, dimerization, and interaction with transcriptional coactivators.

The discovery of two human cell lines (HepG2 and Hep3B) that produce *in vitro* erythropoietin in a fashion inversely related to the pericellular oxygen tension[169] was an enormous step forward for investigating the mechanisms along which a fall of the oxygen tension (hypoxia) could stimulate erythropoietin gene transcription on the cellular level. It turned out that hypoxia signaling likely follows a novel nonclassical pathway (Fig. 92.9).

This exciting novel pathway was unraveled by milestone publications within the last few years, emphasizing a central mediator role of the HIF-1α subunit. It turned out that the HIF-1 protein contained two groups of oxygen-sensitive domains, those determining protein stability (oxygen degradation domain [ODD]), and

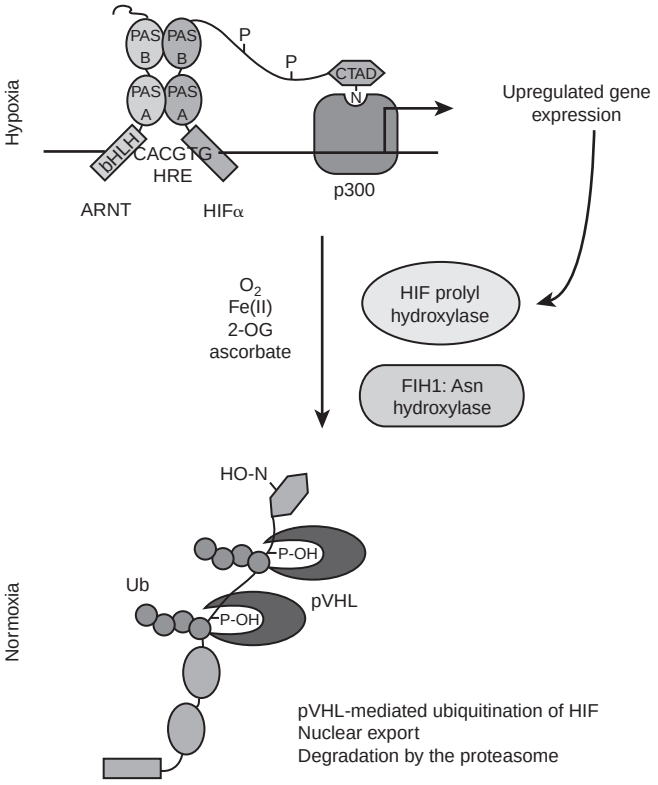

FIGURE 92.9 Hypoxia-mediated regulation of HIF stabilization and activation. Under normoxic conditions (bottom), two proline residues within the oxygen degradation domain of the HIF-α subunit are modified by HIF-prolyl hydroxylases, allowing for HIF recognition by a protein-ubiquitin ligase complex containing pVHL, and leading to HIF-α degradation by the proteasome. Meanwhile, the asparaginyl hydroxylase FIH-1 modifies the CTAD of the HIF-α, blocking its interaction with transcriptional coactivators such as p300. When oxygen levels decrease, both prolyl and asparaginyl hydroxylation are blocked. HIF-α accumulates and interacts with the HIF-β subunit (ARNT) and the larger transcriptional machinery, thereby promoting transcription of downstream HIF target genes. *(With permission from Bruick RK. Oxygen sensing in the hypoxic response pathway: regulation of the hypoxia-inducible transcription factor. Genes Dev 2003;17: 2614−2623.)*

those regulating transactivity (NH_2-terminal and COOH-terminal transactivating domains), which are independently regulated by oxygen.[195,196] In addition, cellular localization of HIF-1α also appears to be O_2 dependent, because translocation from the cytosol to the nucleus is increased under hypoxia.[197]

While steady-state levels of HIF-1α and HIF-1ß mRNA are not significantly affected by hypoxia, the cellular HIF-1α protein content increases greatly under hypoxia.[198] The hypoxia inducibility of the HIF-1 complex is solely achieved by hypoxic accumulation of the α-protein subunit, since the β-subunit is constitutively expressed. In normoxic cells, HIF-1α is barely detectable due to rapid degradation via the ubiquitin proteasome pathway.[199,200] HIF-1α is continuously synthesized irrespective of the oxygenation status of the cells, providing a

very rapid response of HIF-1α accumulation when hypoxia occurs, simply by blocking the degradation of the protein, and allows an almost instantaneous response to hypoxia by accumulation of HIF-1 without activating the transcriptional/translational machinery.[201]

Proteolytic regulation of HIF-1α and HIF-2α is critically dependent on the von Hippel-Lindau tumor suppressor protein (pVHL), with pVHL functioning as the substrate recognition component of a multicomponent ubiquitin E3 ligase.[202–204] VHL protein binds to the two oxygen-dependent degradation domains (ODD) of HIF-1α, which confer oxygen-dependent instability on the HIF-1α protein.[200,205,206] The HIF–pVHL protein interaction is suppressed by the classical HIF-activating stimuli of cobaltous ions, iron chelation, and hypoxia. The interaction sites for pVHL within the two HIF ODDs contain the amino acid proline within the LxxLxP motif for hydroxylation.[207] It was confirmed that the interaction between HIF-1α and pVHL is regulated by enzymatic hydroxylation of these specific prolyl residues (for human HIF-1, at Pro 402 and at Pro 564).[207–209] Since the only previously characterized mammalian prolyl hydroxylases (pro-collagen prolyl hydroxylases) are 2-oxoglutarate-dependent oxygenases, it was predicted that the HIF prolyl hydroxylases would also belong to this family of enzymes.

Subsequently, in mammalian cells, three isoforms were identified, termed prolyl hydroxylase domain (PHD) enzymes (PHD1-PHD3), and shown to hydroxylate HIF-α *in vitro*.[210,211] These enzymes have an absolute requirement for dioxygen as cosubstrate. The overall reaction results in insertion of one oxygen atom into the HIF-α peptide substrate at the prolyl residue, the other generating succinate from 2-OG with the release of CO_2. Relatively labile binding of Fe(II) at the 2-His-1-carboxylate centre results in striking sensitivity to inhibition by iron chelators and metals such as Co_{II} that can exchange for Fe_{II} at this site. As predicted, the activity of the recombinant PHD enzymes is strongly inhibited by cobaltous ions, and iron chelation. Furthermore, reactions conducted in a controlled oxygen environment showed that the activity of the purified enzyme is strikingly sensitive to graded levels of hypoxia *in vitro*.[211] Thus, the properties of these nonhaem iron enzymes fit those of the postulated ferroprotein sensor underlying the classic characteristics of the erythropoietin/HIF response. The activity of PHDs depends on the availability of oxygen and thus qualifies these enzymes as O_2 sensors. Recently, the O_2 affinity has been determined and suggests appropriate sensitivity in the physiological relevant PO_2 range.[212] Under hypoxia, activity of the enzymes is greatly reduced, the specific proline residues in HIF-α are no longer hydroxylated, and HIF-α subunits can accumulate to activate HIF-1-dependent genes such as EPO. HIF-1α and HIF-2α also contain two transactivation domains (TADs): an N-terminal TAD overlapping the ODD, and a C-terminal TAD that is distinct from the ODD[196,205,206] and manifests oxygen-regulated interaction with p300/CBP.[195,213] The C-TAD is modulated by an O_2-sensitive hydroxylation on the asparagine residue 803 in human HIF-1α.[214] Here, hydroxylation of asparagine under high oxygen pressure inhibits recruitment of the transcriptional coactivator CBP/p300[199,215] necessary for hypoxic HIF-1 activity. This asparagine hydroxylase had been identified earlier as factor inhibiting HIF-1 (FIH-1), because its interaction hydroxylation of asparagine N803 inhibited the transactivity of HIF-1.[216] It has also been reported that FIH interacts with pVHL and forms a ternary complex with the HIF-α C-TAD.[216] Although interaction with pVHL is not an absolute requirement for FIH activity,[199,212] these findings fit well with studies of HIF-dependent transcription in pVHL-defective cells. Upregulation of HIF-target gene expression in such cells is essentially complete,[203,217,218] which implies that all oxygen-dependent controls of HIF, and not just proteolytic regulation, are disabled in the absence of VHL. This suggests that VHL is intimately involved with the hypoxia response, its functions extending beyond those of an E3 ligase. FIH-1-like PHDs turned out to be a 2-oxoglutarate-dioxygenase requiring O_2 and iron for its function.[212,219] It is of note that PHDs and FIH-1 are localized in different cellular compartments[220] and display differences in O_2 affinities.[221,222] Numerous pieces of evidence point to a further mode of HIF regulation involving oxygen-dependent nuclear/cytoplasmic localization of HIF-α.[207] In normoxia, HIF-1α levels are low and subcellular localization cannot be directly observed. However, overexpression of HIF- or HIF-1α–GFP fusion proteins that are less rapidly degraded yields detectable protein in normoxic cells and several,[197,223] although not all,[224] studies have observed that this protein shifts to the nucleus only in hypoxia, implying a distinct oxygen-regulated step. Interestingly, as with the other modes of HIF regulation, the effect of hypoxia is mimicked by iron chelators, which suggests that subcellular localization is also regulated by the same or similar Fe_{II}- and 2-OG–dependent oxygenases.[197] The underlying mechanisms of this effect still have to be clarified.

To date, analyses of the regulatory mechanisms underlying HIF activation by hypoxic and nonhypoxic stimuli have emphasized the involvement of different types of pathway and different modes of HIF activation. Whilst proteolysis of HIF-subunits is strikingly oxygen dependent,[187,225,226] is the rate of HIF-1 translation largely independent of oxygen,[227] but is responsive to growth factor and oncogenic stimulation.[228–230] Phosphorylation cascades such as the mitogen-activated

protein kinase (MAPK) and phosphoinositide-3 kinase (PI3K) pathways are activated by growth factor stimulation, and amplify the HIF response to hypoxia by post-translational[231,232] as well as translational controls.[228–230]

HIF-1α is ubiquitously expressed, but is not the only member of this subfamily of PAS proteins. HIF-2α[233–236] and HIF-3α[237] partly overlap with HIF-1α in their expression pattern, but assignment of specific functions to the different HIF-αs has not yet been achieved. Knockout mice for HIF-1α and HIF-2α significantly differ in their phenotype. Whereas HIF-1α -/- mice die around midgestation due to severe cardiovascular and central nervous system malformations,[238] HIF-2α -/- mice display different phenotypes, probably related to the genetic background.[239–241] Although all of these mice die soon after birth, no clear conclusions regarding defects in EPO expression can be drawn from these animals. In contrast, heterozygous HIF-1α knockout mice developed normally but, among other impaired physiological responses to hypoxia, these mice had delayed erythrocytosis on exposure to hypoxia,[242] apparently suggesting a dominant role for HIF-1α for EPO regulation.

First evidence that HIF-2α rather than HIF-1α might regulate renal Epo synthesis came from descriptive studies demonstrating *in situ* overlapping of HIF-2α but not HIF-1α with the peritubular, interstitial EPO producing cells.[243] Similar results have been reported using chemical PHD inhibition.[244] The critical role of HIF-2α was further confirmed by RNAi experiments in liver-derived hepatoma.[245]

Such a central role of HIF-2α hypothesis would be supported by a study on the retinopathy of prematurity to which expression of EPO in the retina significantly contributes.[246] In this study, HIF-2α knockdown, that is, reduction of HIF-2α expression to about one-fifth of the normal level, lowered EPO expression induced by relative hypoxia that was not compensated by unchanged HIF-1α accumulation.[246] In addition, in two cell lines producing EPO that express both HIF-1α and HIF-2α, downregulation of HIF-2α but not HIF-1α by siRNAs blunted the EPO response.[245] These results were subsequently confirmed in a hepatic HIF-2α knock-out mouse model.[247] Quite surprisingly, an independent HIF-2α global knock-out mouse strain turned out to be viable and these mice were indeed anemic with decreased renal Epo expression.[248] Conditional global deletion of HIF-2α but not HIF-1α also resulted in anemia in adult mice.[249] Finally, a kidney-specific conditional knock-out mouse model confirmed the non-redundant role of HIF-2α in oxygen-regulated Epo gene expression.[250]

Together, plasma erythropoietin concentrations are regulated by an effective negative feedback loop, in which the kidney integrates a number parameters such as arterial oxygen tension, oxygen-carrying capacity of the blood and metabolic rate to one signal, namely, the pericellular oxygen tension in the cortex, which then is transduced by the hydroxylation of prolyl and aspargyl residues into a stabilization and activation of HIF-α protein, which in turn triggers in concert with HIF-β the transcriptional activity of the erythropoietin gene (Fig. 92.10).

Dysregulated EPO gene expression by PHD2, VHL or HIF-2α mutations in familial erythrocytosis: In contrast to worms and insects, in vertebrates both the PHD oxygen sensors and the HIFα transcription factor subunits are encoded by three distinct but related genes. All three PHD family members are expressed in the kidney.[251] The physiological relevance of a potential fourth family member, called PH-4, is less clear: HIFα seems to be regulated under PH-4 overexpression conditions only.[252,253] There exist three related genes even for HIF-β/ARNT (i.e. ARNT2, ARNTL and ARNTL2) and all of them seem to be able to interact with HIF-2α, at least *in vitro*.[254] However, whether these additional ARNT family members play any role for Epo gene expression is currently unknown. Regarding the

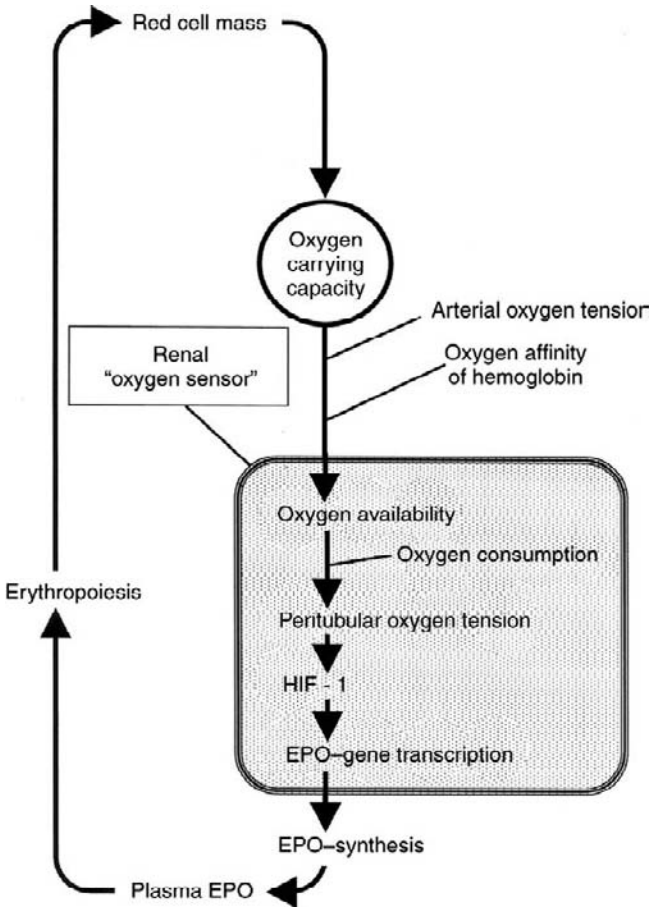

FIGURE 92.10 Negative feedback loop controlling the renal production of erythropoietin.

PHD and HIFα gene families, the question arises which family member(s) is/are responsible for oxygen-regulated Epo gene expression. Mouse gene targeting and human hereditary diseases provided genetic answers to this question.

Two independent inducible PHD2 knock-out mouse models showed increased erythropoiesis and angiogenesis as well as evidence for dilated cardiomyopathy and premature death.[255–257] These findings are in line with *in vitro* data demonstrating that PHD2 is the main oxygen sensor responsible for normoxic HIFα turnover.[258] Consistently, systemic PHD2 but not PHD1 or PHD3 knock-out mice die during embryonic development.[259] Only when all three PHDs are deleted simultaneously in a conditional knock-out mouse model, even the liver can become a rich source of Epo expression.[260] A further confirmation for the major role PHD2 is playing in oxygen-regulated Epo synthesis *in vivo* comes from the identification of gene mutations that cause familial erythrocytosis: the affected amino acids identified up to date confer residues P317, R371 and H374 of PHD2.[261–263] Neither PHD1 nor PHD3 mutations in familial erythrocytosis have been reported so far.

Due to its nature as a tumor suppressor, a large number of mutations in the human VHL gene were known before its role as HIFα E3 ubiquitin ligase was discovered. In accordance with its essential and non-redundant role in normoxic HIFα degradation it did not come as a surprise that such mutations can also cause erythrocytosis.[264] Interestingly, Chuvash polycythemia is caused by a pVHL R200W mutation in the absence of cancer.[265] A number of additional pVHL mutations causing congenital erythrocytosis have been identified thereafter.[266–268] Finally, a genetically altered mouse model recapitulated the polycythemic phenotype.[269]

As already mentioned before HIF-2 rather than HIF-1 is the physiological regulator of EPO gene transcription. Support to this conclusion is provided by the identification of HIF-2α P534L, M535V, M535I, G537W, G537R and D539E mutations that cause human familial erythrocytosis.[270–276] No HIF-1α or HIF-3α mutations have been reported so far to be involved in erythrocytosis.

Altogether, there is now compelling evidence that the oxygen sensing pathway regulating renal and hepatic Epo synthesis consists of the PHD2-VHL-HIF-2 axis.

Negative feedback loops and cross-talks of the Phd-Vhl-Hif oxygen signaling pathway: Although the main players for Epo gene regulation have been identified, there is clearly more complexity in the oxygen signaling pathway. Of particular physiologically importance are negative feedback mechanisms that limit or actually downregulate Epo induction under chronically hypoxic conditions. It is well known that hypoxically induced plasma Epo levels decrease clearly before the hematocrit is increased, excluding an early negative feedback loop via the subsequent increase in blood oxygen content.[119] The drop in plasma Epo is paralleled by a drop in renal Epo protein and mRNA levels and is independent of changes in extracellular Epo levels.[122,123] These findings suggest one or several negative feedback loop(s) intrinsic to the PHD-VHL-HIF axis controlling renal Epo synthesis.

Of note, the ratios between the levels of PHDs and HIFs are interconnected. If either one is upregulated it overcomes the function of the other. As well as an increase in PHD synthesis leads to HIFα degradation, an increase in HIFα synthesis leads to its own stabilization by saturating the degradation machinery. Even under hyperoxic conditions the PHDs are not fully active,[221] and a further decrease in the oxygenation as well as a decrease in the PHD levels allows for the stabilization of HIFα.[277–280] This feature explains why regulation of the PHD levels is of physiological relevance: the slightest up- or downregulation of PHD abundance and/or activity potentially affects HIF-2-dependent Epo expression. A very likely, albeit unproven, mechanism regulating Epo production hence might consist of the HIF-dependent transcriptional increase in PHD levels. PHD2 and PHD3, but not PHD1 or FIH, are HIF target genes induced under hypoxic conditions.[211,258,281–287] Hypoxically increased PHD2 and PHD3 in turn downregulate HIF-2α protein and hence Epo mRNA levels. This model shows a biphasic response, with an early PHD3 and a late PHD2 induction, and it allows for ongoing oxygen sensing, suggesting that it could easily adapt to both acute and chronic changes in oxygenation.[277–280]

There exist a large number of additional mechanisms regulating PHD and HIF abundance and activity, but due to the lack of appropriate renal cell culture models, their role in Epo gene regulation remains largely unknown. Basically, PHDs are regulated on three levels: transcription, protein abundance/stability and enzymatic activity. Up to date, little is known about the tissue-specific and growth factor-induced PHD transcription. Estradiol is known to induce PHD1 gene expression,[288,289] and TGF-β1 has been shown to inhibit PHD2 gene expression.[290] Whether these data are relevant to the sex-specific and developmentally regulated Epo gene expression is currently unknown. PHD protein abundance and activity can further be regulated by protein-protein interactions as well as by cellular metabolites and other small molecules. More than a dozen different proteins have been identified to interact with PHDs, all of them representing candidate Epo regulators, but none of them have ever been tested for Epo regulation (for an overview see[291]).

Cellular small molecule regulating PHD enzymatic activity include the redox-active substances ascorbate,

transition metals, nitric oxide and other reactive oxygen species.[292–298] Transition metal ions, such as cobalt, nickel and manganese, are very well known to induce Epo gene expression both *in vitro* and *in vivo*.[299,300] The discovery of the PHD oxygen sensors finally provided the molecular explanation for their function. Cellular metabolites that potently inhibit PHD activity are the Krebs cycle intermediates succinate and fumarate.[301–303] Germline mutations of the genes encoding fumarate hydratase (FH) or succinate dehydrogenase (SDH) result in the accumulation of fumarate and succinate, respectively, two potent inhibitors of PHD activity.[304,305] Moreover, mutations in the gene encoding isocitrate dehydrogenase-1 (IDH-1) lead to a decrease in the PHD co-substrate 2-oxoglutarate and an increase in HIF-1α levels.[306] Thus, the PHDs link oxygen sensing with mitochondrial metabolism. However, whether Krebs cycle enzyme mutations contribute to dysregulated Epo gene expression, for instance in familial erythrocytosis, is a major focus of ongoing research.

Modulation of Renal Erythropoietin Production

Renal perfusion: Renal erythropoietin production is not significantly changed unless renal perfusion is reduced to less than 10% of its normal value.[307,308] This may explain why renal artery stenosis is only rarely associated with erythrocytosis.

Although not yet proven, a likely explanation for the insensitivity of erythropoietin production toward changes of renal blood flow may arise from the fact that in the kidney oxygen consuming function and renal blood flow are directly linked. A fall of renal perfusion will decrease glomerular filtration and will lower the workload of the proximal tubule leading to a reduced oxygen demand of the proximal tubule. Thus, in spite of the fact that a decline of renal perfusion will lower the oxygen delivery to the cortical interstitium, it will not necessarily lower the pericellular oxygen tension, because the oxygen demand is also reduced in this situation. Because of this relationship, the kidney is in fact an "ideal" organ to sense changes in the systemic oxygen delivery independent of the renal perfusion.

Acid–base state: A physiological parameter that can effectively modulate renal erythropoietin production is the acid–base state of the organism, in a way that hypercarbia inhibits erythropoietin production while hypocarbia enhances it.[309–311] It was confirmed that not only respiratory but also metabolic acidosis markedly attenuates the stimulation of erythropoietin in response to arterial hypoxia or to a reduction of the oxygen-carrying capacity of the blood by an effect related to the hypoxia triggering of erythropoietin production.[121] The mechanisms of this pH sensitivity of oxygen sensing in the control of erythropoietin production have not yet been clarified.

Blood viscosity: In addition, blood viscosity appears to be a determinant for the efficacy of hypoxia to stimulate renal erythropoietin production. Patients with hypergammaglobulinemia may develop anemia that is not always explained by displacement of erythroid progenitors in the bone marrow, and that is characterized by plasma erythropoietin concentrations that are relatively low for the degree of anemia.[312,313] In fact, an inverse correlation between erythropoietin production and plasma viscosity unrelated to kidney function was found for those patients.[314] Plasma exchange experiments in rats showed that the renal expression of erythropoietin mRNA in response to anemia was inversely related to plasma viscosity.[314] Although the mechanism for this marked influence of plasma viscosity is not yet understood, it may provide an additional mechanism along which the circulating red cells mass could exert influence on the renal production of erythropoietin. Since it is well established that the packed red cell volume is the major determinant for whole-blood viscosity *in vivo*, it is conceivable that a fall of blood viscosity during anemia contributes to the enhancement of erythropoietin production, while an increase of viscosity during polycythemia would support inhibition of erythropoietin production.

Inflammatory cytokines: Based on the observation that chronic inflammatory diseases can lead to anemia and that plasma erythropoietin levels are relatively low in those patients, the possibility has been considered that inflammatory cytokines might exert an effect on erythropoietin production.[315] Indeed, it was found that interleukin-1 and tumor necrosis factor (TNF-α) potently suppress hypoxia-induced erythropoietin production and erythropoietin mRNA accumulation in cultured hepatoma cells.[316,317] This notion was confirmed in isolated perfused rat kidneys, where TNF-α attenuated hypoxia-induced erythropoietin production.

Iron Metabolism and Epo Gene Regulation

Of major physiologically relevance is the cross-talk between the oxygen and iron signalling pathways. Increased Epo production is futile unless sufficient iron is available for incrased erythropoiesis, the major iron consuming process of our body. Therefore, iron metabolism is directly regulated by oxygen supply and Epo production is directly regulated by iron availability. The most obvious possible cross-talk between the two pathways would be the strict requirement of the PHD oxygen sensors for iron.[298,318] Indeed, iron chelators are known for a long time to induce HIFα protein stability and HIF-dependent target gene induction, including Epo gene expression.[319,320]

PLASMA ERYTHROPOIETIN CONCENTRATION AND REQUIREMENT FOR ERYTHROPOIESIS

In healthy humans, the plasma erythropoietin concentration ranges independently of gender between 10–20 mU/ml with rather moderate diurnal variations.[321] Very similar values are measured in laboratory animals. Erythropoietin concentrations are given in terms of a biologic activity resulting from a comparison with an international reference standard.

Given a specific biologic activity of between 130,000 U/mg of protein for urinary erythropoietin and 200,000 U/mg of protein for pure human recombinant erythropoietin,[8] normal plasma concentrations in humans are then calculated to around 10 pmol/liter. In view of the absolute dependency of definitive erythropoiesis on erythropoietin, it follows that an insufficient formation of erythropoietin can be a major reason for anemia. To determine whether erythropoietin formation is appropriate or not, it is not sufficient to consider plasma erythropoietin levels alone. Since erythropoietin formation is mainly triggered by the oxygen delivery to the renal cortex, erythropoietin formation relative to the oxygen availability reflected by the hemoglobin concentration is the more reliable parameter to estimate the appropriateness of erythropoietin production. In laboratory animals, hemoglobin concentration can be changed under more controlled conditions, and those experiments have established an inverse semilogarithmic relationship between plasma concentration of erythropoietin and hemoglobin concentration, or the hematocrit, that is not dependent on the maneuver used to lower hemoglobin concentration such as irradiation, bleeding, or induction of hemolysis (Fig. 92.6). A very similar inverse semilogarithmic relationship is also found in humans suffering from regenerative, hemolytic, or iron-deficiency anemias (Fig. 92.11).[131,132] Depending on the degree of anemia, plasma erythropoietin concentrations can certainly increase up to 1000-fold, that is, up to 10 nmol/liter. The physiological reasons of such high plasma concentrations of erythropoietin are difficult to understand in view of the fact that the dissociation constant of the erythropoietin receptor is in the range of 10–50 pmol/liter, and that those concentrations are sufficient to stimulate CFU-E proliferation *in vitro* (see above). Studies in humans have shown that only moderate elevations of plasma erythropoietin concentrations are required to effectively stimulate erythropoiesis. This is most evident in patients suffering from renal anemia in which hemoglobin levels can be triggered to almost any extent by the subcutaneous administration of recombinant erythropoietin. Upon subcutaneous administration of erythropoietin, plasma erythropoietin concentrations, however, only rarely exceed a level of 100 pmol/liter. Thus, the reasons for the highly exaggerated plasma erythropoietin concentrations seen during severe anemia and severe arterial hypoxia are not yet understood. In more complex forms of anemia, such as postsurgery forms, or during chronic inflammation or tumor disease, the characteristic inverse relationship between plasma concentrations of erythropoietin and hemoglobin/hematocrit flattens,[322–324] suggesting that erythropoietin production is in appropriately low in those patients. In chronic renal disease, a positive relationship between plasma erythropoietin concentration and the hemoglobin concentration appears, indicating insufficient erythropoietin formation (Fig. 92.11).[132] In the latter instance, plasma erythropoietin concentrations reflect its efficacy on erythropoiesis rather than the efficacy of the renal oxygen erythropoietin sensor to regulate erythropoietin production in response to changes of the oxygen availability.

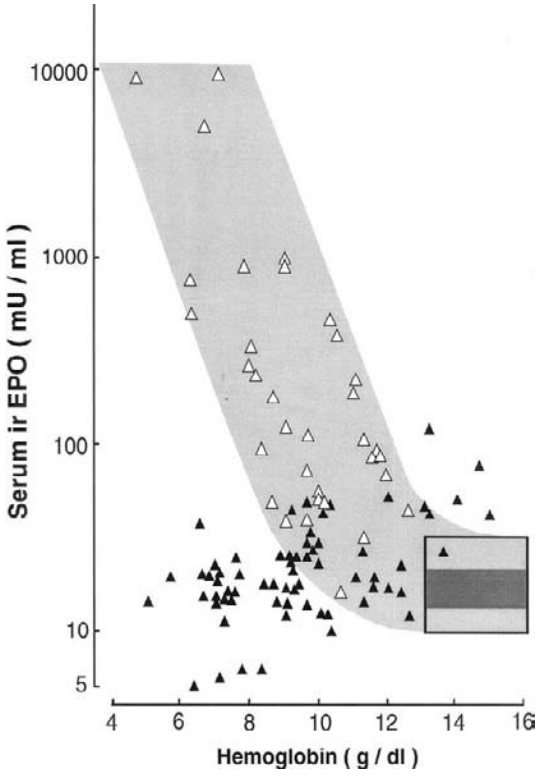

FIGURE 92.11 Relationship between serum immunoreactive (ir) EPO levels and hemoglobin concentration in patients with hypo- and hyper-regenerative nonrenal anemias (black triangles) and in patients with chronic renal failure (white triangles) (excluding patients with polycystic kidney disease). The rectangle depicts the interquartile range (dark stippled) and 95% confidence range of EPO levels in non-anemic healthy adults. *(With permission from Kurtz A, Eckardt KU. Erythropoietin production in chronic renal disease before and after transplantation. Contrib Nephrol 1990;87:15–25.)*

RENAL ANEMIA

Pathophysiology

Since the association of kidney disease with anemia was first documented in 1836,[7] anemia has been recognized as a characteristic symptom of chronic renal failure. This anemia is usually normocytic and normochromic, and develops almost invariably and largely independent of the underlying kidney disease when the creatinine clearance decreases to less than 20–30 ml/min.[325,326] It was an early observation that patients with renal failure lack the increase in serum erythropoietin levels that normally occurs as a response to reduced hemoglobin levels.[131,327] All three causes that can lead to anemia in general, namely, hemolysis, blood loss, and mainly impaired erythropoiesis, play a role in the pathogenesis of renal anemia. Although the contribution of hemolysis and blood loss to the anemia of patients with renal diseases is variable, and in selected patients may become predominant factors, both mechanisms are usually of a severity that can be compensated for by a moderate increase in the red cell production rate. Characteristically, however, erythropoiesis in renal failure is not enhanced, despite the persistence of anemia, as reflected by a lack of an appropriate increase in the number of reticulocytes and in iron kinetic studies. The determinants of this lack of response are therefore key elements in the pathogenesis of renal anemia.

Erythropoietin production during renal disease: Numerous investigators have demonstrated that endogenous erythropoietin production is severely blunted in patients with renal failure, and that erythropoietin levels do not rise appropriately for the degree of anemia (Fig. 92.11). It is also clear, however, that the erythropoietin deficiency is relative, rather than absolute, since levels in uremics are usually within or slightly above the normal range of nonanemic individuals. Even anephric patients maintain some basal erythropoietin production, which is presumably of hepatic origin.[328,329]

The reason for the inadequate production of erythropoietin relative to the degree of anemia is far from being understood. Although it might be assumed that renal disease implies damage to the cellular production sites of the hormone, the issue is more complex. When patients with chronic renal failure experience acute blood loss or hemolysis superimposed on their preexisting anemia, marked increases in circulating erythropoietin levels have been observed,[330] whereas conversely, red cell transfusions lead to a slight reduction in serum EPO.[327,329] Erythropoietin levels in patients with renal anemia also rise when oxygen supply is further compromised by a reduction in the arterial oxygen saturation of hemoglobin.[330] Although the response may be subnormal, these increases in erythropoietin under acute hypoxia are often of a magnitude that would certainly be sufficient to correct renal anemia, if they persisted.

These oxygen-dependent changes of plasma erythropoietin in patients with renal failure may in part reflect alterations in hepatic synthesis of the hormone. In general, the quantitative role of the liver for erythropoietin production in humans remains unknown, but a substantial hepatic contribution to the total erythropoietin mRNA expression has been found in anemic and hypoxic rats,[71,76] and hepatic erythropoietin mRNA accumulation was found not to be reduced in uremic animals.[76] Furthermore, in patients with renal anemia serum, erythropoietin and erythropoiesis can be transiently enhanced during episodes of viral and toxic hepatitis.[331] Although the mechanisms stimulating erythropoietin in inflamed and/or regenerating liver tissue have not been clarified, such observations suggest that the hepatic capacity for erythropoietin production would in principle be sufficient to compensate for inappropriately low renal synthesis.

Additional evidence indicates that a substantial production capacity for erythropoietin can also be maintained in diseased kidneys. A marked increase in erythropoietin mRNA has been found in remnant-kidney five-sixths nephrectomized rats after hypoxic exposure.[76] In experimental models of local renal tissue, injury expression of the erythropoietin gene was found to be reduced, but not abolished in areas of tubular atrophy and interstitial fibrosis.[97] Data about erythropoietin production in human diseased kidneys are sparse, but in patients developing erythrocytosis after successful kidney transplantation, selective measurements of erythropoietin in the veins draining the transplant and the endogenous kidneys have revealed an elevated erythropoietin production in the end-stage kidneys, which probably maintains the inappropriate increase in red cell production.[332,333]

In summary, it appears that in chronic renal failure, a considerable production capacity for erythropoietin is preserved, and that some feedback control of erythropoietin production is still operative, although the mechanisms linking erythropoietin production to the degree of anemia are disturbed. Given the evidence discussed above indicating that transport capacity of tubular cells plays a role in the control of erythropoietin production, it is conceivable that a reduction of tubular function contributes to inhibition of the normal erythropoietin response. Moreover, some evidence suggests that erythropoietin production in diseased kidneys may be inhibited by immunomodulatory cytokines, as mentioned earlier.[316,317]

Although erythropoietin production is generally unrelated to the etiology of renal failure, cystic kidney disease provides an interesting exception. Autosomal dominant polycystic kidney disease is a genetically determined structural and functional disorder that leads to chronic renal failure in the adult. The degree of anemia in patients with end-stage polycystic kidney disease is generally less severe than usual, and occasionally patients may become polycythemic.[334] In addition, acquired cysts in end-stage kidneys and single cysts may lead to erythrocytosis.[335,336] Plasma erythropoietin concentrations in patients with autosomal dominant polycystic kidney disease are, on average, twofold greater than in end-stage renal disease of noncystic origin,[334] and significant arteriovenous concentration differences for erythropoietin exist in polycystic kidneys.[87] The mechanisms by which cysts may stimulate erythropoietin production have not been resolved, although it is conceivable that compression and remodeling of pericystic tissue leads to regional hypoxia. In the cyst walls of patients with autosomal polycystic kidney disease, interstitial cells have been shown to express erythropoietin mRNA,[87] and cysts derived from proximal, but not those derived from distal tubules, may contain high concentrations of erythropoietin that are on average four-fold above the plasma concentration.[87] It has also been shown that single cysts derived from proximal tubules can contain high concentrations of erythropoietin,[337] indicating that erythropoietin formation is linked to the phenomenon of cysts formation itself rather than to the genetic abnormalities in polycystic kidney disease.

Therapy of Renal Anemia with rhEPO

Large multicenter trials have unequivocally shown that rhEPO is a highly effective therapy for renal anemia, with approximately 95% of patients responding. Primarily, rhEPO was used in dialysis patients only, but it is equally effective in predialysis patients and, importantly, was found not to accelerate the progression of renal failure in this population.[338,339] It appears rational therefore to start rhEPO therapy once a significant anemia develops, irrespective of whether renal replacement therapy is already necessary. Initial phase I clinical trials with rhEPO demonstrated that, depending on the dose of rhEPO, a steep increase in hemoglobin levels can be achieved within few weeks.[340,341] However, a very rapid correction of anemia is generally not necessary, not cost effective, and may be associated with a higher incidence of side effects. Thus, while initially doses of up to 1500 IU/kg of body weight per week were used, it is meanwhile recommended to use 75–120 IU/kg per week in order to achieve and maintain a hemoglobin value of 11 g/dl. The dose requirement in individual patients is quite variable, probably as a reflection of the complexity of the pathophysiology of renal anemia. In cases of primary treatment failure and when the response to rhEPO declines during therapy, the factors mentioned above that interfere with EPO efficacy should be evaluated. The majority of patients require iron supplementation to achieve an optimal effect with EPO therapy, and parenteral iron is frequently superior to oral supplements.[342] As outlined above, some effects of erythropoietin are unrelated to hematopoiesis. Those effects have to be taken into account for side effects of treatment with recombinant erythropoietin.

PHD Inhibitors as Future Therapeutics?

Albeit not fully understood regarding renal Epo production, the wealth of novel insights into the basic mechanisms of oxygen sensing and signalling opened new routes towards the treatment of diseases related to oxygen sensing. In kidney failure, oxygen consumption is decreased, resulting in increased tissue pO_2, decreased renal Epo production and anemia. Kidney dialysis patients hence need lifelong Epo treatments. Pharmaceutical interference with protein hydroxylase enzymatic activity proved to be efficient *in vitro* and beneficial for the treatment of a number of diseases in animal models *in vivo*, including tissue ischemia, kidney injury and transplantation.[244,343–346] Protein hydroxylase inhibitors also stimulated Epo production in mouse and rhesus macaque models.[254,347] Clinical phase II studies are being conducted to test the safety and efficacy of protein hydroxylase inhibitors in the treatment of patients with renal anemia. The near future will answer the question as to whether the currently available inhibitors of the oxygen sensing protein hydroxylases are sufficiently efficient and specific to serve as novel therapy strategies for the treatment of anemia caused by renal disease.

Erythropoietin Production after Renal Allotransplantation

Prior to the availability of rhEPO, renal allotransplantation has been the only way to definitely correct renal anemia. Hemoglobin concentrations usually normalize within a few weeks following successful renal allotransplantation. If one accepts that it is mainly an inappropriate erythropoietin production that leads to anemia in end-stage renal disease (ESRD), then consideration of erythropoietin production after renal transplantation becomes interesting. In fact, provided immediate excretory graft function, plasma erythropoietin levels rise

within 3–4 days after transplantation.[348–350] When hemoglobin concentrations subsequently have normalized, plasma erythropoietin declines to normal values.[351] These findings suggest that the transplant is capable of registering the anemia of ESRD and of responding with an increase in erythropoietin production. The oxygen dependency of erythropoietin formation becomes even more obvious when patients experience acute blood loss in the post-transplant period.[349] Regarding the mechanisms responsible for a disturbance of erythropoietin production during kidney failure, the analysis of erythropoietin formation after transplantation is of particular interest in those cases where the graft initially lacks excretory function. In this situation, erythropoietin formation was found to be rather unpredictable and variable. In some cases, temporal increases occur and plasma erythropoietin levels may display an irregular spiking pattern with no relationship to hemoglobin concentrations.[349] In others, no evidence for erythropoietin production by transplanted kidney is obtained at all, and a reduction in hemoglobin concentrations does not evoke an increase in erythropoietin. As soon as excretory function commences, erythropoietin production increases in primary inactive kidneys, or stabilizes in those cases where inconsistent elevations occurred during graft failure. In both instances, erythropoietin levels after onset of excretory function reach the values typical for cases with immediate graft function.[349] Irrespective of the different behavior of erythropoietin formation in individual cases, it appears as if during kidney failure the production capacity for erythropoietin may be preserved, but becomes decoupled from oxygen-dependent regulation. Furthermore, the temporal concurrence between the onset of excretory renal function and a regular oxygen dependency of erythropoietin formation in all cases may indicate that ongoing excretory function in the kidney is a prerequisite for the regulation of erythropoietin. This may have to do with the oxygen consumption of proximal tubules, which apparently is of relevance for the oxygen sensing.

