CHAPTER

56

Chemoreceptors, Breathing and pH

Eugene Nattie

The Geisel School of Medicine at Dartmouth, Lebanon, New Hampshire, USA

INTRODUCTION

Our thinking on mammalian acid–base regulation focuses on pH. Intracellular pH, which is of great importance in the maintenance of normal protein function, is regulated by membrane ion transporters, intracellular buffers, and by changes in cell metabolism.[94,111] The success of intracellular pH regulation is dependent on the extracellular pH being constrained in its variation.[107] Renal processes can alter extracellular proton and bicarbonate balance by changes in ion excretion. In this chapter we focus on how breathing can affect the partial pressure of carbon dioxide in extracellular fluid, here the partial pressure of carbon dioxide in arterial blood, $PaCO_2$. The traditional approach utilizes the straightforward relationships shown in Eqs 1 and 2.

$$CO_2 + H_2O = H_2CO_3^- = H^+ + HCO_3^- \quad (59.1)$$

$$pH = pK^- + \log([HCO_3^-]/[S \times PCO_2]) \quad (59.2)$$

where S = the solubility of CO_2 in blood and pK^- is a combined dissociation constant.

Note that pH can be affected by primary changes in either bicarbonate or PCO_2. Arterial bicarbonate changes by a small amount as CO_2 is changed due to the presence of blood buffers. But by far the most important changes in arterial bicarbonate occur either as the result of a primary metabolic disturbance, which changes the ionic composition of blood thereby affecting bicarbonate, or as the result of the kidney, which can also change the ionic composition of blood thereby affecting bicarbonate.

CO_2

Ventilation and CO_2

Arterial blood pH is the clinically relevant extracellular variable because changes in breathing alter the $PaCO_2$ directly. The $PaCO_2$ is determined by the ratio of CO_2 production and alveolar ventilation. For a constant metabolic rate (and CO_2 production), an increase in alveolar ventilation will lower the $PaCO_2$ and, conversely, a decrease in alveolar ventilation will elevate the $PaCO_2$. Both events have acid–base consequences. Hyperventilation eliminates CO_2 faster than it is being produced and, as a result, pH increases; hypoventilation eliminates CO_2 more slowly than it is being produced and, as a result, pH decreases. The changes are quantitatively speaking not small. If alveolar ventilation doubles, the normal $PaCO_2$ of 40 mm Hg will quickly attain a new value of 20 mm Hg. Arterial pH will quickly change from the normal value of 7.40 to 7.70. Conversely, if alveolar ventilation is reduced by half, arterial PCO_2 will quickly attain a new value of 80 mm Hg. Arterial pH will change from the normal value of 7.4 to 7.10. Changes in alveolar ventilation quickly and dramatically affect $PaCO_2$ and pH. A 10% increase in alveolar ventilation will decrease $PaCO_2$ by 4 mm Hg and increase arterial pH from 7.40 to 7.45 all within seconds. This change in arterial pH is determined by the decrease in PCO_2 and by the effectiveness of blood buffers, which include most importantly the red blood cell hemoglobin concentration. In the absence of any protein buffers, the pH change would be much greater. If the hyperventilation and

DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00056-2

hypocapnia are sustained, there are secondary renal adjustments that act to excrete more bicarbonate and to lessen the initial alkalosis. These events take minutes to hours and are governed by the lowered PCO_2. Changes in PCO_2, whether decrease or increase, are quickly reflected in all blood and tissue compartments due to the diffusability of CO_2.

Tissue CO_2

Tissue PCO_2 levels are determined by the arterial value, the tissue rate of CO_2 production, and the amount of tissue blood flow. Changes in blood flow and cell metabolism can affect cell PCO_2 and pH for any given arterial PCO_2. For example, the brain has blood vessels that determine blood flow resistance and are very sensitive to changes in CO_2. An increase in $PaCO_2$ would tend to directly cause an increase in tissue and cell PCO_2 and a decrease in their pH. The strong vasodilatory action of high CO_2 on cerebral vessels would decrease resistance and allow blood flow to increase, which would clear more CO_2 and indirectly minimize the increase in tissue and cell PCO_2. Tissue and cell PCO_2 and pH are determined by blood flow for any $PaCO_2$ value and by metabolic rate.

CO_2 and Ventilation

A change in pH is detected by a physiological process called chemoreception. The pH sensors are present in the peripheral blood at the bifurcation of the carotid artery, the carotid body,[26,38,43,54,67] and within the brainstem at multiple locations.[5,56,69–72,105,106] Both the carotid body and the brainstem respond to a fall in pH, for example, by increased stimulation of breathing, which lowers $PaCO_2$ and tends to minimize the initial acidosis. This feedback control of the alveolar ventilation level, and hence the $PaCO_2$, by chemoreceptor-detected changes in pH is the essence of this chapter. The body can detect small pH changes at many sites and quickly bring about a change in breathing that acts to correct the initial perturbation. It is an appropriate response to correct pH. This system detects arterial pH at the carotid body and at the central chemoreceptors; it likely detects a pH value somewhere between the arterial and brain interstitial fluid pH.

PERIPHERAL CHEMORECEPTORS

Location of Carotid Body

The carotid body is well located to detect changes in arterial pH and PCO_2. In fact, this location at the bifurcation of the carotid body rapidly detects small changes in $PaCO_2$ that reflect minor variations in the normal level of alveolar ventilation, and thus serves admirably as a feedback control detector site for the maintenance of a normal level of alveolar ventilation. This site is also a useful one for the detection of pH changes that reflect abnormal physiology, but for this purpose it is difficult to construct an argument that makes this anatomical location of special utility. In fact, a chemoreceptor site closer to the tissue location of altered metabolism in a metabolic acid–base disorder might theoretically be of greater use. For example, mixed venous CO_2 receptors have long been sought for in order to explain the tight link between increased metabolism in muscular exercise and alveolar ventilation. Here venous CO_2 levels rise; but arterial PCO_2 remains normal or decreases slightly as alveolar ventilation changes to match the increase in metabolic rate. Sporadically, the discovery of mixed venous chemoreceptors has been reported, but none of these have stood the test of time. Specific central chemoreceptor locations in the brain might well reflect tissue and cell PCO_2 and pH, that is, tissue chemoreceptors may be present.

Carotid Body Function

The carotid body is a fascinating tissue. It is quite small, and is difficult to find by gross anatomical dissection, but has a large metabolic rate and a high perfusion. This tissue is arguably the only and certainly the major detector of low O_2 levels. Hypoxia strongly excites the carotid body with powerful stimulatory effects on breathing and arousal.[38,43,54] It is the detector for the hypoxia emergency warning system, and also detects changes in PCO_2, including values that may drop below normal. In non-rapid eye movement sleep, apneas that occur within seconds of a transient hyperventilation have been attributed to hypocapnia sensed at the carotid body. Thus, in sleep there is a tonic nervous activity from the carotid body to the brain that maintains a normal level of ventilation. Transient diminution of this activity by brief hypocapnia can lead to apnea, the cessation of breathing.[26,108] There is evidence as well for tonic carotid afferent activity that is important in the maintenance of appropriate levels of ventilation in wakefulness.[17,38] Surgical removal of the carotid bodies in experimental animals and in humans results in a stable new steady state of hypoventilation. The animal then maintains a "normal" $PaCO_2$ that is a few mmHg higher than in animals with intact peripheral chemoreceptors. This state is maintained despite the presence of central chemoreceptors.[31,38,67,100] It seems that normal ventilation

requires the tonic afferent input from peripheral chemoreceptors. In 1938, Heymans received the Nobel Prize for the discovery of the carotid body. He proposed that the carotid body was the major detector of CO_2, as well as for hypoxia.[43]

CENTRAL CHEMORECEPTORS

There is clear evidence for receptors within the brain that detect changes in PCO_2 or pH and bring about a change in ventilation. The ventilatory response to changes in pH as mediated by central chemoreceptors is very sensitive. Figure 56.1 shows data obtained from unanesthetized goats in a series of classic experiments.[34,89] Alveolar ventilation, VA, is plotted against the pH in cerebrospinal fluid. The shaded area presents data obtained during chronic metabolic acidosis and alkalosis maintained for days in the goats as they breathed air or inhaled CO_2 from 0 to 10%. Note that in these steady-state conditions of chronic metabolic acid–base disorders, the response of alveolar ventilation to changes in cerebral pH is very sensitive—it doubles for a cerebrospinal fluid (CSF) pH change from 7.33 to 7.28. The X symbols in Fig. 56.1 will be discussed below.

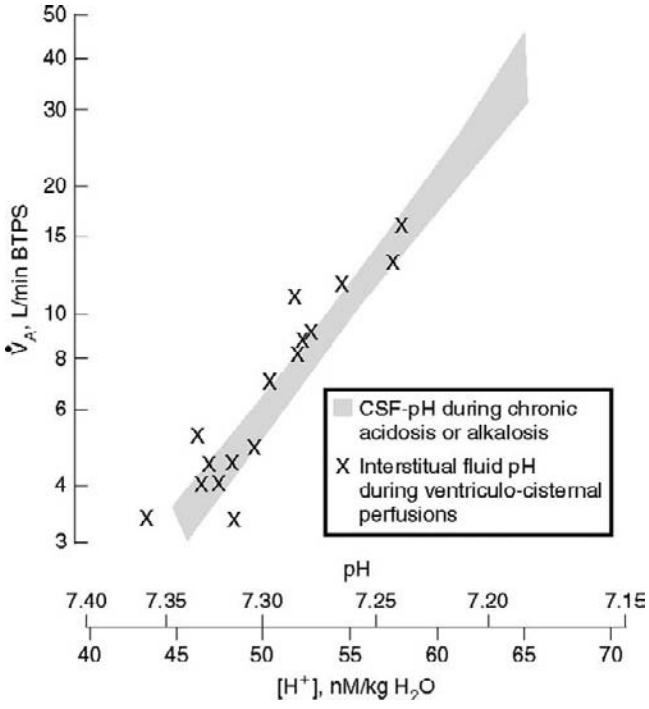

FIGURE 56.1 The alveolar ventilation response to chronic acid–base disorders and to inhaled CO_2 is shown versus the pH measured in cerebrospinal fluid in the shaded area, which presents ±SEM (standard error of measurement) of 81 separate measurements obtained in five goats. The crosses derive from experiments in which the goats had ventriculo-cisternal perfusion of cerebrospinal fluid with differing bicarbonate concentrations. Alveolar ventilation in these cases is plotted versus the pH calculated for a site that lies three-quarters of the distance along the concentration gradient between ventricular cerebrospinal fluid and blood. *(With permission of the American Physiological Society, from Figure 12, from ref. [34].)*

History: Ventrolateral Medulla

The presence of central chemoreceptors was first suggested by the continued presence of a ventilatory response to an increase in $PaCO_2$ after surgical removal of the peripheral chemoreceptors[31,38,42,67] and solidified by the presence of a ventilatory response to an acid load applied directly into the cerebral ventricles.[55] Direct application of small pieces of cotton, soaked in an acidic solution, to various brainstem surfaces further localized the site of central chemoreception to the surface of the ventral lateral medulla,[56,60,105,117] a site that still captures the imagination of investigators.[62] All of these studies were performed under surgical anesthesia, which has a powerful depressant effect on the sensitivity of the ventilatory response to CO_2, and required very acidic stimuli. Further, the blood supply to the medulla arises from vessels on the ventral surface, which could have easily carried the stimulus to deeper structures.[13,58] Cooling or coagulation of this area decreased ventilatory output dramatically in anesthetized animals.[14,106]

The effects of anesthesia on chemosensitivity cannot be overemphasized. For example, Akilesh et al.[4] found that in rats, the change in ventilation breathing 7% CO_2 compared to breathing air is decreased by about 70% with the introduction of anesthesia. There are many similar examples of how much anesthesia affects the chemoreceptor response sensitivity.[37,87] Nevertheless, these early studies demonstrated that chemoreception is present in the medulla, and it is accessible from the ventral medullary surface.

Widespread Central Chemoreception

More recently, a series of studies have led to the proposal that central chemoreception is a phenomenon that is widely present in the hindbrain.[16,32,69–72] Before proceeding, a few clarifying definitions are warranted. A functional definition for chemoreception refers to a ventilatory response to a change in CO_2/pH. Chemosensitivity or chemodetection refers to the response of a described unit, say a particular type of neuron, to changes in CO_2/pH. Chemosensitivity and chemodetection do not necessarily translate to chemoreception, that is, the presence of a type of neuron with

a known sensitivity *in vitro* to changes in CO_2/pH does not necessarily mean that the neuron is important in a chemoreceptor response, one that involves a change in ventilation *in vivo*.

A number of experimental approaches support the concept that central chemoreception is a widely distributed function within the hindbrain. Experiments using expression of the early gene, c-fos, following exposure to elevated CO_2, described the presence of activated neurons at locations near the ventral lateral medullary surface, as proposed in early studies, but also deeper in the brainstem at other locations including the locus ceruleus, nucleus tractus solitarius, medullary raphe, rostral aspect of the ventral respiratory group, and fastigial nucleus of the cerebellum.[28,88,90,95,102,116] Studies of neurons in slice preparations of the medulla that included the deeper nucleus tractus solitarious, locus ceruleus, and medullary raphe have all described neurons that were excited by CO_2.[24,53,91,96,98,99] These experimental approaches did not demonstrate chemoreception, however. The neurons expressing c-fos could have been "downstream" to the actual chemodetector cells, and the neurons in the slice preparations were not connected to a ventilatory output.

A series of experiments have utilized the approach of examining the ventilatory response to a small region of focal acidosis produced at various sites within the brainstem. While studying the role of carbonic anhydrase in cerebral pH regulation, Coates et al.[15] noted that focal application of acetazolamide, an inhibitor of carbonic anhydrase, resulted in focal acidosis. They then used tiny 1-nl injections of acetazolamide to produce very focal acidosis in the brainstem of anesthetized cats and rats.[6,16] The presence of a ventilatory response following such injections indicated the presence of chemoreception at that site. Central chemoreception was present at many locations, including the retrotrapezoid nucleus (RTN) just below the ventral medullary surface (a possible site for the older surface chemoreceptors), nucleus tractus solitarious, locus ceruleus, midline medullary raphe, rostral aspect of the ventral respiratory group, and fastigial nucleus in the core of the cerebellum (the same sites as described by the c-fos studies). Focal acidosis produced by the 1-nl injections of acetazolamide resulted in an increase in fictive ventilatory output in these anesthetized animals, which provided functional evidence for multiple central chemoreceptor locations. Brain pH measurements showed the tissue pH change to be similar to that observed with a 20-mm Hg increase in arterial PCO_2 in anesthetized animals. A second approach to induce a focal acidosis in various regions of the brainstem utilizes reverse microdialysis with a CO_2 laden artificial cerebrospinal fluid (aCSF)[60–62], which reduced brain tissue pH by an amount like that observed with an increase in arterial PCO_2 of 5-6 mm Hg, a small stimulus intensity[63]. This approach demonstrated ventilatory responses in the sites shown in Fig. 56.2.

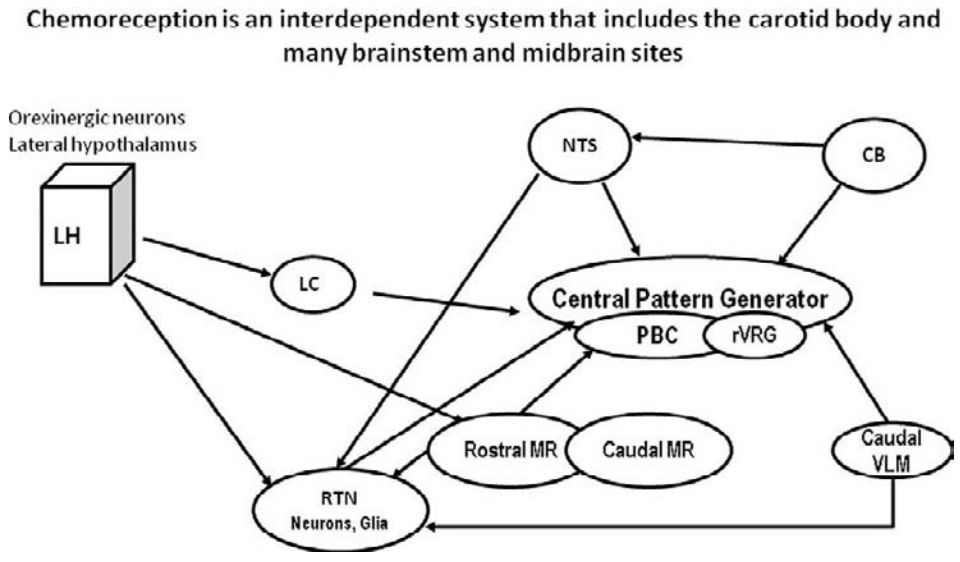

FIGURE 56.2 A simplified, schematic view of chemoreceptor sites that, when stimulated, can increase ventilation in wakefulness. Solid lines identify connections known to be present in wakefulness. LH, lateral hypothalamus; LC, locus ceruleus; NTS, nucleus tractus solitarius; CB, carotid body; PBC, pre-Bötzinger complex; rVRG, rostral ventral respiratory group; MR, medullary raphe; VLM, ventrolateral medulla. Putative Chemoreceptor Cell Type

What cell type is responsible for the detection of CO_2 or pH within the brainstem chemoreceptor sites? This seemingly simple question has proven difficult to answer because there are numerous possibilities. While it is difficult to study the response of a given cell type to acidic stimulation in a brainstem slice preparation or in cultured neurons, it is even more difficult to interpret *in vivo* findings of chemoreception. Nonetheless, there is *in vitro* and *in vivo* complementary evidence for involvement of serotonergic, noradrenergic, and glutamatergic neurons. This evidence is discussed below.

Serotonergic Neurons

Serotonergic neurons are chemosensitive when studied in slices taken from young rats or in neurons taken from newborn rats and grown in culture for several days.[96–99,119–121] These neurons are in the midline medullary raphe in close proximity to large penetrating blood vessels. The blood supply of the medulla arises from vessels on the ventral surface that penetrate deep into the tissue supplying neurons through to the dorsal aspect of the medulla.[13] A serotonergic neuron in culture will increase its firing rate with a mild CO_2 stimulus, e.g., from 1 to 3 Hz. If expressed as the percent change in firing rate, these neurons are quite sensitive in this reduced preparation. This sensitivity *in vitro*, response to mild stimulus intensities, and anatomical proximity to large vessels has been interpreted to indicate that serotonergic neurons are major central chemoreceptors. *In vivo* data support this hypothesis. Serotonergic neurons can be specifically destroyed by injection of a cell toxin, saporin, which has been conjugated to an antibody to the serotonin transport protein (anti-SERT-SAP).[84] The antibody recognizes the serotonergic cell, the conjugate is internalized, the saporin is released, and, over a period of days, the cell is killed. Such injections reduce the number of serotonergic neurons in the medullary raphe region of the rat by 28%, and also reduce the ventilatory response to CO_2 by 15 and 18%, respectively, in wakefulness and in NREM sleep. Serotonergic neurons are clearly involved in chemoreception. These data do not prove that they are chemodetector neurons *in vivo*.

One can inhibit serotonergic neurons reversibly by stimulation of serotonin 1A receptors, which are primarily inhibitory autoreceptors, by direct application via reverse microdialysis of 8-OH-DPAT ((R)-(+)-8-hydroxy-2(di-n-propylamino)tetralin). When this is done in the medullary raphe region of the unanesthetized rat, the CO_2 response is reduced. Dialysis of 10 mM 8-OH-DPAT reduces the CO_2 response by ~20%, while dialysis of 30 mM 8-OH-DPAT reduces it by 40% (Taylor et al., unpublished observations). When DPAT is dialyzed in the medullary raphe region of the unanesthetized newborn piglet, the CO_2 response is again reduced, but only in piglets older than seven days. In younger piglets, dialysis of DPAT increases the CO_2 response.[59] Serotonergic neurons are clearly involved in chemoreception but not in the early postnatal period. Again, these data do not prove that they are chemodetector neurons *in vivo*.

Finally, daily focal administration of the SERT inhibitor, fluoxetine, over 21 days in the unanesthetized rat, which should make more serotonin available in the medullary raphe region, results in an enhanced ventilatory response to CO_2.[114]

Serotonergic neurons cell bodies are located in specific sites within the brainstem and have very widespread connections within the higher brain and spinal cord. They are most active in terms of firing rate in wakefulness and less so in NREM sleep, and are almost quiescent in REM sleep. Their main function remains incompletely understood; the concept that they may be chemodetectors important in ventilatory chemoreception is somewhat paradoxical.

In sum, these *in vitro* data showing the sensitivity of serotonergic neurons to CO_2 but not proving their involvement in chemoreception, and these *in vivo* data showing that serotonergic neurons are involved in chemoreception but not demonstrating that they are directly chemosensitive, present a constellation of findings most easily interpreted as involving serotonergic neurons as chemodetectors. It is likely that these serotonergic neurons also modulate other aspects in regulating breathing and, in respect to chemoreception, they may act as modulators as well as detectors.

Glutamatergic Neurons

Glutamatergic neurons in the region of the retrotrapezoid nucleus (RTN) have also been proposed as the central chemosensitive neurons. The RTN, at first glance, is a rather unimpressive group of small, difficult-to-find neurons that lie in a small sliver of space between the ventral border of the facial nucleus and the ventral surface of the medulla. This group of neurons was discovered at about the same time by two quite different experimental approaches. In one, viral retrograde tracers injected into the phrenic motor nucleus demonstrated the presence of second-order neurons at this site;[27,109] in the other, very small injections in the RTN of an excitatory amino acid toxin, kainic acid, stopped breathing and substantially reduced the ventilatory response to CO_2 in anesthetized cats

and rats.[76,77] A series of studies then showed in unanesthetized rats that:

1. Focal stimulation of the RTN by reverse microdialysis of a CO_2-rich artificial cerebrospinal fluid stimulated breathing, which indicated the presence of chemoreception in the RTN.[57]
2. Dialysis of the GABA-A receptor agonist muscimol decreased the ventilatory response to CO_2, supporting the presence of chemoreception in the RTN.[78]
3. Dialysis of the GABA-A receptor antagonist, bicuculline, stimulated breathing, which indicated the presence of a tonic GABAergic inhibition in the RTN.[83]
4. Stimulation of neuronal activity in the RTN by CO_2, which supported the presence of chemoreception in the RTN.[18,82]
5. Unilateral excitatory amino acid toxin-induced lesions reduced the ventilatory response to CO_2, but had no effect on baseline breathing or on the response to hypoxia supporting the presence of chemoreception in the RTN.[4]
6. Bilateral lesions of RTN neurons that express the neurokinin-1 receptor by injection of a cell-specific toxin, substance P (the ligand for the neurokinin-1 receptor) conjugated to the cell toxin saporin, decreased the ventilatory response to CO_2 and induced hypoventilation, which supported the presence of chemoreception in the RTN.[81]

Recent studies have identified the putative chemoreceptor neuron within the RTN as glutamatergic.[62] In anesthetized rats, RTN neuronal activity was shown to be sensitive to CO_2 delivered to the whole rat, even when other aspects of the respiratory control network were inhibited by systemic administration of a broad-spectrum glutamate receptor antagonist or by an opioid receptor antagonist. Further, the excitable neurons were shown by juxtacellular labeling to express the RNA message for the glutamate transport protein, VGLUT2, thereby identifying the neurons as glutamatergic. These authors also found that nearby serotonergic neurons were not responsive to CO_2, but they did not test serotonergic neurons at other sites where they are plentiful. Studies in brainstem slices also showed these glutamatergic neurons to be CO_2 sensitive. The RTN is a central chemoreceptor site, and glutamatergic neurons in the RTN certainly seem to be involved in chemoreception and may be chemodetector neurons at this site.

Noradrenergic Neurons

Like serotonergic neurons, the noradrenergic neurons have cell body localization within the brainstem with widespread projections into the higher brain and spinal cord, fire in a state-dependent manner with firing greatest during wakefulness, followed by NREM sleep, which in turn is followed by REM sleep, and seem to play a role in both basic physiological control as well as in the modulation of higher nervous system behaviors. When studied in brainstem slices, the noradrenergic neurons of the locus ceruleus are chemosensitive, which suggests that they could be involved in chemoreception. In brain slices, the locus ceruleus cell firing rate is increased by ~56% as bathing medium CO_2 is increased from 5 to 10% CO_2,[91] and by 93% as the bathing medium CO_2 is increased to 15%.[35] In anesthetized rats, hypercapnia increases the locus ceruleus neuron firing rate together with splanchnic nerve activity even after denervation of the carotid bodies.[29] The baseline firing rate of one neuron was ~3 Hz; on average, the firing rate increased by 20% at 5% CO_2 and 47% at 10% CO_2.[29] The expression of the early gene, c-fos, is also increased in TH-ir neurons of the locus ceruleus region in response to increased CO_2 (15% CO_2 for 60 minutes), which suggests a role for these cells in central chemoreception.[41] Focal acidification of the locus ceruleus region by microinjection of acetazolamide increases fictive ventilatory output (phrenic nerve activity) in anesthetized cats and rats, indicating that this location contains chemoreceptors that can affect breathing.[16] Cell-specific killing of noradrenergic neurons in locus ceruleus and in other brainstem regions, that is, the A5, C1, and C3 regions, decreases the ventilatory response to CO_2 in rats during sleep and wakefulness (Li and Nattie, unpublished observations). Injections of the cell-specific toxin, anti-DBH-SAP, into the fourth ventricle, reduced the number of TH-ir cell profiles counted in the A6 region by 84% and in the A5 region by 78%. These injections had little effect on TH-ir cells in more rostral sites as demonstrated by the lack of effect on TH-ir cell profile counts in a portion of the A9 region. This was associated with a 25–28% reduction in the ventilatory response to systemic hypercapnia in both sleep and wakefulness.

Cholinergic Receptors

There is *in vivo* evidence suggesting that muscarinic cholinergic receptors in the region of the retrotrapezoid nucleus are also involved in central chemoreception.[63] In anesthetized cats, focal inhibition of muscarinic receptors by application of antagonists to the ventral medullary surface and by their microinjection into the ventral medullary tissue decreased the ventilatory response to CO_2. Use of relatively specific muscarinic-receptor subtype antagonists produced effects suggesting that the M3 subtype was most potently involved; a greater fraction of M3 receptor antagonist injections inhibited the CO_2 response than did M1 or M2 receptor antagonist injections.[75]

Small Ventral Surface Cells

A number of investigators have noted the presence of small cells along the ventral medulla surface that express the early gene c-fos after CO_2 stimulation. These cells have been proposed as chemodetectors.[8,39,117] The size and character of these cells differ from the glutamatergic neurons that have been recently proposed in this region as chemodetectors.[62] In fact, they resemble glial cells. Could glia be central chemodetectors? There is evidence to support the idea that glia can, at the least, modulate central chemoreception. Focal inhibition of glial function in the RTN by microdialysis of fluorocitrate, which preferentially inhibits metabolism in glia, results in the development of focal acidosis and stimulation of breathing in anesthetized rats.[30] In unanesthetized rats, fluorocitrate application focally into the RTN region stimulates breathing both in air and in various CO_2 levels.[46] If glia can be depolarized, and thus "excited," by changes in pH, their release of substances like ATP or glutamate could act like "neurotransmitters," which can then stimulate nearby neurons (see Putnam et al.[94]). Glia seems to regulate local interstitial fluid (ISF) pH, and thus they likely modulate central chemoreceptor function.

ATP and P2X Receptors

There is quite a bit of evidence from experiments in anesthetized animals that supports a role of some type for ATP and P2X receptors in central chemoreception. P2X receptors are present in the ventral lateral medulla; application of P2 receptor antagonists decreases the ventilatory response to CO_2, ATP is released from cells in the ventrolateral medulla during CO_2 stimulation, and application of ATP to this region stimulates breathing.[112] These observations suggest that ATP release with subsequent stimulation of cells with purogenic receptors is involved in central chemoreception.

Why so Many Central Chemoreceptor Sites?

Which sites are the most important? There is no evidence as yet to show that one central chemoreceptor site, or that one central chemodetector cell type, is of primary importance in the unanesthetized mammal. Much evidence obtained both *in vitro* and *in vivo* supports a role for medullary raphe serotonergic neurons, RTN glutamatergic neurons, and medullary noradrenergic neurons in central chemoreception. The quantitative nature of responses to focal acidic stimulation is basically similar in anesthetized or unanesthetized animals at all sites tested, which include the RTN, medullary raphe, locus ceruleus, nucleus tractus solitarius, rostral aspect of the ventral respiratory group, and fastigial nucleus of the cerebellum. Similarly, lesions of the RTN, medullary raphe, and medullary noradrenergic cells, and focal inhibition of the RTN or the medullary raphe all decreased the ventilatory response to CO_2 but none abolished it. In fact, the largest proportional inhibition that has been observed in conscious animals has been a ~40% decrease in the ventilatory response to CO_2: (1). following destruction of RTN neurons by an excitatory neurotoxin,[4] and (2). following reversible inhibition of medullary raphe serotonergic neurons by reverse microdialysis of 8-OH-DPAT, an inhibitor of serotonergic neurons (Taylor et al., unpublished observations). In the first case, this effect was measured 18 days following induction of the lesion; in the second case, the effect was measured immediately. No one has as yet produced a total lesion or total inhibition of all neurons located at a single anatomical location or of all neurons identified by a single chemical phenotype. One possible exception is an experiment in which neonatal rats were treated with a serotonergic toxin, 5,7-dyhydroxytryptamine.[61] When studied as adults, these rats showed a decrease of about 50% in ventilatory response to CO_2. Because no histology was performed, the extent of the serotonergic lesion is unknown, although tissue levels of serotonin were dramatically reduced.

Given the presence of multiple cell types that are chemosensitive *in vitro* together with *in vivo* observations that indicate chemoreception occurs at sites containing these neurons and that lesions or neuronal inhibition at these sites interfere with the ventilatory response to CO_2, it seems unlikely that there is a predominant chemodetector neuron or chemosensitive site. The sum of all the evidence supports the concept of multiple central chemoreceptor sites and multiple chemodetector cells.

Why is Central Chemoreception Such a Distributed Property?

A number of hypotheses, briefly described in the following, have been proposed to answer this question:[32,70–72]

Geographic Specificity

Various brain regions, in a geographic or anatomical sense, each have their own set and type of chemoreceptors. These could be organized among physiological functions, such as control of blood pressure versus breathing, or within a single function, such as the various brainstem sites involved in the control of breathing.

Stimulus Intensity

Sites may vary according to stimulus threshold and stimulus intensity required to bring about a response. To obtain the very high overall sensitivity of the system, many or all sites must be stimulated at the same time.

Stimulus Specificity

CO_2 may stimulate some sites, and pH may stimulate others. Some may detect intracellular pH, and others extracellular pH.

Temporal Specificity

Some sites may be oriented to detect blood pH, others to detect brain interstitial fluid pH or to detect cell pH. These various sites may detect pH changes at different times during an acid–base event.

Syncytium

Chemodetector cells at certain sites could be part of a network connected by low-resistance junctions.[25] This could be a way to enhance the system response to a small focal response at the cellular level.

Arousal State

Some sites could respond in sleep, others in wakefulness, and still others in both states. Evidence from focal stimulation studies supports this to some extent.

The role of various central chemoreceptor sites has been evaluated in unanesthetized animals by employing the technique of reverse microdialysis to deliver CO_2 into restricted brainstem regions. By equilibration of artificial cerebrospinal fluid with high CO_2 concentrations, and by rapid flow through the dialysis system, a focal and moderate level of tissue acidosis can be produced. In the rat, such focal acidosis in the region of the retrotrapezoid nucleus increases ventilation in wakefulness,[57] whereas in the midline medullary raphe region it does so in sleep (Fig. 56.3).[79] These two sites are within a millimeter or so of each other anatomically. The fact that focal CO_2 administration at the medullary raphe increases ventilation by affecting breathing frequency only in sleep, while focal CO_2 administration in the RTN increases ventilation via an effect on tidal volume only in wakefulness, provides functional evidence that this technique does produce a focal stimulus. These data also suggest that various chemoreceptor sites may have different roles. Focal CO_2 administration in the nucleus tractus solitarius increases ventilation in both sleep and wakefulness via an effect on both breathing frequency and tidal volume.[80] In the unanesthetized goat, focal acidification in the medullary raphe increases ventilation in wakefulness,[44] and focal acidification at two medullary raphe sites produces twice the effect on breathing.[45] The stimulus intensity observed with focal CO_2 dialysis in rats, as measured by tissue pH electrodes, is similar to that observed with a 6-mm Hg increase in $PaCO_2$. The goat studies used a similar stimulus intensity.

Evolutionary Considerations

Satinoff[101] published the idea of a hierarchical control system for mammalian temperature regulation, with levels in the hierarchy determined by physiological processes added during steps in evolution.

New demands cause new mechanisms and new sites of regulation. It is possible that the presence of multiple central chemoreceptor sites is the result of a similar evolution. As organisms progressed during evolutionary time, major events occurred, each of which could have resulted in the development of a new chemoreceptor site with new functional emphasis. For example, the transition from water-to-air breathing, development of homeothermy, requirement for sleep, and further differentiation of sleep into NREM and REM components, could have been associated with the need for the development of a new chemoreceptor site and mechanism.

What is the Role of Peripheral versus Central Chemoreceptors?

If we group the central chemoreceptors together, the issue remains of the importance and function of the central chemoreceptors versus that of the peripheral chemoreceptors. Heymans and Bouckaert,[43] among others, have argued that the peripheral chemoreceptors can explain most of the chemical control of breathing while others, most notably Pappenheimer and colleagues,[34,89] have suggested that the opposite is more likely. Experiments with clearly interpretable results have not been forthcoming. There have been many attempts to surgically remove the carotid bodies and then compare the sensitivity of the ventilatory response to CO_2 to that observed prior to peripheral chemodenervation. Generally, these studies in both anesthetized and in unanesthetized animals have suggested that the peripheral chemoreceptor can account for 20–40% of the total CO_2 response.[38,42,67] The problem that makes the interpretation of these data difficult is that the carotid bodies provide a tonic afferent excitatory input to the respiratory control system. Thus, peripheral chemodenervation removes both a tonic source of system excitation as well as the CO_2-dependent increase in excitation. Consequently, a subsequent reduced sensitivity to CO_2 cannot be interpreted as the outcome of losing CO_2 detection alone. In fact, this loss of a tonic excitation may be the explanation for the common observation in chemodenervated animals and humans

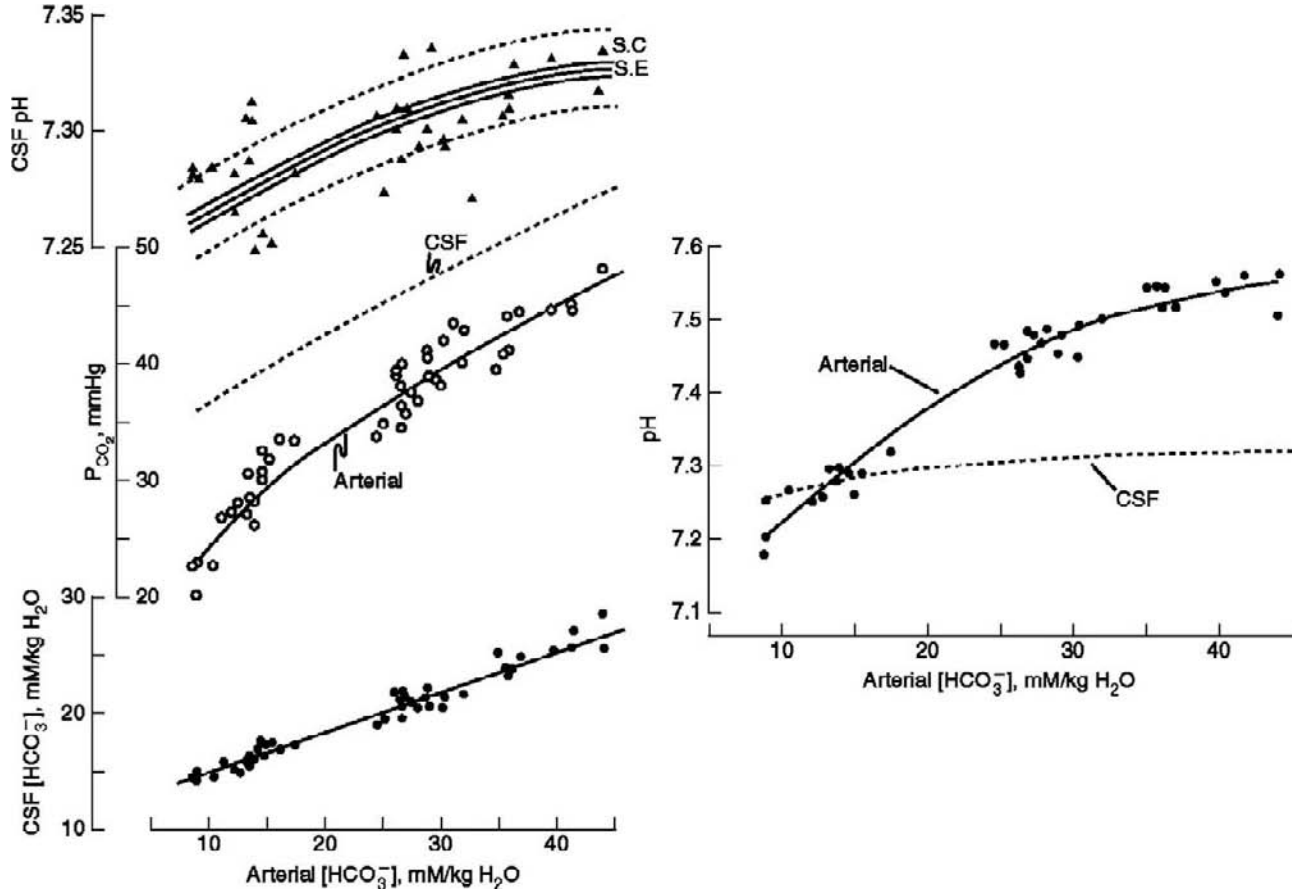

FIGURE 56.3 The three panels at the left show pH and bicarbonate in cerebrospinal fluid, and both CSF and $PaCO_2$ versus arterial bicarbonate in five goats with chronic acid–base disturbances. The panel at the right shows both arterial and CSF pH versus arterial bicarbonate. These data are very representative of such data obtained in humans with chronic acid–base disorders. Note that CSH pH changes very little in comparison to arterial pH, and that this results from both a smaller change in CSF bicarbonate than in blood and from the changes in $PaCO_2$ that reflect chemoreceptor-induced changes in alveolar ventilation. (*With permission, from Figures 2 and 3, in.* [34])

that hypoventilation ensues following peripheral chemodenervation. The remaining chemoreceptor sites do not make up for the loss of peripheral excitatory input from the carotid bodies. This absence of recovery following chemodenervation also occurs after removal of at least one central chemoreceptor site, the RTN.[81] Here, with bilateral destruction of RTN neurons, the unanesthetized rat also hypoventilates while breathing air at rest. The rat behaves just like it does following loss of the carotid bodies. Following RTN destruction, the remaining chemoreceptors, including the carotid body, do not make up for the presumed loss of tonic excitatory input from neurons within the RTN region. The RTN can be viewed as containing glutamatergic chemodetector neurons as well as providing tonic excitation to the respiratory control system.

Smith and Dempsey have used an elegant preparation that has the potential to unravel how peripheral and central chemoreceptor sites interact.[25,108] In the dog, these authors denervated the peripheral chemoreceptor on one side and created an investigator-controlled perfusion system for the other side. They controlled the PO_2 and PCO_2 of peripheral and central chemoreceptors independently. The major finding from these studies to date is the importance of the peripheral chemoreceptors in detecting rapid changes in $PaCO_2$ either as hypocapnia or hypercapnia. In various experiments, responses to changes in $PaCO_2$ at the carotid body are on average twice as fast as when the change in $PaCO_2$ is isolated to the central chemoreceptors. Remarkably, these data are in agreement with deductions made from analysis of time constants of the ventilatory response to single breath changes in CO_2 in humans with and without peripheral chemoreceptors.[31] They also agree with older data in decerebrate cats.[9] The possible role of peripheral chemoreceptors as a rapid-response detector is intriguing and important, as Dempsey and colleagues[26] have shown that in some

cases, apneas in sleep may be potentiated by sudden, rapid decreases in PCO_2 brought about by transient increases in ventilation that involve only a few breaths.

PARADOX: CENTRAL CHEMORECEPTORS LOCATED IN AN ENVIRONMENT WITH TIGHT pH REGULATION

Acid–Base Regulation in Brain Fluids

The central nervous system has two extracellular compartments; the ventricles containing CSF, and tissue interstitial fluid (ISF). CSF and ISF have different volumes, 10 and 20% of brain weight, respectively, and communicate without diffusional restriction. The ionic composition of both is regulated and this provides a stable chemical environment for neuronal function.[22,23,33,34,36,51,68] As a first approximation, we can estimate brain ISF pH by measurement of CSF pH. CSF pH is regulated by a combination of ion secretory and exchange processes at the choroid plexus and blood–brain barrier (BBB), which determine the ionic composition of CSF and ISF, respectively, and cerebral blood flow and alveolar ventilation, which determine ISF PCO_2.[68] CSF pH changes very little in acid–base disturbances.[22,33,34] Figure 56.4 shows the small change in CSF pH that accompanies chronic experimental acid–base disturbances produced in goats that vary arterial bicarbonate from less than 10 to more than 40 mmol/liter. The figure also shows that CSF pH changes much less than arterial pH under these conditions. Also in Fencl et al.,[34] a summary of data obtained from nine separate studies of humans with chronic acid–base disorders showed the very same relationships. These goat data are fully representative of the changes in these variables observed in human subjects. ISF pH homeostasis provides a stable environment for cell pH regulation and allows normal neuronal function at the membrane and synaptic levels. Disorders of pH caused by ionic or CO_2 imbalance initiate both types of brain responses—ionic and blood flow/ventilatory. The brain can regulate its own ionic environment—as the kidney does systemically—and alter brain and body PCO_2. This regulatory system for brain ISF pH contributes to body pH homeostasis as well.

Choroid Plexus

Specialized cells in choroid plexus secrete the CSF, a clear colorless liquid with low protein content (~25 mg/100 ml) in comparison to plasma (~6.5 gm/100 ml). It circulates through the ventricles and exits to the venous system via the arachnoid villi. CSF secretion involves a number of ion exchange proteins in choroid plexus epithelium.[48] Facing CSF, a sodium/potassium ATPase extrudes sodium, decreasing cell sodium concentration and maintaining the sodium concentration gradient from plasma to cell. At the plasma membrane, sodium/proton and chloride/bicarbonate antiporters operate to enhance sodium and chloride entry. Cell carbonic anhydrase catalyzes the rapid production of bicarbonate and protons used for these ion exchanges. Sodium chloride cotransport appears at both membranes as well.[48] The secreted CSF has a higher sodium and chloride concentration and lower potassium concentration and pH than does plasma.

Blood–Brain Barrier

Not all CSF originates in the choroid plexus. Pollay and Curl[92] perfused a portion of the rabbit fourth ventricle after removing the plexus. Dilution of their perfusate indicated the presence of a fluid added from the brain. This fluid, which accumulated at one third the rate of total CSF, was thought to originate at the capillary endothelial cells that form the BBB. Brain capillaries, because of endothelial tight junctions, have no Starling-type bulk-flow fluid exchange with ISF, and this barrier has low ion permeabilities, low hydraulic conductivity, and high electrical resistance.[11,103,104] Thus, ion movement that accounts for the observed fluid flow must occur by a secretory process.

Ion transport proteins are present at the BBB.[8,11] As reviewed by Schielke and Betz,[103] an amiloride-sensitive nonselective cation channel,[7,8,118] a sodium/chloride cotransport protein, and sodium/proton[64] and chloride/bicarbonate antiporters[110] are found at the barrier. At the ISF-facing membrane, there is a sodium/potassium ATPase.[12,88] The sodium/proton antiporter has been demonstrated in isolated cerebral capillaries,[7] and potassium and chloride channels have been suggested based on observations made in analogous systems. This model can account for an actively secreted ISF originating at brain capillary endothelium and provides possible sites for ISF pH regulation.

Bulk Flow of Interstitial Fluid

Brain ISF can move by a pressure-dependent bulk flow through ISF spaces into ventricular CSF.[19,20,48] The clearance of 900-, 4000-, and 69,000-Da tracer molecules injected into brain parenchyma was found to be similar, results explicable by bulk flow but not diffusion.[19] Part of this clearance occurs via ventricular CSF, and part by other pathways, such as cervical lymphatics.[113] Thus, a CSF-like fluid formed by secretory

processes at the endothelial cells moves by bulk flow through ISF to the ventricles or to cervical lymphatics.[48,113] This flow pathway for brain ISF raises the following questions: What is the role of ventricular CSF in the regulation of ISF? Is CSF merely an effluent drainage system or does it modify brain ISF? Tracer molecules perfused via the cerebral ventricular system do enter the parenchyma (e.g.,[10]) by diffusion or bulk flow if the normal flow-determining pressure gradients are disturbed. It seems reasonable to suggest that ISF, especially near the ventricles, is exposed to the ionic constituents of CSF. This would help to maintain ISF ion concentrations within the narrow range required for normal neuronal function.

Potassium

As an example, we consider the role of choroid plexus and BBB in the tight regulation of ISF and CSF potassium.[11,52] Potassium measurements by ion-selective electrodes in rats of different ages show that ISF potassium regulation is present, developmentally, before that of ventricular CSF.[49] Sodium/potassium ATPases, described at the brain-facing surface of both choroid plexus and BBB cells, have a K_m of 3 mM, the normal ISF and CSF concentration.[104] Cotransport of potassium with chloride is present at the choroid plexus and, perhaps, at the BBB, and many potassium channels have been identified in capillary endothelial cells.[52] Mechanisms exist at both choroid plexus and the BBB for potassium regulation in brain ISF and CSF. Such a model should also apply to pH regulation in brain ISF and CSF.

PCO_2 at Choroid Plexus

The bicarbonate concentration of freshly secreted CSF depends on the PCO_2. At choroid plexus, an increase in PCO_2 increases the bicarbonate, and decreases the chloride, concentrations of secreted CSF.[51,65,66] The sodium concentration is also increased in the immediate response.[50,65,66] These ionic responses are involved in CSF pH regulation—as the bicarbonate concentration increases, the pH of the secreted fluid is less acidic. With a decrease in PCO_2, the reverse occurs—bicarbonate decreases and chloride increases. The mechanisms for these changes in the ionic character of secreted CSF involve sodium/proton and chloride/bicarbonate antiporters as: (1) Antagonists of these proteins inhibit the CSF bicarbonate response to hypercapnia;[73,74] (2) the full CSF bicarbonate response to hypercapnia requires the presence of carbonic anhydrase;[122] (3) changes in pH affect choroid plexus cell ion concentrations and sodium entry from blood to CSF via an amiloride-sensitive process.[64]

PCO_2 at Blood–Brain Barrier

At the BBB, CO_2 sensitive ionic processes help to regulate ISF pH, and may affect the composition of ventricular CSF. In anesthetized cats, hypercapnia quickly increased cortical-surface ISF bicarbonate concentrations and decreased chloride concentrations.[2,3] The responses were thought to reflect glia–ISF exchange of chloride and bicarbonate, a rapid cell response to regulate ISF pH. However, such an exchange would acidify the glia. An alternative explanation places the bicarbonate/chloride exchange at capillary endothelial cells. Katsura et al.[50] measured ISF and brain tissue ions of rat cortex in response to hypercapnia. ISF bicarbonate and sodium increased, and chloride decreased, within minutes. Tissue bicarbonate also increased within minutes, as found by others.[65,122] A chloride for bicarbonate and sodium for proton exchange between cell and ISF was proposed; that is, cells lost bicarbonate, or gained H^+, and ISF pH was regulated at the expense of cell pH. The major observation to support this interpretation was the absence of any measurable change in tissue (cell) sodium and chloride content. But, due to the small size of the ISF space and the greater sodium and chloride concentration in ISF than in the cells, it is difficult to detect changes in cell sodium or chloride by whole-tissue measurements. The CO_2-stimulated changes in ISF sodium, chloride, and bicarbonate could arise from BBB processes.

The view that brain cells lose bicarbonate during hypercapnia in order to regulate ISF pH requires greater acidification of the cells involved. Simultaneous measurements of brain cell and ISF pH using 31P-NMR show that cell pH decreases: (1) Less than ISF pH after 10 minutes of hypercapnia;[93] (2) less than blood pH following 50 minutes of hypercapnia.[86] That cell pH changes minimally in acute hypercapnia does not support the idea of cell acidification for regulating ISF pH. The rapid changes in brain ISF sodium, bicarbonate, and chloride during hypercapnia appear to represent events that occur between ISF and blood, rather than cell and ISF. Thus, rapid ion movements at the BBB likely play an important role in ISF pH regulation in hypercapnia. Such ISF pH regulation would optimize cell pH regulation at neuronal and glial membranes.

Bicarbonate Entry from Blood

ISF pH changes rapidly following changes in blood pH produced by infusion of acid or base with arterial

PCO_2 maintained at a constant value. In the steady state, the ISF pH changes are approximately one-third of those in blood.[21,47,115] Measurements on the cortical surface in anesthetized cats given a bolus infusion of sodium bicarbonate with constant arterial PCO_2 showed a rapid increase in ISF bicarbonate accompanied by a decrease in ISF chloride.[3] In contrast, no change in CSF pH[21,47] or cell pH[1] is observed in these types of acute experiments. In chronic systemic acid–base disorders, CSF pH does change in the direction of the change in blood pH but by a very small amount, much less than in blood and, presumably, ISF.[33,34,89]

SUMMARY

Brain ISF is produced by capillary endothelial cells and moves through the interstitium via clearance of bulk flow by ventricular CSF and cervical lymphatics. ISF pH is, in part, regulated by ionic processes at the choroid plexus and BBB. Both CO_2 and blood bicarbonate (ions) have independent effects.[40,85] Some of these processes respond to changes in PCO_2, although the means by which they are controlled is unknown. It is likely that cell pH affects ion transport proteins.

BREATHING AND pH REGULATION

Effectiveness of Breathing in pH Regulation

Chemoreceptors provide a very sensitive means by which ventilation can be stimulated by a small decrease in pH; conversely, they are inhibited by a small increase in pH (see Fig. 56.1). The peripheral chemoreceptors can be viewed as a detector with rapid-response dynamics, and the central chemoreceptors as having slower dynamics. We can demonstrate, by means of simple calculations, the effectiveness of this very sensitive central chemoreceptor system to small changes in cerebral pH in regulating peripheral arterial pH as well as brain pH. Under normal baseline conditions in humans, arterial pH is 7.40, $PaCO_2$ is 40 mm Hg, arterial bicarbonate is 24 mmol/liter, and CSF pH is 7.3. In metabolic acidosis with arterial bicarbonate decreasing from the normal value of 24 mmol/liter to, say, 20 mmol/liter, without any ventilatory response such that $PaCO_2$ remains at 40 mm Hg, and arterial pressure will decrease from 7.40 to 7.32. With this mild acidosis in the presence of a ventilatory response, in humans the $PaCO_2$ will decrease by about 5 mm Hg to a value of ~35 mm Hg (see data for humans, Figure 13 in Feldman et al.[32]). The corresponding pH will be 7.38. The increase in alveolar ventilation, which will decrease $PaCO_2$ from 40 to 35 mm Hg, has a substantial effect on pH regulation. The fall in $PaCO_2$ reduces the decrease in pH from 7.40 to 7.38 instead of 7.32 or a change in pH of 0.2 pH units instead of 0.8 pH units. The ventilatory response to the acidosis reduces the arterial pH change in this example by 75%.

Where Do Chemoreceptors Detect the pH Change?

Examination of Fig. 56.4 shows that in these chronic acid–base disturbances, the ventilatory response (as inferred from the observed changes in $PaCO_2$, or as observed directly from the measured alveolar ventilation in Fig. 56.1) could be related either to the large changes in arterial pH shown in the right panel or to the smaller changes in CSF pH shown also in the right panel. In an elegant set of experiments and deductions, Pappenheimer, Fencl, and colleagues[34,89] performed a perfusion of the entire brain ventricular system in goats with chronic acid–base disturbances using fluids of varying bicarbonate concentration. They then related alveolar ventilation in all conditions, chronic acid–base disorders, CO_2 inhalation, and ventriculo-cisternal perfusion of differing HCO_3 concentrations, to pH at one site only, a virtual site that lies three-quarters of the distance between the large ventricle CSF and arterial blood. All of the ventilatory responses fit one stimulus location only with pH calculated for this site. The pH at this site is represented by the X symbols in Fig. 56.1. Referring to Fig. 56.4, we can imagine that the pH detected by central chemoreceptors lies between arterial and CSF pH, but closer to arterial pH.