Post-Transplant Polycythemia

In about 10% of the patients undergoing successful renal allotransplantation, a polycythemia develops, which in turn may give rise to thromboembolic complications.[352] Plasma erythropoietin concentrations in these patients were reported to be elevated,[333,353] and in some cases serial determinations showed as sustained elevation of erythropoietin after transplantation despite an increase in hemoglobin.[351] As to the question about the source of erythropoietin in these patients, both the native kidneys left in situ and the graft have to be considered. In some instances, an association with rejection, artery stenosis,[354] or hydronephrosis of the transplanted kidney has been reported. Extirpation of native kidneys has been found to cure post-transplant polycythemia,[355,356] suggesting a substantial role of the native kidneys as a source of inappropriate erythropoietin secretion.[357] This clinical inference is supported by multiple site estimates in post-transplant patients with polycythemia, demonstrating significant arteriovenous concentration differences for erythropoietin in the native kidneys.[332,353] At first view, it appears somewhat contradictory that after transplantation erythropoietin formation by diseased kidneys appears to induce polycythemia, whereas before transplantation erythropoietin formation was inappropriately low resulting in anemia. Although not yet proven, one may assume that the removal of uremia by the working graft and or suppression of inflammation by immunosuppressants play a major role. In any case, it appears also in the situation of post-transplant polycythemia the native kidneys have defect in adapting erythropoietin production appropriately to the oxygen availability. Interestingly, the enhanced formation of erythropoietin by the native kidneys can be lowered by theophyilline by a mechanism that is not yet understood.[358]

THROMBOCYTOPOIESIS

Platelet Formation

Like red cells, platelets derive from the pluripotent stem cells (Fig. 92.12). Due to mechanisms that are not well understood, stem cells become committed to the megakaryocytic pathway ending up with the platelets. Between the committed stem cells and the megakaryocyte as the histologically clearly identifiable differentiation state, there lie a number of cell divisions and differentiation steps. Under the influence of a variety of stimuli, the committed cells give rise to the earliest detectable progenitor, the megakaryocyte colony–forming unit (CFU-M), which is close to the megakaryocyte. When acted upon by appropriate regulatory substances, the CFU-M may be triggered to differentiate and to pro-liferate. During this period of development, these cells retain the normal diploid complement of DNA, and some cytoplasmic maturation does begin to occur as mitotic amplification proceeds including the accumulation of acetylcholinesterase activity, a cytochemical marker specific for megakaryocytes. Mitosis ceases in these early progenitor cells shortly after the appearance of acetylcholinesterase activity, as a result of this early cytoplasmic maturation. Cessation of mitotic activity does, however, not halt DNA synthesis. Rather, DNA synthesis

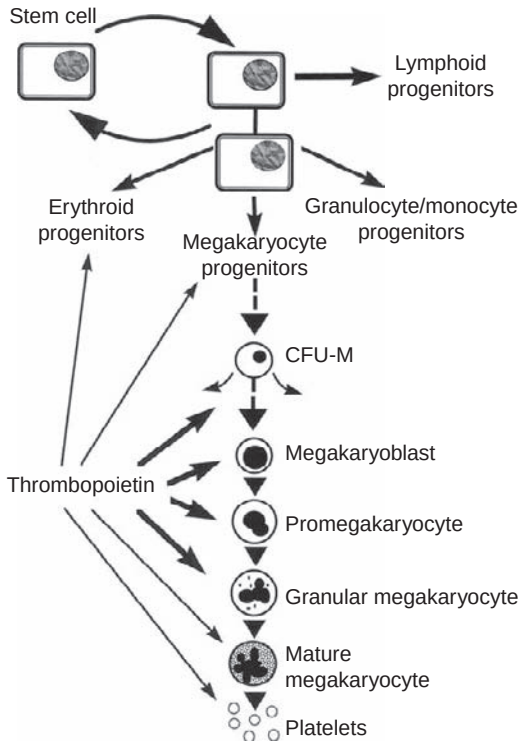

FIGURE 92.12 Schematic demonstration of differentiation steps of platelet formation and the action sites of thromobopoietin.

continues to occur in the form of nuclear endoreduplication. It is this unique megakaryocyte characteristic that allows these cells to become polyploid. Early megakaryocytes begin to form platelet granules and to form cytoplasmic invaginations that ultimately build up the platelet demarcation membrane system. Increasing cell ploidy is accompanied by increases in cell size, nuclear lobulation, cytoplasmic granulation, and changes in RNA content. As the ploidy level increases, the megakaryocyte progenitors enter the terminal stages of differentiation and become morphologically recognizable at the level of light microscopy. Platelet formation is initiated when pseudopodia are extended out of the megakaryocyte and penetrate the bone marrow sinusoids. The pseudopodia then fracture in the sinusoidal lumen and the fragments are carried to the lung. Either during passage to the lung or in the lung itself, the megakaryocyte fragment becomes a platelet, as organization of the microtubular and dense tubular systems induces its typical discoid shape.

Platelet formation appears to be controlled at least by two main factors. One is thrombopoietin, which increases DNA synthesis in young megakaryocytes, increases the number of immediate megakaryocyte precursors, augments their differentiation into mature megakaryocytes, increases the ploidy of megakaryocytes and platelet volume.[359] Although thrombopoietin seems to be the primary regulator of megakaryocyte development and platelet production,[360–362] a specific megakaryocyte-stimulating activity (Meg-CSA) that is regulated independently from thrombopoietin has also been suggested.[363]

Current models also suggest that early acting megakaryocyte colony stimulating factors, such as IL-3 or c-kit ligand are required for expansion of hematopoietic progenitors into cells capable of responding to late-acting megakaryocyte potentiators, including IL-6, IL-1,[364] and thrombopoietin. All together, it appears as if thrombopoietin is the primary and main regulator of megakaryocyte development and platelet production.

THROMBOPOIETIN

Historical Development

Initial studies concerning the regulation of megakaryocytopoiesis conclusively demonstrated a relationship between peripheral blood platelet numbers and alterations in their production. These alterations, which were manifested by the changes in megakaryocyte number, size, mitotic index, and ploidy values, appeared to be similar in both human and animal species. By analogy to the effect of erythropoietin on erythropoiesis, it was postulated that all of these effects were under the control of a single humoral regulatory substance designated thrombopoietin, which could be assayed by its ability to raise platelet counts in recipient animals.[365] It was recognized that plasma taken from thrombocytopenic patients or animals was able to increase platelet count or 35S-incorporation into platelets in healthy recipients. Attempts were made to purify thrombopoietin from the plasma of thrombopenic animals, however, were not met with great success. By chance it was found that the culture medium conditioned by the human embryonic kidney cell line (HEK) contained activity that was thrombopoietic both *in vivo* and *in vitro*.[366] The breakthrough came in 1994 when three groups reported the cloning of the thrombopoietin gene and demonstrated that thrombopoietin was a novel protein.[367–369] Important for the cloning strategy was the previous finding that platelets express the c-mpl proto-oncogene product, which was found to belong to the cytokine receptor superfamily.[370–372] Ingeniously anticipating that this receptor could be the thrombopoietin receptor, an assumption that was subsequently confirmed, affinity purification of thrombopoietin with the help of c-mpl was possible. The cloning of the thrombopoietin gene not only gave information about the structure of thrombopoietin and provided molecular tools for further investigations, but also led to the production of recombinant

thrombopoietin, which is available now for clinical trials in the treatment of thrombocytopenia.

Thrombopoietin Structure

Thrombopoietin has a predicted molecular mass of 35 kD.[367,369] Human full-length recombinant thrombopoietin has 332 residues. cDNAs for human, dog, and mouse are highly conserved and contain open reading frames for proteins of 353, 352, and 356 amino acids, respectively, including predicted 21 As signal peptides.[367,368] The protein backbone contains 6 N-carbohydrate linkage sites[368] and one O-carbohydrate linkage site to which complex carbohydrates are bound.[373] At the N-terminus, thrombopoietin has a high similarity to erythropoietin. Similar to the erythropoietin protein, the thrombopoietin protein probably contains two disulfide bonds (Cys 7−151 and Cys 29−85) that thus form a looped molecule.

Earlier attempts to purify thrombopoietic activities from HEK cells or from plasma or urine of thrombopenic beings led to activities with apparent molecular masses of around 30 kD and smaller sizes. In addition, thrombopoietic activity purified from canine or porcine thrombopenic plasma by binding to c-mpl appeared to be smaller than expected, namely with masses of 30, 25, and 20 kD,[367,368] but was found to have the same amino terminus as 25-kD thrombopoietin. It appears likely therefore that native thrombopoietin is cleaved into smaller products. This assumption is compatible with the fact that thrombopoietin contains two dibasic−amino acid sequences at positions 153−154 and 245-246, which could serve as potential processing sites. Although the cleavage mechanism is not yet understood, recent evidence suggests that thrombin could be involved in the physiologic cleavage of thrombopoietin.[374] However, in the circulation as well as in cell culture, this characteristic cleavage of thrombopoietin appears to occur.

Taken together, it appears as if thrombopoietin is produced as a glycoprotein with a protein backbone of around 330 amino acids, which physiologically becomes cleaved into a smaller fragments with a main size of around 30 kD. The fragments are biologically active and they share the same N-terminus, indicating that the N-terminus is essential for transmitting the biologic activity.

Thrombopoietin Gene

Controversial information has been reported about the structure of the thrombopoietin gene. While there is consensus that the human thrombopoietin gene contains a single copy on chromosome 3q26−28,[375−377] variable information exists about the length and organization of the gene. One group reported that the human thrombopoietin gene encompasses 6.2 kb with six exons and five introns,[376,377] whereas others found that the human thrombopoietin gene spans over 8 kb, consisting of seven exons and six introns.[375] Evidence suggests the existence of RNA splice variants for thrombopoietin.[369] The promoter region of the thrombopoietin gene contains no canonical TATA box. Investigations of regulating the thrombopoietin promoter have just begun. Early results suggest that the Ets transcription factor could play a role in its regulation.[378]

Thrombopoietin Receptor

Analysis of a leukemogenic retrovirus genome revealed the existence of a region coding for the so-called c-mpl proto-oncogene, which was expressed in hematopoietic tissue, and shared strong structural analogies with the hematopoietin superfamily.[372] Subsequently, it was shown that the c-mpl protein transduces a proliferative signal in hemopoietic cells.[371] Demonstration that oligodesoxynucleotides antisense to c-mpl specifically inhibited *in vitro* megakaryopoiesis led then to the assumption that c-mpl is the physiologic receptor for thrombopoietin.[370] c-Mpl-deficient mice have a marked (85%) decrease of platelet count and megakaryocytes, but have normal amounts of other hematopoietic cell types.[379,380] C-mpl is found in early progenitors of the various lineages and particularly in cells of the megakaryocytic lineage including platelets. This is a major difference compared to erythropoietin receptors, which are mainly expressed in late erythroid progenitors (CFU-E) and then decline and are absent from red blood cells.

Like other members of the hematopoietin/cytokine receptor superfamily, C-mpl consists of one extracellular domain, a single transmembrane domain and a cytosolic region.[381] Essential for the signaling are less than 100 amino acids of the cytoplasmic tail proximal to the transmembrane domain.[382] This region contains two boxes that are essential for tyrosine phosphorylation induced by thrombopoietin, and the thrombopoietin receptor itself is a substrate for phosphorylation.[383] Similar to the erythropoietin receptor, the signaling mechanism essentially starts with the receptor association and activation of Janus-kinase 2 (JAK2) and subsequent activation of STAT proteins.[382−385] The C-terminus of the c-mpl intracellular domain was found to be required for induction of Shc phosphorylation and c-fos mRNA accumulation, suggesting also involvement of the Ras signal transduction pathway.[382] In addition, the MAP kinase pathway becomes activated by thrombopoietin.[386] Finally, it has been found that thrombopoietin like erythropoietin activates phosphatidylinositol-3-kinase,[387] which causes an as yet unknown signaling pathway in megakaryocytes.

In addition to the membrane-anchored thrombopoietin receptor, a soluble form of the thrombopoietin receptor exists, of smaller size, and which has biologic

activity probably by associating with the target cells.[65] The binding characteristics of the thrombopoietin/MGDF receptor suggest the existence of a single affinity binding site with a dissociation constant of around 190 pmol/liter and about 30 binding sites per platelet.[388] The number of thrombopoietin binding sites on megakaryocytes is presumably higher but has not yet been determined.

Thrombopoietin Action

Mouse thrombopoietin activates human mpl, and human thrombopoietin activates mouse mpl, indicating the absence of strict species specificity.[389] Thrombopoietin increases megakaryocyte number and size in the bone marrow.[390] Thrombopoietin *in vivo* also increases DNA content of mouse bone marrow megakaryocytes indicating the induction of polyploidization.[391] Recombinant thrombopoietin also supports *in vitro* megakaryocyte formation, and acts at late stage of development to increase megakaryocyte size, polyploidization, and expression of differentiation markers. *In vivo* recombinant thrombopoietin stimulates platelet production by expanding the number of megakaryocytes and their progenitors in marrow and spleen. Transgenic mice overexpressing human thrombopoietin exhibit chronic thrombocytosis.[392] Conversely, animals with a disrupted thrombopoietin gene have low numbers of platelets and megakaryocytes. Thrombopoietin is therefore the major physiological regulator of both proliferation and differentiation of hematopoietic progenitor cells into mature megakaryocytes.[393] In addition to acting as a proliferation and differentiation factor, it has also been suggested that thrombopoietin suppresses apoptosis and behaves as a survival factor for megakaryocytes.[394,395] Interestingly, thrombopoietin appears not to be essential for a very late step in thrombocytopoiesis, namely proplatelet formation.[396]

Apart from these effects of thrombopoietin on late thrombopoiesis, however, thrombopoietin appears—in contrast to the action of erythropoietin—to also exert influence on early progenitors of different lineages. Thus, recombinant thrombopoietin increases not only the number circulating platelets but also the number CFU-M in primates.[397] Furthermore, thrombopoietin synergizes with stem cell factor or interleukin-3 to act on early multipotential hemopoietic progenitors.[398] The hematopoietic progenitor cell compartment responds to thrombopoietin as a whole, and therefore thrombopoietin can stimulate BFU-E, CFU-GM, and CFU-Mk formation *in vivo*.[399,400] Since erythroid progenitors respond to thrombopoietin, thrombopoietin can therefore augment erythropoiesis in states of bone marrow failure[401] by enhancing the effect of erythropoietin on early progenitors.[402] Physiologically increased levels of thrombopoietin, however, do not stimulate erythropoiesis.[403] Similarly, physiologically increased levels of erythropoietin do not stimulate thrombopoiesis,[403] while high doses of recombinant erythropoietin stimulate platelet production in mice[36] by synergizing with thrombopoietin to stimulate proliferation of CFU-M[404] or by cross-activation of the thrombopoietin receptor.

The existence of thrombopoietin receptors on circulating platelets in contrast to the lack of erythropoietin receptors on circulating red blood cells, suggests that thrombopoietin could also exert effects in mature platelets. In fact, there is accumulating evidence to suggest that thrombopoietin by itself does not change platelet activity, but substantially enhances platelet activation induced by ADP, thrombin, or other factors.[405–407]

Sites of Thrombopoietin Production

Given that the human embryonic kidney (HEK) cell line produces thrombopoietin activity, it was assumed that the kidney is a major site of thrombopoietin production.[366,408] Studies in nephrectomized animals, however, produced inconsistent results. Only one study reported a lack of response of platelet production in thrombocytopenic nephrectomized rats.[409] From a more clinical point of view, it can be noted that anephric patients on regular dialysis who are not treated with rhEPO are severely anemic, but not regularly thrombocytopenic.[410] It appeared reasonable therefore to conclude that other organs such as the liver[411] are able to compensate for the lack of renal thrombopoietin production. This assumption was confirmed by the finding that liver and kidney are the main sites of thrombopoietin mRNA expression in the body,[368,369] while thrombopoietin mRNA abundance is greater in the liver than in kidneys. In situ hybridization localized thrombopoietin mRNA to proximal tubules and hepatocytes, with no signal in renal peritubular cells.[412] From these findings, it appears as if liver and therein hepatocytes are the main site of thrombopoietin mRNA expression.[413] Apart from kidney and liver thrombopoietin, mRNA is found in spleen and bone marrow,[414] albeit at substantially lower levels. Some evidence has been provided to suggest that thrombopoietin produced by stromal cells in a hematopoietic environment stimulates proliferation and maturation of megakaryocytes.[415]

Regulation of Plasma Thrombopoietin Levels

The data about the plasma concentration of thrombopoietin are as yet rather scarce. It was reported that in healthy humans, plasma thrombopoietin concentrations are around 0.7 fmol/liter with no gender difference or age dependency,[416] which is consistent with another report that normal values are below 150 pg/ml.[417] Plasma thrombopoietin levels are increased during

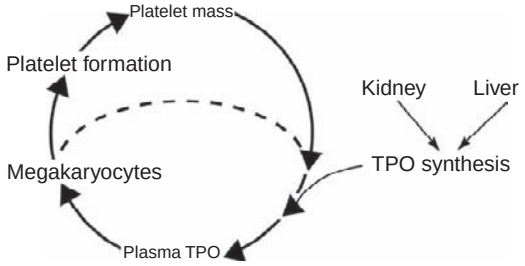

FIGURE 92.13 Negative feedback regulation of plasma thrombopoietin concentration.

thrombocytopenic states of different etiology. Up to know highest levels of thrombopoietin were reported for patients with aplastic anemia in which values up to 18 fmol/ml[418] or 4000 pg/ml[417] were measured.

Thrombopoietin levels are usually inversely related to the number of circulating platelets, in striking similarity to the relationship between plasma erythropoietin levels and red cell counts. As for erythropoietin, liver and kidney as the main production sites for thrombopoietin apparently do not contain significant stores of preformed hormone, since successful isolation of thrombopoietin from organs has not yet been reported. One may infer that thrombopoietin secretion into the bloodstream is mainly determined by the rate of de novo synthesis in liver and kidney. In marked contrast to the regulation of the erythropoietin gene, however, changes in platelet counts have no effect on thrombopoietin mRNA levels in liver, kidney, and spleen,[414,419] although a certain upregulation may occur in the bone marrow during thrombocytopenia.[412,414] The lack of relationship between thrombopoietin mRNA levels in the organs mainly responsible for thrombopoietin production and the circulating thrombopoietin level strongly suggests that the regulation does not occur at the level of its mRNA, and that the production rate either depends on regulation at the post-transcriptional level or that changes in circulating thrombopoietin levels do not reflect changes in its production rate. Although a post-translational regulation cannot be excluded, the evidence currently available favors the idea that changes in circulating thrombopoietin levels are mainly regulated by thrombopoietin metabolism rather than by alterations of its production. From the observation that plasma thrombopoietin changes reciprocally with changes of platelet counts, it was postulated that platelet mass may directly play a role in regulating the circulating levels of thrombopoietin (Fig. 92.13).[420] Evidence was in fact provided that thrombopoietin levels are directly determined by the number of circulating platelets,[393] because they bind thrombopoietin to the c-mpl receptor,[421] and internalize and metabolize thrombopoietin.[419,421,422] Moreover, megakaryocytes appear to affect thrombopoietin levels and to contribute to thrombopoietin degradation.[422,423] In line with this inference, it has been reported that megakaryocyte mass is an essential determinant of circulating thrombopoietin levels,[417] and it is assumed that not only platelets but also megakaryocytes must be involved in the regulation of the level of circulating thrombopoietin.[424,425] In patients with aplastic anemia, however, no direct correlation between thrombopoietin levels and the degree of thrombocytopenia was found,[426] suggesting that parameters different from circulating platelets (and number of megakaryocytes) also influence plasma thrombopoietin levels.

FUTURE ASPECTS

Although understanding the role of the kidney in hematopoiesis has been significantly expanded in recent years, some obvious questions are still unanswered. Thus, it will be interesting to learn why only a special subset of interstitial fibroblasts around proximal tubules elaborate EPO. Furthermore, the reasons for why renal cells producing EPO in situ do not do so *in vitro* have to be clarified, as well as those underlying the observation that a number of extrarenal cells (primary cultures and cell lines) express EPO in an inverse fashion with the oxygen tension. Understanding how the renal oxygen sensor controlling erythropoietin production works will also help in learning why, in chronic renal disease, erythropoietin production is decoupled from oxygen availability, since significant production capacity of the kidney to elaborate erythropoietin appears to be preserved.

CHAPTER

93

Individualizing the Dialysate to Address Electrolyte Disturbances in the Dialysis Patient

Biff F. Palmer

Professor of Internal Medicine, Department of Internal Medicine, Division of Nephrology
University of Texas Southwestern Medical School

INTRODUCTION

The goal of dialysis in patients with end-stage renal disease is to restore the composition of the body's fluid environment to normal. Dialysis is performed by creating an artificial situation in which the blood is separated from a disposable second solution (the dialysate) by a semipermeable membrane (the dialyzer or the peritoneal membrane). Solutes will diffuse from the blood through the membrane in proportion to their membrane permeability and the concentration gradient. The physician is able to decrease or prevent removal of a solute by adding it to the dialysate, thereby decreasing the concentration gradient for diffusive movement. One may also introduce solute into the dialysate in a concentration in excess of that usually found in the plasma water so that diffusive movement of this solute into the patient is favored. This chapter focuses on the changes that take place in electrolytes and acid–base during hemodialysis and peritoneal dialysis.

SODIUM

Hemodialysis

The patient with end-stage renal disease is dependent on dialysis to remove sodium from the body in an amount that matches sodium intake so that balance can be maintained. Sodium is free to cross the dialysis membrane primarily by the process of diffusion, and to a lesser extent by convection. The concentration of sodium in the dialysate plays a pivotal role in determining whether sodium balance is maintained at a level that avoids volume overload and yet provides adequate cardiovascular stability during the procedure.

As dialysis has evolved, there has been continued interest in adjusting the dialysate sodium concentration in an attempt to improve the tolerability of the procedure. In the early days of dialysis, a low-sodium dialysate was typically utilized to reduce the complications (such as hypertension and congestive heart failure) of chronic volume overload. However, with reduced dialysis treatment times it became apparent that such therapy contributed to hemodynamic instability by exacerbating the decline in plasma osmolality (particularly early in the dialysis procedure) and intravascular volume. Subsequent studies demonstrated that raising dialysate sodium to between 139 and 144 mEq/liter was associated with improved hemodynamic stability and general tolerance to the procedure.[19,74,175]

There was concern that an increased dialysate sodium concentration would produce a dipsogenic effect resulting in increased weight gain and poor blood pressure control. Studies addressing this issue confirmed that a higher-dialysate sodium modestly increased interdialytic weight gain. However, this excess weight was found to be readily removed with improved tolerance to ultrafiltration.[74]

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00093-8

More recently, there has been interest in varying the concentration of sodium in the dialysate during the procedure so as to minimize the potential complications of a high-sodium solution while retaining the beneficial hemodynamic effects.[154] A high dialysate sodium concentration is used initially with a progressive reduction toward isotonic or hypotonic levels by the end of the procedure. This method allows for a diffusive Na influx early in the session in order to prevent the rapid decline in plasma osmolality due to the efflux of urea and other small-molecular-weight solutes. During the remainder of the procedure, when the reduction in osmolality accompanying urea removal is less abrupt the lower dialysate Na level minimizes the development of hypertonicity and any resultant excessive thirst, fluid gain, and hypertension in the interdialytic period (Figure 93.1).

As outlined in Table 93.1, several studies have compared the hemodynamic and symptomatic effects of a dialysate in which the sodium concentration is varied during the procedure to that in which the sodium concentration is fixed. Dumler et al. used a dialysate sodium of 150 mEq/liter during the initial 3 hours of dialysis at the time of ultrafiltration. The dialysate sodium was decreased to 130 mEq/liter for the last hour.[49] The control group was dialyzed against sodium concentration fixed at 140 mEq/liter. Use of the high/low sodium hemodialysis was associated with a smaller decline in systolic pressure and fewer symptomatic hypotensive episodes.

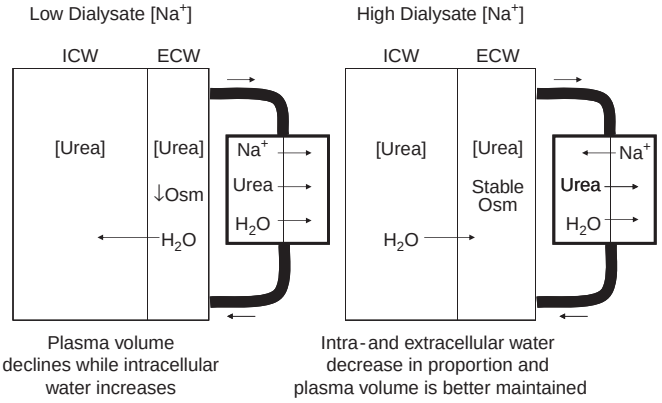

FIGURE 93.1 Use of a low sodium dialysate is more commonly associated with intradialytic hypotension. In the initial period of dialysis the extracellular urea concentration falls creating an osmotic driving force for water movement into the cell due to the higher intracellular urea concentration. This drop in extracellular osmolality and movement of water into the intracellular space is exacerbated in the setting of a low dialysate Na concentration. As a result plasma volume falls and the risk of hypotension increases. A high sodium dialysate helps to minimize the development of extracellular hyposmolality allowing for better refilling of the intravascular compartment. Plasma volume remains better preserved and the risk of hypotension is reduced.

Other investigators have varied dialysate sodium according to a sodium-gradient protocol in which the sodium is set to decrease from a high to a low level over the course of a dialysis session. The mixed results from these experiences are outlined in Table 93.1. Raja et al.[145] and Daugirdas et al.[37] found no measurable benefit. Acchiardo et al.[1] found a reduction in hypotensive episodes, and Sandowski et al. had similar results in young patients.[152] The linear and step sodium modeling programs have been found to be better in lowering the risk of intradialytic headache compared to the exponential program. The linear program was the only individual program that alleviated interdialytic cramps. The most striking reduction in the risk for post-treatment hypotension occurred with the step program.

Differences in the incidence of symptomatic hypotension during dialysis or in the degree of interdialytic weight gain between the fixed and variable sodium protocols have been difficult to demonstrate. Levin et al. studied a group of patients who were specifically selected because of the frequent occurrence of symptoms upon dialysis—such as headaches, cramps, and lightheadedness.[104] In a crossover trial, these patients were assigned either to a fixed sodium dialysate and a constant rate of ultrafiltration or to a gradient protocol in which the initial sodium concentration and ramping pattern were individually adjusted to minimize thirst. Use of patient-specific sodium gradient profiles was associated with improvement in all patients with headache and in 70% of patients with lightheadedness. The majority of patients reported an increase in thirst, but there were no differences in interdialytic weight gain or in pre-dialysis and postdialysis mean arterial pressure.

Utilizing a more general dialysis population, Sang et al. compared a linear or step sodium gradient (155−140 mEq/liter) protocol to a fixed sodium dialysate (140 mEq/liter).[156] In this study, sodium modeling was associated with a significant reduction in cramps and symptomatic hypotension. However, these benefits were followed by increasing thirst, fatigue, and weight gain between dialysis sessions—as well as by a higher predialysis blood pressure. The authors concluded that only 22% of patients had a significant benefit from the modeling programs. Finally, a study by Movilli et al.[122] found improved blood volume preservation by using a pattern of high-to-low sodium change (160−133 mEq/liter). The changes in blood pressure were similar between this high-to-low variation and conventional dialysis.

In summary, the available data suggest that in most chronic dialysis patients changing the dialysate Na during the course of treatment offers little advantage over a constant dialysate Na of between 140 and

TABLE 93.1 Summary of Recent Studies Examining Effects of Na Gradient Protocols

Study (reference)	Design	Intervention	Results
Dumler et al.,[49]	10 patients, crossover design	Fixed (140) vs high (150)/low (130), Uf only with 150	50% decrease in cramping episodes (no statistical comparison possible)
Raja et al.,[145]	10 patients, crossover design	Fixed (135 and 140) vs high (145)/low (135) vs low (135)/high (145)	No difference in hypotensive episodes between high/low and 140, but both better than 135 and low/high protocols
Daugirdas et al.,[37]	7 patients, crossover design	Fixed (143,135) vs gradient (160 to 133)	No difference in hypotensive episodes or cramps among 3 groups
Acchiardo et al.,[1]	39 patients, crossover design	Fixed (140) *vs* gradient (149 to 140 linear, exponential, step)	50% reduction in hypotensive episodes and cramps with gradient protocol
Sandowski et al.,[152]	16 patients (16–32 years of age), crossover design	Fixed (138) *vs* gradient (149 to 138, linear, exponential, step)	Decrease in intra- and interdialytic morbidity with gradient, no differences in symptomatic hypotension
Levin et al.,[104]	11 symptomatic patients and 5 asymptomatic patients, crossover design	Fixed (140) *vs* ramped Na (155–160 to 140) and Uf, each individually tailored	Significant decrease in dialysis morbidity with ramped protocol
Sang et al.,[156]	23 patients, crossover design	Fixed (140) *vs* gradient (155 to 140, linear or step)	Decrease in cramps and hypotension with gradient but only 22% of patients with significant benefit

145 mEq/liter. The inability to clearly demonstrate a superiority of Na modeling may be due to the fact that the time-averaged concentration of Na was similar in many of the comparative studies. For example, a linear decline in dialysate Na from 150 to 140 mEq/liter will produce approximately the same postdialysis serum Na as occurs when a dialysate Na of 145 mEq/liter is used throughout the procedure. In addition, the optimal time-averaged Na concentration (whether administered in a modeling protocol or with a fixed dialysate concentration) is likely to vary from patient to patient (as well as in the same patient) during different treatment times.[159] This variability is supported by studies demonstrating wide differences in the month-to-month pre-dialysis Na concentration in otherwise stable dialysis patients.[57]

Nevertheless, in selected patients Na modeling may be of benefit (Table 93.2). Patients initiating dialysis with marked azotemia are often deliberately dialyzed so as to decrease the urea concentration slowly over the course of several days in order to avoid the development of the dialysis disequilibrium syndrome. The use of a high-/low-Na dialysate in these patients may minimize fluid shifts into the intracellular compartment and decrease the tendency for neurologic complications. Na modeling may also be beneficial in patients suffering frequent intradialytic hypotension, cramping, nausea, vomiting, fatigue, or headache. In such patients, the modeling protocol can be individually tailored to minimize increased thirst, weight gain, and hypertension.

TABLE 93.2 Indications and Contraindications for use of Na Modeling (high/low programs)

A. Indications

- Intradialytic hypotension
- Cramping
- Initiation of hemodialysis in setting of severe azotemia
- Hemodynamically unstable patient (as in intensive care unit setting)

B. Contraindications

- Intradialytic development of hypertension
- Large interdialytic weight gain induced by high Na dialysate
- Hypernatremia

Combining dialysate Na profiling with a varying rate of ultrafiltration may provide additional benefit in particularly symptomatic patients.[169,198] Ultrafiltration profiling is the deliberate use of a high rate of ultrafiltration in the initial part of the treatment when the volume of interstitial fluid available for vascular refilling is maximal and then sequentially decreasing the rate so as to parallel the anticipated fall in interstitial fluid volume. Use of this combined approach may be of particular benefit in ensuring hemodynamic stability in patients with acute renal failure in the intensive care unit.[132]

When prescribing a Na gradient protocol it is important to monitor the patient for evidence of a progressive increase in total body Na. Use of a low-dialysate

Na during the terminal phase of the procedure does not necessarily guarantee negative Na balance. In some patients, a high/low Na protocol can lead to large interdialytic weight gain or cause intradialytic hypertension (Table 93.2). Such adverse effects are more likely to occur when the time-averaged Na concentration is greater than the pre-dialysis serum Na concentration. In one report, this complication was avoided when the time-averaged Na concentration was kept 0.5–0.8 mmol/liter lower than the patient's pre-dialysis serum sodium concentration.[168,93]

A Na gradient protocol can be administered in such a way that the amount of Na exchanged is the same as with a fixed Na dialysate while better preserving blood volume during ultrafiltration. Coli et al., has described a procedure termed profiled hemodialysis.[32–34,181] This technique is based on a mathematical model in which baseline patient characteristics are used to construct a patient-specific sodium profile dialysate prior to each treatment. Initial experience with this procedure has shown improved cardiovascular hemodynamics when compared to a fixed dialysate sodium concentration despite the same total mass of sodium being removed.[33,34]

In hypertensive patients, adjusting the protocol to achieve negative Na balance may be of therapeutic benefit in the long-term control of blood pressure. In this regard, Flanigan et al. recently compared a fixed dialysate Na of 140 mEq/liter to a gradient protocol in which the dialysate Na was lowered in an exponential fashion from 155 to 135 mEq/liter and then held constant at 135 mEq/liter for the final half-hour of the procedure.[58] Ultrafiltration was discontinued during the final half hour of the session. Use of the variable Na dialysate permitted a 50% reduction in the dose of antihypertensive medication without significant changes in pre-dialysis blood pressure or interdialytic weight gain. Although not specifically measured, use of the terminal low-sodium period likely caused a decrease in the total-body exchangeable Na—thus accounting for improved blood pressure control in Na-sensitive patients. Several other trials have noted a modest reduction in the dialysate Na can be an effective maneuver in lowering blood pressure in dialysis patients.

Sodium loading during the dialysis procedure by stimulating thirst can result in expansion of extracellular fluid volume and cause increased cardiac output and blood pressure. Volume independent mechanisms may also play a role in the hypertensive effect of a salt load.[15] For example, increased sympathetic outflow has been linked to hypernatremia in the Dahl salt-sensitive rat. Increased brain Na and osmolality is associated with increased angiotensin II levels. In addition to potential vasoconstrictive and vasculotoxic effects, angiotensin II stimulates sympathetic outflow by binding to AT_1 receptors centrally. *In vitro*, high medium Na concentration results in hypertrophy of cardiac myocytes and vascular smooth muscle cells.[65] Increased medium Na also leads to endothelial cell stiffness and decreased nitric oxide production in the presence of aldosterone.[127] Taken together these observations suggest sodium overload and hypernatremia induced by a high dialysate Na concentration may play an important role in hypertension and abnormal vascular function in dialysis patients.

The ability to achieve neutral sodium balance requires the dialysate sodium concentration to be individualized such that with each treatment a constant end-session plasma sodium concentration is reached. In dialysis patients, interdialytic sodium and water loads vary from one patient to another and from treatment to treatment. Water balance can be achieved by making total ultrafiltrate volume equal to interdialytic weight gain. If over time end-dialysis weight and plasma sodium concentration are kept constant (assuming no change in sodium distribution volume), one can assume that the patient will be in sodium balance. As currently practiced, dialysate sodium concentrations (whether fixed or varied) are not chosen with the primary aim of achieving sodium balance. In fact, pre-dialysis serum sodium levels may vary between 125 and 147 mEq/liter in dialysis patients, but for any individual patient the standard deviation of the pre-dialysis serum sodium value is less than or equal to 2.5 mEq/liter.[56,96] As a result, a dialysate sodium concentration that achieves neutral sodium balance for one patient may cause salt loading when applied to another. This approach risks a pathologic excess in the total sodium mass, which over time can lead to clinical manifestations of volume overload such as hypertension and congestive heart failure.

To properly calculate the dialysate sodium concentration required to maintain sodium balance, measurement of plasma water sodium concentration at the beginning of the treatment is required. Hemodynamics were recently compared in 27 patients dialyzed against dialysate Na set at 138 mEq/liter versus dialysate Na set to match the average pre-dialysis Na concentration multiplied by the Donnan coefficient of 0.95 (individualized Na dialysate).[39] This latter step was undertaken to better approximate the ionic concentration of Na rather than its total concentration. The ionic concentration of Na better reflects the amount available for movement across a dialysis membrane because a small amount of total Na is unavailable for diffusive flux due to Donnan effects and complexes formed with certain anions. Use of the individualized Na dialysate was associated with less interdialytic weight gain, decreased thirst, and improved blood pressure control.

The ionic activity of sodium can also be measured through the use of conductivity measurements. Locatelli et al. have recently described the use of a biofeedback system that allows for the automatic determination of plasma water and dialysate conductivity such that blood sampling can be avoided.[108–110] With these measurements—along with session time, desired weight loss, and expected end-treatment plasma water conductivity—the dialysate conductivity is automatically adjusted in order to achieve the prescribed final plasma water conductivity. Application of this conductivity kinetic model to patients treated with a variant of hemodiafiltration achieves near-zero hydrosodium balance and improves intradialytic cardiovascular stability.[109] Such techniques may also be useful in patients with a low pre-dialysis Na concentration who are prone to positive sodium balance when dialyzed against a fixed dialysate Na.[120] Newer technology will allow for plasma water and dialysate conductivity to be measured repetitively during the procedure, allowing automatic adjustment of the dialysate sodium online throughout the procedure.[21,113,139]

With increased ability to individualize the dialysate sodium concentration, one can envision a scenario in which a patient initiated on hemodialysis is initially treated with a dialysate sodium concentration designed to achieve negative sodium balance. Once the patient becomes normotensive or requires minimal amounts of antihypertensive medication, the dialysate sodium can be adjusted on a continual basis to ensure that sodium balance is maintained. In this manner, management of sodium balance would be made similar to management of fluid intake. Achieving the optimal total body sodium content will likely become just as important as determining an accurate dry weight.

Peritoneal Dialysis

Ultrafiltration in peritoneal dialysis is achieved by instilling into the peritoneal cavity a fluid that is hyperosmolar relative to plasma. The creation of this osmotic gradient results in net movement of free water into the peritoneal cavity. The degree of hypertonicity, the dwell time, and peritoneal transport characteristics are the main determinants of volume removal. The magnitude of ultrafiltration is determined clinically by subtracting the volume of fluid instilled in the peritoneal cavity from the effluent volume.

The osmotic driving force of peritoneal dialysate can be adjusted by changing the dialysate glucose concentration. A 1.5% glucose dialysate is only slightly hypertonic to plasma, and small volumes of ultrafiltration will be expected. In contrast, ultrafiltration rates of up to one liter per hour have been obtained with a 4.25% solution. The osmolality of the infused dialysate declines over time due to the movement of water into the peritoneal cavity and the absorption of glucose from the peritoneal cavity. Due to a sieving coefficient across the peritoneal membrane of less than one, the sodium concentration in the ultrafiltrate during peritoneal dialysis is usually less than the extracellular fluid. As a result, there is a tendency for water loss and the development of hypernatremia. Commercially available peritoneal dialysates have a sodium concentration of 132 mEq/liter to compensate for this tendency toward dehydration. This effect is most pronounced with increasing frequency of exchanges and with increasing dialysate glucose concentrations. Use of the more hypertonic solutions with frequent cycling can result in significant dehydration and hypernatremia. As a result of stimulated thirst, water intake and weight may increase—resulting in a vicious cycle.

There are three components that determine sodium transport in peritoneal dialysis. The components that account for removal of sodium from the body are diffusion (due to the concentration gradient between blood and dialysate) and convection (due to ultrafiltration). Acting to oppose sodium removal is peritoneal absorption. Lymphatic and intestinal tissue fluid absorption leads to the convective movement of sodium from the dialysate to blood. There is a strong positive correlation between net ultrafiltration volume and the total mass of sodium removed from the body.[187] Ultrafiltration not only increases sodium removal by convection but increases the diffusive flux by secondarily increasing the concentration gradient from blood to dialysate. The more favorable gradient results from the sodium-sieving effect such that the fluid entering the peritoneal space is hypotonic and dilutes the dialysate sodium concentration.

The use of a peritoneal solution containing the standard sodium concentration of 132 mEq/liter creates a relatively small concentration gradient for sodium diffusion. As a result, more sodium is removed by convection compared to diffusion.[90–97] Differences in osmolality of the solutions utilized and dwell time account for the variability in sodium removal among the different modalities of peritoneal dialysis. Automated forms of peritoneal dialysis (APD) are characterized by rapid exchanges and short dwell times. Although hypertonic exchanges during APD lead to a more pronounced fall in dialysate sodium concentration, there is little time available for diffusion. It is for this reason that sodium removal in APD is lower than chronic ambulatory peritoneal dialysis, in which dwell times are much longer. Patients treated with APD may achieve adequate ultrafiltration with hypertonic solutions but have inadequate sodium removal.

Sodium and water removal is more difficult to achieve in patients with increased membrane permeability. These patients have increased diastolic blood pressures and are prone to volume overload. In addition, patient and technique survival may be decreased in this setting. Sodium transport in this patient group is characterized by a high peritoneal absorption rate and a decreased ultrafiltration rate. The diffusive flux of sodium is not significantly different in these patients.[187] Typically, such high-transport patients are placed on APD to minimize dialysate dwell time. An alternative strategy that could be utilized is to lower the sodium concentration in the dialysate. Studies examining ultrafiltration and sodium kinetics using a dialysate sodium concentration of either 102 mmol/liter (383 mOsm/kg) or 105 mmol/L (348 mOsm/kg) have shown that a low-sodium dialysate is more effective in the removal of excess sodium compared to a conventional sodium solution.[79,102]

Enhanced sodium removal may be the result of an increased diffusive flux of sodium or may be secondary to enhanced convective transport due to the higher glucose concentrations used in low-sodium solutions. Alternatively, the decreased sodium concentration in the dialysate may contribute to less sodium absorption. In short-term clinical trials, use of a low-sodium dialysate (98 mmol/liter and 120 mEq/liter) has been shown effective in reducing both body weight and blood pressure in volume-overloaded patients on chronic ambulatory peritoneal dialysis.[92,124,125] Limited data also suggest that this strategy may be of use in patients receiving APD.[90–92]

An additional strategy for enhancing sodium removal and preventing volume overload in patients with increased membrane permeability is to substitute icodextran for glucose as the osmotic agent.[118,185] Icodextran is a glucose polymer that is isosmolar to plasma but still capable of generating an ultrafiltrate through the process of colloid osmosis. This process is based on the principle that water is transported from capillaries in the direction of impermeable large solutes rather than down an osmotic gradient (as occurs with glucose-containing solutions). Water movement occurs through small pores, whereas in the osmotic effect of glucose water movement is primarily through ultrasmall transcellular pores. Sodium sieving does not occur with icodextran as a result of this difference.

In a six-hour dwell, the 7.5% icodextran solution generates an ultrafiltrate volume that is higher than that generated by 1.5% dextrose—despite having a lower osmolality (285 *vs* 347 mOsm/kg). With prolonged dwell times of 8–12 hours, the icodextran solution provides equivalent or higher ultrafiltrate volumes than that generated by the 4.25% dextrose solution (486 mOsm/kg).[138] In prospective randomized studies, use of icodextran has been found more effective in reducing extracellular water[95] and in removing sodium[38] compared to standard glucose solutions. The ability to maintain a colloid osmotic pressure for prolonged periods makes this solution ideal for overnight dwells in patients on continuous ambulatory peritoneal dialysis and for daytime dwells for those on automated peritoneal dialysis regimens.

In patients with ultrafiltration failure who would otherwise be transferred to hemodialysis, use of icodextran has been shown to extend the time that patients remain on peritoneal dialysis by many months.[26] In addition use of icodextran is associated with less weight gain, improved lipid control, and less hyperinsulinemia as compared with dextrose-containing solutions. It is likely that icodextran will become the preferred agent for the long dwell in most peritoneal dialysis patients.

POTASSIUM

Regulation of Potassium in Renal Disease

Acute kidney injury may lead to marked decreases in distal delivery of salt and water which may secondarily decrease distal K^+ secretion. For this reason, hyperkalemia tends to occur more commonly in oliguric renal failure. Hyperkalemia is much less common in non-oliguric renal failure since distal delivery of salt and water is plentiful.

Chronic kidney disease is more complicated than acute renal failure. In addition to the decreased GFR and secondary decrease in distal delivery, there is nephron dropout and a smaller number of collecting ducts to secrete K^+. However, this is counterbalanced by an adaptive process in which the remaining nephrons develop an increased ability to excrete K^+. In a study of normokalemic patients with stage 4 chronic kidney disease, the fractional excretion of K^+ was 126% compared with 26% in normal controls.[195] The fractional excretion of Na^+ in the two groups was 2.3% and 15%, respectively. Following the intravenous administration of amiloride, the fractional excretion of K^+ decreased by 87% in the patients with chronic kidney disease compared with 19.5% in control patients. These findings support the idea that patients with chronic kidney disease are able to maintain a normal serum K^+ concentration through an adaptive increase in renal K^+ secretion that is largely amiloride sensitive.