SUMMARY

In a metabolic acid–base disturbance, CSF bicarbonate changes less than blood bicarbonate due to the presence of ionic secretory processes at choroid plexus and the BBB that regulate CSF bicarbonate. In addition, central chemoreceptors detect the acidosis, most likely at a site lying between arterial blood and CSF. The central chemoreceptors increase alveolar ventilation, which decreases $PaCO_2$ as well as the PCO_2 in tissue and in CSF. This CO_2 change further minimizes the degree of acidosis in CSF and it acts importantly to diminish the pH change in arterial blood. Peripheral chemoreceptors also contribute to the increase in alveolar ventilation. This complex system has a set of ionic regulatory processes to control brain fluid ions, and a superimposed ventilatory system response to control brain CO_2 that mirrors, in the body, the set of ionic regulatory processes in the kidney that control body fluid

ions, which also has superimposed a ventilatory system response to control $PaCO_2$.

Renal Ammonium Ion Production and Excretion

Norman P. Curthoys

Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, Colorado, USA

INTRODUCTION

The maintenance of systemic acid–base balance is essential for survival. Increased renal ammoniagenesis and gluconeogenesis from plasma glutamine constitute an essential physiological response to metabolic acidosis that partially restores acid–base balance.[1–3] Onset of acidosis triggers a rapid and pronounced increase in extraction and catabolism of plasma glutamine within the renal proximal convoluted tubule. The mitochondrial phosphate-activated glutaminase (GA) catalyzes the initial reaction in the primary pathway for the renal catabolism of glutamine and is a key regulator of the increased renal ammoniagenesis and gluconeogenesis.[4] Glutamine extracted by the kidney is both deamidated and deaminated to yield two ammonium ions. The increased renal ammoniagenesis provides an expendable cation that facilitates the excretion of titratable acid while conserving sodium and potassium ions. In rats and humans, the resulting α-ketoglutarate is primarily converted to glucose.[5] This pathway generates HCO_3^- ions that partially compensate the systemic acidosis. During chronic acidosis, this adaptive response is sustained, in part, by cell-specific increases in expression of various enzymes and transport proteins. The adaptive increases in GA and the cytosolic phospho*enol*pyruvate carboxykinase (PEPCK) are paradigms for characterization of the mechanisms that mediate the pH-responsive regulation of renal gene expression. The pronounced increase in GA results from stabilization of the GA mRNA, while the more rapid increase in PEPCK is initiated by activating transcription of the *PCK1* gene[6] and sustained, in part, by a gradual stabilization of the PEPCK mRNA. A decrease in intracellular pH activates multiple signal transduction pathways within proximal tubule cells that mediate the increased expression of PEPCK[7] and the exocytosis[8] and increased expression[9] of NHE3, the apical Na^+/H^+ exchanger. The latter protein contributes to the active translocation of H^+ and NH_4^+ ions into the urine.[10,11] A significant portion of the ammonium ions, generated in the proximal tubule, is subsequently reabsorbed within the medullary thick ascending limb to produce a high interstitial concentration of ammonium ions within the renal medulla.[12] This gradient provides the driving force for the final transport of ammonium ions into the urine that occurs via specific ammonia channels[13] located within the basolateral and apical membranes of the collecting ducts.[14] All of these steps are subject to fine regulation to ensure that the level of renal ammonium ion production and excretion are appropriate to sustain normal acid–base balance. As a result, excess production of acid or insufficient adaptations lead to various pathophysiologies.[15]

ROLE OF RENAL AMMONIUM ION PRODUCTION AND EXCRETION IN THE MAINTENANCE OF ACID–BASE BALANCE

All higher eukaryotes maintain the pH of the extracellular fluid and of various intracellular compartments within narrow limits. For example, in humans, normal arterial plasma pH is set at 7.40 ± 0.04. Blood pH values outside this narrow range define an acidosis ($pH<7.36$) or an alkalosis ($pH>7.44$). The relative concentrations of HCO_3^- and CO_2 are the primary

determinants of plasma pH. The reaction of H^+ with HCO_3^- to form H_2CO_3 has a pK of 6.1 and thus would appear to be a relatively ineffective buffer at pH 7.4. However, the resulting carbonic acid is rapidly equilibrated with CO_2 and H_2O by multiple carbonic anhydrases. The combined reactions provide an effective buffer system due to the ability of the lungs to maintain a constant CO_2 concentration through changes in the rate of respiration. A constant blood pH of 7.40 is produced by maintaining a pCO_2 of 40 mmHg and a blood HCO_3^- concentration of 24 mM. The kidney contributes to the maintenance of a constant blood HCO_3^- concentration by recovering nearly all of the HCO_3^- that is filtered by the glomeruli. In humans, the daily filtered load of HCO_3^- is approximately 4000 mmol.

About 70–80 percent of the filtered HCO_3^- is reabsorbed in the proximal tubule.[16] This process requires the pumping of H^+ ions into the tubular lumen via NHE3, the apical Na^+/H^+ exchanger, and various H^+-ATPases (Figure 57.1). A luminal carbonic anhydrase uses the H^+ ions to protonate the filtered HCO_3^- to form CO_2 and H_2O. After diffusing into the epithelial cells of the proximal tubule, a cytosolic carbonic anhydrase hydrates the CO_2 to reform HCO_3^- and regenerate the excreted H^+ ions. The HCO_3^- ions are then transported across the basolateral membrane by NBC1, a $Na^+/3HCO_3^-$ cotransporter. The overall process of HCO_3^- absorption is inhibited by alkalosis and hypocalcemia and is increased by acidosis, hypercalcemia and by increased levels of angiotensin II.[17] Additional regulation occurs in the distal nephron segments that are responsible for the recovery of the HCO_3^- that remains in the fluid leaving the proximal tubule.[18,19] The type A intercalated cells within the cortical and outer medullary collecting ducts secrete H^+ ions via the apical H^+-ATPase and an electroneutral H^+/K^+-ATPase. The reabsorbed HCO_3^- is subsequently transported across the basolateral membrane by AE1, a HCO_3^-/Cl^- antiporter.

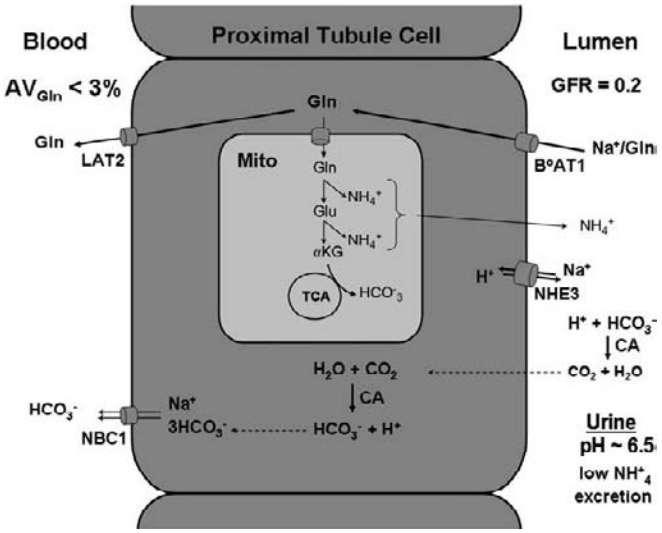

FIGURE 57.1 Pathways of bicarbonate reabsorption and glutamine catabolism within the renal proximal tubule during normal acid–base balance. The glomerular filtrate is slightly acidified by the apical Na^+/H^+ exchanger (NHE3). The translocated H^+ ions titrate most of the filtered HCO_3^- ions producing carbonic acid which is converted to CO_2 and H_2O by the apical carbonic anhydrase (CA). The CO_2 diffuses into the proximal tubule and is hydrated by the cellular carbonic anhydrase (CA) to reform HCO_3^- ions that are then translocated across the basolateral membrane by the $Na^+/3HCO_3^-$ cotransporter (NBC1). The glutamine (Gln) filtered by the glomeruli is transported across the apical membrane by a Na^+-dependent neutral amino acid transporter (B^oAT1). Most of the recovered glutamine is then transported across the basolateral membrane by a Na^+-independent neutral amino acid transporter (LAT2). A small proportion of the recovered glutamine is transported into the mitochondria where it is catabolized to generate the basal level of ammonium ions that are excreted in the slightly acidified urine.

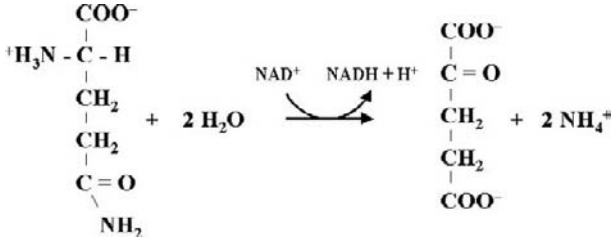
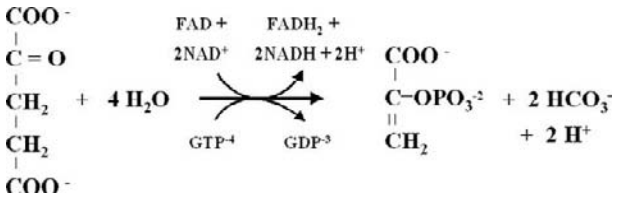
Catabolic pathways result in a net production of volatile and non-volatile acids. The major acid generated as a product of carbohydrate and fat catabolism is CO_2 which is reversibly hydrated to form carbonic acid. A normal individual generates approximately 20 moles of CO_2 per day. However, this acid is volatile and is effectively expelled by the lungs. In contrast, the catabolism of protein also produces non-volatile acids including H_2SO_4 and H_3PO_4. These are strong acids that rapidly dissociate to generate H^+ ions and the corresponding anions. The H^+ ions combine with HCO_3^- to form CO_2 and H_2O. However, this process causes a decrease in blood HCO_3^- concentration and a corresponding decrease in blood pH. The average person eating a western diet generates about 70 mmol per day of nonvolatile acids from the catabolism of proteins and amino acids. To maintain normal acid–base balance, the kidneys of this individual must accomplish the net synthesis of an equivalent amount of HCO_3^- ions.

The renal production of HCO_3^- is primarily accomplished by the extraction and catabolism of plasma glutamine.[2] This process occurs largely within the proximal convoluted tubule and is primarily initiated by the mitochondrial glutaminase (GA) and glutamate dehydrogenase (GDH). The combined reactions accomplish the deamidation and oxidative deamination of glutamine and generate two ammonium ions and α-ketoglutarate:



The subsequent conversion of α-ketoglutarate to phospho*enol*pyruvate is accomplished by reactions of the tricarboxylic acid cycle and the phospho*enol*pyruvate carboxykinase (PEPCK). This process also generates two HCO_3^- and two H^+ ions:



The two H^+ ions that are produced in these reactions are consumed when the phospho*enol*pyruvate is either converted to glucose, a neutral molecule, or is oxidized to CO_2 and H_2O. The net effect of the combined reactions is the catabolism of glutamine to yield two NH_4^+, two HCO_3^- ions, and one-half molecule of glucose. For this process to result in the net production of HCO_3^- ions, the resulting NH_4^+ ions must be excreted in the urine. Ammonium ions that are added to the renal venous blood are utilized in the liver to form urea, a process that consumes HCO_3^- ions.[20] Therefore, the amount of ammonium ions excreted in the urine is equivalent to the net production of HCO_3^- ions by the kidney.

PATHWAYS OF RENAL AMMONIAGENESIS

During normal acid–base balance, the kidneys extract and metabolize very little of the plasma glutamine.[21] The measured rat renal arterial-venous difference is less than three percent of the arterial concentration of glutamine, whereas only seven percent of the plasma glutamine is extracted by the human kidneys even after an overnight fast.[22] Therefore, renal uptake is significantly less than the fraction of plasma glutamine that is filtered by the glomeruli and enters the lumen of the nephron (Figure 57.1). Most of the filtered glutamine is reabsorbed within the proximal convoluted tubule.[23] This uptake is probably mediated by B^oAT1, a Na^+-dependent neutral amino acid transporter that is localized to the apical membrane of the small intestine and the renal proximal tubule.[24] Mutations in the *SLC6A19* gene that encodes this transporter are associated with Hartnup's disorder.[24,25] Most of the recovered glutamine is subsequently transported across the basolateral membrane via the LAT2 isoform (SLC7A8) of the Na^+-independent system L family of amino acid transporters.[26,27] Transporters of this family have a preference for leucine, but also recognize a broad range of neutral amino acids including glutamine. The LAT2 isoform is expressed predominantly in the basolateral membrane of intestinal epithelial cells and the renal proximal tubule.[28] Thus, it functions in the cellular release of glutamine that was absorbed from the intestinal lumen or the glomerular filtrate. However, it also catalyzes an exchange of extracellular and intracellular amino acids[29] that may contribute to basolateral glutamine uptake by intestinal epithelial cells in a post-absorptive state and by the proximal tubule during metabolic acidosis.

Utilization of the small fraction of extracted plasma glutamine requires its transport into the mitochondrial matrix where glutamine is deamidated by a phosphate-activated GA and then oxidatively deaminated by GDH (Fig. 57.1). Glutamine uptake occurs via a mersalyl-sensitive electroneutral uniporter.[30] The mitochondrial glutamine transporter has been purified from rat kidney and was shown by reconstitution in lipid vesicles to be specific for glutamine and asparagine and inhibited by various thiol reagents.[31] Kinetic measurements using isolated rat renal mitochondria indicated that the rate of glutamine transport is not rate limiting for glutamine catabolism.[32,33] However, the basal level of GA is much greater than what is required to accomplish the basal catabolism of glutamine. Therefore, either the activity of the mitochondrial glutamine transporter or the GA must be largely inhibited or inactivated *in vivo* during normal acid–base balance to account for the effective reabsorption of glutamine. Finally, during normal acid–base balance, the urine is only slightly acidified. Thus, only two-thirds of the ammonium ions produced from glutamine are trapped in the tubular lumen and are excreted.[34] The remainder is added to the renal venous blood.

ACUTE REGULATION OF RENAL AMMONIAGENESIS

Acute onset of a metabolic acidosis produces acute alterations in the interorgan metabolism of glutamine[35] which support the rapid and pronounced changes in glutamine catabolism that occur in the kidney (Figure 57.2). Typically, acute acidosis has been induced by stomach loading rats with 2.0 mmol NH_4Cl/100 g body weight.[36] Within 1 to 3 h, the arterial plasma glutamine concentration is increased twofold, primarily due to an increased release of glutamine from muscle tissue.[37] Significant renal extraction of glutamine becomes evident as the arterial plasma concentration is increased.[36] After 3 h, net extraction reaches 25% of the plasma glutamine, a level that slightly exceeds the percent filtered by the glomeruli. Thus, the direction of the basolateral glutamine

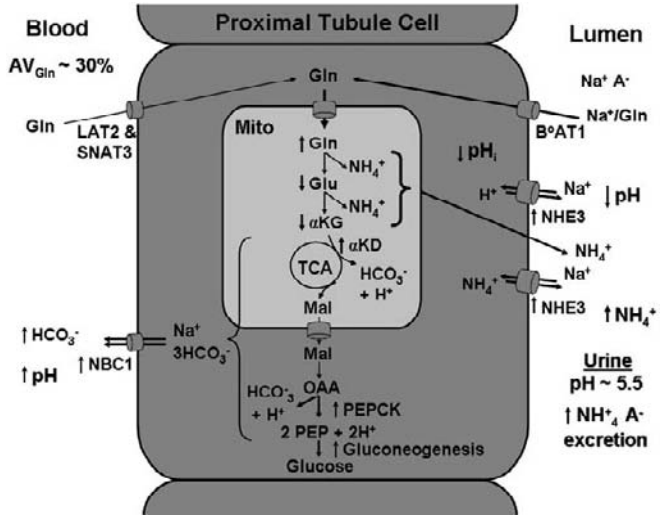


FIGURE 57.2 Pathway of glutamine catabolism within the renal proximal tubule during acute acidosis. The onset of an acute acidosis leads to a rapid reversal of glutamine (Gln) flux across the basolateral membrane that may be due to the exchange activity of LAT2 or the increased expression of SNAT3. Acute acidosis also produces a decrease in intracellular pH (pH_i) that activates flux through the mitochondrial glutamine transporter and α-ketoglutarate dehydrogenase (αKD). The combined effects produce an increase in mitochondrial glutamine and a decrease in glutamate (Glu) and α-ketoglutarate (αKG) levels that increase flux through glutaminase and glutamate dehydrogenase, respectively. The rapid transcriptional activation of the phospho*enol*pyruvate carboxykinase (PEPCK) gene may also contribute to the decrease in cellular glutamate and α-ketoglutarate levels. The acute translocation and activation of NHE3 causes a prompt acidification of the urine and facilitates the apical transport of ammonium ions. The combined increases in renal ammonium ion excretion and gluconeogenesis produce a net synthesis of HCO_3^- ions that are transported across the basolateral membrane by the Na^+-dependent bicarbonate transporter (NBC1).

transport must be reversed in order for the proximal convoluted tubule cells to extract glutamine from both the glomerular filtrate and the venous blood. Adrenalectomized rats exhibit an impaired ability to increase plasma glutamine and to extract glutamine during onset of acute acidosis, suggesting that this response may be mediated, at least in part, by an adrenal hormone.[36] Within 4 h, plasma HCO_3^- decreased from 28 mM to 17 mM, urine pH decreased from 7.2 to 5.8, and renal ammonium ion excretion increased 6-fold.[34] The prompt acidification of the urine may result from the rapid translocation[38] and acute activation[39] of NHE3, the apical Na^+/H^+ exchanger. This process facilitates the rapid removal of cellular ammonium ions[40] and ensures that the bulk of the ammonium ions generated from the amide and amine nitrogens of glutamine are excreted in the urine.

The acute increase in renal ammoniagenesis from plasma glutamine is initiated more rapidly than the adaptive increases in the levels of GA and GDH.[34,41] The rapid increase in ammoniagenesis may result from an acute activation of the mitochondrial glutamine transporter.[42] In addition, the cellular concentrations of glutamate and α-ketoglutarate within the renal cortex are decreased significantly in acute acidosis.[43] The latter compounds are products and potent inhibitors of the GA and GDH reactions, respectively. The decrease in concentrations of the two regulatory metabolites may result from a pH-induced activation of α-ketoglutarate dehydrogenase[43] and the rapid induction of PEPCK.[44,45] The increased level of the latter enzyme would facilitate the cataplerotic removal of intermediates of the tricarboxylic acid cycle. Thus, increased renal catabolism of glutamine initially results from a rapid activation of key transport processes, an increased availability of glutamine, and a decrease in product inhibition of the GA and GDH activities. The net effect is a rapid and pronounced increase in the excretion of ammonium ions and titratable acid in the urine.[34]

Various indirect studies also support the hypothesis that changes in product inhibition may contribute to the acute regulation of renal catabolism of glutamine. For example, inhibition of glutamate uptake both *in vivo*[46] and in renal cell culture[47] reduces the cellular glutamate concentration and stimulates flux through GA leading to increased ammoniagenesis. In addition, a mutation in GDH, that increases *in vivo* activity by reducing GTP inhibition, is responsible for the hyperinsulinism/hyperammonium syndrome.[48] Similarly, systemic activation of GDH can be produced by feeding rats a non-metabolizable analog of leucine that functions as an allosteric activator of GDH. The latter protocol produced a mild hyperammonemia that resulted from a renal specific increase in ammoniagenesis.[49] All of these observations support the concept that acute activation of flux through GA and GDH may contribute to the acute regulation of renal ammoniagenesis.

Only a few studies have characterized the changes in renal glutamine extraction and ammoniagenesis that occur in humans during acute[50] and chronic acidosis.[51] Both studies enrolled hypertensive patients who were undergoing renal vein catheterization to assess plasma renin activity. In the acute study, half of the patients were fed 3 doses of NH_4Cl during the 24 h before catheterization.

This protocol produced a significant decrease in arterial pH (7.41 to 7.33), arterial HCO_3^- (23 mM to 15 mM), and urine pH (5.6 to 4.7), but increased total renal ammonium ion production by only 60%. The acidotic patients exhibited no significant changes in arterial glutamine or renal extraction of glutamine (~6%), but did exhibit an increased extraction of plasma glycine, proline and ornithine.[50] During chronic acidosis, glutamine extraction by the human kidney was

increased even though blood glutamine levels were decreased.[51] The combined data indicate that the mechanism to increase renal catabolism of plasma glutamine is not acutely activated in humans and that amino acids in addition to glutamine may contribute to total renal ammoniagenesis.

CHRONIC ADAPTATIONS TO METABOLIC ACIDOSIS

Role of Increased Gene Expression

During chronic metabolic acidosis, the acute decreases in the renal concentrations of glutamate and α-ketoglutarate are partially compensated and the arterial plasma glutamine concentration is decreased to 70% of normal.[1] However, the kidneys now extract nearly 40% of the total plasma glutamine[21,34] in a single pass through this organ (Figure 57.3). Renal catabolism of glutamine is now sustained by increased expression of the genes that encode various ion transporters and key enzymes of glutamine metabolism.[6] Following onset of acidosis, a rapid induction of PEPCK gene expression occurs only within the S1 and S2 segments of the proximal tubule.[52] The more gradual increase in the levels of the mitochondrial GA[53,54] and GDH[55] also occur solely within the proximal convoluted tubule. Previous micropuncture studies[56] and assays using microdissected nephron segments[57] established that the preponderance of renal ammoniagenesis in normal or acidotic rats occurs within the convoluted portion of the proximal tubule. The decreases in plasma pH and HCO_3^- concentration during metabolic acidosis produce a comparable and sustained decrease in the intracellular pH (pH_i) of the proximal convoluted tubule.[58,59] Thus, the adaptive increases in gene expression may be initiated by a decrease in pH_i. This hypothesis is supported by the findings that similar changes in gene expression occur in response to feeding a high protein diet or chronic hypokalemia, conditions that decrease intracellular pH but produce either no change in extracellular pH or a pronounced alkalosis, respectively.[6,60] The adaptations in GA and PEPCK levels result from increased rates of synthesis of the proteins[61,62] that correlate with comparable increases in the levels of their respective mRNAs.[45,63] However, the increase in GA results from the selective stabilization of the GA mRNA,[64–66] whereas the more rapid increase in PEPCK activity is initiated by enhanced transcription of the *PCK1* gene.[67] The activities of the apical Na^+/dicarboxylate co-transporter, NaDC-1,[68] the mitochondrial glutamine transporter,[42] the basolateral SNAT3 glutamine transporter (SLC38A3),[69] the apical Na^+/H^+ exchanger, NHE3,[9] the basolateral Na^+-$3HCO_3^-$ co-transporter, NBC1,[9] the medullary Na^+K^+-$2Cl^-$ co-transporter,[70] and the ammonia channel, RhCG[71] are also increased during chronic acidosis.

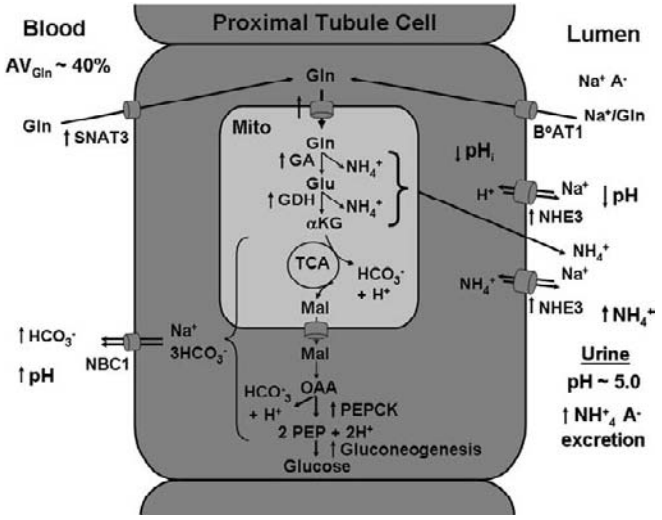

FIGURE 57.3 Pathway of glutamine catabolism within the renal proximal tubule during chronic acidosis. Increased renal catabolism of glutamine is sustained during chronic acidosis by increased expression of the genes that encode glutaminase (GA), glutamate dehydrogenase (GDH), phospho*enol*pyruvate carboxykinase (PEPCK), the mitochondrial glutamine transporter, the apical Na^+/H^+ exchanger (NHE3), and the basolateral glutamine transporter (SNAT3). The increased protein expression is indicated by the arrows. Increased expression of NHE3 contributes to the transport and trapping of ammonium ions in the luminal fluid. The combined increases in renal ammonium ion excretion and gluconeogenesis result in a net synthesis of HCO_3^- ions that are transported across the basolateral membrane by the $Na^+/3HCO_3^-$ co-transporter (NBC1).

The adaptation in the NaDC-1 transporter contributes to an increased reabsorption and metabolism of citrate within the proximal tubule. This reduces the excretion of a weak acid in the urine. Following cellular uptake, citrate is metabolized through one of two pathways, a cytoplasmic pathway involving citrate lyase or a mitochondrial pathway involving the citric acid cycle.[72] During acidosis, the activities of cytoplasmic citrate lyase and mitochondrial aconitase are also increased.[68] Since both pathways generate HCO_3^-, the increased reabsorption of citrate is equivalent to a decrease in base excretion.[60] Enhanced catabolism of citrate also produces substrates that support the increased gluconeogenesis. By contrast, the onset of acidosis produced a decreased transcription of the apical sodium-dependent phosphate transporter, NaPi-II, in rat kidney and in OK cells.[73,74] This adaptation may contribute to an increased excretion of phosphate, a titratable acid. However, the onset of acidosis in mice decreased the expression of NaPi-IIa and NaPi-IIb mRNAs, but increased levels of both isoforms in isolated brush border membranes.[75] Thus, the transient

increase in phosphaturia may be caused by a direct effect of H^+ ion concentration on the activity of the phosphate transporter.

Chronic acidosis also leads to a pronounced increase in the levels of the SNAT3 glutamine transporter (SLC38A3) in rat kidney.[76] Adaptive increases in this transporter also occur in response to chronic dietary potassium restriction and a high protein intake, conditions that also cause an increase in renal ammonia synthesis and excretion.[77] A comprehensive survey of the adaptive response of known amino acid transporters in mouse kidney, demonstrated that only the basolateral SNAT3 transporter exhibits a rapid and pronounced increase in both mRNA and protein levels during onset of acidosis.[78] Surprisingly, expression of the y^+-LAT1 (SLC7A7), a basolateral cationic/neutral amino acid exchanger subunit, was decreased significantly during acidosis. The SNAT3 transporter has a high affinity for glutamine.[79] It was initially cloned by its homology to the vesicular GABA transporter.[80] It catalyzes a Na^+-dependent uptake of glutamine that is coupled to the efflux of H^+ ions.[26,81] However, under physiological conditions, this reaction is reversible. Thus, it can also catalyze H^+ ion uptake coupled to glutamine efflux. In brain, the SNAT3 transporter is expressed primarily in glial cells,[80] while in liver, it is found solely in the perivenous hepatocytes.[82] Under normal acid–base conditions, it is localized solely to the basolateral membrane of the proximal straight tubules within the outer stripe of the outer medulla in rat kidney.[69] All of these cell types express high levels of glutamine synthetase.[83] Thus, the SNAT3 transporter may function primarily to catalyze a pH-dependent release of glutamine. However, during chronic acidosis, increased expression of the SNAT3 transporter occurs primarily in the basolateral membranes of the S1 and S2 segments of proximal tubule, the site of increased glutamine catabolism.[76] Given the sustained increase in H^+ ion concentration within these cells, the increased expression of the SNAT3 transporter is likely to contribute to the basolateral uptake of glutamine. Therefore, the adaptive increase in the SNAT3 transporter may contribute to both the rapid reversal of glutamine transport across the basolateral membrane that occurs during acute acidosis and the elevated and sustained extraction of plasma glutamine during chronic acidosis.

The increase in apical Na^+/H^+ exchanger activity sustains the acidification of the fluid in the tubular lumen and contributes to the active transport of ammonium ions.[8,84] Thus, the increased renal ammoniagenesis continues to provide an expendable cation that facilitates the excretion of titratable acids while conserving sodium and potassium ions. The increased Na^+/H^+ exchanger activity also promotes the tubular reabsorption of HCO_3^- ions. In humans, the α-ketoglutarate generated from glutamine is primarily converted to glucose and to a lesser extent oxidized to CO_2[5]. Either process requires the cataplerotic activity of PEPCK to convert intermediates of the tricarboxylic acid cycle to phospho*enol*pyruvate. This product is either utilized to initiate gluconeogenesis or converted to pyruvate that re-enters the mitochondria and is oxidized to CO_2. However, both pathways generate 2 HCO_3^- ions per mole of α-ketoglutarate. Activation of NBC1, the basolateral $Na^+/3HCO_3^-$ co-transporter, facilitates the translocation of reabsorbed and of *de novo*-synthesized HCO_3^- ions into the renal venous blood. However, this process occurs without an increase in the level of the NBC1 protein.[85] Thus, the combined adaptations also create a net renal release of HCO_3^- ions that contribute to the ability of the kidney to partially restore acid–base balance. In addition to these adaptations, the renal proximal tubule undergoes an extensive hypertrophy during chronic acidosis.[86]

Difference gel electrophoresis along with proteomic and bioinformatic techniques were used to identify proteins that are differentially expressed in the rat renal proximal convoluted tubule during metabolic acidosis.[44] Tubules were prepared by incubation of minced rat renal cortex with collagenase and purified by Percoll density gradient centrifugation.[87] The purity of the isolated proximal convoluted tubules was confirmed by western blot analyses using antibodies to proteins that are expressed only within a single cortical segment of the nephron. This analysis indicated that the purified tubules retained proteins that are expressed only in this segment, but essentially lacked proteins specific for the thick ascending limb, distal tubule, and cortical collecting duct. Nearly 2000 protein spots were resolved when the proximal tubule lysates were fractionated by two-dimensional gel electrophoresis. The protein spots that were differentially expressed were picked and analyzed by mass spectrometry. This analysis identified 21 proteins which are increased between 1.5- and 8.4-fold, including GA (8.4-fold), PEPCK (7.0-fold) and GDH (3.0-fold), and 16 proteins that are decreased between .67- and .03-fold.[44] The observed changes indicate that amino acid catabolism, an ER-stress response, and Ca^{++}-signaling are activated, while conversion of glycine to creatine, oxidation of pyruvate, and fatty acid catabolism are decreased in the proximal convoluted tubule during chronic metabolic acidosis. Many of the observed changes, including activation of an ER-stress response, were confirmed by western blot analysis.

A recent microarray analysis[88] characterized the mRNA isolated from whole kidneys of control mice and of mice that were made acidotic by providing 0.28 M NH_4Cl as the drinking water. After 2 d, this protocol produced a significant acidosis (arterial blood

pH of 7.10 and 12 mM HCO_3^-) that was partially compensated by seven days. Microarray analysis detected 13,000 mRNAs or ~40% of the genes on the mouse genomic array. The levels of 333 mRNAs were up-regulated and another 342 were down-regulated during both acute and chronic acidosis. Cluster analysis indicated that a large proportion of the regulated genes encode solute transporters and proteins involved in cell growth, proliferation, apoptosis, ammoniagenesis, water homeostasis, and energy metabolism. As expected, the mRNAs that encode GA, GDH, PEPCK and the SNAT3 transporter were among those that exhibited the most pronounced increases. The changes in five mRNAs were confirmed by RT-PCR of mRNA isolated from dissected S1 and S2 segments. It remains uncertain which of the other changes occur within the proximal convoluted tubule, within other cell types, or within multiple segments of the nephron. However, this analysis clearly established that expression of a very large number of genes is altered in the kidney in response to acidosis.

Properties of Mitochondrial Glutaminase

The human *GLS1* gene that encodes the kidney-type GA[89] spans 82 kb on chromosome 2, contains 19 exons and uses alternative splicing and different polyadenylation sites to form multiple mRNAs. The human, rat and mouse kidney-type GA genes have identical exon and intron lengths. The primary GA mRNA expressed in rat kidney, termed KGA mRNA, lacks the sequence encoded by exon 15 and utilizes alternative polyadenylation signals to produce a more abundant 5.0-kb and a less abundant 3.6-kb mRNA that encode the same protein sequence.[90] The two mRNAs are coordinately increased and decreased in response to changes in acid–base balance.[45,91] Thus, it is unlikely that differential selection of the polyadenylation site contributes to altered expression of the KGA mRNA. The first sixteen amino acids of this sequence form an amphipathic α-helix that functions as a mitochondrial targeting sequence.[90]

A variant of the human KGA cDNA, termed GAC, was initially cloned from a human carcinoma cDNA library.[92] The human GAC mRNA is formed by splicing together the sequences contained in exons 1 through 15 of the *GLS1* gene, but lacks sequence encoded by exons 16 through 19. As a result, the GAC mRNA contains a unique C-terminal coding sequence and 3′-untranslated region. Both the KGA and GAC mRNAs are highly expressed in human kidney.[92] However, the cell specific expression of the two GA mRNAs in human kidney has not been characterized. The rat and pig orthologs of the human KGA and GAC cDNAs have also been cloned and sequenced.[89] From the cloned sequences, it appears that the KGA and GAC mRNAs contain an identical 5′-sequence and thus may be produced from the same promoter. The unique C-terminal sequences of the two kidney-type GA proteins are highly conserved in the three species, suggesting that they may form distinct functional domains.

Eukaryotic GA has been purified from pig[93] and rat[94] kidney, from pig,[95] rat[96] and cow brain,[97] and from Erlich ascites-tumor cells.[98] All of these protocols were reported before it was realized that multiple isoforms are produced from the KGA gene. Based upon subsequent analysis, it is likely that the purified rat and pig enzymes are predominately the KGA isoform. The enzymes were solubilized from mitochondria by treatment with Triton X-100, freeze-thaw fractionation, or lyophilization in the presence of a borate and phosphate buffer. The solubilized GA undergoes extensive polymerization in the presence of borate and phosphate (MW>10,000,000), whereas dialysis into a Tris-phosphate buffer produces an active tetrameric enzyme with an apparent mass of 250,000 Da. This reversible association-dissociation was used to purify the GA either by repeated precipitation and solubilization or by repeated chromatography on a gel filtration column. Truncated forms of the recombinant GA protein containing an N-terminal His_6-tag have been expressed in bacteria and purified by Ni^+-affinity chromatography.[99] More recently, a highly conserved core fragment of GA (amino acids 221 to 533) has been co-crystallized with bound glutamate. The 3-dimensional structure of this complex is available from the Protein Data Bank (http://www.rcsb.org/pdb/explore/explore.do?structureId=3CZD).

The kinetic properties of the kidney-type GA have been characterized using permeabilized mitochondrial extracts[100,101] or the highly purified enzyme.[93] The GA activity is greatly enhanced by the addition of a broad range of polyvalent anions. The most commonly used activator is phosphate, which produces half-maximal activation at concentrations of 20–30 mM. However, the physiological activator of the GA is unknown. The kidney-type GA exhibits a relatively low K_M for glutamine and is strongly inhibited by glutamate.[101] The K_M for glutamine decreases from 36 to 4 mM as the phosphate concentration is increased from 5 to 100 mM. Glutamate was found to be a competitive inhibitor with respect to glutamine at both high and low concentrations of phosphate. However, the K_I for glutamate increased from 5 to 52 mM with increasing phosphate. These results indicate that glutamine and glutamate interact with the same site, but the conformation and specificity of this site is determined by the concentration of the activator.

The kinetic properties of the GAC variant of the mitochondrial GA have not been characterized. However, a truncated form of recombinant GA that lacks either C-terminal domain retains full activity and similar kinetic properties.[99] Thus, the distinct C-terminal domains of the kidney-type GA may function as protein binding domains that lead to association with an anchoring protein of the inner mitochondrial membrane or with different enzymes of glutamate metabolism. This hypothesis is supported by the finding that the C-terminal domain of the human liver-type GA binds to a unique GA-interacting protein.[102]

The biosynthesis and submitochondrial localization of the rat kidney KGA has been studied extensively. Pulse-chase experiments performed both *in vitro*[103] and in cultured cells[104] established that the rat kidney KGA is translated as a 74-kDa cytosolic precursor that is rapidly translocated into the mitochondrial matrix where it undergoes two sequential processing reactions that are catalyzed by the matrix processing peptidase.[105] The initial reaction removes the N-terminal mitochondrial targeting signal to form a 72-kDa intermediate. This product is subsequently cleaved at either of two sites to form either a minor 68-kDa or the predominant 66-kDa subunit. The deduced sequence of the 66-kDa subunit indicates that mitochondrial KGA lacks a membrane spanning domain or a targeting sequence that would initiate the translocation of the mature subunit to the intermembrane space.[89,90] Submitochondrial fractionation and biophysical studies indicate that the mature GA is either localized in the matrix compartment or loosely associated with the inner surface of the inner mitochondrial membrane.[4] Digitonin and Lubrol fractionation and swell-shrink sonication techniques were used to demonstrate that the rat renal GA is associated with the inner surface of the inner mitochondrial membrane.[106] Similar studies suggested that the rat renal GA is contained primarily within the mitochondrial matrix.[107] Either localization is consistent with the relative concentration of detergent required to release the mitochondrial GA and the inability to inhibit enzyme activity with membrane impermeable sulfhydral reagents and Fab antibodies that rapidly inactivate the solubilized GA.[108]

As a result of the submitochondrial localization of the GA, the catabolism of glutamine requires its initial translocation across the inner mitochondrial membrane. Glutamine uptake in mitochondria isolated from normal rats is mediated through glutamine/glutamate and glutamine/malate antiporters.[109] However, transport of glutamine into mitochondria prepared from acidotic rats occurs through a uniport mechanism[110] that uses a unique carrier.[32,111] Characterization of this process is made difficult by the rapid rate of mitochondrial transport, the high level of GA activity, and the lack of a specific and effective GA inhibitor. Thus, it has not been possible to measure initial rates of glutamine transport in intact mitochondria in the absence of metabolism.[112] However, experiments performed with isolated inner membrane vesicles that lack GA activity also indicate that the activity of the glutamine transporter is increased during both acute and chronic acidosis.[42,30] The rat renal mitochondrial glutamine uniporter has been purified and partially characterized by reconstitution into lipid vesicles.[31] However, neither a cDNA nor the gene that encodes the transporter has been cloned or identified, respectively. Thus, this important step in glutamine metabolism remains poorly characterized.

Stabilization of GA mRNA

The level of GA activity is increased in rat kidney during progressive development of chronic acidosis.[4] In normal rat kidney, the mitochondrial GA is greatest in the distal tubule and collecting duct, intermediate in the proximal convoluted tubule, and very low in glomeruli and the proximal straight tubule.[53,54] Within 1 d following the onset of acidosis, the GA activity is increased 2-fold, but only within the proximal convoluted tubule. Due to the cell specificity of the increase and the greater level of activity associated with distal tubules, 2 to 3 d are required to observe a significant increase in the GA activity measured in a crude homogenate of whole kidney. The total GA activity increases gradually and eventually plateaus after 7 d of acidosis at a value that is 3-fold greater than normal. However, this increase is due to a 7- to 8-fold increase in GA activity[53,54] and protein[44] within the proximal convoluted tubule. This adaptation correlates with the increased renal NH_4^+ ion synthesis that occurs in the proximal convoluted tubule. The physiological function of the non-responsive, but significant levels of GA in the distal segments of the nephron is unknown.

Immunological and pulse labeling experiments established that the increase in renal GA activity is due to the presence of an increased amount of protein[113] that results from a corresponding increase in the relative rate of GA synthesis.[62] However, the increase in GA occurs without an increase in the rate of transcription of the GA mRNA,[45] suggesting that this adaptation is due to a selective stabilization of the GA mRNA. Eukaryotic mRNAs contain a 5′-^{7Me}GpppG cap and a 3′-poly(A) tail that bind initiation factors and poly(A) binding proteins, respectively. Protein-protein interactions between eIF4E and the poly(A) binding protein form a circular structure that stabilizes the mRNA and enhances translation. Rapid degradation of a mammalian mRNA is initiated by the binding of specific

proteins to AU-rich elements within the 3′-UTR.[114–116] The RNA binding proteins recruit a poly(A)-specific deadenylase[117] and the exosome, a complex of 3′→5′ exonucleases,[118] to remove the poly(A) tail and accomplish the rapid 3′→5′ degradation of the deadenylated mRNA. Alternatively, the deadenylated mRNA may undergo decapping and 5′→3′ exonucleolytic degradation. Recent studies have identified cytoplasmic loci termed processing bodies, which contain the decapping enzyme, Dcp1/Dcp2, and a 5′→3′ exonuclease, Xrn1.[119] Thus, processing bodies are thought to constitute the site of 5′→3′ degradation. A third mechanism of mRNA turnover is initiated by sequence-specific endonucleolytic cleavage that generates sites for rapid exonucleolytic degradation by the exosome and the processing bodies.[120]

The presence of a sequence element that regulates the turnover of the GA mRNA was initially demonstrated by stable expression of various β-globin (βG) reporter mRNAs[64] in LLC-PK_1-F^+ cells, a pH-responsive line of porcine proximal tubule-like cells.[121] Expression of the parent βG construct produced a high level of a very stable mRNA ($t_{\{1/2\}}$>30 h). The turnover of the βG mRNA was not affected by transfer of the cells to acidic medium. A second construct, pβG-GA, includes the 956-bp segment that encodes the 3′-nontranslated sequence that is common to the two rat KGA mRNAs that are produced by use of alternative polyadenylation sites. The βG-GA mRNA exhibits a decreased expression that results from its more rapid turnover ($t_{\{1/2\}}$ = 4.6 h). Transfer of the cells expressing this construct to acidic medium resulted in a pronounced stabilization and a gradual induction of the βG-GA mRNA. These studies indicated that the 3′-nontranslated segment contains a pH-responsive instability element (pH-RE).

RNA gel-shift assays established that a direct repeat of 8-base AU sequences within the 3′-UTR of the GA mRNA functions as a specific protein binding site.[66] Site-directed mutation of both 8-base AU-sequences completely abolished protein binding and the pH-responsive stabilization of the βG-GA mRNA.[65] In addition, insertion of a 29-bp segment containing either the direct repeat or a single 8-base AU-sequence was sufficient to impart a 5-fold pH-responsive stabilization to a chimeric βG mRNA. Thus, the 8-base AU-sequence is both necessary and sufficient to function as a pH-RE. Extracts prepared from the renal cortex of rats that were made acutely acidotic exhibit an increased protein binding to the pH-RE.[122] The time course of the increase in binding activity correlated with the temporal increase in GA mRNA.

A tetracycline-responsive promoter system was developed to perform a pulse-chase analysis of the degradation of various chimeric βG mRNAs in LLC-PK_1-F^+ cells.[123] This approach accomplishes the rapid shut-off of the synthesis of a single mRNA and avoids potential indirect effects that may be caused by the use of a general transcription inhibitor.[124] With this approach, the measured half-life of the βG-GA mRNA is 2.9 h in cells maintained in normal medium and is increased >5-fold when the cells are transferred to acidic medium. RNase H cleavage and Northern analysis of the 3′-ends established that rapid deadenylation occurred concomitant with the rapid decay of the βG-GA mRNA in cells grown in normal medium. Stabilization of the βG-GA mRNA in acidic medium is associated with a pronounced decrease in the rate and extent of deadenylation. Mutation of the pH-RE within the βG-GA mRNA blocked the pH-responsive stabilization but not the rapid degradation, whereas insertion of only a 29-bp segment containing the pH-RE was sufficient to produce both rapid degradation and pH-responsive stabilization.

A biotinylated oligoribonucleotide containing the pH-RE was used as an affinity ligand to purify the pH-RE binding protein from a cytosolic extract of rat renal cortex.[125] The purified protein retained the same specific binding properties as observed with crude extracts. Mass spectroscopic analysis of the purified protein identified 11 peptides (~50% sequence coverage) that are identical to tryptic peptides derived from rat ζ-crystallin/NADPH:quinone reductase (ζ-cryst). This identification was confirmed by western blot analysis. In addition, specific antibodies to ζ-cryst blocked the formation of the complex between the pH-RE and either a crude cytosolic extract or the purified protein. Purified recombinant ζ-cryst also binds with high affinity and specificity to the two AU-sequences in the GDH mRNA.[126] Thus, ζ-cryst is the primary protein in extracts of rat kidney cortex that binds to the pH-RE. A second protein purified by the affinity protocol was identified as the T-cell restricted intracellular antigen-related protein (TIAR). This protein functions as the matrix for formation of stress granules[127] that constitute a site for the triage and remodeling of mRNA/proteins complexes in response to multiple stress conditions.[128,129] However, the affinity purified TIAR did not bind to the pH-RE and antibodies to TIAR did not block the binding interaction between the pH-RE and a protein in a cytosolic extract.[125]

To test the function of ζ-cryst binding, adenoviruses were produced that over express mouse ζ-cryst or a shRNA that is specific for the porcine ζ-cryst. Neither a pronounced over expression (50-fold) nor a significant knockdown (85%) of ζ-cryst in LLC-PK_1-F^+ cells had an effect on the normal turnover or the pH-responsive stabilization of the βG-GA mRNA.[130] Thus, ζ-cryst binding is not likely to be the rate limiting or sole factor that accounts for the rapid degradation or the

pH-responsive stabilization of GA mRNA. The process of mRNA stabilization in the proximal tubules may involve additional proteins or redundant pathways, such that the knockdown of ζ-cryst has very little effect on the overall process. Alternatively, the endogenous ζ-cryst may be present in such large excess that a small fraction of the normal level is sufficient to mediate the turnover of the GA mRNA.

RNA gel shift assays demonstrated that the recombinant p40 AUF1 also binds to the pH-RE of the GA mRNA with high affinity and specificity.[123] AUF1 is a known RNA binding protein that interacts with the 3′-UTRs of various unstable mRNAs including c-myc,[131] TNFα,[132] GM-CSF,[133] and COX-2.[134] AUF1 was also identified as hnRNPD,[135] a protein that shuttles between the nucleus and the cytoplasm.[136] Four isoforms of AUF1 (p37, p40, p42 and p45) are produced by alternative splicing of the initial AUF1 transcript.[135] Western blot analysis demonstrated that rat kidney cortex and various kidney cell lines express multiple isoforms of AUF1.[123] Additional experiments have established that recombinant HuR also binds to the pH-RE (unpublished data of Y. J. Lee and N. P. Curthoys). HuR is normally sequestered in the nucleus. However, in response to various stress conditions, HuR is translocated to the cytosol where it binds to AU-rich elements and promotes mRNA stabilization.[137] Recent studies indicate that the nuclear/ctyoplasmic distribution of HuR is determined by its level of phosphorylation.[138] Therefore, AUF1 and HuR may augment or counteract the effect of ζ-cryst and contribute to the regulation of the turnover of the GA mRNA.

Proteomic analysis of rat renal proximal tubules isolated from control and from 1 d, 3 d and 7 d acidotic rats identified two proteins including PEPCK that are fully induced within 1 d and eight proteins that exhibit more gradual induction profiles similar to GA and GDH.[44] All of the mRNAs that encode the latter proteins and the PEPCK mRNA contain an AU-sequence that is highly homologous to the pH-RE found in the GA mRNA. More recent studies have established that a pH-responsive stabilization contributes to the sustained increase in PEPCK mRNA in LLC-PK_1-F^+ cells treated with acidic medium. Thus, selective mRNA stabilization may be the predominant mechanism by which protein expression is increased or sustained in response to acidosis.

Enhanced Expression of PEPCK mRNA

The cytosolic isoform of PEPCK is a primary site of regulation of both hepatic and renal gluconeogenesis.[67] However, this activity is not regulated by allosteric mechanisms or by covalent modifications. Instead, it is regulated solely by mechanisms that determine the level of the PEPCK mRNA and thereby control the level of the PEPCK protein. This is accomplished through changes in either the rate of synthesis or the rate of degradation of the PEPCK mRNA. The *PCK1* gene that encodes the cytosolic PEPCK is composed of 10 exons and 9 introns and is approximately 6 kb in length.[139] It encodes a single 2.6-kb mRNA that is translated into a 69 kDa protein. The level of PEPCK mRNA in rat kidney is increased rapidly following acute onset of acidosis.[45] The increase is initiated within 1 h and reaches a maximum within 7 h at a level that is 6-fold greater than normal. Transcription run off experiments[45] indicated that changes in the relative rate of transcription of the *PCK1* gene account for the initial induction of PEPCK mRNA. Furthermore, the observed changes in PEPCK mRNA levels closely correlated with earlier data that measured changes in the relative rates of PEPCK protein synthesis in normal and acidotic rats.[61] However, the 6-fold induced level of PEPCK mRNA is sustained in rats that are made chronically acidotic even though the relative rate of transcription gradually decreases and plateaus at a level that is only 2-fold greater than observed in normal rats.[91]

Various segments of the PEPCK promoter, as well as the core promoter (-460 to +73 bp) containing specific block mutations in regulatory elements, have been extensively analyzed in transgenic animals to determine their role in controlling *PCK1* gene expression.[140] The wild type core promoter fused to the bovine growth hormone (bGH) gene contains all of the information necessary to insure appropriate expression and hormonal regulation in liver. A larger 2.3-kb segment of the PEPCK promoter was required to drive expression of the transgene in adipose tissue. However, both of these constructs were expressed at low levels in the kidney. In contrast, a CRC362 transgene that contains only 362 bp of the promoter but all of the downstream exons and introns of the rat *PCK1* gene was expressed at normal levels in the kidney.[141] This transgene differed from the endogenous gene only by the substitution of a segment of the chicken *PCK1* gene into the portion of the final exon that encodes the 3′-UTR of the PEPCK mRNA. The latter construct also exhibits a significant renal-specific induction when the transgenic mice were made acidotic.[142] These observations suggest that only 362 bp of the promoter along with an element in a downstream exon or intron is sufficient to recapitulate the pH-responsive induction of the *PCK1* gene.[142]

LLC-PK_1-F^+ cells exhibit a pH-responsive induction of PEPCK mRNA.[143] Previous attempts to identify a pH-responsive element by transient expression of

various PEPCK-chloramphenicol acetyltransferase reporter constructs in LLC-PK_1-F^+ cells produced contradictory results.[144–146] However, these studies clearly established that binding of HNF-1 to the P2 element is essential for basal expression of the renal PEPCK and that this protein:DNA interaction may contribute to increased expression during acidosis. Other experiments have established that in kidney, C/EBP_β[147] and ATF-2[7] bind to the CRE-1 element within the *PCK1* promoter.

Previous studies have also demonstrated that the half-life of the PEPCK mRNA is increased in liver in response to cAMP[148] and glucocorticoids.[149] Increased stability may also contribute to the sustained induction of renal PEPCK mRNA during chronic acidosis.[91] The tetracycline-responsive promoter system was used to quantify the half-life of various chimeric β-globin-PEPCK (βG-PCK) mRNAs in LLC-PK_1-F^+ cells.[150] The βG-PCK-1 mRNA, which contains the entire 3′-UTR of the PEPCK mRNA, was degraded with a half-life of 1.2 h. RNase H treatment indicated that rapid deadenylation occurred concomitant with degradation of the βG-PCK-1 mRNA. Previous studies[151] indicated that PCK-7, a 50-nt segment at the 3′-end of the 3′-UTR, binds an unidentified protein that may contribute to the rapid decay of the PEPCK mRNA. However, the chimeric βG-PCK-7 mRNA has a half-life of 17 h. Inclusion of the adjacent PCK-6 segment, a 23-bp AU-rich region, produced the βG-PCK-6/7 mRNA that has a half-life of 3.6 h. The βG-PCK-3 mRNA that contains the 3′-half of the 3′-UTR was degraded with the same half-life. Surprisingly, the βG-PCK-2 mRNA, containing the 5′-end of the 3′-UTR, was also degraded rapidly ($t_{\{1/2\}} = 5.4$ h). RNA gel-shift analyses established that AUF1 binds to the PCK-7, PCK-6 and PCK-2 segments with high affinity and specificity. Mutational analysis indicated that AUF1 binds to a UUAUUUUAU sequence within PCK-6 and an AU-rich element and adjacent CU-region within a stem-loop structure in PCK-7. The two AU-rich elements are highly conserved in all of the mammalian *PCK1* genes that have been sequenced. Thus, AUF1 binds to multiple destabilizing elements within the 3′-UTR that participate in the rapid turnover of the PEPCK mRNA.

RNA gel-shift assays established that purified recombinant HuR also binds with high affinity and specificity to same AU-rich elements and CU-sequence that bind recombinant p40-AUF1[250]. siRNA knockdown of HuR decreased basal expression and significantly inhibited the pH-responsive increase in PEPCK protein. Therefore, the pH-responsive stabilization of PEPCK mRNA in LLC-PK_1-F^+ cells, and possibly in the renal proximal tubule, may be mediated by a remodeling of the competitive interaction of HuR and AUF1 with the elements that mediate the rapid turnover of the mRNA. Thus, the same mechanism that accounts for the more gradual induction of the GA mRNA may also contribute to the sustained increase in PEPCK mRNA levels during chronic acidosis.

SIGNAL TRANDSDUCTION PATHWAYS THAT MEDIATE THE ADAPTIVE RESPONSES TO ACIDOSIS

Increased Expression of PEPCK

Analysis of the signal transduction pathways that mediate the pH-responsive induction of PEPCK gene expression[6] and the translocation and activation of NHE3[60] provide excellent paradigms to characterize the molecular mechanisms by which proximal tubule cells sense a slight decrease in intracellular pH and rapidly activate renal ammoniagenesis. The transfer of LLC-PK_1-F^+ cells to an acidic medium produced a rapid and pronounced increase in phosphorylation and activation of ERK1/2 and p38 MAPKs.[7] The potential involvement of the MAPK pathways was examined by determining the effects of specific inhibitors on basal and acid-induced PEPCK mRNA levels. SB203580, a specific p38 MAPK inhibitor, produced a dose-dependent inhibition of the pH-responsive induction of PEPCK mRNA and blocked phosphorylation of the downstream transcription factor, ATF-2. By contrast, the ERK1/2 inhibitors, PD098059 and U0126, and the JNK specific inhibitor, curcumin, had no effect on basal or acid-induced PEPCK mRNA levels. The octanucleotide sequence of the CRE-1 site in the PEPCK promoter (TTACGTCA) is a perfect match to the consensus element for binding ATF-2.[152] Gel-shift analysis using a labeled oligonucleotide containing the CRE-1 element produced a band that was partially supershifted with antibodies specific for ATF-2. Subsequent experiments[153] using dominant negative and constitutively active constructs of MKK3 and MKK6, the kinases that are immediately upstream of p38 MAPK, confirmed the role of p38 MAPK in mediating the pH-responsive induction of PEPCK. Thus, the SB-sensitive p38 MAPK/ATF-2 pathway may function as the pH-responsive signaling network for induction of PEPCK mRNA during acidosis.[154] However, the signaling mechanism that functions upstream of p38 MAPK to sense changes in intracellular pH in LLC-PK_1-F^+ cells is unknown. In addition, the pH-responsive increase in GA mRNA levels in LLC-PK_1-F^+ cells is not blocked by SB203580, suggesting that either a kinase upstream of the p38 MAPK or an alternative signaling pathway may mediate this response.[7]

Transforming growth factor-β (TGF-β) is a primary mediator of renal hypertrophy and was hypothesized

to enhance the catabolism of glutamine by activating GA and NHE3 gene expression.[155] Western blot analyses established that TGF-β activated the ERK1/2, p38 MAPK and Smad1/5/8 pathways in LLC-PK$_1$-F$^+$ cells, but not the JNK and Smad2/3 pathways.[156] However, TGF-β caused only a transient increase in PEPCK mRNA levels, but produced a gradual and stable increase in GA mRNA. In addition, the effects of acidic medium and TGF-β were additive. Therefore, TGF-β is not likely to mediate the altered gene expression that occurs following onset of metabolic acidosis.

Translocation and Activation of NHE3

The majority of the apical H^+ ion secretion in the proximal tubule is mediated by NHE3.[157] The development of chronic acidosis produces a gradual increase in total NHE3 protein in the S1 and S2 segments of the proximal tubule and in the medullary thick ascending limb of the rat kidney.[158] The NHE3 abundance is increased 60% by 7 d and nearly 2-fold by 14 d. In the medullary thick ascending limb, NHE3 activity, mRNA levels and protein abundance are increased about 70% during chronic metabolic acidosis.[159] A more rapid response occurs in OKP cells, a clonal line of opossum proximal tubule-like cells. Transfer of OKP cells to an acidic medium produced an increase in NHE3 mRNA levels that was initially detectable at 12 h and that reached a 2-fold increase after 24 h.[160] Interestingly, the abundance of the NHE3 protein within the apical membrane, as measured by surface biotinylation, is increased 2-fold within 6 h of transferring OKP cells to acidic medium.[38] Thus, the increase in apical Na^+/H^+ antiporter abundance precedes the increase in mRNA levels. The associated increase in apical activity is inhibited by ethylisopropylamiloride, an NHE3-specific inhibitor. The acute activation of NHE3 is caused by an increase in the rate of exocytosis and is inhibited by latrunculin B, an inhibitor of microfiliment formation. This process is mediated by a Rho kinase-dependent formation of stress fibers.[161] Therefore, the prompt acidification of the urine during acute onset of acidosis[40] may result from a rapid increase in translocation of the NHE3 protein to the apical membrane.

Treatment of OKP cells with endothelin-1 (ET-1), which binds to ET(B) receptors, also causes a 2- to 3-fold increase in apical abundance of NHE3.[162] This response occurs within 15 min and with no change in the level of total NHE3. Activation of the ET-1 signaling stimulates exocytosis of NHE3 and increases phosphorylation of multiple serine and threonine residues within NHE3.[163] The increase in phosphorylation exhibits a time course, an ET(B) receptor specificity, and a concentration dependence similar to the ET-1 activation of NHE3 translocation, suggesting that the two processes are linked. The potential *in vivo* role of the ET-1/ET(B) receptor signaling pathway in the response to metabolic acidosis was examined using ET (B) receptor deficient mice.[164] Acid ingestion for 7 d increased renal cortical ET-1 mRNA expression 2.4-fold in both wild type and ET(B) receptor deficient mice, but caused a greater acidosis in the homozygous deficient animals. Chronic acidosis also increased apical membrane NHE^3 in wild type, but not in ET(B) deficient mice. The combined studies indicate that increased synthesis of ET-1 and activation of the ET(B) receptor may mediate the increased apical expression of NHE3. Similar studies indicate that the pH-responsive increase in NaDC-1, the apical citrate transporter, is also mediated by the ET-1/ET(B) signaling pathway.[165]

Incubation of MCT cells, an SV40 transformed mouse proximal tubule cell line, in acidic medium for 30−45 sec produced a 2-fold increase in activity of c-Src,[166] a soluble tyrosine kinase. The pH-responsive increase in apical NHE3 activity in OKP cells was selectively inhibited by herbimycin A, a tyrosine kinase inhibitor, and by overexpression of carboxyl-terminal src kinase (csk), a physiological inhibitor of c-Src.[167] Additional studies demonstrated that expression of a dominant negative c-Src construct prevented the increase in NHE3 activity.[168] These observations indicate that a decrease in pH_i leads to rapid activation of c-Src and that the family of soluble protein tyrosine kinases plays a key role in the pH-responsive translocation of NHE3. More recent studies have identified Pyk2, a member of the focal adhesion kinase family of tyrosine kinases, as the upstream activator of c-Src.[169] Incubation of OKP cells in acidic medium caused a rapid, but transient increase in phosphorylation of Pyk2. Expression of a dominant negative form of Pyk2 or a Pyk2-specific siRNA blocked activation of c-Src and the downstream increase in NHE3.

Isolated Pyk2 is phosphorylated and activated *in vitro* by treatment with a slightly acidic medium.[169] The data suggest that autoactivation of Pyk2 may function as the sensor of a slight decreases in pH_i and initiate the downstream events that lead to increased expression of NHE3.[170] However, the principle effect of the *in vitro* activation is to decrease the K_M of Pyk2 for ATP from 129 μM to 51 μM. As a result, the pH-responsive activation of Pyk2 was only observed using 10 μM ATP as the substrate. Therefore, to function as an *in vivo* pH-sensor, Pyk2 must be localized to a region of the cell that maintains a lower than normal level of ATP.[60] The Pyk2 pathway is also involved in activation of basolateral HCO_3^- secretion.[171]

The combined studies suggest that activation of Pyk2 and c-Src function upstream of the increased synthesis and release of ET-1 that in turn binds to the ET(B) receptor and activates the translocation of NHE3.[60]

Treatment of MCT cells with acidic medium also causes a rapid activation of the ERK1/2 MAPK pathway that may activate transcription of multiple immediate early response genes, including *c-fos*, and *c-jun*.[172] This response is not blocked by inhibitors of Pyk2/c-Src/ET-1 pathway. However, the ERK1/2 inhibitor, PD98059, does inhibit the pH-responsive activation of NHE3.[168] Therefore, cross-talk between the two independently activated pathways may be required to activate the transcription and release of ET-1 that initiates the translocation and increased apical expression of the NHE3.[60]

The pH-responsive induction of PEPCK is not blocked by tyrosine kinase inhibitors.[7] Thus, it is unlikely that the Pyk-2/c-Src/ET-1 pathway contributes to increased expression of PEPCK. Therefore, multiple signaling pathways may be activated in response to a decrease in pH_i. Alternatively, the two pathways were characterized primarily in porcine and opossum kidney cells, respectively. Thus, different species may utilize different signaling pathways to mediate the adaptive response to acidosis. The physiological response of the kidney to metabolic acidosis has not been characterized in either the pig or the opossum. Therefore, further analysis of the signaling pathways should utilize a more physiologically relevant model system.

COUNTERCURRENT TRANSPORT OF AMMONIUM IONS

Secretion of Ammonium Ions within the Proximal Tubule

Initial micropuncture studies established a strong correlation between the level of ammonium ions in the luminal fluid of the late proximal convoluted tubule and the level of renal ammonium ion excretion.[173,174] Subsequent studies using dissected tubular segments indicated that the bulk of the ammonium ions produced by the kidney are synthesized in the proximal convoluted tubule.[57] Therefore, secretion into the luminal fluid of the proximal tubule is the initial step in renal excretion of ammonium ions. It was initially hypothesized that this process occurred by diffusion trapping.[175] This model assumes that the concentrations of ammonium ions (NH_4^+) and ammonia (NH_3) are maintained in equilibrium and that biological membranes allow the rapid diffusion of ammonia, but exhibit low permeability to ammonium ions. As a result, ammonia would rapidly equilibrate across the membrane and ammonium ions would accumulate in a compartment that exhibits a decreased pH. Thus, acidification of the luminal fluid would provide a sufficient driving force to account for tubular secretion and excretion of ammonium ions. While diffusion trapping clearly contributes to renal excretion, the transport of both ammonia and ammonium ions are now known to be mediated by specific proteins.

In the early portion of the proximal tubule, the preferential secretion of ammonium ions into the luminal fluid occurs before the development of a significant pH gradient.[176] The pH gradient in this portion of the nephron, as measured by *in vitro* microperfusion, is not sufficient to account for the observed ammonium ion secretion.[177] A significant portion of the measured ammonium ion secretion was inhibited by amiloride and this effect was only partially reversed by lowering the pH of the luminal perfusate.[11] These observations suggest that luminal secretion of ammonium ions is mediated, in part, by NHE3, the apical Na^+/H^+ exchanger. Experiments performed with isolated brush border membrane vesicles also indicated that ammonium ion transport can occur via the apical Na^+/H^+ exchanger.[10] However, both the basolateral and the apical membranes of the proximal tubule exhibit a high permeability to ammonia.[178] Additional studies demonstrated that ammonia entry into the lumen of the proximal tubule is affected by luminal pH and by the flow rate.[179] Thus, transport via NHE3 may be the dominant mechanism of ammonium ion secretion within the S1 segment, the initial portion of the proximal convoluted tubule, whereas diffusion and trapping of ammonia may be the primary mechanism within the S2 segment where significant acidification of the luminal fluid has occurred.

The rat S3 segment, the terminal straight portion of the proximal tubule, has a very low level of mitochondrial GA activity[53] and thus is unlikely to be a major site of ammoniagenesis. However, this segment, which extends into the outer stripe of the outer medulla, may participate in transepithelial transport of ammonium ions. Countercurrent transport of ammonium ions produces a high interstitial concentration within the medulla. As a result, basolateral uptake may result from the binding of NH_4^+, in place of K^+, to the basolateral Na^+/K^+-ATPase.[180] Subsequent apical secretion may occur via diffusion and trapping of ammonia within the acidified luminal fluid. Recycling at this site may contribute to the maintenance of the zonal gradient of ammonium ions.

Renal ammonium ion production and excretion are inversely affected by the concentration of K^+ ions.[181,182] Hypokalemia is associated with an increase in ammonium ion production that leads to an

increased excretion in spite of an increase in urinary pH. In contrast, hyperkalemia suppresses renal ammonium ion excretion. Microperfusion studies performed with isolated mouse S2 segments indicate that altered K^+ ion concentration has opposing effects on ammonium ion production by the proximal tubule.[183] Reduced K^+ ion concentrations enhanced ammonium ion production, whereas elevated K^+ concentrations inhibited production. These results are consistent with the observed effects of hypo- and hyperkalemia. However, reduced K^+ ion concentrations reduced proximal tubular ammonium ion secretion, whereas net secretion was unchanged with elevated K^+ ion concentrations. Thus, altered K^+ ion concentration must also affect the transport of ammonium ions that occurs within the loop of Henle and the collecting ducts.

Microperfusion studies also indicate that production and secretion of ammonium ions within the proximal tubule is regulated, in part, by angiotensin II.[184] Addition of physiological concentrations of angiotensin II to the basolateral surface of mouse S2 segments produced an increase in intracellular Ca^{++}, stimulated ammonium ion production, and enhanced luminal acidification.[185] However, unexpectedly, luminal secretion of ammonium ions was inhibited slightly. In contrast, the addition of angiotensin II to the luminal perfusate produced a similar increase in ammonium production, but stimulated an amiloride-sensitive increase in ammonium ion secretion in parallel with the increase in luminal acidification.[186] The effects of luminal angiotensin II were blocked by saralasin, an angiotensin II receptor inhibitor, and by nifedipine, a calcium channel blocker.

Additional studies were performed to compare the effects of luminal angiotensin II on ammonium ion secretion in perfused S2 tubules that were isolated from normal and acutely acidotic mice.[187] Tubules isolated from acutely acidotic mice exhibit an adaptive increase in ammonium ion secretion that was blocked when losartan was co-administered during the induction of acidosis. The addition of angiotensin II to the luminal fluid enhanced ammonium ion production and secretion to a greater extent in tubules isolated from the acidotic mice compared to normal mice. The stimulatory effects of angiotensin II were also blocked by losartan. Similar results were obtained using microperfused S2 segments obtained from mice feed NH_4Cl for 7 d.[188] In the latter studies, losartan also blocked the acid-induced apical expression of NHE3, but had no effect on the increased expression of GA or PEPCK. Recent studies also demonstrated that acute feeding (18 h) of NH_4Cl produced a 2-fold increase in total and apical surface expression of AT(1), the type 1 angiotensin II receptor.[189] The acute increase in cell surface expression of AT(1) was reproduced by treatment of cultured mouse S1 proximal tubules cells with an acidic medium for two hours and was blocked by colchicine. The combined data suggest that angiotensin II may play an important role in the adaptive increase in proximal tubular ammonium ion production and secretion by stimulating NHE3 translocation during the acute onset of acidosis. However, the effect of angiotensin II is not specific for NHE3. Infusion of angiotensin II in rats caused an acute (20 min) increase in the translocation of multiple proteins from subapical cytoplasmic vesicles to the apical brush border membrane.[190]

Reabsorption of Ammonium Ions in the Medullary Thick Ascending Limb

Microperfusion studies demonstrated that ammonium ions are reabsorbed from the luminal fluid between the proximal tubule and the accessible portion of the distal convoluted tubule.[74,96] However, the descending and ascending thin limbs of the loop of Henle exhibit high permeabilities for both ammonia and ammonium ions.[191,192] Therefore, this segment probably functions to equilibrate the ammonium ions within the interstitial space and the luminal fluid. Such a process could contribute to the countercurrent multiplication by recycling ammonium ions that have accumulated within the medulla. The primary site of ammonium ion reabsorption is the thick ascending limb of the loop of Henle.[193] Between 40 and 80% of the ammonium ions contained within the terminal portion of the proximal convoluted tubule are reabsorbed within this segment.[56] This process generates the corticomedullary concentration gradient that facilitates the final transport of ammonium ions into the collecting duct and their excretion in the urine.

The medullary thick ascending limb is a further site of luminal fluid acidification and HCO_3^- reabsorption. The developing pH gradient would favor the further translocation of ammonium ions into the luminal fluid. Therefore, reabsorption within this segment is not mediated by diffusion and trapping of ammonia. The addition of NH_4Cl to most cells causes a rapid alkalinization of the cytosol due to the more rapid entry of ammonia that is subsequently protonated and thereby reduces the intracellular concentration of H^+ ions. In contrast, the addition of NH_4Cl to the luminal surface of the medullary thick ascending limb causes a rapid acidification of the cytosol1.[195] This observation suggests that the apical membrane of the thick ascending limb is relatively impermeable to ammonia, while ammonium ions are rapidly and selectively transported into the cell. Some of the entering ammonium ions undergo rapid deprotonation to increase the

concentration of H^+ ions. Numerous studies have demonstrated that ammonium ion reabsorption by the thick ascending limb is sensitive to furosemide and is inhibited by K^+ ions.[196] Studies with apical membrane vesicles prepared from medullary thick ascending limbs also demonstrated that ammonium ions stimulated a bumentanide-sensitive Na^+ uptake and inhibited a bumentanide-sensitive rubidium ion flux.[197] These observations are consistent with ammonium ion transport via the apical Na^+-K^+-$2Cl^-$ cotransporter, BSC1/$NKCC_2$. Inhibitor studies suggest that in normal acid–base balance approximately two-thirds of the ammonium ion reabsorption within the thick ascending limb balance is mediated by BSC1/$NKCC_2$. Hyperkalemia also causes a reduction in ammonium ion reabsorption within the thick ascending limb and a reduced medullary interstitial concentration of ammonium ions.[198] Competition between NH_4^+ and K^+ ions for binding to the BSC1/$NKCC_2$ transporter could account for the reduction in ammonium ion excretion that is associated with hyperkalemia.[199] The remainder of the ammonium ion uptake within the thick ascending limb may occur via a barium- and verapamil-sensitive electroneutral K^+/NH_4^+ antiporter[200] that is localized within the apical membrane.[201]

The medullary thick ascending limbs express both an apical (NHE3) and basolateral (NHE1) Na^+/H^+ exchanger. NHE3 may contribute to the acidification of the luminal fluid and reduce the intracellular acidifying effect of the rapid entry of ammonium ions.[202] In isolated perfused tubules, the transepithelial transport of HCO_3^- ions is inhibited by addition of amiloride to the basolateral, but not the luminal surface of the thick ascending limb.[203] Thus, the NHE1 may contribute to the reabsorption of HCO_3^- ions.

During metabolic acidosis, the medullary thick ascending limb exhibits an increased rate of ammonium ion reabsorption.[204] This increase results from increased delivery from the proximal tubule and an adaptive increase in the level of the BSC1/NKCC2 transporter.[205] Incubation of isolated rat medullary thick ascending limb segments in an acidic medium produced a nearly 2-fold increase in BSC1/$NKCC_2$ transport activity and a corresponding increase in BSC1/NKCC2 mRNA and protein levels. Similar adaptations were observed in medullary thick ascending limb segments that were isolated from chronically acidotic rats. This adaptive increase is not mediated by increased transcription, but is due to selective stabilization of the BSC1/$NKCC_2$ mRNA.[70] This response requires the 3′-UTR of the BSC1/$NKCC_2$ mRNA, which contains four AU-rich sequences in which 7 of the 8 nucleotides are identical to the pH-REs that mediate the adaptive increases in GA and GDH mRNAs.[6] More recent experiments[206] have demonstrated that deletion of a single AU-rich sequence (ARE3) was sufficient to block the pH-responsive increase in BSC1/NKCC2 mRNA. Mouse TAL cells exhibit a two-fold increase in ζ-cryst when the cells are treated with an acidic medium. Over expression of mouse ζ-cryst also resulted in an increased level of wild type BSC1/$NKCC_2$ mRNA, but not the construct lacking ARE3. In addition, cells that over express ζ-cryst failed to exhibit a further increase in BSC1/NKCC2 mRNA when treated with acidic medium. Finally, siRNA knockdown of ζ-cryst (by 60%) reduced the basal level and completely abolished the pH-responsive increase in BSC1/$NKCC_2$ mRNA. Thus, this study provides convincing evidence that ζ-cryst plays an essential role in determining the level of BSC1/$NKCC_2$ mRNA in TAL cells.

Chronic metabolic acidosis also causes an adaptive increase in NHE3 mRNA and protein levels in the rat medullary thick ascending limb.[159] The mechanism and significance of this adaptation is uncertain, since selective inhibition of the apical Na^+/H^+ exchanger has no effect on ammonium ion reabsorption.[202] However, this adaptation may contribute to the increased HCO_3^- reabsorption that occurs within the thick ascending limb during acidosis.[194]

EXCRETION OF AMMONIUM IONS

Approximately 80% of the excreted ammonium ions are translocated across the cells of the collecting duct. The various segments of the collecting duct exhibit a very low permeability to ammonium ions, but are highly permeable to ammonia.[207] A portion of this secretion occurs within the cortical collecting duct[56] even though the interstitial concentration of ammonium ions within the cortex is relatively low. The mechanism for uptake of ammonium ions into the epithelial cells of this segment is not well defined. The observation that ammonium secretion by the cortical collecting duct is not inhibited by ouabain suggests that this transport is not mediated by the basolateral Na^+/K^+-ATPase.[194] However, this protein may contribute to ammonium ion uptake within the inner medulla where the interstitial concentration of ammonium ions is sufficient to effectively compete with K^+ ions for binding to the Na^+/K^+-ATPase.[208] A basolateral K^+/NH_4^+ antiporter has been defined in cultured mouse inner medullary collecting duct cells, but not in isolated segments.[209] Finally, a Na^+-K^+-$2Cl^-$ cotransporter, BSC2/NKCC1, has been immunolocalized to the basolateral membranes of the α-intercalated cells of the outer and initial inner medullary collecting ducts of the rat[210] and the terminal portion of the inner medullary collecting ducts of the mouse.[211] The observation that expression of BSC2/NKCC1 is increased in the rat

collecting duct during chronic acidosis suggests that this transporter may contribute to the basolateral uptake of ammonium ions.[212]

The process of apical secretion of ammonia is tightly coupled to the process of luminal acidification.[213] Within the rat, the cortical and outer medullary segments of the collecting duct lack a luminal carbonic anhydrase.[214,215] Thus, the combination of the secreted H^+ and luminal HCO_3^- ions results in the formation of carbonic acid that slowly dissociates to form CO_2 and H_2O. The resulting disequilibrium in carbonic acid produces a greater luminal acidification that contributes to the trapping of ammonia. Evidence for this hypothesis was obtained by the observation that infusion of carbonic anhydrase markedly reduces ammonium ion secretion in the cortical collecting duct.[213] During chronic acidosis, there is a marked increase in ammonium ion secretion along the entire length of the collecting duct.[56] This increase is paralleled by a corresponding increase in acid secretion. Within the inner medullary collecting duct, the increased luminal acidification is primarily mediated by an H^+/K^+-ATPase.[216] Consistent with this conclusion, intercalated cells from mice deficient in the alpha(1) and alpha(2) subunits of the H^+/K^+-ATPase exhibit a reduced acid excretion.[217]

The mammalian genome encodes a family of ammonia transport proteins, two of which participate in renal ammonium ion excretion.[218,219] Initially, the erythroid Rh antigen, Rh associated glycoprotein (RhAG), was shown to have structural homology to the family of yeast and plant ammonia transport proteins.[220] Subsequent cloning led to the identification of two additional mammalian homologs, RhBG and RhCG, that are selectively expressed in tissues that transport ammonia.[221] In the rat kidney, RhBG is expressed in the basolateral membrane of the distal convoluted tubule, the connecting segment and the cortical collecting duct.[222] Within the outer and inner medullary collecting ducts, RhGB expression appears to be limited to the α-intercalated cells that are involved in acid secretion. In the mouse, the pendrin-positive β-intercalated cells, which mediate HCO_3^- secretion during alkalosis, do not express basolateral RhBG immunoreactivity.[223] RhCG has an identical distribution along the rat nephron except that it was initially localized to the apical membrane.[224] However, more recent studies indicate that RhCG is expressed in both the basolateral and apical membranes.[225] Within the collecting duct, expression of both RhBG and RhCG is greater in the α-intercalated cells than in the principal cells.[223,224] Because the former cells are the primary site of H^+ ion secretion within the collecting duct, the disequilibrium decrease in luminal pH would be greatest in the region adjacent to the apical membrane of the α-intercalated cells. The high levels of the two ammonia transporters in these cells would facilitate the rapid transport and subsequent luminal trapping of ammonia.[14]

The X-ray crystallographic structure of an ammonia channel, the AmtB protein from *E. coli*, was recently solved at a 1.35 Å resolution.[226] The integral protein has 11 membrane-spanning α-helices. It also contains a vestibule that recruits ammonium ions, a binding site for an NH_4^+ ion, and a 20 Å long hydrophobic channel that lowers the pK_a for ammonium ions from 9 to less than 6. The channel conducts ammonia by forming favorable hydrogen bonding interactions with specific histidine residues that are conserved in all members of the family of ammonia transporters including the mammalian RhBG and RhCG proteins.[226] Thus, the latter proteins are also likely to function as specific channels to facilitate the rapid diffusion of ammonia.[13] While most membranes exhibit moderate permeability to ammonia, the expression of an ammonia channel would accelerate ammonia transport at sites where diffusion through the bilayer is slow relative to the physiological need. The cell specific expression of RhBG and RhCG within the kidney and in various non-renal tissues is consistent with this hypothesis.

Initial studies indicated that the cellular content and localization of RhBG are unaltered by development of chronic acidosis.[227] Furthermore, the total knockout of the *RhBG* gene had no apparent effect on systemic ammonium ion metabolism or ammonia permeability in isolated perfused collecting ducts.[228] In addition, the knockout mice responded to a chronic acid challenge with an appropriate increase in ammonium ion excretion. Thus, it was concluded that RhBG is not essential for the physiologic transport of ammonia, but may instead function as an ammonia sensor.[229] However, a more recent study demonstrates that the level of RhBG is increased in both the cortex and outer medulla in response to a metabolic acidosis that is induced by HCl administration.[230] In addition, mice which lack RhBG only in intercalated cells exhibit normal acid–base parameters and normal levels of ammonium ion excretion when fed a standard diet. However, mice with the cell-specific knockout exhibit a decreased response in ammonium ion excretion during early onset of metabolic acidosis, but not after 5 d of acid feeding. Therefore, the RhBG expressed in the intercalated cells may contribute to increased ammonium ion excretion during onset of acidosis. Previous studies established that mice exhibit a decrease in glutamine synthetase levels during metabolic acidosis.[231] Surprisingly, the intercalated cell specific knockout of RhBG resulted in a decreased expression of glutamine synthetase during normal acid–base balance and a greater than normal decrease following 5 d of metabolic acidosis.[230] Thus, the greater decrease in glutamine synthetase may

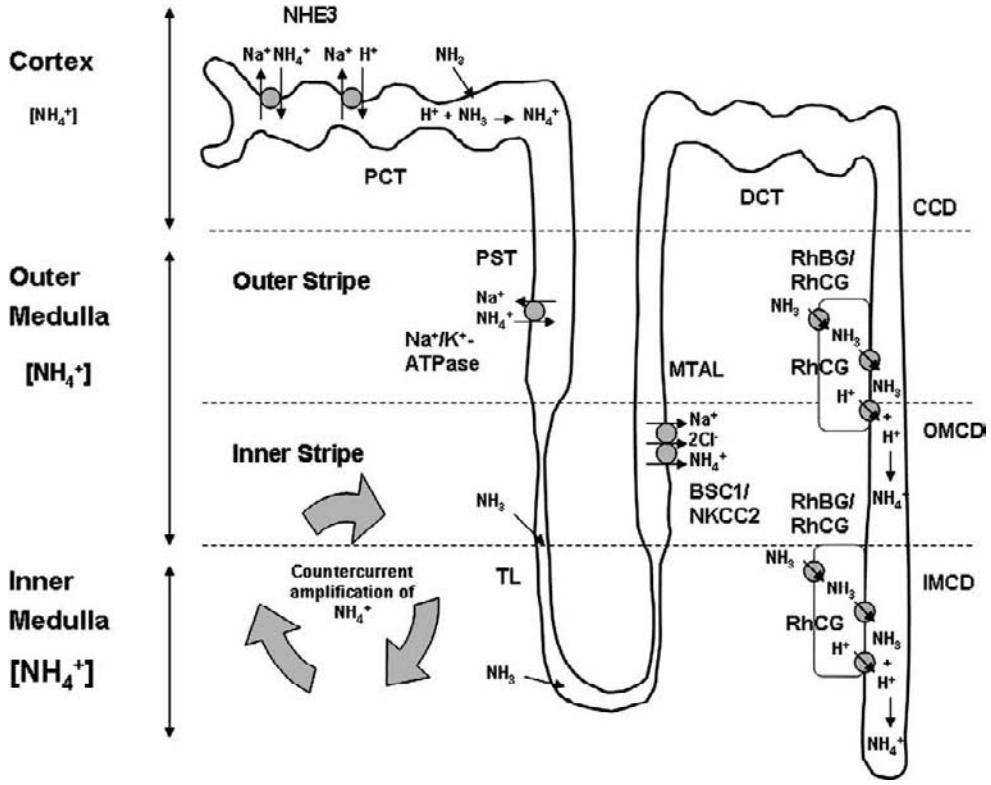

FIGURE 57.4 Primary sites and mechanisms of ammonium ion transport within the kidney. Ammonium ion transport in the proximal tubule is primarily mediated by NHE3, the apical Na^+/H^+ exchanger, by ammonia diffusion and trapping, and by the basolateral Na^+/K^+-ATPase. The formation of a corticomedullary gradient of ammonium ions is accomplished primarily by the secondary active transport of ammonium ions out of the medullary thick ascending limb by the apical Na^+-K^+-$2Cl^-$ cotransporter, BSC1/NKCC2, and by the reentry of ammonia within the thin limb of the loop of Henle. The transport of ammonia within the collecting duct is mediated primarily by the basolateral (RhBG & RhCG) and apical (RhCG) ammonia channels and by the trapping of ammonium ions in the acidified luminal fluid. The various segments of the nephron are abbreviated as: PCT, proximal convoluted tubule; PST, proximal straight tubule, TL, thin limb of the loop of Henle; MTAL, medullary thick ascending limb; DCT, distal convoluted tubule; CCD, cortical collecting duct; OMCD, outer medullary collecting duct; and IMCD, inner medullary collecting duct.

contribute to the appropriate level of ammonium ion excretion observed in the knockout mice when fed a normal diet or when fully adapted to a chronic acidosis.

Immunostaining[71] and immunogold-labeling[227] experiments indicate that the levels of RhCG are selectively increased in the apical membrane during chronic acidosis. The observed increases occur without a corresponding increase in RhCG mRNA and may result from increased apical targeting or the selective expansion of the apical membrane in the intercalated cells of the medullary collecting duct. Mice lacking RhCG exhibit abnormal urinary acidification and reduced ammonium ion excretion during NH_4Cl-induced metabolic acidosis.[232] Microperfused collecting ducts isolated from acidotic *RhCG*$^{(-/-)}$ mice exhibit reduced ammonia permeability and transepithelial transport. Similar defects were observed when RhCG was knocked out only the collecting duct[233] or the intercalated cells.[234] The combined data indicate that RhCG expression in both types of cells is necessary to produce the appropriate increase in renal ammonium ion excretion during metabolic acidosis.

The overall process of proximal tubular secretion of ammonium ions, reabsorption with the medullary thick ascending limb, and re-entry of ammonia in the collecting duct is summarized in Figure 57.4.

PATHOPHYSIOLOGY

The overall process of renal ammonium ion synthesis and excretion is both complex and finely regulated. It is exquisitely designed to generate an amount of HCO_3^- ions that is equivalent to the daily production of non-volatile acids. The primary pathway of HCO_3^- and ammonium ion synthesis within the proximal tubule is well delineated. In addition, considerable progress has been made in understanding how the expression of genes that encode key enzymes and

transporters is regulated during chronic acidosis. However, knowledge of the acute mechanisms that rapidly sense relatively minor changes in intercellular pH and activate specific signaling pathways to produce appropriate changes in ammonium ion production and transport and achieve the correct level of ammonium excretion is less satisfying. A major deficiency is the lack of knowledge of the molecular mechanism of mitochondrial glutamine transport and the regulation of this key step in ammoniagenesis.

In humans, the level of ammonium ion excretion is increased at least 5-fold in response to chronic acidosis.[235] However, pronounced renal insufficiencies in humans result in a proportionate reduction in ammonium ion production and excretion.[236] Various investigators demonstrated that in rats a 65–80% ablation of the kidneys is necessary to produce a reduction in total ammonium ion excretion and a reduced response to a high protein diet[237] or acid load.[238] However, even with this level of ablation, the ammonium ion production per remaining nephron is increased to partially compensate for the loss of renal tissue.[238,239] Thus, the processes of renal ammoniagenesis and excretion exhibit a high capacity and broad adaptive range.

The ability of the kidneys to contribute to acid–base balance by excreting the appropriate level of ammonium ions is also significantly influenced by various hormones including glucocorticoids,[240] endothelin[60] and the aldosterone/angiotensin system.[241] Glucocorticoids are essential to produce the appropriate increases in PEPCK[61] and SNAT3, the basolateral glutamine transporter.[242] In addition, glucocorticoids,[243] endothelin[60] and angiotensin II[188] enhance the translocation of NHE3 to the apical membrane. Furthermore, K^+ ion homeostasis1[82] also affects acid–base balance, in part, from the fact that NH_4^+ and K^+ ions compete for binding to a number of transport proteins and, in part, from the effect of extracellular K^+ ion concentration on intercellular pH. As a result, various conditions that result in adrenal insufficiency,[240] altered angitensin II levels,[241,244] hyperkalemia[245,246] and hypokalemia[247] can adversely affect renal ammonium ion excretion and acid–base balance. An impaired ability to acidify the luminal fluid, due to defects in H^+ transporters or a back leak of H^+, results in an inappropriate level of ammonium ion secretion and causes a distal renal tubular acidosis. In contrast, proximal renal tubular acidosis is produced by a defect in HCO_3^- reabsorption within the proximal tubule. This condition also causes a decrease in ammonium ion production due to an increase in intercellular pH[248] and in ammonium ion excretion due to the production of a more alkaline urine.[249] The pathophysiologies associated with each of these conditions are described in detail in other chapters of this monograph.

FUTURE DIRECTIONS

Our current knowledge of the adaptations in the renal production and excretion of ammonium ions that occur in response to changes in acid–base balance has been derived largely from hypothesis-driven experiments. Through this approach, a number of genes that are differentially expressed in the various segments of the nephron have been identified. Characterization of the increased expression of the mitochondrial GA has defined a novel mechanism of pH-responsive mRNA stabilization. The characterization of the cytosolic PEPCK gene has served as a paradigm to characterize the mechanism of pH-responsive changes in transcription. Activation of NHE3 has served as the paradigm for characterization of acid-induced translocation of key transporters to the plasma membrane. Limited progress has also been made in identifying the signal transduction pathways that mediate this adaptive response. However, given the complexity of this process and the number of participating cell types, the expression of a large number of additional genes are likely to also respond to changes in acid–base balance. Further understanding of the complexity and the regulation of this important physiological process may be derived from the application of genomic and proteomic techniques to identify the broad set of genes that are differentially expressed in individual nephron segments in response to changes in acid–base balance. The resulting data will identify the full spectra of genes that are activated or repressed by metabolic acidosis or alkalosis and classify those which are regulated through transcriptional or post-transcriptional mechanisms. It may also identify sets of genes, and their associated regulatory elements, that are temporally affected by mechanisms that have not, as yet, been characterized. Such techniques can also be used to more fully characterize the signal transduction pathways that mediate and coordinate the overall response.

Clinical Syndromes of Metabolic Alkalosis

Orson W. Moe, Robert J. Alpern and Donald W. Seldin

Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, TX, USA
Office of the Dean Yale University School of Medicine, New Haven, CT, USA

INTRODUCTION

Homeostatic control of acid–base parameters within discreet limits is vital to all living organisms. Acid–base disturbances are conditions that reflect underlying pathophysiology, which can stem from a broad range of etiologies. In humans with a filtration-reabsorption nephron, >4,000 mEq of HCO_3^- is filtered daily at the glomerulus and virtually all of it is reabsorbed by the tubules (Figure 58.1).

HCO_3^- absorption is an energy-requiring process. Under normal circumstances with a more or less fixed capacity to reabsorb elevated filtered [HCO_3^-], the renal tubule does not commensurately increase energy consumption or bicarbonate reabsorption therefore bicarbonaturia invariably ensues. Given this background, one wonders why metabolic alkalosis should supervene. In contrast to metabolic acidosis where the pathophysiology reflects increased acid production, reduced acid excretion, or both, the maintenance of metabolic alkalosis is a quintessential disease of altered renal HCO_3^- handling. Even though extrarenal factors contribute, the final effectors of maintaining a high plasma [HCO_3^-] reside in the kidney. Metabolic alkalosis is a tubulopathy.

A few definitions are necessary. *Alkalosis* denotes an excess of base in total body fluids. *Alkalemia* refers to a state of decreased H^+ activity in the plasma (increased plasma pH). Alkalosis can exist with little alkalemia due to respiratory compensation and without alkalemia because alkalosis might be part of a mixed acid–base disturbance. Conversely, alkalemia can be present without total body alkalosis. The adjective *metabolic* denotes that the disturbance is caused by a primary gain of base (e.g., HCO_3^-) or loss of H^+ from the body; as opposed to primary disturbances in carbon dioxide excretion.

The only compartment that is accessible to clinical testing is the ECF; hence ECF composition has defined most clinical acid–base disorders. Note that the direction of alterations in intracellular fluid (ICF) H^+ activity might differ from ECF.[1,2] The pathogenesis of metabolic alkalosis involves two distinct derangements—*generation* and *maintenance*. The increased ECF [HCO_3^-] that characterizes metabolic alkalosis is usually due to excessive ECF HCO_3^- content with noted exceptions such as massive contraction of ECFV around a constant amount of HCO_3^-, or shift of H^+ into cells with intracellular K^+ depletion. ECF HCO_3^- addition might occur through oral or intravenous routes. Of equal importance is H^+ removal from ECF which is tantamount to HCO_3^- addition.

H^+ can leave the body (external H^+ loss) through the gastrointestinal tract by vomiting or the kidney through stimulated urinary H^+ excretion. In either case, H^+ loss is synonymous with formation of HCO_3^- from the gastric or renal cell, respectively, which then enters the ECF. Alternatively, H^+ can move from the ECF into the ICF (internal H^+ loss) as seen in K^+ depletion. The phase of metabolic alkalosis in which addition to the ECF exceeds HCO_3^- exit from ECF thus raising ECF [HCO_3^-], is called the *generation phase*.[3] Normally, excess ECF HCO_3^- is readily and rapidly excreted by the kidneys. Persistent excess ECF HCO_3^-

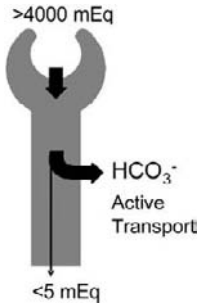

FIGURE 58.1 Filtration-absorption mechanism of bicarbonate handling by the nephron.

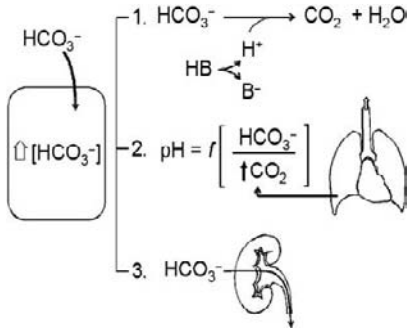

FIGURE 58.2 Three lines of defense against a HCO_3^- load: 1. Redistribution and buffer. 2. Hypoventilation to increase pCO_2. 3. Renal excretion of HCO_3^-.

content and concentration is usually due to inhibition of the ability of the kidney to excrete HCO_3^-. This is referred to as the *maintenance phase*.

Metabolic alkalosis is the most common acid–base disorder in hospitalized patients.[4] The magnitude of metabolic alkalosis correlates with morbidity,[5] mostly as a marker of severe underlying conditions but also a direct contributor to adverse events. A careful approach guided by the known pathophysiology of this order can direct diagnosis and management of the underlying disorders.

In this chapter, we will cover how one normal copes with the defense against high extracellular fluid HCO_3^- concentration, the systemic factors that act on the kidney to "reset" the plasma HCO_3 concentration, the proximal and distal tubular mechanisms responsible for this feat and finally, the clinical syndromes of metabolic alkalosis.

DEFENSE AGAINST EXCESS EXTRACELLULAR FLUID (ECF) HCO_3

As with any acid–base disturbance, one can envision three fronts of defense (Figure 58.2). First, the excess base confronts constituents of the fluid compartments, which harbors chemical components of defense. Second, the ventilatory system adjusts one determinant of ECFV pH, namely the CO_2 tension, to minimize the pH deviation. Third and the most important of all is the definite correction by the kidney with external elimination of the excessive base.

Systemic Response to ECF HCO_3^- Addition

Distribution of HCO_3^- Added to ECFV

Unlike a non-decomposable anion such as sulfate, HCO_3^- is partially dissipated by body buffers,[6] so its distribution does not fit into a single body compartment. The apparent distribution space of added HCO_3^- has been partitioned into anatomic and non-anatomic divisions (Figure 58.3).

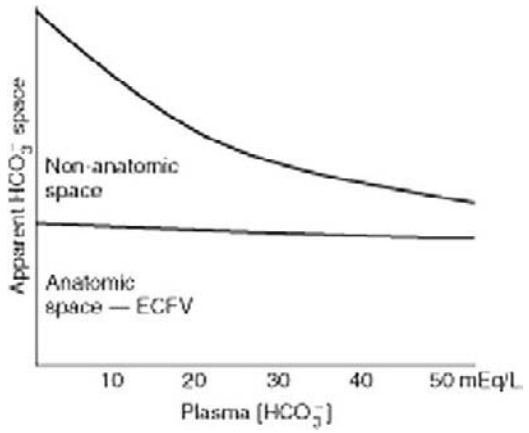

FIGURE 58.3 Apparent HCO_3^- space. This entity is theoretically partitioned into anatomic ECF volume and a non-anatomic space whose size is dependent on existing plasma [HCO_3^-].

The "anatomic" division refers to mainly the ECF compartment where added HCO_3^- is freely distributed. The "non-anatomic" division refers to the theoretical volume that accommodates the added HCO_3^- which cannot be accounted for by the anatomic space (ECF). This presumably represents some HCO_3^- that has entered cells and some that has been titrated by H^+ released from non-HCO_3^- buffers (such as hemoglobin and phosphate) thus constituting a virtual "space." At normal pH, these two divisions are approximately equal and together yield a total apparent HCO_3^- space of about 40 to 50% of total body weight.[6,7] Apparent HCO_3^- space is inversely related to preexisting ECF [HCO_3^-], with the non-anatomic fraction decreasing in size as the ECF [HCO_3^-] increases.[8] Decreasing size of the non-anatomic division with increasing ECF [HCO_3^-] is due to progressive narrowing of the titration range for non-HCO_3^- buffers at higher ECF [HCO_3^-].[8] Thus, a higher preexisting ECF [HCO_3^-] indicates

greater titration of non-HCO_3^- buffers, causing a greater rise in ECF [HCO_3^-] in response to a given quantity of added HCO_3^-. As with H^+, HCO_3^- added to ECF is buffered by cellular and extracellular processes.[7] Compared to acid, a smaller fraction of added base is buffered in the cell,[9] so a greater fraction of added HCO_3^- is retained in the ECF. In addition, there is less stabilization of intracellular pH in the alkaline range compared to the acid range.[10] This highlights the importance of rapid renal HCO_3^- removal in the systemic defense against excess ECF HCO_3^-.

Respiratory Response to a Primary Increase in ECF [HCO_3^-]

Respiratory mechanisms alleviate but do not fully correct the elevated plasma pH (Figure 58.2). The pH increase from added ECF HCO_3^- is attenuated by a concomitant rise in pCO_2. The acute component begins within seconds of HCO_3^- addition due to neutralization of added HCO_3^- by H^+ derived from titrated non-HCO_3^- buffers as follows:

$$NaHCO_3 + H\ Buffer \rightarrow NaBuffer + H_2CO_3 \rightarrow CO_2 + H_2O$$

The CO_2 generated by this reaction stimulates ventilation, returning pCO_2 toward but not precisely to normal. This acute response is followed by a more chronic one commencing at about 1 hour in which the alkalemia suppresses ventilation, leading to a sustained increase in pCO_2.[11,12] This effect on the central ventilatory centers is probably mediated through alkalinization of cerebral interstitial fluid.[13] The hypercapneic response to metabolic alkalosis takes several hours to complete and attenuates the rise in body fluid pH (but does not return pH to normal). In general, the pCO_2 increase in metabolic alkalosis is about 0.74 mm Hg for every 1 mEq/L increase in ECF [HCO_3^-].[14,15] The compensatory fall in alveolar ventilation is limited by hypoventilatory hypoxemia which can override the pH effect.

Renal Excretion of HCO_3^-

Despite the importance of buffering and respiratory responses which provides transient amelioration, the kidney has the ultimate responsibility for disposal of excess ECF HCO_3^-. Although its usual task is to completely recover filtered HCO_3^- and excrete a nearly HCO_3^--free urine, the normal kidney has an extraordinary capacity to excrete HCO_3^-. The normal kidney excretes ingested HCO_3^- more rapidly than it excretes ingested H^+.[16]

The classic experiment of Pitts and Lotspeich (Figure 58.4) demonstrated that renal HCO_3^- reabsorption does not increase after plasma [HCO_3^-] is beyond about 24 mM- a "threshold" at the whole organism

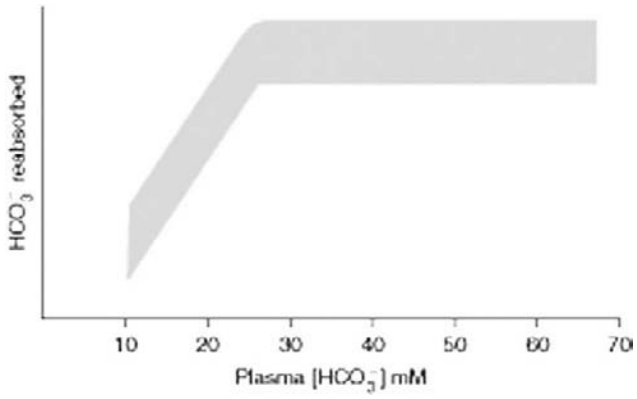

FIGURE 58.4 Whole kidney HCO_3^- absorption as a function of plasma [HCO_3^-]. HCO_3^- reabsorption increases as plasma [HCO_3^-] increases (assuming constant glomerular filtration rate) up to a point which is the plasma [HCO_3^-] threshold beyond which bicarbonaturia ensues. The inflection point is not sharp in the sense that there is a slight splay. Above the threshold the maximal capacity of renal HCO_3^- reabsorption is reached.

level.[17] Bicarbonaturia commence beyond the threshold which is when the tubular reabsorptive capacity is reach (Figure 58.4). The inflection point does not have a sharp angle but rather has a splay (Figure 58.4). Chronic oral $NaHCO_3^-$ loads as large as 24 mEq/kg/day are readily excreted in humans with minimal changes in ECF [HCO_3^-],[18] and acute intravenous loads are excreted entirely within 24 hours.[7] The kidney also increases excretion of organic anions (e.g. citrate) which are HCO_3^- equivalents (metabolism of which produces HCO_3^-) in response to ingested HCO_3^-,[19] contributing to the defense against metabolic alkalosis. Urine HCO_3^- excretion in response to administered HCO_3^- might theoretically be mediated by increased glomerular filtration rate (GFR), reduced tubule HCO_3^- reabsorption, or a combination of both. Intravenous isotonic $NaHCO_3^-$ induces massive urinary HCO_3^- excretion with minimal or no change in GFR[20] highlighting the importance of the renal tubule in mediating bicarbonaturia. Acute HCO_3^- infusion reduces fractional HCO_3^- reabsorption in the proximal[21] and distal nephron.[22] In addition, juxtamedullary nephrons excrete proportionally more HCO_3^- than do superficial ones in response to an acute intravenous HCO_3^- load.[23] Thus, the fixed or even suppressed capacity of HCO_3^- reabsorption is the predominant mechanism that mediates bicarbonaturia in response to an acute HCO_3^- load.

Acute HCO_3^- infusion tests the nephron's response to extreme HCO_3^- loads and massive bicarbonaturia is the usual response. However, mammals are rarely exposed to such massive alkali insults in their natural habitats and more subtle means of base excretion are utilized such as reduced net acid excretion and

citraturia.[24] More physiologic alkali challenges have been modeled using dietary $NaHCO_3$. Chronic oral $NaHCO_3^-$ reduces urine net acid excretion (urine ammonium + titratable acid − urine base) by decreasing excretion of ammonium and titratable acid as well as by increasing organic anion (primarily citrate) and HCO_3^- excretion.[25] Decreased ammonium and titratable acid excretion with maintained GFR is caused by decreased distal nephron acidification.

The inference from clearance studies was confirmed by direct measurements showing reduced acidification in distal[26] and collecting[27] tubules in animals ingesting $NaHCO_3$. Because HCO_3^- is both reabsorbed (mediated largely through H^+ secretion) and secreted in the distal[28,29] and collecting[27] tubule, decreased acidification in these distal segments can actually be mediated by increased HCO_3^- secretion and/or decreased H^+ secretion. Animals chronically ingesting $NaHCO_3$ have increased HCO_3^- secretion in the distal[30,31] and collecting[27] tubule while distal tubule H^+ secretion is less affected.[32] H^+ ingestion increases H^+-ATPase staining activity in collecting ducts.[33,34] Thus, stimulated HCO_3^- secretion is more prominent than reduced H^+ secretion as the predominant mechanism by which dietary HCO_3^- decreases distal nephron acidification.

Renal Disposal of Excess ECF HCO_3^-

Peritubular and Luminal Acid–Base Composition

Because increased ECF [HCO_3^-] is accompanied by simultaneous increase in [HCO_3^-] in the proximal tubule luminal fluid *in vivo*, it is difficult to separate the effects of peritubular from luminal acid − base changes on tubular HCO_3^- reabsorption in response to ECF [HCO_3^-] addition. This is best studied by measuring renal tubule HCO_3^- reabsorption in response to unilateral changes of acid–base composition in a renal tubule or its adjacent peritubular capillary *in vivo*.

In the proximal tubule, increased peritubular [HCO_3^-] and pH decrease net HCO_3^- reabsorption and increased luminal [HCO_3^-] increases it (Figures 58.5 and 58.6).[26,35] When H^+ secretion (transcellular active transport) is measured with varying luminal [HCO_3^-] at two levels of constant plasma [HCO_3^-],[36] two features are evident. First, the proximal HCO_3^- threshold is not 25 mM but rather 40-50 mM.[36] The threshold depicted in Figure 58.4 of 24 mM is a whole animal phenomenon. Second, increase in peritubular [HCO_3^-] reduces the HCO_3^- transport capacity of the proximal tubule (Figure 58.6). Acute increases in plasma [HCO_3^-] and pH (peritubular) also decrease distal tubule HCO_3^- reabsorption *in vivo*.[37] On the other hand, increases in luminal [HCO_3^-] increases HCO_3^- reabsorption in both proximal[35] and distal[37] tubules. Acute HCO_3^- addition

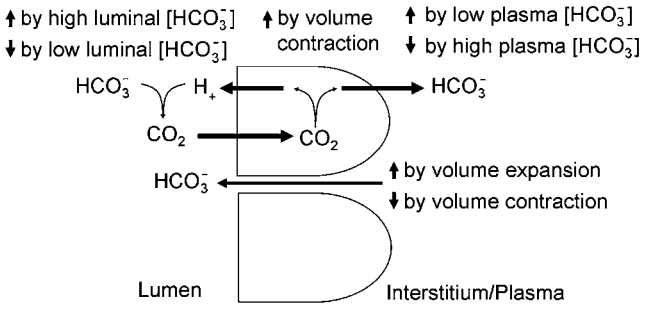

FIGURE 58.5 Regulation of proximal tubule transcellular HCO_3^- absorption (H^+ secretion). Transcellular bicarbonate reabsorption is regulated by both luminal and plasma [HCO_3^-] and pH, and ECF volume while paracellular HCO_3^- back-leak is regulated by extracellular fluid volume.

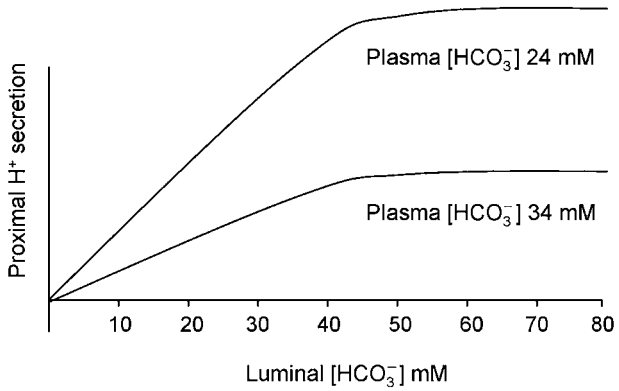

FIGURE 58.6 Interaction of luminal and plasma [HCO_3^-] on rate of transcellular H^+ secretion in rat proximal tubule. At each level of luminal [HCO_3^-], plasma [HCO_3^-] influences proximal acidification.

to ECF will inhibit both proximal and distal HCO_3^- reabsorption by increasing peritubular [HCO_3^-] but the concurrent increase in luminal [HCO_3^-] will stimulate proximal absorption and depending on whether the increased luminal [HCO_3^-] is translated axially down the nephron, it may offset the distal effect of increased peritubular [HCO_3^-].