Once a patient reaches end-stage renal disease the capacity for renal potassium excretion is no longer present. Interestingly, despite this limitation, total body potassium (in particular, intracellular potassium) in patients with end-stage renal disease is low or

normal.[17,20,119] The low intracellular potassium content has been attributed to decreased activity of the Na,K-ATPase, which is a characteristic finding in uremia.[28,196] Studies in red blood cells taken from uremic patients have shown that the diminished activity of the pump can be reversed when cells are incubated in normal plasma. There is also an improvement in the activity of the pump following dialysis.[28,80,97,144] Red blood cells taken from normal individuals and incubated in uremic plasma acquire the defect.

Decreased potassium concentration, increased sodium concentration, and decreased resting membrane potential have been demonstrated in skeletal muscle from uremic patients.[35] After seven weeks of hemodialysis, these physiologic parameters were restored to normal. These observations suggest the presence of a circulating inhibitor of the Na^+,K^+-ATPase in some uremic patients.[84] In other patients, there may be a decrease in the number of pump sites rather than decreased activity. A decrease in pump activity or a decrease in the total number of pumps may account for the impaired extrarenal potassium disposal reported in some uremic patients.

In the absence of renal function, the cellular uptake of potassium becomes an important defense against the development of hyperkalemia. Studies of patients on dialysis have shown a defect in this extrarenal mechanism of potassium disposal.[3,7,55] Fernandez et al. compared the disposition of an oral potassium load (0.25 mEq/kg/body weight) in a group of dialysis patients and in normal controls.[55] The normal controls excreted 67% of the potassium load within 3 hours and translocated 51% of the retained potassium intracellularly. In contrast, the dialysis patients did not excrete any of the potassium and only 21% of the retained potassium was translocated intracellularly. The increment in plasma potassium was significantly different between the two groups. The plasma potassium concentration increased by 1.06 mEq/liter in the dialysis patients, whereas only a 0.39-mEq/liter increase was noted in the control group. The impairment in potassium disposal persists even when the potassium load is accompanied by oral glucose, although glucose-induced stimulation of insulin attenuates the maximal rise in potassium levels.[3]

In patients with renal failure, a significant proportion of daily potassium excretion occurs via the gastrointestinal tract. Gastrointestinal losses are important in maintaining potassium balance in chronic dialysis patients because hemodialysis removes approximately 80−100 mEq/treatment (300 mEq/week), yet dietary potassium intake is usually 400−500 mEq/week. In a balance study performed in patients already on peritoneal dialysis, 25% of the daily potassium intake was lost via the feces.[71,72] The amount of potassium excreted in the stools correlates directly with the wet stool weight.[79,80] Therefore, constipation should be avoided because it will decrease the gastrointestinal elimination of potassium and increase the tendency toward hyperkalemia.[174]

The mechanism of the increased gastrointestinal potassium loss is not known. The process appears to be due to active secretion, as it is unrelated to plasma potassium or total body potassium.[114,135,185] In fact, hemodialysis patients continue to have enhanced rectal potassium secretion even after dialysis—their plasma potassium being less than that of controls. Potassium transport in the large intestine was recently studied in patients with end-stage renal disease using a rectal dialysis technique.[116] Rectal potassium secretion was found to be three fold greater in end-stage renal disease patients as compared to control patients with normal renal function. When barium (a potassium channel inhibitor) was placed in the lumen, colonic potassium secretion was reduced by 45% in the end-stage renal disease patients while no effect was seen in the control group. Immunostaining using an antibody directed to the α-subunit of the high conductance potassium channel protein revealed greater expression of the channel in surface colonocytes and crypt cells in the end-stage renal disease patients while only a low levels of expression was observed in the control group. These data are consistent with increased expression of potassium channels as the mechanism for the adaptive increase in colonic potassium secretion in patients with end-stage renal disease.

Elevated levels of plasma aldosterone may play an important role in stimulating the gastrointestinal excretion and cellular uptake of potassium in patients with end-stage renal disease.[5] Exogenous administration of mineralocorticoids has been shown to decrease the serum potassium in anuric dialysis patients, presumably by increasing colonic potassium excretion.[78] In a prospective study, fludrocortisone administered at 0.1 mg/d was compared with no treatment in 21 hyperkalemic hemodialysis patients.[47] At the end of 10 months, the serum K^+ concentration in the two groups was not statistically different. However, there was a decrease in serum K^+ compared with pretreatment values in patients who received the drug.

A recent study examined the effects of glycyrrhetinic acid food supplementation on the serum K concentration in a group of maintenance hemodialysis patients.[50] This substance inhibits the enzyme 11β-hydroxysteroid dehydrogenase II which is found not only in the principal cells of the renal collecting duct but also epithelial cells in the colon. This enzyme converts cortisol to cortisone thereby ensuring the mineralocorticoid receptor remains free to only interact with aldosterone since cortisone has no affinity for the receptor. In 9 of 10

patients given the supplement there was a persistent decrease in measured predialysis serum potassium concentration. In addition, treatment with the supplement significantly decreased the frequency of severe hyperkalemia. These beneficial effects occurred without weight gain or increases in systemic blood pressure suggesting glycyrrhetinic acid supplementation may be of benefit in enhancing colonic K secretion and minimizing the risk of hyperkalemia in dialysis patients.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers have both been reported to cause hyperkalemia in patients treated with hemodialysis and peritoneal dialysis.[94,142] The development of hyperkalemia with these drugs may be due to decreased colonic potassium excretion resulting from lower circulating levels of aldosterone or decreased activity of angiotensin II. In this regard, enhanced colonic potassium excretion in renal failure has been attributed to upregulation of angiotensin II receptors in the colon—suggesting that angiotensin II has a direct effect in stimulating colonic potassium excretion.[70] Blocking the mineralocorticoid receptor with spironolactone given at a dose of 25 mg/day does not raise the serum potassium concentration in hemodialysis patients.[155]

Hemodialysis

Dialysis is required to maintain normal or near-normal serum potassium concentrations in patients with end-stage renal disease. The removal of excess potassium by dialysis is achieved by the use of a dialysate with a potassium concentration lower than that of plasma, creating a gradient favoring potassium removal. Its rate is largely a function of this gradient.[51] Typically, one should not expect more than about 80−100 mEq of potassium removal even with the use of a potassium-free dialysate. Plasma potassium concentration falls rapidly in the early stages of dialysis, but as the plasma concentration falls potassium removal becomes less efficient. Because potassium is freely permeable across the dialysis membrane, movement of potassium from the intracellular space to the extracellular space appears to be the limiting factor in potassium removal. Factors that importantly dictate the distribution of potassium between these two spaces include changes in acid−base status, tonicity, glucose and insulin concentration, and catecholamine activity (Table 93.3).

The movement of potassium between the intra- and extra-cellular spaces is influenced by changes in acid−base balance that occur during the dialysis procedure.[89,173] Extracellular alkalosis causes a shift of potassium into cells, whereas acidosis results in potassium efflux from cells. During a typical dialysis, there is net addition of base to the extracellular space—which promotes cellular uptake of potassium and therefore attenuates the removal of potassium during dialysis. With routine dialysis, the change in blood pH is of small magnitude and the effect on potassium removal is not profound.

TABLE 93.3 Factors Affecting Potassium Removal during Hemodialysis

A. Shifts K into cell thereby ↓ dialytic K removal
• Exogenous insulin • Glucose containing dialysate vs glucose free dialysate • Beta agonists • Correction of metabolic acidosis during dialysis
B. Shifts K to extracellular space or impairs cell K uptake thereby ↑ dialytic K removal
• Beta blockers • Alpha adrenergic receptor stimulation • Hypertonicity

By contrast, dialysis in patients who are acidotic will result in less potassium removal because potassium is shifted into cells as the serum bicarbonate rises. Weigand et al. described five patients in whom the serum potassium concentration decreased during dialysis even though the dialysate potassium concentration was higher than the original serum potassium concentration.[189] The decline in potassium concentration occurred in association with a marked rise in pH. In one patient, the decline in potassium concentration was of such magnitude that she became quadriplegic and developed respiratory failure. There appears to be no difference in potassium removal whether acetate or bicarbonate is chosen as the dialysate buffer.

Conversely, the serum potassium concentration can influence the net addition of base. Redaelli et al. found that a potassium-free dialysate was associated with less bicarbonate uptake compared to a dialysate that contained a potassium concentration of 2 mEq/liter.[147] It was postulated that a lower potassium dialysate that results in a high plasma-to-dialysate potassium concentration gradient causes less hydrogen ion movement from the intracellular space to the extracellular space and hence less downward titration of the extracellular bicarbonate concentration. As a result, the concentration gradient favoring diffusion of bicarbonate from the dialysate to the extracellular space is reduced. This relationship should be considered when dialyzing an acidotic patient.

Insulin is known to stimulate the cellular uptake of potassium, and it can therefore influence the amount of potassium removal during dialysis. This effect of

insulin was demonstrated in studies comparing potassium removal using glucose-containing and glucose-free dialysates.[161,188] The use of a glucose-free dialysate was found to result in greater amounts of potassium removal when compared to patients treated with a glucose-containing bath. The use of a glucose-free dialysate would be expected to result in lower levels of insulin. As a result, there is increased movement of potassium to the extracellular space—where it becomes available for dialytic removal.

Changes in plasma tonicity can affect the distribution of potassium between the intra- and extra-cellular spaces.[173] Administration of hypertonic saline or mannitol is sometimes used in the treatment of hypotension during dialysis. These agents would be expected to favor potassium removal during dialysis because the resultant increased tonicity would favor potassium movement into the extracellular space. There are no studies addressing whether there is any significant clinical benefit with this approach.

Beta-adrenergic stimulation is known to shift potassium into cells and thus lower the extracellular concentration. Inhaled beta stimulants have been reported to be effective in the acute treatment of hyperkalemia. Thus, such therapy prior to dialysis may lower the total amount of potassium removed during the dialytic procedure. Allon et al. found that the cumulative dialytic potassium removal was significantly lower in patients treated with nebulized albuterol 30 minutes prior to the procedure compared to patients in whom the albuterol treatment was omitted.[4]

Alterations in serum potassium concentration during dialysis can conceivably have important effects on systemic hemodynamics. A decrease in serum potassium concentration during hemodialysis would be predicted to increase systemic vascular resistance. Hypokalemia has been shown to increase resistance in skeletal muscle, skin, and coronary vascular beds—possibly through effects on the electrogenic Na-K pump in the sarcolemmal membranes of vascular smooth muscle cells.[22] In addition, decreased serum potassium concentration may enhance the sensitivity of the vasculature to endogenous pressor hormones.[105]

Despite the potential for hypokalemia to increase systemic vascular resistance, Pogglitsch et al. found that the incidence of hypotensive episodes were in fact reduced when supplemental potassium was administered during the final 30 minutes of dialysis.[141] One explanation for this seemingly paradoxical finding rests on the known interaction between hypokalemia and the autonomic nervous system. For example, hypokalemia has been found to be associated with dysautonomia in patients with hyperaldosteronism.[18] It is reasonable to speculate that in patients with advanced renal failure, who already have a propensity for autonomic insufficiency, a fall in plasma potassium may uncover or cause impairment in sympathetic responses.[73]

In support of this suggestion, Henrich et al. found that hypokalemic dialysis was accompanied by a fall in plasma catecholamine concentration compared to dialysis in which serum potassium concentration was held constant.[75] Moreover, despite similar reductions in blood pressure the isokalemic dialysis group had a significant increase in heart rate after dialysis and the hypokalemic group demonstrated no significant change. Further studies are needed to investigate the effects of fluctuations in serum potassium concentration during dialysis on the autonomic nervous system.

Changes in serum potassium concentration during dialysis may also influence systemic hemodynamics through effects on myocardial performance. Dialysis is associated with an increase in contractility, which can be attributed to an increase in ionized serum calcium. Increased ionized calcium is most closely related to improved ventricular contractility, but modifying effects of concomitant decreases in potassium may also be important. Haddy et al. have demonstrated that the inotropic effect of increased serum calcium concentration is enhanced by simultaneous decreases in plasma potassium concentration.[67] In this regard, Wizemann et al. found that improvement in myocardial contractility during a series of isovolemic dialysis maneuvers was related to a simultaneous increase in plasma calcium and a decrease in plasma potassium concentration.[193] In the presence of an elevated plasma potassium concentration, a high plasma calcium concentration failed to exert a significant inotropic effect.

An increase in peripheral vascular resistance secondary to the development of hypokalemia could have potential detrimental effects on dialysis efficiency. This decrease in efficiency would result from decreased blood flow to urea-rich tissues (such as skeletal muscle) and in effect increase the amount of body-wide recirculation. In support of this possibility, Dolson et al. found that a dialysate potassium concentration of 1.0 mmol/liter compared to 3.0 mmol/liter resulted in lower values for both the urea reduction ratio and Kt/V in 14 patients with end-stage renal disease.[45] By contrast, Zehnder et al. found no effect of dialysate potassium on dialysis adequacy.[197] Although more studies are needed in this area, it is likely that any effect of a low dialysate potassium concentration to decrease dialysis adequacy is small in magnitude. In addition, increasing the dialysate potassium concentration to improve dialysis adequacy will increase the risk of hyperkalemia during the interdialytic period.

Most patients dialyzed with a fixed potassium dialysate tolerate the procedure well and do not suffer from complications of hypokalemia or hyperkalemia.

Nevertheless, there are clinical conditions in which an individualized dialysate potassium concentration may be useful. Patients with underlying heart disease, particularly in the setting of digoxin therapy, are prone to arrhythmias as hypokalemia develops toward the end of a typical treatment. The risk of arrhythmias is also increased in the early stages of a dialysis session, when the plasma potassium concentration may still be normal but rapidly declining.[146] The sudden reduction in the plasma potassium concentration during the initial portions of the dialysis procedure has recently been shown to unfavorably alter the QTc (a marker of risk of ventricular arrhythmias) even in dialysis patients without obvious heart disease.[36,112] Patients who have suffered a cardiac arrest in the dialysis unit are more likely to have been dialyzed against a 0- or 1.0-mEq/liter potassium dialysate compared to patients without this complication.[85]

With these considerations in mind, Redaelli et al. have studied the effects of modeling the dialysate potassium concentration in such a way as to minimize the initial rapid decline in the plasma potassium concentration.[148] Patients with frequent intradialytic premature ventricular complexes were dialyzed using a dialysate with a fixed (2.5 mEq/liter) potassium level or one with an exponentially declining potassium level (from 3.9 to 2.5 mEq/liter) that maintained a constant blood-to-dialysate potassium gradient of 1.5 mEq/liter throughout the procedure. In the fixed dialysate group, the blood-to-dialysate potassium gradient decreased over the treatment from 3.0 /liter to 1.4 mEq/liter. The variable potassium dialysate decreased premature ventricular complexes—a finding most evident during the first hour of the procedure. The total drop in the serum potassium concentration was no different between the fixed and variable potassium dialysate groups.

In addition to decreasing arrhythmias, maintenance of a constant blood-to-dialysate potassium concentration may prove useful in patients who tend to develop worsening hypertension during the course of the dialysis procedure. Hypokalemia increases resistance in skeletal muscle, skin, and coronary vascular beds—possibly through effects on the electrogenic Na-K pump in the sarcolemmal membranes of vascular smooth muscle cells.[22] In addition, decreased serum potassium concentration may enhance the sensitivity of the vasculature to endogenous presser hormones.[105] In chronic dialysis patients, postdialysis rebound hypertension is greater with a 1.0-mEq/liter than with a 3.0-mEq/liter potassium dialysate.[46] Although not yet studied, preventing the initial rapid decline in the plasma potassium concentration with a ramped dialysate potassium may help attenuate the hypertensive response some patients exhibit toward the end of a dialysis treatment.

In summary, due to the kinetics of potassium movement from the intra- to the extra-cellular space one can expect only up to 70−90 mEq of potassium to be removed during a typical dialysis session. As a result, one should not overestimate the effectiveness of the dialytic procedure in the treatment of severe hyperkalemia. The total amount removed will exhibit considerable variability and will be influenced by changes in acid−base status, changes in tonicity, changes in glucose and insulin concentration, and catecholamine activity. Given the tendency for the plasma potassium to rise in the immediate postdialysis time period, the most efficient way of removing excess potassium stores would be to prescribe two- to three-hour periods of dialysis separated by several hours.

Studies examining the hemodynamic effect of potassium fluxes during hemodialysis are limited. More importantly, deliberate alterations in dialysate potassium concentration to effect hemodynamic stability would not be without risk. Use of low-potassium dialysate concentration may contribute to arrhythmias, especially in those patients with underlying coronary artery disease or those taking digoxin. On the other hand, use of dialysate with high potassium concentration may predispose patients to pre-dialysis hyperkalemia. In patients at high risk for arrhythmias on dialysis, modeling the dialysate potassium concentration so as to maintain a constant blood-to-dialysate potassium gradient throughout the procedure may be of clinical benefit.

Peritoneal Dialysis

Potassium is cleared by peritoneal dialysis at a rate similar to that of urea. With continuous ambulatory peritoneal dialysis (CAPD) and 10 liters of drainage per day, approximately 35−46 mEq of potassium is removed per day. Daily potassium intake is usually greater than this amount, and yet significant hyperkalemia is uncommon in these patients. Presumably, potassium balance is maintained by increased colonic secretion of potassium and by some residual renal excretion. Given these considerations, potassium is not routinely added to the dialysate.

Maximal removal of potassium with peritoneal dialysis is approximately 10 mEq/hr even in the setting of severe hyperkalemia.[24] It should be noted that removal rates with Kayexalate enemas far exceed this value and may approach 30 mEq/hr. In patients undergoing frequent exchanges, hypokalemia may develop. In these instances, potassium can be added to the dialysate to achieve a final concentration of 2−3 mEq/liter. This is particularly important in patients receiving digoxin because the development of hypokalemia can precipitate arrhythmias.

CLINICAL DISORDERS OF POTASSIUM IN THE DIALYSIS PATIENT

Hypokalemia

In the hemodialysis patient hypokalemia can be a sign of poor oral intake and severe malnourishment. On occasion hypokalemia can result from K^+ binding in the gastrointestinal tract. Although not a dialysis patient, a serum K^+ concentration of 0.9 mmol/L was found in a three year old girl following several days of oral and rectal administration of bentonite given as a home remedy for the treatment of constipation.[16] Bentonite, also called montmorillonite or fuller's earth, is a type of clay primarily composed of hydrated aluminum silicate. Clay eating (geophagia) can be a manifestation of pica and has been reported to cause hypokalemic paralysis during pregnancy and in the postpartum period.[178,179] Clay eating is also practiced by some dialysis patients and should be considered in the setting of unexplained hypokalemia.

Cation exchange resins are frequently used to manage hyperkalemia in patients with chronic kidney disease. Abuse of these resins can result in hypokalemia, hypomagnesemia, and occasionally metabolic alkalosis.[27] The most commonly used resin is sodium polystyrene sulfonate but calcium polystyrene sulfonate is also available. Following the oral administration of these drugs sodium or calcium is released from the resin in exchange for hydrogen H^+ in the gastric juice. As the resin passes through the rest of the gastrointestinal tract H^+ is exchanged for other cations such as potassium which is present in greater quantities particularly in the colon. The affinity of different cations for these resins is as follows: $Ca^+ > Mg^+ > K^+ > Na^+ >$ and H^+. In addition to differences in affinity and concentration, cation binding to the resin is influenced by duration of exposure primarily dictated by gut transit time.

The primary complication of using sodium polystyrene sulfonate is the development of sodium overload. The absorption of liberated sodium from the resin can lead to hypertension, congestive heart failure, and occasionally hypernatremia. Since the resin also binds divalent cations, hypomagnesemia and hypocalcemia can also develop when using this agent. Decreased plasma levels of magnesium and calcium are more likely to occur in patients taking diuretics or those with poor nutrition. Use of the resin can also lead to metabolic alkalosis when administered with antacids or phosphate binders such as magnesium hydroxide or calcium carbonate. As magnesium and calcium binds to the resin, the base is free to be absorbed into the systemic circulation. Chronic use of the resin can also be associated with small and large bowel ulcerations.

Hyperkalemia

Inadequate dialysis is an important consideration in the workup of hyperkalemia. Frequently missed treatments or shortening of the treatment time on a repetitive basis are frequent causes. In patients who are deemed to be otherwise compliant, one should consider recirculation within the vascular access as a potential cause of the disorder.

Dietary indiscretion is one of the most common reasons for hyperkalemia in the dialysis patient. In the presence of normal renal and adrenal function it is difficult to ingest sufficient K^+ in the diet to produce hyperkalemia. Rather, dietary intake of K^+ as a contributor to hyperkalemia is usually observed in the setting of impaired kidney function. Dietary sources particularly enriched with K^+ include melons, citrus juice, and commercial salt substitutes containing potassium (reviewed in Ref.[133]). Other hidden sources of K^+ reported to cause life threatening hyperkalemia include raw coconut juice (K^+ concentration of 44.3 mmol/L) and Noni juice.[6,7] While clay ingestion can cause hypokalemia due to binding in the gastrointestinal tract, river bed clay is K^+ enriched (100 mEq K^+ in 100 gm clay) and can cause life threatening hyperkalemia in chronic kidney disease patients. Ingestion of burnt match heads (cautopyreiophagia) can also be a hidden source of K^+. This activity was found to add an additional 80 mmol of K^+ to one dialysis patient's daily intake and produced a plasma K^+ concentration of 8 mmol/liter.

Hyperkalemia can also occur as an iatrogenic complication in the hospital setting. A 16-day-old infant with newly diagnosed maple syrup urine disease was placed on continuous venovenous hemofiltration to treat markedly elevated levels of leucine, isoleucine, and valine.[13] To treat a decrease in serum K^+, a 10 ml vial containing 20 mEq KCl was injected into a 5 liter bag of replacement fluid. Within four minutes, ventricular premature beats developed that rapidly deteriorated into ventricular fibrillation. The serum K^+ concentration was 9.6 mEq/l. The rapid development of hyperkalemia was attributed to injecting the KCl into the dependent portion of the hanging 5-liter bag though a port immediately adjacent to the exit port. As a result of poor mixing, the concentrated KCl was immediately delivered into the patient, resulting in life-threatening hyperkalemia.

Severe hemolysis can produce an endogenous K^+ load sufficient to cause hyperkalemia, particularly in the setting of impaired renal function. A chronic dialysis patient with a prosthetic aortic valve developed severe hemolysis and hyperkalemia, following the abrupt onset of atrioventricular nodal reentrant tachycardia.[136] The hemolysis and release of K^+ was attributed to fragmentation of red blood cells by the

prosthetic value due to the hemodynamic turbulence brought on by the arrhythmia.

Blood transfusions can be a contributing factor in the development of hyperkalemia. The risk of transfusion-associated hyperkalemia is related to not only the number of red blood cell transfusions but also the rapidity in which the units are given. Concomitant conditions such as low cardiac output, metabolic acidosis, hypocalcemia, hyperglycemia, and hypothermia increase this risk.[167]

Whole blood and PRBC are stored in anticoagulant preservative solution and have a shelf-life of approximately 35 d. The duration of storage can be extended to 42 d through the addition of an additive solution which contains varying concentrations of adenine, dextrose, and other substances.[12] During storage, K^+ leaks into the supernatant due to aging of red blood cell membranes and decreased synthesis of adenosine triphosphate. The magnitude of this leak increases with duration of storage.

Irradiation of blood to inactivate T-lymphocytes and minimize the risk of graft-versus-host disease enhances K^+ leakage from red cells due to subtle membrane injury. Depending on the conditions, the supernatant of stored red blood cell units may contain more than 60 mEq/l of K^+. If fresh PRBCs are unavailable, the risk of post transfusion hyperkalemia can be minimized by washing the cells and decreasing the amount of additive solution. These maneuvers are of particular use in neonatal patients undergoing surgery for congenital heart disease who require irradiated blood due to the concomitant presence of cell-mediated immunodeficiency disorders.[176]

Renin-angiotensin system blockers are frequently used to treat hypertension in patients with end-stage renal disease. Hyperkalemia is a potential concern with these drugs even in the functionally anephric patient to the extent that aldosterone levels fall and colonic K^+ excretion decreases. Indeed, a small number of patients undergoing dialysis have been described who developed hyperkalemia in association with ACEI and ARB therapy. By contrast, this complication did not occur in a prospective crossover study of 69 maintenance hemodialysis patients treated with either ACEI or ARB therapy alone or in combination.[68]

Acid–Base

During the course of advancing renal failure, the ability of the kidney to regenerate consumed bicarbonate becomes progressively impaired. As a result, daily acid production leads to a fall in serum bicarbonate concentration. In the long term, the serum bicarbonate concentration eventually stabilizes despite continuing positive acid balance. A stable, though low, serum bicarbonate concentration is maintained at the expense of other buffer stores such as bone bicarbonate. The goal of dialysis in acid–base balance is to transfer sufficient base to the patient to neutralize metabolic acid production and thus correct the metabolic acidosis and prevent depletion of body buffer stores. Base transfer across the dialysis membrane has been achieved using bicarbonate- or acetate-containing dialysate.

Hemodialysis

The early use of bicarbonate as the base in dialysis solutions required a cumbersome system in which CO_2 was continuously bubbled through the dialysate to lower pH in order to prevent the precipitation of calcium and magnesium salts. As a result, in the 1960s acetate became the standard dialysate buffer used to correct uremic acidosis and to offset the diffusive losses of bicarbonate during hemodialysis.

Acetate was an effective buffer in dialysis patients because it is metabolized to bicarbonate primarily in muscle and liver. However, over the next several years reports began to accumulate linking routine use of acetate with cardiovascular instability and hypotension during dialysis. This intolerance to acetate was found to be particularly common in patients with decreased muscle mass where acetate influx would be expected to exceed the capability of converting acetate to bicarbonate.[186] In particular, critically ill patients undergoing acute hemodialysis (especially with the use of large surface area dialyzers) were found to exhibit vascular instability when exposed to acetate in dialysis fluid. Acetate intolerance became more of an issue with the introduction of high-efficiency dialyzers in the 1980s. In this setting, accumulation of acetate was associated with nausea, vomiting, fatigue, decreased myocardial contractility, peripheral vasodilation, and arterial hypoxemia. A more detailed discussion of acetate dialysate is available in the third edition of this book and elsewhere[134] (Table 93.4).

Given these observations, bicarbonate-containing dialysate began to reemerge as the principal dialysate buffer—especially as advances in biotechnology made the use of bicarbonate dialysate less expensive and less cumbersome to use. Producing bicarbonate dialysate requires a specifically designed system that mixes a bicarbonate concentrate and an acid concentrate with purified water. The acid concentrate contains a small amount of either lactic or acetic acid, and all the calcium and magnesium. The exclusion of these cations from the bicarbonate concentrate prevents the precipitation of magnesium and calcium carbonate that would otherwise occur in the setting of a high-bicarbonate

TABLE 93.4 Mechanisms by which Acetate Buffer Contributes to Hemodynamic Instability

Directly decreases peripheral vascular resistance (in approximately 10% of patients)
• Stimulates release of the vasodilator compound, interleuken 1
• Induction of metabolic acidosis via bicarbonate loss through the dialyzer
• Associated with arterial hypoxemia and increases in oxygen consumption
• ? Myocardial effects of acetate

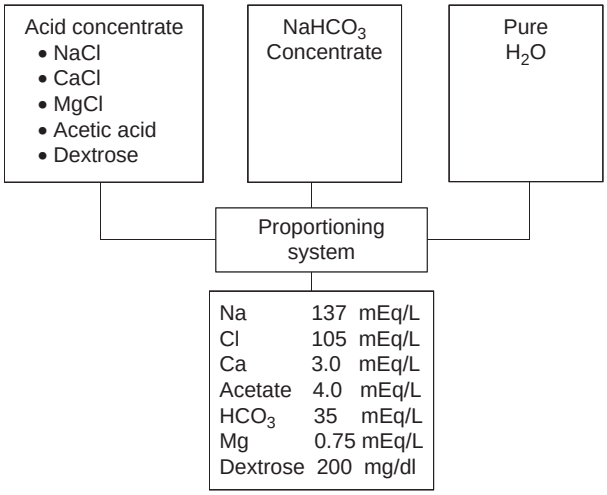

FIGURE 93.2 Use of a bicarbonate dialysate requires a proportioning system that mixes a bicarbonate concentrate with an acid concentrate and purified water. Calcium and magnesium are kept separate from the bicarbonate concentrate to prevent precipitation.

concentration. During the mixing procedure, the acid in the acid concentrate will react with an equimolar amount of bicarbonate to generate carbonic acid and carbon dioxide. The generation of carbon dioxide causes the pH of the final solution to fall to approximately 7.0–7.4. This more acidic pH, as well as the lower concentrations of calcium and magnesium in the final mixture, allows for these ions to remain in solution. The final concentration of bicarbonate in the dialysate is generally fixed in the range of 33–38 mmol/liter (Figure 93.2).

The use of a bicarbonate dialysate is associated with a number of potential complications.[103,184] The liquid bicarbonate concentrate can be responsible for microbial contamination of the final dialysate, largely because the bicarbonate concentrate is an excellent bacterial growth medium. This complication can be minimized by short storage time and by filtration of the concentrate during the production procedure. Use of a bicarbonate cartridge can further minimize this complication. This device allows for the bicarbonate concentrate to be produced on-line by passing water through a column containing powdered bicarbonate. The concentrate is produced and proportioned immediately before mixing with the acid concentrate. Hypoxemia may occur during bicarbonate dialysis when high concentrations of bicarbonate are used. This complication appears to be the result of suppressed ventilation secondary to the increase in pH and serum bicarbonate concentration. In addition, excessively high levels of bicarbonate in the dialysate may result in acute metabolic alkalosis—causing mental confusion, lethargy, weakness, and cramps.

The factors that determine bicarbonate requirements in hemodialysis patients include acid production during the interdialytic period, the removal of organic anions during the hemodialysis procedure, and the buffer deficit of the body. Because these factors are likely to vary from patient to patient, there is increasing interest in individualizing the dialysate bicarbonate concentration. The optimal level of dialysate bicarbonate would be a concentration low enough to prevent significant alkalosis in the postdialytic period and yet high enough to prevent predialysis acidosis.[6,11] The need for individualization is highlighted in data from the first 1000 patients randomized in the HEMO study (Hemodialysis Study Group).[180] Using a set dialysate bicarbonate concentration of 35 mEq/liter, the mean pre-dialysis plasma bicarbonate concentration was 21.6 mEq/liter. However, in 25% of patients the predialysis bicarbonate concentration was less than 19 mEq/liter.

Maintaining a pre-dialysis total CO2 concentration greater than 23 mmol/liter can be achieved in most patients by individually adjusting the dialysate bicarbonate concentration. Oettinger et al. found that 75% of patients exceeded this level with a dialysate bicarbonate concentration of 42 mmol/liter.[130] Use of this high-bicarbonate dialysate did not result in progressive alkalemia, even in patients beginning the study with a normal predialysis total CO_2 using a standard bicarbonate dialysate concentration of 36 mmol/liter. In addition, the high-bicarbonate dialysate did not cause hypoxia or hypercarbia or alter the pre-dialysis calcium, ionized calcium, or phosphorus.

Using high-bicarbonate dialysate may improve nutrition and bone metabolism.[131] Graham et al. examined protein turnover in a group of chronic dialysis patients in whom dialysate bicarbonate concentration was increased from 35 to 40 mmol/liter. Supplemental oral bicarbonate therapy was given to two patients whose predialysis tCO_2 concentration did not exceed 23 mmol/liter.[63] The mean tCO_2 concentration increased from 18.5 to 24.8 mmol/liter during the high-bicarbonate dialysate. Correction of the acidosis was

associated with a significant decrease in protein degradation, as suggested by leucine kinetic studies. In a similarly designed study, these investigators found an increase in the sensitivity of the parathyroid glands to calcium in patients using a dialysate bicarbonate concentration of 35–40 mmol/liter.[64]

Another strategy that may be effective in improving the acidosis of chronic dialysis patients is to use citric acid in place of acetic acid in the acid concentrate. In a recent study of 22 patients, use of citric acid decreased the number of patients with a pre-dialysis bicarbonate concentration less than 23 mEq/liter from 14 to 7.[2] Use of the citric acid dialysate was also associated with an increased delivered dose of dialysis, an effect postulated to be due to improved membrane permeability resulting from citrate's local anticoagulant effect. Improved membrane permeability with greater diffusive flux of bicarbonate from dialysate to blood or metabolism of citrate to bicarbonate in liver and muscle are the most likely explanations for the improvement in bicarbonate concentration.

The bicarbonate concentration used in most dialysis centers is set at 35 mmol/liter and is rarely adjusted. Given the increasing evidence that correction of chronic acidosis is of clinical benefit, clinical practice guidelines now recommend that the midweek predialysis plasma bicarbonate level be no less than 22 mmol/liter. In addition to increasing the dialysate bicarbonate concentration, supplemental oral bicarbonate therapy will be required in some patients to achieve this goal. Substitution of citric acid for acetic acid in the acid concentrate is a maneuver worthy of further investigation.

Prospective and retrospective studies have demonstrated that use of sevelamer hydrochloride is associated with significantly lower predialysis total CO_2 as compared to calcium containing phosphate binders.[143,170] Some of this difference may be the effect of decreased intake of potential alkali (calcium acetate or carbonate) in patients prescribed sevelamer. However the chemical structure and mechanism of action of sevelamer suggests the drug may directly lead to an acid load to the patient.[23,194] For this reason close attention should be paid to changes in total CO_2 following the prescription of sevelamer. In some patients supplemental bicarbonate may be required to keep total CO_2 at goal. In a study of 20 hemodialysis patients raising the dialysate bicarbonate concentration to 40 mEq/L was effective in correcting both acidosis and hyperkalemia over a 24 month period despite the ongoing use of this non-calcium containing phosphate binder.[126] To overcome this adverse effect on acid-base balance sevelamer is now produced and marketed as sevelamer carbonate.[14] This form of the drug does not adversely affect the serum bicarbonate concentration.

Peritoneal Dialysis

The buffer present in most commercially available peritoneal dialysate solutions is lactate. In patients with normal hepatic function, lactate is rapidly converted to bicarbonate such that each mM of lactate absorbed generates 1 mM of bicarbonate. Even with the most vigorous peritoneal dialysis, there is no appreciable accumulation of circulating lactate.[151] The rapid metabolism of lactate to bicarbonate maintains the high dialysate-to-plasma lactate gradient necessary for continued absorption. This absorption may be somewhat less with use of dialysate containing higher concentrations of dextrose. Under these conditions, increased ultrafiltrate formation may dilute the concentration of lactate in the peritoneal cavity and therefore decrease the concentration gradient for diffusion. Lactate is normally provided as a racemic mixture of the dextro and levo isomers in approximately equal concentrations. There is some evidence that the natural isomer (L-lactate) is more rapidly absorbed than the D-isomer (D-lactate).[151]

The pH of commercially available peritoneal dialysis solutions is purposely made acidic by adding hydrochloric acid in order to prevent dextrose caramelization during the sterilization procedure. Once instilled into the abdomen, the pH of the solution rises to values greater than 7.0. The acidic nature and buffer composition of currently available solutions further contributes to the bioincompatibility of peritoneal dialysate.[31,53]

To address this issue, neutral pH solutions buffered with bicarbonate or with a mixture of bicarbonate and lactate have been introduced into clinical practice.[61] Until recently, bicarbonate was not able to be used as the buffer in peritoneal dialysis solutions because calcium and magnesium would precipitate in the presence of bicarbonate in the setting of an alkaline pH. Omitting magnesium and calcium from the dialysate was not an option because patients undergoing chronic peritoneal dialysis would develop deficits of these divalent cations. These limitations have largely been overcome by the development of a two-chamber dialysate bag in which one chamber contains the bicarbonate or buffer and the other contains a solution with calcium and magnesium. The system is designed so that the two solutions are mixed just prior to entering the patient, thus avoiding the problem of precipitation. In addition to having a neutral pH, there are fewer glucose degradation products because the bicarbonate is sterilized separately from the other components of the solution.

In a recent randomized trial of 106 patients, a pH-neutral bicarbonate-/lactate-based peritoneal dialysis solution was compared to the conventional acidic lactate buffered solution in which markers of peritoneal membrane integrity and inflammation were

examined.[82,83] At the end of 6 months, patients treated with the pH-neutral solution had a significantly greater increase in dialysate CA 125 (a marker of viability and cell mass of the mesothelium). The same group also had a significantly greater decrease in dialysate hyaluronan (a marker of inflammation in the peritoneal cavity). The pH-neutral solution is associated with less inflow pain, and no adverse effect has been demonstrated on peritoneal transport.[82,83] Use of the pH-neutral solution has also been shown to result in long-term improvement in peritoneal macrophage function compared to conventional solutions.[83] Similar benefits have been found with this solution in patients receiving automated forms of peritoneal dialysis.[59]

The dual-chamber bag has also been used to separate glucose from the other solution components. The advantage of this setup is that glucose can be sterilized at a much lower pH compared to a single chamber bag and as a result the formation of glucose degradation products is markedly reduced. Mixing of the two components at the time of abdominal installation effectively raises the pH. The application of this solution has been studied in a randomized trial of 80 patients.[149] Compared to conventional treatment, patients treated with the study solution had significantly greater dialysate CA 125 and significantly lower dialysate hyaluronan. Over a 24-month follow-up there were no adverse effects on parameters of peritoneal transport (Table 93.5).

Metabolic Alkalosis

The discussion to this point has focused on the development and treatment of metabolic acidosis in patients with end-stage renal disease. These patients are also prone to the development of metabolic alkalosis due to an inability to excrete alkaline loads. Even in patients with mild reductions in renal function exogenous administration of bicarbonate can lead to metabolic alkalosis due to decreased bicarbonate clearance. Decreased renal function is a critical event in the pathogenesis of milk-alkali syndrome. In this syndrome consumption of large quantities of milk and calcium containing antacids result in hypercalcemia and metabolic alkalosis.[8] Self-administration of large quantities of antacids containing $NaHCO_3$ can occur as a manifestation of pica during pregnancy or for self-treatment of abdominal pain.[6,7] Volume depletion or renal insufficiency increases the risk of severe metabolic alkalosis in this setting.

A moderate degree of metabolic alkalosis may be present post-dialysis, and more so with bicarbonate-buffered dialysate and especially if the concentration of the bicarbonate buffer exceeds 35 mEq/liter. End-stage renal disease patients are more susceptible to alkalosis developing as a consequence by vomiting or nasogastric suction. Excessive consumption of oral bicarbonate (a teaspoon of baking soda contains 40 mm of bicarbonate) is not an infrequent cause of metabolic alkalosis among the dialysis population.

Extensive use of crack cocaine has been implicated as a cause of metabolic alkalosis in a dialysis patient.[44] Cocaine hydrochloride is the salt form of the drug. This form is not suitable for smoking because the temperature at which it vaporizes is very close to the temperature at which it burns. By contrast, cocaine base "free base" vaporizes at a low temperature making it more suitable for smoking. Free base is made by dissolving cocaine hydrochloride in water and then adding an alkali. In this patient, the source of the alkali was "Draino" which contains NaOH. The chemical reaction produces a precipitate composed of three components: (1) excess NaOH, (2) a white powder often referred to as "the cut" containing talc or baking soda added to increase the weight and thus the street value of the preparation and (3) the free base cocaine. On two separate occasions following extensive crack cocaine use this patient developed a serum bicarbonate concentration of >40 mEq/L. Presumably the cocaine preparation contained a considerable quantity of base and the alkali load was unable to be excreted to the presence of renal failure.

Net gain of HCO_3^- can occur in the setting of massive transfusion due to administration of citrate found in packed red blood cells. A similar situation can complicate plasmapheresis when citrate containing fresh frozen plasma is used as a replacement fluid.[111,121,123,137] The use of citrate for the purpose of regional anticoagulation in patients undergoing

TABLE 93.5 Advantages and Disadvantages of new Peritoneal Dialysis Solutions

Solution	Advantage	Disadvantage
Icodextran	Sustained ultrafiltration in overnight dwell in CAPD, long dwell in APD, and during peritonitis, avoids effects of glucose absorption, iso-osmotic	Skin reactions (<10%), maltose accumulation
Amino acids	Improves malnutrition	Azotemia and metabolic acidosis
Bicarbonate and bicarbonate/lactate buffer	Improved biocompatibility due to neutral pH, ↓ glucose degradation products	Two chamber bags to separate Ca and Mg from bicarbonate
Glucose sterilized separately at lower pH	Improved biocompatibility, ↓ glucose degradation products	Two chamber bag required

continuous renal replacement therapy can cause metabolic alkalosis.[30,42,88] Citrate is rapidly metabolized to bicarbonate by the liver and skeletal muscle. The risk for alkalosis during citrate regional anticoagulation can be lowered by using anticoagulant citrate dextrose formula A (ACD-A) because this formulation produces 33% less bicarbonate in comparison to hypertonic trisodium citrate.

In the absence of renal function, no route exists for elimination of extra bicarbonate. A bicarbonate dialysate can be fashioned with a lower than normal amount of buffer so that the serum bicarbonate may be decreased.[60] An acetate-buffered dialysate may also be used. In this situation, the larger than normal bicarbonate transmembrane gradient will favor increased loss of buffer and (because the rate of acetate metabolism is already near maximal) the net effect should be a decrease in plasma bicarbonate. If the patient is not overly symptomatic or having respiratory or cardiovascular compromise, one may simply choose to wait for normal endogenous acid production to titrate the excessive amount of bicarbonate.

Conversely, if cardiopulmonary function is compromised an intravenous infusion of hydrochloric acid can be given. In general, HCl can be safely administered as a 0.15-0.25 normal solution in normal saline or D5W given through a central line. Due to the sclerosing properties of HCl, it is imperative that the position of the central line in the superior vena cava be verified by chest x-ray prior to initiating infusion. Infusion rates should be no more than 0.2 mmol per kilogram of body weight per hour. One should use a bicarbonate space of 50% of ideal body weight when calculating the amount of HCl to be given. As an example, to reduce the plasma bicarbonate from 50 to 40 mmol/L in a 70 kilogram patient the amount of HCl required is 350 mmol ($10 \times 70 \times 0.5$). If the physician wishes, the HCl can be added to an amino acid solution in TPN and given centrally.