ECF Volume and Dietary NaCl

Classic clearance studies showed increasing bicarbonaturia as ECF [HCO_3^-] (and HCO_3^- filtered load) rises above baseline in response to isotonic $NaHCO_3^-$ infusion[17] suggesting that the kidney ordinarily operates near its maximal capacity for HCO_3^- reabsorption. Renal HCO_3^- reabsorption can be dramatically enhanced above control levels when ECF [HCO_3^-] and filtered HCO_3^- load are increased with hypertonic $NaHCO_3^-$ infusion with minimal concomitant volume expansion.[38,39] In the absence of volume expansion, proximal tubule HCO_3^- reabsorption increases robustly in response to increasing luminal [HCO_3];[36] showing

partial saturation at a luminal [HCO_3] that is nearly twice that of plasma.[36] These studies highlight the kidneys' large intrinsic capacity for HCO_3^- reabsorption—an ability that is important in maintaining metabolic alkalosis.

Renal HCO_3^- reabsorption is inversely related to the state of effective ECF volume (Figure 58.5).[40] Volume expansion decreases fractional HCO_3^- reabsorption in the proximal convoluted tubule whether it is achieved with isotonic Ringers solution or with salt-poor hyperoncotic albumin.[41] Decreased proximal tubule HCO_3^- reabsorption induced by volume expansion is due to increased HCO_3^- permeability from peritubular blood to the tubule lumen, which likely increase "back-leak" of HCO_3^- into the tubule lumen and reducing net HCO_3^- reabsorption;[36] volume expansion induced no changes in proximal tubule H^+ secretion.[36] Thus, adequate ECF volume is an important permissive factor for renal excretion of excess ECF HCO_3^-. Dietary restriction or excess of NaCl yields subtle changes in ECF volume and influence steady-state ECF [HCO_3^-] via modulation of renal HCO_3^- excretion. Animals ingesting a NaCl-restricted diet have higher plasma [HCO_3^-] and lower urinary HCO_3^- excretion.[32] Furthermore, humans given $NaHCO_3$ increase their ECF [HCO_3^-] when they concomitantly ingest an NaCl-restricted diet.[42] Dietary NaCl restriction also increases ECF [HCO_3^-] in animals[43] and humans[44] with uremic acidosis. Dietary NaCl also induce distal HCO_3^- secretion.[32] Thus, supplemental dietary NaCl facilitates excretion of HCO_3^- added to ECF.

Potassium Status

K^+ deficiency is associated with intracellular acidosis independent of the extracellular pH.[45] To a renal epithelial cell, this likely provides a signal that calls for augmentation of HCO_3^- absorption. K^+ depletion causes metabolic alkalosis in rats[46] and humans[14] by multiple mechanisms, some of which are not fully clarified. Because K^+ depletion causes renal Cl^- wasting,[47] the effects of K^+ depletion with respect to renal HCO_3^- handling might be due in part to KCl depletion. Renal HCO_3^- reabsorption is greater in K^+-deplete compared to K^+-replete animals, and K^+ loading augments urinary HCO_3^- excretion in response to HCO_3^- infusion at all levels of ECF volume.[48] Acute $NaHCO_3$ infusion induces less renal HCO_3^- excretion and higher ECF [HCO_3^-] in KCl-deplete animals compared to K^+-replete ones.[22,49] Thus, KCl depletion reduces renal ability to excrete excess ECF HCO_3^- and helps to maintain metabolic alkalosis. There is a very modest increase in the mRNAs for the subunits of H,K-ATPases in the outer medulla;[50–52] the physiologic significance of this finding is not known.

Hormones Affecting Renal HCO_3^- Excretion

Addition of HCO_3^- to the ECF may modulate renal HCO_3^- excretion. ECF volume expansion due to $NaHCO_3$ administration decreases angiotensin II and aldosterone levels,[2] both being stimulatory hormones for renal tubule HCO_3^- reabsorption.[53,54] More importantly, euvolemic increases in ECF [HCO_3^-] and pH generated by dialysis decrease plasma aldosterone concentration.[45] Vasoactive intestinal peptide which increases after meals,[55] increases distal tubule HCO_3^- secretion,[30] possibly facilitating postprandial urinary HCO_3^- excretion. Dietary $NaHCO_3$ increases urinary prostacyclin, which also augments distal tubule HCO_3^- secretion.[31] Altered actions of these and other agonists induced by ECF HCO_3^- addition might contribute to urinary HCO_3^- excretion. In contrast, disturbances in such responses might contribute to the persistence of excess ECF HCO_3^- and maintenance of metabolic alkalosis.

MECHANISMS OF METABOLIC ALKALOSIS

When the rate of HCO_3^- generation or administration exceeds the capacity of regulatory mechanisms to immediately correct it, transient disequilibrium metabolic alkalosis can occur. Most commonly, the generation of excess ECF HCO_3^- is not sustained and ECF acid–base composition is returned to normal. Sustained metabolic alkalosis is hard to achieve with normal renal HCO_3^- excretory ability[18] and invariably involves compromised renal ability to excrete HCO_3^- and/or failure to reduce net acid excretion.

Generation of Excess ECF HCO_3^-

Figure 58.7 summarizes the factors that generate the elevation of plasma [HCO_3^-] which is broadly segregated into alkali (HCO_3^-) gain and H^+ loss. It is important to indicate that generation alone cannot beget the clinical syndrome without augmenting maintenance factors.

Exogenous Alkali (HCO_3^-) Gain

Administration of HCO_3^- or its precursors adds HCO_3^- to ECF and causes sustained metabolic alkalosis if renal HCO_3^- excretion is compromised. Some patients ingest $NaHCO_3$ to relieve indigestion, whereas others receive intravenous $NaHCO_3$ for various reasons. Large amounts of HCO_3^- precursors such as citrate might be administered during massive blood transfusions or plasmapheresis, which when metabolized, adds HCO_3^- to ECF. Metabolizable organic

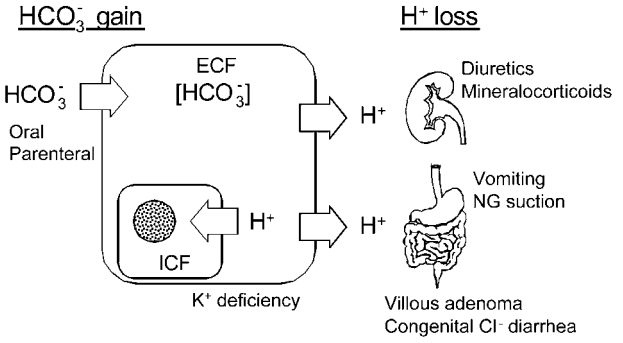

FIGURE 58.7 Generation of high plasma [HCO_3^-]. Elevation of [HCO_3^-] in the ECF can result from gain of HCO_3^- equivalent or loss of H^+ into the ICF, or out of the body via the kidney or gastrointestinal tract. Decrease of a massively expanded ECFV from isotonic NaCl and water loss (e.g., aggressive natriuretic therapy) around a fixed amount of HCO_3^- can raise the plasma [HCO_3^-] (not shown in figure). Note this requires a large fall in ECFV. For instance, if a grossly expanded ECFV of 28 L with a ECF [HCO_3^-] of 24 mM is reduced to 22 L by a 6 L NaCl-water loss, the resultant ECFV [HCO_3^-] will rise to 30 mM.

anions such as ketoacids and lactate are also HCO_3^- precursors. Treatment of organic acidosis with HCO_3^- might generate excess ECF HCO_3^- when the inciting metabolic disturbance is corrected and retained organic anions are metabolized. Metabolic alkalosis can be encountered transiently in these settings but is eventually corrected if renal HCO_3^- excretory mechanisms are intact. Dialysis against a dialysate with high [HCO_3^-] in an anephric patient can also generate metabolic alkalosis until the HCO_3^- is neutralized by endogenous acid production.

External H^+ Loss

Extrarenal H^+ loss primarily is due to gastric fluid loss from vomiting or nasogastric suction is the most common extrarenal H^+ loss that generates metabolic alkalosis. Gastric parietal cells add H^+ to the lumen and HCO_3^- to adjacent perigastric blood.[56] Gastric fluid entering the duodenum is neutralized by HCO_3^--containing pancreatic and biliary secretions,[57] so that acid–base balance is maintained under normal circumstances. External gastric fluid loss perturbs this balance as well as increases gastric pH, stimulating further luminal H^+ addition and perigastric HCO_3^- addition.[56] The generated excess ECF HCO_3^- initially causes bicarbonaturia with urine Na^+ and K^+ losses;[58] both of these contribute to the subsequent maintenance of metabolic alkalosis. Less commonly, extrarenal external H^+ loss generates metabolic alkalosis through lower GI fluid losses in some unusual diarrheal states. Diarrheal fluids are commonly alkali but H^+-rich diarrheal fluids occur with some villous adenomata[59] and with congenital chloridorrhea.[60]

Renal H^+ loss is another important source. For each mEq of renal net acid excretion, a mEq of HCO_3^- is added to ECF.[16] When renal acid excretion (HCO_3^- generation) exceeds H^+ addition (HCO_3^- consumption) to the body, excess ECF HCO_3^- accumulation occurs. Loop diuretics increase renal acid excretion,[61] and increase ECF [HCO_3^-],[62] and chronic administration of these agents can induce metabolic alkalosis, particularly when combined with a low intake of dietary Na and K.[63] Mineralocorticoids increase urine net acid excretion and ECF [HCO_3^-][64] by increasing distal nephron H^+-ATPase and H^+ secretion.[52] Ingestion of a NaCl-restricted diet blunts the ability of mineralocorticoid to induce volume expansion and metabolic alkalosis.[65] The combination of increased mineralocorticoid activity with inappropriately high distal Na^+ delivery greatly enhances distal nephron acidification[66] and K^+ loss, which further augments distal acidification[67] by increasing ammonium production[68] and activating distal nephron H^+,K^+-ATPase.[52]

Internal H^+ Shift

Potassium depletion induces metabolic alkalosis by multiple mechanisms.[66] Severe K^+ depletion induces movement of ECF H^+ into ICF in partial cationic replacement of lost intracellular K^+,[69] generating ECF HCO_3 by mechanisms discussed earlier. Conversely, K^+ repletion of K^+-depleted animals with metabolic alkalosis decreases ECF [HCO_3] in part by titration of ECF HCO_3^- by H^+ exiting from ICF in cationic exchange for administered K^+.[70] In severe K^+ depletion, there may be an enormous amount of H^+ accumulation in the cell such that there may be a total body H^+ excess hence warranting the designation of "metabolic acidosis" even though the ECF [HCO_3^-] may be high.[71] This is a potentially confusing but important concept to grasp.

No Net loss or Gain of H^+/HCO_3^-

Not shown in Figure 58.7 is what is referred to as "contraction alkalosis." ECF [HCO_3^-] can theoretically be increased by decreasing ECF volume around a constant HCO_3^- content through reductions in ECF NaCl and H_2O. In the purest form of contraction alkalosis, there is no true generation of HCO_3^-. In clinical settings, this mechanism of increased ECF [HCO_3^-] rarely occurs in isolation but more often exists in concert with other mechanisms that generate HCO_3^- such as GI and renal H^+ loss. Experimental models that explore this mechanism of generating metabolic alkalosis have been created in animals subjected to acute urinary losses induced by furosemide.[72] The rise in ECF [HCO_3^-] in this setting cannot be attributed exclusively to reduced ECF volume because furosemide also increases excretion of K^+ and H^+,[61] each of which generates metabolic

alkalosis. The rise in ECF [HCO_3^-] in these animals is proportionately less than the decrease in ECF volume, due in part to HCO_3^- entry into ICF, titration by non-HCO_3^- buffers, and urinary HCO_3^- excretion.[60,73]

Maintenance of Excess ECF HCO_3^-

While metabolic acidosis can result from acid production overwhelming maximal renal acid excretion, alkalosis is maintained primarily by compromising renal HCO_3^- excretion. In settings where metabolic alkalosis is due exclusively to excess HCO_3^- ingestion or generation, the disorder is self-limited and is associated with alkaline urine, reflecting an appropriate renal response. In sustained metabolic alkalosis, the urine is not alkaline, reflecting little to no urine HCO_3^- excretion in the presence of elevated plasma [HCO_3^-].

As shown in Figure 58.8, high plasma [HCO_3^-] can be maintained by low GFR or increased renal tubule HCO_3^- reabsorption. The following section describes factors that play a role in the chronic maintenance of excess ECF HCO_3^-: (1) Decreased GFR. (2) K^+ depletion. (3) ECFV depletion or Cl^- depletion. (4) Mineralocorticoid excess. The latter three are the most important.

Decreased GFR

Reduction in GFR can theoretically normalize the amount of HCO_3^- filtered despite a high plasma [HCO_3^-]. Indeed, the level of GFR reduction in some experimental models of chronic metabolic alkalosis yields a filtered HCO_3^- load (GFR x plasma [HCO_3^-]) and absolute renal HCO_3^- reabsorption that is not different from control.[74] This will be a mechanism of maintenance where low GFR is the sole culprit and there is no tubulopathy. Administration of crystalloid to this model increases GFR and reduces the ECF [HCO_3^-].[74] Infusion of atrial natriuretic peptide increases GFR and reduces excess ECF HCO_3^-.[75] However, establishing reduction of GFR as a major maintenance factor for metabolic alkalosis has been problematic. In some models of chronic metabolic alkalosis, GFR is comparable to control[49] or even higher.[76] Exogenous HCO_3^- administration to animals with reduced GFR still induces appropriate urinary HCO_3^- excretion[77] indicating that tubular responses return acid–base status towards normal despite low GFR. In humans, the slight GFR reduction in subjects with chronic metabolic alkalosis contributes minimally to maintenance compared to enhanced renal tubular HCO_3^- reabsorption. Most published studies show that GFR is normal[78] to slightly reduced[79] in humans with chronic metabolic alkalosis. In human studies that did show reduced GFR, the level of GFR reduction is not sufficient to account for the rise in ECF HCO_3^-, indicating a concomitant enhancement of renal HCO_3^- reabsorption must exist.[80,79] Kunau and coworkers convincing showed that isohydric expansion of ECFV in the presence of renal arterial restriction to keep GFR low successfully resulted in bicarbonaturioa and correction of alkalosis.[81] In summary, GFR reduction may contribute but does not play a major role in maintaining chronic metabolic alkalosis in humans. A tubulopathy has to come to play.

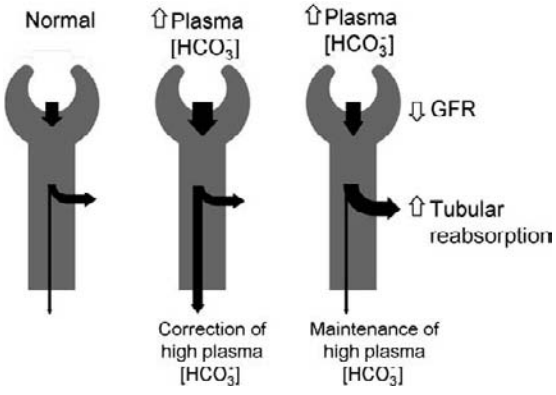

FIGURE 58.8 Renal maintenance of high plasma [HCO_3^-]. Normally there is little or no HCO_3^- in the urine (left panel). With elevation of plasma [HCO_3^-], the increased filtered load leads to obligatory bicarbonaturia and correction of the alkalosis (middle panel). High plasma [HCO_3^-] can be maintained by either reduced GFR or increased tubular reabsorption (right panel); the latter being much more important.

K^+ Depletion

Depletion of total body K^+ maintains metabolic alkalosis by multiple complex mechanisms (Table 58.1). K^+ depletion reduces urine HCO_3^- excretion in response to administered HCO_3^-.[22,48] Thus, K^+ depletion limits renal HCO_3^- excretion after generation of metabolic alkalosis. Decreased renal HCO_3^- excretion has been shown to be mediated by increased HCO_3^- reabsorption in both the proximal[81,82] and distal[67,82] nephron in animals with K^+ depletion.

TABLE 58.1 Mechanisms by which K^+ Depletion Contributes to Metabolic Alkalosis

Reduction of GFR
Increased ammonia production
Hypocitraturia
Increased proximal tubule acidification
Increased distal tubule acidification
Increased renal Cl^- wasting

Increased renal tubule HCO_3^- reabsorption might be due to reduced intracellular pH in renal tubule cells of K^+-depleted animals.[83] This electrolyte abnormality also increases renal ammonia production,[68] which would facilitate augmented net H^+ excretion,[84] the latter generating and maintaining metabolic alkalosis by the mechanisms discussed earlier. Potassium depletion causes renal Cl^- wasting[47] and thereby volume depletion, which can maintain metabolic alkalosis. Severe K^+ depletion can also decrease GFR,[85] which might contribute somewhat to maintain metabolic alkalosis. As noted earlier, K^+ depletion enhances metabolic alkalosis induced by exogenous mineralocorticoids.[64] However, K^+-depletion *per se* reduces mineralocorticoid production.[86] which is expected to reduce renal acidification.[52] Nevertheless, K^+-depleted animals with metabolic alkalosis and reduced serum aldosterone levels[87] still have increased proximal[49] and distal[49,87] tubule acidification, suggesting that other factors can increase renal acid excretion in this setting. K^+ depletion clearly is an important maintenance factor for metabolic alkalosis and should be searched for and treated if found in patients with metabolic alkalosis as part of the management of patients with this acid–base disorder.

ECF Volume Depletion

Reduced ECF volume is probably the single most important maintenance factor for metabolic alkalosis in the clinical setting in humans[78] and is a feature of many experimental models of this acid–base disorder.[3] In a gastric acid loss model of metabolic alkalosis in humans, volume repletion reduces excess ECF HCO_3^- leading to correction of the alkalosis.[58] In support of the pivotal importance of ECF volume depletion rather than hypochloremia is the demonstration that in diuretic-induced hypochloremic alkalosis, expansion of ECF volume with hypochloric solutions corrected the metabolic alkalosis without raising the serum chloride concentration.[88] Still unsettled is whether total body Cl^- depletion independent of ECF volume depletion can maintain metabolic alkalosis. Nevertheless even in purported volume-replete experimental models of metabolic alkalosis in which the removed NaCl is replaced with equimolar $NaHCO_3$, ECF volume depletion can occur due to a shift of ECF $NaHCO_3$ into ICF as HCO_3^- space is larger than ECF.[1] Volume-deplete subjects clearly excrete less of an administered HCO_3^- load compared to volume-replete or volume-expanded ones.[48,89] Dietary NaCl restriction increases activity of the proximal tubule Na^+/H^+ exchanger.[90] In addition, dietary NaCl restriction reduces luminal Cl^- delivery in the distal tubule,[32] limiting the Cl^- available to promote luminal HCO_3^- secretion.[91,92] Depending on the degree, volume depletion can also decrease GFR[93] and stimulate the renin-angiotensin system[94] and increase angiotensin II, which increases HCO_3^- reabsorption in both the proximal[95] and distal[30] nephron.

Cl^- Depletion

A longstanding controversy has been whether Cl^- depletion *per se* contributes to metabolic alkalosis independent of ECF volume contraction. In support of this view is the fact that Cl^- administration to some Cl^--deplete experimental models of metabolic alkalosis decreases ECF [HCO_3^-] independent of changes in both ECF volume[96,97] and body K^+ stores.[58,96,97]

Although suggestive, interpretive issues still cloud unequivocal proof that Cl^- depletion independent of ECF volume depletion maintains metabolic alkalosis. The intimate relationship of total body Cl^- to ECF volume renders separating the two, even experimentally, exceedingly difficult. Models in which NaCl removal is replaced with equimolar $NaHCO_3$ can induce ECF volume depletion due to shifts of Na^+ out of the ECF as HCO_3^- is distributed in the non-anatomic space as indicated earlier.[1] Experimental models where reduction of total body Cl^- is not accompanied by detectable ECF volume contraction[49,98] are difficult to reconcile with clinical practice where Cl^- depletion is almost invariably associated with ECF volume depletion. Cl^- depletion and repletion both carry changes in the accompanying cation which is either Na^+ or K^+; both of which can affect HCO_3^- homeostasis per se. The one mechanism that Cl^- can affect distal HCO_3^- secretion independent of Na^+ and K^+ is by activiting distal Cl^-/HCO_3^- exchange. Thus far, data supporting Cl^- depletion per se as an independent factor independent of ECF volume and K^+ depletion are not conclusive.

Excess Mineralocorticoid Activity

Hypermineralocorticoid states have long been associated with metabolic alkalosis[3,99] and correction of the excess mineralocorticoid state in humans effectively reduces excess ECF HCO_3^-.[65] Two points are noteworthy. First, one is referring to a primary increase in mineralocorticoid activity rather than the elevation in response to volume contraction or hyperkalemia.[94] High aldosterone activity in subjects with volume depletion contributes to maintenance of excess HCO_3^- where distal Na^+ delivery is high such as in gastric alkalosis with bicarbonaturia and in diuretic therapy. Second, excess mineralocorticoid activity denotes a heightened state of biologic activity rather than just levels of mineralocorticoids. One action of mineralocorticoids is to increase distal nephron and net acid excretion acidification,[54,100] which can generate and maintain excess ECF HCO_3^-.

The ability of mineralocorticoids to generate and maintain metabolic alkalosis depends on the Na^+

and K^+ status of the subject. It is very important to note that humans on a low-salt diet given mineralocorticoid do not develop metabolic alkalosis or hypokalemia.[65,101,102] Exogenous mineralocorticoids lead to minor changes in net acid excretion in K^+-replete dogs in contrast to a large increase in acid excretion in K^+-deplete animals.[64] Patients with primary hyperaldosteronism with the most severe K^+ depletion have the worst metabolic alkalosis.[103] This illustrates the importance of multiple factors in the maintenance of metabolic alkalosis.

Derangements in Renal Acidification in Metabolic Alkalosis

How do the above factors act to maintain the abnormal tubular function? There is a prevailing but yet unproven dogma that the renal tubule is completely normal but simply misdirected by the incoming signals to maintain a high rate of acid excretion and low rate of HCO_3^- secretion in the face of a high plasma [HCO_3^-]; somewhat of a mendicant organ just blindly taking orders so to speak. Unflattering as it may sound, this is widely believed to be true mainly due to the rapid reversal when the principal defects of ECFV contraction, K^+ depletion, and high mineralocorticoid activity are corrected.

Different experimental models of metabolic alkalosis may use diverse generation and maintenance mechanisms.[49] In several models, it is maintained by increased whole-kidney HCO_3^- reabsorption, which stems from both proximal and distal mechanisms. One difficulty in interpretation of the current body of animal data is the heterogeneity of the models and to a lesser extent species variation. Table 58.2 summarizes the documented or predicted changes in the three pivotal pathophysiologic factors affecting renal acidification in various models of metabolic alkalosis. ECF volume contraction and K^+ depletion increases proximal acidification. All three factors affect distal acidification.

TABLE 58.2 Mechanisms of Metabolic Alkalosis in Selected Models

Model	ECFV↓	K^+↓	MC↑
$NaHCO_3$ load	−	±	−
Replace NaCl with $NaHCO_3$	+/−	+	+/−
Diuretic	−	−	+
K^+ depletion	+/−	+	−
Exogenous MC	−	+	+

ECFV, extracellular fluid volume; MC, mineralocorticoid.

Proximal Tubule and Thick Ascending Limb

This is best exemplified by the classic experiment of Maddox and Gennari.[104] Absolute proximal tubule HCO_3^- absorption increases with increasing filtered HCO_3^- (Figure 58.9). When metabolic alkalosis is induced with acute infusion of $NaHCO_3$, filtered load is increased but reabsorption is not, resulting in massive bicarbonaturia. During the maintenance phase of chronic metabolic alkalosis, even when both the plasma [HCO_3^-] and filtered load are as high as in the acute situation, proximal HCO_3^- continues to increase (Figure 58.9) instead of the expected inhibition by high plasma [HCO_3^-] (Figures 58.5 and 58.9). This finding indicates there are intrinsic changes in the proximal tubule epithelium.

Proximal tubule HCO_3^- reabsorption is increased in K^+- and Cl^--deplete model of diuretic-induced metabolic alkalosis.[49,76] The increase is related in part to the augmented filtered HCO_3^- load delivered to the proximal tubule.[49,76] The effect of increased luminal [HCO_3^-] on HCO_3^- reabsorption in the proximal tubule is offset by the increased ECF [HCO_3].[35] ECF volume contraction also increases proximal tubule Na^+/H^+ exchange activity[40] and the proximal tubule autocrine/paracrine renin angiotensin system.[105] Thus, proximal tubule HCO_3^- reabsorption is not decreased, as would be expected to be homeostatically appropriate in the setting of excess ECF HCO_3.

The stimulation of proximal tubule HCO_3^- reabsorption by K^+ depletion[81] is possibly mediated by intracellular acidification.[83] Chronic hypokalemia increases the proximal tubule ensemble of Na^+/H^+ exchanger (NHE3),[106,107] ammoniagenic enzymes.[68,108,109] Na^+-dicarboxylate (citrate) cotransporter (NaDC-1)[110] and citrate metabolism[111] and Na-bicarbonate cotransporter[106] and expression of angiotensin II receptor, AT1;[112]

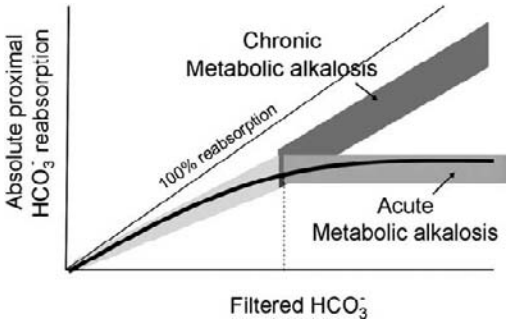

FIGURE 58.9 The relationship of absolute proximal tubule HCO_3^- absorption as a function of filtered load of HCO_3^- under free flow condition. The dotted line denotes the normal filtered load. The heavy solid line represents the normal relationship between filtered and absorbed HCO_3^-. In the acute setting, this is only a very small deviation from normal. In chronic metabolic alkalosis, tubular reabsorption is increased so the increased filtered load is reclaimed.

probably all mediated by intracellular acidification. Inhibition of the proximal Na-sulfate cotransporter NaSi-1[113] does not affect proximal acidification *per se* but the increased distal sulfate delivery of a non-absorbable anion can increase distal H^+ secretion. Note that simple $NaHCO_3$ loading without persistent metabolic alkalosis led to a decrease of NHE3[114] and NBC-1[115] suggesting the conglomerate changes listed above are involved with the maintenance of metabolic alkalosis. Other possible explanations of the increased proximal tubule HCO_3^- reabsorption in metabolic alkalosis is volume depletion,[116] with its attendant changes in proximal tubule HCO_3^- permeability[35] and its resulting hormonal changes, including stimulation of the renin-angiotensin system.[94,105] In addition, diuretic-induced metabolic alkalosis is associated with increased renal endothelin-1 secretion,[87] which can increase Na^+/H^+ exchange.[117] These changes are summarized in Figure 58.10.

Derangements in the thick ascending limb are less consistent in metabolic alkalosis. Absorption of HCO_3^- is increased by either $NaHCO_3$ or NaCl administration but reduced by NaCl restriction.[118] The effect of ECF volume may dominate over the effects of high plasma pH and $[HCO_3^-]$. K^+ depletion may facilitate delivery of ammonium to the collecting thus contributing to increase net acid excretion.[84] The role of the thick limb in the maintenance of metabolic alkalosis is unclear.

Distal Convoluted and Collecting Tubule

In distal renal tubular acidosis or overproduction acidosis, distal H^+ secretion is insufficient to effect the net acid excretion so as to maintain net acid balance,[89] but the distal nephron nevertheless contributes to overall acid excretion to correct the acidosis. In contrast, metabolic alkalosis is maintained by distal acidification that is inappropriately increased which makes it the guilty party resulting in maintenance of the alkalosis.

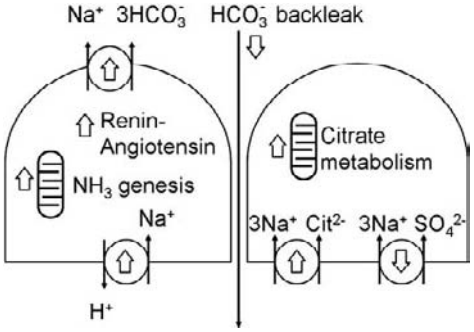

FIGURE 58.10 Proximal tubule pathophysiology in metabolic alkalosis. Changes are caused predominantly by effective ECF volume contraction and K^+ deficiency. A host of metabolic and transport changes that culminate in increased proximal H^+ secretion and HCO_3^- absorption.

In a KCl-deplete model of diuretic-induced metabolic alkalosis, HCO_3^- reabsorption measured *in situ* in the surface distal tubule is increased.[49] Both fractional and absolute HCO_3^- reabsorption in the distal tubule are higher[49] so this is not just due to increased filtered load but rather to augmented distal tubule H^+ secretion.[29,119] Although distal tubule HCO_3^- secretion is also increased, likely driven by increased plasma $[HCO_3^-]$,[29] the increased HCO_3^- secretion is smaller in magnitude compared to the increased H^+ secretion so that net distal tubule acidification is increased.[49] This can be mediated by ECF volume contraction, K^+ deficiency or high aldosterone.

K^+ depletion increases distal acidification[120] mediated in part by stimulated distal nephron colonic isoform of H^+,K^+-ATPase activity.[37,87,121,122] Animals with diuretic-induced K^+-depletion and chronic metabolic alkalosis also have increased distal tubule Na^+/H^+ activity mediated in part by endogenous endothelins.[87] On the other hand, K^+ depletion decreases aldosterone secretion,[86] that is expected to decrease distal nephron H^+-ATPase activity[52] and decrease distal nephron acidification. In a diuretic-induced K^+-depletion model of metabolic alkalosis, neither aldosterone levels nor H^+-ATPase activity are increased, yet distal acidification is stimulated.[87] In addition, K^+ depletion increases proximal ammonia production by inducing ammoniagenic enzymes,[123,124] which in the presence of increased distal acidification, increases urine net acid excretion.[84] Therefore, K^+ depletion increases distal nephron acidification mediated by increased activity of at least two distal nephron H^+ transporters. This augmented distal nephron acidification hampers excretion of excess ECF HCO_3^-. Potassium depletion can both generate and maintain metabolic alkalosis.

Mineralocorticoids can increase distal nephron acidification by a number of mechanisms. Mineralocorticoids increase collecting tubule Na^+ reabsorption and luminal electronegativity,[125] which increases electrogenic acidification.[125] Aldosterone also increases activity of collecting tubule Na^+/K^+-ATPase,[125] lowering intracellular Na^+ and thereby stimulating luminal Na^+/H^+ exchanger.[37] Finally, aldosterone directly stimulates activity of H^+-ATPase, a major H^+ transporter in the cortical and medullary collecting tubule.[52] The ECF $[HCO_3^-]$ of animals with metabolic alkalosis is higher when activities of both H^+-ATPase (stimulated by high mineralocorticoid levels) and H^+,K^+-ATPase (stimulated by K^+ depletion) are increased, compared to isolated increased activity of either transporter.[52]

In acute alkali loading, the anion-exchanger-1 (AE1) on the basolateral membrane of acid-secreting β-intercalated cells is much reduced consistent with an appropriate compensation to lower H^+ secretion.[126] It is unclear what is causing the impairment of this

compensation in chronic metabolic alkalosis. One possibility is the limited luminal Cl^- in ECF volume contraction due to increased proximal Cl^- absorption. Regardless of whether there are more Cl^-/HCO_3^- exchangers, paucity of luminal Cl^- can impair the apical Cl^-/HCO_3^- exchange and HCO_3^- secretion in this segment.[91,127,128]

An apical membrane Cl^-/base exchanger in the distal nephron, Pendrin (gene product of *Slc26A4*), should be the main player in base secretion in the collecting duct and theoretically assume a central pathogenic role in the maintenance of metabolic alkalosis. $NaHCO_3$ loading *per se* increases pendrin expression suggesting it does defend against alkalosis.[129,130] In a model of hypermineralocorticoid activity, pendrin is upregulated presumably to augment apical HCO_3^- secretion [131] but in a K^+ depletion model, Pendrin is down regulated suggesting that it is actually the culprit.[132] Pendrin-/- animals at baseline do not have high plasma [HCO_3^-] but when subjected to induction of metabolic alkalosis have higher plasma [HCO_3^-] than Pendrin + / + animals.[131] Interestingly, K^+ depletion did not elicit increased Pendrin expression[130] despite the fact that the ECF [HCO_3^-] is high. This discrepancy may be attributable to the presence of intracellular acidosis in K^+ depletion. At present, although one expected Pendrin to assume a central role in maintaining metabolic alkalosis, the experimental data are inconclusive.

One player that has recently been implicated in the maintenance of metabolic alkalosis is the epithelial Na^+ channel ENaC. While ENaC is considered to be mainly important for Na^+ absorption and K^+ secretion, it does provide the luminal negative voltage that is important for H^+. As discussed below, dominant gain-of-function mutations of ENaC subunits can lead to metabolic alkalosis. The presence of alkalemia per se appears to stimulate ENaC independent of aldosterone activity which can contribute to the heightened acidification.[133]

The delivery of Na^+ salts of poorly reabsorbable anions increases distal nephron acidification in association with increased mineralocorticoid activity.[93] Na^+ absorption without an accompanying anion greatly increases luminal electronegativity[134] and promotes distal H^+ secretion.[93] Non-reabsorbable anions that can induce this phenomenon include sulfate,[135] nitrate,[93] and the penicillin class of antibiotics.[136,137] The pathophysiology of distal acidification is summarized in Figure 58.11.

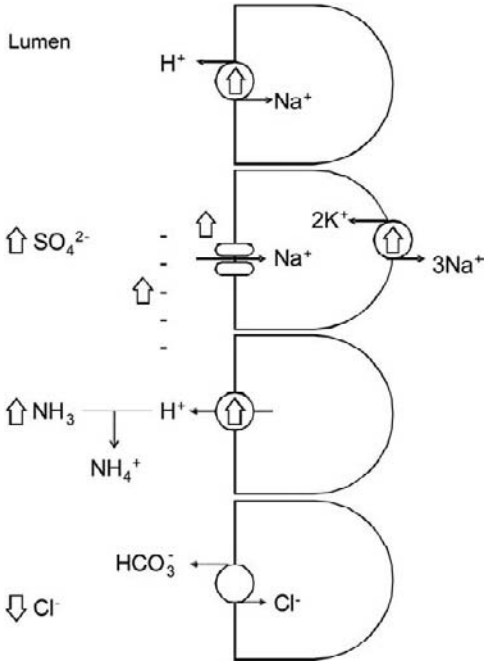

FIGURE 58.11 Distal tubule pathophysiology in metabolic alkalosis. The changes can be caused by K^+ depletion, hypermineralocorticoid activity and effective ECF volume contraction. The changes include increased H^+ secretion, reduced HCO_3^- absorption, increased luminal negativity and buffer capacity.

Consideration of an Intrinsic Tubular Defect

Although there is no doubt that metabolic alkalosis can only be sustained by changes in the renal tubules. Thus far, one is working with the assumption that the kidney is merely being misdirected by the incoming signals described above. There are some highly fundamental questions that need to be considered. Is the kidney capable of independently sensing and setting plasma pH and [HCO_3^-]? The sensing of pH and [HCO_3^-] are fundamentally different biologic processes that utilize different molecular mechanisms. If such sensing ability exists, why is the kidney not responding to the higher plasma [HCO_3^-] but remaining obedient to the erroneous signals. Does metabolic alkalosis represent a state where there is a resetting of the sensors in the kidney? There is strong *in vitro* evidence that renal epithelial cells can sense and respond to changes in ambient pH and [HCO_3^-].[138] A host of proteins with pH and [HCO_3^-] sensing capabilities have been identified and a subset of them is expressed in the kidney.[139] Direct sensing of intracellular [HCO_3^-] is performed by the soluble adenylyl cyclase (sAC) which is also expressed in the rodent and human kidney.[140,141] Recently, a tyrosine kinase, the insulin-related receptor (IRR) was shown to be an extracellular pH sensor that reacts to alkaline pH changes.[142] Despite the fact that the pH required for activation is way higher than the typical clinical range (>7.9), genetic disruption of IRR resulted in blunted bicarbonaturia and higher plasma [HCO_3^-] in response to HCO_3^- loading in situations where ECF volume contraction K^+ deficiency or

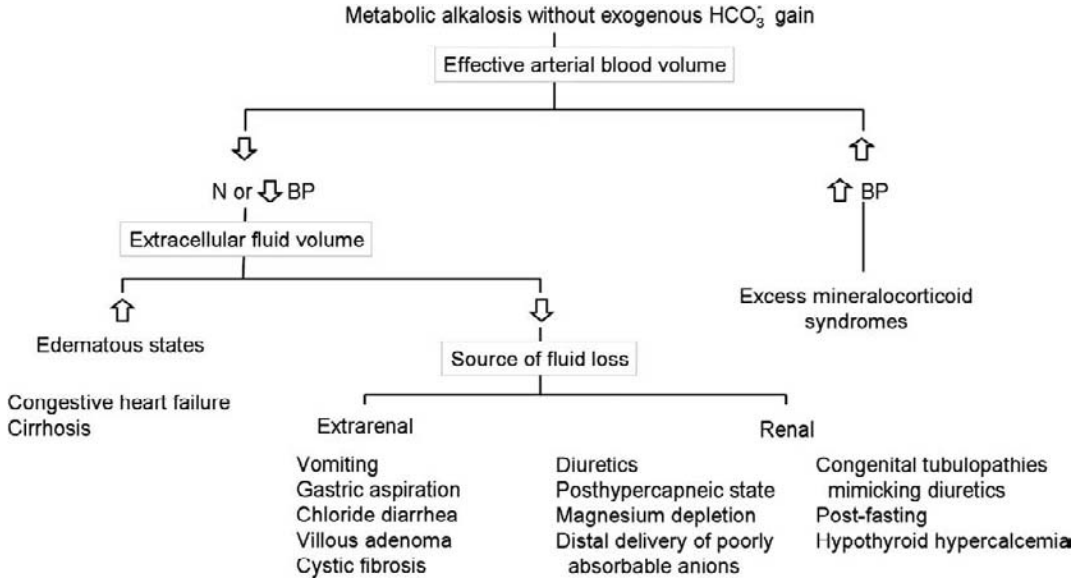

FIGURE 58.12 Summary of pathophysiology of maintenance of metabolic alkalosis. In one model, the three principal signals extrinsic to the kidney govern renal acidification to render the urine HCO_3^- and maintains a high ECFV [HCO_3^-]. The renal tubules are not defective but simply misguided. In the bottom situation, an alternative concept is presented. H^+ or HCO_3^- sensors in the kidney are reset to a new set-point to regulate renal acidification to maintain ECFV [HCO_3^-] at a higher level independent of incoming signals. These two mechanisms are not necessarily mutually exclusive.

heightened mineralocorticoid activity is are unlikely to be present.[142] This is the first demonstration that a primary renal defect in HCO_3^- sensing can "reset" the plasma [HCO_3^-] at least transiently without invoking the triple cardinal systemic factors that maintain metabolic alkalosis which is conceptually completely different from the classic view of the renal tubules responding to the three cardinal incoming signals. It will be extremely informative to explore whether renal "resetting" actually occurs in the common syndromes of metabolic alkalosis.

CLINICAL SYNDROMES OF METABOLIC ALKALOSIS

Approach to Patients with Metabolic Alkalosis

The first presentation to a clinician is almost always a chemical one often with the serendipitous discovery of an elevated ECF [HCO_3^-] or total CO_2 on the panel of serum electrolytes. The level of ECF pH elevation combined with associated life-threatening conditions that are caused or exacerbated by the alkalosis will determine whether therapeutic interventions are required to acutely lower ECF pH. Rapid intervention lowers pH either chemically by adding acid (usually HCl),[143] or diffusively with dialysis,[144] independent of the pathophysiology and/or etiology of the metabolic alkalosis. These interventions treat the chemistry but not necessarily the underlying disorder. Thus correction of the chemistry by whatever means does not negate the search for and treatment of the underlying cause. If acute intervention is not necessary, then the principal duty for the clinician is to identify the underlying conditions causing the disorder and address them. As one peruses through the individual clinical syndromes in the following section, always keep in mind that one is dealing with a disorder of renal HCO_3^- absorption and the three salient factors that lead to maintenance of this state are decreased circulating volume as sensed by the kidneys, K^+ deficiency, and hypermineralocorticoid activity on the renal tubule.

History and Physical Examination

A careful history frequently reveals the etiology of metabolic alkalosis. The clinician should probe for factors that might generate excess ECF HCO_3^-, such as intake of HCO_3^- and/or its metabolic precursors, or H^+ loss as might occur from the GI tract (i.e., vomiting) or the kidney (i.e., diuretics). One should also assess the patient's ability to excrete excess ECF HCO_3^- by determining whether the patient has renal failure, loss of body fluids, and/or poor dietary NaCl intake. Furthermore, the clinician must inquire about factors that maintain metabolic alkalosis, such as conditions that cause volume depletion and intake of medications that might induce renal excretion of H^+ and/or K^+ (e.g., diuretics, mineralocorticoids).

By far, the two most important elements of the physical exam in determining the etiology of metabolic alkalosis are the blood pressure and indicators of the ECF volume. One of the major mediators through which decreased ECF volume maintains metabolic alkalosis is reduced effective arterial volume. Some pathologic conditions such as heart failure, liver failure, and nephrotic syndrome alter systemic hemodynamics in such a way as to reduce renal perfusion pressure even when ECF volume is increased. These conditions are often referred to as states of decreased *effective* arterial blood volume (EABV).

Laboratory Investigation

Because respiratory acidosis can also increase ECF [HCO_3^-] due to the physiologic response to elevated pCO_2,[13] arterial blood gases should be done to rule out this respiratory disorder. The distinction is often but not invariable achieved by history and physical examination alone. Metabolic alkalosis is confirmed by demonstrating a primary increase in ECF [HCO_3^-], with any rise in pCO_2 being secondary. The laboratory values most pertinent in determining the etiology are those that assess EABV such as urine [Cl^-] and [Na^+], and those that determine the degree of activation of the renin-angiotensin-aldosterone system, including serum levels of renin and aldosterone. Not all these laboratory studies are needed in every patient with metabolic alkalosis. Selected use of laboratory determinations with the history and physical exam can permit the clinician to arrive at the diagnosis.

Consequences of Metabolic Alkalosis

Metabolic alkalosis in the outpatient setting is most commonly mild, and its clinical importance often relates to identifying the underlying metabolic disorder such as hypermineralocorticoid states, K^+ deficiency, or natriuretic overuse. In the inpatient setting, it can be a severe metabolic disturbance with marked elevations of ECF pH and associated life-threatening consequences. Combined metabolic and respiratory alkalosis is the most common acid–base disturbance in critically ill patients.[145] Studies of this patient population show a direct correlation between ECF pH $>$ 7.48 and mortality.[146] This relationship represents not only a marker of the catastrophic underlying conditions but also direct consequences of alkalemia as well. The direct adverse effects of metabolic alkalosis are summarized in Table 58.3. While we repeatedly emphasize the need to search and treat the underlying disorder, the direct adverse effects of a high [HCO_3^-] and pH justify chemical correction even if one cannot rectify the root of the problem.

TABLE 58.3 Adverse Effects of Metabolic Alkalosis

1. Ventilatory depression
2. Vasoconstriction
3. Decreased O_2 delivery by hemoglobin
4. Cardiac arrhythmias

Metabolic alkalosis decreases ventilation causing hypercapnea and hypoxemia[11–13,99,147,148] and it can do so with some severity, particularly in patients with underlying lung disease, causing severe hypoxia.[148] This effect is mediated via both central and peripheral chemoreceptors.[149,150] Metabolic alkalosis has many other untoward cardiovascular effects, such as vasoconstriction of various systemic vascular beds.[151] Vasoconstriction has been documented in isolated coronary strips, saphenous, and mesenteric veins *in vitro* by alkaline pH produced either by raising [HCO_3^-] or lowering pCO_2.[152–154] In intact organisms, a high plasma [HCO_3^-] and/or pH reduces blood flow to coronary arteries leading to myocardial ischemia[152] and cerebral vasculature leading to compromised CNS function.[155,156] The adverse consequences of hypoxia are compounded by the alkalosis-induced leftward shift of the hemoglobin-O_2 dissociation curve, which increases O_2 affinity decrease release to tissues.[151,157] In combination with vasoconstriction and hypoxia, this further reduces tissue O_2 delivery, resulting in anaerobic metabolism, possibly contributing to the anion gap frequently described in patients with severe metabolic alkalosis.[158]

Alkalosis lowers the threshold for cardiac arrhythmias, especially those associated with digitalis.[159–161] Arrhythmias concomitant with metabolic alkalosis are reported to be refractory to treatment until the alkalosis is corrected.[161] However, the number of subjects in these reports is relatively small and it is difficult to establish the correct incidence. Critically ill patients frequently have lots of reason to have cardiac dysrhythmias.

Metabolic Alkalosis with Exogenous HCO_3 Gain

Distinct clinical syndromes will be discussed. It is important to state that these conditions may involve exogenous HCO_3^- gain but are usually associated with impaired renal HCO_3^- excretion in order for sustained metabolic alkalosis to be present. Subjects with normal ability to excrete HCO_3^- can ingest large and chronic oral loads of HCO_3^- and its metabolic precursors (e.g., citrate, lactate) without developing sustained elevations of plasma [HCO_3^-]. Acute infusion of up to 1500 mEq of $NaHCO_3$ only transiently elevated plasma

[HCO_3^-].[7] Even chronic administration of this magnitude only raised plasma [HCO_3^-] slightly.[18] Treatment includes limiting or discontinuing alkali intake and increasing renal excretory ability. Other sources of exogenous HCO_3^- include those given during cardiopulmonary arrest, metabolism of citrate in stored blood given during massive transfusions or plasmapheresis, and metabolism of organic acids (e.g., ketoacids) in combination with HCO_3^- therapy for metabolic acidosis.[123]

Non-absorbable antacids (aluminum and magnesium carbonate) can cause metabolic alkalosis when intake is combined with cation exchange resins.[162] The metal carbonate salts usually form metal Cl^- salts when they contact gastric HCl, consuming gastric H^+. When the metal salts reach the HCO_3^--rich upper small bowel, they form insoluble metal carbonate salts which are excreted. Under usual circumstances, ingestion of these metal carbonate salts results in equimolar H^+ and HCO_3^- excretion without changing acid-base balance. However, concomitant ingestion of exchange resin binds the aluminum or magnesium of the antacid, precluding these metals from forming insoluble carbonate salts in the HCO_3^--rich fluid of the upper small intestine. The cation liberated by the exchange resin, usually Na^+, combines with HCO_3^- to form easily absorbable $NaHCO_3$ Consequently, ingestion of the metal carbonate salts with exchange resins leads to consumption of secreted gastric H^+, but subsequent reabsorption of $NaHCO_3$ causing a net HCO_3^- gain. Metabolic alkalosis is sustained when base excretion from the ECF is limited. This is one syndrome where continued exogenous base ingestion does contribute to the metabolic alkalosis.

Milk-Alkali syndrome. Metabolic alkalosis occurs in patients with peptic ulcer disease who ingest large quantities of milk and antacids or more recently in patients on calcium alkali salts for osteoporosis or habitual chewing of betel nuts in Asia.[163–165] Each Alka-Seltzer tablet for instance contained 1.9 g of $NaHCO_3$. Important components of the milk alkali syndrome include high alkali intake, reduced glomerular filtration, and increased tubular reabsorption of HCO_3^-. Hypercalcemia impairs, but the suppressed parathyroid hormone can stimulate proximal HCO_3^- reabsorption. Hypercalcemia also has loop diuretic-like effect that produces Na^+, Cl^- and K^+ wasting via the basolateral calcium sensing receptor.[166] The main mechanism of metabolic alkalosis in the milk alkali syndrome is likely ECF volume contraction. The combination of high urinary calcium and alkaline urine can also lead to nephrocalcinosis.[167] Treatment consists of discontinuation of alkali and calcium.

Metabolic Alkalosis without Exogenous HCO_3 Gain

When history excludes exogenous HCO_3^- gain, the presence or absence of hypertension can be used to categorize patients for subsequent workup. Figure 58.12 provides a general outline. It is important to state that this type of algorithm serves as a guide and to streamline the approach and under no circumstance should it replace the critical thinking that is required to identify the underlying pathophysiology of a patient with metabolic alkalosis. Two critical points in this diagnostic algorithm are the determination of whether there is hypertension and whether effective arterial blood volume is decreased. The latter is not always obvious on clinical grounds alone. Thereafter, whether or not EABV is decreased will further sort the diagnostic possibilities and guide the clinician as to the necessary laboratory tests. Although physical exam findings indicative of ECF volume depletion can be rapidly and cheaply obtained, bear in mind that they may have questionable value in extrapolating to the assessment of effective renal perfusion.[168] Urine indices including fractional excretion of Na^+ and Cl^- have a better predictive value for renal perfusion in such patients.[168]

Metabolic Alkalosis with Decreased Effective Arterial Blood Volume

Decreased EABV with expanded ECFV (edema). This encompasses all the patients with edematous states who despite the expanded ECF volume, have reduced renal perfusion which provides the main contribution to maintenance of metabolic alkalosis. Congestive heart failure is the most relevant condition for discussion in this instance.[169] Metabolic alkalosis occurs in patients with cirrhosis but is often buried in a host of metabolic and respiratory acid–base disturbances.[170,171] The generating and maintenance mechanisms of metabolic alkalosis are not completely understood although multiple hypotheses abound.[172] In addition to the impaired renal perfusion from the primary disease, edematous patients are almost invariably treated with diuretics, most of which will increase H^+ excretion, providing a mechanism for generation of metabolic alkalosis. Further reduction in EABV as well as diuretic-induced K^+ depletion maintains the disorder. Treatment of metabolic alkalosis in these patients is a formidable challenge because they need diuretic therapy. One can improve renal perfusion by reducing diuretic dose, and/or including agents that do not increase renal H^+ and K^+ excretion (e.g., K^+-sparing diuretics amiloride, triamterene, and spironolactone). The most effective treatment is correction or improvement of the underlying disease.

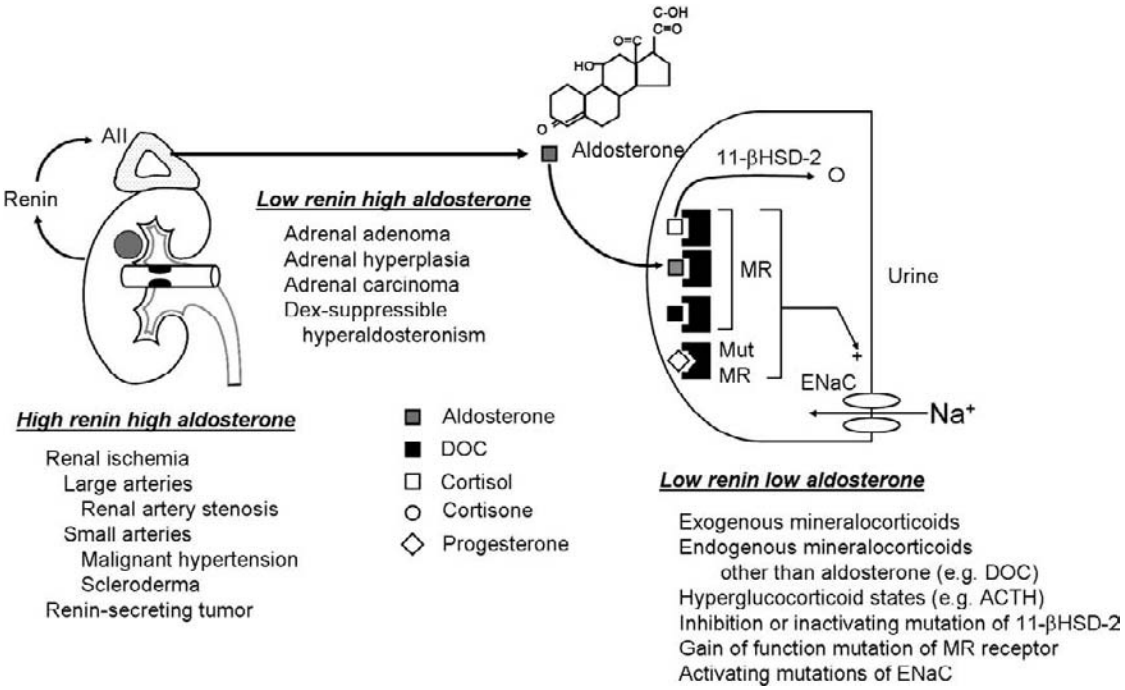

FIGURE 58.13 Hypermineralocorticoid states with hypertension and metabolic alkalosis. Three categories based on renin and aldosterone levels are shown. Left panel- Renal-originated renin disorders. Middle panel-Adrenal disorders. Right panel- Systemic and end organ disorders. DOC: Desoxycorticosterone. 11-βHSD-2: 11-beta-hydroxysteroid dehydrogenase type 2. ENaC: Epithelial Na^+ channel. MR: Mineralocorticoid receptor. Mut MR: Mutant mineralocorticoid receptor.