If patients are not ill enough to warrant the risk of central venous catheterization and the infusion of intravenous hydrochloric acid, they probably do not need their alkalosis corrected acutely. Administration of ammonium chloride is not recommended because the ammonium will tend to increase urea nitrogen levels. Arginine chloride is not recommended because of the possibility of inducing hyperkalemia.[25]

CALCIUM

Hemodialysis

During the course of advancing chronic kidney disease, there is a tendency for patients to develop hypocalcemia. The pathophysiology is multifactorial and includes increased tissue deposition due to phosphate retention and the resultant increase in the calcium-phosphate solubility product. Decreased circulating levels of $1,25(OH)_2$ vitamin D lead to decreased absorption of calcium from the gastrointestinal tract. In addition, low vitamin D levels as well as hyperphosphatemia impair the ability of parathyroid hormone to mobilize calcium from bone. Finally, patients with chronic kidney disease are prescribed phosphate-restricted diets that by necessity are also low in calcium.

In the setting of chronic kidney disease, more than 60% of plasma calcium is not protein bound and is subject to forces leading to movement across the dialysis membrane. Calcium diffusion into the body can either be positive or negative, depending on the concentration gradient established across the membrane. The net flux of calcium is also influenced by a component of convective loss that occurs during ultrafiltration. Given these considerations, the goal of dialytic therapy for many years was to choose a dialysate calcium concentration that would result in a net flux of calcium into the patient. A dialysate calcium concentration of 3.5 mEq/liter (1.75 mmol/liter) became relatively standard because this concentration usually prevented intradialytic calcium losses.

Raising the dialysate calcium concentration has been associated with beneficial effects on indices of metabolic bone disease. Wing showed that raising the dialysate concentration of calcium from 2.5 to 3 mEq/liter arrested the biochemical and radiographic changes of hyperparathyroidism.[192] Metacarpal bone thickness was found to be stable with use of a dialysate calcium concentration of 3.5 mEq/liter, whereas thickness declined over time in patients dialyzed with a 2.5-mEq/liter calcium bath. Use of a high-dialysate calcium concentration has also been shown to reduce parathyroid hormone levels to a greater extent than does a low-calcium dialysate. As discussed in more detail in material following, use of vitamin D analogues has largely supplanted upward adjustments in the dialysate calcium concentration for purposes of treating secondary hyperparathyroidism. However, this strategy may be useful in carefully selected patients.[69]

A limitation of using higher dialysate calcium concentrations is the development of hypercalcemia. This complication has become more common with the widespread use of calcium-containing phosphate binders as a substitute for aluminum and the wider use of high doses of intravenous $1,25(OH)_2$ vitamin D to treat secondary hyperparathyroidism. As a result, the typical dialysate calcium concentration has generally fallen from that used several years ago.

Using a dialysate calcium concentration of 2.5 mEq/liter, Slatapolsky et al. were able to control the serum phosphorus in 21 patients with calcium carbonate at an average daily dose of 10.5 g with no instances of hypercalcemia.[165] In an earlier study utilizing a dialysate calcium concentration of 3.5 mEq/liter, large doses of calcium carbonate were also effective in controlling the serum phosphorus—but only at the expense of several instances of hypercalcemia.[166] The beneficial effect of combining high-dose calcium-containing phosphate binders with a low dialysate calcium concentration has been confirmed by other investigators.[157] In a similar manner, Van der Merwe et al. treated patients with secondary hyperparathyroidism with high-dose oral calcitriol combined with a low-calcium dialysate concentration.[182] During the course of the study, there was a significant fall in the parathyroid hormone level and alkaline phosphatase concentration without the development of hypercalcemia.

Despite the enthusiasm for use of low-calcium dialysate, some recent studies have emphasized that such an approach requires careful monitoring to ensure that the patient does not develop negative calcium balance or worsening secondary hyperparathyroidism.[177] Argiles et al. found that serum immunoreactive parathyroid hormone (iPTH) levels increased significantly in patients treated with a 2.5-mEq/liter dialysate calcium bath compared to a control group of patients dialyzed with dialysate calcium of 3.0 mEq/liter.[8] This increase in iPTH occurred despite 2.4-fold more oral $CaCO_3$ ingested in the low-dialysate calcium group. Although the increase in oral calcium intake was not sufficient to prevent the stimulation in iPTH, subsequent treatment with 1,25 $(OH)_2$ vitamin D was effective in reversing the rise in iPTH levels.

Similar results were reported by Fernandez et al. in a group of patients sequentially dialyzed against a 3.5-/liter and then a 2.5-mEq/liter Ca bath.[54] While on the low-calcium dialysate, there was a significant increase in serum iPTH and serum alkaline phosphatase levels. These changes occurred despite the fact that oral calcium carbonate was administered at doses ranging from 3 to 6 g/day while on the low-calcium dialysate. As determined by clearance studies, the authors suggested that the low-calcium dialysate resulted in negative calcium balance—which in turn contributed to the worsening hyperparathyroidism. Furthermore, the maintenance of a normal serum calcium concentration noted in the study occurred at the expense of PTH-induced calcium mobilization from bone. Utilizing measurements of total and ionized calcium in serum and in spent dialysate, Argiles et al. have confirmed that a 2.5-mEq/liter calcium dialysate is associated with negative calcium balance.[10] Based on the potential of a 2.5-mEq/liter dialysate calcium to cause negative calcium balance and to worsen secondary hyperparathyroidism, these authors now utilize a dialysate calcium of at least 3.0 mEq/liter in the majority of chronic dialysis patients.[9]

In addition to effects on metabolic bone disease, varying the dialysate calcium concentration can affect hemodynamic stability during dialysis. Maynard et al. studied 12 patients in a prospective crossover trial and found that a high dialysate calcium concentration (3.75 mEq/liter) was associated with significantly less fall in systolic blood pressure and in mean arterial pressure than a low-calcium dialysate (2.75 mEq/liter).[117] In a double-blind prospective study, Sherman et al. studied 20 patients who underwent alternate hemodialysis with dialysate calcium concentrations of 2.5 and 3.5 mEq/liter.[160] The use of a low dialysate calcium concentration was associated with a minor but statistically significant reduction in mean blood pressure during hemodialysis. This effect may become clinically important in patients with congestive heart failure. One study found that a 3.5 mEq/liter Ca dialysate offered clear hemodynamic benefits over a 2.5-mEq/liter dialysate in patients with an ejection fraction less than 40%.[183]

In patients prone to intradialytic hypotension who are at risk for hypercalcemia, dialysate calcium profiling can be utilized as a strategy to improve hemodynamic stability and yet minimize the potential for hypercalcemia.[99] In one study, patients were dialyzed for 4 hours in which the dialysate calcium concentration was set low (1.25 mmol/liter) for the first two hours and then increased to 1.75 mmol/liter for the last two hours.[99] Use of the varying dialysate calcium concentration was associated with greater hemodynamic stability compared to a fixed dialysate calcium concentration of either 1.25 or 1.5 mmol/liter. This hemodynamic benefit was accomplished via an increase in cardiac output. At the end of three weeks, there was no difference in the pre-dialysis ionized calcium concentration among the three groups.

Changes in serum calcium concentration may influence blood pressure through alterations in either systemic vascular resistance or the determinants of cardiac output, or both. In an attempt to determine the physiologic mechanisms for calcium-induced changes in systemic arterial pressure, Fellner et al. studied hemodynamic variables that determine arterial blood pressure as a function of changes in dialysate calcium concentration.[52] Eight patients underwent hemodialysis three times within a single week with dialysate calcium concentrations of 1.0, 3.5, or 5.0 mEq/liter. As in previous studies, changes in blood calcium concentration correlated directly with blood pressure. In addition, higher levels of calcium augmented left ventricular stroke volume and cardiac

output while leaving total vascular resistance unchanged. It was concluded that alterations in blood calcium concentration affected blood pressure primarily through changes in left ventricular output rather than in peripheral vascular tone.

In addition to changes in ionized calcium concentration, hemodialysis leads to alterations in several factors that could conceivably be responsible for the observed changes in ventricular function. Henrich et al.[76] performed a series of dialysis maneuvers to determine the contribution of dialyzable toxins, ionized calcium, and acidemia to left ventricular performance during routine hemodialysis. The dialysate of each maneuver was adjusted to produce three effects: isovolemic dialysis in which neither ionized calcium nor bicarbonate was allowed to increase (this procedure tested the effects of uremic toxin removal), isovolemic dialysis during which ionized calcium increased but bicarbonate was held constant, and isovolemic dialysis in which bicarbonate increased but ionized calcium was kept constant.

Echocardiographic studies showed that left ventricular end-diastolic and end-systolic volumes decreased and ejection fraction and velocity of circumferential shortening increased only in the procedure in which plasma-ionized calcium increased. This study suggested that the rise in ionized calcium is a major element in the observed improvement in myocardial contractility. Similar findings were recently reported by Lang et al.[101] Using dialysates differing only in calcium concentration, myocardial contractility was shown to correlate directly with plasma ionized calcium. The mechanism by which increases in ionized calcium seen during hemodialysis led to enhanced ventricular function is not known.

In summary, the dialysate calcium concentration has implications with regard to metabolic bone disease and hemodynamic stability. As with the other dialysate constituents, the calcium concentration should be individually tailored to the patient[106] (Table 93.6). In patients prone to intradialytic hypotension, avoidance of a low dialysate calcium concentration may be of benefit. On the other hand, the use of a lower calcium concentration in the dialysate will allow the use of increased doses of calcium-containing phosphate binders and will lessen any dependence on aluminum-containing binders. In addition, use of 1,25 $(OH)_2$ vitamin D can be liberalized so as to reduce circulating

TABLE 93.6 Considerations when Individualizing Components of the Dialysate

Dialysate component	Advantage	Disadvantage
Na: Increased	More hemodynamic stability Less cramping	Dipsogenic effect, Increased interdialytic weight gain, ? chronic hypertension
Decreased (rarely used)	Less interdialytic weight gain	Intradialytic hypotension and cramping more common
Ca: Increased	Suppression of PTH, promotes hemodynamic stability	Hypercalcemia with Vitamin D and Ca containing phosphate binders
Decreased	Permits greater use of vitamin D and calcium containing phosphate binders	Potential for negative calcium balance, stimulation of PTH, slight decrease in hemodynamic stability
K: Increased	Less arrhythmias in setting of digoxin or coronary heart disease, Less rebound hypertension	Limited by hyperkalemia
Decreased (ramped dialysate K ideal, prevents rapid initial decline in plasma K)	Greater dietary intake of K with less hyperkalemia? improvement in myocardial contractility	Increased arrhythmias, may exacerbate autonomic insufficiency
HCO_3: Increased	Corrects chronic acidosis thereby benefits nutrition and bone metabolism	Post-dialysis metabolic alkalosis
Decreased	Less metabolic alkalosis	Potential for chronic acidosis
Mg: Increased	? Less arrhythmias ? Hemodynamic benefit	Hypermagnesemia
Decreased	Permits use of Mg containing phosphate binders	Hypomagnesemia
PO_4 (rarely added to dialysate)	Treats or prevents hypophosphatemia in malnourished, chronic disease state, overdose setting, daily dialysis	Hyperphosphatemia

levels of parathyroid hormone with less fear of inducing hypercalcemia. However, when using low dialysate calcium concentrations (< 3.0 mEq/liter) one needs to monitor patients closely to ensure that negative calcium balance does not develop and that iPTH levels remain in an acceptable range.[115,150] This latter issue will become increasingly important as calcium-free phosphate binders such as sevelamer and lanthanum are more frequently used.[29,43]

One other critical consideration in the discussion of dialysate calcium is the description of calcium loading as being a factor in the development and progression of vascular calcification.[126] To date there is no consensus guidelines for the integrated prescription of dietary calcium and phosphorus, choice of phosphate binders, vitamin D analogs, calcimimetics, and dialysate calcium in hemodialysis patients. The most recent Improving Global Outcomes (KDIGO) Clinical Practice Guideline suggests using a dialysate calcium concentration between 2.5 and 3.0 mEq/L (1.25 and 1.5 mmol/l).[48,62] The working group in making this recommendation felt this concentration would provide near-normal calcium balance for most patients. The pros and cons of this recommendation continue to be debated.[48,62] Further research is needed to define the optimal mix of dialysate calcium concentration, dose of vitamin D, amount of calcium and non calcium containing phosphate binder, and use of the calcimimetic agent cinacalcet.

Peritoneal Dialysis

To avoid negative calcium balance and to potentially suppress circulating parathyroid hormone, commercially available peritoneal dialysis solutions evolved to contain a calcium concentration of 3.5 mEq/liter (1.75 mmol/liter). This concentration is equal to or slightly greater than the ionized concentration in the serum of most patients. As a result, there is net calcium absorption in most patients when using a conventional dialysis regime such as $3 \times 1.5\%$ and $1 \times 4.5\%$ glucose solutions.[191] When ultrafiltration volume is high, as occurs with use of 4.25% dextrose concentration at high rates of exchange, net transfer of calcium can be reversed such that calcium balance becomes negative. In this setting, the convective flux of calcium exceeds the diffusive flux such that net calcium balance can become negative.[164]

As the use of calcium-containing phosphate binders has increased, hypercalcemia has become a common problem when utilizing the 3.5 mEq/liter calcium dialysate. This complication has been particularly common in patients treated with peritoneal dialysis because these patients have a much greater incidence of adynamic bone disease compared to hemodialysis patients.[162] In fact, the continual positive calcium balance associated with the 3.5 mEq/liter solution has been suggested as a contributing factor in the development of this lesion. The low bone turnover state typical of this disorder impairs the accrual of administered calcium, contributing to the development of hypercalcemia. As a result, there has been increased interest in using a strategy similar to that employed in hemodialysis; namely, lower the calcium content of the dialysate. This strategy can allow for increased usage of calcium-containing phosphate binders as well as more liberal use of 1,25 $(OH)_2$ vitamin D in order to effect decreases in the circulating level of parathyroid hormone. In this manner, the development of hypercalcemia can be minimized.

Several studies have confirmed that a stable serum calcium concentration can be maintained when using low-calcium dialysis solutions.[81,190] In a large randomized controlled multicenter trial, Weinreich et al. studied 103 stable CAPD patients in a comparison of 1.0 and 1.75 mmol/liter calcium solutions over six months.[190] Aluminum-containing binders were given in place of $CaCO_3$ in cases of hypercalcemia. In the low-calcium group, serum calcium levels were maintained within the normal range—with a threefold reduction in the incidence of hypercalcemia and significant reduction in the need for $Al(OH)_3$ compared to the conventional dialysate. One concern with use of a low-calcium dialysate is that parathyroid hormone levels might be stimulated. However, in this study PTH levels remained within the desired range. In addition, there was no radiologic evidence of renal osteodystrophy or demineralization of bones.

More recently, Johnson et al. reported data from a randomized prospective double-blind trial in 45 CAPD patients comparing treatment with 1.25 and 1.75 mmol/liter dialysate calcium over 12 months.[81] In this study, the low-calcium dialysate was associated with less hypercalcemia and at the same time permitted larger quantities of calcitriol and $CaCO_3$ to be prescribed. Increased use of these agents, however, may explain why use of $Al(OH)_3$ could not be reduced in the low-calcium group. Increased doses of calcitriol can preserve the need for $Al(OH)_3$ by increasing intestinal calcium absorption and thereby limiting the maximum dose of $CaCO_3$ that could be used, and by increasing phosphate absorption—thereby increasing the total dose of phosphate binders required for satisfactory phosphate control. In addition, PTH levels increased in the low-calcium group but returned toward baseline after the first six months of the study. Bone mineralization studies showed no differences between the two groups.

Sanchez et al. performed a one-year randomized multicenter study comparing the effects of a 1.25 versus a 1.75 mmol/liter calcium-containing solution on bone histology.[153] The patients assigned to the low-calcium solution had a greater increase in serum parathyroid hormone, but there was no differences noted in bone histology between the two groups.

In summary, peritoneal dialysis solutions are widely available with a calcium concentration of either 1.25 or 1.75 mmol/liter. The decision to use one concentration or the other should be made on an individual basis. The majority of patients can be treated with a dialysis solution that contains 1.75 mmol/liter calcium. On the other hand, a low dialysate calcium solution offers a valuable therapeutic option to treat patients with increased doses of calcium-containing phosphate binders and calcitriol with a much lower incidence of hypercalcemia. Close monitoring of patients is required when using a low-calcium solution to ensure that secondary hyperparathyroidism is not exacerbated. This is particularly so in patients who are questionably compliant with their calcium-containing phosphate binders or when sevelamer or lanthanum is used as the primary phosphate binder. Monitoring of bone mineralization is also indicated with long-term use of low-calcium dialysate.

MAGNESIUM

Hemodialysis

The usual concentration of magnesium in the dialysate is 0.5–1.0 mEq/liter and is only rarely manipulated. In an attempt to minimize the development of hypercalcemia and calcium loading associated with the use of calcium-containing phosphate binders and vitamin D, there has been interest in using magnesium-containing compounds as a phosphate binder.[171,172] The use of oral magnesium requires the use of a low-magnesium dialysate concentration to avoid the development of hypermagnesemia.

Depending on which magnesium salt is used, this strategy has had variable success.[66,129] Use of oral $Mg(OH)_3$ in association with a magnesium-free dialysate had little or no effect on phosphate and increased mean serum magnesium to 4.3 mg/dl. In addition, diarrhea was a frequent side effect. More favorable results have been reported with oral $MgCO_3$. Donovan et al. reported good control of the serum phosphorus level using oral $MgCO_3$ and a magnesium-free dialysate.[128] On this regimen, diarrhea was mild and transient and the serum concentration of magnesium did not change. More recently, Kelber et al. examined the feasibility of using a magnesium-free dialysate in the setting of high-efficiency dialysis.[86] Despite the use of oral $MgCO_3$, patients developed severe muscle cramping that was immediately relieved by adding magnesium back to the dialysate. It was determined that measured magnesium removal exceeded the estimated predialysis extracellular fluid magnesium pool. By contrast, dialysate magnesium of 0.6 mg/dl in combination with oral $MgCO_3$ was well tolerated.

Use of this latter regimen was then examined in a prospective randomized crossover study.[40] Patients were studied while taking $MgCO_3$ and half the usual dose of $CaCO_3$ along with dialysate magnesium of 0.6 mg/dl, and again while ingesting $CaCO_3$ given in the usual dose with dialysate magnesium of 1.8 mg/dl. There was no difference in the serum concentrations of phosphorus, calcium, or magnesium between the two phases of the study. In addition, the $MgCO_3$-low $CaCO_3$ regimen permitted a greater amount of intravenous calcitriol to be used without the development of hypercalcemia. It was concluded that use of oral $MgCO_3$ as a phosphate binder and a low dialysate magnesium concentration may be a useful strategy in patients.

The dialysate magnesium has also been varied in an attempt to obtain better hemodynamic stability in the setting of a low dialysate calcium concentration.[100] Lowering the dialysate calcium concentration from 1.75–1.25 mmol/liter in the setting of a dialysate magnesium concentration of 0.25 mmol/liter results in deleterious effects on mean arterial pressure, cardiac index, and stroke volume. These hemodynamic effects are prevented by raising the dialysate magnesium concentration from 0.25 to 0.75 mmol/liter even though the dialysate calcium concentration is kept low.

Peritoneal Dialysis

Initially, the standard peritoneal dialysis solution contained 1.5 mEq/liter magnesium. The concentration has since been lowered to 0.5 mEq/liter to lessen the frequency of hypermagnesmia that was observed with the higher magnesium concentration. As discussed with hemodialysis, a lower dialysate magnesium concentration may allow use of magnesium salts as an additional calcium-free phosphate binder.

Dialysate Phosphate

In patients with mild to moderate hyperphosphatemia, hemodialysis has been estimated to remove 250–325 mg/day of phosphorus when extrapolated to an average week.[41,77] Because a diet that provides adequate protein may provide approximately 900 mg of phosphorus daily, it follows that dialysis cannot provide adequate control of phosphate by itself. Rather,

management of hyperphosphatemia requires a combination of dietary restriction, oral phosphate binders, and dialysis.

The limited ability of dialysis to remove phosphorus is primarily related to the kinetics of phosphorus distribution within the body, and not to inadequate clearance across the dialyzer.[98] In a typical dialysis session, the rate of phosphorus removal is greatest during the initial stages of the procedure and then progressively declines to a low constant level toward the end of the treatment. This decline is due to the decrease in plasma concentration and the slow efflux of phosphorus from the intracellular space and/or mobilization from bone stores. Although dialysis membranes differ with respect to plasma clearance of phosphate, it is the slow transfer of phosphorus to the extracellular space (where it becomes accessible for dialytic removal) that is the most important factor limiting phosphorus removal.[158,163]

There are only a few situations in which one might consider adding phosphorus to the dialysate (Table 93.6). Hypophosphatemia can be an occasional finding in the chronic dialysis patient who is malnourished and suffering from some chronic disease state. In such patients, adding phosphorus to the dialysate may be an effective means of treating hypophosphatemia without having to utilize a parenteral route of administration. The phosphate must be added to the bicarbonate component of a dual proportioning system to avoid the precipitation of calcium phosphate that would result from addition to the calcium-containing acid concentrate. Kaye et al. described three hypophosphatemic dialysis patients treated by adding phosphorus to the dialysate in a single proportioning system.[87] In these patients, phosphate was added to a bicarbonate concentrate that contained no calcium. To avoid hypocalcemia, calcium was infused into the venous drip chamber as a 10% $CaCl_2$ solution. A final phosphate concentration of 1–2 mmol/liter was found effective in correcting the hypophosphatemia by the end of a four-hour session.

Another situation in which addition of phosphate to the dialysate may be useful is in the setting of an overdose. In a patient with normal renal function and a normal serum phosphate concentration, use of a phosphate-free dialysate will commonly result in hypophosphatemia. In most circumstances, the hypophosphatemia is of short duration and is of little clinical consequence. However, some intoxications may increase the risk for complications of hypophosphatemia such that addition of phosphate to the dialysate may be warranted.

Due to the slow equilibration of phosphorus between the intravascular and intracellular space, long frequent hemodialysis sessions are more effective in removing dialysis.[107] In fact, hypophosphatemia has been noted in some patients treated with prolonged daily nocturnal hemodialysis.[140] In this setting, adding phosphate to the dialysate may prove useful as a means of normalizing the serum phosphate concentration.

Homeostasis of Solute and Water by the Transplanted Kidney

J. Harold Helderman[1], *Heidi Schaefer*[1], *Anthony J. Langone*[1] *and Simin Goral*[2]

[1]Vanderbilt University Medical Center, Nashville, Tennessee, USA

[2]Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania, USA

INTRODUCTION

The transplanted kidney is a healthy organ responding to a multiplicity of complex and variant clinical experiences and insults. There is no single model to adequately explain the manner in which solutes are handled by the transplanted kidney or the physiologic derangements that might be encountered. There is an ordered sequence of transplant events that can be isolated and provide the impetus for unique alterations in function that can be delineated. The hemodynamic state of the donor prior to harvesting can adversely affect early function of the graft. Perioperative circumstances, including the effects of warm and cold ischemia on the donor kidney, produce functional abnormalities similar to those intentionally produced by investigators examining ischemic acute renal failure.[42,99,151] Intraoperative factors including hypotension, blood loss, and technical damage establish conditions capable of deranging the function of the transplant. Additionally, the transplanted kidney, both early and several months after engraftment, is a denervated organ with all the consequences to tubular function attendant upon that state.[30,32] The use of newer immunosuppressive agents, which directly alter physiologic function of the kidney, also affects the performance of the new graft.

The placement of a functioning allograft in a setting in which ischemic effects have been minimized and engraftment has been uncomplicated may result in the passage of salt and water during the early post-transplant period. The nature and amount of salt and water are a function of volume and osmolar loads imposed by the azotemic state, which presents excess solute loads and stimuli for the elaboration of saluretic hormones.[37,92,116,128,155] The effect of other comorbid disorders associated with uremia, such as secondary hyperparathyroidism, which may persist post-transplant, can alter the handling of such solutes as calcium, phosphorus, hydrogen ion, and bicarbonate even when excretory function is excellent.[31]

The maintenance of a functioning allograft depends on forestalling immunologically mediated assault. For all but identical twins, transplant recipients are maintained on immunosuppressive medications, some of which may have an impact on salt and water regulation. For example, many recipients receive corticosteroids early in the transplant period regardless of the additional immunosuppressive medicines during the maintenance regimen. These drugs have profound effects on sodium, chloride, potassium, and water regulation.[58] Other immunosuppressive agents including calcineurin inhibitors and rapamycin may alter renal transplant tubular function.[35] Since the early 1980s, calcineurin inhibitors have been the mainstay of maintenance immunosuppression in the allograft recipient. Both cyclosporine and tacrolimus have the ability to profoundly alter renal blood flow and thus renal function[50,203] through reduced glomerular filtration with resultant effects on the handling of sodium, potassium hydrogen and uric acid.[203] Rapamycin, one of the newer agents to be added to the armamentarium may also lead to tubular dysfunction and altered solute transport.[7] On this background, immunologic assault in the form of acute and chronic rejection can profoundly alter the handling of salt and water by the transplanted kidney, possibly related to effector cells or their released cytokines.[96,133]

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00094-X

This review, updated from its previous version, first explores the intrinsic capacity of the transplanted kidney to modulate solute and water, and to maintain the internal milieu in homeostatic balance. By using the classic observations of Bricker et al.[30,31,32] and more recent studies of tubular function that minimize warm ischemia and avoid the confounding variables of immunosuppressive drugs and rejection, the handling of solutes and water by the denervated transplanted organ will be characterized.

The remainder of this review deals with the various derangements of solute and water handling observed clinically after successful engraftment. These separate syndromes will be explained employing clinical data and observations in the human. When experimental data from transplant or related fields of research derived from animal models are applicable, they will be discussed and placed in proper context in an attempt to explain the etiology of or the physiologic basis that underlies the clinical syndromes.

The effect of immunosuppressive therapies on renal function and metabolic derangements has been extensively studied. This revised chapter makes a special effort to explicate the impact of these potent agents, particularly that of calcineurin inhibitors and rapamycin. Those experiments that reveal the multiplicity of effects of these agents in general are reviewed in an attempt to suggest a unifying theory as to their physiologic consequences.

INTRINSIC CAPACITY OF THE DENERVATED TRANSPLANTED ISOGRAFT

To observe the intrinsic capacity of the transplanted kidney to maintain solute and water homeostasis, an experiment must be designed to minimize the effects of ischemia related to harvest, the solute load that the azotemic patient presents to the new kidney, the use of immunosuppressive medications, and the effects of rejection. These criteria were best met by the classic renal autotransplantation studies reported by Bricker et al.[32] in the dog. These researchers left one kidney intact, excised the contralateral kidney, and retransplanted it into a discreet hemibladder. In this two-kidney autotransplantation model in nonuremic animals, renal hemodynamics, maximal concentration and dilution capacity, response to vasopressin, sodium, and potassium excretion, response to modulation of plasma volume by hypertonic and isotonic infusion, and the response to mercurial diuretics were studied. When renal hemodynamics had returned to normal after surgery in the transplanted kidney, the measured tubular functions were virtually equal in the just transplanted kidney to those observed in the contralateral, undisturbed kidney. Sodium excretion rates factored for respective solute loads were also equivalent to the contralateral, undisturbed kidney as was the ability to maximally concentrate or dilute the urine after several days. This study illustrates the ability of the denervated autotransplanted kidney to maintain normal solute and water balance.

In healthy individuals, head-out water immersion increases sodium excretion.[63] Interestingly, in renal denervated dogs, the natriuretic response to head-out water immersion is completely abolished, suggesting a major role for the renal nervous system for this response.[140] Yet, despite renal denervation, it has been shown that patients with well-functioning renal transplants of less than two months duration are capable of a normal natriuretic response to head-out water immersion.[174] This observation suggests that renal nerve activity is not essential for a normal natriuretic response to head-out water immersion in renal transplant recipients. When six renal transplant recipients were compared to, six normal individuals subjected to head-out water immersion, it was demonstrated that the denervated, transplanted kidneys of the six recipients were able to maintain a sodium excretory response to head-out water immersion identical to that obtained in the normal controls.[49] These studies, taken together with the earlier reports, illustrate that the denervated autotransplanted kidney is able to maintain normal solute and water balance.

More precise experimental observations about renal tubular function in the transplanted kidney were made in the studies of Muller-Suur et al.[145] and Norlen et al.[152] These investigators used a rat model in which recipient animals underwent bilateral nephrectomy just prior to isotransplantation. Using standard micropuncture techniques to assess tubular function, Muller-Suur et al.[145] were able to show that five minutes after reestablishment of circulation to the donor kidney that had suffered the least amount of cold ischemia, there was no statistical difference in the single-nephron glomerular filtration rate (GFR) of the transplant compared to the untransplanted normal kidney (13.4 nl/min per 100 g of body weight vs 14.1). After an initial polyuric phase related to solute load, a phenomenon discussed later, the passage of sodium and potassium into the urine was equivalent in the transplant to that of the normal, untransplanted kidney. Norlen et al.[152] measured proximal tubule reabsorptive capacity using micropuncture techniques in a similar experimental rat model. They demonstrated that there was normal proximal tubular fluid reabsorption (TF/P inulin ratio of 2.1 [$\pm$ 0.4]) as well as normal whole-kidney function and normal single-nephron GFR. These studies show that bulk solute handling by the denervated,

isotransplanted kidney is normal on a whole-kidney clearance basis. These nonrejecting grafts can maintain a relatively undisturbed total GFR, single-nephron GFR, and proximal tubular absorptive capacity as determined by micropuncture.

The functional integrity of the more distal nephron segments as well as the intrinsic capacity of the transplanted kidney to exhibit tubuloglomerular (T-G) feedback was investigated further by Muller-Suur et al.[145] in the rat isotransplant model. Two experimental paradigms were employed. In the first, the isograft was punctured in the presence of the normal contralateral kidney; in the second, the puncture occurred in the solitary isograft after contralateral nephrectomy. In contrast to the observations by Norlen et al.[152] the investigators found that the whole-kidney GFR of the transplanted kidney fell approximately 40% when the contralateral kidney was left in place. Yet when the remnant kidney was removed, the GFR in the isotransplant rose toward but not entirely to the two-kidney control value. These animals were then studied 15 hours after isotransplantation at a time when single-nephron GFR had risen essentially to normal in order to measure the effects of T-G feedback. There was normal urine flow rate, normal sodium and potassium excretion, a normal TF/P inulin, and a slightly reduced GFR. When unilateral nephrectomy was performed, urine flow and sodium/potassium excretion rates increased in both the transplanted kidney and in the control. Interestingly, T-G feedback was found to be intact, permitting appropriate modulation of GFR in response to solute load by the transplanted kidney when the contralateral, normal kidney was in place. An increase in osmotic and solute load that would occur after the contralateral kidney was removed would be expected to have produced a substantial reduction in GFR if no other compensatory mechanisms were at play. In the actual experimental situation, the single remaining transplanted kidney demonstrated a decreased sensitivity of the T-G feedback mechanism, measured as a shift in the T-G set-point (Fig. 94.1). This attenuation of the feedback sensitivity set-point allowed the GFR to rise toward normal rather than fall in the transplanted single kidney to maintain normal clearance despite the increased solute load reaching the macula densa. Muller-Surr et al.[145] advanced the hypothesis that increased interstitial pressure and volumes to which the transplanted kidney is exposed after contralateral nephrectomy explains resetting of T-G feedback. In summary, the isotransplanted kidney, when studied with a functioning renal remnant, retains its capacity to modulate GFR to solute load, but resets the T-G feedback set-point to maintain GFR in the face of increased bulk blood flow when placed in an environment devoid of additional functioning nephron mass represented by a normal remnant kidney.

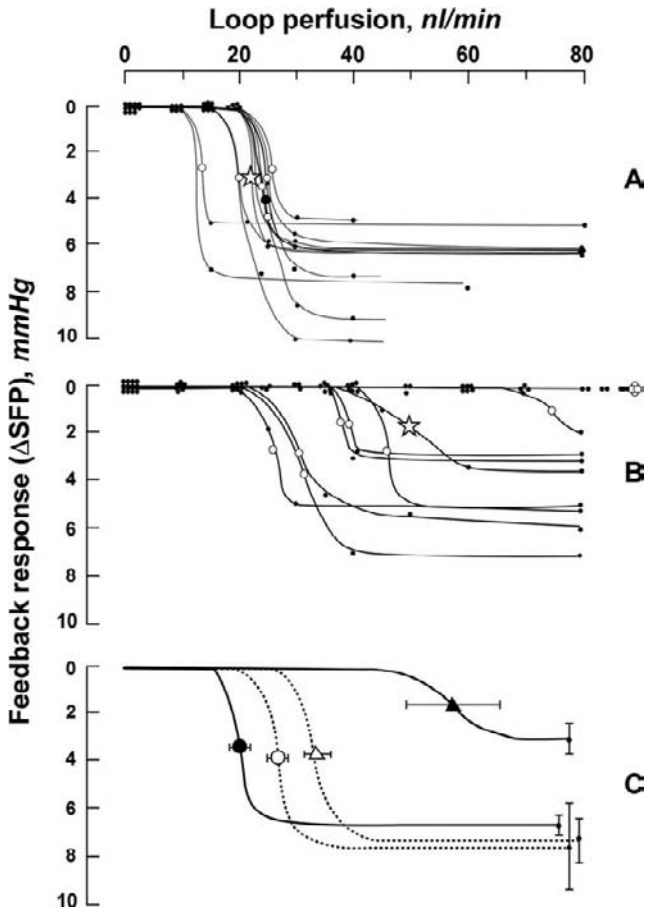

FIGURE 94.1 Feedback responses (change in stop-flow pressure [SFP]) (ordinates) to different loop perfusion rates (abscissa) in kidneys 1 day after transplantation. A: Data on single experiments. The open circles indicate the graphically determined turning points. B: As in A, but after uninephrectomy. One individual tubule was studied both before and up to 30 minutes after unilateral nephrectomy. This tubule is marked by an asterisk in A and B. C: Mean curves from A and B for transplanted kidneys (solid lines) and for control kidneys (broken lines). Note the shift to the left in transplanted (closed circles) kidneys compared with controls (open circles), and to the right after uninephrectomy in controls (closed triangles) and transplanted (Δ) animals. *(From Muller-Suur R, Norlen BJ, Persson AEG. Resetting of tubuloglomerular feedback in rat kidneys after unilateral nephrectomy. Kidney Int 1980;18:48–50.)*

Kidney transplantation between identical twins provides an interesting clinical counterpart to the rat and dog isograft studies. Bricker et al.[30] analyzed the intrinsic capacity of the human kidney allograft to maintain solute and water homeostasis in the original set of identical twins transplanted at the then Peter Bent Brigham Hospital (now Brigham & Women's Hospital) in Boston in 1954, an advance in clinical medicine recognized for the Nobel Prize of 1990. Recipients of an identical twin kidney allograft require no

immunosuppressive therapy and rarely exhibit rejection. When compared to the remaining kidney function of the identical donor sibling, the transplanted organ was able to maintain an equivalent filtration fraction and showed a normal ability to concentrate and dilute urine as well as to acidify and to alkalinize the urine when challenged. Further, the allograft could increase and decrease the rate of sodium excretion in the face of load, to respond to various volume- and drug-related stimuli, and to retain the capacity to alter filtration fraction and renal blood flow acutely while maintaining extracellular fluid volume and composition. One can conclude from isograft studies in animals and from the observations in identical twin human allografts that the transplanted denervated kidney retains the capacity to modulate solute and maintain volume homeostasis.[30,78]

ISCHEMIA ATTENDANT TO HARVEST, PRESERVATION, AND ENGRAFTMENT

Experimental models and clinical observation demonstrate that the transplanted kidney has the intrinsic capacity to maintain solute and water homeostasis. Unfortunately, the allograft in clinical settings is exposed to injurious environmental pressures to which it must respond by modifications of physiologic function. This section of the chapter will attempt to isolate several of the insults to which the functioning allograft is exposed and reveal the means by which the transplant has successfully responded to these challenges or delineate the derangements that flow from unsuccessful responses.

Although every attempt is made to minimize the ischemic effect of kidney transplantation by paying scrupulous attention to donor management, to conditions of harvest, organ preservation, and to conditions of engraftment, some degree of ischemic injury is a uniform phenomenon. Even in the early studies of Bricker et al.[32] of autotransplantation in the dog, an initial drop in GFR and renal plasma flow that normalized several days after surgery was observed. This initial drop in GFR was felt to be due to tissue ischemia induced by the operative procedure and did not have any lasting effects on kidney function as revealed by their measurements.

Muller-Suur et al.[145] also noted important consequences of early ischemia in their Munich-Wistar rat isograft model. They observed that even in the group of animals that received the least amount of protocol-determined cold ischemia prior to implantation, a group able to maintain normal single-nephron GFR, there still were increases in urine flow rate with diminished urinary concentration (approximately 100 mOsm/kg) during the first three hours postoperatively, thought a consequence of surgical ischemic injury. During this initial polyuric phase, there was an additional increase in sodium and potassium excretion paralleling the enhanced urine flow rate. An initial polyuria and the formation of hypotonic urine, even when GFR is normal, were felt to be a universal consequence of the unavoidable ischemia of the transplantation event.

These findings have been confirmed in reperfusion studies in renal allografts in humans.[5] Alejandro et al., noted that in the ensuing hours of post-transplant, fractional excretion of rates of sodium were elevated to $>20\%$ with an impairment of urinary concentrating ability even in those with normofiltration. Although significant tubular dysfunction occurred, by morphometric analysis, only $\sim 2\%$ of proximal tubular cells exhibited necrosis and obstruction of the tubular lumen. Unlike studies in the native kidney[157] and supporting the work of others,[192] this points away from an important contribution of tubular obstruction to postischemic injury in the transplanted allograft.

In turn, it has been suggested that afferent arteriolar constriction with an attendant fall in the glomerular perfusion pressure is the primary mechanism by which glomerular filtration is affected in the freshly transplanted kidney.[5] One contributing mechanism may be that the high fraction of filtered sodium reaching the macula densa mediates afferent vasoconstriction via tubulo-glomerular feedback. In patients with persistent hypofiltration post-transplantation, loss of polarity of proximal tubular cells with redistribution of cytoskeletal proteins including Na^+/K^+-ATPase, fodrin and ankyrin from the basolateral membrane to the cytoplasm has been noted[4,119] with subsequent impairment of proximal tubular sodium reabsorption.

In addition to tubuloglomerular feedback, vascular mediators are felt to contribute to a state of afferent arteriolar vasoconstriction. With sustained injury and delayed function of the transplant, both elevation in plasma renin activity and endothelin-1 levels have been observed.[5] In addition, there appears to be resistance of afferent arterioles to the vasodilator actions of endogenous atrial natruiretic peptide, which is present in excess.[220] Thus, postischemic allograft injury appears to be accompanied by an imbalance that favors constrictor hormones over those that dilate the afferent arteriole with a resultant depression in GFR by lowering of glomerular perfusion pressure.

Urinary exosomes released into the urine by fusion of the outer membrane of multivesicular bodies with the apical plasma membrane of renal epithelial cells[101,168] are shown to include membrane and cytosolic proteins, which have the characteristics of all renal tubule epithelial cells, podocytes, and transitional epithelial from the urinary collecting system.

Importantly, several of these proteins found in urinary exosomes have been implicated in various kidney diseases and suggest that the examination of urinary endosomes may allow for a non-invasive measurement of site-specific biomarkers.[167]

Several studies have demonstrated changes in excretion of urinary exosomal Na^+/H^+ exchanger isoform 3 (NHE3)[60] and fetuin-A[234] after renal ischemia/reperfusion. NHE3, a sodium transporter protein in the proximal tubule, was present in the urine within 24 hours after renal allograft transplantation with levels returning to undetectable 48 hours after transplantation relating to a marked improvement in renal function.[60] Conversely, NHE3 levels were not increased in the urine in the setting of acute allograft rejection. This data suggests that NHE3 may be a temporal marker of renal ischemia/reperfusion injury. Urinary exosomal fetuin-A levels have been shown to be increased after ischemia/reperfusion in allograft recipients[234,193] but also in donor patients[193] suggesting this may be a response to a change in renal hemodynamics and not specific to renal ischemia/perfusion injury.

The excretion of urinary exosomal aquaporin-1 has been studied both in animal models and in human allograft recipients. Aquaporin-1 is a water channel protein abundantly expressed in renal epithelial cells of the proximal tubules and the descending limb. It is known that renal ischemia/reperfusion in the native kidney leading to acute kidney injury is associated with decreased renal aquaporin-1 expression[80] with subsequent data showing a decreased abundance of urinary exosomal aquaporin-1 in Sprague-Dawley rats subjected to unilateral renal ischemia/reperfusion as well as a renal transplant recipient at two and six days after renal transplantation despite a dramatic decrease in the plasma creatinine concentration following the operation.[193] There was no decrease in urinary exosomal aquaporin-1 excretion in both animal models of nephrotic syndrome and patients with proteinuria. These data suggest that urinary exosomal aquaporin-1 may be a useful urinary biomarker to predict post-transplant acute kidney injury related to ischemia/reperfusion injury. Follow-up studies in larger sets of patients will be needed to confirm these findings and validate the utility of the role of urinary exosomal proteins in the detection of renal/ischemia reperfusion injury.

Norlen et al.[151] used microsphere injection techniques to evaluate alterations in intrarenal blood flow during varying lengths of warm and cold ischemia of the renal transplant. Analysis of cross sections of rat kidney showed that microspheres injected during the reperfusion phase after two hours of cold ischemia showed no areas of preferential blood flow. Longer degrees of ischemia (12–16 hours) resulted in poor filling of the medulla. Except for the polyuric phase, which always seems to accompany such ischemia, there was no functional or structural abnormality after two hours of cold ischemia. On the other hand, after 12–16 hours of cold ischemia, there were dilated and collapsed tubules interspersed with morphologically "normal" tubules. The dilated tubules exhibited no glomerular filtration and were thought a consequence of obstruction by swollen epithelial cells in the corticomedullary region. This study provides anatomic correlates to the ischemic engraftment and preservation procedures.

The different studies in animals taken together show that short-term ischemia may derange volume homeostasis and concentration ability. Longer periods of ischemia may result in delayed reperfusion of the corticomedullary region, possibly due to cellular swelling in that area.[151] The effect of the more prolonged ischemia to the transplant is a fall in GFR and an early loss of concentrating ability of the tubule. These alterations are potentially reversible spontaneously and may lead to no long-term sequelae. Clinically, the absence of urine formation after surgery suggests longer ischemic injury, whereas some element of the universally encountered polyuria is a consequence of shorter periods of ischemia.

Most data, however, would suggest that early ischemia/reperfusion injury of short duration does not lead to untoward long-term consequence to the allograft. Prolonged injury on the other hand, may contribute to late renal allograft deterioration and failure.[89,148,211] To evaluate the association between initial ischemia/reperfusion injury occurring secondary to organ retrieval, storage, and transplantation and late renal allograft deterioration and failure, Azuma et al.[11] studied the patterns of proteinuria, cellular infiltration, cytokine expression, and glomerular sclerosis over time in 344 Lewis and Fischer rats after 45 minutes of warm ischemia of a singe kidney. Intracellular adhesion molecule I, endothelin, and major histocompatibility complex (MHC) class II expression were found to be upregulated within two to five days after the injury, which enhances the antigen load presented to the recipient and the appropriate signal pathways to enhance antigen recognition, culminating in a drive for additional acute and later chronic rejection. In the animals, proteinuria developed after 8 weeks, and glomerulosclerosis, arterial obliteration, and interstitial fibrosis occurred after 16 weeks. These data suggest that early ischemia and reperfusion, if severe enough, may not only contribute to early dysfunction but also to late renal deterioration and chronic rejection. Further studies are needed for better understanding of the factors mediating these abnormalities.

ALLOGRAFT IN THE AZOTEMIC SOLUTE-LOADED RECIPIENT

Clinical observations teach that the placement of a functioning allograft into an azotemic patient leads to copious urine formation. The typical diuretic phase postoperatively has been attributed to several potential etiologies. As has been previously discussed, ischemia per se affects the concentrating ability of the nephron.[145] Solutes that accumulate in azotemic patients, even in the face of adequate dialysis, can induce an osmotic diuresis when GFR is adequate.[128,155] Additionally, the administration of loop diuretics such as furosemide and osmotic diuretics such as mannitol during the transplant operation will contribute to this polyuric phase. Lastly, the etiologic role of atrial natriuretic peptide (ANP) as the basis for some of this polyuric phase has been suggested by observations in humans and studies on animals using a volume-overloaded ischemic kidney model and measurements of that peptide in early clinical transplant experience.[37]

During the immediate postoperative period, the diuresis that frequently occurs can be profound and, if not followed assiduously with appropriate replacement therapy, can be life threatening.[128] In their study of six patients after native nephrectomy and transplantation, Ogden et al.[155] observed diuresis of 5−14 liters over the first 24 hours after transplantation. The diuresis was osmotic, with the osmolar clearance of electrolytes accounting for more than 50% of the total solute clearance. Although these patients were relatively hyperosmolar due to retained blood urea nitrogen (BUN), their osmotic diuresis post-transplant was not primarily driven by urea but by electrolytes, principally sodium. Swenson et al.[199] studied sodium balance in four patients who had undergone kidney isotransplantation and found negative sodium balance of 150−1000 mEq during the immediate postoperative period. They found that the rate of sodium loss correlated with pretransplant overexpansion of extracellular space (ECS) and that water excretion was more a function of sodium than urea excretion. Additionally, they observed hypovolemia related to this osmotic diuresis in several patients with postural hypotension and tachycardia when urine output was inadequately replaced. These data suggest that the osmotic diuresis may be a result of an inability to retain filtered sodium when required and not merely of the presence of increased filtered loads.

As was discussed in the previous section, the ischemic insult of transplantation alters the ability of the tubule to concentrate urine, in particular the proximal tubule. This occurs even in the optimal setting of live donor transplantation whereby ischemia is minimized. In a study of eight renal allograft recipients of live donor kidneys, Bugge et al.[33] noted a high fractional excretion of sodium during the first hour after surgery correlating with a high urinary excretion of N-acetyl-ß-glucosaminidase. NAG is a lysosomal enzyme found in high concentrations in renal tubules, especially in the S3 segment of the proximal tubule. The data taken together suggest that it is the defect in proximal tubular transport contributing to the post-transplant osmotic diuresis that hitherto was thought to be a consequence of solute loads presented to disordered cortical collecting tubules.

Diuretics, including both osmotic and loop, given during the perioperative period also contribute to the post-transplant polyuria. Mannitol has been shown to reduce the frequency of postsurgical acute renal failure after renal transplantation.[213] It has been suggested that the combination of mannitol and volume expansion gives better protection than volume expansion alone, but the mechanism for this protective effect is not known. By its osmotic activity, mannitol increases plasma volume expansion, decreases systemic and renal vascular resistance, and counteracts swelling of tubular cells. All of these properties of mannitol may contribute to its protective effect against ischemic renal injury. Loop diuretics reduce sodium reabsorption and oxygen consumption in the thick ascending limb of Henle, and simultaneously, increase the oxygen availability for the S3 segment of the proximal tubule that may protect against ischemic injury.[94]

One might infer that the correct clinical response to the expansion component of the diuresis would be to restrict perioperative volume loads. In fact, such inference is absolutely false, as it has been shown that challenges of hypervolemia during renal transplantation decrease the post-transplant period of dysfunction due to postsurgical acute renal failure.[38] It has long been known that salt loading prior to ischemia or nephrotoxic insults delimits the physiologic display of injury; the transplant condition is not different in this regard. Some have hypothesized that the protective effect of volume expansion may be due to released atrial natriuretic factor (ANF). One argument is that the intrinsic hypervolemia of the transplant recipient at the time of surgery and the additional volume loads imposed by the transplant team generate high levels of ANF, which protect the nephron from ischemic injury, an unavoidable consequence of the surgical event. Measurements of pulmonary artery pressure (PAP), pulmonary wedge pressure (PWP), and central venous pressure (CVP) as an estimate of systemic volemia in seventeen patients during allograft placement were compared with levels of ANF. Although it was difficult to statistically relate measures of these parameters of volume status to

markedly elevated levels of ANF, there was a clear positive correlation between the changes in ANF and acute changes in central volemia (Fig. 94.2). This study suggests that during transplantation ANF is elevated at the time of surgery and its release is facilitated by therapeutic volume challenges. Additional data by Nyberg et al.[154] and Plum et al.[170] lend further support to this view. In a study of 14 patients undergoing live donor kidney transplantation, Nyberg et al. showed that ANF levels rose significantly after transplantation and volume expansion and by stepwise multiple linear regression analysis was the strongest determinant of post-transplant diuresis. Similar findings were also reported by Plum et al. in the early post-transplant period.

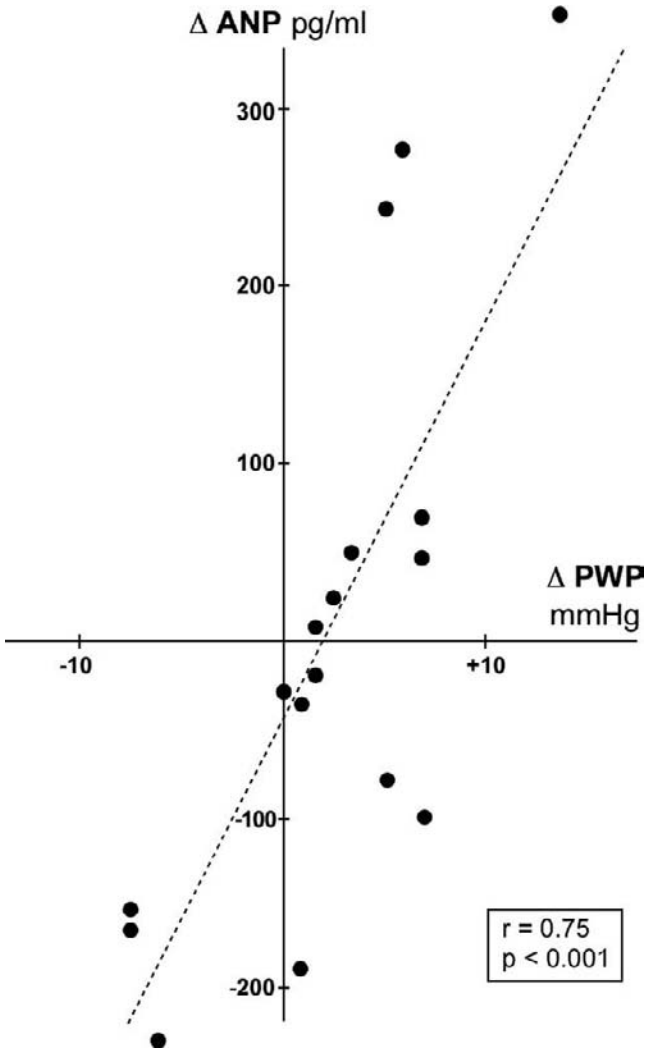

FIGURE 94.2 Correlation between atrial natriuretic factor (ANF) and pulmonary wedge pressure (PWP) variations during renal transplantation. *(From Gianello P, Squifflet JP, Carlier M, et al. Beneficial effect of atrial natriuretic factor on ischemically injured kidneys in the rat. Transplantation 1989;48:9–14.)*

The protective role of ANF on the ischemic injury of transplantation has been suggested by animal models. By using an ischemic renal injury rat model, Gianello et al.[76] investigated whether the atrial natruiretic peptide by itself was able to improve early renal function after an ischemic injury. In a group of Wistar rats subjected to right nephrectomy and left renal artery occlusion for 30 minutes followed by a two hour infusion of rat atrial natruiretic peptides, there was a significant improvement in early recovery of renal function as compared to those rats who received isotonic saline alone. There was a notable increase in urinary flow rate, sodium excretion and improvement In GFR recovery. A similar experiment confirmed and extended these observations in a dog model[77] showing protective ANF effects with low doses of human exogenous ANF. It is worth noting in both animal models, a striking increase in GFR after ANF infusion. In the intact kidney, the enhanced GFR induced by ANF results from a hemodynamic effect as noted by vasodilation of the preglomerular afferent arteriole and constriction of the efferent artery. It has been hypothesized that a similar mechanism of action of ANF is involved in the ischemically injured kidney model.

In addition to the glomerular effects, ANF also considerably improves natriureisis and fractional sodium reabsorption rates suggesting that ANF may also have direct tubular effects and may be direct or mediated by an inhibition of the renin-angiotensin-aldosterone system.

These experiments in animals show that volume expansion and the resultant diuresis is protective of recovery after ischemic renal injury. This conclusion is corroborated by studies in renal transplant recipients who have improved graft function after perioperative volume expansion.[38] The onset of a rapid osmotic diuresis after transplantation heralds a rapid recovery and all attempts should be made to augment the early and copious formation of urine through volume expansion and diuretics. There is evidence to suggest that the protective nature of volume expansion leading to early renal recovery from surgical injury may be partially related to ANF release.

In addition to hypervolemia-induced release of ANF, there is evidence that glucocorticoids, a standard concomitant of clinical transplantation, directly stimulate ANF release and by doing so provide further protection to the renal transplant against ischemic injury. Eight healthy men were studied by Weidmann et al.[224] in a cross-over, "blinded" study of the effect of prednisone (50 mg/day for nine days) on ANF while on a diet containing 130 mmol of sodium and 75 mmol of potassium. During the prednisone therapy period, there was no change in sodium balance, blood pressure, or weight compared with the placebo period.

Over the nine-day study period, the mean supine ANF was nearly threefold greater during prednisone intake than during placebo intake in controls. Confirmatory studies in Sprague-Dawley rats by Gardner et al.[74] showed that rats injected with dexamethasone, 1 mg/day, for one to two days while water deprived, exhibited a twofold increase in ANF. These animals were then killed and slot-blot analysis of atrial cells by using a cDNA probe for ANF showed 1.5-fold to two-fold increase in mRNA for ANF in those animals treated with steroids. These findings suggest that glucocorticoids directly stimulate ANF synthesis by atrial cells. Although not directly studied in transplantation, the early use of glucocorticoids in that setting may enhance the release of ANF in the early post-transplant period, play some part in the observed initial polyuria, and serve as a protective therapeutic maneuver against perioperative ischemia.

Although it has been shown in animal models of acute ischemic renal failure that ANF ameliorates renal damage, administration of synthetic ANF in humans following renal transplantation in attempts to promote initial graft function have not shown any beneficial effects. In a prospective, double-blind study by Sands et al.[186] 10 pairs of cadaveric kidneys were transplanted into 20 recipients. Upon revascularization of the allograft, paired recipients received either humanized ANF or placebo administered intravenously as a 50-μg bolus, followed by a 4-hour infusion at 0.1 μg/kg/min. Renal allograft function was determined both by serum creatinine and measurements of GFR by (125I)iothalamate. No significant differences were noted in renal allograft function between the two groups. Similar results have been obtained by others.[175,191] These results do not mean that ANF plays no role in preserving renal function after transplantation as extracellular volume expansion is a major stimulus for endogenous ANF secretion. It suggests that hANF alone is not superior to conventional extracellular volume expansion.

The early diuretic phase after transplantation is important for the long-term outcome of the graft.[36] Although there is suggestion that the early diuretic phase is related to impairment of function in the concentrating segment and proximal tubule, the impairment is transient, with no long-term sequelae. The osmotic load provided by the azotemic state and the perioperative volume expansion with resultant additional solute loads presented to the kidney, all contribute to diuresis directly and further stimulate ANF, which is responsible for an additional component of urine formation. Every attempt should be made to facilitate post-transplant diuresis, which improves immediate graft function, enhances the rapid recovery of the transplant recipient, helps to make the early management period less difficult for the transplant team, and culminates in a substantial increase in graft survival.

SOLUTE REGULATION DURING REJECTION

The most unique syndrome that a transplanted kidney must deal with is that of acute rejection. Derangements of renal function, which characterize this immune assault on the allograft, include not only a decrease in the GFR but also altered solute excretion. The diminution of sodium concentration in the urine has even been used by some as a useful clue to the diagnosis of acute rejection.[64,90,97,156] Renal retention of sodium reflects intrarenal ischemia, the final result of the immunologic assault on the transplanted allograft. In general terms, renal inflammation with organ swelling and edema can extrinsically reduce renal blood flow. More precise mechanisms responsible for physiologic dysfunction during rejection are doubtless at play and are worthy of a great deal of study. Acute cellular rejection of the kidney is associated with the release of monokines from activated T lymphocytes and from monocytes, which are in great measure responsible for the changes one calls inflammation. One important cytokine released is interleukin-2 (IL-2).[48] Although not formally studied in kidney transplantation, patients who are receiving supraphysiologic doses of IL-2 for immunotherapy of metastatic melanoma or renal cell carcinoma exhibit functional changes in solute handling similar to those encountered during acute rejection.[75,171,202,223] IL-2 regimens result in systemic hypotension due to systemic vasodilatation associated with azotemia and low urinary excretion rates of sodium. Although the amount of systemic IL-2 released during rejection is insufficient to cause systemic hypotension, the local release of the cytokine into the renal circulation may be sufficient to vasodilate renal beds directly or indirectly, open endothelial tight junctions, and contribute to the edema and high intrarenal pressures thought to be responsible for extrinsic reduction in total renal blood flow and sodium avidity.

Another cytokine, tumor necrosis factor (TNF), is found to be elevated during acute rejection episodes.[133] In a group of prospectively monitored transplant recipients, TNF elevation was diagnostic of rejection in half of the cases. Even when not diagnostic of acute allograft rejection alone, elevated TNF measured during rejection amplifies the importance of cytokines during the immunologic assault. The effects of human TNF on glomerular histology in rabbits given doses of 0.08, 0.8, and 80 g/kg/liter for five hours were studied by Bertani et al.[23] At the 0.8g/kg/liter dose

administered, there was leukocyte infiltration of glomerular capillaries as well as inflammatory cells within the glomerular capillaries. At the dose of 8 g/kg/hr, there was renal failure accompanied by the leukocyte infiltration with fibrin accumulation. The effects of TNF on renal vascular resistance released during acute rejection may mediate the observed endothelial damage.

Inflammatory prostanoids of the vasoconstrictive variety released from activated monocytes infiltrating the allograft have been implicated in the reduction of renal blood flow and impaired excretory function of rejection. The role of arachidonic acid metabolites in the transplant physiologic derangement during acute rejection has been studied by Coffman et al.[45] using a rat allograft model between inbred rat strains (Lewis rat donors to Brown-Norway recipients). Associated with the histologic evidence of cellular rejection based on interstitial and perivascular infiltrates of mononuclear cells and the reduction of inulin clearance rates, there was an increase in the production of thromboxane B2 (TXB2) without a correlative increase in prostaglandin E2 (PGE2) or 6-ketoPGF1α (the stable metabolite of prostacyclin [PGI2]) (Fig. 94.3). Attempts at reversal of the cellular rejection by using cyclophosphamide resulted in improvements in the clearance of inulin as well as in a reduction in the urinary levels of TXB2. Additionally, the use of a thromboxane synthetase inhibitor resulted in an improvement in GFR and renal blood flow during acute cellular rejection episodes when administered before an immune assault on the organ.[45] The fact that a thromboxane synthetase inhibitor did not completely ameliorate the detrimental effects of the acute cellular rejection suggests that other factors also may be at play during rejection. In another study by Munger et al.[146] kidneys were transplanted from Munich Wistar (MW) rats to syngeneic controls and MHC-incompatible recipients to evaluate the effects of surgery and acute rejection on glomerular hemodynamics by clearance and micropuncture techniques. A significant decrease in both single-nephron GFR and glomerular capillary pressure was found in animals with acute rejection. Micropuncture studies showed that the principal derangement in renal microvascular function during acute rejection is intense preglomerular vasoconstriction. Interestingly, the glomerular histology was normal, suggesting that locally acting vasoconstrictor influences such as TXA2 and leukotrienes were most likely responsible for the depressed renal function.

A recent study by Velic et al.[214] examined the effect of transplant rejection on the functional activity and regulation of transporters involved in sodium reabsorption in the proximal tubule using a rat allograft model of acute rejection without immunosuppression.

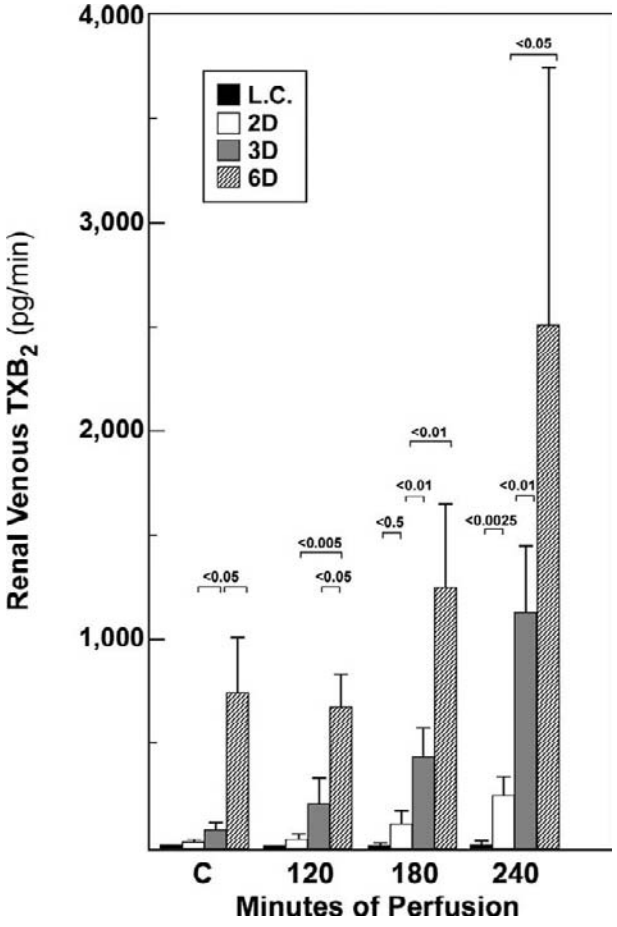

FIGURE 94.3 Renal venous thromboxane B2 (TXB2) production by ex vivo perfused Lewis control kidneys (L.C.) and 2-d (2D), 3-d (3D), and 6-d (6D) allografts. The control period (C) represents renal TXB2 production determined for all groups before bradykinin stimulation. Renal TXB2 production by all groups also is indicated after 120, 180, and 240 minutes of bradykinin stimulation (1 μg given as a bolus every 30 minutes). Bars represent mean plus standard error of the mean (SEM). Statistically significant differences between groups are indicated by brackets with the corresponding p value. *(From Coffman TM, Yarger WE, Klotman PE. Functional role of thromboxane production by acutely rejecting renal allografts in rats. J Clin Invest 1985;75:1242–1248.)*

In those kidneys with histologic evidence of acute rejection, downregulation of mRNA and protein levels for Na + /H + exchanger type-3 (NHE-3) were noted, independent of ischemia.

In follow-up, the same group extended their experiments to the distal nephron to further characterize the role of rejection on expression and function of transporters and receptors.[215] In the cortical collecting duct, mRNA expression and function of the epithelial Na^+-channel (ENaC) and mRNA and protein expression of the water-channel AQP2 were downregulated. To differentiate between possible effects of acute rejection and those directly related with the transplant process

such as denervation or ischemia/reperfusion, syngeneic transplantations were performed. Whole kidney mRNA and protein expression of ENaC and AQP2 remain unchanged. Addition of cyclosporine abolished the downregulation of both channels, again supporting the notion that these changes are the result of acute rejection. Both studies show that in models of acute rejection, transporters important in Na^+ reabsorption and consecutively solute and volume reabsorption may lead to a significant decrease in energy consumption and represent a period of adaptation by the kidney to support recovery of the stressed organ and protect it from further non-immunologic and immunologic damages.

These studies taken together suggest that changes in expression of proteins involved in tubular transport may be subjected to rejection-associated mechanisms. This is a fertile area for future research and may provide therapeutic targets for the accelerated recovery of acute rejection of the allograft, and therefore, the prognosis of the renal transplant.

In summary, true rejection is a state of low GFR, intrarenal vasoconstriction, and sodium avidity related to the immune activity within the graft that often persists beyond the abrogation of the cellular infiltration or humoral assault on the tissue. This may reflect the consequences of inflammatory mediators released by various infiltrating cells and adaptive tubular regulation of solute transport. This is a fertile area for future research and may provide therapeutic targets for the accelerated recovery of acute rejection of the allograft, and therefore, the prognosis of the renal transplant.

RENAL TUBULAR ACIDOSIS ASSOCIATED WITH ISCHEMIA AND REJECTION

Renal tubular acidosis (RTA) is the most commonly encountered group of tubular abnormalities found after successful renal transplantation and may cause profound changes in acid base balance.[20,107] One can describe various types of renal tubular acidosis including proximal RTA, Fanconi syndrome, distal RTA and Type IV RTA with hyporeninemic hyperaldosteronism, some of which may overlap and vary as a function of time during the lifespan of the allograft. For example, proximal RTA and Fanconi syndrome have been noted to occur early in the post-transplant period and resolve spontaneously suggesting that this may be in part attributable to acute ischemic renal failure related to the harvest procedure. Other types of renal tubular acidosis, particularly distal RTA may appear months to years after the transplant and are due to chronic rejection or drug-induced nephrotoxicity, including calcineurin inhibitors. Secondary hyperparathyroidism, obstructive uropathy and urinary tract infections may also contribute to the pathogenesis of RTA. Chronic RTA following transplantation is important as it may interfere with bone metabolism and at times lead to nephrocalcinosis and nephrolithiasis.

The presence of hyperchloremic, nonanion gap acidosis in the transplant patient was first described by Massry et al. in 1967.[130] In their case, hyperchloremic acidosis appeared on day 33 after successful transplantation when GFR was improving and the serum potassium was 3.3 mEq/liter, chloride was 1215 mEq/liter, and plasma bicarbonate was 15 mEq/liter. Additionally, this patient had glycosuria, aminoaciduria, and hyperphosphaturia along with the metabolic acidosis, suggesting a complete Fanconi syndrome due to proximal tubular dysfunction. The clinical picture was best defined as a dual effect located in the distal and the proximal tubule, in part because of the failure to acidify the urine, even with administration of exogenous acid coupled to the Fanconi syndrome. Better[24] additionally showed that when excess buffer base was provided to the distal nephron, this patient was unable to generate a steep hydrogen ion gradient, indicating that there was a distal tubular defect in transporting hydrogen ions either into the lumen from the tubular cell or from the blood into the lumen. In the report of Rubini et al. from 1967,[182] an early post-transplant tubular dysfunction similar to the Fanconi syndrome with spontaneous resolution was observed. Rubini et al.[182] also suggested that distal tubular dysfunction was found along with the Fanconi syndrome, arguing that the form of RTA observed in the early post-transplant period is a mixed disorder of proximal and distal tubular dysfunction perhaps the result of ischemic injury encountered during the harvest and engraftment procedure.

The impact of high circulating levels of parathyroid hormone (PTH) of the recipient on proximal tubular acidification may contribute to the early post-transplant RTA as shown by studies of Arruda et al.[9] in dogs in which PTH was infused acutely. Animals receiving a human PTH infusion of 1 U/min or a bolus of 100 U followed by a continuous infusion of 5 U/min exhibited an increase in bicarbonate excretion and an increase in urinary pH. The increase in urine pH was associated with an increase in total titratable acid due to an increase in proximal tubular rejection of phosphate. The next acid excretion remained unchanged during the bicarbonaturia due to a decrease in ammonia excretion. The urine−blood (U-B) PCO2 ratio remained stable during the study period, suggesting the distal tubular ability to secrete H^+ was not altered by the PTH infusion.

Purer forms of distal tubular acidosis are the types of acid–base disorders most likely to persist after transplant and can become a clinical problem requiring intervention. In a study by Better et al.[24] six patients not receiving cyclosporine were shown to have urinary acidification defects after successful cadaveric transplant. All these patients showed an inability to create a steep gradient for hydrogen ion exchange in the distal tubule. Follow-up studies done over the next 15 months showed that each patient was able to acidify the urine and excrete titratable acid, in spite of the development of chronic transplant rejection in two patients. Indeed, Better et al.[24] concluded that neither rejection nor the immunosuppressive medications used at the time of their study played an important role in the urinary acidification defect that they were observing in transplant recipients. They argued that the defect observed was truly the result of ischemic injury attendant on the transplantation event and organ retrieval, which slowly resolves over time.

The natural history of RTA after renal transplantation has been best described in studies by Wilson and Siddiqui[230] in 32 patients prospectively studied for one to three years with repetitive urinary acidification testing. The authors argued that there are two clinical pictures of RTA after renal transplantation. Fourteen of the 32 patients initially had a distal RTA with an inability to reduce the urine pH below 5.3 in the face of systemic acidosis. Ten other patients initially had a systemic, hyperchloremic acidosis with depressed serum bicarbonate levels but with a normal ability to acidify the urine in the face of the acidosis. In this latter group, two patients had clearly demonstrable proximal tubular bicarbonate wasting. The presumed proximal bicarbonate wastage and the hyperchloremic acidosis disappeared or improved with time in seven of the ten patients. Partial distal defects of hydrogen ion transport with a persistent acidification defect remained in nine of the 14 patients with distal lesions. They concluded that initially after surgery, a wide variety of tubular transport defects may be found from pure forms of proximal RTA, sometimes with a complete Fanconi syndrome, to distal RTA, although a mixed defect was most commonly encountered. With a resumption of normal organ function, there is a fairly rapid recovery of the proximal tubular acidification capacity. In most patients, a distal acidification defect remains for a greater length of time with ultimate resolution in most. Those with persistent distal lesions become a management problem with respect to potassium homeostasis and healing of the metabolic bone disease of renal failure, which requires the careful attention of the astute clinician.

A second group of patients will develop new defects in renal tubular acidification because of the immunologic complications of rejection. Wilson and Siddiqui[230] also described the new appearance of a distal tubular acidification defect in patients who had no previous abnormalities of acid–base tubular homeostasis, which they suspected was due to superimposed renal rejection. Batlle et al.[18] directly studied the role of chronic rejection on hyperchloremic metabolic acidosis. In five of six carefully studied patients with chronic rejection, urine pH could not be acidified below 5.5, and the U-B PCO2 difference was not increased after a sodium sulfate buffer base infusion. A tubular defect of distal hydrogen ion secretion was found to account for this inability to acidify the urine. These investigators emphasized the development of interstitial infiltrates by round cells characteristic of chronic rejection in five of these six patients, who ultimately lost renal function. A similar pathologic picture, with the infiltration of round cells into the parenchyma associated with the development of RTA, is seen in other states of immune activation and renal infiltration by immune cells such as in Sjögren syndrome. The distal RTA of Sjögren syndrome may result from an absence of the H^+-ATPase pump, a key enzyme in distal urinary acidification by the intercalated cells of collecting ducts,[16,46] and it has been hypothesized that this deficiency may also account for the RTA of kidney transplant rejection. Jordan et al.[102] studied six kidney transplant patients with biopsy proven rejection and two control patients physiologically and by immunohistochemistry. Impaired ammonium excretion as well as impaired proton secretion with reduction in urinary PCO_2 was noted in those patients with rejection. In none of the patients was there a total absence of intercalated cell H^+-ATPase staining as seen in Sjögren syndrome, but there was an inverse relationship between the abundance of H^+-ATPase staining and degree of scarring. A direct relationship was noted in the abundance of H^+-ATPase-stained intercalated cells and 100/plasma creatinine. It may be that the tubulitis of rejection not only affects H^+-ATPase-mediated acidification by individual intercalated cells but also, via disruption of tubular anatomy, reduces the transepithelial voltage leading to defective ammonium excretion and a distal RTA. The development of secondary distal RTA may be an early sign of the immunologic process that leads to rejection.

In summary, renal tubular acidoses that affect all portions of the nephron can be observed after successful renal transplantation. Proximal tubular defects including the complete Fanconi syndrome are found most often in the perioperative period. The proximal tubular abnormality resolves as the transplant function improves. Distal tubular defects of acidification are encountered both early and late after successful renal transplantation and are the most common lesions encountered. These lesions can persist throughout the

functional life of the kidney, although they usually recede at a slower rate than the early proximal RTA. These defects have been described in patients before the introduction of calcineurin inhibitors to the immunosuppressive protocol. The nature of RTA in the transplant patient will be revisited in our discussion of the impact of immunosuppressive medications on renal function. Ischemic injury related to organ retrieval and placement has been described as the cause for the abnormalities seen early after transplantation. A second, spontaneously appearing distal RTA is seen in patients whose graft is undergoing rejection. The development of distal RTA may be an early sign that a transplant is having an immunologic insult.

SYNDROMES OF POTASSIUM HANDLING

After successful renal transplantation, potassium transport was generally normal in the precyclosporine era.[117] Postoperatively, if one did encounter a problem with potassium homeostasis, hypokalemia was frequently observed.[24,130] The most common cause for this hypokalemia is polyuria and inadequate replacement during the diuretic phase, as was discussed earlier in this chapter.[128,199] A large osmotic diuresis drives potassium into the urine and limits the tubular capacity to modulate potassium. In addition, a distal RTA and the use of relatively high doses of steroids early in the postsurgical period may contribute to the hypokalemia. These circumstances aside, persistent hypokalemia has been found to be uncommon after the immediate postoperative period.

Hyperkalemia also has been described after renal transplantation in the absence of impaired filtration, significant acidosis, potassium supplementation, or calcineurin inhibitor use. DeFronzo et al.[53] observed clinical hyperkalemia in 23 of 75 patients in the first three months following successful transplantation. Four patients of this group were studied in detail to ascertain the mechanism for their hyperkalemia. As would be expected after a successful renal transplant, these patients responded appropriately to volume and sodium challenges with respect to the renin-angiotensin-aldosterone axis. Increased distal delivery of solute achieved by a loop diuretic, by a carbonic anhydrase inhibitor, or by bicarbonate infusion did not enhance potassium excretion, suggesting that a distal sodium-potassium exchanger was defective. Therapeutic challenge with 9-fluorohydrocortisone also failed to reduce serum potassium. The failure to enhance potassium excretion by increasing the solute delivery and the impaired mineralocorticoid response pointed to impaired distal tubular potassium transport as the etiology for the observed hyperkalemia. Thiazide diuretics were able to diminish the serum potassium level and enhance potassium excretion, suggesting that this defect was not structural. Indeed, studies of these patients showed that hyperkalemia disappeared with time, further suggesting that the distal tubular defects of potassium transport may resolve as transplant function improves.

The presence of the syndrome of pseudohypoaldosteronism originally described by DeFronzo et al.[53] remains controversial, with confirmation by some and rejection by others.[96] The quoted rate of occurrence of 30% has been most vigorously challenged. In one supporting study of a 56-year-old woman with hyperkalemia, Uribarri et al.[210] found diminished kaliuresis and a marked kaliuretic response to 9-fluorohydrocortisone after successful renal transplantation. Other clinicians pointed to hypoaldosteronism in patients related to adrenal failure and renal transplantation.[178] In two such patients, low plasma renin and aldosterone levels in the salt-restricted, volume-contracted, upright posture were absent. When challenged with 9-fluorohydrocortisone, these patients had a normal kaliuretic response. Several other reports of transient hypoaldosteronism supported this initial observation by Perez and Oster[162] and Rosenbaum et al.[179] These studies suggested that after transplantation, impaired secretion of potassium from the distal tubule may appear to be due either to direct tubular dysfunction or to mineralocorticoid deficiency. This pseudohypoaldosteronism is observed early in the post-transplant period and resolves spontaneously. The functional defect can be corrected with thiazide diuretics. The hyperkalemia of true hypoaldosteronism also can appear after transplantation and responds to replacement therapy.

It is important to emphasize that although potassium-handling defects were interesting before the use of calcineurin inhibitors, their clinical significance was trivial. With the introduction of cyclosporine and tacrolimus into the immunosuppressive armamentarium, the problem of hyperkalemia has become more prominent. A complete discussion of the effect of calcineurin-inhibitor immunosuppressants on tubular handling of potassium is the subject of a later section of this chapter.

MINERAL METABOLISM STATES AFTER TRANSPLANT

Renal transplant handling of elements related to mineral metabolism is perhaps the most complex of the matters discussed in this chapter. The alterations in hormonal status and in the synthesis of regulators of these elements provided by the azotemic milieu coupled to the circumstances that surround surgery and

early patient management added to the intrinsic transplant properties contribute to several different distinct syndromes found in a temporal sequence (Table 94.1). Patients may be hypercalcemic, eucalcemic, or hypocalcemic. They may be hypophosphatemic and/or hypomagnesemic. Parathyroid gland function may be normal or exhibit persistent secondary hyperparathyroidism or rarely autonomous function (tertiary hyperparathyroidism). Renal hydroxylation of vitamin D may be subnormal early or normal late. The tubule may intrinsically leak phosphate, calcium or magnesium. This section attempts to isolate these factors and provide a context for understanding the impact of renal transplantation on renal metabolic bone disease.

Almost all allograft recipients have some degree of secondary hyperparathyroidism, which may be unmasked, when the transplant is placed. Serum PTH concentrations decrease progressively during the first three to six months after grafting;[103] however, 1 year after transplantation, resolution of hyperparathyroidism is incomplete in 50% of recipients.[125] Pretransplant factors associated with persistent secondary hyperparathyroidism after kidney transplantation include duration of dialysis, parathyroid gland size, and the development of nodular hyperplasia of parathyroid glands.[110] Due to the long lifespan of parathyroid cells of approximately 20 years and the cell renewal rate of approximately 5% per year, the process of involution of the parathyroid glands may take from a few months to several years. Incomplete normalization of renal function, suboptimal levels of calcitriol and decreased intestinal calcium absorption secondary to corticosteroid therapy also may contribute to the high PTH concentrations after transplant.[207] In great measure, the impact of persistent hyperfunction of the gland characterizes renal handling of ions important for mineral metabolism in transplant recipients.

TABLE 94.1 Mineral Metabolic States After Transplant

Hypercalemia
Persistent secondary hyperparathyroidism
Tertiary hyperparathyroidism
Tubular phosphate leak
Calcium-containing antacids
Low or normal calcemia
Early
High-dose steroids
1,25-dihydroxy vitamin D
Late
Normal renal function
Tubular calcium leak
Hypophosphatemia
Early
Persistent secondary hyperparathyroidism
High-dose steroids
Antacids
Late
Persistent secondary hyperparathyroidism
Tubular phosphate leak
Hypomagnesemia
Early
High-dose steroids
Diuretics
Late
Cyclosporine A

During the initial period of graft function, hypercalcemia is commonly observed due to the effect of hyperparathyroidism.[137] High PTH concentrations stimulate the renal production of calcitriol leading to increased intestinal calcium absorption and improved skeletal mobilization of calcium. Additional factors contributing to the resolution of the skeletal resistance to PTH include correction of uremia and normalization of serum phosphorus levels, thus facilitating the release of calcium due to osteoclastic bone resorption. Finally, resorption of soft tissue calcifications can contribute to the post-transplant hypercalcemia.

Transient hypercalcemia post-transplant is common, and spontaneous resolution occurs in most cases within one year after grafting. In approximately 5–10% of recipients, hypercalcemia persists beyond the first year but resolves gradually within two to five additional years.[129] Such persistent mild hypercalcemia is usually well tolerated and not associated with untoward effects on the allograft. If severe hypercalcemia (>12 mg/dl) is encountered post-transplant, complications including renal dysfunction, nephrocalcinosis, pancreatitis and vascular calcifications become significant risks and may require elective parathyroidectomy.

During the initial period of graft function, hypercalcemia is commonly observed due to the effect of hyperparathyroidism.[137] Despite elevated PTH levels, the gland retains its capacity to respond to short-term administration of calcium by downregulation of PTH formation and release.[134] The higher levels of ionized calcium required to suppress PTH secretion show that the parathyroid gland has an altered "calcium stat" (Fig. 94.4). In spite of successful renal transplantation, the parathyroid gland continued to require a higher threshold of ionized calcium to suppress function

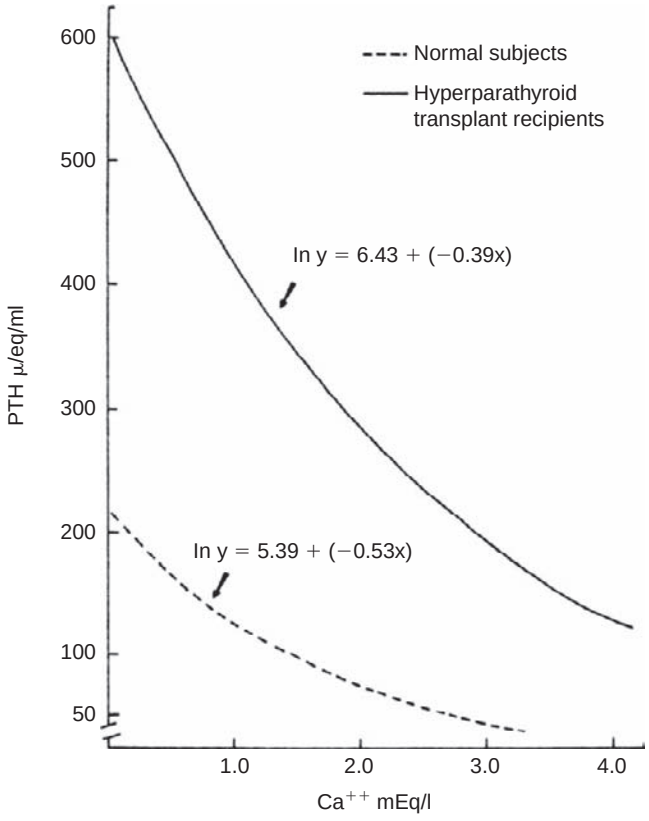

FIGURE 94.4 Parathyroid gland responsive to calcium infusion in renal transplant recipient compared with normal. *(With permission from American Society for Clinical Nutrition, McCarron DA, Bennett WM, Muther RS, Barry JM, Krutzik S. Post transplantation hyperparathyroidism: demonstration of retained control of parathyroid function by ionized calcium. Am J Clin Nutr 1980;33:1536–1540.)*

completely.[134] In this circumstance, the higher serum calcium sometimes found in these patients is a consequence of an appropriate response to the fixedly elevated PTH concentration and reset threshold. Other potential causes for hypercalcemia include calcium-containing antacids used to prevent the ulcerogenic potential of high-dose steroids used during the early post-transplant period.[184] Additionally, if serum calcium levels are unable to reach the new set-point for gland suppression parathyroid hyperfunction will continue.[135] There is also the potential for the loss of suppressive ability that calcium has on parathyroid gland function. This conversion from what is called "secondary" to what has been labeled "tertiary" hyperparathyroidism can occur before the transplant surgery or thereafter, but is a rare event. If allowed to continue without surgical reduction in gland mass, tertiary hyperparathyroidism can cause persistent hypercalcemia and hypophosphatemia at a cost primarily to bone mineralization.[135]

Normal or even low levels of serum calcium after successful transplantation in the face of elevated PTH have also been encountered. Confounding variables that characterize the early post-transplant period, which can impair gut absorption of calcium, include high doses of steroids used to prevent rejection[88] and inadequate hydroxylation of vitamin D by the transplant.[184] That the "normal" or low levels of calcium often persist in the setting of persistent elevation of PTH levels, even when gut absorption of calcium returns toward normal as prednisone is reduced and the graft hydroxylation of vitamin D normalizes, suggests the presence of additional alterations in calcium metabolism. By using isotopic calcium excretion studies, Sakhaee et al.[184] were able to show that a primary tubular calcium leak occurred in such patients in spite of normal or even elevated PTH levels, normal 1,25-dihydroxy vitamin D levels, and normal intestinal absorption of calcium. This primary calcium leak provides a persistent stimulus for PTH generation, explaining the measured abnormalities, in part, years after successful transplantation in some patients.