Decreased EABV without expanded ECF volume (edema). This is the largest group of patients with metabolic alkalosis without hypertension. Decreased ECF and EABV are expected to induce renal conservation of Na^+ and Cl^-, the major cation and anion of ECF. This is indeed true in patients with extrarenal fluid and solute losses; the most important of which derive from the gastrointestinal tract (Fig. 58.13). The gastrointestinal fluid loss can generate and maintain metabolic alkalosis. The second and equally important subgroup is renal fluid loss (Fig. 58.13). This broad group of diseases elegantly illustrates some of the most fascinating mechanisms of generation and maintenance of metabolic alkalosis. Specific syndromes will be discussed below.

Gastric alkalosis. Gastric fluid contains about 80-100 mEq/L of HCl and varying amounts of Na^+ and K^+. Removal of gastric HCl in humans raises ECF HCO_3^-. The estimated reduction in ECF volume can account for only minor part of the rise in ECF [HCO_3^-][78] so HCO_3^- must be added to the ECF.[73] This is initially associated with an alkaline urine and decreased urine net acid excretion, with about half of the latter mediated by bicarbonaturia.[78] In this dysequilibrium state, bicarbonaturia is accompanied by renal Na^+ and K^+ loss.[78] This is one instance where low urinary [Cl^-] is accompanied paradoxically by high urinary [Na^+] because of the obligatory natriuresis in bicarbonaturia.

Although the cation that accompanies HCO_3^- at the glomerular filtrate is primarily Na^+, the high aldosterone activity at the distal tubule causes exchange of luminal Na^+ for K^+ which results in significant K^+ wasting. Alkalosis may itself increase renal K^+ excretion.[173] This sets the stage for the maintenance phase which is mediated by both ECF volume and K^+ depletion. A few days following cessation of gastric HCl removal, urine pH and net acid excretion return to acid values with little or no Na^+, K^+, or HCO_3^- in the urine despite persistent metabolic alkalosis and the subject is in acid–base balance.[78] These data are consistent with an inappropriate renal tubule response to the persistent excess ECF HCO_3^-. Direct measurements of GFR show this parameter to be no different from control, consistent with an overall increase in renal tubular HCO_3^- reabsorption.[78] KCl or NaCl administration increases urine pH and decreases net acid excretion with subsequent normalization of ECF [HCO_3^-].[78] Treatment involve cessation of gastric loss. If nasogastric suction cannot be discontinued, gastric HCl production might be reduced with H_2-blockers or H^+/K^+ ATPase inhibitors.[174] The cornerstone of therapy is disruption of maintenance by NaCl and KCl replacement.

Congenital chloride diarrhea and villous adenoma. In contrast to gastric fluid, lower intestinal content tends to be alkaline so its loss should not generate metabolic alkalosis. This disorder was discovered in the 1940s where infants present with profuse watery diarrhea, high stool Cl^- and the cardinal feature of metabolic alkalosis.[175,176] Two decades elapsed before the pathophysiology guided the proper nomenclature of congenital chloridorrhea or congenital chloride diarrhea.[177] This is an autosomal recessive disease that seems to cluster in Finland[178] and the Middle East[179] and is due to mutation of the Cl^-/HCO_3^- exchanger DRA (*down-regulated in colonic adenoma*; gene product of *SLC26A3*) in the ileal and colonic luminal membrane. Of the list of congenital diarrheal syndromes,[180] this is the only one that causes metabolic alkalosis. The functional lesion has been identified physiologically,[60,181] and subsequently confirmed by the molecular identity[182,183] of the defect. Stool $[Cl^-]$ far exceeds stool $[Na^+ + K^+]$ giving rise to a "cation gap" which is primarily NH_4^+. Parallel activities of Na^+/H^+ exchange and Cl^-/HCO_3^- exchange results in net NaCl absorption. When Cl^-/HCO_3^- exchange exceeds Na^+/H^+ exchange as it does in the colon, it normally creates an alkaline lumen normally. With inactivating mutations of the DRA Cl^-/HCO_3^- exchanger, Na^+/H^+ exchange runs in isolation and converts the intestine into an acid-secreting epithelium. Luminal free H^+ is buffered by NH_3 from the blood or NH_3 generated by the bacterial flora. The end result is copious amounts of Cl^- in the stool accompanied mainly by NH_4^+ and to a lesser extent Na^+ and K^+. Metabolic alkalosis is generated by H^+ loss and maintained by continued H^+ loss, ECF volume, and K^+ depletion from both diarrheal and renal origins. Kaliuresis is a result of intermittent bicarbonaturia, distal Na^+ delivery, and volume-stimulated high aldosterone activity. The only treatment is lifetime replacement of NaCl, KCl, and water.

Rarely, metabolic alkalosis develops in patients with villous adenomata of the colon as first described by Bartter and colleagues in 1965.[184] The secretory nature of these tumors elaborate up to 3 L/day of a clear fluid with high concentration of Cl^-, Na^+, K^+ and variable amount of NH_4^+.[59,185,186] When the concentration of NH_4^+ is high enough, it generates and maintains metabolic alkalosis with mechanisms similar to that described fro congenital chloride diarrhea. Not all villous adenomata cause metabolic alkalosis.

Recent reports suggest another often overlooked cause of extrarenal ECF loss is cystic fibrosis which can present with metabolic alkalosis due to volume contraction and K^+ deficiency.[187–189] The next group of disorders involves primarily renal loss of H^+ as a generating mechanism.

Diuretic-induced metabolic alkalosis. Diuretics are the most common cause of metabolic alkalosis. Loop and thiazide diuretics induce a hypotonic urine with low $[HCO_3^-]$ and comparatively high $[Cl^-]$, reducing ECF volume while preserving ECF HCO_3^- content.[190] Diuretics generate metabolic alkalosis by several mechanisms. They induce a small degree of contraction alkalosis which is quantitatively of minor importance.[191] Since both loop and thiazide diuretics are kaliuretics, the loss of K^+ cause some H^+ shift into cell.[69] the most important generating factor is loss of H^+ into the urine. Furosemide and thiazides are the prime examples where distal Na^+ delivery is uncoupled to aldosterone levels; both are high. This results in excessive distal H^+ secretion and high net acid generation,[61] and metabolic alkalosis ensues. Once generated, the alkalosis is maintained by volume contraction, K^+ deficiency and high aldosterone. Patients with persistent diuretic-induced metabolic alkalosis have acidic urine, indicative of a failure of the renal tubules to respond appropriately to the excess ECF HCO_3^-. Finally, loop diuretics may have direct stimulatory effects on distal H^+ secretion as there is experimental data showing the H^+ secretion can remain higher than control levels even when NaCl and KCl are replaced intravenously.[62,192] However, this increment in H^+ secretion is probably not sufficient to maintain high plasma $[HCO_3^-]$ as diuretic-induced metabolic alkalosis is decreased with NaCl and KC1 repletion.[190] One needs to exercise caution in the interpretation of urinary electrolytes in diuretic users. Urinary $[Na^+]$ and $[Cl^-]$ may be extremely high or low depending how the measurement is timed with the administration of the drug.

Post-hypercapneic state. Chronic respiratory acidosis is associated with the physiologic compensatory increase in ECF HCO_3^- which is mediated by cellular buffering (primarily erythrocytes) in minutes and within a few hours by a renal response of increased net acid excretion resulting in a resetting of plasma $[HCO_3^-]$ to about 0.3 mEq/L for every 1 mm Hg rise in pCO_2. When the chronically elevated pCO_2 is suddenly decreased (e.g., intubation and mechanical ventilation) ECF $[HCO_3^-]$ often fails to decrease leading to a metabolic alkalosis.[193] The immediate bicarbonaturia obligates urinary Na^+ and K^+ losses. Along with the volume-stimulated aldosterone activity, the bicarbonaturia ceases before ECF $[HCO_3^-]$ completely returns to normal and the patient settles on a new steady state of maintenance of metabolic alkalosis. Urinary $[Cl^-]$ is generally very low but urinary $[Na^+]$ may not be low during the bicarbonaturic phase. Patients with chronic respiratory acidosis who experience this reduction in pCO_2 require adequate NaCl and KCl supplement to effect the necessary

urinary excretion of HCO_3^- to reduce ECF [HCO_3^-] to normal.

Magnesium depletion. Severe magnesium (Mg^{2+}) depletion causes hypokalemia and metabolic alkalosis. Humans with experimentally-induced Mg^{2+} depletion waste K^+ in the urine possibly through an aldosterone-related mechanism and the kaliuresis can be blocked by spironolactone.[194,195] The absence of hypertension suggests that the excess mineralocorticoid activity is not primary and may be secondary to defective renal Na^+ conservation. Mg^{2+} deficiency can result from a variety of acquired causes such as cisplatin[196] or aminoglycoside toxicity,[197] or from congenital defects in ion channels or paracellular proteins.[198] These conditions are reviewed in detail in another chapter. The mechanism of generation and maintenance is not entirely clear but K^+ deficiency is likely the culprit. Mg^{2+} and K^+ repletion is the definitive treatment.

Distal delivery of poorly absorbable anions. The administration of poorly absorbable anions that end up in the distal nephron in conjunction with high mineralocorticoid activity results in hypokalemic metabolic alkalosis.[93,134] This is another example where urinary [Cl^-] is not accompanied by low urinary [Na^+]. All anions are comparatively less absorbable than Cl^-. Of intermediate permeability is HCO_3^- as encountered in patients with gastric alkalosis with ongoing vomiting and bicarbonaturia.[78] Other common clinical examples include non-reabsorbable anionic antibiotics such as penicillin, ampicillin, and carbenicillin.[122,136] These patients are particularly susceptible when they have concomitant volume depletion.[93] These patients respond to removal of the offending agent and/or restoration of depleted ECF volume. Excessive urinary sulfate and nitrate can also cause dissociation of urinary Na^+ and Cl^- experimentally but clinical scenarios of significant "sulphaturia" and "nitraturia" are not encountered.

Congenital tubulopathies mimicking diuretics. This is a group of rare Mendelian genetic diseases that has seen enormous progress in the last decade. A brief account will be delivered here. More detailed discussions of these diseases are found elsewhere in this textbook.

In 1962, Bartter and associates reported patients with hypokalemic metabolic alkalosis, normal to low blood pressure and increased plasma renin and angiotensin.[199] In addition, these patients have hypercalciuria, impaired vasopressor effect to exogenous angiotensin II, hyperprostaglandinuria, and histologically, they have hyperplasia of the juxtaglomerular cell. The original cluster of findings that have become cardinal features of Bartter's syndrome are all accurate but it was difficult to discern primary vs. secondary findings. Over the years these features have stimulated a variety of conjectures that experienced everything from popularity to notoriety. Almost 20 years after the original description, Bartter himself proposed that this is a disorder of primary renal NaCl wasting and all other features are secondary.[200] Now this genetic thick ascending limb tubulopathy is known to be caused by a heterogeneous group of inactivating mutations of the Na-K-2Cl cotransporter, the ROMK K^+ channel, Cl^- channels ClC-Ka and ClC-Kb, Cl^- channel subunit Barttin, and activating mutations of the calcium sensing receptor.[201] The final common pathway is disruption of the transcellular NaCl resorptive ensemble in the thick ascending limb with a phenotype identical to a perpetual state of loop diuretic administration. The mechanisms of maintenance include volume contraction, K^+ depletion, excess aldosterone with increased distal Na^+ delivery, and Mg^{2+} depletion.

A similar but distinct parallel cause of genetic hypokalemic metabolic alkalosis, Gitelman's syndrome, was described in 1966.[202] Gitelman's can be distinguished from Bartter's clinically by older age of onset, less severe phenotype and hypo instead of hypercalciuria.[203] Gitelman's syndrome is homogeneously due to inactivating mutations of the Na-Cl cotransporter.[204] Akin to Bartter's patients, Gitelman's patients live with a phenotype resembling lifelong thiazide therapy. The mechanism of metabolic alkalosis is similar to that of Bartter's syndrome.

Post-fasting metabolic alkalosis. Early in starvation ketoacidosis, ketoanions are excreted as Na^+ and K^+ salts, and a minority as undissociated ketoacids. With the activation of renal ammoniagenesis, most ketoanions are excreted with NH_4^+ which creates a new steady where ketoacid production is matched by heightened renal NAE.[205–207] Patients develop metabolic alkalosis upon glucose refeeding following a prolonged fast.[208] Generation of excess ECF HCO_3^- and its maintenance persists for about a week after glucose refeeding and then ECF [HCO_3^-] returns to its pre-fast level.[208] Metabolic alkalosis and its short-term maintenance in this setting might be due to the increased net acid excretion caused by augmented ammoniagenesis in response to fasting-induced ketosis.[123] Glucose refeeding stops ketoacid production quickly and converts plasma ketoanions to base equivalents, but the increased net acid excretion normalizes more slowly to match the new and lower metabolic acid production.[37] Thus, net acid excretion is temporarily greater than intrinsic H^+ production, leading to excess ECF HCO_3^- generation. When net acid excretion eventually decreases to match intrinsic H^+ production after a few days, the physiologic renal HCO_3^- excretory mechanisms would normalize ECF HCO_3^-. Although physiologically plausible, this explanation is not

entirely supported by the data.[208] Intracellular H^+ movement generating ECF HCO_3^- has also been proposed as a contributing factor.[123] Both glucose and insulin can stimulate proximal tubule $NaHCO_3$ absorption.[208–210] During early refeeding, the kidney is extremely antinatriuretic to the point that the patients becomes edematous—a condition called refeeding edema. The mechanism of the maintenance phase is equally obscure. In short, the etiology for this uncommon form of metabolic alkalosis remains unresolved.

Hypoparathyroid hypercalcemia. Interestingly, the hypercalcemia due to hyperparathyroidism can be associated with a very mild metabolic alkalosis, hyperchloremic metabolic acidosis, or no acid–base disturbance.[211,212] In contrast, hypercalcemia from accelerated bone release such as in malignancy, metabolic alkalosis is frequently seen.[213,214] This is likely due to increased alkali release from dissolution of calcium carbonate combined with impaired renal HCO_3^- excretion. Suppressed parathyroid hormone may increase proximal HCO_3^- absorption[215,46,216,217] by inhibition of the Na^+/H^+ exchanger.[218,219] Hypercalcemia *per se* can directly stimulate H^+ secretion.[220] Through the calcium sensing receptor, hypercalcemia also has a loop diuretic effect on the thick ascending limb via inhibition of the apical K^+ channel.[221]

Metabolic Alkalosis with Hypertension

Most patients in this group have increased renal mineralocorticoid effects that generate and maintain metabolic alkalosis by the mechanisms discussed earlier. Patients can be categorized according to EABV although the clinical evaluation of this parameter can be challenging. Urine [Cl^-] and [Na^+] are less helpful diagnostically in these patients with metabolic alkalosis because few of them have decreased EABV and thus few will have decreased urine Cl^- or Na^+ excretion. The most important challenge facing the clinician is diagnosing the cause. Measurement of serum renin and aldosterone levels is the most helpful laboratory test to categorize patients for more detailed investigation. This constitutes one of the most fascinating assemblage of etiologies for metabolic alkalosis and hypertension. The best approach to organize these disorders is by the renin and aldosterone levels (Figure 58.13).

High renin and high aldosterone. These are primarily renal disorders (Figure 58.13). These patients have primary increases in renin secretion uncoupled from feedback mechanisms that normally turn off renin production, leading to increased aldosterone secretion and metabolic alkalosis by the mechanisms discussed earlier. Rare renin-producing tumors and juxtaglomerular hyperplasia cause metabolic alkalosis, although the most prominent feature is severe hypertension.[222,223] Metabolic alkalosis and hyperaldosteronism is unusual but has been described in patients with renal artery stenosis.[224,225] A prevalence of 10% has been suggested but the true prevalence is probably unknown as many cases may be due to diuretic-induced metabolic alkalosis. Another confounder is simultaneous renal artery stenosis and unrelated primary hyperaldosteronism.[226,227] A classic state of hyperreninemic hyperaldosteronism is found in patients with small vessel disease such as malignant hypertension, vasculitis, or scleroderma where renal ischemia stimulates renin secretion, secondary hyperaldosteronism, and hypokalemic metabolic alkalosis.[228,229] Renin-secreting tumors are rare but have been described with numerous histologic types- hemangiopericytoma, hamartomas, Wilm's tumor, and even pulmonary malignancies.[222,223,230–232]

Low Renin and High Aldosterone. These are primarily adrenal diseases (Figure 58.14) where aldosterone has achieved autonomy escaping the control by renin-angiotensin and renin secretion is suppressed. A common cause is an adrenal adenoma.[233] Surgical resection of the adenoma usually corrects both the hypertension and metabolic alkalosis. Patients in this group can also have bilateral adrenal hyperplasia. Although bilateral adrenal resection corrects both the hypertension and metabolic alkalosis,[233] the resulting adrenal insufficiency favors pharmacologic suppression of mineralocorticoid secretion or inhibition of its action. A biochemical adjunct to discern adrenal adenoma from hyperplasia is postural changes in aldosterone levels. Serum aldosterone levels tend to decrease with upright posture in patients with adenomas, whereas they increase in patients with hyperplasia.[233] Because of the less than perfect predictive value of this test and the improved resolution of computerized tomography, this postural test is seldom done. Non-functional anatomic lesions are quite common so radiographic adrenal adenomas require biochemical validation of hyperaldosteronism and adrenal venous samples to confirm the source of aldosterone before commitment to surgery.

In a rare variant of bilateral adrenal hyperplasia described by Biglieri and associates known as indeterminate hyperaldosteronism, exogenous mineralocorticoids seem to normalize aldosterone levels.[234] Very little is known about this exceeding rare condition. In 1966, Laidlaw and associates described patients whose aldosterone levels decreased with administration of the pure glucocorticoid dexamethasone. This group of disorders have been termed glucocorticoid suppressible aldosteronism.[82] Lifton and associates described the molecular defect in this condition when two tandem genes CYP11B1 and CYP11B2 encoding for 11-β-hydroxylase and aldosterone synthase respectively

undergoes unequal cross-over so the ACTH-responsive 5′-flanking promoter region of 11-β-hydroxylase is driving the transcription of aldosterone synthase. The end result is control of aldosterone synthase by ACTH[235,236] leading to hypersecretion of aldosterone uncoupled from its feedback inhibition but suppressible by dexamethasone. A similar autosomal dominant syndrome has been described with the exception that the hyerpaldosteronism is not suppressible and they do not harbor the hybrid CYP11B1/CYP11B2 gene described above.[237,238] A number of candidates were excluded and a locus has recently been mapped.[239,240]

Rarely, metabolic alkalosis can be due to pure aldosterone secretion by an adrenal cortical carcinoma.[241] Adrenal carcinomas more commonly secrete desoxycorticosterone and corticosterone, which has mineralocorticoid activity and suppress both renin and aldosterone.[242]

Low renin and low aldosterone. This group of diseases is represented on the right panel of Figure 58.14 and can be subdivided into three categories: (1) A hormone other than aldosterone is activating a normal mineralocorticoid receptor. (2) A gain-of-function mutation of the receptor resulting in its activation. (3) Activation of transport mechanisms downstream to the receptor.

Patients with Cushing's syndrome can secrete mineralocorticoids other than aldosterone such as desoxycorticosterone causing most clinical features of aldosteronism including hypokalemic metabolic alkalosis and hypertension.[242] Although aldosterone levels are usually not increased in Cushing's syndrome,[243] 30 to 40% of these patients do develop hypokalemic metabolic alkalosis due to secretion of non-aldosterone mineralocorticoids[244] and to mineralocorticoid effects of corticosterone.[245] Hypokalemic metabolic alkalosis is very common when Cushing's syndrome is caused by ectopic adrenocorticotropic hormone (ACTH) secretion because these patients frequently secrete high levels of corticosterone, desoxycorticosterone, and cortisol.[246] The principal treatment strategy for these syndromes is identification and correction of the underlying disorder.

Exogenous mineralocorticoids, both synthetic and natural, can produce the entire syndrome of aldosterone excess including hypokalemic metabolic alkalosis.[234] Excessive intake of the synthetic mineralocorticoid fludrocortisone acetate, causes hypokalemic metabolic alkalosis with physiology not unlike that of endogenous compounds.

Glucocorticoids such as cortisol can activate the mineralocorticoid receptor with similar in vitro affinity as aldosterone due to the much higher (2-3 log orders) plasma levels compared to aldosterone.[247] However, the mineralocorticoid receptor is usually protected from glucocorticoids by the co-expression of the type 2 11-β-hydroxysteroiddehydrogenase enzyme (11-β-HSD-2).[247] In the absence of adequate 11-β-HSD-2 activity in mineralocorticoid target tissues, a hypermineralocorticoid state will emerge. This can occur when cortisol levels are so high that 11-β-HSD-2 is overwhelmed as in ACTH-secreting tumors. In addition, glycyrrhizic acid or its hydrolytic product glycyrrhetinic acid, compounds found in natural but not synthetic licorice and in some chewing tobaccos, is an inhibitor of 11-β-HSD-2, and can cause the syndrome.[248–250] In addition to acquired inhibitors of 11-β-HSD-2, a genetic syndrome of apparent mineralocorticoid excess was described in the 1970s[251,252] Inactivating mutations of the 11-β-HSD-2 enzyme can cause its inactivation which leaves the mineralocorticoid receptor unprotected from the physiologic levels of cortisol.[253,254]

A number of adrenogenital syndromes can cause hypokalemic metabolic alkalosis due to production of various steroids with mineralocorticoid activity. Defective 11-hydroxylation blocks conversion of desoxycortisol to cortisol and desoxycorticosterone to corticosterone. Although aldosterone synthesis is intact, the relative glucocorticoid deficiency associated with this syndrome drives adrenal steroid synthesis, accumulating high levels of desoxycortisol and desoxycorticosterone upstream from the block. These compounds have less mineralocorticoid activity than aldosterone, but their high levels can exert marked mineralocorticoid effects.[234]

A less common syndrome involves defective 17-hydroxylation, which blocks conversion of pregnanediol to 17-pregnanediol and progesterone to 17-hydroxyprogesterone. These are steroid precursors to cortisol, androgens, and estrogens. The reduced cortisol levels lead to increased ACTH secretion with stimulates both desoxycorticosterone and aldosterone synthesis. Exogenous glucocorticoids reduce mineralocorticoid production and metabolic alkalosis in both syndromes.

The above syndromes involves the engagement of the mineralocorticoid receptor by steroid ligands with natural affinity and for various reasons indicated above, these steroids achieve levels far above the physiologic state. The next syndrome involves a different mechanism where the mineralocorticoid receptor acquires affinity for a novel ligand which results in it activation.

Geller, Lifton and colleagues reported a gain-of-function mutation of the mineralocorticoid receptor that causes constitutive receptor activation and alters receptor specificity so progesterone and other steroids lacking 21-hydroxyl groups, even antagonists become potent agonists. This mutations explains the progesterone-induced hypertension in pregnancy but

these patients tend not to develop K^+ wasting or metabolic alkalosis.[255]

A final cause of hypermineralocorticoid state is a constitutive activation of an aldosterone effector (Figure 58.13). A channelopathy that has received a lot of attention is one described by Liddle and associates back in 1963.[256] Liddle's syndrome is a rare autosomal dominant disorder exhibiting all the clinical features of mineralocorticoid excess but without increased secretion of any identifiable mineralocorticoid nor could it be reversed by inhibition of steroid synthesis or mineralocorticoid receptor blockers.[256–258] However, inhibitors of electrogenic distal tubule Na^+ reabsorption reversed the electrolyte abnormalities and normalized the elevated blood pressure,[258] consistent with an intrinsic tubule defect. The genetic lesion is now known to be due to mutations of the epithelial Na^+ channel which lead to reduced channel degradation and excessive apical Na^+ absorption.[259–261] The molecular mechanisms of how these mutant channels lead to a dominant trait of excessive Na^+ current is discussed elsewhere in the textbook. The mechanism of generation and maintenance of metabolic alkalosis is the same as with the other hypermineralocorticoid states. These patients can be treated with diuretics with direct effects on the renal tubule to inhibit the electrogenic Na^+ channel, such as amiloride and triamterene, and with K^+ supplements.

CONCLUDING REMARKS

Metabolic alkalosis is a common clinical acid–base disorder in both inpatients and outpatients. It is generally mild but it can have significant adverse effects particularly in the critically ill patient. In the ambulatory setting, the alkalosis *per se* is likely of no dire effect. Its predominant clinical importance resides in its role as a sentinel for the underlying conditions causing it, which might have grave consequences if remain unrecognized. Clinicians must pursue an expeditious and scientifically-based diagnostic tactic. While the use of diagnostic algorithms assists thought organization and streamlines the process, it is not intended to and under no circumstances should it replace the rigorous analysis based on pathophysiology.

Of all the acid–base disturbances encountered clinically or experimentally, metabolic alkalosis exemplifies the quintessential renal disorder of HCO_3^- transport. It is virtually impossible to induce sustained elevations of plasma [HCO_3^-] in normal individuals with even massive HCO_3^- infusion or ingestion. Given the vast capacity of the filtration-reabsorption nephron to excrete excess ECF HCO_3^-, the renal derangements in metabolic alkalosis are indeed remarkable and involve complex mechanisms. The overall scheme of generation and maintenance is summarized in Figure 58.13. If this is the prototypical tubulopathy that resets the plasma [HCO_3^-], the general consensus still favors the paradigm that there is no intrinsic defect in the renal tubule. It is simply a state of misguidance by incoming signals which presides over the kidney; a state akin to the salt retention and edema in renal hypoperfusion. It is important to note that it is still not proven that there is absolutely no intrinsic defect in the kidney; it is simply based on absence of proof.

The quest to uncover pathophysiology is of utmost importance and priority in clinical medicine which may be slowly, but dangerously and steadily eroding. Instead of resorting to rote memory of diagnostic algorithms and lists, the superb clinician is compelled to pose three kinds of questions regarding this state of inappropriately augmented renal HCO_3^- absorption. First is *what*. Almost all metabolic alkalotic syndromes work through a combination of the three pivotal pathophysiologic mechanisms: Contraction of effective arterial blood volume, K^+ deficiency, and excessively high mineralocorticoid activity. Decades of investigation furnished this foundation. Second is *how*. The mechanisms by which renal HCO_3^- is altered by each of these three pathophysiologic factors are complex and incompletely understood but what is known is summarized in this chapter. The third and most difficult but interesting and important question to ponder is *why*. Here one can merely speculate. Since HCO_3^- is a major ECF anion and the defense of the integrity of the circulation and organ perfusion is of such paramount importance, the kidney will recruit all mechanisms to maintain ECF volume, even at the expense of sacrificing on the chemical milieu of body fluids. Circulatory volume is preserved at the expense of plasma pH. This situation is akin to the hyponatremia seen in compromised effective arterial blood volume where the kidney foregoes osmoregulation to defend circulatory volume, or the massive sodium retention in edematous states. One can view this as a trade-off for a greater good. In the case of K^+ deficiency, the proximal nephron may be attempting to reclaim all HCO_3^- to prevent further K^+ wastage which will occur downstream in the distal nephron if significant luminal HCO_3^- is present. In addition to K^+ conservation, the intracellular acidosis in K^+ deficiency is signaling both the proximal and distal renal epithelial to defend against an apparent "acid excess state" even though the H^+ have simply migrated from the extracellular to intracellular space. Primary escalation of mineralocorticoid activity is elegantly manifested in the host of disorders of the renin-angiotensin-aldosterone axis from elevation of renin to inappropriate activation of mineralocorticoid

effector targets. This is a manifestation *par excellence* of the multiple roles of mineralocorticoids in regulating Na^+, K^+ and H^+ handling by the kidney. The uncoupled situation of the excessive luminal Na^+ with high mineralocorticoid activity leads to excessive H^+ secretion in a fashion quite inappropriate and oblivious to the high plasma [HCO_3^-]. Finally, a most fundamental question remains as to whether the kidney can sense and set plasma [HCO_3^-] and whether metabolic alkalosis represents an intrinsic disorder in the tubule rather than simply a state of obedient but misguided behavior in response to erroneous commands.

Although much has been learned about the pathophysiology of metabolic alkalosis, much more remains to be uncovered using a synergistic combination of bedside physiology and bench research. Efforts devoted to this cause can only result in improved care of patients and heightened interests for practitioners.

INTRODUCTION

The maintenance of normal systemic acid–base regulation requires the subtle integration of a number of organ functions and physiologic mechanisms such as extracellular and cellular buffering processes and integrated responses of the kidney, lung, liver, gastrointestinal tract, and skeleton. Disturbances of acid–base homeostasis are the predictable consequences of many pathophysiological processes. Their recognition may lead the clinician to the diagnosis of specific diseases and/or complications thereof. In addition, it has become increasingly clear that adaptation to acid–base disturbances is characterized by a number of important metabolic and endocrine derangements. Thus, whereas there is no evidence that there is any defense of extracellular pH to any homeostatic value or "set-point," there is evidence for homeostatic regulation of intracellular pH. Such regulation of intracellular pH affords unimpaired function of a multitude of cellular, enzymatic, and molecular processes. However, many adverse and clinically important effects of systemic acid–base disturbances *in vivo* have been recognized that might be viewed as maladaptive or constituting a "trade-off" for the maintenance of acid–base homeostasis.

In this chapter, we review the renal and systemic response to acidosis or acid load. Next, special emphasis is placed on the clinical consequences of acidosis such as on protein, divalent ion, and bone metabolism, and sodium and potassium balance as well as secondary endocrine disturbances. Finally, the various clinical entities of metabolic acidosis and their diagnostic recognition are described. The number of cited references had to be reduced for this edition. Therefore, not all important work of all authors that have contributed to the knowledge of the field could be cited. The reader will find additional references in the second to fourth editions of this book.

DEFINITION OF METABOLIC ACIDOSIS

Metabolic acidosis is the acid–base disturbance initiated by a primary decrease in plasma bicarbonate concentration. The resultant acidification of neural chemoreceptors stimulates ventilation and leads to a predictable secondary hypocapnia. The primary hypobicarbonatemia causing metabolic acidosis can occur due to: (1) loss of bicarbonate salts from the gastrointestinal tract or kidney, (2) excess of noncarbonic acid presented to body buffers from endogenous or exogenous sources, and/or (3) a decrease in the kidney's set-point for regulation of plasma bicarbonate concentration. The latter circumstance might or might not be associated with a decrease in the kidney's ability to excrete acid.

Metabolic acidosis is defined as acute on the basis of the characterization of an early steady-state period in which stable acid–base and electrolyte composition is observed during at least the initial six hours after an acid load.[319,376] Within 120 minutes after an acid load and following a large net retention of administered acid, renal net acid excretion is significantly increased[376] and is fully augmented within 72 hours. Net acid excretion is increased to values whereby the rate of acid excretion approaches the rate of endogenous acid production. Daily acid balance is again essentially achieved and the steady state of chronic metabolic acidosis has occurred.[98,207] In chronic

metabolic acidosis, the occurrence of an approach to daily acid balance permits the maintenance of stable but depressed plasma bicarbonate concentrations. The resulting decrease in plasma bicarbonate concentration in such conditions of extrarenal metabolic acidosis reflects the magnitude and anionic character of the acid load/production as well as the potency of the acid excretory response. Large variations in naturally occurring diet-induced acid production from 0 to 150 mmol protons/day correlate inversely and significantly with ambient plasma bicarbonate concentration,[214] and lower bicarbonate concentrations are associated with higher blood acidity. Thus, normal subjects ingesting higher acid loads occupy the lower domains of the normal range of plasma bicarbonate concentration, whereas those that self-select smaller acid loads exhibit bicarbonate values within the upper domain of the normal range of values. The observation that higher acid-generating diets produce relatively small decrements in plasma bicarbonate and small increments in blood acidity reflects the potency of renal acid excretory mechanisms to adjust to changes in acid load as well as other factors such as primary or secondary changes in $PaCO_2$ as discussed in subsequent sections. Thus, plasma bicarbonate concentrations within the clinically normal range do not signify the rigorous absence of an acidotic process.

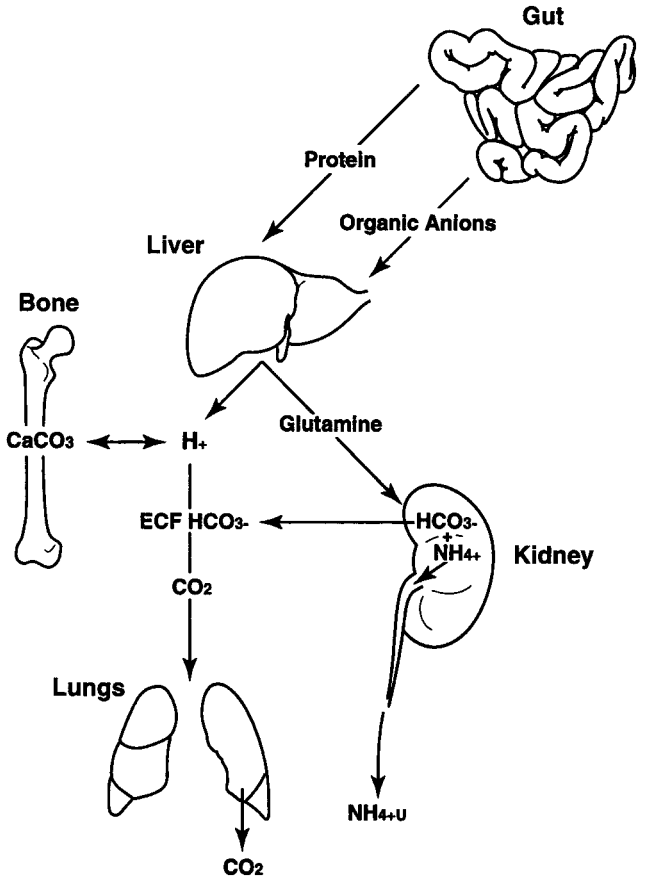

FIGURE 59.1 Integration of liver, lung, kidney, bone, and gut in regulation of acid–base homeostasis. Endogenous acid (H^+) production occurs primarily during metabolism of dietary protein in the liver. Protons produced titrate HCO_3^- in the extracellular fluid with generation of CO_2, which is eliminated by the lungs. Glutamine supply from the liver to the kidney is the prerequisite for renal production of HCO_3^- (added to the extracellular fluid) and NH_4^+ (excreted with urine) and thus allows regeneration of HCO_3^-. Bone-derived base (CO_3^{2-}) is recruited to buffer H^+ during normal variations of acid production. Depending on diet composition, up to 50% of H^+ produced during protein metabolism is titrated by base (organic anions) resorbed through the gastrointestinal tract.

SYSTEMIC AND RENAL ACID–BASE HOMEOSTASIS

Systemic acid–base homeostasis requires the coordinated and integrated action of the lung, kidney, liver, skeleton, and gastrointestinal tract (Fig. 59.1). Cellular metabolism produces about 15,000 mmol of CO_2 daily that, if received as a nonvolatile acid or a volatile acid in a closed system would constitute a major acid load according to the following relationship:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow HCO_3^- + H^+$$

Although equimolar quantities of acid and base are produced by the dissociation of carbonic acid, the produced protons would be expected to have a much greater influence on acid–base equilibrium due to the basal concentration of H^+ being six orders of magnitude lower than the corresponding value for bicarbonate (40 nmol/liter vs 25mmol/liter).

However, under steady-state circumstances the HCO_3^-/H_2CO_3 buffer system behaves as an "open" buffer system, whereby CO_2/H_2CO_3 is eliminated at a rate necessary to maintain $PaCO_2$ at the level dictated by alveolar ventilation, the rate of that is, in turn, controlled by neural chemoreceptors. Accordingly, when regulation of alveolar ventilation is undisturbed, only noncarbonic acids normally contribute to net acid production or to appreciable acid retention.

In the healthy individual, the primary source and magnitude of an acid load results from hepatic metabolism of dietary protein. Neutral amino acids are metabolized without net proton consumption or production, and metabolism of dicarboxylic amino acids consumes protons, while sulfur-containing as well as cationic amino acid catabolism results in net hepatic proton production. Due to the prevalence of sulfur-containing amino acids in the animal protein-rich nutrients typical of the "Western diet," endogenous acid production is around 1 mmol per kilogram of body weight per day.[161]

Endogenous acid production is also influenced by organic acid production from neutral precursors and alkali lost through stool.[225] Many of the clinical syndromes of metabolic acidosis are characterized by an increase in organic acid production and/or organic acid metabolism (such as ketoacidosis, lactic acidosis) and will be discussed in subsequent sections.

Hepatorenal Interactions

As illustrated in Fig. 59.1, the proton load produced by hepatic amino acid metabolism will titrate extracellular bicarbonate resulting in production of CO_2 that is eliminated by the lungs. To maintain plasma bicarbonate constant, the kidney has two pivotal tasks. First, it must reclaim the bicarbonate present in the glomerular ultrafiltrate (filtered load of bicarbonate) and, second, it must regenerate bicarbonate to replete the bicarbonate consumed during endogenous acid production. The first task is accomplished by virtually complete tubular reabsorption or reclamation of the filtered bicarbonate along the nephron (predominantly in the proximal tubule). The kidney regenerates bicarbonate (bicarbonate neogenesis) by excretion of protons either as ammonium (NH_4^+) or as titratable acid (TA) in amounts sufficient to offset those protons produced daily by oxidation of dietary foodstuffs. The amount of renal proton excretion or, equivalently, bicarbonate neogenesis/regeneration is measured as net acid excretion (NAE), which reflects the sum of NH_4^+ and titratable acid excretion minus any urinary bicarbonate excreted (that which escapes tubular reabsorption):

$$\text{Net acid excretion} = NH_4^+U + TAU - HCO_3^-U$$

The rate of renal hydrogen ion secretion is thus expressed as the sum of excreted hydrogen ions (NAE) and filtered bicarbonate reabsorbed:

$$\text{Renal } H^+ \text{ secretion} = HCO_3^- \text{ reabsorption} + NH_4 + U + TAU$$

where

$$HCO_3^- \text{ reabsorption} = (GFR \times [HCO_3^-]\text{plasma}) - HCO_3^-U$$

Excretion of NH_4^+ requires the interaction of hepatic and renal glutamine metabolism and intact renal ammoniagenesis. Urea synthesis in peripheral hepatocytes consumes equal amounts of bicarbonate and NH_4^+ and thus is without impact on acid–base balance. However, a small fraction of NH_4^+ is diverted to glutamine synthesis in hepatocytes located in the center of the hepatic lobule and such hepatic production of glutamine has been argued to be an important homeostatic substrate for renal NH_4^+/net acid excretion.[155,156] Acidemia stimulates and alkalemia inhibits glutamine synthesis.[155,156] Under certain conditions, acidemia has been demonstrated to be associated with decreased urea synthesis thereby increasing the supply of NH_4^+ for glutamine synthesis, raising the question that the liver might control the renal acid excretory response to metabolic acidosis.[278] Nevertheless, a significant role for acute metabolic acidosis in altering urea production rate *in vivo* has not been found when tested robustly in rats.[158] In addition, in humans, a negative correlation between ureagenesis and plasma HCO_3^- concentration was observed over a wide range of HCO_3^- concentrations that were altered both chronically and acutely (Fig. 59.2).[173] Thus, the ureageneic process per se may even be maladaptive for acid–base regulation in

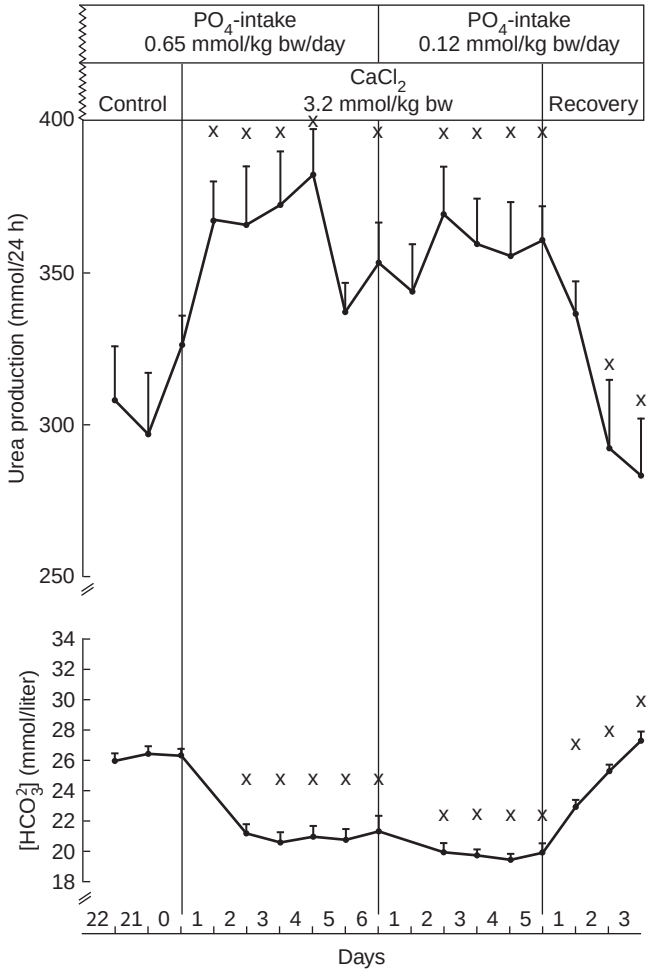

FIGURE 59.2 Effect of $CaCl_2$-induced chronic metabolic acidosis on 24 urea production rates in normal human subjects. Acidosis increases urea production rate significantly and independently of variations in the oral intake of phosphate. *(With permission, from Hosch M, Muser J, Hulter HN, Krapf R. Ureagenesis: evidence for lack of hepatic regulation of acid–base equilibrium in humans. Am J Renal Physiol 2003;286:F94–F99.)*

humans and does not appear to have a discernible homeostatic effect on acid–base equilibrium. It is likely that other metabolic pathways operate in metabolic acidosis to offset the accelerated HCO_3^- consumption of ureagenesis (e.g., oxidation of glutamate or other alkali generating reactions), but this issue has not been addressed experimentally either in animals or humans.

Glutamine supply to the kidneys is also increased by enhanced release of glutamine from skeletal muscle[317] and increased intestinal glutamine absorption, thus providing higher levels of glutamine in the splanchnic circulation.[4] In aggregate, acidemia increases glutamine synthesis or release and delivery of glutamine to the kidney.

In the proximal tubule, two deamidation/deamination steps, both positively regulated by low pH (glutamine deaminase, glutamate dehydrogenase) yield two NH_4^+ and two HCO_3^- molecules. NH_4^+ and HCO_3^- are then separated, NH_4^+ is excreted in the urine and HCO_3^- is added to the extracellular fluid. Therefore, glutamine catabolism in the kidney leads to excretion of protons (as NH_4^+) and reabsorption of equal amounts of HCO_3^-. Excess glutamine, not taken up by the kidney, is returned to the liver and deamidated/deaminated, a process that stimulates ureagenesis, inhibits further glutamine synthesis and thus constitutes a feed-back loop regulating glutamine (and thus potential NH_4^+ and bicarbonate) supply to the kidney. In contrast to the kidney, HCO_3^- and NH_4^+ are not physically partitioned or differentially excreted in the liver, but metabolized with a stoichiometry of 1:1 during ureagenesis. It is thus renal control of NH_4^+ excretion, not hepatic control of glutamine vs. urea synthesis that relates changes in plasma acid–base composition to changes in NH_4^+ metabolism and thus to possible effects on acid–base balance.

Role of the Gut

The gut affects acid–base homeostasis not only by absorbing sulfur-containing amino acids, but also by absorbing potential base. Organic anions in the gut are intrinsic to a whole food diet and are also derived in situ from dietary carbohydrates, protein and fat. They are absorbed (constituting potential base), or excreted in feces (around 10 to 60 mmol/day) or intestinally metabolized to organic acids by bacteria with subsequent reaction with HCO_3^- in ileum and colon. The amount of enterally absorbed base from a human whole food diet has been estimated to be about 50% of the magnitude of endogenous acid production.[222]

The amount of base absorbed can be estimated as the difference between diet and stool anion gaps. In both diet and feces, alkali content is estimated as the sum of noncombustible cations ($Na^+ + K^+ + Ca^{2+} + Mg^{2+}$) minus the sum of noncombustible anions ($Cl^- + 1.8$ P), where 1.8 represents the average valence of phosphate at pH 7.4.[224]

The same arithmetic version of the urinary anion gap ($[Na^+ + K^+ + Ca^{2+} + Mg^{2+}] - [Cl^- + 1.8$ P]) has also been shown to be correlated directly and positively with the diet-stool anion gap in metabolically controlled human subjects.[276] This would allow an estimate of gastrointestinal alkali absorption without measuring stool composition. However, the urinary anion gap cannot reliably estimate gut base absorption under conditions in which net systemic organic acid production is altered or in which net bone accretion or dissolution prevails (i.e., typical clinically encountered conditions) as this construct of the urinary anion gap reflects the combined effects of cellular and bone buffering, endogenous organic acid production as well as gastrointestinal base absorption.

There is only weak evidence that intestinal absorption might adapt to acidosis. An insignificant decrement in the stool anion gap of 7 mEq/day was noted during the first six days of acid loading (potential secondary systemic gain of alkali) in human subjects, but this decrement subsequently decreased to only 2.5 mEq/day during prolonged acidosis.[225] The measured 2.5 mEq/day increment in gut base absorption in metabolic acidosis is a very small response in comparison to the simultaneous increment in renal net acid excretion (from 44 to 247 mEq/day).[225] Thus, quantitative considerations and the fact that the estimation of the stool anion gap rests completely on an unknown valence for phosphate, and that only 5% of the fecal phosphate is dialyzable (suggesting that most of stool phosphate is either intracellular or sequestered in calcium/magnesium salts) are the most important arguments against an adaptive role of the gut in acidosis.

Role of Bone

Bone is a large reservoir of exchangeable base as calcium carbonate and dibasic phosphate. Exogenous and endogenous metabolic acid loads, both acute and chronic, liberate calcium and base (carbonate) from bone.[57,58] Calcium is subsequently lost in the urine.[222]

There is evidence from human studies (reviewed in Lemann et al.[224]) that when acid production is increased experimentally, renal net acid excretion does not increase as much as acid production. The difference in acid neutralization (i.e., the positive acid balance) is attributed to bone buffering of retained protons (or liberation of bone base) (Fig. 59.3). Similarly, renal net acid excretion does not decrease as much as acid production when base ($KHCO_3$) is administered. Under

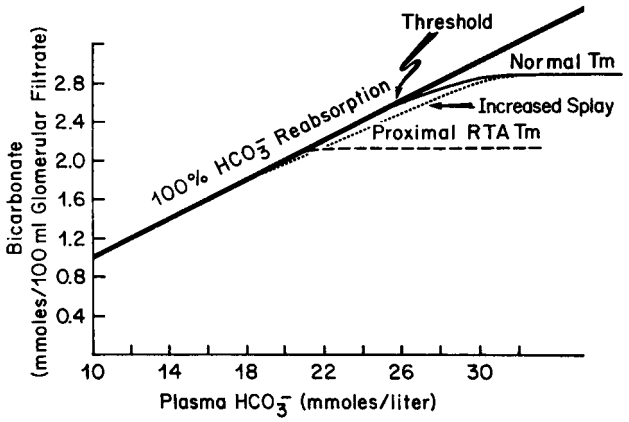

FIGURE 59.3 The relationship between plasma bicarbonate concentration and renal tubular reabsorption of bicarbonate is demonstrated for both normal individuals and patients with proximal renal tubular acidosis (RTA). The renal bicarbonate threshold represents the plasma bicarbonate concentration at which bicarbonate first appears in the urine. The bicarbonate T_{max} (or Tm) represents the bicarbonate concentration at which maximal renal tubular bicarbonate reabsorption occurs. The portion of the curve between the threshold and the T_{max} is called the splay.

these experimental conditions, subjects are likely in small negative acid or positive base balance, with incorporation of base into bone. Positive acid balance is accompanied by equivalent cation loss (loss of Ca^{++} and possibly K and/or Na from bone), negative acid balance by equivalently positive cation balance (incorporation of Ca^{++} and K and/or Na). Scanning ion microprobe analysis indicates that bone buffer content (i.e., HCO_3^- and phosphate) is decreased significantly in mouse calvariae in *in vitro* models of both acute and chronic metabolic acidosis. This consumption of proton buffers may attenuate the severity of both acute and chronic metabolic acidosis, but does so at the expense of a decrease in bone mineral content.[60]

Based on these and other observations that acidotic normal subjects and patients with renal failure that were shown to be in positive acid balance and yet were able to maintain stable plasma bicarbonate concentrations,[147,223] it is assumed that bone contributes in a quantitative important way to proton buffering in response to acid loads. However, in the chronic acidosis of renal failure, quantitative considerations of the required large magnitude of bone alkali have raised the possibility that available bone alkali content is insufficient to offset a possible underexcretion of acid relative to that needed for daily acid balance. While it has been argued that increased gut organic anion absorption may account for this needed base,[361] such a conclusion is not a compelling one when based on a computation of acid balance that depends on a constant and assumed phosphate valence for whole food diets and stool (see Role of Gut section).

Renal Regulation of Acid–Base Equilibrium

As discussed, the kidney maintains a stable $[HCO_3^-]p$ through two processes: (1) HCO_3^- reclamation, the reabsorption of filtered HCO_3^-, and (2) HCO_3^- regeneration, the neogenesis of HCO_3^- that has been decomposed by the invasion of fixed acids into the extracellular fluid or HCO_3^- lost from the body through extrarenal or renal routes.

The relationship between the $[HCO_3^-]p$ and renal HCO_3^- reclamation is shown in Fig. 59.4. When the $[HCO_3^-]p$ is reduced below the normal range, about 25 mEq/liter, the kidney reclaims all filtered HCO_3^-. As the $[HCO_3^-]p$ increases toward normal, complete HCO_3^- reclamation continues until a critical HCO_3^- concentration is reached. This concentration is about 25 mmol/liter in normal humans' "bicarbonate threshold," and thus explains that normal subjects excrete only trivial quantities of bicarbonate in their urine (usually less than 5 mmol/day). Above the bicarbonate threshold, some filtered bicarbonate escapes reclamation and is excreted in the urine. As the $[HCO_3^-]p$ increases further, HCO_3^- reclamation also increases, but not in proportion to the increment in the filtered HCO_3^- load. Therefore, despite greater reclamation, increasing quantities of HCO_3^- enter the urine. Finally,

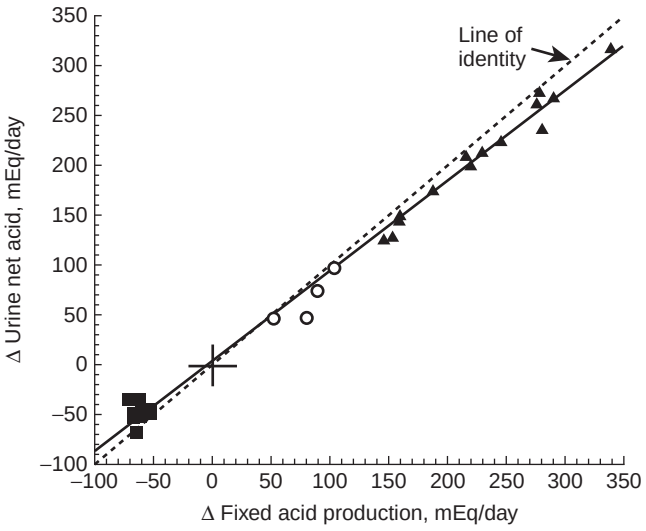

FIGURE 59.4 Changes from control in daily urinary net acid excretion in relation to changes from control in daily endogenous fixed acid production among healthy adults given different acid and base loads. If all endogenous acid produced were eliminated by the kidney, the values should fall on the line of identity. The figure illustrates, however, that acid balances become positive when acid production is increased markedly reflecting buffering by bone. Similarly, acid balances become negative when large amount of base is given reflecting buffering of base by bone. *(With permission, from Lemann J Jr, Bushinsky DA, Hamm LL. Bone buffering of acid and base in humans. Am J Physiol Renal Physiol 2003;54:F811–F832.)*

a $[HCO_3^-]p$ is reached beyond which further increases elicit no greater HCO_3^- reclamation. At this $[HCO_3^-]p$ (about 28 mEq/liter in normal humans), an apparent maximal reabsorptive rate, or apparent T_{max} for HCO_3^-, has been achieved. When the $[HCO_3^-]p$ increases above the apparent T_{max}, the resultant increment in the filtered HCO_3^- load is entirely excreted into the urine.

In addition to HCO_3^- reclamation (reabsorption), the kidney must also regenerate the HCO_3^-, that has been decomposed by the entry of fixed acids into the extracellular fluid (ECF) or lost in urine or stool. The kidney regenerates HCO_3^- by excreting acid. The vast majority of protons are excreted in the form of NH_4^+ or titratable acid as the free proton concentration at the minimal urinary pH of 4.5 is less than 0.1 mmol/liter. The net effect of renal acidification can be measured as net acid excretion.

$$\text{Net Acid excretion} = NH_4^+ + \text{Titratable Acid} - HCO_3^-$$

Quantitatively, changes in renal NH_4^+ excretion account for most of the changes in renal acid excretion both in response to changes in endogenous acid production and in the adaptation to acid–base disturbances. In adaptation to changes in acid load, NH_4^+ excretion is regulated at multiple levels including glutamine supply to the kidney, production of NH_3 in the proximal tubule (ammoniagenesis), secretion of NH_3 into the tubular lumen and various transport processes of NH_3/NH_4^+ along the nephron. (For a discussion of these mechanisms, see Chapters 54 and 56)

Phosphate and organic anions such as citrate, acetate, beta-hydroxybutyrate and creatinine contribute as filtered buffers to titratable acid excretion. Amongst these substances, the buffer pair di- and mono-basic phosphate $(HPO_4^-/H_2PO_4^-)_2$ is the most important buffer due to its pKa of 6.8 and urinary excretion values on the order of 20 to 50 mmol/day. Titration of the other potentially titratable species is severely limited due to their pKa values residing below 5.0. The importance of phosphate as a urinary proton buffer is illustrated by the effects of both neutral phosphate loading and depletion. Increases in neutral phosphate load significantly enhance net acid excretion[315] and are able to generate as well as maintain metabolic alkalosis even without a concomitant increase in renal cation resorption or sodium avidity.[174,206] Although phosphate delivery to distal acidification sites has been demonstrated to be rate limiting for renal acid secretion in acidotic dogs,[180] under phosphate loading conditions, the generation of phosphate-induced secondary hyperparathyroidism appears to provide the major stimulus to enhanced renal acid excretion.[177] Phosphate depletion reduces both phosphate and titratable acid excretion and induces positive hydrogen balance.[140] It is unclear whether these changes are best explained by a rate-limiting role of luminal phosphate for renal acid excretion or by the observed renal HCO_3^- wasting.[140]

Determination of Net Acid Excretion

Although enzymatic ammonium assays in serum are widely performed in clinical medicine and this assay method is valid in urine, ammonium values are seldom requested in urine for reasons that have not been reported. As an alternative to requesting an ammonium value in urine, a simplified version of the urinary anion gap is frequently used as an indirect index of ammonium excretion:[142]

$$\text{Urinary anion gap} = Na^+u - K^+u - Cl^-u$$

The rationale is that in chronic metabolic acidosis, ammonium excretion is elevated, is a cation, and balances part of the negative charge of the major urinary cation, chloride. Thus, the urinary anion gap should become progressively negative as the rate of ammonium excretion increases in response to acidosis or to acid loads. However, the urinary anion gap is not a quantitative index of ammonium excretion.[381] Its potential role in the clinical differential diagnosis of hyperchloremic metabolic acidosis will be discussed in subsequent sections.

Calculation of titratable acid requires determination of urinary pH (UpH), blood pH (BbpH), urine phosphate, estimation of the pKa (near 6.8) and an arithmetic computation:

$$\begin{aligned}TAexc = &[[Pexc/\text{antilog}\,(UpH - pK')] + 1]] \\ &- [[Pexc/\text{antilog}\,(BpH - pK')] + 1]]\end{aligned}$$

Although use of a pKa phosphate value of 6.8 is sufficient for most clinical purposes, the pK′ of phosphate can be corrected for ionic strength and pH for improved accuracy.[319]

CLINICAL CONSEQUENCES

Ventilatory Response to Acidosis: Homeostatic and/or Maladaptive?

The most characteristic clinical manifestation of metabolic acidosis is hyperventilation. Because the depth of ventilation increases to a much greater degree than the respiratory rate, hyperventilation may not be clinically apparent until acidemia becomes severe. Then,

patients may experience labored breathing and their chief complaint is dyspnea.

Metabolic acidosis rapidly causes secondary hyperventilation, which reduces the $PaCO_2$ and tends to increase the blood pH toward normal. This secondary respiratory response is usually fully developed in 12–24 hours. Peripheral chemoreceptors in the carotid and aortic bodies and central chemoreceptors on the ventral surface of the medulla trigger the respiratory response to metabolic acidosis. Some controversy still exists as to which chemoreceptors are more important.

During acute metabolic acidosis (initial six hours after an acid load) $PaCO_2$ falls by 0.85 mm Hg for every millimole-per-liter decrease in $[HCO_3^-]p$ (Fig. 59.5). In response to sustained acidosis, the respiratory response is further stimulated and is maximal by 24 hours. Then, $PaCO_2$ is decreased by about 1.1 mm Hg for each millimole-per-liter fall in $[HCO_3^-]p$ in acidotic human subjects.[208] Several other helpful guides can be used at the bed side to determine whether respiratory compensation is appropriate: (1) metabolic acidosis should reduce the $PaCO_2$ so that it approximates the decimal digits of the pH. For example, when metabolic acidosis reduces the pH to 7.30, the pCO_2 should be about 30 mm Hg. Maximal hyperventilation in patients with extreme acidemia will reduce the $PaCO_2$ to about 10 mm Hg. (2) Another useful rule is that the $PaCO_2$ should approximate the $[HCO_3^-]p + 15$. 9. (3) In uncomplicated metabolic acidosis the decrease in $PaCO_2$ after full adaptation may also be calculated as follows:

$$PaCO_2 = 1.5[HCO_3^-] + 8 \pm 2$$

The respiratory response to metabolic acidosis may be slightly different in patients with different forms of metabolic acidosis. For example, it has been suggested that lactic acidosis generates greater hyperventilation and a lower $PaCO_2$ than equally severe ketoacidosis. This could be the result of a lower intracellular pH in the patients with lactic acidosis. However, others find that secondary hyperventilation in lactic acidosis is not different from other metabolic acidoses.[107,128]

A chronically low $PaCO_2$ (hypocapnia) lowers the $[HCO_3^-]p$ as a result of transient bicarbonaturia or decreased renal net acid excretion. In dogs, experimental hypocapnia caused the kidney to decrease $[HCO_3^-]p$ (transient renal acid retention) even in the context of metabolic acidosis with preexisting hypobicarbonatemia.[76,235] The decrease in $[HCO_3^-]$ was strictly proportional to the induced hypocapnia over a wide range of $PaCO_2$ values and $[HCO_3^-]p$ (fall in $[HCO_3^-]p$ of 0.54 mmol/liter per 1-mm Hg fall in $PaCO_2$). The hypocapnia-induced decrement in $[HCO_3^-]p$ was sufficient to increase blood acidity. These findings

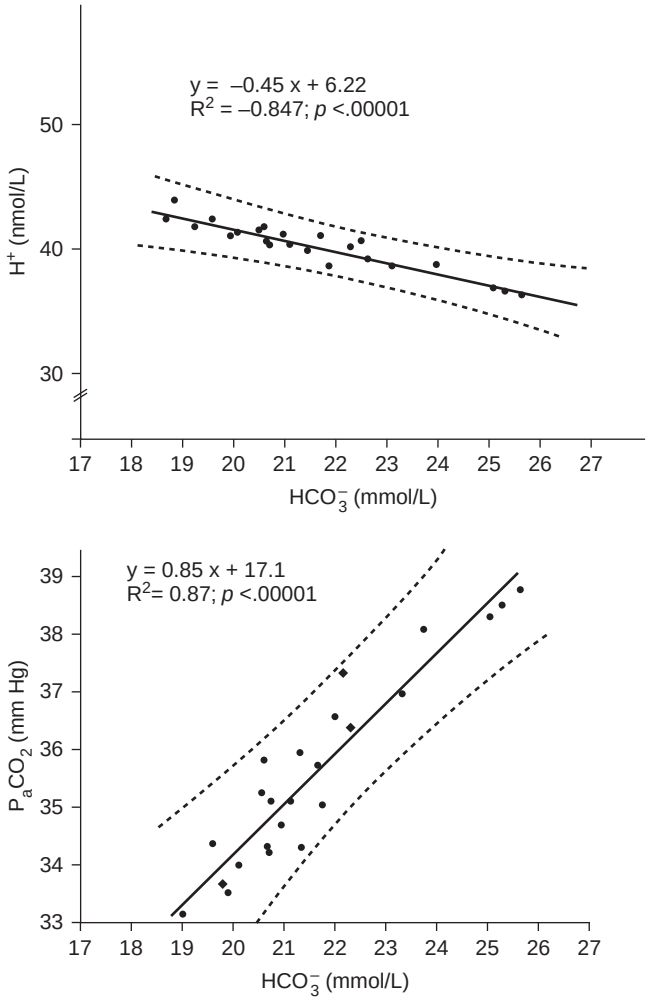

FIGURE 59.5 Relations of $PaCO_2$ to plasma bicarbonate and blood hydrogen ion concentrations in acidotic subjects. The shaded area represents the 95% confidence limits for uncomplicated, acute metabolic acidosis. *(With permission, from Wiederseiner JM, Muser J, Lutz T, Hulter HN, Krapf R. Acute metabolic acidosis: characterization and diagnosis of the disorder and the plasma potassium response. J Am Soc Nephrol 2004;15:1589–1596.)*

demonstrated that the renal response to metabolic acidosis is not primarily geared at the defense of pH[76] and that secondary hypocapnia elicits a maladaptive renal response.[235] In contrast to dogs, however, humans exhibit an alkalemic response to hypocapnia (increase in blood pH) (Fig. 59.6) irrespective of the presence or absence of preexisting metabolic acidosis ($[HCO_3^-]p$ between 25 and 10 mmol/liter),[209] despite the finding that hypocapnia also caused transient renal acid retention. The reason for this species difference is that the inhibitory effect of hypocapnia on renal acid excretion (decrease of $[HCO_3^-]p$ by 0.41 mmol/liter per 1-mm Hg fall in $PaCO_2$) is too small in humans to offset the direct alkalemic effect of the decrease in $PaCO_2$ as dictated by the HCO_3^- Henderson-Hasselbalch

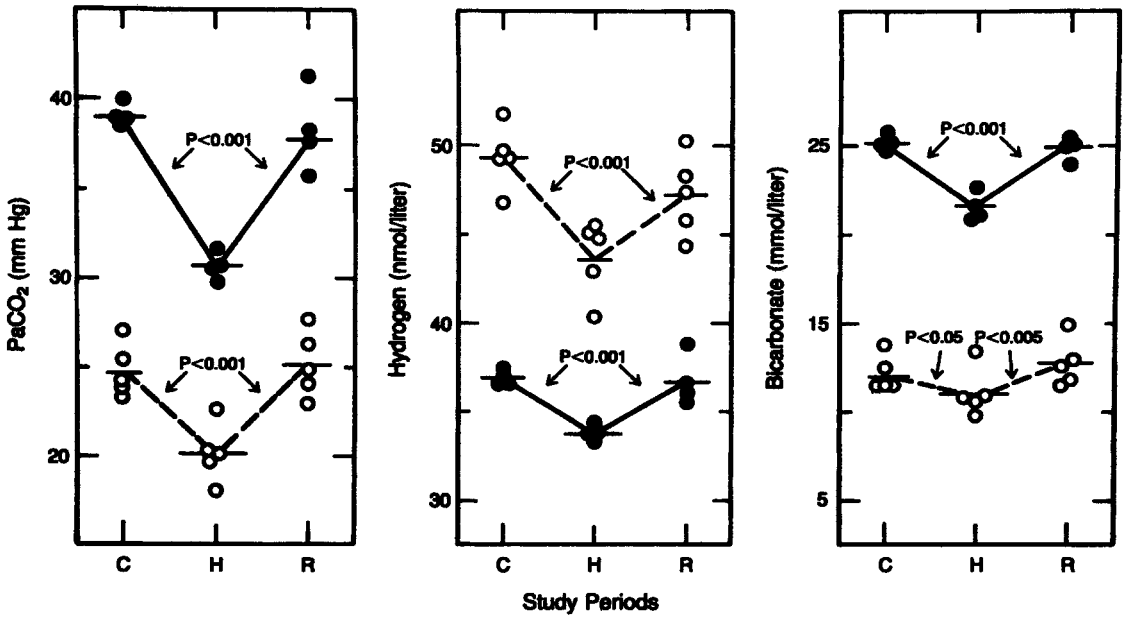

FIGURE 59.6 Steady-state plasma acid–base indexes during control (C), hypocapnia (H), and recovery (R) in normal subjects with and without experimentally induced (NH4CL feeding) acidosis. Solid lines and circles represent subjects with preexisting acidosis. Hypocapnia elicits an alkalemic response irrespective of the control steady-state plasma bicarbonate concentration. *(With permission, from Krapf R, Beeler I, Hertner D, Hulter HN. Chronic respiratory alkalosis. The effect of sustained hyperventilation on renal regulation of acid–base equilibrium. N Engl J Med 1991;324:1394–1401.)*

equation. However, if the slope of line for the relation of the $[HCO_3^-]p$ on $PaCO_2$ extends to $[HCO_3^-]p$ below 10 mmol/liter, it can be predicted that at the lowest end of the range of values for $[HCO_3^-]p$, hypocapnia might worsen acidemia in humans as well as dogs.[208] Figure 59.7 illustrates these differences in the prediction of blood $[H^+]$ when chronic hypocapnia is superimposed on chronic metabolic acidosis when a $[HCO_3^-]/PaCO_2$ slope of 0.54 is used (as reported for dogs; dashed lines) or when a $[HCO_3^-]/PaCO_2$ slope of 0.41 is used as reported for normal human subjects.[209]

Metabolic and Endocrine Consequences of Metabolic Acidosis

Effects of Acidosis on Nitrogen Balance and Protein Metabolism

Metabolic acidosis results in reversible growth failure in children with tubular acidosis and in rats.[248] It affects protein metabolism both by accelerating proteolysis (resulting in negative nitrogen balance) and amino acid oxidation and by decreasing protein synthesis.[244,293] Quantitatively, metabolic acidosis may be the most important factor[18] in the wasting syndrome associated with many illnesses—that is, uremia,[284] sepsis, trauma, and chronic diarrhea—and thus may affect adversely the prognosis of these conditions.[203]

Among the different proteolytic pathways, metabolic acidosis activates the ATP-dependent ubiquitin-26S proteasome pathway, which mediates muscle proteolysis.[16,255] The balance between glucocorticoids and insulin regulates mRNA expression of ubiquitin-proteasome genes and thus muscle proteolysis. Glucocorticoid activity is stimulated in acidosis[327] and, both *in vitro* and *in vivo*, the acidosis-induced stimulation of skeletal muscle proteolysis as well as the induction of ubiquitin-26S proteasome gene expression was shown to be glucocorticoid-dependent.[188] Insulin is the chief counterregulatory factor opposing the catabolic effects of glucocorticoids via the ubiquitin-proteasome pathway.[26] Since there is evidence for insulin resistance in metabolic acidosis,[3,94,325,326] and acidosis was shown to impair insulin signaling via insulin-receptor substrate-1, associated phosphoinositide 3-kinase (PI3K) in muscle cells,[123] both increased glucocorticoid activity and impaired insulin signaling might mediate increased rates of proteolysis in response to acidosis. In addition, decreased concentrations of free IGF-1, an inhibitor of ubiquitin gene expression, and altered thyroid function (mild primary hypothyroidism) have been reported in metabolic acidosis[53,54] and constitute additional potential mechanisms for increased proteolysis.

Protein synthesis is also affected by metabolic acidosis. Muscle protein synthesis and albumin synthesis

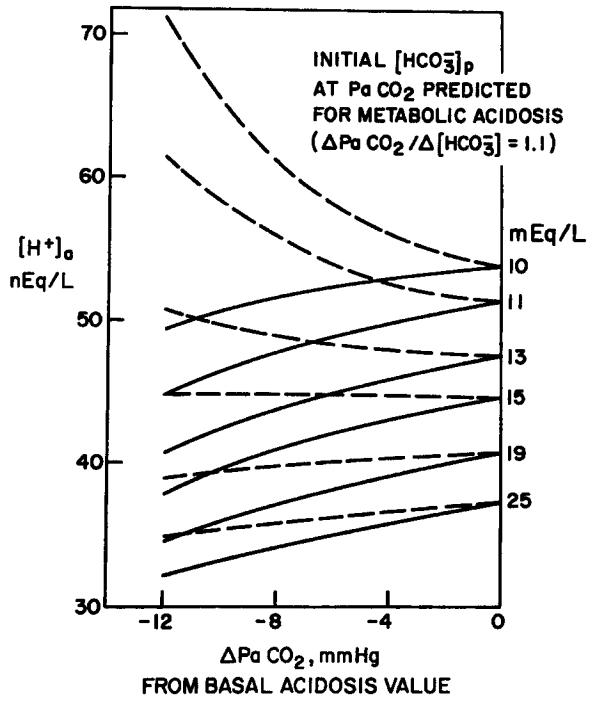

FIGURE 59.7 Nomogram for predicting blood $[H^+]$ when chronic hypocapnia is superimposed on chronic metabolic acidosis over a range of values of initial $[HCO_3^-]$. Solid lines represent the blood $[H^+]$ responses (nmol/liter) to hypocapnia in humans with initial plasma $[HCO_3^-]$ from 10 to 25 mmol/liter, based on the slope of $[HCO_3^-]/PaCO_2 = 0.41$. (*From Gonick HC. Trace metals and the kidney. Miner Electrolyte Metab 1978;1:107–120.*) The dashed lines show the blood $[H^+]$ responses when a $[HCO_3^-]/PaCO_2$ slope of 0.54 (reported for dogs and used in most textbooks) is applied. $\Delta PaCO_2$ values represent changes in $PaCO_2$ from the intial $PaCO_2$ using a relationship of $PaCO_2/HCO_3^- = 1.1$, which is characteristic of uncomplicated metabolic acidosis. Hypocapnia results in a uniform alkalemic response when the human slope is employed, while a deflection point for acidemic versus alkalemic response is apparent at initial $[HCO_3^-]p$ <16 mmol/liter when the canine slope is used. If the slope of 0.41 extends to inital $[HCO_3^-]p$ <10 mmol/liter, it can be calculated that a deflection point would exist between very low $[HCO_3^-]p$ between 6 and 8 mmol/liter. *(With permission, from Krapf R, Hulter HN. Renal response to chronic hypocapnia: qualitative differences between dogs and humans? Clin Chem 1992;38:444–445.)*

(the latter only after several days of metabolic acidosis) are inhibited in humans,[18,200] but not in rats.[242] Correction of acidosis has been effective in both increasing free IGF-1 and albumin serum concentrations[375] as well as in conserving muscle mass and protein homeostasis in patients with chronic renal failure and metabolic acidosis (cited in Kleger et al.[200]).

Effects of Metabolic Acidosis on Sodium Homeostasis

It is well known that both acute and chronic metabolic acidosis are associated with natriuresis.[97,156] Both proximal and distal tubular sodium reabsorption appear to be inhibited.[72,98,226,240,366] The proximal effect is the result of downregulated organic-anion stimulated NaCl absorption,[366] while HCO_3^- reabsorption is enhanced as a consequence of increased expression and activity of Na^+/H^+ exchange (sodium–hydrogen exchanger isoform 3, NHE-3).[11,37] The natriuresis of acidosis induces extracellular volume depletion and increased renin-angiotensin-aldosterone activity, which significantly counteracts and limits the acidosis-induced negative sodium balance and weight loss.[169] Inhibition of angiotensin II action by the AT-1 receptor antagonist losartan resulted in decreased renal net acid excretion in pre-existing metabolic acidosis.[169] Therefore, distal nephron angiotensin II activity is a coregulator of the renal-tubular response to metabolic acidosis and, thereby, is important in determining the severity of acidosis. Increased aldosterone is also expected to limit the severity of metabolic acidosis by stimulation of distal nephron acidification. However, inhibition of aldosterone action by spironolactone exacerbated human metabolic acidosis by an extrarenal mechanism (increased endogenous acid production[169] precluding an analysis of its effect on renal acidification. Thus, the quantitative role of acidosis-induced hyperaldosteronism in the tubular response to metabolic acidosis and the resultant severity of metabolic acidosis remain to be determined.

Effects of Metabolic Acidosis on Potassium Homeostasis

Both extrarenal cellular potassium shifts and the renal regulation of potassium transport have been examined in metabolic acidosis. Contrary to a widely expressed opinion, there is no compelling evidence—either in acute mineral or acute organic acidosis—for a demonstrable increase in plasma potassium in response to acidosis.[2,376] Under carefully controlled conditions, arterialized venous plasma potassium increased nonsignificantly by only +0.02 mmol/liter per mmol/liter decrease in plasma $[HCO_3^-]$ in acute, NH_4Cl-induced metabolic acidosis in normal human subjects.[376] Previous studies in dogs and humans (cited in Wiederseiner et al.[376]) had described both unchanged and increased plasma potassium concentrations albeit with unusually large variances. Failure to detect hyperkalemia in the most recent and some of the previous reports[376] does not preclude, however, the existence of acidosis-induced net K^+/H^+ exchange across cell membranes with efflux of K^+ from cells. The finding of a hyperinsulinemic response (with concomitant decrease in glucagon concentration and unchanged catecholamine levels) in response to

acidosis suggests that an insulin response counterregulates any acidemia-induced cellular potassium efflux, resulting in stable plasma potassium concentrations.[376] This occurred despite an increase in the insulin/glucose ratio, suggesting the insulin resistance in acute acidosis may not involve transcellular potassium balance. A similar mechanism may operate in acute organic acidosis.[3] In the case of organic acidosis, organic anions may enter cells along with protons thus obviating exit of potassium.[280] In conclusion, acidosis-induced hyperinsulinemia seems to prevent acidosis-induced hyperkalemia. The plasma potassium response in acutely acidotic subjects with insulin deficiency or preexisting insulin resistance needs further investigation. In the clinical setting, therefore, the plasma potassium response must always be interpreted with a diligent analysis of the presence of factors in addition to acidemia that are known to influence potassium distribution between intra- and extracellular spaces such as changes in osmolality, sympathoadrenergic activity, aldosterone, and the activity of glucoregulatory hormones (insulin and glucagon).

Acute metabolic acidosis (less than two hours) initially reduces renal potassium excretion, based in large part on effects in the CCT. Experimental reduction of luminal pH in the isolated perfused CCT results in diminished K secretion.[40] The effect of acute acidification of CCT principal cells is believed to be mediated by the effect of cellular acidity to decrease the open probability of potassium channels in the apical membrane.[367] Metabolic acidosis of longer duration is a potent stimulus of renal K excretion and may lead chronically to significant hypokalemia and substantial potassium depletion.[209,307,327] This increase in potassium excretion is probably the consequence of increased volume/sodium delivery to the distal tubule and collecting duct[338] and hyperaldosteronism.[309,313,327]

Effect of Metabolic Acidosis on Divalent Ion, PTH, and 1,25 $(OH)_2D$ Metabolism

Metabolic acidosis profoundly affects calcium and phosphate metabolism resulting in calcium loss from bone[57] in association with hypercalciuria.[222,223] Hypercalciuria is the result of an increase in filtered load and decreased tubular reabsorption of calcium, the cellular mechanisms of which are poorly understood although calcium reabsorption is correlated with luminal $[HCO_3^-]$ in the distal tubule. Important clinical sequelae of the resultant negative calcium balance are a metabolic bone disease with poorly characterized features of osteomalacia/low formation rate/high resorption rate[7,290,298] and calcium nephrolithiasis. Metabolic acidosis induces hypophosphatemia in association with increased renal phosphate clearance and increased fractional excretion of phosphate; in brief, metabolic acidosis induces renal phosphate depletion.[207,222,223] The mechanism of decreased tubular phosphate reabsorption in the proximal tubule is likely to be complex. High ambient proton concentration was shown to stimulate phosphate transport by a glucocorticoid-dependent, posttranslational mechanism.[190] Isohydric decreases in $[HCO_3^-]/PaCO_2$, on the other hand, stimulated phosphate transport in OK-cells via a transcriptional effect.[190] In addition, metabolic acidosis has been shown to decrease [IGF-1]s in humans, providing a plausible mechanism for decreased renal phosphate reabsorption. Thus, metabolic acidosis seems to affect renal regulation of phosphate reabsorption both directly (via effects of acid−base changes on phosphate transport) and indirectly via endocrine changes (increased glucocorticoid activity, decreased IGF-1 levels).[50,326] The relative importance of these mechanisms remains to be elucidated.

Acute and chronic metabolic acidosis was demonstrated to induce renal magnesium wasting and hypomagnesemia.[239,286] The cellular mechanisms of acidosis-induced renal magnesium wasting are largely unknown, although extracellular acidity has been shown to decrease magnesium uptake in mouse distal tubular cells.[85]

In animals, metabolic acidosis was found to decrease $[1,25(OH)_2D]$s,[217] an effect generally attributed to decreased activity of renal 1-alpha-hydroxylase.[218] However, chronic metabolic acidosis was demonstrated repeatedly to increase $[1,25(OH)_2D]$s (by stimulation of its production rate) and to concomitantly decrease [PTH]s in humans.[207,239] The effects of metabolic acidosis on ionized calcium concentration (hypercalcemia not observed or very mild in humans, but prevalent in rats) and on the severity of phosphate depletion/hypophosphatemia seem to differ among species. Thus, it is likely that the changes in $[1,25(OH)_2D]$s and [PTH]s observed are primarily determined by the occurrence or the severity of acidosis-induced hypercalcemia, which has been shown to override other potent stimuli of $1,25(OH)_2D$ production including phosphate depletion unless the latter is quite severe.[59,176]

It is interesting to speculate that the elevated $[1,25(OH)_2D]$s in response to metabolic acidosis could serve a homeostatic role, or, that elevated $[1,25(OH)_2D]$s could contribute to the normal acid excretory response to an acid load/acidosis. This question merits investigation in as much as vitamin D deficiency was shown to result in metabolic acidosis in chicks[37] and chronic $1,25(OH)_2D$ administration results in metabolic alkalosis (in part of renal origin) in thyroparathyroidectomized dogs.[178]

In summary, metabolic acidosis in humans induces (1) hypercalciuria due to release of calcium from bone and decreased renal tubular calcium reabsorption, (2) renal phosphate depletion and hypophosphatemia, (3) renal magnesium wasting, and (4) increases [1,25(OH) 2D]s and decreases in intact [PTH]s.

Effect of Metabolic Acidosis on Bone

The effects of metabolic acidosis on bone mineral content—that is, reduced levels of mineral sodium, potassium, carbonate, calcium, and phosphate—are consistent with the role of bone as a proton buffer. In mouse calvariae *in vitro*, exposure to acid media (low HCO_3^-) induces initial physicochemical mineral dissolution. Cell-mediated bone resorption follows and is characterized by both increased osteoclastic and inhibited osteoblastic activities paralleled by alterations in the expression of a number of osteoclastic and osteoblastic genes.[62] In particular, increased osteoblastic RNA expression of the osteoclast activator RANK-ligand with unchanged expression of its soluble decoy receptor, osteoprotegerin, may provide a central mechanism by which metabolic acidosis enhances osteoclastogenesis and osteoclast activity. The effect is mediated—at least in part—by acidosis-induced enhancement of osteoblastic prostaglandin E2 (PGE2) secretion. Both RANK-L expression and cell-mediated calcium efflux from bone are inhibited by cyclooxygenase inhibition, confirming the central role of acidosis-induced PGE2 stimulation.[61]

Since glucocorticoid activity is increased in metabolic acidosis[326] and glucocorticoids are known to dramatically decrease bone mineral content, it is possible that acidosis-induced hyperglucocorticoidism might contribute to calcium efflux from bone. Surprisingly, however, *in vitro* cortisol inhibited rather than stimulated acid-induced, cell-mediated osteoclastic bone resorption through a decrease in osteoblastic PGE2 production.[212]

Other Endocrine Effects of Metabolic Acidosis

Endothelin

Metabolic acidosis induces renal endothelial cells to release endothelin-1, which was demonstrated to play a key role in the renal defense to an acid load. Both proximal acidification (by activation of the proximal tubule Na/H antiporter, NHE-3) and collecting duct acidification are stimulated involving signaling via the endothelin receptor B (ETB). In the distal tubule, both direct (endothelin-induced activation of Na^+/H^+ exchange) and indirect (stimulation of H^+-ATPase via endothelin-induced increases in aldosterone) effects may be operative to stimulate proton secretion.[197] When ETB is inhibited by the unselective ET-receptor antagonist bosentan (Tracleer) in rats or ETB is knocked out in mice, the metabolic acidosis resulting from a given acid load is more severe.[215,371] The mechanisms of acid-induced increased endothelin expression and endothelin-1/ETB signaling are complex, but quite well characterized and involve activation of a putative acid-sensor, a proline rich tyrosine kinase 2, Pyk2.[227] Interpretation of the effects of bosentan in rats to decrease distal H^+ secretion has been difficult since bosentan has also induced a decrease in chronic net acid excretion/endogenous acid production, which in itself, dictates lower tubular acidification rates along the nephron. In summary, renal endothelin-1 acting via ETB receptor is quantitatively important in the renal defense against an acid load in mice and rats. The importance of the acid-induced renal endothelin response has not yet been investigated in humans.

Growth Hormone (GH)/IGF-1 Axis

Important effects of metabolic acidosis on the GH/IGF-1 endocrine axis were suggested by the observation[250] that growth retardation in children with renal-tubular acidosis was reversible upon administration of alkali. In humans, IGF-1 serum concentrations are decreased in response to metabolic acidosis. The primary abnormality in humans and rats is most likely due to peripheral insensitivity to GH action with GH secretion rates presumably elevated based on the demonstration of an exaggerated increase in GH in response to stimulation by GH releasing hormone.[53,279] The recent observations that administration of GH both partially corrected metabolic acidosis by a renal mechanism (primarily by an increase in ammonium excretion)[327] and corrected acidosis-induced negative nitrogen balance, corrected renal phosphate depletion as well as hypophosphatemia and attenuated renal magnesium wasting[239] is evidence for the notion that acidosis-induced changes in the GH/IGF1 endocrine axis may be important in the mediation of some important metabolic effects of metabolic acidosis.

Thyroid Hormones

Chronic metabolic acidosis in humans mildly decreases freeT3 and freeT4 and significantly increases TSH serum concentrations with no change in reverse T3,[54] findings consistent with a primary thyroidal decrease in thyroid hormone secretion, that is, mild primary hypothyroidism. The quantitative importance of these changes in thyroid function with respect to acidosis-induced negative nitrogen balance and to renal acidification is presently unknown.

Catecholamines

Acidosis induces release of catecholamines, which attenuate both the negative inotropic effect of acidosis on cardiac contractility and the peripheral vasodilatory effect of acidemia.[256] With severe acidosis, catecholamine responsiveness decreases and cardiac collapse may result. Acidosis can also decrease the ventricular fibrillation threshold.[139] Peripheral arterial vasodilatation is a direct effect of acidosis but is also offset by catecholamine release, so that peripheral vascular resistance remains relatively constant. However, in the venous system, the direct effect of acidosis is vasoconstriction, which is further enhanced by catecholamine release.[323] Peripheral venoconstriction can shift blood from the peripheral vascular system to the pulmonary vascular bed. In patients with severe acidosis, this may contribute to pulmonary edema. Therapeutic administration of $NaHCO_3$ constitutes an important additional risk factor.

It is not known whether the catecholamine response affects the renal response to acidosis in humans, although alpha-adrenergic stimulation has been shown to enhance proximal tubule bicarbonate reabsorption in rats.[67]

In moderately severe acute metabolic acidosis in humans (decrease of $[HCO_3^-]p$ from 25 to about 19 mmol/liter), there was no significant effect on catecholamine levels.[376] Thus, the effects described previously may be more applicable to severe forms of metabolic acidosis or to a pattern of sympathetic stimulation that does not result in overt systemic catecholamine spillover.

Glucocorticoids

Observations carried out in rats suggest that increased glucocorticoid activity in response to metabolic acidosis might modulate acidosis-induced increase in protein degradation, at least in part.[245] It is also possible that increased glucocorticoid activity could co-determine the systemic and renal response to an acid load, given the effects of glucocorticoids on renal acidification[181] and renal tubular acid–base transport mechanisms.[27,198] Chronic metabolic acidosis in humans significantly increases glucocorticoid activity based on determination of the daily urinary excretion rates of cortisone and cortisol.[327] In addition, neutralization of dietary acid production (decrease in renal acid excretion from ~80 to 10 mEq/day) significantly decreased urinary free-cortisol and THF excretion over 24 hours in normal humans.[244] However, reports from another group indicated that chronic metabolic acidosis did not affect cortisol homeostasis in humans[313] as analyzed by serum profile and urinary 17-OH-corticosteroid excretion rates. The reasons for this discrepancy are not clear.

Effects of Metabolic Acidosis on Renal Citrate Metabolism

The effects of metabolic acidosis on renal citrate metabolism have important clinical consequences and are, therefore, briefly discussed here. Citrate is derived from carbohydrate metabolism and contains three negatively charged carboxyl groups. Complete oxidation of citrate thus generates three HCO_3^- ions per mole and thus increased renal reabsorption and metabolism of citrate would be expected to serve a homeostatic role in the adaptation to metabolic acidosis. Citrate is freely filtered at the glomerulus and reabsorbed and metabolized almost exclusively in the proximal tubules (Fig. 59.8), with these processes determining the amount of urinary citrate excretion.[44] In metabolic acidosis, tubular reabsorption is increased and urinary excretion decreased due to both increased protonation of trivalent to divalent citrate, the substrate for the sodium/citrate cotransporter in the proximal tubule and increased expression and activity of Na^+/citrate cotransporter NaDC1.[15,191] In addition, cellular (i.e., cytoplasmic) metabolism of citrate (Fig. 59.8) is increased in the proximal tubule. Enhanced cytoplasmic metabolism in response to metabolic acidosis is mediated by a specific increase in renal ATP citrate lyase activity and expression.[251] Mitochondrial citrate metabolism is also stimulated in metabolic acidosis as shown by the increased activity of mitochondrial aconitase, the first step in mitochondrial citrate metabolism.[252] These findings are clinically important

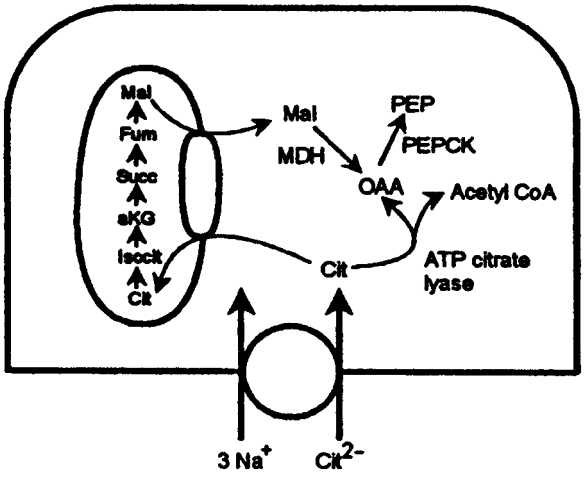

FIGURE 59.8 Citrate metabolism in the proximal tubule. *(With permission, from Alper S. Genetic diseases of acid–base transporters. Annu Rev Physiol 2002;64:899–923.)*

because of citrate's role in calcium complexation, inhibition of stone formation and prevention of nephrocalcinosis. Indeed, a high proportion of patients with nephrolithiasis have low urinary citrate levels.[269] A high-protein intake (which increases endogenous acid production) decreases urinary citrate excretion in rats by renal mechanisms described previously.[10]

Miscellaneous Clinical Effects of Metabolic Acidosis

Renal Growth

In contrast to the growth inhibitory effect in nonrenal tissue, metabolic acidosis leads to hyperplasia and hypertrophy in renal tissue with an apparent predilection for the renal tubules.[230] Interestingly, acidosis induces metabolic effects in the kidney that also contrast with its systemic consequences: renal IGF1 levels are increased and renal protein degradation is decreased.[112,136] Decreased protein degradation is a cell-cycle independent mechanism for renal hypertrophy. Whether cell-cycle dependent mechanisms (via cyclin kinases) are important in metabolic acidosis as they are in diabetic nephropathy or compensatory renal hypertrophy remains to be investigated.

Based on the hypothesis that renal hypertrophy is associated with progression of renal disease, it is possible that acidosis might accelerate the rate of decline of renal function in renal insufficiency. The following evidence from animal studies suggests that such an effect of acidosis may be present: (1) ammonia has been proposed to be responsible for tissue injury, possibly by acting as a convertase for the alternate pathway of complement activation.[266] (2) The remnant kidney model in the rat is associated with increased ammoniagenesis by residual nephrons.[233] (3) Systemic alkalinization has been shown to reduce ammoniagenesis and to mitigate proteinuria and the histological damage typically seen in this model.[267]

Acidosis-induced promotion of growth may be most relevant in polycystic kidney disease. Patients with hyperaldosteronism and potassium depletion (which leads to intracellular acidosis and stimulation of ammoniagenesis) were shown to have a greatly increased incidence of renal cysts.[353] Furthermore, in Han:SPRD rats, a rat model for polycystic kidney disease, induction of acidosis by NH_4Cl enhances, while systemic alkalinization by HCO_3^- slows the rate of cyst formation.[356] Thus, correction of acidosis may be most important in patients with polycystic kidney diseases. However, no human studies have yet been performed to evaluate the effect of complete correction of acidosis on the progressive decline in renal function both in cystic and non-cystic kidney diseases.

O_2 and CO_2 Dissociation Curves

Metabolic acidosis, as mediated by an increase in hydrogen ion concentration, shifts the hemoglobin saturation curve to the right, that is, less oxygen is bound to hemoglobin for a given PO_2. This circumstance provides for acute acidosis-enhanced oxygen release in tissues. Quantitatively, this effect is quite small; however, at least for the pH changes observed *in vivo* and can be estimated using the Bohr factor (BF):

$$BF = \Delta \log P50/\Delta pH$$

where P50 is the half-saturation PO_2, normally around 27 mm Hg (3.6 kPa). Since the Bohr factor in human blood is about 0.5, it can be calculated that a change in blood pH of 0.1 U will shift the half-saturation of hemoglobin by about 1 mm Hg. When metabolic acidosis persists beyond 6–8 hours, the dissociation curve is shifted back toward its normal position (leftward) due to the more prolonged effect of acidosis to decrease erythrocyte 2,3-diphosphoglycerate. It is not known with certainty which of these effects is predominant during sustained metabolic acidosis *in vivo*.

Hemoglobin displays a higher affinity for hydrogen ion in the reduced form (Haldane effect) and roughly half of acute buffering of an acid load is due to nonbicarbonate buffers including Hb. The decrease in oxygen saturation (or increase in reduced hemoglobin) for a given PO_2 associated with acute acidosis could therefore increase the hemoglobin buffering capacity of an acute systemic acid load and thus limit the fall in $[HCO_3^-]p$. At the same time, the Haldane effect increases the CO_2 transport capacity of blood at the low pCO_2 values of metabolic acidosis. The quantitative *in vivo* contribution of the Haldane effect to the early plasma bicarbonate response to acid loads remains to be determined.

The Trade-Off Hypothesis

As was described earlier and shown in Fig. 59.9A, normal acid–base balance is achieved and maintained when renal net acid excretion equals endogenous acid production at normal $[HCO_3^-]p$. As illustrated in Fig. 59.9B, an increase in endogenous acid production leads to renal and extrarenal cellular adaptations, ultimately increasing net acid excretion to again balance endogenous acid production. While it was demonstrated that increases in dietary-induced acid production correlate inversely and significantly with $HCO_3^-]p$ during metabolic balance studies,[214] $[HCO_3^-]p$ generally does not fall out of the wide normal range when determined in clinical practice. Thus, an ongoing acidotic process may be present albeit not recognized due to the efficient adaptation of acid excretory

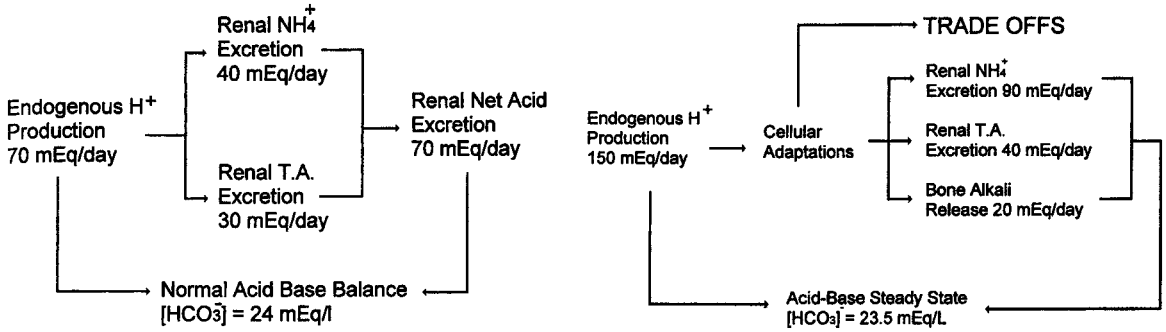

FIGURE 59.9 (A) Shows concept of acid–base balance. (B) Depicts trade-offs, that is, cellular adaptations due to increased acid production. *(With permission, from Alpern RJ, Sakhaee K. The clinical spectrum of chronic metabolic acidosis: homeostatic mechanisms produce significant morbidity. Am J Kidney Dis 1997;29:291–302.)*

mechanisms and the imperfections of routine laboratory analysis. The term eubicarbonatemic[9] metabolic acidosis (Table 59.1) circumscribes this entity. It is instructive to review, therefore, to which extent some of the metabolic and endocrine effects of metabolic acidosis discussed previously also occur during normal dietary variation of acid production and/or during physiologic declines in acid excretion such as during the aging process.[125]

Habitual ingestion of protein-rich diets has repeatedly been linked to clinical disorders, in particular nephrolithiasis, osteoporosis, and fracture incidence.[1,48,228] The potential clinical and epidemiological relevance of the trade-offs of the adaptation to increases in endogenous acid production or decreases in acid excretion (minimal metabolic acidosis) was demonstrated recently by the finding—both in postmenopausal women and young adults—that neutralizing endogenous acid-production by oral administration of $KHCO_3$ significantly decreased urinary nitrogen losses, induced positive calcium and phosphate balances by decreasing renal excretion of these ions and decreased markers of bone resorption.[124,244,321] Thus, eubicarbonatemic metabolic acidosis may be an important cause of osteoporosis, nephrolithiasis and loss of lean body mass. Therefore, although the degree of diet-dependent (and other etiologies of) eubicarbonatemic metabolic acidosis (Table 59.1) is mild as judged by the degree of perturbation of blood acid–base equilibrium, it cannot be considered mild as judged by its adverse biological consequences and may be of great epidemiological and economic impact when considered under the aspects of dietary habits and increased longevity.

TABLE 59.1 Causes of Eubicarbonatemic Metabolic Acidosis

Western diet
Age
Chronic diarrhea
Incomplete distal tubular acidosis
Mild renal insufficiency

There is a large literature on positive epidemiological associations between diets assumed to be acid-generating (prototype: Western diet rich in animal, dairy, and wheat-flour proteins) and osteoporosis, bone loss, and/or fracture rates.[165] However, an equally large literature supports beneficial effects of animal protein (acid generating) on bone, which is probably explained by the protein-induced stimulation of GH/IGF1 axis and/or stimulatory effects on intestinal calcium absorption.[166,205] Thus, evaluation of the role of diet-induced endogenous acid production on bone mineral content (osteoporosis) and fracture rates will need to be performed in a prospective, long-term clinical trial where endogenous acid production is effectively neutralized.

CLINICAL DISORDERS

Daily metabolic reactions generate and consume several thousand milliequivalents of organic acids, including lactic, pyruvic, citric, and acetoacetic acids. The metabolic conversion of organic acids to neutral products, such as glucose, consumes both the organic anion and the H^+ ion. Metabolic conversion of organic acids to H_2O and CO_2, which is exhaled, also removes both the organic anion and H^+ from body fluids. Normally, organic acid generation and consumption rates are balanced, so that acid accumulation does not occur. However, if organic acids are generated more rapidly than they are consumed, their accumulation results in metabolic acidosis. To the extent that this occurs, the accumulating H^+ decomposes HCO_3^-, while the concentration of organic anions increases. For

example, when lactic acid accumulates, the products are:

$$\text{H lactate} + HCO_3^-$$
$$\text{lactate}^- + H_2CO_3$$
$$H_2O + CO_2$$

The increase in [lactate$^-$] and decrease in [HCO_3^-] are reciprocal. One may assume that ECF lactate$^-$ replaces HCO_3^-. The accumulated lactate represents decomposed HCO_3^-. In addition, because lactate can be metabolized and thereby regenerate HCO_3^-, the accumulated lactate also represents potential HCO_3^-. When lactate$^-$ is converted to glucose or oxidized to H_2O and CO_2, lactic acid is removed from the ECF and HCO_3^- is regenerated, as follows:

The generation of HCO_3^- from such organic anions does not require renal intervention. Contrast these events with the accumulation of an inorganic acid such as HCl:

In this case, Cl$^-$ replaces HCO_3^- in the ECF and also represents decomposed HCO_3^-—. However, unlike lactate$^-$, Cl$^-$ cannot be metabolized. Regeneration of HCO_3^- must be accomplished by the kidney, which filters NaCl, reabsorbs the Na^+, and excretes H^+. This results in increased net acid excretion and HCO_3^- regeneration.

Infused sodium salts of organic acids such as Na lactate are converted to $NaHCO_3$ when the anion is metabolized to neutral products or oxidized to H_2O and CO_2. Metabolism of the organic anion, such as lactate, is accompanied by H^+, which is derived from plasma water, as illustrated here:

Therefore, metabolism of the sodium salts of lactate, citrate, acetate, and other organic anions generates 1 mole of $NaHCO_3$ for each mole of carboxylate.

Anion Gap Acidosis

The ionic profile of normal serum is depicted in Fig. 59.10. The law of electroneutrality states that the quantity of positive charges in any solution must equal the quantity of negative charges. If every ion present in serum is measured in charge units such as metabolic equivalents per liter, then electroneutrality is found. However, if only the quantitatively most important electrolytes—Na^+, Cl$^-$, and HCO_3^- are considered, then [Na^+]p normally exceeds the sum of [Cl$^-$]p + [HCO_3^-]p. This difference, [Na^+] − ([Cl$^-$] + [HCO_3^-]), is the anion gap. The anion gap calculated in this manner is normally 12 + 4 mEq/liter (+ 2 standard deviations). Note that [K^+]p is not included in the calculation due to its relatively minor quantitative contribution.

The anion gap does not measure any specific ionic constituent. It includes the net unmeasured negative

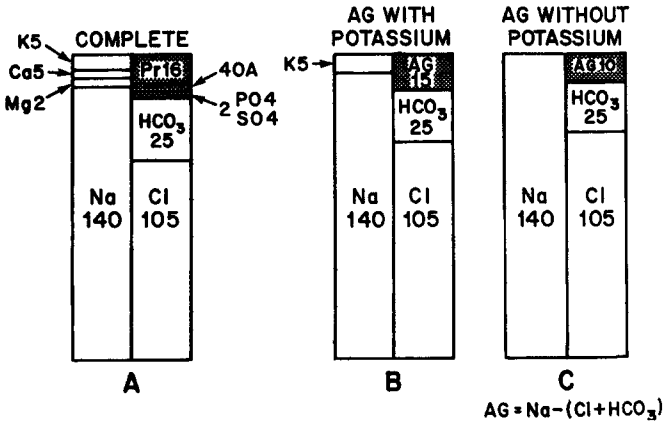

FIGURE 59.10 Ionic anatomy of serum. Normal serum electrolyte pattern and the calculation of the anion gap (AG). Numbers refer to serum concentration in mEq/liter. OA, organic acids, Pr, proteins. *(Adapted from Field M, Block MB, Levin R, Rall DP. Significance of blood lactate elevations among patients with acute leukemia and other nephroplastic proliferative disorders. Am J Med 1966;40:528–547.)*

protein charge (primarily from albumin), inorganic phosphate, sulfate, organic anions, and other ions less unmeasured cations such as potassium, calcium, and magnesium. The anion gap is used to classify the metabolic acidoses and is also a clue to the presence of various mixed acid–base disorders. These aspects of anion gap interpretation are reviewed in the following sections.

Occasionally, the anion gap is abnormally small, or even negative. This may be due to random measurement errors. If a low anion gap exists, each electrolyte measurement should be reconfirmed. Systematic errors that depress the [Na^+]p (e.g., pseudohyponatremia due to hyperlipidemia or hyperproteinemia) or increase the [Cl$^-$]p (e.g., pseudohyperchloremia due to bromism) produce reproducible reductions in the anion gap. Increased concentrations of cations other than Na^+ (e.g., abnormal cationic myeloma proteins, extreme hypermagnesemia, lithium poisoning) also depress the anion gap because [Cl$^-$]p increases without a proportionate change in [Na^+]. Table 59.2 lists the causes of a reduced or negative anion gap.

H^+, which accumulates in the ECF, is primarily buffered by the following reaction:

$$H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow CO_2 + H_2O$$

To the extent that H^+ accumulates, a nearly equimolar decrease in [HCO_3^-]p occurs. If HA, a strong acid, accumulates in the ECF, then the reduction in [HCO_3^-]p is accompanied by a similar increase in [A^-]. The net effect of HA addition to the ECF is the replacement of HCO_3^- by A^-. If HA represents HCl, then the decrease

Extreme hypercalcemia, hypermagnesemia, lithium intoxication

in $[HCO_3^-]p$ is counterbalanced by a similar increase in $[Cl^-]p$, while the anion gap remains relatively stable. (The anion gap actually decreases slightly, because a decrease in pH increases H^+ binding by proteins. This reduces the net negative charge on proteins, principally albumin.) Alternatively, if HA is any non-HCl acid (i.e., lactic, acetoacetic, phosphoric, sulfuric), then HA accumulation in the ECF decreases the $[HCO_3^-]p$ and reciprocally increases the anion gap. Figures 59.11 and 59.12 illustrate the development of hyperchloremic and anion gap metabolic acidoses. The causes of hyperchloremic and anion gap metabolic acidoses are listed in Table 59.3.

Occasional patients develop mixed anion gap and hyperchloremic acidosis. Such hybrid metabolic acidoses may occur when early renal failure progresses toward overt uremia.[372] Hyperchloremic metabolic acidosis occurs commonly with early renal disease as a result of inadequate ammonia synthesis and excretion. At this time, the GFR is still adequate to excrete the normal exogenous and endogenous anion load (phosphate, sulfate, etc.). The hyperchloremic acidosis that develops in this setting is a form of type IV renal tubular acidosis. Later, when renal function deteriorates, anion retention develops and typical uremic–anion gap acidosis evolves. In the intervening period, mixed hyperchloremic–anion gap acidosis may exist as shown in Fig. 59.13.[374]

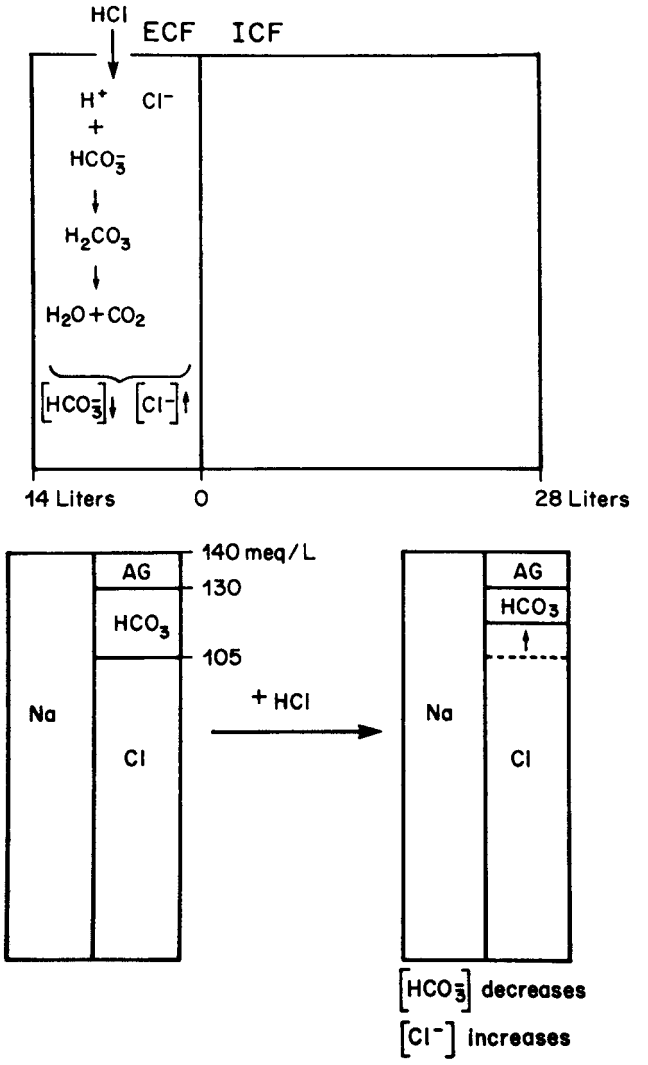

FIGURE 59.11 The addition of 10 mmol/liter of HCl to ECF results in a proportionate reduction in $[HCO_3^-]s$ and increase in $[Cl^-]$. Hyperchloremic acidosis develops while the anion gap remains unchanged.

Ketoacidosis

Ketoacidosis is usually due to an accumulation of acetoacetic acid and beta-OH butyric acid in the ECF. Mild ketoacidosis develops in normal individuals during starvation. More severe fasting ketoacidosis may develop in chronic alcoholics, pregnant women, and young children. The most common cause of severe ketoacidosis is untreated, or inadequately treated, insulin-dependent diabetes mellitus. Several inherited enzyme disorders also generate severe ketoacidosis and lactic acidosis during a fast. They include glucose-6-phosphatase deficiency (von Gierke disease), and fructose-1,6-bisphosphatase deficiency. Ketoacids other than acetoacetic acid and beta-butyric acid can accumulate in children with enzyme defects that produce branched chain organic acidurias and disorders of propionate metabolism.