Of all the reported electrolyte abnormalities that follow renal transplantation, hypophosphatemia is the most commonly encountered,[82,93,127,222] occurring in up to 93% of patients during the first few months after transplantation.[67] Although this phenomenon is usually limited to the early post-transplant period, hypophosphatemia may persist for more than 10 years.[69] Traditionally, several pathogenic factors have been implicated in the development of post-transplant hypophosphatemia including persistent hyperparathyroidism, relative deficiency of calcitriol, use of glococorticoids. Pabico and McKenna[158] reconfirmed the findings of McCarron et al.[134,135] with respect to responsiveness of the parathyroid glands to calcium infusions and extended those findings to examine tubular handling of phosphate. Despite an elevated parathyroid hormone level in the six study patients, an infusion of 15 mg/kg of ionized calcium over 3 hours raised serum calcium into the normal range, lowered serum PTH toward normal levels, and diminished urinary cyclic AMP appropriately. Serum phosphorus rose commensurate with an increase in tubular reabsorption of phosphorous (TRP) reflecting the relationship between TRP and PTH levels. Parfitt et al.[161] confirmed the possibility that a primary leak of phosphorus existed in their study of a group of transplant patients with normal serum calcium, slightly elevated parathyroid hormone level, and normal urinary cyclic AMP, but high tubular rejection rates of phosphorus as a function of glomerular filtration rate. These two studies make several points in general and about phosphorus as a function of glomerular filtration rate. These two studies make several points in general and about

phosphate handling in particular. Transplant impact on mineral metabolism is complex. In most, there is persistent hyperparathyroidism even after successful renal transplantation, whichh is responsive to calcium infusion albeit with a higher calcium stat or setpoint. Second, phosphorous handling by the tubule in some reflects PTH levels and in others reflects a primary tubular leak as clearly shown by Graf et al.[82]

These effects may be compounded by the use of immunosuppressive, antacid and diuretic drugs. Micropuncture studies performed on Sprague-Dawley rats by Frick et al.[72] suggest that glucocorticoids may cause an increased tubular rejection of phosphorus in the proximal tublule. Rats receiving a diet stable in calcium and phosphorus infused with a modified Ringer's lactate solution, which contained an increased dose of inorganic phosphorus, while receiving 0.03 mg/kg/min of hydrocortisone 90 minutes before micropuncture reabsorbed only 29% of the filtered phosphorus load in the proximal convoluted tubule, as opposed to 41% proximal tubule reabsorption in a control group. Another confounding variable in the equation of post-transplant hypophosphatemia is the frequent, often indiscriminate use of antacids. These agents bind phosphate in the gut lumen and prevent absorption.[184] The decreased intestinal absorption magnifies the hypophosphatemia owing to the PTH effect at the tubule and to the intrinsic tubular phosphorus leak. It has become clear in the face of recent data, that none of these factors can explain hypophosphatemia in its entirety. Recently, a new family of phosphorus-regulating hormones termed "phosphatonins" have been described that may play an important role in the pathophysiology of phosphorus wasting in the post-transplant period.

Although elevated PTH levels are noted in the majority of patients after kidney transplantation, a growing body of evidence suggests that it is not the primary cause of defective renal phosphorus reabsoprtion. In one study, identical serium PTH levels were observed in post-transplant recipients with normal and low serum phosphorus concentrations.[180] In addition, suppression of PTH levels with intravenous calcium infusion failed to normalize serum phosphorus concentration and fractional excretion of phosphorus in those sujbects with hypophosphatemia. Further support suggesting a non-PTH humoral mechanism in the development of hypophosphatemia came from an in-vitro study using opossum kidney cells incubated with sera from end-stage renal disease, chronic kidney disease and recipents both "early" (two weeks to one month) and "late" (9 to 12 months) post-kidney transplant.[83] Sodium-dependent phosphorus transport was measured by radioactive phosphorus flux. There was significant inhibition of Na^+-dependent phosphorus transport in those with ESRD, CKD and early post-transplant which persisted following the addition of a bovine PTH inhibitor. It was hypothesized that a humorally mediated adaptation mechanism maintains phosphorus homeostasis in renal failure by inhibiting phosphorus transport and sodium/phosphorus activity along the proximal tubule. Persistence of this putative circulating factor for some time following successful transplantation could therefore lead to hypophosphatemia accompanied by increased phosphaturia. Exciting work by several groups[13,67] have suggested that fibroblast growth factor-23 (FGF-23) may be one such factor.

FGF-23 induces phosphaturia and inhibits renal 1-α hydroxylase leading to decreased calcitriol synthesis.[189] Recent studies have shown that FGF-23 levels increase as CKD progresses and contribute to the declining calcitriol levels observed.[86,121] In a prospective longitudinal study of 27 patients undergoing living donor kidney transplantation, 85% developed hypophosphatemia, including one who had previously undergone parathyroidectomy.[13] Although FGF-23 levels decreased after transplantation, the levels remained significantly above mean levels reported in healthy individuals. FGF-23 was independently associated with serum phosphate, urinary excretion of phosphate and calcitriol levels. PTH was not independently associated with any of these parameters. This data has been corroborated by others[67,66] and the term "tertiary hyperphosphatonsim" coined. In longitudinal follow-up of renal transplant recipients, FGF-23 declined over time with regression of renal phosphorus wasting.[66] Taken together, it is reasonable to conclude that high FGF-23 levels that developed as a compensatory mechanism with worsening kidney function, persist post-transplant and contribute to the hypophosphatemia and phosphaturia noted in the early-transplant period. Other phosphatoninins have recently been described including secreted frizzled related protein-4 (sFRP-4), matrix extracellular phosphoglycoprotein (MEPE) and FGF-7.[22,181] Their physiologic role in kidney transplant recipients remains to be determined.

Hypophosphatemia may be compounded by the use of immunosuppressive, antacid and diuretic drugs. Micropuncture studies performed on Sprague-Dawley rats by Frick et al.[72] suggest that glucocorticoids may cause an increased tubular rejection of phosphorus in the proximal tubule. Rats receiving a diet stable in calcium and phosphorus infused with a modified Ringer's lactate solution, which contained an increased dose of inorganic phosphorus, while receiving 0.03 mg/kg/min of hydrocortisone 90 minutes before micropuncture reabsorbed only 29% of the filtered phosphorus load in the proximal convoluted tubule, as opposed to 41% proximal tubule reabsorption in a

control group. Another confounding variable in the equation of post-transplant hypophosphatemia is the frequent, often indiscriminate use of antacids. These agents bind phosphate in the gut lumen and prevent absorption.[184] The decreased intestinal absorption magnifies the hypophosphatemia owing to the PTH effect at the tubule and to the intrinsic tubular phosphorus leak.

Clinically, patients may present with muscle weakness and osteomalacia when the plasma phosphate concentration is below 1.4 mg/dl. Although severe phosphate depletion with phosphate concentrations below 0.9 mg/dl is rare, it may lead to hemolytic anemia, rhabdomyolysis, decreased myocardial contractility, and respiratory failure. Oral phosphate supplements are capable of normalizing the serum phosphate concentrations after transplantation. Furthermore, the administration of neutral phosphate increases net acid excretion and may lead to a more rapid recovery of the latent metabolic acidosis observed during the early post-transplant period.

Both hypercalcemia and hypophosphatemia are metabolic conditions that may have profound effects on urinary acidification and systemic acid−base status. Studies in animals and humans show that acute infusion of synthetic PTH results in increased proximal tubular bicarbonate wasting and decreased net acid excretion.[9] In a study of artificially induced hyperparathyroidism in normal humans, which is analogous to placing a healthy allograft in a patient with hyperparathyroidism, Hulter and Peterson[98] showed that normal healthy male patients who were fed a stable diet and infused with synthetic PTH at a dose of 6800 U/mg for a period of 12−13 days exhibited a transient, early, mild hyperchloremic metabolic acidosis due to inhibition of proximal tubule bicarbonate regeneration and to a decrease in net titratable acid excretion. When a new steady state was achieved in which net acid returned to normal and plasma bicarbonate levels were elevated, the acidosis was terminated, and subjects were left in a mild metabolic alkalosis. These results oppose the clinical observation that hyperparathyroidism is associated with persistent metabolic acidosis. Although high serum levels of PTH can transiently produce metabolic acidosis because of bicarbonate rejection and a decrease in net acid excretion, the renal or extrarenal mechanism that propagates this metabolic acidosis related to persistently elevated PTH remains uncertain.

Alterations in magnesium homeostasis after transplantation can also be directly related to hyperfunction of the parathyroid gland.[187] This having been said, multiplicities of factors that make up the transplant experience alter the direct relation between excess PTH and magnesium level. Variations in serum levels of magnesium are importantly related to magnesium intake. The protein and caloric malnutrition frequently encountered before and after transplantation is a contributor to magnesium homeostasis.[221] During the early post-transplant period, steroid therapy[130] and diuresis[130] contribute to the hypomagnesaemia. Additionally, hypercalcemia can reduce tubular reabsorption of magnesium, leading to magnesium wasting.[130] Although hypomagnesemia is commonly seen after transplant, it has rarely been of clinical consequence until the use of calcineurin inhibitors. The effects of the calcineurin inhibitors on the handling of magnesium will be discussed later in the chapter.

In summary, the disorders of divalent ion metabolism after transplantation are a function of three factors. The first factor relates to the background into which a working renal transplant is placed, with nutritional status and even more important, persistence of secondary hyperparathyroidism. The second factor is that drugs used after transplant affect the modulation of divalent ions. Finally, the third factor is that intrinsic abnormalities of tubular handling of calcium and phosphorus by recently identified phosphatonins can impair the maintenance of normal mineral metabolite levels and worsen any single abnormality. Taken together, all can synergistically contribute to the development of osteodystrophy and increased cumulative incidence of fractures post-kidney transplant.

HANDLING OF URATE AFTER TRANSPLANT

Hyperuricemia is a common complication of renal transplant with gout affecting approximately 2−13% of patients.[43] Several factors may contribute to the high prevalence of hyperuricemia and gout. Renal allograft recipients are prone to hypertension and edema, and diuretics are frequently used in their management. Both loop and thiazide diuretics reduce uric acid excretion, presumably by causing mild volume depletion with consequent enhancement of proximal tubular reabsorption. Also, loop agents may compete with uric acid for secretion by the proximal organic acid transporter. Delayed graft function or the development of chronic allograft nephropathy may contribute to the impaired excretion of uric acid. However, a correlation between serum creatinine or creatinine clearance and serum urate levels has not always been found.[81,226] When uric acid handling was examined in patients with functioning kidney transplants in the period before widespread use of calcineurin inhibitors, no consistent abnormalities in fractional reabsorption or excretion of uric acid emerged arguing against any specific impairment in uric acid excretion inherent to the

transplant itself.[24] It is clear that the greatest risk of hyperuricemia and gout can be attributed to the use of calcineurin inhibitors. The mechanisms by which cyclosporine and tacrolimus contribute to the altered handling of uric acid by the transplanted kidney will be discussed in subsequent sections.

RENAL TRANSPORT AND IMMUNOSUPPRESSIVE DRUGS

Successful allograft transplantation requires acceptance of the grafted tissue by the immune system of the host. For nearly all patients, some form of immunosuppressive medicine to maintain graft survival is required. Although an array of physiologic derangements can be a consequence of immunosuppressive therapy, most patients with successful transplants exhibit essentially normal renal functional characteristics. Studies by Lewis et al.[123] and Blaufox et al.[29] in recipients of live-related transplants after bilateral nephrectomy revealed normal exchangeable sodium and potassium in spite of immunosuppressive therapy with prednisone and azathioprine. Balance studies on both high (200 mEq/day) and low (10 mEq/day) sodium diets showed balance was achieved in all patients within four days. Almost all studies that have examined the renin-angiotensin-aldosterone system in nonhypertensive renal transplant recipients with stable graft function have found that the conventional immunosuppressive protocol of prednisone and azathioprine do not affect the kidney's ability to modulate plasma renin activity when GFR is maintained.[28,84,105,112,113,196]

Having just delineated the general failure to relate tubular transport abnormalities to drug regimens in the past, one must yet uncover those instances of pathophysiology that flow directly from drug therapy. Glucocorticoids have been the backbone of the various regimens used to prevent rejection of the allograft and frequently are employed to reverse the process once underway. Since most patients are maintained on glucocorticoids in the initial post-transplant period, the impact of these agents on renal function is important. No direct studies have been undertaken to define the effects of glucocorticoids on renal allograft transplant function. One must posit a set of drug related changes based indirectly on studies in normal subjects. Studies by Connell et al.[47] of renal function in such normal humans who receive cortisol at a dose of 50 mg every 6 hours over five days showed an increase in GFR to 113% based on insulin clearance. This increase was not found when creatinine clearance was measured.[47] They proposed that the increase in creatinine turnover due to cortisol limited the usefulness of creatinine as a measure of GFR.[47] The exact cause for this increase in GFR induced by glucocorticoids is unknown, but micropuncture studies in rats show that both pre- and postglomerular arterioles are vasodilated, suggesting that the exuberant GFR is a consequence of increased glomerular flow.[19] The cortical collecting tubule responds to the mineralocorticoid activity of the high-dose prednisone, the form of steroid almost exclusively employed in transplantation, by reabsorbing sodium in exchange for potassium and hydrogen ions.[107] The nephron escapes from the sodium retention by decreasing sodium reabsorption in segments other than the cortical collecting tubule.[103] The escape is characterized by increased renal arterial pressure transmitted to the microcirculation, which contributes to decreased sodium reabsorption, by the proximal tubule.[87] The relationship of steroids to calcium absorption in the gut, phosphorus wasting in the kidney, and potassium handling has been previously discussed.

Antibodies directed to lymphoid elements are directly used to induce graft acceptance along with glucocorticoids during initiation of immunosuppression therapy and to reverse episodes of rejection. Polyclonal preparations have no known direct effect on tubular function. On the other hand, initial doses of the monoclonal preparation OKT3 result in a wave of IL-2 and TNF release, which alters intra renal blood flow and can produce systemic hypotension and a pre-renal state that can result in a fall in GFR and fall in fractional excretion of sodium if severe enough.[1,164] One can observe in treated patients an actual increase in serum creatinine, an increase in filtration fraction, and pathologic synergy with other nephrotoxins. The powerful capacity of the drug to reverse acute rejection has generated a search to block the physiologic derangements rather than abandon the use of this agent. Early studies with blockade of TNF have shown great promise.[70]

The introduction of the potent calcineurin inhibitor agents such as Cyclosporine A and tacrolimus have so greatly improved graft survival as to make their use almost ubiquitous for maintenance of renal as well as extrarenal organ transplants. These agents have profound effects on renal physiology, coloring greatly the function of the kidney already altered by circumstances of engraftment. The effects of the calcineurin inhibitors on the kidney are observed when the kidney is the engrafted organ, but functional alterations in renal function are described in patients receiving these agents for extrarenal organ transplantation as well.[160] A complete discussion of the renal effects of the calcineurin inhibitors then is essential to any full discussion of the impact of immunosuppressive drug therapy on transplant physiologic function.

Cyclosporine A is a profound regulator of renal blood flow and of glomerular filtration rate.[50] Cyclosporine A universally reduces the glomerular filtration rate in all patients receiving the drug whether for transplantation or for disorders in which the immune system is thought to play a role.[55,63,188] Using glomerular micropuncture, Barros et al.[15] have demonstrated that acute intravenous administration of cyclosporine A at a dose of 50 mg/kg in the Munich-Wistar rat causes intense efferent arteriolar vasoconstriction. Additionally, there is an increase in afferent arteriolar resistance, which results in an increase in mean glomerular capillary hydrostatic pressure. These findings coupled to a fall in glomerular ultra-filtration coefficient culminate in a fall in both single nephron and total glomerular filtration rates. Although effective renal blood flow decreases, Barros et al.[15] found that the filtration fraction increases or does not seem to be altered suggesting to those investigators that the major site of action of cyclosporine is at the efferent arteriole.

Some have dismissed the findings of Barros et al.[15] because of the high dose (50 mg/kg) of cyclosporine A used. But the rat is resistant to cyclosporine and doses of this magnitude are required for immunosuppression. Unfortunately, these doses lead to whole animal dysfunction, characterized by anorexia, weight loss, and volume depletion, which color the interpretation of many rat studies.[204] Micropuncture studies performed by Thomson et al.[206] used pair-fed controls and plasma volume expansion to minimize these effects of cyclosporine A. In male Munich-Wistar rats receiving cyclosporine A at a dose of 30 mg/kg for 8 days prior to study, Thomson et al.[206] were still able to demonstrate an important decrease in single-nephron GFR and in glomerular capillary hydrostatic pressure gradient without a substantial change in glomerular ultrafiltration coefficient (LpA). The partitioning of resistance between afferent (AR) and efferent (ER) arterioles in the cyclosporine A–treated rats showed a higher AR-ER ratio than compared to their controls. In contrast to the conclusions of Barros et al.[15] Thomson et al.[206] concluded that the hemodynamic changes related to cyclosporine A are focused at increases in afferent arteriolar resistance.

Using a similar pair-fed control study, English et al.[62] measured the effect of chronic cyclosporine A dosage of 50 mg/kg in male Fisher rats on glomerular filtration rate, fractional sodium and lithium excretions, as well as on arteriolar diameter by vascular perfusion cast examination (Fig. 94.5). After 14 days of cyclosporine A, there was a decrease in GFR and luminal diameter of the afferent arterioles as measured by scanning electron microscopy decreasing to 8.9 (± 0.4) as compared to 13.5 (± 0.4) in pair-fed controls. The study further supports the theory that the afferent arteriole is the major site of cyclosporine A vasoconstriction. Thus, cyclosporine acutely and chronically reduces GFR owing to its impact on the elements of glomerular hemodynamics. Vasoconstriction of all contractile elements can be found with the effect on the afferent arteriole of largest magnitude.

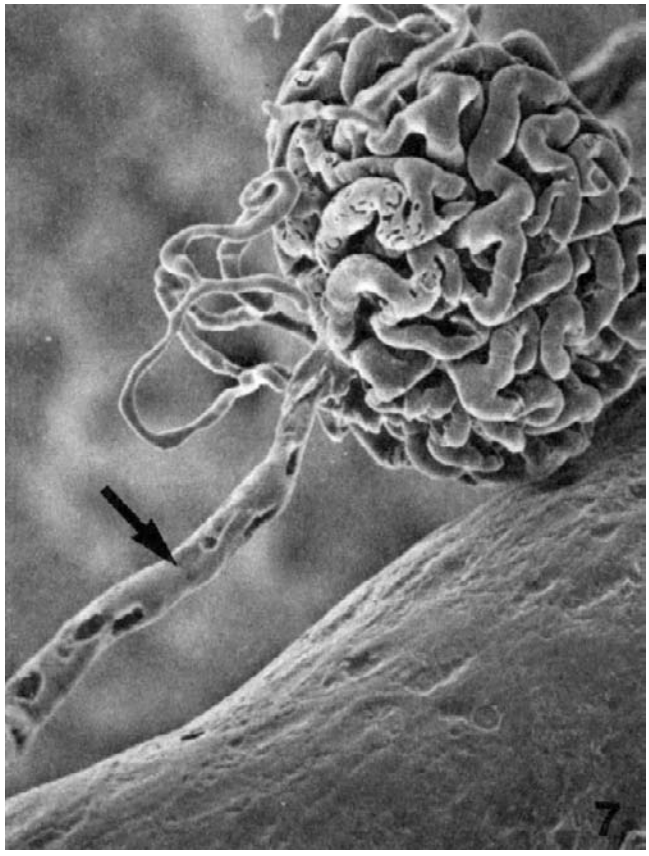

FIGURE 94.5 After 14 days of cyclosporine treatment, the entire length of an afferent arteriole (arrow) shows narrowing. *(From English J, Evan A, Houghton DC, Bennett WM. Cyclosporine induced acute renal dysfunction in the rat: evidence of arteriolar vasoconstriction with preservation of tubular function. Transplantation 1987;44:135–141.)*

In addition to drug-induced reductions in GFR is the almost universally encountered decline in renal blood flow. The exact cause of this decrease in renal blood flow is uncertain, but several possible mechanisms can be discerned from well-described cyclosporine effects. The renal blood flow may be constrained because of (1) the acute stimulation of the renin-aldosterone-angiotensin axis; (2) alterations in arachidonic acid metabolism; (3) increase in T-G feedback; (4) endothelin release; (5) stimulation of the autonomic nervous system (Table 94.2). Perico et al.[163,165] proposed that the infusion of cyclosporine A at a dose of 25 mg/kg for 20 or 45 days in rats resulted in an increase in plasma renin activity associated with a fall in GFR. There is also direct renin release by rat

juxtaglomerular cells grown in culture after cyclosporine A exposure confirming activation of this system after acute administration of drug.[118] The importance of cyclosporine A stimulation acutely of the renin-aldosterone-angiotensin axis is further supported by the micropuncture studies by Barros et al.[15] in which cyclosporine A effects on GFR and renal blood flow were markedly ameliorated when an angiotensin converting enzyme inhibitor was infused. Because angiotensin converting enzyme inhibition did not completely abrogate the glomerular hemodynamic effects of cyclosporine A, the authors suggest that the renin-aldosterone-angiotensin axis is only partially responsible for the fall in renal plasma flow and GFR. Taken together, these studies suggest that during the acute phase of cyclosporine A effect on the tubule, there is an increase in the activity of the renin-aldosterone-angiotensin axis. The actual contribution of this system to the reduction in effective renal plasma flow is currently in debate.

There is no uniformity of view with respect to the etiologic role of the renin-aldosterone-angiotensin axis in cyclosporine-induced reduction in GFR, however, Dieperink et al.[56] in Copenhagen confirmed that rats treated with cyclosporine A at a dose of 25 mg/kg for 13 days prior to the study exhibited an appropriate fall in GFR and renal plasma flow, but they failed to reproduce the salutary effect of captopril on renal plasma flow or glomerular filtration as compared to untreated cohorts. Furthermore, studies attempting to stimulate the renin-aldosterone-angiotensin axis by diuretics or low salt intake show a blunted response in renin plasma activity in the face of cyclosporine A use.[51,91,195] Weir et al.[225] showed in normal healthy humans that an acute infusion of cyclosporine A at a dose of 4 mg/kg resulted in an appropriate reduction in GFR from 108.8 (± 2.5) ml/min to 9.1 (± 2.2) ml/min, a dose that led to no significant changes in renal plasma flow or systemic blood pressure. It was noted that during the period of reduced GFR, there was no change in plasma renin activity, angiotensin II, or aldosterone levels compared to the controls.

A second theory advanced to explain the fall in GFR after cyclosporine A administration is attributed to an increase in T-G feedback that has been measured.[79] Histologic studies of kidneys after cyclosporine A administration in both rats and humans show a hypertrophy of juxtaglomerular cells after cyclosporine A administration.[217] A mechanism for the increase in T-G feedback has been proposed by Gnutzmann et al.[79] based on micropuncture studies of the thick ascending limb of the loop of Henle in Munich-Wistar rats receiving an acute infusion of cyclosporine A at a dose of 15 mg/kg. Gnutzmann et al.[79] found an increased delivery of sodium and chloride to the thick ascending limb and the early distal tubule, which should be sensed by the macula densa adjacent to the thick ascending limb stimulating the T-G feedback mechanism in order to decrease GFR.[79]

The third theory advanced to explain the manner in which cyclosporine A alters renal blood flow is related to the ability of the drug to alter eicosanoid synthesis leading to an increased generation of the vasoconstrictor metabolites.[20] In a postischemic denervated rat model in which cyclosporine A was administered at a dose of 50 mg/kg over 12–14 days, Coffman et al.[44] uncovered an increase in the renal excretion of TXB2 associated with a fall in the clearance of insulin and in renal blood flow. There was no associated increase in PGE2 excretion during this period of decreased renal blood flow. Additionally, when arachidonic acid was perfused to stimulate eicosanoid production during the cyclosporine A–induced altered physiology there was an increased production of TXB2 in both the study and control animals, but the PGE2 production was also greatly increased in the cyclosporine A–treated animals as compared to controls (Fig. 94.6).[44] This suggests that the cyclosporine A–induced inhibition of PGE2 production can be overcome by increased concentrations of the precursor. These results are corroborated by studies in humans by Weir et al.[225] in which acute infusion of cyclosporine A (4 mg/kg over a six-hour period) resulted in a reduction of the GFR without affecting renal plasma flow as would be suggested by predominant vasoconstriction at the locus of the afferent arterial associated with an increase in urinary excretion of the TXA2 metabolite TXB2 without a correlative increase in 6-keto prostaglandin F1A.[225] During the period of study, there was no measured increase in circulating levels of TXB2, suggesting that the increased urinary levels of this TXA2 metabolic originated from the kidney.[225] In another study by Petric and colleagues, it has been demonstrated that urinary TXB2 excretion increased significantly following cyclosporine administration in Sprague-Dawley rats.[167] A concomitant rise in proximal tubular sodium reabsorption was observed as well as an increase in the excretion of urinary PGE2 and 6-keto-prostaglandin F2I without a change in plasma levels. Functional

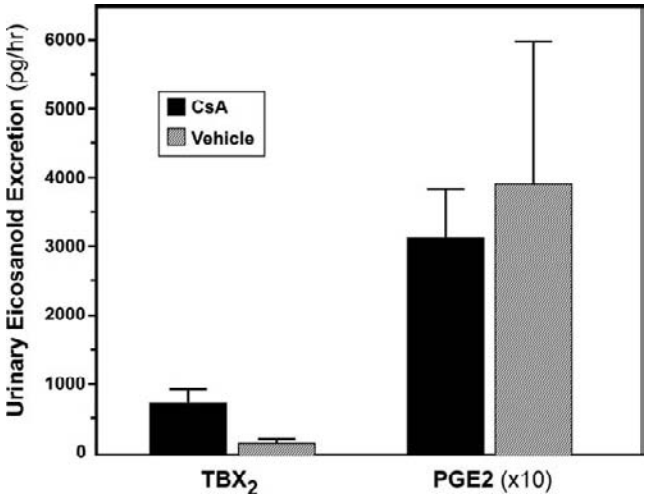

FIGURE 94.6 Urinary excretion of thromboxane B2 (TXB2) was significantly elevated in rats treated with cyclosporine versus controls ($p < 0.025$). There was no difference in prostaglandin E2 (PGE2) excretion in cyclosporine-treated rats when compared with controls. The measured levels of PGE2 are 10 times the values graphically represented *(Adapted from Coffman TM, Carr DR, Yarger WE, Klotman PE. Evidence that renal prostaglandin and thromboxane production is stimulated in chronic cyclosporine nephrotoxicity. Transplantation 1987;43:282–285.)*

changes accompanied to these biochemical changes were a decrease in renal blood flow, and in the clearance of creatinine and urea. Renal morphology showed severe vacuolization and necrosis confined to the proximal tubular region of the cortex.

The exact source of the altered eicosanoid production related to cyclosporine toxicity is unclear but may reflect cyclosporine A alteration of immune cell metabolism rather than of the graft itself. Cyclosporine A has been shown to increase thromboxane production in inflammatory cells aspirated from renal allografts[177] as well as in vascular endothelial cells[150] while decreasing prostaglandin production in isolated glomerular cells grown in culture.[194] Various experimental drugs that further block thromboxane synthesis[190] or stimulate intrinsic prostacyclin synthesis while inhibiting thromboxane production[200] have been shown to reduce cyclosporine nephrotoxicity. The blunted response in PGE2 excretion associated with an increase in thromboxane B2 excretion in cyclosporine A–treated rats as a function of increase renal vascular resistance when compared to controls suggests that cyclosporine A causes a shift in arachidonic acid metabolism from the production of prostaglandins such as PGE2 and prostacyclin to the vasoconstricting TXA2.[44]

The role of the very potent vasoconstrictor peptide endothelin in renal transplantation was explained by Badr et al.[12] who showed that infusion of endothelin at a dose of 10 pmol/min decreased renal blood flow by 40% in micropunctured rats associated with sharp increases in afferent arteriolar resistance (65%) and efferent arteriolar resistance (82%) accompanied by a reduction in ultrafiltration coefficient to a third of its preinfusion value. There is marked similarity between the endothelin effect on glomerular hemodynamics and the picture presented by Badr et al.[12] for that of acute cyclosporine A infusion. Kon et al.[164] were able to show in Munich-Wistar rats receiving high-dose cyclosporine infusion a substantial increase in circulating endothelin of almost 30-fold associated with the expected fall in single-nephron GFR. When a rabbit antiporcine endothelin serum was infused concomitantly with cyclosporine A, thus blocking the endothelin receptor sites, there was no significant difference in single-nephron glomerular filtration as compared to preinfusion levels. Further supporting these tantalizing findings relating endothelin-induced alterations in renal function to cyclosporine A was the study of Perico et al.[164] using the isolated perfused rat kidney model. A rabbit anti-rat endothelin antibody given prior to cyclosporine A infusion blunted reductions in renal blood flow and GFR in this second model (Fig. 94.7). To close the intellectual loop, Kon et al.[164] in cows and Bunchman and Brookshire[34] were also able to inhibit the release of endothelin by concomitant calcium channel blockade, angiotensin converting enzyme inhibition, and cyclooxygenase inhibition.[164] These studies taken together point strongly to endothelin as a partial culprit in the acute, early reduction in renal blood flow associated with cyclosporine A toxicity, and possible mechanisms to explain the clinical observations relating cyclosporine A toxicity sparing effects of certain treatments. It remains to be seen if the more chronic reduction in GFR found with cyclosporine A use can be related as well to endothelin.

A discussion of the effect of cyclosporine A on renal blood flow would not be complete without mentioning direct stimulation of the sympathetic nervous system. In the use of cyclosporine A for nonrenal transplants or other immune disorders, such direct stimulation may add importantly to those causes of reduction in GFR and renal blood flow already discussed. Denervation, a consequence of renal transplant surgery, protects the renal transplant from this cyclosporine A effect as shown by Moss et al.[141] Using a unilateral denervation rat model, they were able to show that acute infusion of cyclosporine A 10 mg/kg resulted in an increase in afferent renal nerve activity by 82% associated with a fall in effective renal blood flow in the innervated side without any noticeable alterations in the denervated side.[141] Murray and Paller[147] were able to reproduce the observation that denervation protects the kidney from cyclosporine A–induced alterations in renal blood flow associated with sympathetic activation, and

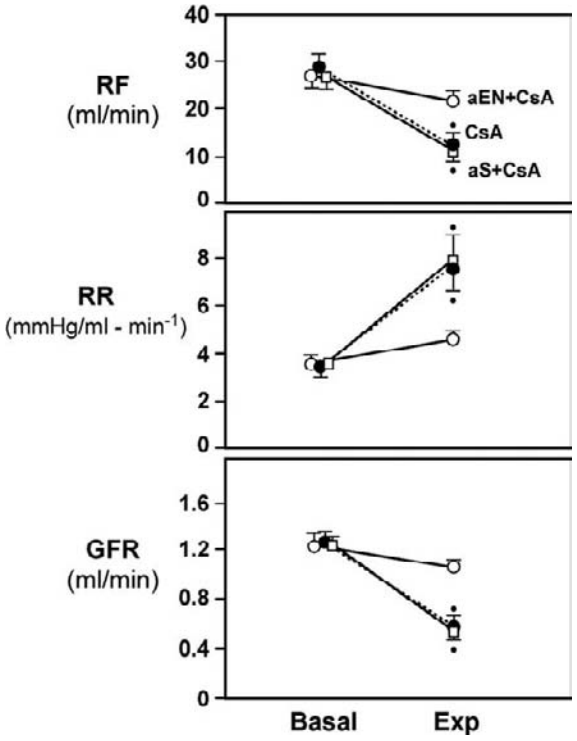

FIGURE 94.7 Effect of cyclosporine (CsA) on renal function parameters in isolated kidneys preexposed to antiendothelin antibody (aEN), nonimmunized rabbit serum (aS), or vehicle. Data represent average values of the two control clearance periods (basal) and the four experimental periods after challenging the kidney with CsA. Values expressed as mean plus standard deviation. p <01, versus aEN+++CsA. *(From Perico N, Dadan J, Remuzzi G. Endothelin mediates the renal vasoconstriction induced by cyclosporine in the rat. J Am Soc Nephrol 1990;1:76–83.)*

they were able to prevent some of the fall in renal blood flow to the innervated kidney through a chemical sympathectomy using an adrenergic antagonist. The decrease in effective renal blood flow that cyclosporine A may induce as a result of the activation of the sympathetic nervous system would therefore not be experienced by the kidney immediately after transplantation. Cyclosporine A–induced activation of the sympathetic nervous system may be an additional mechanism by which renal blood flow is reduced when that drug is used for autoimmune disease or for transplantation other than the kidney. Cyclosporine A may alter renal hemodynamics through the stimulated sympathetic nervous system remotely after transplantation either through hyper responsiveness to adrenergic receptors within the chronically denervated kidney or through regeneration of renal innervation.[141,147] The isolated perfused rat kidney was used to study the acute effects of cyclosporine A and its metabolites by Roby et al.[176] Metabolite levels can greatly exceed parent drug levels, especially in patients with abnormal liver function. Interestingly, all of the metabolites caused significant reductions in GFR, some even in very low concentrations, which may be an important and unrecognized factor in cyclosporine-induced nephrotoxicity. Cyclosporine metabolites did not increase tubular potassium reabsorption.

Renal tubular acidification capacity was studied in 12 patients treated with cyclosporine for idiopathic uveitis and in 5 patients with idiopathic uveitis not treated with cyclosporine, thus with intact native kidney function.[2] After intravenous bicarbonate loading fractional excretion was similar in both groups indicating normal proximal tubular acidification function. Plasma renin activity, plasma aldosterone and transtubular potassium gradient were similar in both groups. On the other hand, distal hydrogen ion secretion evaluated by the ability to increase U-B PCO2 in highly alkaline urine was impaired in cyclosporine-treated patients as compared to controls suggesting a distal acidification defect associated with cyclosporine therapy. Quereda and colleagues studied the response of urinary acidification parameters and electrolytes to furosemide administration in nine psoriatic patients treated with low-dose cyclosporine (5 mg/kg).[173] The post-furosemide urinary pH decrease and ammonium and titratable acid increase were significantly lower in cyclosporine-treated patients suggesting an abnormal distal tubular response to furosemide and a possible alteration in the H^+-ATPase pump associated with cyclosporine use.

In addition to the striking changes in renal blood flow and GFR, cyclosporine A may have direct effects on renal tubular transport capacity thought to be a consequence of cellular toxicity.[138] There are well-described morphological changes in the proximal tubular cells related to high concentrations of cyclosporine A in rats and humans such as tubular inclusions by isometric, ubiquitous vacuolization, and tubular microcalcifications.[138,216] Whiting et al.[229] evaluated evidence of functional correlates to observe cellular alterations due to cyclosporine A by measuring levels of urinary excretion of enzymes released from injured tubular cells. The lysosomal hydrolase, N-acetyl-β-D-glucosaminidase (NAG) is found in the urine of humans and rats exhibiting clinical features of cyclosporine A toxicity. The proximal tubule brush border enzyme G-glutamyltranspeptidase (gGT) has also been found in the urine at excess after cyclosporine A toxicity in rats. The increase in NAG enzymuria occurs prior to the fall in renal function or the presence of structural abnormalities that can be seen by biopsy.[229]

There is no consensus as to whether there is any physiologic correlation to the proximal tubule morphologic changes associated with cyclosporine A excess.[139] Extensive examination of salt and water handling by

the proximal tubule while under the influence of cyclosporine A has been undertaken. To study the ability of the proximal tubule to reabsorb sodium and water, lithium clearance studies have been employed to provide a measurement of isosmotic tubular fluid delivery from the end of the proximal tubule to the loop of Henle.[205] Lithium, which is not handled by the loop of Henle or the distal tubule, has thus been taken as a measure of proximal tubular function during cyclosporine A therapy. Dieperink et al.[55] first looked at the clearance of lithium as a function of proximal tubular transport in rats chronically receiving cyclosporine A at a dose of 50 mg/kg/day for 13 days. In these animals, falls in the clearance of inulin and to a greater extent the clearance of lithium were found, suggesting an increase in fractional tubular reabsorption by the proximal tubule. They propose that the increase in fractional tubular reabsorption of the proximal tubule is the result of lower ultrafiltration pressure related to cyclosporine A.[55] Human studies performed by Vincent et al.[219] using clearance of lithium as a measure of proximal tubule function showed that there was an increase in the renal vascular resistance associated with a fall in the clearance of lithium in the early post-transplant period after cyclosporine A administration. They also theorized that the proximal tubule is able to increase renal reabsorption in the face of cyclosporine A–induced alterations in glomerular hemodynamics. With a model of chronic cyclosporine nephropathy in the uninephrectomized salt-depleted rat, the relationship between renal functional impairment and structural changes was studied by Elzinga and colleagues.[61] Groups of uninephrectomized rats maintained on a salt-depleted or salt-repleted diet were treated with cyclosporine. Although GFR was similarly depressed in cyclosporine-treated animals on either diet, tubulointerstitial injury was largely confined to cyclosporine-treated rats on salt-depleted diet. Despite the apparent recovery of renal function after cyclosporine withdrawal, the degree of tubular atrophy and interstitial fibrosis did not improve indicating that once structural damage is established, the withdrawal of cyclosporine does not lead to its reversal. In addition, although the mechanism is unclear, this study demonstrates the importance of sodium depletion in promoting cyclosporine-induced tubulointerstitial injury.

Whiting and Simpson[228] repeated the study by Dieperink et al.[55] with several technical changes. They used creatinine as a measure of GFR and allowed for the continual availability of water during the lithium infusion study periods. These investigators were able to reproduce the decrease in the clearance of lithium as well as the increase in fractional reabsorption of sodium. They noted the fall in total clearance of sodium and potassium as well as the fall in absolute reabsorption of sodium, potassium, and water distal to the proximal tubule. As opposed to Dieperink et al.[55] Whiting and Simpson[228] felt that the increased fractional reabsorption of the proximal tubule associated with cyclosporine toxicity was due to a direct but undefined tubular defect distal to the proximal tubule independent of the well-defined hemodynamic alterations of the drug. In their human studies, Propper et al.[172] showed that in cyclosporine A–treated patients with stable graft function several months after transplant, there was a persistent decrease in the clearance of lithium compared to their azathioprine-treated cohorts and to untreated subjects. They additionally noted a much lower absolute reabsorption of sodium and water in the distal nephron compared to the azathioprine-treated group. Whiting et al.[227] theorized that increased proximal tubular reabsorption was the result of cyclosporine A toxicity at a site downstream from the proximal tubule, which resulted in decreased sodium reabsorption with subsequent increase in tubuloglomerular feedback. The decreased absolute reabsorption of sodium from the distal tubule as seen in rats and humans would be sensed by the juxtaglomerular apparatus and cause afferent arteriolar constriction with resultant decrease in GFR and proximal tubule sodium avidity. The studies of Dieperink et al.[55] and Vincent et al.,[219] and those of Whiting et al.[227] differ in their proposed mechanisms for cyclosporine A–induced increase in proximal tubular reabsorption; yet all agree that the proximal tubule transport function is not directly a consequence of tubular drug toxicity.

Tacrolimus, another calcineurin inhibitor agent commonly employeed in renal transplantation with a similar mechanism of immunosuppresion but on entirely different molecular structure, shares much of the vasoconstrictive properties of cyclosporine. The impact of this agent on the renin-angiotensin-aldosterone axis remains similarly time dependent with early stimulation of renin and endothelin and late inhibition. Sodium avidity by the proximal tubule remains the rule although a rate sodium wasting syndrome related to hyporesponsive of the distal nephron to aldosterone has been reported by Sakamoto and colleagues.[183]

Clinical syndromes that derive from altered renal transport support the experimental thesis that the proximal tubule responds appropriately to the hemodynamic alterations induced by cyclosporine A and distal tubular transport reflecting direct cellular toxicity of the drug (Fig. 94.8). For example, the clinical observation of mild and sometimes symptomatic hyperuricemia in patients receiving cyclosporine A after renal transplantation can be related primarily to hemodynamic changes. The first studies to suggest the relationship between cyclosporine and hyperuricemia were

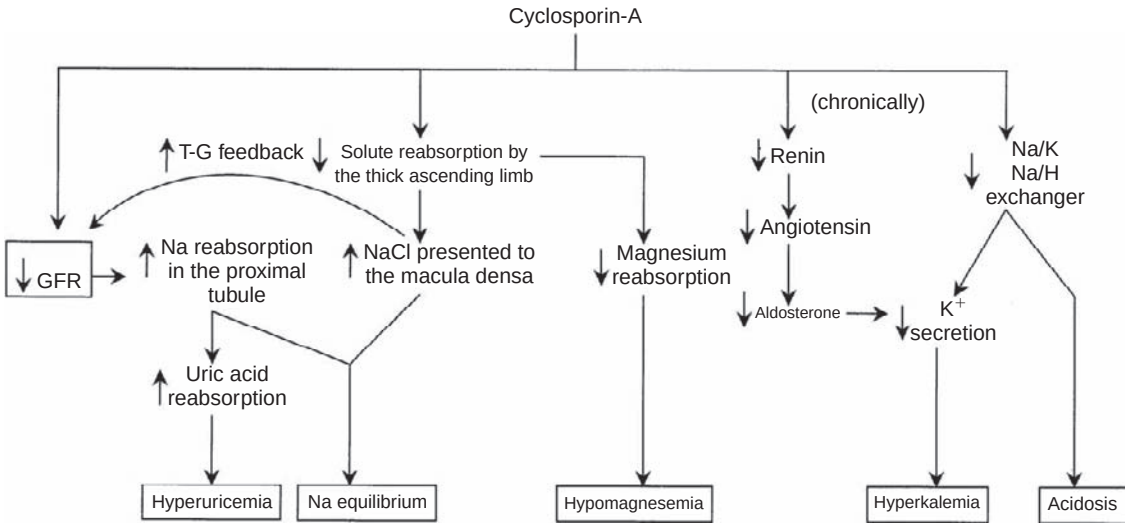

FIGURE 94.8 Diagrammatic representation of cyclosporine effects on the nephron with corresponding clinical syndromes.

those of Chapman et al.[40] who reviewed the Oxford experience of high-dose cyclosporine A in 1983–1985. Patients (n = 62) receiving a mean dose of cyclosporine A of 17.5 mg/kg/day had serum uric acid levels nearly 12 times that of their azathioprine- and prednisone-treated cohorts. The increase in serum uric acid was felt to reflect the decreased filtration fraction exhibited uniformly by the cyclosporine-treated group. Unfortunately, this study did not account for the possibility of increased uric acid turnover or for the alterations in uric acid metabolism related to other commonly used drugs post-transplant that may have interfered with uric acid excretion. Versluis et al.[218] studied 23 patients receiving cyclosporine A at a dose titrated to maintain a predetermined therapeutic level while in a metabolic ward measuring urinary and fractional excretion of uric acid before and after removal of cyclosporine A in a protocol designed to convert to an azathioprine dominated regimen. In those patients with successful removal of the cyclosporine A, the serum uric acid levels fell without a significant change in fractional clearance of uric acid. When stratified for the serum creatinine, the mean uric acid level was significantly higher during cyclosporine A therapy as compared to that after conversion to azathioprine for any given level of GFR. Although Versluis et al.[218] carefully accounted for metabolic alterations that change uric acid production rates, the GFR observations are weak in that they rely on serum creatinine as its measure of GFR. Creatinine clearance is a poor measure of true glomerular filtration rates during cyclosporine A treatment as tubular secretion of creatinine through the aromatic acid and base pathway is fully intact despite sharp constraints on glomerular filtration. Creatinine clearance thus overestimates GFR and calls into question conclusions reached in studies such as Versluis et al.[218] in which GFR is so improperly measured.[21,159] These two clinical studies highlight the interpretative dilemma between cyclosporine A–induced electrolyte abnormalities as a function of hemodynamics alterations or direct tubular toxicity. Flaws in study design required new observations to solve this dilemma.

A study in 19 pediatric renal transplant recipients demonstrated that patients with hyperuricemia had lower 51-EDTA, PAH, and urate clearances and serum urate concentration correlated with cyclosporine dose and inversely with urate, and lithium clearances.[120] Urate clearance showed a significant positive correlation with lithium clearance and an inverse correlation with fractional proximal tubular reabsorption. These data supported the idea for proximal tubular urate reabsorption rather than decreased secretion as one of the mechanisms in cyclosporine-induced hyperuricemia. In another study by Zurcher et al.[235] 82 cyclosporine-treated patients (50 bone marrow transplant recipients and 32 renal transplant recipients) and 28 healthy, living, related kidney donors were prospectively followed for up to two years. Plasma uric acid levels, inulin clearances, and fractional clearances of uric acid were examined. After one year of cyclosporine treatment, hyperuricemia was found in 36% of bone marrow transplant patients, in 53% of renal transplant patients, and 30% of living-related kidney donors. The GFR at one year, measured by inulin clearance, was identical in the cyclosporine-treated groups and slightly higher in the living-related kidney donors. The fractional clearance of uric acid did not change

significantly over time, suggesting that there is no evidence for impaired tubular handling of uric acid induced by a cyclosporine-specific tubulo-toxic effect. Hyperuricemia in cyclosporine-treated patients is thought to be a consequence of cyclosporine-induced diminished renal function.

The effects of calcium channel (amlodipine) and angiotensin converting enzyme (perindopril) blockade on glomerulotubular function in cyclosporine-treated renal allograft recipients were evaluated in a randomized, double-blind crossover fashion.[188] Both drugs maintained GFR and effective renal plasma flow and lowered mean arterial pressure to a similar extent. Sodium clearance and fractional excretion of sodium were not affected by either drug. Interestingly, output of fluid from the proximal tubules measured as clearance of lithium and uric acid was higher after amlodipine. Consequently, distal absolute reabsorption of sodium was higher and serum uric acid was lower after amlodipine in comparison with perindopril.

Although it has been difficult to rigorously prove that cyclosporine A has a direct toxic effect on proximal tubular transport function in the face of prior assumptions based on morphologic expectations, the physiologic and clinical evidence for isolated and specific cyclosporine A–induced transplant defects in more distal structures of the nephron are stronger. We have already reviewed the manner in which sodium and volume handling exhibited by the whole kidney during cyclosporine use is a function of, in part, a normal response of the proximal nephron to reduced GFR and to, in part, a function of a disordered loop. Additional specific defects exist in the loop of Henle in response to cyclosporine A. In one study of a segmental analysis of nephron function in cyclosporine A–treated animals, most measurements of transport appeared unaltered by the drug but a hint of defective loop and thick limb function was offered.[144] This hint was fleshed out by Gnutzmann et al.[79] who performed micropuncture experiments on Munich-Wistar rats after a 10-day course of cyclosporine A at 15 mg/kg or after a single intravenous infusion of 5 mg/kg of cyclosporine A. They reported an increase of luminal sodium chloride concentration in the thick ascending limb of Henle as a consequence of decreased limb transport diluting capacity.[79] They theorized that the impaired sodium chloride absorption in the thick limb provides stimulus to the macula densa that culminates in excitement in T-G feedback signals and lowering GFR. This study is a micropuncture counterpart to the clinical observations of Whiting et al.[227] who argued that the increased absorption of sodium by the proximal tubule is a consequence of constrained GFR and flows from a compensatory response to distal tubular defects created by the drug. The effect of chronic cyclosporine administration on volume regulation was also studied in mongrel dogs.[41] Dogs were given either cyclosporine or vehicle on a constant sodium diet. It has been demonstrated that cyclosporine administration induced a chronic state of avid sodium retention with associated activation of renin-angiotensin-aldosterone system and suppression of circulating atrial natriuretic factor. In addition, the ability of the kidney to acutely excrete sodium in response to saline volume expansion was attenuated because of the enhanced tubular reabsorption of sodium.

A second example of a precise transport defect in the distal nephron related to cyclosporine A derives from clinical and basic studies of magnesium handling. Exploring potential transport defects from serum measurements or even whole-kidney clearance studies for magnesium is fraught with interpretative errors. As discussed earlier in this chapter, PTH excess, diuretic use, and the use of osmotic agents drive serum magnesium downward. Patients receiving cyclosporine A for maintenance of bone marrow grafts are more instructive in that these confounding variables are not in play. A clear decline in serum magnesium levels in general, and an increase in urinary magnesium excretion in particular, once cyclosporine A is initiated, strongly suggest a direct drug-related transport derangement in renal magnesium handling.[104] Cyclosporine infusion in rats also culminates in plasma magnesium reduction, a consequence of urinary wasting of magnesium that resolves completely upon cessation of cyclosporine A, which is strong evidence that the abnormalities are a direct consequence of this drug.[231] When Nozue and colleagues determined the serum and tissue levels of magnesium in cyclosporine-treated Sprague-Dawley rats, they found that serum magnesium levels were significantly lower in the cyclosporine-treated groups than in the control group.[153] Serum magnesium concentration fell in a dose-dependent manner. Interestingly, urinary magnesium excretion was inappropriately increased and there was no significant difference between the control and cyclosporine-treated groups with regard to total urinary excretion of magnesium indicating the impaired renal conservation of magnesium. On the other hand, magnesium content in the kidney, muscle, and liver was significantly higher in the cyclosporine-treated group than in the control group, which suggested a role for intracellular migration of magnesium on cyclosporine-induced hypomagnesemia. Calcineurin inhibitors appear to transiently increase intracellular calcium levels in mouse distal convoluted tubule cells (MDCT). In addition, calcineurin inhibitors, inhibit PTH stimulated magnesium entry in MDCT cells resulting in wasting.[109]

Tacrolimus has been associated with more profound magnesium wasting than cyclosporine, with lower

serum levels and higher dietary requirements.[10] It is thought that the calcineurin inhibitors in general, and tacrolimus in particular, block the basolateral sodium-potassium pump in the loop of Henle decreasing an otherwise lumen-positive gradient resulting in decreased paracellular magnesium reabsorption.[10] The result is an inappropriately high fractional excretion of magnesium despite low serum concentrations. The hypomagnesemia independent of diuretic use or diarrhea may also be a consequence of tacrolimus use. This effect is believed one of direct tubular transport functional alterations not explained by the confounding variables of tissue distribution of the cation or by parathyroid hormone status.[126] Serum magnesium levels correlate inversely with serum tacrolimus levels and creatinine clearance. Magnesium replacement doesn't appear to influence the fractional excretion of magnesium[149]

Tacrolimus decreases intracellular magnesium in osteoblast cells by inhibiting activation of the extracellular signal-regulated kinases (ERK). Tacrolimus effects on intracellular magnesium and ERK may partially explain some of its untoward effects on bone metabolism.[100]

Hypomagnesemia has been shown to be an independent predictor of new onset diabetes after transplantation. It has long been known that diabetics have lower serum magnesium levels than non diabetics.[106] Although one can reason that low magnesium levels are a consequence of the diabetic state due to osmotic diuresis or impaired magnesium absorption in the thick ascending limb due to insulin resistance, there appears to be an independent and direct effect of low magnesium on insulin sensitivity that improves with supplementation.[112]

The use of sirolumus results in hypomagnesemia as well. Sirolimus use leads to an increased transtubular potassium gradient (compared to cyclosporine) leading to hypokalemia and tubular dysfuction resulting in polyuria and hypomagnesemia. Sirolimus decreases the expression of NKCC2 in the thick ascending limb (the princial sodium transporter), reduces aquaporin-2 expression and increases the expression of TRPM6 (Mg permeable channel on the apical membrane of the distal convoluted tubule). Rosiglitazone prevents sirolimus induced hypokalemia and hypomagnesemia by increasing the protein expression of sodium transporters and aquaporin-2.[52]

The best characterized transport defect associated with cyclosporine is that of potassium with hyperkalemia, the consequence of a well-recognized disorder of electrolyte excretion during this form of immunosuppressive therapy either in kidney transplant recipients or following its uses in autoimmune diseases.[57,71] Mineralocorticoid status of the transplant recipient is an important controlling influence on potassium handling by the graft as discussed earlier. Interestingly, there is a dialectical response of the renin-angiotensin-aldosterone axis to cyclosporine A administration. Acutely after cyclosporine A intravenous infusions in normals and in the first days of cyclosporine use in animals and humans, renin is directly stimulated leading to increases in aldosterone. After chronic administration and for the bulk of the time a patient keeps the transplant, renin responsiveness is reduced and a state of hypoaldosteronism is common. This reduction in renin response in patients receiving cyclosporine A raises the possibility that reductions in distal tubular sodium/potassium exchange, a function of this relative aldosterone deficiency, account for the majority of clinical instances of hyperkalemia.[14] Chan et al.[39] compared 20 renal allograft recipients receiving cyclosporine A in doses of 10 mg/kg/day to a group of 17 patients given azathioprine immunosuppression, observing that the fractional excretion of potassium is lower than would be predicted by the decrement in GFR related to cyclosporine A alone. These data support the concept of distal tubular reduction in sodium/potassium exchange. Deppe and colleagues[54] studied the principal and intercalated cell properties of the distal nephron in order to investigate the influence of cyclosporine A on key plasma membrane ion transport systems. It has been demonstrated that cyclosporine A decreased the activities of Na^+,K^+-ATPase and Na^+-K^+-2Cl cotransporter in cells of the distal nephron thereby contributing to the hyperkalemia observed in patients treated with cyclosporine A.[122,208,232]

In addition to the mineralocorticoid state of the transplant recipient, other derangements in potassium handling produced by cyclosporine have been proposed. Batlle et al.[17] in their detailed analysis of acidification highlight defects in the distal tubule that extend to potassium. Accompanying an impaired ability to secrete hydrogen ions distally were decreases in potassium excretion, failure to excrete a potassium load, and failure to increase the fractional excretion of potassium in the face of increased plasma potassium concentration, findings confirmed by micropuncture.[17,159] They proposed that cyclosporine A causes a voltage-dependent defect in hydrogen ion and potassium excretion that is clinically evident in patients receiving cyclosporine A as hyperkalemic, metabolic acidosis.[39]

Just as the immunosuppressive mechanism of action of tacrolimus is similar to that of cyclosporine, much of the toxicity profile is similar as well, including neurotoxicity, nephrotoxicity, and hypertension. It has been demonstrated in rat kidneys that tacrolimus blocks the angiotensin II–induced activation of Na^+,K^+-ATPase, which is an enzyme that is present in the basolateral membrane of all renal tubular cells.[8] Na^+,K^+-ATPase

plays a pivotal role for sodium reabsorption and subsequently for regulation of blood pressure. Studies demonstrated that tacrolimus is as nephrotoxic as cyclosporine A, it also induces both morphologic and biochemical changes in animal models. Animals treated with 10 mg/kg/day of tacrolimus intraperitoneally were found to have juxtaglomerular apparatus hyperplasia and juxtaglomerular cell transformation with vascular changes.[233] While the urinary excretion of TXB2 was significantly high, urinary excretion of 6-keto-PGF1A was low, which reflected increased production of TXA2 leading to glomerular vasoconstriction. The cellular enlargement of juxtaglomerular cells along with a decrease in renal cortical blood flow has also been shown by Ueda et al. using the hydrogen ion clearance method.[209] In an *in vitro* model, using electrical resistance pulse sizing technique, Lieberman and colleagues demonstrated that tacrolimus causes a dose-dependent contraction of isolated glomeruli that can be inhibited by blockade of calcium channels.[124] In addition, tacrolimus was found to have a direct cytotoxic effect on cultured porcine proximal tubular epithelial cells,[143] as well as periodic-acid-Schiff (PAS) stain positive large granules and vacuolar changes in the convoluted part of the proximal tubules in rats.[233] It also has been shown to inhibit porcine[136] and human[27] proximal tubular cell proliferation in a dose-dependent manner, which was thought to be a contributing factor along with altered prostaglandin metabolism and enhanced endothelin secretion in tacrolimus-induced nephrotoxicity.[142]

Hyperkalemia may be more frequent with tacrolimus use than cyclosporine.[95] *In vitro*, cyclosporine inhibits the activity of the $Na^+/K^+/2Cl^-$ cotransporter whereas tacrolimus stimulates the activity of the cotransporter which should increase serum concentrations of potassium.[3] In addition to common mechanisms that have been described, tacrolimus inhibits calcium-dependent exocytosis of catecholamines from adrenal chromaffin cells, which may lead to potassium shifting out of cells contributing to elevated plasma concentrations.[132] Additionally there appears to be a differential effect on potassium channel currents between the undecapeptide immunosuppressant cyclosporine and the two macrolide antibiotic agents, sirolimus and tacrolimus. Both of the macrolides enter cells to bind with a carrier protein the class of which are called immunophilins. The precise immunophilin utilized by the macrolides, called the FK-binding protein (FKBP), is different from that for cyclosporine and has a unique role in potassium homeostasis prolonging the mean opening time of the channel enhancing serum potassium concentrations.[201] Both of the macrolides increase the action potential duration prolonging recovery from inactivation of potassium channels responsible for repolarization in mouse ventricles.[59] Interestingly, all three of the immunosuppressants inhibit insulin release through disordered regulation of the ATP-sensitive potassium channel further contributing to cellular shifts in potassium favoring hyperkalemia.[73]

Both cyclosporine and tacrolimus impair tubular reabsorption of phosphate after kidney transplantation. One study suggests that tacrolimus treated patients exhibit significantly faster recovery from the drug impairment related tubular phosphate reabsorption than with cyclosporine. The effects on phosphate wasting with cyclosporine is still seen two years after renal transplantation.[68]

The array of transport abnormalities that might be encountered after using the newest class of immunosuppressants—which inhibit the mammalian target of rapamycin or mTOR—are not yet understood. Some of the effects of the main agent in this class sirolimus share transport alterations with its chemical cousin tacrolimus as a function of its macrolide structure as discussed with respect to potassium channel deviations. Uric acid handling appears to be unaffected,[85] while the potassium effects seem to involve the KFBP alteration of channel function and insulin secretory inhibition. It has been recognized for sometime that renal allografts have impaired phosphate handling and sirolimus may prolong renal phosphate leak resulting in low serum phosphate concentrations the first weeks after renal transplantation.[198] Sirolimus appears to promote hypophosphatemia by inhibiting the intestinal phosphate transporter as well as regulating the major renal tubular phosphate transporter (NaPi-IIa) resulting in phosphaturia independent of serum phosphorous concentrations. Kemp and colleagues using both a xenopus oocyte recorder system *in vitro* and a murine *in vitro* model confirmed the inhibition of the NaPi-IIa phosphate transporter through inhibition of the serum—and glucocorticois—inducible kinase. There is also inhibition of Hg FGT23 probably responding to direct tubular wasting of phosphorous. In time 1,2 $(OH)_2D3$ increases due to stimulation of 1 alpha-hydroxylase by cellular phosphate depletion. This increase in vitamin D leads to increased intestinal absorption of phosphate despite on going renal wasting of phosphorous with sirolimus. Serum concentrations of phosphate will normalize as a result.[108]

In summary, the universal employ of novel immunosuppressant agents with complex molecular mechanisms of action has uncovered an array of renal physiologic derangements in the successfully renal engrafted patient. Sodium handling, uric acid metabolism, homeostasis of divalent cations, potassium balance, acid−base alteration have become important accretions to the appropriate clinical management of

the renal transplant recipient who will enjoy dwindling numbers of rejection episodes and prolonged allograft survival. A clear understanding of normal renal physiology and the manner in which standard drug regimens alter transport from normality has become an essential component of renal transplant management.

INTRODUCTION

Numerous drugs are eliminated by the kidney. For others, polar metabolites are formed by metabolism or conjugation (usually in the liver)—that are then excreted by the kidney. Renal impairment thereby leads to the accumulation of drugs and their metabolites. For many drugs, doses must be adjusted to attain concentrations similar to those obtained in patients with normal renal function. Renal dysfunction can also affect distribution of drugs, primarily by effects on protein binding. Last, changes in renal function can affect response to drugs independent of any change in disposition.

Several general characteristics of a drug allow prediction as to whether renal dysfunction is likely to affect its disposition sufficiently to mandate changes in drug dosing (Table 95.1).[1–2] If a drug has a wide therapeutic index, accumulation in patients with renal insufficiency to concentrations several-fold higher than in patients with normal renal function has little, if any, consequence, and dose adjustment can be ignored. For example, a number of penicillin derivatives and many cephalosporins are primarily eliminated by the kidney but can accumulate with little risk. Toxic accumulation of these drugs can sometimes occur, but usually only with massive doses in patients with compromised excretion.

The amount of a drug or active metabolite excreted in the urine can allow predictions as to the potential for clinically important drug or metabolite accumulation in patients with renal insufficiency. In general, if about 40% or more of a drug dose is excreted in urine, dose adjustment will be needed in patients with renal insufficiency—assuming the drug in question has a sufficiently narrow therapeutic index to be of concern. An exception to this rule of thumb is drugs with the potential for undergoing a "futile cycle," which refers to the fact that the metabolic route serves to form a reservoir for parent drug. Thus, the metabolic step is "futile" (see the section on metabolism). With such agents, little (if any) drug itself is normally excreted in the urine—yet renal insufficiency can result in its accumulation in plasma. The mechanism of this effect, and the few drugs to which it applies, are discussed in material following. It is also important to note that some drugs are metabolized to active metabolites in which case, both drug and metabolite are pharmacologically potent. Further, some drugs are pro-drugs, which are themselves inactive, but are converted to active compounds (e.g., clopidogrel or irnotecan). For these drugs, the focus of dosing adjustment should be on the active compounds.

It should be apparent from the foregoing that for drugs that have not been explicitly studied in patients with renal insufficiency one can make reasonable predictions as to the need for adjusting therapy. Although lack of quantitative guidelines makes dose adjustments tentative, a worse problem is ignoring the need to do so. When no information concerning the relevant characteristics of a drug is available, one therapeutic strategy is to use a drug of the same class—but with no

TABLE 95.1 General Characteristics of Drug That Predict Important Influences of Renal Function

Characteristics	Implications
Therapeutic index	If the drug has a wide therapeutic index, its accumulation poses negligible risk.
Protein binding	A high degree of binding (>90%) to albumin makes displacement likely in uremic patients. A high degree of binding to either albumin or α1-acid glycoprotein means little drug is available for removal by dialysis.
Amount of drug excreted in the urine unchanged	If ≥40% of a drug is excreted in the urine unchanged, it is highly likely to accumulate in patients with renal insufficiency.
Active metabolites excreted in the urine	The metabolites can accumulate, with attendant effects.
Volume of distribution	A small volume of distribution (that of total body water or less; that is, ≤0.7 liter/kg) means the drug may be accessible for dialytic removal if it is not highly protein bound. A large volume of distribution means little if any removal by dialysis.

dependence on the kidney for elimination. For example, if a clinician wishes to prescribe a cardio-selective beta-adrenergic antagonist to a patient with renal insufficiency one alternative is to administer atenolol in a modified dose. Another option is to administer metoprolol, which is eliminated by the liver and needs no dose adjustment in patients with renal insufficiency.[2] The converse would apply to patients with liver disease. However, there is a growing body of literature that suggests that drug metabolism may be altered in patients with renal dysfunction,[3–6] and increasingly the U.S. Food and Drug Administration is requiring studies of the effects of renal dysfunction on new drugs that are cleared by non-renal routes.[7] Therefore, some caution should be exercised in simply switching a patient from a drug predominantly eliminated by the kidney to a drug with a predominant nonrenal elimination.

ROLE OF THE KIDNEY IN DRUG DISPOSITION

Most drugs are excreted via the kidneys, either in the form of the unchanged drug molecule or after conversion of the parent drug into polar metabolites. Mechanisms by which the kidney excretes drugs are analogous to its normal physiologic processes of glomerular filtration, active secretion, and active and passive reabsorption. Below, the processes of importance for the handling of drugs are briefly described. Effects on any of these processes, e.g., through interactions between concomitantly administered drugs or through renal disease, can mandate changes in drug dosing. The influence of altered kidney function on systemic drug disposition, and corresponding dosing strategies are discussed in more detail in subsequent sections.

Glomerular Filtration

The glomerulus offers no barrier to filtration of the unbound fraction of most drugs.[8–9] Glomerular pores allow passage of molecules up to molecular weights of about 65,000 Daltons, and the vast majority of xenobiotics (including many biologic agents) are approximately two orders of magnitude smaller than this. Exceptions include larger proteins and dextran. Dextran is a good example of the role of molecular size; it can be administered as several different preparations, the size of which determines their ability to be filtered.[10] Thus, dextran 1 (MW=1000) is freely filtered and is eliminated rapidly by the kidney—with a half-life of elimination of about 2 hours.[11] In contrast, dextran 70 is too large to be filtered and is eliminated slowly by metabolism. It is detectable in plasma for 4 to 6 weeks.[11–12] Dextran 40 is a mixture of both higher- and lower-molecular-weight species so that the smaller dextrans are freely filtered and eliminated quickly, with selective retention of the larger components.[10–11]

For drugs freely filtered at the glomerulus, such as aminoglycoside antibiotics, renal elimination can be quite rapid. For many other drugs, binding to serum proteins restricts filtration and thus only the unbound fraction can be filtered and renal excretion, depending on the extent of binding, may be negligible. The limits to glomerular filtration of a drug, then, are usually not the glomerular barrier itself but factors that prevent filtration—predominantly binding to macromolecules too large to be filtered.

Secretion and Reabsorption

The overall renal drug clearance is determined by the relative importance of filtration, secretion of drug into the primary urine, and reabsorption back into the blood. It follows that secretion must occur if the rate of excretion is higher than that of filtration, and conversely, if the rate of excretion is lower than the filtration rate, the drug is by necessity reabsorbed.

Secretion: The classical method described for assessing drug secretion by the kidney was that of Cross and Taggart, using incubations of renal cortical slices.[13]

The sine qua non for secretion was a slice-to-medium–concentration ratio greater than unity. Numerous more sophisticated methods for characterizing secretion have since evolved, including microperfusion of isolated nephron segments, use of isolated proximal tubular cells or vesicles derived from peritubular or luminal membranes of proximal tubules, and cellular expression systems for detailed studies of drug transport by specific membrane transporters.[14–16]

Drugs gain access to secretory sites via the peritubular capillary. If 20% of renal plasma flow is filtered, the remaining 80% of flow reaches sites of secretion. This process is active because an uphill concentration gradient can be generated. Moreover, depriving the proximal tubule of energy also inhibits movement of drugs from the peritubular to the tubular side of the cell.[8,17] The energy for active secretion is ultimately obtained from ATP hydrolysis, either directly driving transmembrane drug flux (i.e., primary active transport), or generating concentration gradients across the cell membranes that, in turn, drive the solute flux (secondary active transport). In the latter case, energy is generated by peritubular sodium-potassium exchange via Na^+,K^+-ATPase.[8,18–19]

The efficiency of secretion is quite impressive. For example, secretion occurs for many drugs that are highly protein bound (such as furosemide).[20] For this and other drugs, the affinity for transport exceeds that for binding. As such, binding to plasma proteins actually facilitates elimination by increasing the amount of drug in the plasma and thereby delivering it to secretory sites.[21] That this is the case has been demonstrated in studies with analbuminemic rats. Administration of furosemide to these animals results in very low plasma concentrations of diuretic because without albumin binding the drug distributes widely outside the vascular space. Consequently, only small amounts are delivered to secretory sites and little is excreted into the urine. Administration of albumin in this setting binds furosemide, keeping it in the vascular space so that more diuretic reaches secretory sites (where more can be secreted into the urine).[21] A similar effect has been shown to occur in humans.[21–22]

Reabsorption: The kidney is capable of both active and passive reabsorption of drugs. Various membrane transporters mediate active luminal-to-abluminal flux of substrate drugs, whereas passive drug reabsorption is the consequence of concentration differences between the primary urine and the blood in the peritubular capillaries, that in turn results either from active drug secretion or, typically, from the reabsorption of water along the nephron. Passive reabsorption relies on diffusion of drugs across the lipid bilayers of the renal tubule epithelium and favors nonpolar drugs. For passive diffusion of drugs that are weak acids or bases, the nonionized form of the drug will be passively reabsorbed since it can cross the tubular membranes. Hence, for both weak acids and bases, urine pH can influence passive reabsorption, and urine pH can be manipulated to reduce passive reabsorption and enhance renal elimination. For example, in the case of patients with aspirin overdose, sodium bicarbonate is administered to alkalinize the urine. In the alkaline urine, salicylate is present predominately in the ionized form and is therefore not reabsorbed.

Renal Drug Transporters

While energy-dependent solute transport in the kidney was demonstrated almost a century ago,[23] the roles of transport proteins in the renal handling of drugs remain an active area of research. The human genome contains more than four hundred membrane transporters classified into the ATP-Binding Cassette (ABC) and Solute Carrier (SLC) gene families, in addition to the numerous aquaporins and ion channels that serve the same purpose of facilitating transmembrane solute flux. Here, we limit the discussion to ABC and SLC membrane transporters that are known to transport drug molecules across the membranes of renal cells, either in the secretory or the reabsorptive direction (Figure 95.1). Data on the clinical relevance of the various membrane transporters continues to emerge, and additional members are likely involved in the renal transport of some drugs. In this section we focus on the function and expression of renal drug transporters under physiological

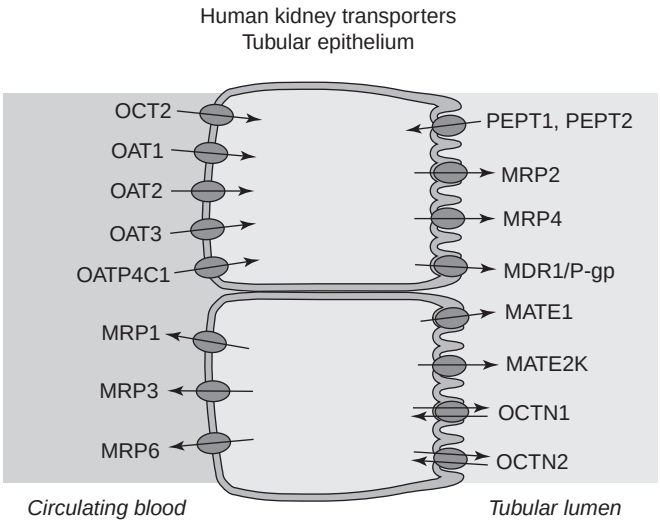

FIGURE 95.1 Cellular localization of clinically important drug transporters in renal epithelia.

conditions, whereas the effects of renal disease is discussed in more detail below (See: Influence of Renal Disease on Drug Disposition and Response).

Early studies defined two separate transport systems for organic solutes in the kidneys, with broad substrate specificities towards organic anions and organic cations, respectively.[17] During the past decades, a large number of distinct transport proteins have been identified as contributors to these transport systems, and functionally characterized with respect to their substrate specificities, cellular localization, genetic variation, and so on. The historical categorization based on substrate charge is, however, not directly mirrored in the assignment of transporters to different gene families based on similarity in amino acid sequence. While substrate specificities often are shared within subfamilies of structurally similar transporters, members of both the anion and the cation systems are found across multiple subfamilies in the ABC and SLC gene families, and some subfamilies contain both anion and cation transporting members.

ABC transporters: The human ABC gene family contains 49 distinct protein coding genes, divided into seven families (ABCA−ABCG) based on amino acid sequence similarity.[24,25] All members contain a highly conserved ATP-binding region, and utilize energy from ATP hydrolysis to drive efflux of substrate molecules from the inside to the outside of cells. ABC transporters of importance for renal drug transport include P-glycoprotein (P-gp/ABCB1) and several members of the Multidrug Resistance Associated Protein (MRP/ABCC) subfamily. P-gp is by far the most well-characterized drug transporter, and has been shown to transport many structurally diverse compounds, typically of a lipophilic and uncharged or weakly basic character (Table 95.2).[24,25] P-gp is expressed in the luminal membrane of proximal tubule epithelium and appears to play a role in the renal clearance of digoxin.[26]

The MRP/ABCC family consists of thirteen transporters, many of which have been shown to accept drugs as substrates, in particular anionic drugs and compounds conjugated with sulfate, glucuronide and glutathione moieties (Table 95.2).[27−31] In the kidney proximal tubule epithelium, MRP2/ABCC2 and MRP4/ABCC4 are expressed in the luminal membrane and mediate secretion of substrates to the urine.[27,30−36] MRP6/ABCC6 is also expressed in the kidney proximal tubules, but is instead localized to the basolateral membrane.[36−38] Expression of MRP1/ABCC1 and MRP3/ABCC3 is highest in more distal parts of the nephron, including the thick ascending loop of Henle, distal tubuli and collecting duct, where their expression in the basolateral membrane suggests involvement in the reabsorption of organic anions.[28,36,39−40] Based on in vivo studies in knockout mice, MRP4 appears to be important in the renal clearance of tenofovir and adefovir, two anti-viral drugs.[41]

SLC transporters: More than 350 human membrane transporters are categorized to the SLC gene family.[42] In contrast to the ABC family, transport by SLCs is not directly coupled to ATP hydrolysis, but is instead dependent on concentration gradients of the transported substrate or of co- or counter-transported ions

TABLE 95.2 Transporters of Emerging Clinical Importance in the Renal Handling of Drugs

Transporter[a]	Gene Symbol	Selected Substrates
P-gp (MDR1)	ABCB1	Digoxin, doxorubicin, irinotecan, loperamide, paclitaxel, ritonavir, saquinavir, vinblastine
MRP1	ABCC1	Daunorubicin, doxorubicin, etoposide, leukotriene C4, methotrexate, saquinavir
MRP2 (cMOAT)	ABCC2	Methotrexate, statins, olmesartan, valsartan, glutathione and glucuronide conjugates
MRP3	ABCC3	Fexofenadine, methotrexate, glucuronide conjugates
MRP4	ABCC4	Adefovir, cyclic AMP, dehydroepiandrosterone sulphate, methotrexate, tenofovir, topotecan
MRP6	ABCC6	Leukotriene C4, BQ123
OCT2	SLC22A2	Amantadine, amiloride, cimetidine, cisplatin, histamin, metformin, serotonin
OCTN1	SLC22A4	Carnitine, pyrilamine, quinidine, verapamil
OCTN2	SLC22A5	Carnitine, cephaloridine, quinidine, verapamil
OAT1	SLC22A6	Acyclovir, adefovir, cidofovir, ciprofloxacin, lamivudine, methotrexate, tenofovir, zalcitabine, zidovudine
OAT2	SLC22A7	Allopurinol, bumetanide, dehydroepiandrosterone sulfate, estrone-3-sulfate, 5-fluorouracil
OAT3	SLC22A8	Bumetanide, cefaclor, ceftizoxime, furosemide, NSAIDs, estrone-3-sulfate
OAT4	SLC22A11	Bumetanide, NSAIDs, tetracycline, urate, zidovudine,
OATP4C1 (OATP-H)	SLCO4C1	Digoxin, estrone sulfate, methotrexate sitagliptin
PepT1	SLC15A1	Amoxicillin, captopril, cephalexin, cefadroxil, enalapril, glycylsarcosine, valacyclovir, dipeptides, tripeptides
PepT2	SLC15A2	Amoxicillin, captopril, cephalexin, cefadroxil, enalapril, glycylsarcosine, valacyclovir, dipeptides, tripeptides

[a]*Alternative transporter symbols in parentheses*

or small endogenous molecules. The SLC family contains many of the transporters necessary for cellular nutrient uptake, including glucose transporters in the SLC2 and SLC5 subfamilies and amino acid transporters in the SLC1, SLC3, SLC6, SLC7, SLC36 and SLC38 subfamilies. Many of these are expressed along the nephron, where they have the important function of limiting the loss of essential nutrients to the urine. The di/tripeptide transporters PepT1/SLC15A1 and PepT2/SLC15A2 have a corresponding role in nutrient reabsorption, but also accept some peptidomimetic drugs as substrates, including β-lactam antibiotics like cephalexin and amoxicillin and angiotensin converting enzyme inhibitors like enalapril and fosinopril (Table 95.2).[43–46]

The SLC subfamilies with the most extensive evidence for a role in drug disposition are the organic anion (OAT) and organic cation (OCT) transporter family SLC22, the organic anion transporting polypeptide family OATP/SLCO, and the recently discovered multidrug and toxic compound extrusion family MATE/SLC47. The SLC22 family contains a mixture of structurally similar organic anion and organic cation transporters.[47] In the kidney proximal tubule, OCT2/SLC22A2 is the primary transporter mediating cellular uptake of organic cations from the blood. Substrates are typically low molecular weight cations, and include drugs such as metformin, amiloride, procainamide, oxaliplatin and varenicline (Table 95.2).[48–51] Recently, MATE1/SLC47A1 and MATE2-K/SLC47A2 were identified as luminal exporters of organic cations in the proximal tubuli, and overlapping substrate and inhibitor specificities between the MATEs and OCT2 have led to the hypothesis that these form a complementary transport system for tubular secretion of small organic cations.[51–58]

Renal organic anion transporters include OAT1–3/SLC22A6–8 and OAT4/SLC22A11. OAT1, 2 and 3 are expressed on the abluminal membrane of proximal tubule cells and mediate cellular uptake of anionic drugs such as para-aminohippuric acid, acyclovir, ciprofloxacin, methotrexate, ceftizoxime, and furosemide (Table 95.2).[47,59–61] OAT4 is expressed on the luminal membrane, and is involved in urate homeostasis and in the reabsorption and/or secretion of anionic drugs.[62,63] In addition to the SLC22s, members of the OATP/SLCO family have been shown to transport numerous anionic drugs. In the kidney, the most prominent member is OATP4C1/SLCO4C1.[61,64] In comparison to the hepatic OATPs 1B1, 1B3 and 2B1, OATP4C1 is so far much less studied. It mediates uptake from the blood into the proximal tubule cells, and substrate drugs include digoxin, estrone sulfate, methotrexate and sitagliptin.[64–66]

Two other transporters in the SLC22 family have been implicated in renal drug elimination: OCTN1 (SLC22A4) and OCTN2 SLC22A5), which transports carnitine in the kidney.[67,68] Mice with mutations in OCTN2 eliminate the model organic cation tetraethylammonium by renal excretion at about half the rate of their wild-type littermates.[67]

Interindividual differences: Genetic variation in membrane transporters can result in increased or diminished drug transport. Such variation has been catalogued as part of genome-wide studies[69–71] and in greater detail in gene family-focused efforts.[72] Many commonly occurring genetic variants in important drug transporters have been characterized in cellular expression systems and some have also been shown to affect the in vivo disposition and pharmacological effect of substrate drugs. For example, torsemide renal clearance was correlated with genetic variation in OAT4/SLC22A11,[73] and a common genetic variant (A270S) in OCT2/SLC22A2 was shown to result in changes in metformin clearance in multiple populations.[74–76]

Several heritable diseases have genetic variants that result in non-functional transporters as their underlying cause. For example, Dubin-Johnson syndrome, which manifests as hyperbilirubinemia, is caused by mutations in MRP2/ABCC2 that reduces biliary excretion of bilirubin.[77–79] The effects of Dubin-Johnson syndrome on renal drug handling is much less studied, but the pharmacokinetics of drugs that utilize MRP2/ABCC2 in their renal excretion may be affected in Dubin-Johnson patients.

In addition to genetic variants that cause direct functional effects by altering or truncating the amino acid sequence, mutations in regulatory genomic regions can have functional effects, by altering expression levels of the transporter. In fact, natural interindividual variation in transporter expression levels can be significant. In liver samples from 110 patients, MRP2/ABCC2 levels varied more than 300-fold,[80] and expression level differences may thus have effects on drug disposition on par with or even greater than many coding region variants. Data on inter-individual differences in renal transporter expression is scarce, but such variation may ultimately affect the disposition of renally cleared drugs.

Renal Metabolism

The kidney has the capacity to metabolize numerous drugs and proteins.[81] The proximal nephron has high levels of glucuronyl transferases, sulfotransferases, and peptidases.[8] The ability of the kidney to conjugate drugs via the transferases has been demonstrated unequivocally in animals, but data in man are fragmentary and less direct. Renal glucuronidation may be substantial. For example, approximately 20% of an

intravenous dose of furosemide and 50% of a dose of morphine may be glucuronidated by the kidney.[82,83]

When glucuronide is conjugated to a xenobiotic, the chemical bond between the two can be either an ether (e.g., phenolic) or an ester (e.g., carboxylic). The latter is called an "acyl-glucuronide." Ether-linked glucuronides are chemically stable and are for the most part excreted in the urine. In contrast, acyl-glucuronides are unstable under physiologic conditions such that the glucuronide can deconjugate back to the parent compound. In addition, the glucuronic acid moiety can migrate to other parts of the molecule (acyl migration).[84]

One implication of this chemical instability is analytical. Consider, for example, that one wishes to measure the amount of a drug excreted in the urine. If not just drug but its acyl-glucuronide is excreted, one must be certain that the metabolite does not deconjugate *ex vivo*—causing a falsely elevated measure of the parent drug. To avoid this phenomenon, samples of urine must be stabilized quickly in acidic buffer (e.g., using 75 μl of 17 M glacial acetic acid in a 20-ml urine aliquot is sufficient).[83,85]

A second implication of acyl-glucuronide formation is the possibility of a futile cycle of drug metabolism (Fig. 95.2). In patients with normal renal function, circulating acyl-glucuronide conjugates that are formed in the liver are readily eliminated in the urine. In patients with renal insufficiency, however, renal excretion is decreased and the conjugate accumulates in plasma—where it can spontaneously hydrolyze to reform the parent compound (Fig. 95.2). This phenomenon leads to a paradox in which a drug may accumulate in patients with renal insufficiency even though negligible amounts of parent drug are eliminated in the urine in patients with normal renal function.

Clofibrate,[86,87] diflunisal,[88,89] and some of the arylpropionic NSAIDs[90–93] have been shown to undergo a futile cycle. It would seem prudent to avoid drugs undergoing acyl-glucuronide conjugation in patients with renal insufficiency, or to at least use them very cautiously in such patients.

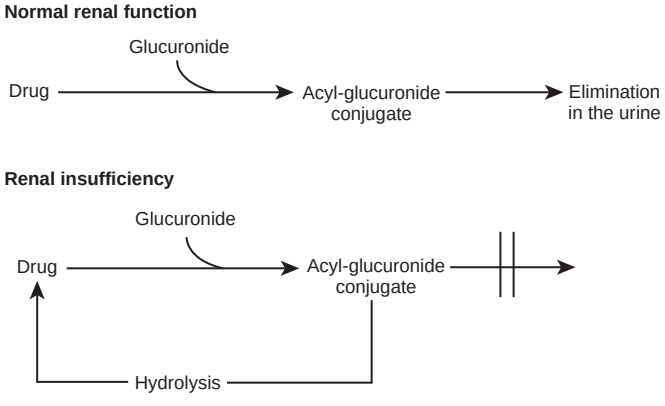

FIGURE 95.2 Schematic illustration of a futile cycle of drug elimination.

The proximal nephron also contains mixed-function cytochrome P450 oxidases (CYP), but in lower amounts than the liver. Interestingly, isoforms of CYP appear to be differentially regulated in the kidney relative to the liver.[94] The relative contribution of renal compared to hepatic metabolism is unknown.[8,81]

The kidney is able to metabolize proteins, such as insulin and other biologic agents—including interleukins, superoxide dismutase (SOD), and likely many others.[95,96] In patients with normal renal function, up to 50% of insulin elimination occurs via renal metabolism. This component of overall elimination diminishes in patients with renal insufficiency and accounts at least in part for the decreased insulin requirement as a patient's renal function deteriorates.[97] Many biologic proteins, such as SOD, are small enough to be freely filtered by the glomerulus. They are then metabolized by the peptidases of the proximal tubule. When renal function declines, renal metabolism is decreased and the substance can accumulate.

Proximal tubule dipeptidases also metabolize imipenem.[98] As such, if imipenem alone is administered to patients, all antibacterial effect in the urine is lost. To attain efficacy for urinary tract infections, imipenem is administered with cilastatin—which inhibits the dipeptidases, allowing sufficient amounts of unchanged imipenem in the urine to kill bacteria.[98]

Overall, then, the kidney is metabolically active toward drugs in a variety of ways. Unfortunately, renal metabolic contributions to drug elimination in man have been inadequately explored and thus clinical implications are for the most part speculative.