Ketogenesis

Figures 59.14 and 59.15 illustrate the endocrine regulation of fatty acid release from adipose triglyceride stores and fatty acid metabolism within hepatic cells.

Hormone-sensitive lipase in adipose tissue is normally inhibited by relatively low levels of insulin.

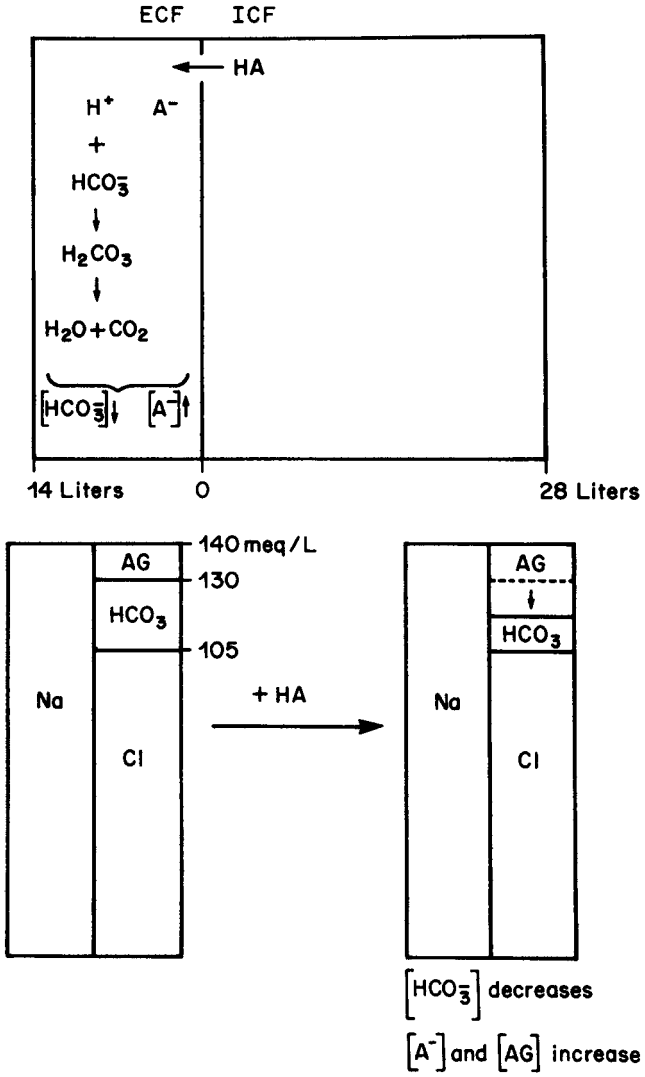

FIGURE 59.12 The addition of 10 mmol/liter of a strong non-HCl acid (HA) (i.e., lactic acid, ketoacids) reduces the [HCO_3^-] and proportionately increases [A^-]. This increases the anion gap while the [Cl^-]s concentration remains relatively stable.

TABLE 59.3 Causes of Hyperchloremic and Anion Gap Metabolic Acidosis

Elevated anion gap acidosis
Ketoacidosis
Lactic acidosis
Methanol poisoning
Ethylene glycol poisoning
Paraldehyde poisoning
Salicylate poisoning
Uremia
Congenital organic acidosis
D-lactic acidosis
Hyperchloremic (normal anion gap) acidoses
Renal
Hypokalemia: proximal tubular acidosis (RTA II), classic, distal tubular acidosis (RTA I), mixed type RTA (RTA III)
Hyperkalemia: generalized distal tubular acidosis (RTA IV)—mineralocorticoid deficiency, mineralocorticoid resistance, tubular voltage defects
Recovery from high anion gap acidosis (renal loss of "potential" HCO_3^-)
Gastrointestinal
Diarrhea
Pancreatic fistula (pancreas transplantation)
Ingestion of HCO_3^--binding salts or resins (CaCl2, cholestyramine)
Mixed gastrointestinal-renal
Uretorosigmoidostomy
Rectal baldder
Ileal loop bladder
Ureterointestinal segments
Other
Posthypocapnia
HCl or HCl precursor infusion or ingestion
Dilution acidosis

Catecholamine, cortisol, growth hormone, and glucagon activate this enzyme (Fig. 59.14). Fasting progressively reduces insulin and elevates the abovementioned counter-regulatory hormones. This triggers lipolysis. Fatty acids released from the triglycerides in adipose tissue flow to the liver where they may potentially enter several metabolic pathways (Fig. 59.15). One involves their combination with glycerol phosphate to reform triglycerides and other lipids. Alternatively, they can enter mitochondria and undergo beta-oxidation to provide energy. This mitochondrial entry step is not passive, but rather is a tightly regulated, carrier-mediated process. Within hepatocyte cytoplasm, long chain fatty acids must first be activated by enzymatic conversion to their acyl-CoA derivatives. Then carnitine palmitoyl transferase I (CPT I), an enzyme associated with the mitochondrial outer membrane, links the acyl-CoA derivatives to carnitine. Now the carnitine–fatty acid complex can cross the inner mitochondrial membrane via a specific acyl-carnitine translocase. At the inner surface of the inner membrane, carnitine is removed by CPT II, reforming the acyl-CoA activated form of the fatty acid. The released carnitine shuttles back through the membrane to be used again as a fatty acid carrier. Within mitochondria, the fatty acyl-CoA undergoes beta-oxidation, which sequentially splits two carbon acetyl-CoA fragments from the long fatty acid molecule.

Two major catabolic pathways generate acetyl-CoA in mitochondria: (1) pyruvate oxidation via the pyruvate dehydrogenase reaction (see Lactic Acidosis section) (Fig. 59.17), and (2) fatty acid oxidation via beta-oxidation. Acetyl-CoA can be further oxidized by the Krebs cycle to yield CO_2 and energy. Acetyl-CoA can also exit from the mitochondria to be used in synthetic reactions (Fig. 59.15).

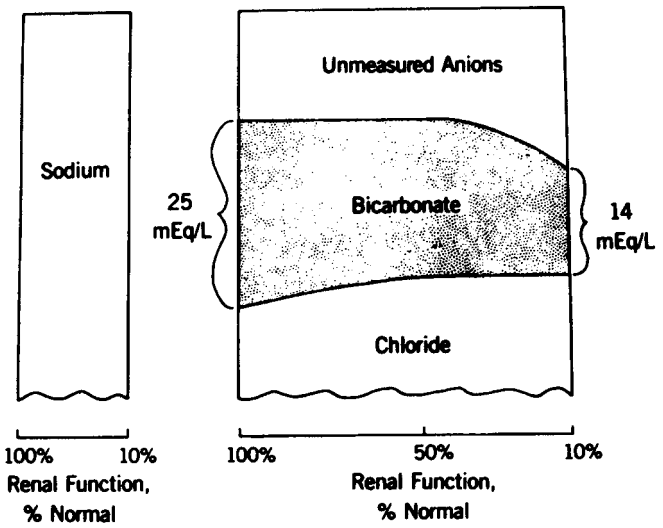

FIGURE 59.13 Early renal failure impairs NH_4^+ excretion before anion retention develops. This results in hyperchloremic metabolic acidosis. As renal failure progresses and the GFR falls, anion retention eventuates. Uremic-anion gap metabolic acidosis will develop. Between these extremes, combined hyperchloremic and anion gap metabolic acidosis is a common finding. *(From Weinstein B, Irreverre I, Watkin DM. Lung carcinoma, hypouricemia and aminoaciduria. Am J Med 1965;39:520–526, with permission.)*

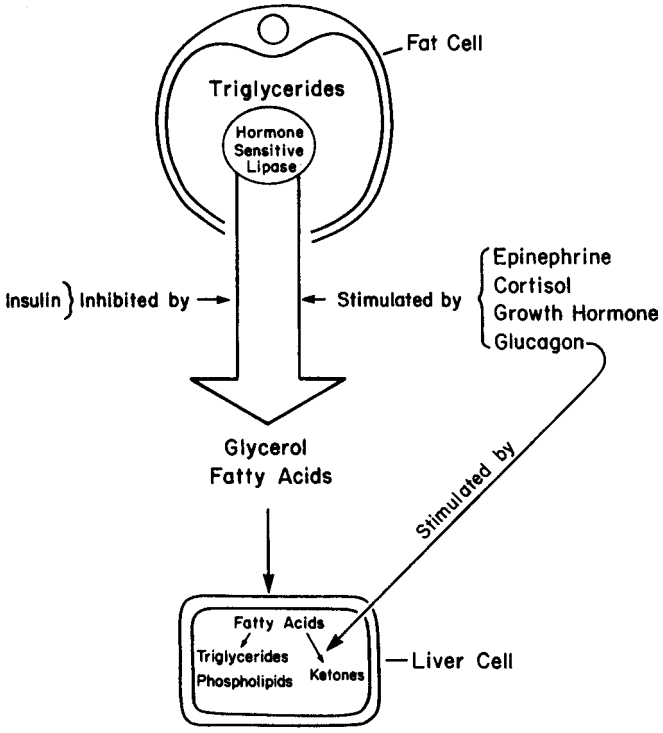

FIGURE 59.14 The release of fatty acids from adipose triglyceride stores under the control of hormone-sensitive lipase.

When the concentration of acetyl-CoA within mitochondria increases markedly, the oxidative capacity of the Krebs cycle is exceeded and ketoacids are generated. Two molecules of acetyl-CoA first condense to form acetoacetyl-CoA. This is then converted into acetoacetic acid via the 3-hydroxy 3-methylglutaryl-CoA pathway.

The low insulin and high glucagon levels produced by a fast create the conditions required for ketogenesis. Adipose tissue hormone-sensitive lipase is activated, releasing fatty acids that are delivered to the liver (Fig. 59.14). Within hepatocytes, the fatty acids are converted to acyl-CoA derivatives and then flow into the mitochondria via the CPT and translocase systems. CPT I is deinhibited by the low cytoplasmic malonyl-CoA levels. Consequently, transport of fatty acyl CoA across the mitochondrial membranes is greatly enhanced with subsequent generation of large quantities of acetyl-CoA via beta-oxidation. Malonyl-CoA levels are low, because acetyl-CoA carboxylase, the enzyme responsible for its production, is inhibited when insulin levels are reduced and glucagon levels are increased.

Acetyl-CoA oxidation by the Krebs cycle may not keep pace with the production rate, so acetyl-CoA accumulates. Relatively low Krebs cycle oxidation is in part due to low oxaloacetate levels. Acetyl-CoA must combine with oxaloacetate to form citrate in order to enter the Krebs cycle. Fasting stimulates oxaloacetate transport out of mitochondria to be converted into glucose. Low mitochondrial oxaloacetate levels limit acetyl-CoA oxidation by the Krebs cycle and acetyl-CoA levels to increase. As its concentration increases, it is converted to acetoacetic acid.

A feed-back mechanism for the regulation of ketoacid production by hydrogen ion concentration is suggested by the observation that in circumstances were ketoacid production is stimulated (fasting obese subjects), acid feeding inhibits, while alkali feeding stimulates ketoacid production. Decreased availability of free fatty acids is an important factor in mediating the inhibition of ketoacid production in response to a decrease in pH.[170] The clinical importance of this apparent feedback mechanism remains to be demonstrated.

The acetoacetic acid that is produced during ketogenesis can be converted to beta-OH butyric acid or to acetone (Fig. 59.16). Acetoacetic acid decomposes to acetone nonenzymatically. Acetoacetic acid and beta-OH butyric acid are interconverted by beta-OH butyrate dehydrogenase, which requires the NAD^+/NADH couple as cosubstrates. At equilibrium, the beta-OH butyrate/acetoacetate ratio is normally about 2:1. However, this ratio varies with the mitochondrial $NADH/NAD^+$ ratio. Both acetoacetic acid and beta-OH butyric acid are almost completely dissociated at

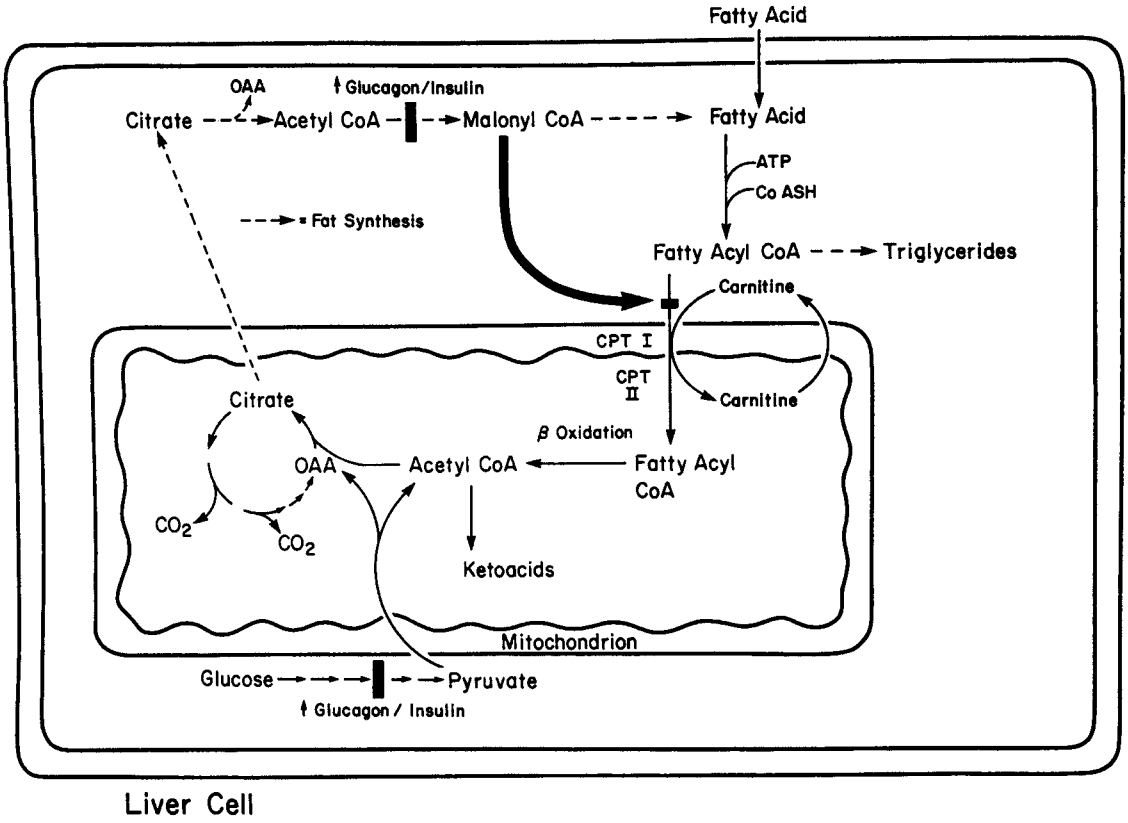

FIGURE 59.15 Fat metabolism in hepatic parenchymal cells. The oxidation of long-chain fatty acids requires that they first be activated in cytoplasm (converted to acyl-CoA derivatives) and then transported into mitochondria. Mitochondria entry is controlled at the level of carnitine palmitoyl transferase I (CPT I). This enzyme is inhibited by malonyl-CoA. When appropriately stimulated, liver cells can also synthesize fatty acids from acetyl-CoA. The fat synthetic pathway is indicated by dashed arrows. These synthetic and oxidative pathways are under the control of insulin and glucagon. OAA, oxaloacetate.

physiologic pH (pK = 3.6 and 4.4, respectively). To the extent that these acids accumulate in ECF, the $[HCO_3^-]$p falls and the anion gap increases. The anion gap increase represents the sum of the beta-OH butyrate and acetoacetate concentrations. Although beta-OH butyrate usually predominates (2:1), the severity of the acidosis is independent of the specific accumulating acid. However, these two acids have different chemical characteristics that affect diagnostic studies. The nitroprusside test for ketones and ketoacids detects acetoacetate (usually about 30% of the plasma ketoacids) but not beta-OH butyrate. If the $NADH/NAD^+$ ratio increases, acetoacetate is shifted to beta-OH butyrate (Fig. 59.16). Under these conditions the nitroprusside reaction decreases, or even becomes negative, despite significant ketoacidosis. Clinically, the nitroprusside reaction can be negative in severe diabetic ketoacidosis probably due to coexisting lactic acidosis (which increases the $NADH/NAD^+$ redox ratio) due to volume depletion, vomiting, and poor hemodynamics. Upon institution of treatment (correction of volume depletion, insulin administration), $NADH/NAD^+$ ratio decreases and the nitroprusside reaction becomes positive. This scenario is the predictable consequence of successful treatment and does not reflect worsening ketoacidosis. Alcoholic ketoacidosis may also produce a high $NADH/NAD^+$ ratio, frequently resulting in a weak nitroprusside reaction.[159] Thus, while the nitroprusside test is a very useful diagnostic tool in patients with ketoacidosis, redox state alterations reduce its value as an index of therapeutic response. Other parameters, such as the clinical status of the patient, the arterial pH, the plasma $[HCO_3^-]$, and changes in the anion gap, should be used to monitor therapy.

Acetone, nonenzymatically derived from acetoacetic acid, is a ketone but not an acid and, therefore, does not reduce the $[HCO_3^-]$p or increase the anion gap. Contrary to current beliefs in most textbooks, acetone does not react with nitroprusside. Acetone is volatile and primarily excreted by the lungs. Small quantities of acetone are also excreted by the kidneys and converted into glucose. Serum acetone levels may increase markedly when severe ketoacidosis develops and then

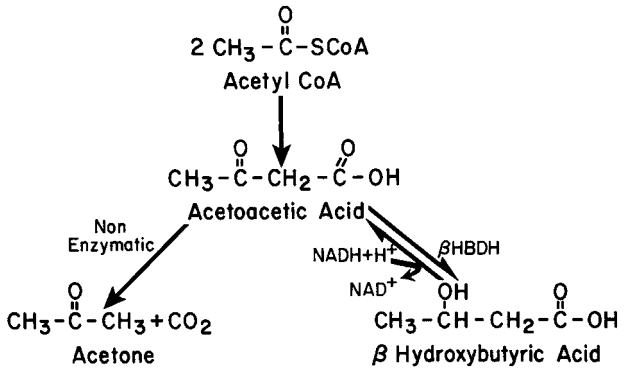

FIGURE 59.16 Ketone body metabolism. The interrelationship among acetoacetic acid, alpha-hydroxybutyric acid (not a true ketoacid), and acetone is shown. The arrow from acetyl-CoA to acetoacetic acid encompasses the intermediate formation of acetoacetic-CoA, and beta-OH alpha-methyl-glutaryl-CoA. β HBDH, beta-hydroxybutyrate dehydrogenase.

persist for several days after resolution of the ketoacidosis.

Isopropyl, or rubbing alcohol, is rapidly metabolized to acetone. Therefore isopropyl alcohol poisoning generates an acetone breath odor, but not ketoacidosis and no positive nitroprusside reaction.[17] The $[HCO_3^-]p$ and anion gap remain normal unless other complications ensue. High acetone levels will raise the plasma osmolality and lead to an osmolar gap.

Clinical Syndromes of Ketoacidosis

Starvation Ketosis

Starvation will generate modest ketoacidosis in normal individuals.[282] During the initial 10–14 hours of fasting, glucose levels are maintained primarily by glycogenolysis. After glycogen stores are depleted, gluconeogenesis becomes the major source of glucose. Hepatic energy requirements are maintained by the oxidation of fatty acids. Accelerated lipolysis and hepatic fatty acid oxidation lead to ketoacidosis, as discussed previously. After 1–2 weeks, the blood ketoacid concentration stabilizes at about 5–6 mEq/liter and the $[HCO_3^-]p$ falls to 18–20 mEq/liter. More fulminant ketoacidosis is aborted as a result of ketoacid-induced release of insulin from pancreatic islet cells.[237] Despite continued starvation, the resultant increase in insulin levels blunts lipolysis. With continued starvation, glucagon and catecholamine levels also decrease toward the normal range and this also slows ketoacid generation. However, pregnant women and young children are particularly vulnerable to more severe ketoacidosis during starvation. In such patients, oral refeeding is frequently impossible due to anorexia, vomiting, and abdominal pain.

Diabetic Ketoacidosis

Diabetic ketoacidosis is usually the result of absolute, or relative, insulin deficiency combined with high glucagon levels. It may be the presenting clinical manifestation of a previously undiagnosed diabetic patient. More often, ketoacidosis occurs in treated diabetic patients because the established insulin program is discontinued or because a superimposed illness, or stress, increases their insulin requirements. Infection, trauma, surgery, and emotional stress activate counter-regulatory hormones that oppose the action of insulin and increase insulin requirements.

Reduced insulin activity, combined with elevated glucagon levels, stimulates glycogenolysis, gluconeogenesis, lipolysis, and fatty acid oxidation. Simultaneously, peripheral glucose utilization falls. Accelerated glucose generation combines with decreased utilization to raise glucose levels. Hepatic ketoacid production exceeds CNS and peripheral ketoacid utilization so that ketoacidosis ensues. Renal Na^+, K^+, and water losses occur as a result of glucose-driven solute diuresis as well as the excretion of large quantities of ketosalts. This leads to volume contraction and renal insufficiency. Nausea, anorexia, and vomiting contribute to the volume deficit and complicate the acid–base abnormalities.

Alcoholic Ketoacidosis

Alcoholic ketoacidosis develops in susceptible individuals who chronically abuse alcohol.[253] Typically, a period of heavy alcohol ingestion is followed by a period of nausea, vomiting, and starvation and then the development of ketoacidosis. Alcoholic ketoacidosis may represent an extreme form of starvation ketosis. However, in these subjects, starvation combines with alcohol withdrawal and volume depletion to elevate markedly counter-regulatory hormones, especially catecholamines. This further accelerates lipolysis and markedly increases fatty acid levels. The fatty acids are oxidized by the liver, which is metabolically primed by low insulin and high glucagon levels.

This form of ketoacidosis is often associated with lactic acidosis and, sometimes, hypoglycemia. Lactic acidosis is in part due to volume depletion resulting from vomiting and decreased oral intake. In addition, ethanol oxidation increases the $NADH/NAD^+$ ratio, which exacerbates lactic acidosis. The high $NADH/NAD^+$ ratio also drives the acetoacetate toward beta-OH butyrate and reduces the nitroprusside reaction.

Hypoglycemia may be the result of glycogen depletion, starvation, and impaired gluconeogenesis. Since the enzymatic steps governing the conversion of non-carbohydrate precursors (e.g., amino acids) to glucose are NAD^+ dependent, the increase in the NADH/

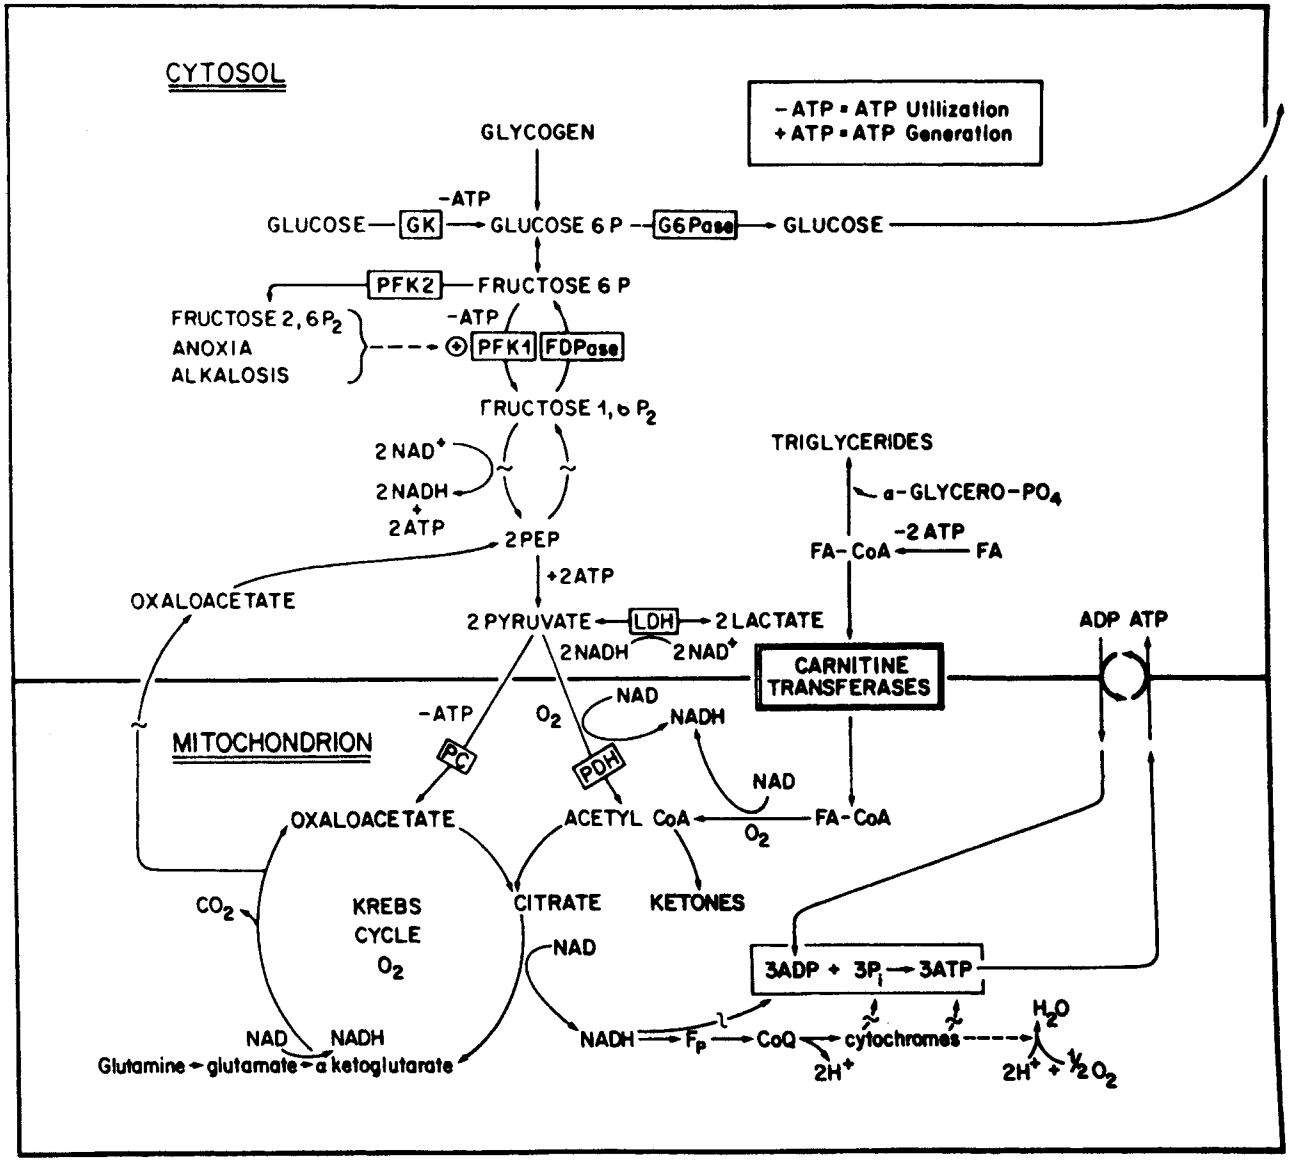

FIGURE 59.17 The metabolic pathways that generate pyruvate and lactate and the pathways that consume pyruvate are summarized. FBPase, fructose bisphosphatase; G6Pase, glucose-6-phosphatase; GK, glucokinase; LDH, lactate dehydrogenase; PC, pyruvate carboxylase; PDH, pyruvate dehydrogenase; PFK, phosphofructokinase.

NAD^+ ratio sharply reduces gluconeogenesis.[236] When this occurs in a setting of hepatic glycogen depletion owing to starvation, hypoglycemia may result.

Alcoholic ketolactic acidosis can generally be rapidly reversed by the intravenous infusion of glucose and saline. Volume expansion improves the circulatory status and reduces catecholamine levels, reversing two factors contributing to lactic acidosis. The glucose infusion corrects hypoglycemia (if present) and increases the insulin/glucagon ratio, thereby suppressing ketoacid production and permitting resolution of the ketoacidosis. Exogenous insulin is rarely necessary unless patients have coexistent diabetes mellitus.

Inborn Errors of Metabolism

Glucose-6-phosphatase and fructose-1,6-bisphosphatase deficiency predispose to both lactic and ketoacidosis. The pathogenesis of these mixed organic acidoses is explained in the next section.

Other rare enzyme disorders also result in ketoacidosis. In some, the accumulating ketoacids are acetoacetic acid and beta-OH butyric acid. However, a variety of other unusual ketoacids can also accumulate.

Lactic Acidosis

Pyruvate, Lactate, and Energy Metabolism Pyruvic and lactic acid metabolism are shown in Fig. 59.17. The

oxidation of glucose and, to a much smaller degree, the deamination of alanine, generates pyruvate, which has four metabolic fates: (1) enter mitochondria and be oxidized to acetyl-CoA via pyruvate dehydrogenase. (2) Enter mitochondria and be carboxylated to form oxaloacetate via pyruvate carboxylase. (3) Remain in cytosol and be aminated to alanine. (4) Remain in cytosol and be reduced to lactic acid.

In most cells, the major metabolic pathway for pyruvate is mitochondrial oxidation to acetyl-CoA. Generally, the rate of mitochondrial pyruvate uptake and oxidation matches the pyruvate generation rate and the cytosol pyruvate concentration is stabilized. Should mitochondrial uptake fail to increase in response to accelerated generation, the pyruvate concentration increases. Decreased mitochondrial uptake, during periods of rapid generation, will increase the pyruvate concentration sharply.

The metabolic–hormonal set of the cell determines how pyruvate, acetyl-CoA, and oxaloacetate are used. In the fed state, energy-yielding substrate is abundant. Exogenous carbohydrates are partially oxidized and partially used to synthesize glycogen and fat. In the fasted state, adipose tissue releases fatty acids, which are oxidized; oxaloacetate and other protein-derived substrates are used to synthesize glucose.

Krebs cycle oxidation of acetyl-CoA transfers electrons and protons, representing chemical potential energy, from this compound to NAD^+, forming $NADH + H^+$. The energy is subsequently released in small steps as the electrons flow down the mitochondrial respiratory (electron transport) chain from the $NADH + H^+$, eventually reduce to oxygen, and form H_2O (Fig. 59.17, bottom at right).

Lactate–Pyruvate Relationship

Lactate dehydrogenase (LDH) catalyzes the interconversion of pyruvic and lactic acids. This reaction requires the cosubstrate $NADH/NAD^+$ couple (Fig. 59.17). A dynamic equilibrium exists between these compounds. Under normal conditions, this reaction is poised toward the left, producing a lactate/pyruvate ratio of about 10:1. At equilibrium,

$$\frac{(\text{pyruvate})(\text{NADH})(H^+)}{\text{lactate}} = \frac{(\text{lactate})(NAD^+)}{[\text{pyruvate}][\text{NADH}][H^+]/[NAD^+]}$$

or

$$\text{lactate} = K\,[\text{pyruvate}][\text{NADH}][H^+]/[NAD^+]$$

where K is the equilibrium constant for the LDH reaction.

The cytosolic lactate concentration is determined by the cytosolic pyruvate concentration, the $NADH/NAD^+$ (redox) ratio, and the cell pH. It is evident that lactate concentrations can increase for three reasons: (1) lactate may increase as a consequence of an increased pyruvate concentration. The lactate/pyruvate ratio would remain about 10:1. (2) Lactate may increase due to a high $NADH/NAD^+$ ratio; the lactate/pyruvate ratio will increase and can exceed 40:1. (3) Lactate may increase as a result of a combined increase of pyruvate concentration and the $NADH/NAD^+$ ratio. This is the usual finding in patients with severe lactic acidosis.

When the $NADH/NAD^+$ or redox ratio and the pyruvate concentration increase together, then lactate levels rise markedly. Huckabee[175] suggested the separation of clinical lactic acidoses into those with normal and those with elevated $NADH/NAD^+$ ratios (as reflected by the lactate/pyruvate ratio) and proposed the concept of "excess lactate." This represents the component of elevated lactate not directly attributed to increased pyruvate. Excess lactate is due to a $NADH/NAD^+$, or redox, shift. Clinically significant lactic acidosis is always associated with a redox shift and excess lactate. Pyruvate concentrations are not routinely measured; however, a redox shift (increased $NADH/NAD^+$ ratio and a lactate/pyruvate ratio greater than 10:1) almost always exists when the blood lactate concentration exceeds 5 mEq/liter. Therefore, this concept of "excess lactate" has been of little clinical use, but it might be useful in conditions like respiratory alkalosis where lactate may be increased separating this entity from incipient lactic acidosis.

Normal Lactate Metabolism

Under steady-state conditions, lactic acid generation and utilization rates are perfectly matched. Tissues that normally release relevant amounts of lactic acid are the skin, brain, exercising muscle, renal medulla, intestine, and red blood cells. Lactic acid is normally taken up and metabolized by the liver.[78] The kidneys also metabolize small amounts of lactic acid.[386] Lactic acid produced in peripheral tissues can be converted back to glucose up by the liver (Cori-cycle). The normal rate of lactic acid generation and utilization is about 15–20 mEq/kg/day (1000–1400 mEq/day). However, these rates can increase markedly. A change in lactate production is usually matched by a parallel change in utilization. The normal steady-state plasma lactate concentration is 1–2 mEq/liter.

When lactate uptake falls behind production, lactate levels increase. Strenuous exercise accelerates muscle lactate production and simultaneously decreases hepatic perfusion. Hepatic lactate uptake lags behind production and lactate levels increase as much as 10–15 mEq/liter. The concentration of serum HCO_3^- falls reciprocally. During postexercise recovery, lactate levels gradually decline as a result of slower production and improved hepatic uptake.[52]

An apparent negative feedback of systemic proton concentration similar to the one described for ketoacid

production has also been demonstrated for lactic acid production.[171] The quantitative importance of this effect in clinical acid–base disturbances is unknown, however.

Ischemia and Lactic Acidosis

Ischemia simultaneously accelerates lactate production and decreases lactate utilization. The final physiologic proton acceptor is oxygen and oxygen deficits impair the oxidation of NADH to NAD^+. NADH accumulates and the $NADH/NAD^+$ ratio increases. A second consequence of tissue oxygen deficits is the failure of oxidative phosphorylation. The energy required to drive the reaction $ADP + P_i - ATP$ is derived from the transfer of electrons and protons from NADH down the electron transport chain to oxygen. If this process is blocked, ATP falls and ADP increases. Therefore oxygen deficiency will generate high $NADH/NAD^+$ and high ADP/ATP ratios.

Oxygen deficiency will also increase the pyruvate concentration. This is due to reduced pyruvate uptake combined with accelerated pyruvate production. Mitochondrial pyruvate utilization requires intact oxidative metabolism. Pyruvate oxidation to acetyl-CoA (via pyruvate dehydrogenase [PDH]) requires NAD^+. Pyruvate carboxylation to oxaloacetate (via pyruvate carboxylase [PC]) requires ATP. Therefore mitochondrial hypoxia decreases pyruvate flux through both reactions and mitochondrial pyruvate uptake decreases. Energy (ATP)-depleted cells compensate by accelerating anaerobic glycolysis. The conversion of glucose into pyruvic and lactic acids is primarily controlled by the rate-limiting enzyme phosphofructokinase-1 (PFK-1). The activity of this allosteric enzyme is increased by hypoxia and energy depletion. ATP inhibits the enzyme while the ATP breakdown products ADP, AMP, and inorganic phosphate activate it. This enzyme also is activated by an alkaline pH and by the regulatory intermediate, fructose-2,6-bisphosphate. Phosphofructokinase-1 [PFK-1] irreversibly phosphorylates fructose-6-phosphate to fructose-1,6-bisphosphate. The enzyme is activated by AMP, ADP, and phosphate, and inhibited by ATP. The glucose regulatory hormones, insulin and glucagon, also regulate the activity of this enzyme. They act through the metabolic intermediate, fructose-2,6-bisphosphate, which is also derived from fructose-6-phosphate. The enzyme phosphofructokinase-2 [PFK-2] converts fructose-6-phosphate into fructose-2,6-bisphosphate. Fructose-2,6-bisphosphate exerts a strong positive effect on PFK-1. Fructose-2,6-bisphosphate levels are increased by insulin, stimulating glycolysis, and decreased by glucagon, inhibiting glycolysis. (Hypoxia and ischemia probably do not directly affect fructose-2,6-bisphosphate levels.) Acceleration of anaerobic glycolysis by ischemia is termed the Pasteur effect.

Thus, ischemia simultaneously accelerates glycolysis, increasing the rate of pyruvate generation, and slows mitochondrial pyruvate uptake. The elevated $NADH/NAD^+$ ratio produced by ischemia drives pyruvate to lactate. Therefore lactate levels increase sharply because high pyruvate levels are combined with a high $NADH/NAD^+$ ratio.

Clinical Syndromes of Lactic Acidosis

Table 59.4 lists the major clinical syndromes associated with lactic acidosis. Most commonly, lactic acidosis results when inadequate oxygen is supplied to a large mass of tissue. Circulatory failure characteristically produces lactic acidosis. Generalized underperfusion triggers the metabolic cascade described previously. Major sources of lactate are skeletal muscle and the intestinal tract. In acute lung injury such as shock lung or the adult respiratory distress syndrome, the lung can also become a major source of lactate. Circulatory failure also reduces hepatic perfusion, superimposing diminished lactate uptake on accelerated production. Plasma lactate concentrations reflect the severity of the process and may be a useful prognostic indicator.[72]

Severe acute arterial hypoxemia, in the absence of decreased perfusion, can generate lactic acidosis.[175] However, this rarely occurs with chronic hypoxemia because multiple compensatory mechanisms generally maintain tissue oxygenation. Increased cardiac output, polycythemia, and a decreased hemoglobin–oxygen affinity, owing to high red cell 2,3-diphosphoglyceric acid levels, maintain tissue oxygen delivery. Therefore, patients with uncomplicated chronic obstructive lung disease rarely develop lactic acidosis despite severe hypoxemia. When lactic acidosis develops in such patients it is usually the result of a superimposed process such as hypotension, sepsis, or superimposed acute hypoxia.

Carbon monoxide poisoning frequently produces lactic acidosis.[56] Carbon monoxide binds to hemoglobin more avidly than oxygen, reducing hemoglobin's oxygen-carrying capacity. In addition, the carbon monoxide–hemoglobin complex shifts the oxygen–hemoglobin dissociation relationship so that hemoglobin's affinity for oxygen increases. This reduces oxygen release to tissues. Hence less oxygen is transported to tissues and less is released. Furthermore, cardiac output, which is usually increased by acute hypoxia, does not generally increase in patients with

carbon monoxide poisoning.[56] Oxygen chemoreceptors, responsible for the afferent limb of this response, respond primarily to arterial PO_2, and the PO_2 does not fall with carbon monoxide poisoning. The displaced oxygen-carrying capacity, left shift of the oxygen–hemoglobin dissociation curve, and deficient cardiovascular response sharply reduce tissue oxygenation. Finally, carbon monoxide binds directly to the electron transport molecule cytochrome a3 and depresses oxidative phosphorylation and mitochondrial respiration. The net result is accelerated lactic acid production and lactic acidosis.

Severe anemia, especially when due to iron deficiency or methemoglobinemia, may trigger lactic acidosis.[328] Anemia directly reduces the oxygen-carrying capacity. In addition, iron is a critical constituent of several electron carriers in the respiratory chain and severe deficiency can depress oxidative metabolism.[117]

Poisons can block oxygen uptake by mitochondria despite normal oxygen delivery. Cyanide is a compound that binds to cytochromes a and a3, blocking the flow of electrons to oxygen. ATP generation falls and the oxidation of NADH to NAD^+ decreases, resulting in lactic acidosis.[155] The arterial–venous O_2 gradient across vascular beds decreases as a result of depressed oxygen uptake. Iatrogenic cyanide poisoning can occur when patients are exposed to nitroprusside for prolonged periods of time. Nitroprusside is metabolized to cyanide, which is then converted to thiocyanate, a less toxic molecule that is excreted by the kidneys. However, impaired renal and hepatic function can result in cyanide poisoning.[184]

2,4-Dinitrophenol (used in manufacturing of dyes, as wood preservative, insecticide or as a reagent) is a compound that poisons mitochondria via another mechanism.[254] This agent uncouples oxidative phosphorylation. Uncouplers do not block the oxidation of NADH to NAD^+, nor do they prevent the flow of protons and electrons to oxygen. However, they separate these energy-releasing reactions from the phosphorylation of ADP to ATP. NADH oxidation, uncoupled from ATP generation, becomes unregulated and rapid. Chemical energy is converted into heat and calories are burned. Similar mitochondrial uncouplers have been used as weight-reducing agents but they can produce life-threatening lactic acidosis.

Many congenital mitochondrial enzyme abnormalities can affect lactate metabolism. Various components of complex enzyme systems such as pyruvate carboxylase, pyruvate dehydrogenase, and the cytochrome electron transport system can be affected. Severe inherited disorders of this type are rapidly fatal. More subtle defects, compatible with life, result in chronic lactic acidosis. Affected individuals typically develop worse acidosis during exercise, when the metabolic load delivered to these enzyme systems is increased. Many also develop severe muscle dysfunction and progressive neurologic abnormalities.

Acquired defects of critical enzyme systems can also generate lactic acidosis. One such example is beriberi, a nutritional disorder due to thiamine deficiency. Thiamine is a required cofactor for several enzyme complexes, including pyruvate dehydrogenase. Severe thiamine deficiency reduces pyruvate dehydrogenase activity and depresses mitochondrial pyruvate oxidation (Fig. 59.17). In addition, high output heart failure occurs frequently and contributes to the development of lactic acidosis. Beriberi lactic acidosis is promptly reversed by the administration of thiamine.[363]

The biguanide metformin is used to treat type II diabetes mellitus, particularly in obese patients. It is not appreciably metabolized and excreted primarily by the kidneys. Metformin can accumulate in patients whose kidney function is impaired, especially in the elderly. High concentrations of biguanides reduce the activity of several mitochondrial enzymes, especially pyruvate dehydrogenase.[86] Although lactic acidosis is 10 to 20 times less frequent with metformin than with phenformin (withdrawn from the market), many cases have been reported generally, but not exclusively, when one of the contraindications for the drug (renal impairment, liver disease, cardiac and respiratory insufficiency, etc.) was overlooked. Estimated mortality remains high at 50%. Metformin can be removed from the body by hemodialysis.

The activity of pyruvate dehydrogenase is increased by insulin[351] and may be decreased in diabetic patients. This may predispose diabetic patients to development of lactic acidosis. However, when lactic acidosis occurs in diabetic patients, it is usually due to a superimposed disorder such as volume contraction or sepsis. Acute inorganic phosphate depletion lowers ATP levels and can produce lactic acidosis. Such a sequence can develop due to severe intracellular phosphate depletion (as in the hyperalimentation-induced phosphate depletion syndrome) or when phosphate is trapped within the cytoplasm. Such phosphate trapping can occur after intravenous infusion of organic substances (such as fructose, xylitol) or when phosphorylated intracellular organic anions can not be efficiently metabolized due to enzymatic deficiencies (i.e., fructose-1-phosphate aldolase in fructose intolerance). Acute reductions in the intracellular inorganic phosphate concentration slow the generation of ATP from ADP. Simultaneously, the Pasteur effect accelerates anaerobic glycolysis. Decreased oxidative phosphorylation combines with accelerated anaerobic glycolysis to generate lactic acidosis.

ADP and AMP accumulate due to decreased rates of ATP synthesis and are metabolized to inosine-5-

monophosphate, which is then converted into ADP, AMP, and uric acid (ATP breakdown products). Therefore, hyperuricemia and hyperuricosuria are observed typically in the phosphate depletion syndrome. Hypermagnesemia is also observed and is the consequence of magnesium release from adenine nucleotide complexes, and impaired renal function. ATP depletion also causes hepatic and renal cortical dysfunction. Hepatic necrosis elevates serum transaminase levels. Proximal renal tubule dysfunction produces a Fanconi syndrome.[260] In addition to the energy depletion, some phosphorylated sugars, such as the fructose-1-phosphate, accumulate in the liver and kidneys and may also have direct toxic effects.

Similar pathophysiological sequences (i.e., trapping of phosphate to organic anions) occur in hereditary glucose-6-phosphate deficiency (von Gierke disease) where glucose release from glucose-6-phosphate is blocked and in hereditary fructose-1,6-bisphosphate deficiency, where generation of glucose during gluconeogenesis is blocked.

The mitochondrial encephalomyopathies—Kearns–Sayre syndrome (KSS), myoclonic epilepsy with ragged fibers (MERRF), mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS)—are all causes of lactic acidosis. In these disorders, pyruvate or acetyl CoA utilization in the mitochondrion is impaired due to defects in proteins of the electron transfer chain.

Nucleoside analogs, widely used in HIV-treatment disrupt the mitochondrial DNA that encodes for the respiratory chain proteins and, thereby, inhibits the transport of pyruvate into the mitochondria and have been reported to cause lactic acidosis in HIV positive patients when used as single agents or, more frequently in combination. Hyperlactatemia developed in about 8% or 73 out of 880 patients of a large cohort of HIV-positive, with only one patient developing severe lactic acidosis (anion gap >16).[38]

Lactic acidosis can develop when lactate production accelerates within local compartments. Hepatic lactate uptake in these conditions may be normal, high, or low. Lactic acidosis associated with strenuous exercise is due to rapid generation of lactic acid in muscle, which is released into the systemic circulation and temporarily exceeds hepatic uptake. Hepatic lactate uptake often falls because strenuous exercise reduces hepatic blood flow. Exhaustive exercise may increase lactate levels above 12 mEq/liter with rapid normalization within one hour.[52] Similar mechanisms may generate lactic acidosis following seizures[280] and after exertion-related heat stroke[164] or strychnine intoxication.[41]

Malignancies, including leukemia, lymphoma, and oat cell lung cancer, may produce chronic lactic acidosis.[115] Afflicted patients often have a large tumor mass. Multiple factors may contribute to this form of lactic acidosis: (1) malignant cells often have a rapid metabolic rate,[35,303] (2) rapidly growing bulky tumors may outstrip their blood supply and develop hypoxic foci, (3) enzymatic defects, which accelerate lactate production, may occur(,[35,303] and (4) extensive metastatic liver disease may decrease hepatic lactate uptake. Cancer-associated lactic acidosis may persist for weeks to months. It is usually refractory to treatment unless the tumor burden can be reduced. Exogenous $NaHCO_3$ infusions are usually not helpful and can actually accelerate lactic acid production.[122] A low systemic pH may break the lactic acid synthetic rate[171] and efforts to increase the pH can stimulate lactate production. The chronic loss of lactate into the urine represents caloric wastage and contributes to weight loss and development of cachexia.[116] Lactic acidosis can be associated with the tumor lysis syndrome.

Severe hepatic dysfunction will depress lactate uptake. However, lactic acidosis is uncommon in patients with uncomplicated liver disease.[294] When such patients develop lactic acidosis, an associated disorder that accelerates lactate generation (such as hypotension or sepsis) usually exists.[239] In some cases, arteriovenous shunting results in a large mass of underperfused tissue.[33] Some malnourished patients with combined liver and renal failure (frequently requiring dialysis) may develop a form of chronic lactic acidosis.[251] This is not due to clinically apparent hypotension, diminished tissue perfusion, or hypoxia. It frequently occurs during a fast and is often accompanied by hypoglycemia. Antecedent starvation often depletes glycogen stores so these patients become dependent on gluconeogenesis to maintain blood glucose levels. Low insulin levels combine with high levels of glucagon, growth hormone, glucocorticoid, and catecholamines to drive gluconeogenesis, lipolysis, and protein catabolism. However, hepatic uptake of glucose precursors, especially alanine and lactate, is reduced, in part as a result of poor hepatic function. The inadequate gluconeogenic response leads to hypoglycemia. Lactic acid increases as decreased hepatic lactate uptake combines with accelerated peripheral generation (due, in general, to hypotension or sepsis). The lactic acidosis further depresses hepatic alanine uptake, which exacerbates the hypoglycemia. Most of these biochemical abnormalities are rapidly reversed by the infusion of glucose. The complex interrelationships among liver failure, renal disease, malnutrition, lactic acidosis, and hypoglycemia are not fully understood. Glucose must play a central role because its infusion rapidly reverses the syndrome.

Increased catecholamine levels, of either endogenous or exogenous origin, raise lactic acid levels slightly.[175] Epinephrine accelerates glycogenolysis and glycolysis while inhibiting mitochondrial pyruvate

uptake. This increases both pyruvate and lactate levels. As long as the $NADH/NAD^+$ ratio remains normal, the increase in lactate remains relatively small (< 5 mEq/liter). However, if catecholamine levels increase markedly, then tissue perfusion is compromised, owing to intense peripheral vasoconstriction and cardiac dysfunction. This elevates the $NADH/NAD^+$ ratio and clinically significant lactic acidosis will then occur.[150] Severe lactic acidosis may also occur in patients with pheochromocytomas[195] or cocaine intoxication as a result of similar metabolic pathology.[192]

Sodium valproate and germanium poisoning can both cause lactic acidosis, the pathogenesis of which is unclear.[106,210] Propofol, an anesthetic drug, can rarely cause lactic acidosis and rhabdomyolysis when applied over extended periods of time and in high doses. Lactic acidosis probably is due to propofol's uncoupling of beta-oxidation at complex II of the respiratory chain.[362]

Therapy for Lactic Acidosis

The treatment of lactic acidosis must be directed at the underlying pathophysiology. When lactic acid is overproduced, the root cause of overproduction should be identified and, if possible, eliminated. The therapeutic approach in patients with lactic acidosis due to shock, sepsis, asphyxia, and poisons is generally self-evident. Despite this, mortality of lactic acidosis remains high and treatment strategies directed at later steps in the metabolic cascade have been evaluated.

Dichloroacetate,[34] which stimulates pyruvate dehydrogenase, accelerates mitochondrial pyruvate oxidation (Fig. 59.17). Improved mitochondrial pyruvate uptake should decrease cytosol concentrations of pyruvate and lactate. Unfortunately, despite these theoretical promises, dichloroacetate had no effect on the course of lactic acidosis when evaluated in a prospective multicenter trial[335] and cannot be recommended as a treatment option for lactic acidosis.

Treatment of lactic acidosis with $NaHCO_3$ infusions and other alkalinizing salts is generally ineffective. Even if the pH and $[HCO_3^-]$ are transiently increased, acidemia promptly recurs unless the basic pathology is reversed. Some animal models of lactic acidosis are even accompanied by poorer survival after $NaHCO_3$ therapy.[13,334] $NaHCO_3$ infusions acutely increase CO_2 generation when H^+ combines with HCO_3^- to form CO_2. If ventilation does not accelerate appropriately, the arterial pCO_2 will increase. Even when the arterial pCO_2 remains normal, capillary, venous, and tissue CO_2 tensions may increase after $NaHCO_3$ infusions. This reduces intracellular pH as CO_2 rapidly diffuses into cells.[300] Recently, a new alkalinizing salt called carbicarb (a combination of Na_2CO_3 and $NaHCO_3$), which should generate less CO_2, has been introduced. However, preliminary studies suggesting this salt may be advantageous compared with $NaHCO_3$[31] were not confirmed in animal models[17] or appropriately designed clinical studies. Thus, the reason why these drugs are of no proven benefit may be explained by the possibility that mortality is not determined by lactic acidosis per se, but rather by its underlying cause such as shock and sepsis.

The infusion of large quantities of hypertonic $NaHCO_3$ can produce hypernatremia and intracellular dehydration. Hypernatremia may be forestalled by appropriate hydration; however, the resultant volume expansion may produce pulmonary edema. If the lactic acidosis is reversed and large quantities of $NaHCO_3$ have been infused, then rebound metabolic alkalosis often develops.[372] The exogenous HCO_3^- combines with HCO_3^- regenerated from circulating lactate to elevate the blood $[HCO_3^-]p$.

Hemodialysis/hemofiltration and peritoneal dialysis can simultaneously deliver HCO_3^-, remove lactate, normalize electrolytes, and stabilize the extracellular fluid (ECF) volume. However, plasma lactate clearance rates achieved by these methods are so low (less than 3% of total lactate clearance) that they cannot be recommended as treatment options.[231]

POISON-ASSOCIATED ANION GAP ACIDOSIS

Alcohols

Alcohols and Osmolal Gap

Under most conditions sodium salts, urea, and glucose generate the osmotic pressure of blood plasma. The plasma osmolality can be calculated using the following equation:

$$\text{osmolality} = 2[Na^+]\text{mmol/liter} + \text{BUN mmol/liter} + \text{glucose mmol/liter}$$

If concentrations of BUN and glucose are expressed as percent milligrams, the values need to be divided by 2.8 (BUN) and 18 (glucose). When the calculated osmolality is compared with the measured osmolality, they should agree to within 10–15 mOsm/liter. When the measured osmolality is greater than the calculated osmolality by 15 mOsm or more, the osmolal gap is increased and one of two possibilities usually obtains. The first possibility is that the serum $[Na^+]$ measurement is spuriously low, resulting in a reduced calculated osmolality. For example, pseudohyponatremia due to hyperlipidemia or hyperproteinemia can reduce the calculated osmolality while the measured

osmolality reflects the true plasma water [Na^+]. When this occurs the measured osmolality is usually normal, while the calculated osmolality is abnormally low. The second possibility is that solutes other than sodium salts, urea, or glucose are present in plasma and elevate its osmolality. Low molecular weight solutes such as mannitol, alcohols, ethylene glycol, and acetone can achieve high plasma concentrations, and thereby elevate measured osmolality. In such cases, the difference between the measured and calculated osmolality is proportional to the concentration of that solute. Methanol's molecular weight is 32 mg/mmol. Therefore a methanol concentration of 32 mg/100 ml = 320 mg/liter = 10 mOsm/liter. Table 59.5 shows the contribution of various clinically pertinent solutes to measured osmolality.