In addition to the metabolic roles of the kidney described previously, the kidney excretes many drug metabolites formed in the liver. Renal insufficiency does not necessarily mean that drug metabolites will accumulate because other excretory pathways exist, such as biliary excretion. In addition, many drug metabolites presumably have no effects. On the other hand, there are numerous examples of metabolite accumulation in which the metabolites are pharmacologically active (Table 95.3).[99,100] Some of the metabolites listed exert pharmacologic effects similar to those of the parent compound (e.g., primidone).[101] Others account for all of the pharmacologic activity, the parent compound having no effect (e.g., enalapril).[102] In other examples, the metabolite has a different pharmacologic profile from the parent drug. For example, normeperidine excites the CNS and can cause seizures in contrast to the sedating effect of the parent compound meperidine.[103,104]

It should be apparent that in order to safely use drugs with active metabolites in patients with renal

TABLE 95.3 Active Metabolites of Drugs that can Accumulate in Patients with Renal Insufficiency

Drug	Active Metabolite
ANALGESICS	
Codeine	Morphine-6-glucuronide
Meperidine	Normeperidine
Morphine	Morphine-6-glucuronide
Propoxyphene	Norpropoxyphene
ANESTHETICS AND DRUGS USED DURING ANESTHESIA	
Atracurium	Laudanoside
Cisatracurium	Laudanoside
Pancuronium	3-OH pancuronium
Remifentanil	Carboxylic acid metabolite
Vecuronium	3-Desacetylvecuronium
ANTIANXIETY AGENTS, SEDATIVES, AND HYPNOTICS	
Buspirone	1-(2-Pyrimidinyl)-piperazine (1-PP)
Midazolam	α-Hydroxymidazolam
ANTICOAGULANTS, ANTIFIBRINOLYTICS, AND ANTIPLATELET AGENTS	
Sulfinpyrazone	Thioether metabolite
ANTICONVULSANTS	
Oxcarbazepine	10,11-Dihydro-10-hydroxycarbamazepine (HYCZ)
Primidone	Phenylethylmalonamide
Valproic acid	Not identified
ANTIHISTAMINES	
Cimetidine	Cimetidine sulfoxide
Ebastine	Carebastine
Hydroxyzine	Cetirizine
Ketotifen	Desmethylketotifen
Nizatidine	N2-monodesmethylnizatidine
ANTI-INFLAMMATORY AGENTS	
Diacerein	Rhein
Oxaprozin	Two hydroxylated metabolites
ANTIMICROBIAL AGENTS/ANTIBACTERIALS	
Cephalosporins	
Cefotaxime	Desacetylcefotaxime
Cefoxitin	Decarbamoylcefoxitin
Cephalothin	Desacetylcephalothin
Cephapirin	Desacetylcephapirin
SULFONAMIDES	
Sulfamethoxazole	Acetyl metabolite
Sulfisoxazole	Acetyl metabolite
URINARY BACTERIOSTATICS	
Nalidixic acid	7-hydroxynalidixic acid
ANTINEOPLASTICS AND ANTIMETABOLITES	
Cyclophosphamide	4-Hydroxycyclophosphamide
	Aldophosphamide
Ifosfamide	4-Hydroxyifosfamide
	Aldoifosfamide
	Isofosforamide
	Acrolein
	Chloracetaldehyde (oral dosing)
ANTISPASTICITY AGENTS	
Dantrolene	Hydroxy and amino metabolites
CARDIOVASCULAR AGENTS	
ANTIARRHYTHMICS	
Disopyramide	Mono-N-desisopropyl-disopyramide (MND)
Flecainide	Meta-O-dealkylflecainide
Lorcainide	Norlorcainide
Procainamide	N-acetylprocainamide (NAPA)
ANTIHYPERTENSIVES	
Acebutolol	N-acetylacebutolol (diacetolol)
Captopril	Mixed disulfides with endogenous thiols
Delapril	5-Hydroxyindane diacid
Losartan	E3174
Methyldopa	Methyldopamine
Metoprolol	α-Hydroxymetoprolol
Minoxidil	Minoxidil sulfate
Nebivolol	β-Hydroxy metabolites
Nitroprusside	Thiocyanate
Pinacidil	Pinacidil-N-oxide
CARDIAC INOTROPES	
Digitoxin	Digoxin
Enoximone	Piroximone

(*Continued*)

TABLE 95.3 (*Continued*)

Drug	Active Metabolite
Flosequinan	7-Fluoro-1-methyl-3-methylsulfinyl-4-quinolone (flosequinoxan)
BLOOD LIPID-LOWERING AGENTS	
Clofibrate	Parachlorophenoxyisobutyric acid (CPIB)
Lovastatin	β-Hydroxy acid
Simvastatin	β-Hydroxy acid
DIURETICS	
Triamterene	Sulfuric ester of hydroxytriamterene
HYPOGLYCEMIC AGENTS	
Acetohexamide	Hydroxyhexamide
Tolbutamide	Hydroxytolbutamide
	Carboxytolbutamide
HYPOURICEMIC AGENTS	
Allopurinol	Oxipurinol
PSYCHOTHERAPEUTIC AGENTS	
Acamprosate	Acetyl-homotaurine
Resperidone	9-Hydroxyresperidone
Tianeptine	Not characterized
Venlafaxine	0-Desmethylvenlafaxine
SYMPATHOMIMETICS	
Dolasetron	R + -hydroxydolasetron

insufficiency one must know the pharmacologic profile of the parent drug and its metabolite(s). One should try to avoid such drugs in patients with renal disease.

INFLUENCE OF DRUGS AND RENAL DISEASE ON DRUG DISPOSITION AND RESPONSE

Inter-individual variation in drug disposition among patients can lead to too high or too low systemic plasma levels and is a major factor in the safe and effective use of drugs. Variation may be associated with gender, age, concurrent drugs (drug-drug interactions) and disease. This section focuses on drug-drug interactions that occur in the kidney and on the effect of renal disease on drug disposition. The recent publication of a whitepaper co-authored by an International Transporter Consortium focused on the role of transporters in drug development and highlighted transporter based drug-drug interactions.[105] Among the interactions described were drug interactions that occur in the kidney and that may contribute to drug toxicity. Clinicians should be aware of these interactions as they may interfere with rational drug therapy. With the molecular identity of many drug transporters, there is an emerging appreciation of the mechanisms that underlie renal drug-drug interactions. Similarly, with the advent of sensitive analytical methods and metabolomic studies, a new appreciation for the molecular mechanisms involved in renal disease induced changes in drug absorption and disposition has emerged. Further, advances in physiologic based pharmacokinetics have led to an increased understanding of the mechanisms by which renal disease may affect drug disposition.[106] In this section, drug-drug interactions in the kidney are described first, followed by the effect of renal disease on drug disposition. New information is highlighted and where possible mechanistic explanations of how drug interactions or disease effects occur are included.

Influence of Drug-Drug Interactions on Renal Pharmacokinetics

Drug-drug interactions are important from a drug safety point of view. In fact, of the drugs withdrawn from the market because of drug safety issues, many are associated with clinical drug-drug interactions.[107] Considerable information is available on drug-drug interactions that occur in the liver and for which one drug alters the metabolism of a second drug. In contrast, there are comparably few studies of drug-drug interactions in the kidney. The recent identification, characterization and localization of a number of ABC and SLC transporters in the kidney have led to increasing recognition of the potential importance of drug-drug interactions in the kidney. With the availability of recombinant human renal transporters expressed in continuous cell lines, it is now possible to determine the potential of various drugs to inhibit the renal transport of other drugs. The concentration of a drug that inhibits transport in cellular assays can be compared to its clinical concentrations to determine whether a potential drug-drug interaction is likely to occur *in vivo*. *In vivo* drug-drug interactions can be investigated in healthy populations or in patients to determine the magnitude of the interaction and whether dosing adjustments will be needed when drugs are administered concomitantly.

The magnitude of effect of a concomitant drug on the systemic blood levels of another drug depends on the following factors. First, the fraction of the dose of the affected drug that is eliminated in the kidney is an important factor. If the fraction is low, renal drug-drug interactions will be unimportant to the overall elimination of the drug. In contrast, for drugs for which a high fraction of the dose is eliminated in the kidney, renal

drug-drug interactions may potentially be important. In particular, an interacting drug may inhibit the entire secretory component of renal elimination of the affected drug. If renal secretion constitutes, for example one-half of the renal clearance of the affected drug, then an interacting drug may reduce the renal clearance of the affected drug by one-half. Thus, to estimate the potential importance of a drug-drug interaction in the kidney, a comparison of the net secretory clearance to the total renal clearance of the drug should be made. Net secretory clearance is equal to total renal clearance minus filtration clearance, which in turn is equal to GFR x fraction unbound. So, for example, if a drug has a renal clearance of 50 ml/min and a fraction unbound of 0.01, then in a patient with a GFR of 100 ml/min, the net secretory clearance would be equal to 50 ml/min minus 0.01*100 ml/min or 49 ml/min. Thus a major portion of the renal clearance would be tubular secretion.

Drug-drug interactions in the kidney are often charge specific. That is, weakly acidic drugs will inhibit the renal elimination of other weakly acidic drugs and basic drugs will inhibit other weak bases. There are however a few drug-drug interactions that are not charge selective. Below clinical drug-drug interactions in the kidney are described for acidic drugs and basic drugs.

TABLE 95.4 Selected Examples of Clinical Drug–Drug Interactions Occurring in the Kidney in which the Renal Elimination is Inhibited by More than 25%

Organic Anion Transport Mediated Drug–Drug Interactions		
Affected Drug	Inhibitor	Reference
Cefamandole	Probenecid	118
Cidofovir	Probenecid	119
Ciprofloxacin	Probenecid	173
Cisplatin	Probenecid	174
Famotidine	Probenecid	175
Furosemide	Probenecid	176
Nafcillin	Probenecid	177
Zidovudine	Probenecid	178
ORGANIC CATION TRANSPORT MEDIATED DRUG-DRUG INTERACTIONS		
Metformin	Cimetidine	179
Procainamide	Cimetidine	180
Quinidine	Cimetidine	181
Triamterene	Ranitidine	182
Zidovudine	Cimetidine	183

Clinical Drug-Drug Interactions Involving Acidic Drugs

As noted previously, many organic anions or weak acids are eliminated in the kidney by renal tubular secretion. In general, OAT1 and OAT3, localized to the basolateral membrane of proximal tubule cells, mediate the first step in the tubular secretion of organic anions. On the apical membrane, ABC transporters, including MRP2 and MRP4, transport acidic drugs into the tubule fluid for excretion. OAT4, on the luminal membrane, is thought to function primarily in reabsorption of anionic drugs, but may participate in secretion. In clinical studies, identification of the specific transporter involved in an interaction is often difficult given that most inhibitors can affect multiple transporters and are not selective for a single transporter. The major drug that has been shown to inhibit renal organic anion secretion is the uricosuric agent, probenecid.[108] Clinical examples of drug-drug interactions with probenecid are shown in Table 95.4 and include a number of cephalosporins[109] and anti-viral agents.[110] In general these drug-drug interactions result in higher systemic blood levels and may cause potential toxicities of the affected drug. Probenecid itself is not substantially eliminated in the kidney; therefore its renal disposition is not altered during the drug-drug interaction. Probenecid has long been used to extend therapeutic plasma levels of penicillins by reducing its renal clearance.[111] It is notable that probenecid has been shown to protect the kidney from the nephrotoxic antiviral drug, cidofovir. In fact, the approved cidofovir label contains the following warning:[112]

> "Renal impairment is the major toxicity of Vistide (cidofovir). Cases of acute renal failure resulting in dialysis and/or contributing to death have occurred with as few as one or two doses of Vistide. To reduce possible nephrotoxicity, intravenous prehydration with normal saline and administration of probenecid must be used with each Vistide infusion."

While not completely understood, evidence suggests that the mechanism of the cidofovir renal toxicity is related to high drug concentrations in proximal tubule cells. Co-administration with probenecid leads to a redirection of cidofovir elimination to almost exclusively involve glomerular filtration, a markedly decreased cellular accumulation, and the prevention of clinical signs of nephrotoxicity.[110] Thus, probenecid exemplifies that drug-drug interactions in the kidney can have pronounced effects on drug levels, and that inhibitors of renal drug transport can be exploited in drug therapy.

Clinical Drug-Drug Interactions Involving Cationic Drugs

Many hydrophilic organic cations are eliminated by renal secretion. Notable examples include the anti-

diabetic drug metformin[113] and the anti-viral drug, zidovudine.[114,115] Other examples are listed in Table 95.4. OCT2 is thought to mediate the first step in tubular secretion of organic cations across the basolateral membrane.[50] On the apical membrane, two transporters are thought to be involved: MATE1 and MATE2-K.[51,52,58] Whereas OCT2 is a facilitative transporter that mediates drug transport in accordance with the electrochemical gradient, MATE1 and MATE2-K appear to be proton exchangers. That is, these transporters efflux their cationic substrates in an apparent electroneutral exchange with protons. Although other inhibitors of tubular secretion of organic cations have been described, cimetidine is the major perpetrator of renal drug-drug interactions that involve organic cations. Until recently, it was thought that the cimetidine mediated renal drug-drug interaction occurred at OCT2; however, recent studies have shown that cimetidine is actually a more potent inhibitor of MATE1.[57] Thus, in vivo, cimetidine may inhibit renal transport of organic cations at MATE1 and not at OCT2.

Digoxin is a neutral compound, which is eliminated primarily in the kidney with a small component of tubular secretion. P-glycoprotein (ABCB1) appears to mediate its renal secretion and a number of P-glycoprotein inhibitors including verapamil,[116] ritonavir,[117] itraconazole[118] and quinidine[119] have been found to inhibit its tubular secretion.

INFLUENCE OF RENAL DISEASE ON DRUG DISPOSITION AND RESPONSE

As illustrated in Fig. 95.3, the concentration of a drug in plasma is influenced by a number of factors—each of which, including processes that are not directly associated with the kidneys, may be affected by renal disease. This can lead to altered drug disposition and ultimately to toxic accumulation of drugs or the loss of pharmacological effect. The dose and dosing interval of a drug are controlled by the physician, and altering them is the only method of compensating for alterations in drug disposition in the patient.

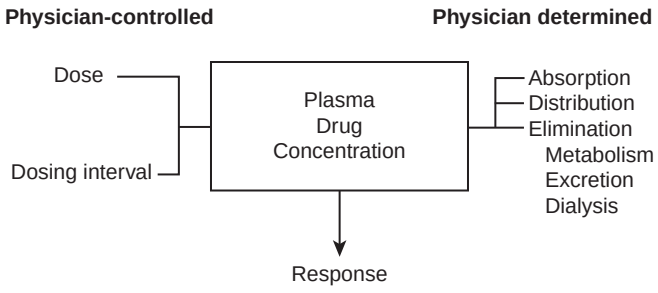

FIGURE 95.3 Determinants of plasma drug concentration and response.

Absorption

By several theoretical mechanisms, renal disease could affect drug absorption. Altered intestinal motility could change rates of gastric emptying of medications to small intestinal absorption sites. Changed regional distribution of blood flow could affect absorption from intramuscular or subcutaneous sites. Such effects on drug absorption remain speculative. Based on current data, clinicians may assume that drug absorption is not changed in patients with renal insufficiency.

Although not strictly an absorptive process, first-pass metabolism by the intestinal mucosa and liver influences the systemic availability of a drug after oral dosing. By largely uncharacterized mechanisms, renal insufficiency can also diminish non-renal (presumably hepatic) elimination of some drugs. For drugs with substantial first-pass elimination, such inhibition of hepatic metabolism could cause greater bioavailability. This mechanism may account for the apparent increase in propoxyphene bioavailability in patients with severe renal insufficiency.[120] Because this phenomenon has not been described with other drugs, clinicians should not extrapolate these findings to all drugs that undergo first-pass elimination.

Distribution

Systemic pH can affect distribution of drugs into tissues. A pH favoring the non-ionized form of a weak acid or base can facilitate its distribution out of plasma and into tissues. This phenomenon has been demonstrated to occur with salicylate. Being a weak acid, a more acidic systemic pH increases the relative amount of non-ionized salicylate and increases the amount reaching the central nervous system (CNS) and toxicity.[121,122] Presumably the acidemia of uremia would increase access of salicylate into the CNS. A similar phenomenon has not been described with other drugs, although this area is little studied.

Protein binding of highly bound drugs is another major determinant of drug distribution. Many acidic drugs, such as nonsteroidal anti-inflammatory drugs (NSAIDs), thiazide and loop diuretics, penicillins, and others bind predominantly to albumin—whereas basic compounds such as lidocaine, propranolol, tricyclic antidepressants, and so on typically bind to the acute-phase reactant α1-acid glycoprotein.[123–126] Patients with renal insufficiency accumulate endogenous organic acids that are normally excreted by the kidney,

and these compounds are able to displace acidic drugs from albumin binding sites.[127–129] The likelihood that such an effect will be important is a function of the degree of binding of the drug. Generally, for drugs bound less than 90% the magnitude of effect is so small as to be irrelevant. In contrast, drugs bound more than 90% may be importantly affected by changes in binding. For example, NSAIDs are more than 99% bound to albumin.[11] Thus, less than 1% is free in plasma and constitutes the active moiety. In uremia, what may appear to be a trivial decrease in binding from 99 to 98% actually results in a doubling of the free unbound concentration from 1 to 2%—a magnitude of change that may be clinically important. In contrast, only about 50% of methotrexate is bound to albumin.[97] A decrease in binding to 45% would have only a minor, clinically negligible effect on unbound methotrexate concentrations.

A frequent misconception is that such an effect results in increased concentrations of unbound pharmacologically active drug, causing an enhanced effect—including toxicity. In the majority of instances, however, there is no increase in concentration of unbound drug and therefore no change in response unless caused by other factors.[130–133] The reason unbound drug concentrations are unchanged is that for many drugs with low total clearance (obeying so-called "restrictive" elimination, in which unbound clearance equals intrinsic clearance), clearance of total drug from plasma from all routes of elimination is directly related to the fraction of unbound drug,[134] calculated as:

$$\text{CL total} = \text{fu} \times \text{CLu}$$

where CL is clearance, fu is fraction unbound, and CLu is unbound clearance. Thus, if displacement from albumin causes the unbound fraction to increase, total clearance increases proportionally but unbound or intrinsic clearance is unchanged—resulting in maintenance of the unbound concentration and pharmacologic effect at its previous level. This similar unbound concentration occurs at a lower total drug concentration. Thus, the fraction that is unbound is increased but the concentration unbound is unchanged.[130–133]

This scenario is true for acidic drugs that are highly protein bound and have low total clearances when displaced from albumin binding sites in uremia. Some other drugs have high organ clearances and extraction rates such that their clearance is less dependent on protein binding but partially or totally dependent on organ blood flow. In this case, unbound clearance will decline as the fraction unbound increases so that unbound drug concentrations increase despite, in some cases, an unchanged total drug concentration.[133] Here, the opposite problem exists in that a dosage adjustment may be necessary even though total drug concentration changes little (if at all).

The degree of protein binding can also allow one to predict the potential for dialytic removal of a drug. A high degree of binding means only small amounts of drug are free in plasma and can be removed by the dialysis procedure. Drugs, either acidic or basic, that are more than 90% bound to plasma proteins will have negligible removal by dialytic procedures except hemoperfusion techniques.

The binding changes described previously can influence the calculation of distribution volume. If calculated based on total drug concentration, the volume of distribution may become larger when binding decreases—particularly for drugs that distribute extensively into intracellular sites and therefore have large volumes of distribution.[130–133] This observation alone can lead to the false conclusion that loading doses need to be increased. In contrast, the distribution volume of the unbound pharmacologically active drug is essentially unchanged—meaning that no adjustment of loading dose should be made. For drugs with smaller volumes of distribution, particularly those restricted to extracellular sites, the total volume of distribution may be insensitive to changes in protein binding. However, there would be almost proportional changes in the unbound volume of distribution, and consequently loading doses should be adjusted.[133]

Unfortunately, the medical literature concerning changes in drug disposition in patients with renal insufficiency is replete with data ignoring unbound drug concentrations. For highly bound drugs, if disposition parameters for total drug (clearance and volume of distribution) are the only values reported—and if these values are increased in patients with renal insufficiency—one must be suspicious that the effect is solely due to displacement from binding. The implication of this conclusion is that disposition parameters for unbound drug are unchanged and that no alteration in dosing is indicated. Clinicians and scientists should be alert to the potential for misinformation from a good deal of the medical literature concerning drugs subject to this phenomenon.

Reductions in protein binding in uremic patients, or with the hypoalbuminemia of nephrotic syndrome, can lead to misinterpretation of serum concentrations of phenytoin owing to the mechanisms discussed previously.[130] In both clinical conditions, binding of phenytoin is decreased. Unbound concentrations are unchanged, although total concentrations are diminished.[130,132] If plasma concentrations of phenytoin are obtained in a patient, the clinical laboratory reports total concentration—a value that could be misinterpreted as being too low even though unbound concentrations are within the therapeutic range. If the misled clinician increased the dose of phenytoin in an attempt to attain a total concentration in the usual therapeutic

range, so doing would also increase the unbound concentration of phenytoin and could result in toxicity. This problem can be avoided by measuring unbound concentrations. Alternatively, one can redefine the therapeutic range for uremic and hypoalbuminemic patients.[135]

Displacement from protein binding in patients with renal insufficiency has therefore been a misunderstood and misinterpreted phenomenon.[130–135] This mechanism is too often cited as causal of altered response to drugs in patients with renal disease. However, because unbound drug concentrations often do not change this mechanism cannot explain altered response to drugs in many uremic patients. Moreover, displacement from binding does not necessarily mandate a change in drug dosing. Clinicians should avoid false conclusions regarding drug disposition from what may be incomplete data in the medical literature; namely, studies of highly bound drugs that quantify only total and not unbound concentrations. The clinical setting in which this phenomenon is most apparent is use of phenytoin in uremic or hypoalbuminemic patients, as described previously.[135]

Digoxin represents a drug for which volume of distribution decreases as renal function diminishes:[136]

$$\text{Volume of distribution (liters/kg)} = 3.84 + 0.0446\ \text{CLcr (ml/min)}.$$

The mechanism of this effect is unknown, but the magnitude is sufficient to mandate dose adjustment. Because volume of distribution influences the loading dose of a drug (as opposed to the maintenance dose), this effect is important only in patients to whom a loading dose is administered. From the previous equation, it should be apparent that the loading dose of digoxin for a patient with end-stage renal disease should be approximately half that of a patient with normal renal function.

Elimination

Both glomerular filtration and active secretion are typically reduced in patients with renal insufficiency, with possible implication for dosing strategies. Renal failure is accompanied by elevated levels of metabolic products that would normally be renally excreted, and that have been associated with multiple pathologies in uremic patients including neuropathy, hypertension, cardiac failure and increased bleeding.[137–140] The molecular identities of these uremic toxins are largely unknown, but elevated levels of, e.g., hippuric acid, indoxyl sulfate, guanidino succinate, trans-aconitate, and 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid (CMPF) have been demonstrated in plasma from uremic patients, and have been demonstrated to cause some of the pathological processes in model systems of renal failure.[141]

It has long been appreciated that constituents of uremic serum can affect renal transport processes. Serum from uremic patients inhibited the uptake of the model organic anion para-aminohippuric acid (PAH) in kidney slices and isolated renal tubules from rat and rabbit,[142–144] and, more recently, CMPF was shown to affect renal PAH uptake, likely through competitive inhibition of the OAT1 and OAT3 transporters[145–149] Similarly, indoxyl sulfate is accumulated in the proximal tubuli of uremic rats, as well as in OAT1/3-expressing human proximal tubuli cells,[150] and may thus compete with tubular uptake of substrate drugs.

In addition to direct inhibition by uremic toxins, several studies demonstrate altered expression of membrane transporters in models of renal disease. For example, decreased expression of OCT2, OAT1, OAT3 and MATE1 have been observed in rats with chronic renal failure.[55,151–155] In contrast, renal expression of the efflux transporters P-gp and MRP2 were increased in such rats,[156,157] possibly as a mechanism of protection from toxic accumulation in proximal tubuli cells.

Notably, the effects of accumulated uremic toxins are not limited to transporters in the kidney. An increasing body of literature demonstrates effects of renal disease on transporter function and expression also in other organs, including the intestine and liver.[6,158–162] Inhibition of hepatic drug-metabolizing enzymes has also been demonstrated, including the Cytochrome P450s CYP2C9, CYP2C19 and CYP3A4.[3,4,163,164] These extra-renal effects have important implications for drug therapy in renal disease, since dosing changes may be necessary also for drugs that undergo extensive hepatic metabolism or are cleared through biliary excretion. In line with the evidence for extra-renal pharmacokinetic effects of renal disease, the U. S. Food and Drug Administration (FDA) now recommends performing pharmacokinetic studies in patients with varying stages of renal impairment, for all chronically administered drugs, regardless of clearance pathway.[7]

Drug Response

Even if the plasma concentration of a drug in a patient with renal insufficiency is identical to that of a patient with normal renal function, response may differ. For example, the effect of pindolol to block exercise-induced increases in heart rate and its effects to decrease plasma renin activity were greater in uremic patients than in normal volunteers despite similar serum concentrations of this beta-adrenergic antagonist.[165] As such, an approximate fourfold greater

plasma concentration was required in healthy subjects to cause the same effect on heart rate as in uremic patients. The mechanism of this enhanced response is unknown.

Unfortunately, comparable studies are not available with the host of drugs used commonly in patients with renal insufficiency. Clinicians must therefore use caution when using drugs in patients with renal disease in addition to adjusting doses to compensate for changes in disposition.

Dialysis

Just as dialytic procedures are used to remove accumulated endogenous end products of metabolism, they can remove drugs and their metabolites. With some drugs, the amount removed is sufficient to require supplemental dosing—or in poisoning settings is helpful in speeding the elimination of the toxin(s).

Drugs restricted to the extracellular, and particularly the plasma, compartment are accessible to removal by hemodialysis unless precluded by protein binding. Drugs with small volumes of distribution on the order of total body water or less (i.e., about 0.7 liter/kg) are likely but not necessarily restricted to the extracellular space, whereas a large volume of distribution often implies wide disbursement of drug throughout tissues. A drug with a small volume of distribution and low-protein binding (e.g., aminoglycoside antibiotics) would be predicted to be substantially removed by dialytic procedures and likely require supplemental dosing after dialysis. In contrast, a drug with a large volume of distribution may pass through a dialysis membrane. However, so little of the drug is in the plasma relative to overall body stores that the amount removed is negligible.

The best method of calculating drug clearance by peritoneal or hemodialysis is to actually measure how much drug is removed. So doing serves as an integrated function of dialyzer clearance throughout the entire procedure.[166,167] The calculation is as follows:

$$\text{Dialyzer clearance} = \frac{\text{Total amount of drug recovered in the dialysate}}{\text{Duration of dialysis} \times \text{drug concentration at the midpoint of dialysis.}}$$

The drug concentration at the midpoint of dialysis can be measured by a single determination or preferably from a regression of serial samples obtained during the dialytic procedure. The considerations cited previously apply to conventional hemodialysis. Removal of drugs by continuous arteriovenous hemofiltration (CAVH) or continuous venovenous hemofiltration (CVVH) may differ from conventional hemodialysis in two ways. First, the pore size of the membrane is larger—allowing drugs of about 5000 angstroms to be freely filtered. Thus, a drug such as vancomycin (the size of which limits conventional dialytic removal) is readily removed by these filtration techniques. Second, other than large-molecular-weight compounds, essentially all of the unbound drug in plasma can be removed by these methods. Thus, drug clearance by ultrafiltration is equal to the unbound fraction times the ultrafiltration rate. This value can be used to estimate whether supplementary drug dosing needs to be given, and if so the amount.

Hemoperfusion techniques allow removal of substantially greater amounts of some drugs than can be accomplished with other methods. In fact, some of these methods are so efficient that all of the drug entering the dialysis cartridge is removed. In other words, the effluent drug concentration is zero.[168–170] It is important to emphasize, however, that this efficient removal from blood may still not remove a clinically important amount of drug from the body. For example, if only 1% of the total amount of drug in the body is circulating (even if hemoperfusion removes all of the circulating drug), 99% of it is still left in body reservoirs inaccessible to the dialyzer. As soon as dialysis is stopped, these reservoirs serve to refill the circulating compartment such that decrements in circulating drug concentrations caused by hemoperfusion are only transient. This concept clearly applies to drugs with large volumes of distribution and accounts for the lack of efficacy of hemoperfusion in treating poisoning with highly lipid-soluble sedative-hypnotics having large volumes of distribution (e.g., glutethimide and methaqualone with volumes of distribution of 2.7 and 6 liters per kilogram, respectively).

Dialytic removal of many drugs has been quantified in clinical studies. Table 95.5 outlines current data that can be used to derive clinical dosing guidelines.[2] For drugs having negligible removal, no dosing regimen adjustment is needed over and above that which occurs due to the patient's level of renal function. In contrast, for drugs having removal of potentially important amounts a supplemental dose equal to the amount removed can be given at the conclusion of hemodialysis. In patients treated with peritoneal dialysis, the dosing regimen can be increased to compensate for the amount of drug removed by the dialytic procedure. Interestingly, most drugs are negligibly removed by peritoneal dialysis (Table 95.5). This observation is in contrast to the substantial absorption of many drugs that occurs when administered with the peritoneal dialysate.[171] For example, although only 20–25% of a dose of an aminoglycoside antibiotic is removed by peritoneal dialysis, in contrast instillation of these drugs into the peritoneum results in 50% or more being absorbed systemically.

TABLE 95.5 Removal of Drugs by Dialysis: Percentage of Dose Removed During Session of Hemodialysis or 24 Hours of CAPD

Drug	Hemodialysis	CAPD

CAPD, continuous ambulatory peritoneal dialysis.

DOSING RECOMMENDATIONS IN PATIENTS WITH RENAL INSUFFICIENCY

Loading Dose

In some clinical conditions, a rapid response to a drug is desired. Attainment of steady-state serum concentrations requires four to five times the drug half-life. If this time is too long for the clinical setting, a loading dose strategy needs to be employed. The loading dose of a drug that is needed is a function of its volume of distribution:

$$\text{Loading dose} = \text{desired concentration} \times \text{volume of distribution.}$$

Values for volume of distribution can be found in standard reference texts, but these sources often ignore changes in this parameter that may occur in patients with renal disease. For example, the volume of distribution of digoxin in patients with end-stage renal disease is about half that of patients with normal renal function.[136] Thus, such patients require a loading dose half that of those without renal disease to attain identical concentrations.

TABLE 95.6 Volume of Distribution of Drugs in Patients with Renal Disease, V_d (liters/kilogram)[a]

Drug	Normal Renal Function	ESRD
ANALGESICS		
Codeine	3.5–6.0	7.3
Nalmefene	8.2	17.1
Salicylate	0.15	Increase (no change)[b]
ANESTHETICS AND DRUGS USED DURING ANESTHESIA		
Thiopental	1.9–2.2[12]	3.0[12]

HORMONAL AGENTS		
Insulin-like growth factor	0.15	0.07–0.09
MISCELLANEOUS		
Bendazac	0.18	Increase (no change)

[a]*Data in parentheses pertain to unbound drug.*
CLCr, creatinine clearance; ESRD, end-stage renal disease; Vd, volume of distribution.

TABLE 95.7 Methods of Adjusting Dosing Regimens in Patients with Renal Insufficiency

- Variable frequency (or interval) method: Individual doses are the same as in patients with normal renal function are administered at more widely spaced intervals.
- Variable dose method: The same dosing interval as in patients with normal renal function is used. Individual doses are diminished. One regimen is designed to attain the same average drug concentration as in patients with normal renal function. An alternative regimen attains the same peak concentrations.
- Kunin method: Half the dose used in patients with normal renal function is administered every half-life.
- Combination method: Both the dosing interval and individual doses are altered.

Table 95.6 lists drugs for which changes in volume of distribution have been documented in patients with renal disease.[2] For those drugs that are highly protein bound, notation is made as to whether the distribution volume of the pharmacologically active unbound drug concentration is altered. In most instances, where unbound drug has been measured there is no change

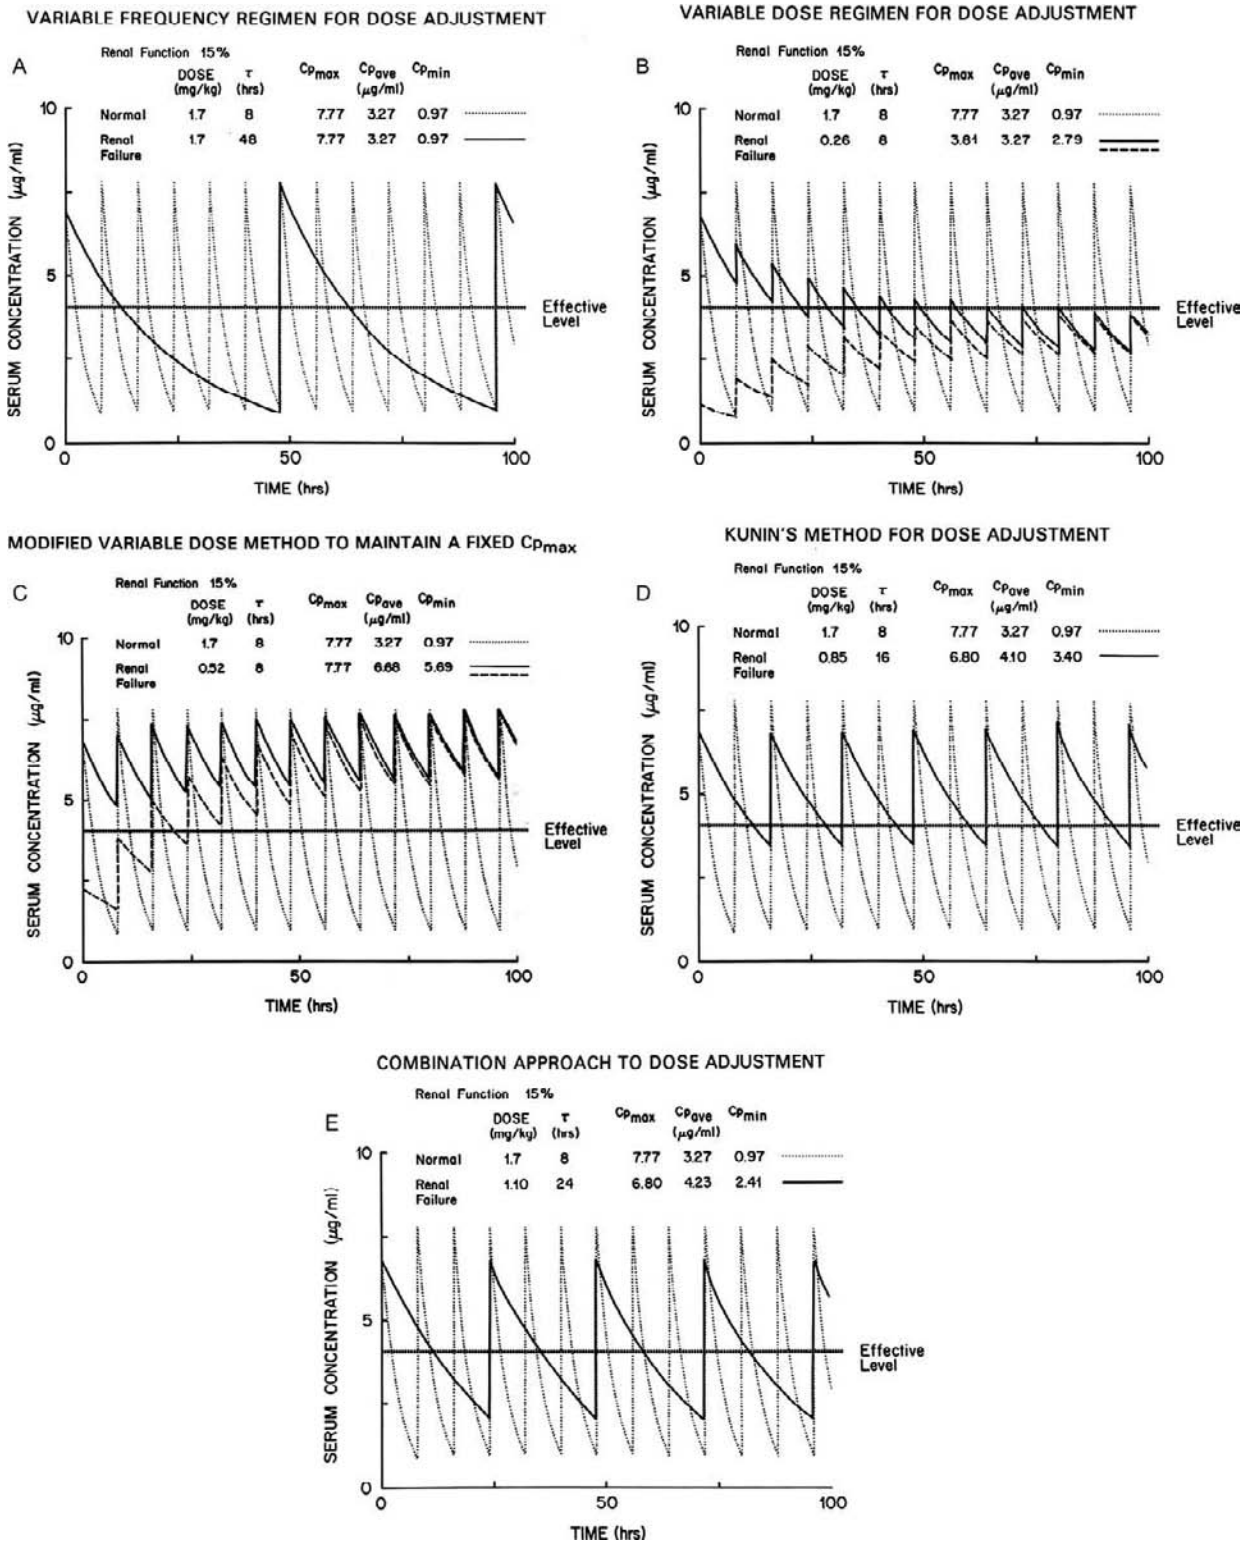

FIGURE 95.4 Schematic representation of the serum concentration versus time profiles of a hypothetical drug that depends on the kidney for elimination that is obtained by different methods of dose adjustment in patients with renal function 15% of normal. Stippled curves represent concentrations in patients with normal renal function. Solid curves represent concentrations in patients with renal insufficiency. Dashed curves in B and C represent concentrations when a loading dose is administered. Dosing regimens and peak, average, and trough serum concentrations are provided in each panel. See text for discussion of individual panels. *(Adapted from Chennavasin P, Brater DC. Nomograms for drug use in renal disease. Clin Pharmacokinet 1981;6:193–214.)*

and therefore no change in loading dose is required. As discussed previously, adjusting therapy based on findings from total concentration of highly bound drugs can lead to errors. Clinicians should be alert that an increase in volume of distribution of total drug when the drug is highly bound to albumin often means no change in terms of unbound drug. Cognizance of this phenomenon should avoid misinterpretation of incomplete data in the scientific literature.

Maintenance Dose

Once it is determined that a maintenance dose of drug needs modification in patients with renal insufficiency, several methods of changing the dosing regimen can be employed (Table 95.7).[172] With most drugs, any of the methods listed in Table 95.7 can be utilized and the choice depends on such factors as ease of the regimen for the patient and size of individual doses relative to tablet strength. In contrast, for drugs for which it is important to achieve specified target peak and trough serum concentrations (e.g., antiarrhythmics or anticonvulsants) the dosing methods differ considerably.

The schematics shown in Fig. 95.4 illustrate the differences in dosing methods in terms of peak and trough serum concentrations attained.[172] The interrupted curves in this figure represent serum concentration profiles of an illustrative drug in an average patient with normal renal function. Values for peak and trough concentrations and the dosing regimen are shown in the figure. The solid curves represent serum concentrations in a patient with renal function 15% of normal. Each panel illustrates a different dosing method. It is important to note that the average drug concentration attained with the variable frequency method and with the first variable dose method is the same as in patients with normal renal function. Keeping the average concentration the same is an adequate goal with the majority of drugs, and thus one of these two simple methods can be employed in most settings.

For drugs where peak and trough as well as average concentration is important the simple methods of dose adjustment are flawed. Thus, the variable frequency method shown in Fig. 95.4A could result in prolonged periods of time with sub-therapeutic serum concentrations. The variable dose method shown in Fig. 95.4B, if used without an initial loading dose, may never result in therapeutic peak concentrations. When a loading dose is given, therapeutic concentrations are initially attained. However, when steady state is reached concentrations become sub-therapeutic. Moreover, trough concentrations with this dosing regimen may be higher than desirable and cause toxicity. Thus, in patients with severe renal insufficiency, the variable dose method could result in diminished efficacy and enhanced toxicity. It should be apparent that the two simplest methods of dose adjustment, although adequate for many if not most drugs, may be seriously

flawed for other drugs where attainment of specific peak and trough serum drug concentrations is required for maximal benefit.

Because of the flaws with simple dose adjustment methods, other strategies have been explored. Fig. 95.4C depicts a method designed to attain target peak concentrations while maintaining the same dosing interval as in patients with normal renal function. But this regimen may be unsuitable for some drugs owing to the very high trough concentrations that occur. For other drugs (such as cephalosporin or penicillin antibiotics) for which maintenance of peak concentrations is critical but there is little concern about elevated trough concentrations, this regimen would be acceptable. Kunin's method for dose adjustment is shown in Fig. 95.4D. Its merits and flaws are similar to those of the regimen in Fig. 95.4C and may therefore be appropriate for some drugs, but it is inappropriate for others.

The combination approach of adjusting both the dose and the dosing interval (Fig. 95.4E) is a compromise aimed at a minor decrease in peak concentration, a modest increase in trough concentration, and a dosing interval that is of less concern in terms of duration of time with potentially sub-therapeutic drug concentrations.

The disposition of many drugs has been studied in patients with renal insufficiency. From such data, dosing guidelines can be derived based on a patient's level of renal function[2] (Table 95.8). Once the table is used to decide the amount of dose adjustment required, the concepts explored in the previous discussion of Fig. 95.4 can be used to decide the method of dose adjustment. These data can then be coupled with those from Table 95.5 in patients receiving dialysis.