The foregoing discussion is based on plasma osmolality measurements made with freezing point depression osmometers. Some osmometers in clinical practice use deviations in vapor pressure to measure osmolality. Although this methodology is appropriate for measuring the osmotic contributions of most solutes, it will not detect volatile solutes such as small alcohols. Therefore freezing point depression osmometers must be used if the difference between measured and calculated osmolality is to be a helpful screening test for such intoxications. However, this calculation is a screening test and both false negative and false positive results may occur.[314,339]

Ethanol Intoxication

Ethanol intoxication is an important cause of both ketoacidosis and lactic acidosis,[211] both of which were discussed in previous sections.

Methanol Poisoning

Methanol, or wood alcohol, is used as an industrial solvent, antifreeze ingredient (especially in windshield washing solutions), and canned solid fuel component. The ingestion of 60–250 ml is potentially lethal in adults. Chronic alcoholics may knowingly, or accidentally, use methanol as an inexpensive ethanol substitute.[30] Methanol poisoning produces initial inebriation similar to ethanol intoxication. Methanol oxidation, primarily by the liver, generates several toxic products, including formaldehyde and formic acid. They begin to accumulate 6–24 hours after ingestion and produce vomiting, abdominal pain, visual disturbances, confusion, and coma. High formic acid levels generate an anion gap metabolic acidosis.[249] Hypoxia, hypotension, and cardiac dysfunction may also produce lactic acidosis. Methanol metabolites that interfere with normal mitochondrial function can potentiate the lactic acidosis.

Both formic acid and formaldehyde are toxic to retinal cells and the optic nerve.[249] Ocular toxicity includes blurred vision, optic disc swelling, pupillary dilation, and blindness. Fundoscopy may be diagnostic of methanol intoxication. Nausea, vomiting, and abdominal pain occur and may be due to pancreatitis. CNS toxicity results in confusion, seizures, coma, and death.

Methanol poisoning must be treated aggressively. An aqueous slurry of activated charcoal, 1–2 g per kilogram of body weight, is administered by mouth or nasogastric tube. This may be followed by a purgative, such as sorbitol (30–50 ml of 70% solution) to hasten transit of unabsorbed alcohol and charcoal through the gastrointestinal tract. Forced vomiting (ipecac syrup) should be reserved for only the most recent intoxications (minutes) as it will severely limit the ability to ingest and retain activated charcoal.

The next phase of therapy is directed at inhibition of alcohol dehydrogenase, the major methanol-oxidizing enzyme system. The relatively specific and potent inhibitor of alcohol dehydrogenase, fomepizole (4-methylpyrazole) blocks development of the anion gap metabolic acidosis as well as other toxic consequences of methanol poisoning and was safe and effective in series of both adult and pediatric intoxications.[46,87] The drug is given at a dose of 15 mg/kg of body weight over 30 minutes intravenously, followed by 10 mg/kg of body weight over the next 12 hours for four consecutive doses.

If fomepizole is not available, metabolism of methanol by alcohol dehydrogenase can be competitively inhibited by ethanol.[247] Alcohol dehydrogenase has a greater affinity for ethanol than for methanol (or ethylene glycol) and ethanol competitively inhibits the oxidation of other alcohols. A therapeutically effective blood ethanol level is 100–150 mg/dl. The ethanol can be administered by mouth, nasogastric tube, intravenously, or via dialysis. An initial loading dose of approximately 600 mg/kg produces the requisite level. In a 70-kg adult, this represents about 42 g of ethanol. The alert patient may ingest 4 oz of 80-proof whiskey. Alternatively, 500 ml of a 10% ethanol solution may be infused intravenously. Subsequent dosing will depend on the rate of ethanol metabolism. Nonalcoholic subjects require about 5 g/hr of ethanol to maintain an adequate level (about 60 ml/hr of a 10% solution, specific weight of ethanol = 0.79). Chronic alcoholics more rapidly metabolize ethanol because of chronic activation of alcohol dehydrogenase. They will require about 10 g/hr (120 ml/hr of a 10% solution).[247] If dialysis is initiated, the ethanol infusion rate must be doubled. Alternatively, ethanol may be added to the dialysate at a concentration of about 100 mg/dl. Folic acid should be given because it may increase formic acid metabolism to CO_2.

Reversal of metabolic acidosis may ameliorate methanol toxicity. Therefore aggressive alkalinization has been recommended. This may be accomplished by parenteral $NaHCO_3$ infusion. However, volume expansion and hypernatremia complicate hypertonic $NaHCO_3$ infusions. Alkalinization can be achieved more rapidly and effectively with hemodialysis. Hemodialysis also rapidly removes methanol and its toxic metabolic products (see subsequent recommendations). Peritoneal dialysis is much less effective than hemodialysis.[196] Forced diuresis is relatively ineffective because renal methanol clearance is very low.

Ethylene Glycol Poisoning

Ethylene glycol is the principal constituent of most automotive engine antifreeze, brake fluid and power steering fluid products and is a widely used organic solvent. It is rarely used as a pharmaceutical solvent (i.e., for lorazepam vials). This colorless and slightly sweet alcohol is sometimes illegally used to enhance the flavor of low quality wine.

Chronic alcoholics may knowingly ingest ethylene glycol as an inexpensive ethanol substitute. However, accidental or suicidal poisoning is more common. Although the lethal adult dose is about 100 ml, occasional individuals survive ingestion of much larger quantities. Similar to methanol, ethylene glycol itself is slightly toxic but is rapidly oxidized to multiple more toxic products, including glycolates and oxalates. Several of these metabolites are relatively strong acids that accumulate and generate an anion gap metabolic acidosis.[130] In addition, cardiovascular collapse occurs commonly and may precipitate lactic acidosis.

Ethylene glycol poisoning usually produces inebriation, nausea, and vomiting soon after ingestion. The ingestion of large quantities may rapidly result in coma, seizures, and death. More commonly, initial mild symptoms persist for about 12 hours and are followed by a second wave of more severe clinical and biochemical alterations.[126] During the latent period, toxic metabolic products accumulate and generate a progressive anion gap metabolic acidosis.[130] Calcium deposition and chelation reduce the ionized $[Ca^{2+}]$, resulting in tetany and seizures. Calcium oxalate precipitates in the lungs, heart, kidneys, and brain.[126]

Patients who survive these initial phases often develop oliguric renal failure, associated with severe flank pain. This may become the dominant clinical problem.[126] Renal failure is partially due to calcium oxalate deposition and may be irreversible. A variety of persistent neurologic deficits, possibly due to neural calcium oxalate deposits, may develop in long-term survivors.

Ethylene glycol intoxication should be considered in patients presenting with confusion, obtundation, or coma and an unexplained anion gap metabolic acidosis. Suspicion increases if the patient has a psychiatric, suicidal, or chronic alcohol abuse history. Other laboratory findings include a large osmolal gap, anion gap metabolic acidosis, and calcium oxalate crystals in the urine. Qualitative analysis of ethylene glycol in blood, urine, or gastric fluid is necessary for definitive diagnosis.

The initial management of ethylene glycol poisoning parallels that described for methanol poisoning. A charcoal slurry is then administered to bind residual ethylene glycol and prevent further absorption. Purgatives that speed gastrointestinal transit may be useful.

Ethylene glycol is also oxidized by alcohol dehydrogenase in the cytoplasm of hepatic cells. Blocking this enzymatic reaction markedly reduces ethylene glycol's toxicity.[365] As with methanol intoxication, ethanol can be used as a competitive substrate for alcohol dehydrogenase. A therapeutic blood ethanol concentration is 100−150 mg/100 ml (see Methanol Poisoning section). However, fomepizole (4-methylpyrazole) has an affinity to alcohol dehydrogenase that is at least three orders of magnitude greater than ethanol and is the treatment of choice in ethylene glycol intoxication.[47]

Severe metabolic acidosis may be treated with parenteral $NaHCO_3$. However, large quantities of $NaHCO_3$ produce volume expansion and may precipitate pulmonary edema. Cardiac and pulmonary toxicity secondary to calcium oxalate deposition increases the likelihood of pulmonary edema in response to a volume challenge.

Pyridoxine and thiamine (100 mg each intravenously per day) are cofactors for the metabolism of ethylene glycol metabolites and should be administered.

Unlike methanol, renal excretion of ethylene glycol and its metabolites is significant. When renal function is adequate, forced diuresis with furosemide and mannitol can be effective.[339] Precautions must be taken to forestall sodium and other electrolyte deficits that can be induced by the diuresis. The effectiveness of such diuresis is greatly amplified if metabolism of ethylene glycol is simultaneously reduced by inhibition of the alcohol dehydrogenase enzyme system. Severe poisoning should be treated with hemodialysis.[127] Ethylene glycol and toxic metabolic products are removed, metabolic acidosis and electrolyte abnormalities are reversed, and volume status normalized.

Ionized calcium levels fall as a result of calcium oxalate precipitates and chelates. To some extent, metabolic acidosis ameliorates the low ionized calcium levels by reducing calcium binding to proteins. Therefore alkalinization may exacerbate hypocalcemic symptomatology and produce tetany and seizures. Dialysis simultaneously corrects the acidosis and

hypocalcemia because oxalate is removed while calcium and alkali are infused.

Indications for Dialysis in Ethylene Glycol and Methanol Poisoning

Firm indications for recommending dialysis are not available. The following indications are, however, generally accepted:

- Methanol or ethylene glycol plasma concentrations in excess of 25 mg/100 ml in asymptomatic patients.
- Ingestion of more than 175 mg/kg body weight of either poison.
- Sustained metabolic acidosis and visual disturbances (methanol).
- Unexplained metabolic acidosis with a high anion gap and a high osmolal gap in a setting where assays for methanol or ethylene glycol plasma concentrations are not readily available.

Paraldehyde Poisoning

Chronic paraldehyde poisoning used to be a rare cause of anion gap metabolic acidosis but paraldehyde (used as a sedative for delirium tremens) is no longer manufactured (see third edition of this book).

Salicylate Poisoning

Salicylate poisoning is a relatively common disorder that produces a characteristic spectrum of clinical, acid–base, and electrolyte abnormalities.[69] Salicylate preparations include salicylic acid, acetylsalicylic acid (aspirin), sodium salicylate, and methylsalicylate. Acetylsalicylic acid is rapidly hydrolyzed by the liver to salicylic acid.

At toxic concentrations, salicylate uncouples oxidative phosphorylation, which accelerates oxygen utilization, heat generation, and CO_2 production;[254] in consequence, hyperthermia and hypoglycemia may result. Multiple other oxidative enzyme systems are inhibited by high salicylate levels. Salicylate also directly stimulates the central respiratory center, increasing minute ventilation.[299] The hyperventilatory response usually more than compensates forthe accelerated CO_2 production, resulting in a respiratory alkalosis (especially in adults).

The metabolic acidosis produced by salicylate poisoning is multifactorial. As mentioned previously, a variety of enzymatic reactions are inhibited and oxidative phosphorylation is uncoupled. Simultaneously, the low pCO_2 increases intracellular pH, which accelerates glycolysis as a result of phosphofructokinase-1 activation. This contributes to the development of lactic acidosis. Vomiting and decreased oral intake produce Na^+ and K^+ depletion. Hypokalemia can generate cardiac arrhythmias. Volume depletion also contributes to the lactic acidosis. Ketoacidosis may develop, especially in young children and pregnant women. In consequence, the anion gap metabolic acidosis is due to an accumulation of lactate, ketoacids, salicylate, and other organic acids.[129] The molecular weight of salicylate is 138 mg/mmol. Therefore, a salicylate level of 100 mg/100 ml will contribute about 7 mEq/liter to the anion gap.

Usually, salicylate poisoning results in a mixed acid–base disturbance, that is metabolic acidosis and coexisting respiratory alkalosis. The age of the patient has an important impact on whether acidemia or alkalemia dominates. Metabolic acidosis is generally more severe in infants and young children, while adults typically manifest a normal or alkaline blood pH.[129,380] The systemic pH will affect the degree of neurotoxicity and the patient survival rate. The low pKa of salicylic acid indicates that more than 99% will be ionized in the physiologic pH range. However, it is the minute unionized fraction of salicylic acid that readily penetrates lipid cell membranes, while the ionized fraction penetrates poorly. The concentration of un-ionized salicylate increases when blood pH falls. For example, its concentration doubles when the blood pH falls from 7.4 to 7.1. Thus, acidemia increases the concentration of un-ionized salicylate, which readily enters parenchymal and brain cells. This nonionic diffusion accounts for the increased mortality rate associated with acidemia in this disorder.[129]

A number of biochemical abnormalities can occur in salicylate-poisoned individuals. Hypoglycemia often develops[80] probably due to interactions with the sulfonylurea receptor. Even when the blood glucose level is normal, brain glucose concentrations may be reduced.[354] Extreme hypouricemia is due to inhibition of renal tubule urate reabsorption by high salicylate levels.[385] Hypokalemia develops as a result of urinary potassium losses, which are exacerbated by alkalinization of distal renal tubule cells (owing to respiratory alkalosis) in a setting of increased distal delivery of sodium salts (nonreabsorbed salicylate) and enhanced Na^+ reabsorption (due to volume depletion). In addition, starvation and vomiting may contribute to the potassium deficits. In alkalotic patients, potassium may also be redistributed from the extracellular fluid into cells.

Clinical manifestations of salicylate poisoning include hyperventilation, confusion, coma, and seizures.[69,129] Noncardiogenic pulmonary edema may occur, especially with chronic salicylate intoxication.[167] Tinnitus, deafness, and vertigo are common complaints. Hyperthermia, in the absence of infection, may occur and reflects increased heat production.

Hemorrhagic manifestations are rare, but severe intoxication can lead to ecchymoses, petechia, and prolonged bleeding related to platelet dysfunction and hypoprothrombinemia (secondary to factor VII synthesis inhibition). Impaired renal function results from salt depletion and salicylate inhibition of renal production of vasodilatory prostaglandins.

The urinary excretion of salicylate metabolites can generate a false positive reaction for ketones (nitroprusside test) and for glucose (reducing substances). Renal glycosuria can, however, develop as a result of proximal tubule dysfunction. A positive glucose oxidase test identifies the presence of true glycosuria. Fanconi's syndrome rarely develops.

Blood salicylate measurements must be interpreted with respect to the time elapsed from ingestion. The decrease in salicylate levels follows first-order kinetics. Toxicity is common with peak levels above 30 mg/100 ml, while severe toxicity and fatalities occur when peak levels exceed 100 mg/100 ml.

Guidelines for the treatment of salicylate intoxication are listed in Table 59.6. The use of gastric lavage is controversial due to side effects (aspiration), limited efficacy and the possibility to enhance propagation of salicylates to the small bowel. However, aggregation of salicylates and gastroparesis are arguments to perform gastric lavage. Gastric lavage may be indicated early after ingestion and the indication is probably best made after endoscopic evaluation. Activated charcoal should be administered (see Methanol Poisoning section). Hypokalemia, hypoglycemia, and metabolic acidosis must be treated aggressively. Hypoprothrombinemia can be corrected with parenteral vitamin K or fresh frozen plasma infusions.

Renal salicylate excretion is accelerated by induction of a large diuresis and alkaline urine. Salicylate filtered by the glomerulus is both reabsorbed and secreted by the renal tubules. In part, it is reabsorbed as undissociated salicylic acid via the process of nonionic diffusion. This occurs when the urine pH is lower than the blood pH. Conversely, if the urine pH exceeds the blood pH, then ionized salicylate is trapped in the urine. If urine pH above 7.5 can be achieved, salicylate clearance may increase several-fold above the glomerular filtration rate. Increased urine flow will also augment salicylate excretion by reducing its concentration in tubular fluid. An alkaline diuresis, with urine flow of about 2 ml/min, should be induced. This can be accomplished with $NaHCO_3$ infusions. However, if the patient is already alkalemic, such infusions must be used cautiously. Further elevation of blood pH can cause severe tetany and seizures.

Inducing bicarbonate diuresis with acetazolamide is discouraged because of its potential to create or aggravate systemic acidosis, which is not always preventable by exogenous $NaHCO_3$ in clinical practice. Acetazolamide's efficacy to remove salicylate is also in doubt since a controlled comparison of bicarbonate administration vs bicarbonate plus acetazolamide in salicylate-toxic dogs resulted in no significant increase in salicylate excretion. Whereas acetazolamide administration does alkalinize the final urine, it results in a disequilibrium pH in the proximal tubule lumen (lower value than the equilibrium value due to its ability to delay the dehydration of luminal carbonic acid) and thus may not provide luminal alkalinity at the nephron site critical for salicylate dissociation.

Hepatic salicylate metabolism is dependent on availability of glycine. Administration of glycine was shown to increase excretion of conjugated salicylic acid and, therefore, elimination of salicylates.[274]

Intravenous fluids to replace volume, induce diuresis, provide $NaHCO_3$, and replace K^+ must be administered cautiously. Increased capillary permeability predisposes these patients to noncardiogenic pulmonary edema, as well as cerebral edema.[167]

If salicylate intoxication is severe and associated with progressive metabolic and/or neurologic derangements, hemodialysis should be used and can be life-saving.[69] Dialysis is also required in those patients who develop acute renal failure or have preexisting renal disease. Hemodialysis very efficiently removes salicylate and corrects metabolic acidosis, electrolyte abnormalities, and volume status. Charcoal hemoperfusion is equally effective as hemodialysis.[134] Peritoneal dialysis, however, is only about one-fourth as effective as hemodialysis[344] and is not recommended as a treatment option.

Uremic Acidosis

As renal mass decreases, several interrelated abnormalities account for the development of metabolic acidosis. Net renal acid excretion (NH_4^+ + titratable acid $- HCO_3^-$) must equal net systemic acid generation to maintain acid balance. Renal insufficiency affects each component of net acid excretion. First, renal ammonia production decreases progressively as nephron mass is reduced.[102] In addition to decreased renal ammonia synthesis, the countercurrent medullary NH_4^+ gradient, which is critical for normal NH_4^+ excretion, becomes deranged. Low ammonia concentrations in the deep medulla decrease ammonia entry into the collecting ducts. The development of hyperkalemia also contributes to the reduction in NH_4^+ synthesis and excretion. Although the ammonia excretory rate—factored for GFR—increases, the absolute ammonia excretory rate falls markedly[102] because of the reduced nephron mass.

Decreased NH_4^+ excretion forces the kidney to become dependent on titratable acid to maintain acid balance. Titratable acid formation is a function of urine pH and the urine concentration of titratable buffers, especially phosphate. As the GFR declines, phosphate excretion may remain relatively constant as a result of increased parathyroid hormone and phosphorus levels. However, when the GFR falls below 25–30 ml/min, phosphorus clearance is generally reduced. Low phosphorus intake, the use of phosphorus binders, and calcium phosphate depositional disease will further depress renal phosphorus excretion.

Despite chronic renal insufficiency, renal tubules usually maintain the ability to acidify the urine maximally.[147,282,295,318,330] For varying periods of time, increased titratable acid excretion can offset the reduction in NH_4^+ excretion. Later, as titratable acid falls, in part due to decreased phosphate excretion, net acid excretion falls below net acid generation and metabolic acidosis ensues.

The third element of net acid excretion is excretion of HCO_3^-. Proximal tubule HCO_3^- reabsorption has been reported to be high, normal, and low with chronic renal failure.[14,216] Chronic renal failure may increase proximal tubule Na^+/H^+ antiporter activity, contributing to enhanced HCO_3^- reabsorption.[77] On the other extreme, proximal tubule HCO_3^- reabsorption may fall for several reasons in these patients. Volume expansion, hyperparathyroidism, solute diuresis, and overperfused residual nephrons may all reduce proximal HCO_3^- eabsorption. However, when patients with overt volume expansion are excluded or Na^+ is restricted from the diet, the HCO_3^- reabsorptive capacity of most patients with renal insufficiency is relatively normal.[14,216] Nevertheless, the aforementioned factors probably increase the fraction of filtered HCO_3^- delivered to the distal tubule, where it is reabsorbed. To the extent that this occurs, limited distal H^+ secretory capacity is utilized for HCO_3^- reabsorption rather than generation of titratable acid and NH_4^+. The consequence of this abnormal physiology can be demonstrated when metabolic acidosis in uremic patients is reversed with exogenous HCO_3^- that is then stopped.[316] The subsequent decline in serum [HCO_3^-] is more rapid than expected from the accrual of endogenous fixed acids. In these subjects, the urine pH often becomes alkaline and remains so until the serum [HCO_3^-] is reduced.[318] A relatively high urine pH combined with severely restricted NH_4^+ excretion results in a very low or negative net acid excretion. As the plasma [HCO_3^-] falls, distal HCO_3^- delivery decreases sufficiently to permit a reduction in luminal pH: titratable acid is again generated and urine pH may be maximally lowered. Occasional patients with chronic renal failure develop true HCO_3^- reabsorptive defects and spill a large fraction of filtered HCO_3^- when the plasma [HCO_3^-] is normal or slightly reduced.

Most patients with severe chronic renal failure generate normal amounts of endogenous acid unless dietary intake is markedly altered. However, their acid excretory rate is 10–20 mEq/day lower than their acid generation rate. Despite continued positive accrual of acid, the serum [HCO_3^-] usually stabilizes. This occurs because the excess acid is buffered by bone-derived alkali. It is likely however, that bone alkali is insufficient to compensate for the decrease in renal acid excretion at least in the long term. Whether increased gut organic anion absorption accounts for the needed base[360] remains to be established.

Most patients with uremic acidosis develop an anion gap elevation that approximates the reduction in [HCO_3^-]p. The excess anion gap is due to retention of phosphate, sulfate, and a variety of organic acids. These acids are generated by normal metabolic processes and the accumulated anions represent decomposed HCO_3^-. Anion retention largely reflects a reduction in the GFR. Thus, the metabolic acidosis is due to tubular malfunction, while the elevated anion gap is due to the GFR reduction. In many patients with renal failure, these two abnormalities progress in parallel, producing a 1:1 correlation between the increase in anion gap and decrease in HCO_3^-. However, with early renal failure (creatinine 2–4 mg/100 ml), a hyperchloremic pattern may develop. When the GFR falls below 20 ml/min, hyperchloremia usually recedes and is replaced by an increased anion gap.[374] Occasionally, hyperchloremic acidosis remains the dominant pattern until much later in the course. In these patients, hyperchloremic acidosis is usually due to a reduction in renal acid excretion that exceeds the fall in glomerular filtration. Sodium salts of fixed acids, representing decomposed sodium bicarbonate, are filtered and excreted. Normally, they would be excreted as NH_4^+ salts or with titratable acid; instead, they are excreted as Na^+ or K^+ salts. Hemodialysis can also generate a hyperchloremic component as organic and inorganic acid anions may be removed more rapidly than HCO_3^- is replaced. Combined anion gap and hyperchloremic acidosis in patients with renal failure is discussed in the section on plasma acid–base profile.

Congenital Organic Acidoses

Inborn errors of metabolism can result in organic acidosis due to the accumulation of lactic acid, the classic ketoacids (acetoacetic acid and beta-OH butyric acid), and a variety of other organic acid intermediates, including several long chain ketoacids. Tables 59.4 and 59.7 list the different causes of congenital organic

TABLE 59.4 Causes of Lactic Acidosis

- Decreased ATP production
  - Circulatory failure
    - Volume depletion
    - Severe heart failure
    - Massive pulmonary emboli
    - Shock: sepsis, anaphylaxis, drugs (nitroprusside)
  - Tissue hypoxia
    - Acute respiratory failure
    - Carbon monoxide poisoning
    - Severe anemia
    - Methhemoglobinemia
  - Mitochondrial defects
    - Electron transport defects: carbon monoxide, cyanide, severe iron deficiency
    - Decreased oxidative phosphorylation: salicylate and 2,4-dinitrophenol intoxication
    - Mitochondrial enzyme defects: pyruvate carboxylase, pyruvate dehdrogenase, cytochrome oxidase defects, MELAS syndrome
    - Decreased pyruvate utilization: metformin, acute thiamin deficiency (beriberi)
    - Phosphate trapping: fructose, xylitol, sorbitol, glucose-6-phosphatase deficiency (von Gierke disease)
    - Other: nucleoside analogs (zidovudine, fialuridine), propofol
- Lactate overproduction (with relative ATP deficiency)
  - Muscle hyperactivity
    - Severe exertion
    - Seizure
    - Exertional heat stroke
    - Strychnine poisoning
    - Hypothermia
  - Disseminated malignant neoplasia (leukemia, lymphoma)
  - Tumor lysis syndrome
  - Shock lung, ARDS
  - Gluconeogenetic enzyme defects
    - Glucose-6-phosphatase defect (von Gierke disease)
    - Fructose-1,6-diphosphatase defect
  - Catecholamine excess (iatrogenic, pheochromocytoma, cocaine poisoning)
  - Methanol
  - Ethylene glycol
  - Ethanol
  - Zinc phosphide
- Decreased lactate utilization

acidosis. For more information, the reader is referred to textbooks dedicated to detailed discussions of inborn errors of metabolism or to the OMIM (Online Mendelian Inheritance in Man) database (www.ncbi.nlm.nih.gov/entrez).

D-Lactic Acidosis

Lactic acid exists in L- and D-optical stereo isomer forms. The L-optical isomer is generated and used in the cells of higher animals, whereas D-lactate is primarily a product of bacterial metabolism. D-Lactic acid is generated by bacteria in the gastrointestinal tract and is excreted into the stool. However, certain pathologic conditions may lead to systemic absorption of bacterial derived D-lactic acid. D-Lactate will then accumulate in the ECF because this compound is slowly metabolized.[157] This unique form of lactic acidosis can occur in short-bowel syndrome and after ileal–jejunal bypass operations. The disorder may be precipitated by the ingestion of carbohydrates, a systemic illness, or therapy that alters the enteric bacterial flora (i.e., broad-spectrum antibiotics, ingestion of yogurt or D-Lactobacillus tablets to treat diarrhea, and possibly the use of lactulose).

D-Lactic acidosis is commonly associated with CNS abnormalities, such as obtundation, confusion, and ataxia. These symptoms may represent a direct neurotoxic effect of D-lactate or may be a manifestation of some other organic acids or unidentified toxins.

The diagnosis of D-lactic acidosis should be considered in patients with gastrointestinal pathology who develop otherwise unexplained anion gap metabolic acidosis. The enzymatic assay for lactic acid uses stereospecific L-lactate dehydrogenase (L-LDH). Therefore, it will not detect D-lactic acid. The diagnosis of D-lactic acidosis can be established with an analogous assay using the enzyme D-LDH. D-Lactate can also be measured with lactic acid analytic techniques that are not stereospecific, such as gas–liquid chromatology.

Immediate treatment should include elimination of all oral intake of food and parenteral nutrition. Poorly absorbed antibiotics (vancomycin, neomycin, and kanamycin) or metronidazol are used to suppress intestinal flora in both the short term and long term. Low-carbohydrate diets or use of fructose or starch instead of glucose are also worth trying.[359]

TABLE 59.6 Treatment of Salicylate Poisoning

General support
Correction of electrolyte disturbances (potassium)
Glucose infusion (neuroglycopenia)
Elimination of toxin
Noninvasive methods
Activated charcoal (1–2 g/kg body weight initially, then 0.5–1 g/kg body weight every 2–4 hours (3–4 times)
Sodium bicarbonate: blood pH should be around 7.5, urine pH >8.0
Glycine, 8 g taken orally initially, 4 g every 2 hours for 16 hours
Invasive methods
(Gastroscopic) lavage in combination with activated charcoal before and after lavage
Hemoperfusion/hemodialysis

Hyperchloremic Metabolic Acidosis

Hyperchloremic acidosis develops when $NaHCO_3$ or other forms of alkali (i.e., Na ketone salts) is lost from the ECF, or HCl or other chloride salts that generate HCl are added to the ECF. Hyperchloremia occurs because the ECF contracts about a fixed quantity of chloride or because exogenous chloride (from NaCl, HCl, or other chloride salts) is added to the ECF. In many circumstances, both mechanisms are responsible. These mechanisms are further characterized in Anion Gap Acidosis and Hyperchloremic Acidosis. The differential diagnosis of hyperchloremic metabolic acidosis is listed in Table 59.3.

Hypokalemic Renal Tubular Acidosis

Proximal Renal Tubular Acidosis

The proximal tubule assumes a pivotal role in reclamation of filtered HCO_3^- and thus preservation of HCO_3^- stores. Around 80% of filtered bicarbonate (around 4 moles/day in a subject with normal GFR) is reabsorbed in this segment via processes that involve apical proton secretion (Na^+/H^+ exchange and ATP driven proton secretion) and basolateral HCO_3^- exit via sodium-coupled HCO_3^- transporters.

The low intracellular [Na^+] also energizes the reabsorption of other filtered solutes including glucose, phosphate, uric acid, amino acids, and organic anions. These compounds and anions are reabsorbed by specific Na^+-linked symporters.

Generalized dysfunction of proximal tubule transport results in $NaHCO_3$ excretion combined with glycosuria, phosphaturia, aminoaciduria, and so on. This combination of multiple proximal tubule defects defines the renal Fanconi syndrome (Lignac–de Toni–Debre–Fanconi syndrome). Less commonly, HCO_3^- wasting occurs as an isolated proximal tubule defect.

As illustrated in Fig. 59.18, a reduction in proximal tubule HCO_3^- reclamation will deliver a larger HCO_3^- load to distal tubule segments that have limited HCO_3^- reclamation capacity. The resulting $NaHCO_3$ diuresis reduces the [HCO_3^-]p and generates ECF volume depletion. Activation of the renin-angiotensin-aldosterone system stimulates distal tubule Na^+ reabsorption and K^+ secretion. Ingested NaCl is retained, partially reversing the ECF contraction. The net effect of these alterations is the development of a hypokalemic, hyperchloremic metabolic acidosis. Several factors combine to produce a steady-state and reestablish relatively normal fractional HCO_3^- reabsorption: (1) the low [HCO_3^-]p reduces the filtered HCO_3^- load. (2) The lower [HCO_3^-]p increases transcellular H^+ secretion and should decrease HCO_3^- back leak in the late proximal tubule. (3) Volume contraction increases HCO_3^- reabsorption. (4) Hypokalemia increases HCO_3^- reabsorption.

As fractional HCO_3^- reabsorption by the proximal tubule increases toward normal, a smaller quantity of $NaHCO_3$ is delivered to distal segments and is normally reabsorbed. Now, normal distal tubule acidification can proceed so that titratable acid and ammonia excretion return to normal. HCO_3^- decomposed by metabolic and dietary acids and HCO_3^- lost in stool can

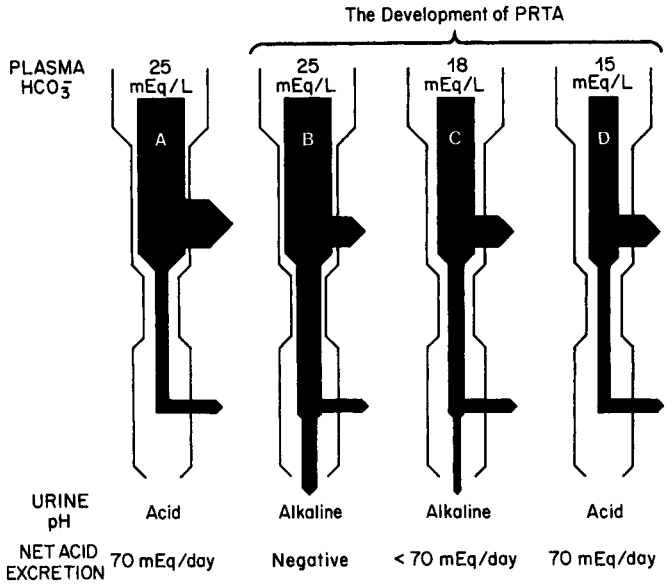

FIGURE 59.18 Schematic representation of the development of the proximal renal tubular acidification (PRTA) defect. (A) Normally, approximately 85% of the bicarbonate load is reabsorbed in the proximal tubule and the remaining 15% is reabsorbed in distal segments. As the urine is further acidified, net urine is generated. (B) The development of a proximal tubule acidification defect decreases the fraction of filtered bicarbonate reabsorbed in the proximal tubule (e.g., in this case, to 60%). Increased delivery of bicarbonate to the distal tubule overwhelms its bicarbonate reabsorptive capacity and leads to severe bicarbonaturia. An alkaline urine and negative net acid excretion result. (C) As the serum bicarbonate concentration declines, less bicarbonate is filtered and less is delivered to the distal tubule. The severity of the bicarbonaturia is decreased. (D) When the plasma bicarbonate is sufficiently reduced, proximal bicarbonate reabsorption is sufficient to reabsorb most of the filtered bicarbonate and thereby reduce distal tubule bicarbonate delivery. Under these conditions, the distal tubule can reabsorb the delivered bicarbonate and normally acidify the urine. In this new steady state, net acid excretion will again be equivalent to net acid production, albeit at the expense of a reduced serum bicarbonate concentration. *(Adapted from Ochwadt BK, Pitts RF. Effect of intravenous infusion of carbonic anhydrase on carbon dioxide tension of alkaline urine. Am J Physiol 1956;185:426–429.)*

now be regenerated by the kidney and acid balance is restored.

Potassium balance may also be restored when these patients achieve acid–base steady-state conditions. As the acidosis evolves, distal $NaHCO_3$ delivery combines with volume contraction and hyperaldosteronism to accelerate distal tubule K^+ secretion. In the steady state, dietary NaCl replaces $NaHCO_3$, restoring ECF volume. Aldosterone levels fall, distal $NaHCO_3$ delivery decreases toward normal, and K^+ secretion is reduced. Mild hypokalemia may persist, reflecting a total body deficit, but K^+ balance is restored and hypokalemia is rarely severe.[322] In the steady state, acid balance is reestablished, albeit at the expense of a lower plasma [HCO_3^-]. This is not true in patients with distal real tubular acidosis (RTA) or uremic acidosis. In those disorders, acid balance is persistently positive. This distinction may account, in part, for the differing skeletal manifestations that develop with these disorders. The skeleton plays a major buffering role in disorders associated with chronic positive acid balance. Thus, with distal RTA, skeletal dissolution helps stabilize the [HCO_3^-]p but also releases Ca^{2+} and Mg^{2+}, which are excreted into the urine. Acidemia (low luminal pH) also reduces renal tubular Ca^{2+} reabsorption.[206] Consequently, overt hypercalciuria develops in about one third of patients with distal RTA.[45] This is in part the reason these patients develop nephrocalcinosis and nephrolithiasis (other contributing factors include hypocitraturia and an alkaline urine pH—discussed later). These patients also develop osteomalacia and children have impaired skeletal growth. Skeletal mobilization of alkaline calcium salts also develops in other chronic metabolic acidoses associated with positive acid balance, such as uremic acidosis. In contrast, isolated proximal RTA does not mobilize skeletal buffers, perhaps because acid balance is reestablished. Hypercalciuria does not develop in these patients; first, because skeletal mobilization does not occur. Second, the increased delivery of HCO_3^- to the distal tubule will stimulate distal Ca^{2+} reabsorption despite systemic acidemia.[285] Furthermore, the two other factors that contribute to nephrocalcinosis and nephrolithiasis in patients with distal RTA also do not occur in those with proximal RTA. Patients with proximal RTA are able to acidify their urine when they are in a steady state and have relatively high urine citrate excretion. The importance of citrate to urine calcium solubility was discussed earlier (Effects of Metabolic Acidosis on Renal Citrate Metabolism section) and subsequently in relationship to distal RTA. Although systemic acidosis and K^+ depletion usually decrease urine citrate excretion, proximal RTA is an exception to this rule. A generalized defect in proximal tubule organic anion reabsorption apparently offsets any tendency to reduce urine citrate excretion (see Hypokalemic Distal Renal Tubular Acidosis section). Thus, nephrocalcinosis and nephrolithiasis are distinctly uncommon in patients with proximal RTA.[221] When phosphate wasting and vitamin D abnormalities complicate proximal RTA, skeletal pathology including rickets and osteomalacia may develop.

Recently, a few patients with isolated proximal tubular acidosis were found to have impaired ammonium excretion when confronted with acid load.[42] These patients could theoretically be in chronic positive acid balance. It remains to be seen whether the defect in this patient segment is decreased ammoniagenesis in the proximal tubule and/or additional more distal

effects such as the one caused by carbonic anhydrase II deficiency in type 3 RTA. Table 59.8 lists the many causes of proximal RTA.

Primary Proximal Renal Tubular Acidosis

Primary proximal RTA is defined as the occurrence of the tubule defect or defects in the absence of any other underlying process or etiology. Primary proximal RTA occurs in children and much less commonly in adults. Idiopathic proximal RTA of children often improves with time.[265,301] Proximal HCO_3^- wasting may be isolated or occur together with full-blown Fanconi's syndrome. Autosomal dominant, autosomal recessive, and sex-linked inheritance patterns have been reported.[43,125]

In autosomal dominant proximal RTA no genetic defect has been reported. The gene encoding NHE-3 (SLC9A3) is considered a candidate as SLC9A3 knock-out mice have combined renal and intestinal defects in HCO_3^- (re)absorption.

In autosomal recessive proximal RTA with ocular abnormalities several mutations in the gene SLC4A4, encoding for the kidney Na/HCO_3 cotransporter (kNBC1) have been described. kNBC1 is localized on the basolateral membrane of the proximal tubule and is—acting in series with the luminal Na/H antiporter (NHE-3)—part of the major pathway of HCO_3^- reabsorption in the proximal nephron. This type of RTA presents with growth failure, and ocular abnormalities (band keratopathy, cataracts, glaucoma) and mental retardation. The ocular and brain abnormalities are consistent with the finding that kidney isoform kNBC1 is also expressed in various ocular tissues and the brain.[186]

No genetic defect has been reported for proximal RTA with sex-linked inheritance.

Inherited Mixed Renal Tubular Acidosis

Various genetic defects of the carbonic anhydrase II gene (CA II) have been described. Patients with this deficiency exhibit a mixed form of tubular acidosis with proximal and distal components, retarded growth, osteopetrosis and cerebral calcifications. Bone marrow or stem cell transplantation corrected only the extrarenal manifestations of this disorder.[8] CA II is known to be expressed by osteoclasts and in proximal and distal nephron segments explaining the increased bone mass and the mixed acidosis with features of both HCO_3^- wasting and defective H^+ secretion. Heterogeneity exists among different defects and the severity of the osteopetrotic phenotype. The metabolic acidosis in these patients is assumed to counteract—albeit incompletely—excessive bone thickening generated by the CA II-dependent inhibition of osteoclast activity.[373]

Secondary Proximal Renal Tubular Acidosis

The secondary varieties of proximal RTA with and without Fanconi's syndrome occur more commonly than the primary forms. Many secondary forms are

associated with hereditary abnormalities of amino acid or carbohydrate metabolism.

Cystinosis is an autosomal recessive lysosomal storage disease caused by mutations in the lysosomal cystine transporter CTNS. Defects in the transporter lead to intracellular cystine accumulation, widespread cellular destruction, Fanconi's syndrome, renal glomerular failure later in childhood. This disorder remains the most common childhood cause of Fanconi's syndrome[379] (see: www.ncbi.nlm.nih.gov/entrez/dispomim.cgi?id = 219800). Treatment with oral cysteamine (beta-mercaptoethylamine), a free thiol that reduces lysosomal cysteine levels and can prevent or delay the complications of cystinosis. A FISH-based method for early molecular diagnosis of the most common 57 kb CTNS deletion mutation is available.[28]

Other organs, including the liver, spleen, and pancreas, muscles, and CNS also accumulate cystine and may develop abnormalities. Occasional patients have a very benign clinical course with minimal renal involvement. Such patients who are asymptomatic may be diagnosed during routine ophthalmologic evaluation when ocular cystine deposits are noted.

Other inherited disorders of amino acid or carbohydrate metabolism such as type I tyrosinemia, galactosemia, and fructose intolerance are listed in Table 59.8. Patients with the X-linked hereditary nephrolithiasis syndrome (Dent's disease) have features of a generalized proximal tubule disorder such as low molecular weight proteinuria, aminoaciduria, and phosphaturia. Interestingly, however, acidosis is not observed in this disease caused by a defect in one of the chloride channel genes (CLCN5).[229]

Lowe's syndrome (oculocerebral syndrome) also exhibits features of Fanconi's syndrome and is caused by mutations in OCRL1, encoding a phosphatidylinositol 4,5-bisphosphate (PIP2) 5-phosphatase (www.ncbi.nlm.nih.gov/entrez/dispomim.cgi?id = 309000). Some mutations in OCRL1 do not cause classical Lowe's syndrome but rather develop a Dent's phenotype without acidosis.[172] The reason and mechanism of this phenotypic heterogeneity remain to be elucidated.

Multiple myeloma is the most common cause of acquired adult Fanconi's syndrome. Some Bence Jones proteins, which are reabsorbed and catabolized by proximal tubule cells, are toxic to these cells.[306,333] Patients with isolated light chain disease,[118,163] benign monoclonal gammopathy,[163] and Bence Jones–protein associated amyloidosis[118,163] have developed Fanconi's syndrome. Fanconi's syndrome occurs more commonly in disorders with monoclonal κ light chains than those with λ light chains. In adult patients with apparent "idiopathic" Fanconi's syndrome the diagnosis of multiple myeloma should always be considered because occult forms of myeloma may become overt years after development of the renal dysfunction.

Primary hyperparathyroidism has been associated clinically with hyperchloremic metabolic acidosis[25,243,261] and large doses of PTH have been shown to suppress proximal tubule HCO_3^- reabsorption at least in part by inhibiting Na^+/H^+ exchange.[284,306] However, experimentally induced chronic PTH excess in humans induces only a transient metabolic acidosis followed by a mild metabolic alkalosis, both generated and maintained by a renal mechanism.[177] Thus, the clinically observed acid–base disturbances in primary and secondary hyperparathyroidism are not the result of isolated proximal PTH action, but rather constitute the final consequence of many, in part opposing mechanisms such as more distal effects of PTH, alkali recruitment from bone, hypercalcemia (which stimulates renal H^+ secretion), phosphaturia, underlying or associated renal disease and secondary changes in 1,25 $(OH)_2D$ levels.[179]

Fanconi's syndrome may develop in individuals with vitamin D deficiency and other disorders of vitamin D metabolism.[154] Secondary hyperparathyroidism often complicates these disorders and may contribute to the tubule dysfunction. Hypocalcemia and hypophosphatemia may also alter proximal tubule function. Administration of appropriate vitamin D metabolites can ameliorate or correct Fanconi's syndrome.

Pharmacologic inhibition of membrane-bound carbonic anhydrase IV in the proximal tubule lumen will generate proximal RTA and have a diuretic effect.[74] Such diuretics are especially useful in patients with metabolic alkalosis. They are also used to reduce intraocular pressure in patients with glaucoma.

Drugs and toxins can damage proximal tubule cells. Outdated tetracycline was responsible for several Fanconi's syndrome epidemics.[127,153] Ifosfamide and tacrolimus (FK506) were reported to cause proximal tubular acidosis in children.[275,330] Fanconi's syndrome was also described in HIV^+ patients, but the pathogenesis (i.e., side effects of drugs therapy, etc.) was not investigated. Aristolochic acid, an ingredient in Chinese herbs, is also believed to be a causal agent in Fanconi's syndrome.[383] Chronic exposure to heavy metals, such as cadmium, lead, and mercury, damages the proximal tubule and can lead to proximal RTA.[70,71,145,219] Damage due to copper deposition with Wilson's disease has already been noted.[375] Other toxins such as D-serine, toluene (glue sniffing), maleic acid, and methyl-3-chromone may also damage proximal tubule cells.[133,162,283]

A variety of interstitial renal diseases, including Sjögren's syndrome, medullary cystic disease, kidney transplant rejection,[377] Balkan nephropathy, and

chronic renal vein thrombosis,[63] have been associated with Fanconi's syndrome.

Some patients with nephrotic syndrome develop proximal tubule abnormalities.[39] Tubule function may be adversely affected by a large reabsorbed protein load. However, uncomplicated nephrotic syndrome does not usually produce proximal tubule defects. When nephrotic syndrome is complicated by renal vein thrombosis, proximal tubule defects become more common.[63] The added vascular insult may increase interstitial damage and lead to the proximal tubule dysfunction. Immunologic tubule injury may also contribute to tubule dysfunction in these patients.

Malignancy may be associated with proximal tubular dysfunction. Fanconi's syndrome has been identified in patients with monocytic and myelomonocytic leukemia as well as lymphoma.[143] Isolated renal tubule uric acid and amino acid wasting can occur with Hodgkin's disease and lung cancer.[29,371]

Hypokalemic ("Classic") Distal Renal Tubular Acidosis

Patients with hypokalemic distal RTA cannot generate a maximally acid urine (<5.5) despite spontaneous or induced metabolic acidosis. This reduces titratable acid and ammonium excretion and results in positive acid balance. Hyperchloremic acidosis, usually associated with hypokalemia and hypercalciuria, ensues. Proximal reabsorption of HCO_3^- and other solutes is preserved. Generalized distal tubule dysfunction is not present, as affected patients tend to be hypokalemic.

In inherited or primary forms of distal RTA, the transport defects in the alpha intercalated cells of the medullary collecting duct are responsible pathogenetically. In these cells, mutations of the genes encoding for the vacuolar H^+-ATPase and basolateral Cl^-/HCO_3^- exchanger (kAE1) have been identified. An additional candidate is the gene for the H^+/K^+-ATPase expressed in cortical and outer medullary collecting duct cells.

The precise localization of the defect(s) in the distal segments and the cellular basis for acquired, classic distal renal tubular acidosis are not well defined and probably heterogeneous. Phenomenologically, the distal acidification defect can be due to abnormal proton secretory pumps that decrease distal H^+ secretion, increase distal tubule permeability to H^+ (which leaks back), or increase HCO_3^- permeability (which leaks into the lumen). Absence of H^+-ATPase in the collecting duct has been found in some, but not all examined patients with Sjögren's syndrome and distal RTA.[89] Candidate transporter defects are H^+-ATPase and basolateral Cl/HCO_3^- in type A intercalated cells and H^+/K^+-ATPase in cortical and outer medullary collecting duct cells (see Primary Distal Renal Tubular Acidosis section). Absence of H^+-ATPase in the collecting duct has been found in some, but not all examined patients with Sjögren's syndrome and distal RTA.[89]

Sodium and potassium wasting are prominent features of distal RTA and result from complex mechanisms. Normally, 50–100 mEq of net acid are produced daily from dietary precursors, metabolic generation, and stool alkali losses. The acid anions, such as PO_42^-, SO_42^-, and Cl^-, transiently replace decomposed HCO_3^- in the ECF. Normally, the kidney filters these anions as Na^+ salts and then reabsorbs the Na^+ in exchange for H^+, which generates NH_4^+ or titratable acid. Thus, regenerated HCO_3^- is returned to the ECF together with Na^+, while the acid anion is excreted into the urine together with a proton. Decomposed bicarbonate is regenerated when the proton and anion are excreted. Excretion of NH_4^+ and the anion or titratable acid and the anion is equivalent, from the acid–base perspective, to excretion of the original acid itself.

Impaired distal H^+ secretion decreases the excretion of these anions as acids and increases their excretion as Na^+ or K^+ salts. ECF contraction and metabolic acidosis result. Acidosis further decreases proximal sodium reabsorption aggravating activation of the renin–angiotensin–aldosterone axis and thus augmenting distal tubule Na^+ reabsorption and K^+ secretion. Histological damage to the medullary collecting duct might also contribute to potassium losses. Dietary NaCl is retained and partially ameliorates the ECF contraction. The net effect is hyperchloremic acidosis and hypokalemia.

Chronic metabolic acidosis and chronic positive acid balance activate skeletal buffering mechanisms. As bone is mobilized, alkali, calcium, magnesium, and phosphate are added to the ECF. This accounts, in part, for the hypercalciuria that develops in many patients with distal RTA. In addition, systemic acidemia may reduce renal tubule calcium absorption in the distal convoluted tubules. Stone formation and renal calcification are commonly observed in untreated distal RTA patients.

The acidosis-induced negative calcium balance observed in distal RTA and, in addition, direct effects of acidosis on bone (inhibition of osteoblasts and stimulation of osteoclasts) (see Role of Bone section), have been shown to effectively decrease bone mass (which can then be improved by alkali treatment).[101] The prevalence of distal RTA in otherwise unexplained "primary" osteoporosis is unknown. However, incomplete distal RTA was found in 9 out of 48 patients with osteoporosis, where other secondary causes had been excluded.[369]

Another important factor that contributes to renal calcification and stone formation is renal citrate

excretion. For the reasons discussed earlier, citrate excretion is greatly diminished in metabolic acidosis. As discussed previously, one exception to this general response to acidosis and acidemia is proximal RTA. The diffuse tubule dysfunction, which commonly occurs together with proximal RTA in Fanconi's syndrome, reduces citrate absorption and thereby increases its renal excretion. This may not be true of pure proximal RTA without any element of Fanconi's syndrome. The proximal RTA produced by acetazolamide decreases urine citrate excretion and is associated with renal calcification.[329]

Citrate is an important calcium chelator that solubilizes urinary calcium.[88,262,273] Low urine citrate levels, a high urine pH (which increases calcium phosphate precipitation), and hypercalciuria combine to produce nephrolithiasis and nephrocalcinosis in patients with distal RTA (see Effects of Metabolic Acidosis on Renal Citrate Metabolism section).

Additional clinical features of distal RTA include secondary erythrocytosis (due to increased erythropoietin concentrations[6]) and renal cyst formation.[187] The pathogenesis of both increased erythropoietin secretion and cyst formation is unknown. Table 59.9 lists disorders associated with distal renal tubular acidosis.

TABLE 59.9 Causes of Distal Renal Tubular Acidosis

- Primary
  - Autosomal-dominant distal RTA (type Ia): defect of AE1 (SLC4A1)
  - Autosomal-recessive distal RTA with sensorineural deafness (type Ib): defect of B1 subunit of H + ATPase, ATP6V1B1
  - Autosomal-recessive distal RTA without sensorineural deafness (type Ic): Defect of a4 subunit of H + ATPase, ATP6V0A4
  - Autosomal-recessive, unclassified: rare AE1, SLC4A1, mutations
  - Mixed RTA (type III) with osteopetrosis: defect in carbonic anhydrase II (CA II)
  - H^+/K^+-ATPase defect
- Secondary to genetically transmitted diseases
  - Ehlers–Danlos syndrome
  - Hereditary elliptocystosis
  - Sickle cell disease
  - Carbonic anhydrase deficiency
  - Medullary cystic disease
  - Wilson's disease
  - Fabry's disease
  - Hereditary hypercalciuria
  - Hereditary fructose intolerance
  - Familial hypergammaglobulinemia
- Secondary to autoimmune disorders
  - Polyconal hypergammaglobulinemia
  - Hyperglobulinemic purpura
  - Cryoglobulinemia
  - Sjögren syndrome
  - Thyreoiditis
  - Pulmonary fibrosis
  - Chronic active hepatitis

  - Osteopetrosis

Primary or Inherited Distal Renal Tubular Acidosis

Both autosomal-dominant and autosomal-recessive inheritance patterns exist in primary distal RTA. The phenotypic spectrum is large and ranges from asymptomatic, mild acidosis, incidental renal stones or renal calcifications to severe metabolic acidosis, stunted growth, rickets or osteomalacia and early nephrocalcinosis with renal failure. In general, dominant forms are associated with a milder phenotype.[193]

Autosomal dominant distal RTA (type Ia, [O]MIM 179800) occurs in patients who are heterozygous for mutations in the SLC4A1 gene encoding for the kidney anion exchanger AE1 (kAE1).[194] kAE1 is expressed on the basolateral surface of type-A intercalated cells in the collecting duct and mediates HCO_3^- reabsorption via Cl^-/HCO_3^- exchange. Several mutants have been identified, which, surprisingly, retain near normal transport function, but seem to be mistargeted away from their proper basolateral destination.[199,305] Thus, the mutations described thus far identify autosomal-dominant distal RTA as a protein trafficking disorder.

The erythroid Cl^-/HCO_3^- exchanger (band 3, eAE1) is the product of the same gene. Defects in this gene lead to spherocytosis. However, erythroid disorders associated with AE1 mutations exhibit no concurrent renal dysfunction, while patients with autosomal-dominant distal RTA lack erythroid abnormalities. The only human exception is one single case with complete deficiency of the eAE1 polypeptide (band 3 Coimbra) exhibiting clinically both phenotypes (i.e., severe hemolytic anemia and distal RTA).[297] The mechanisms

by which a particular mutation in the AE1 gene leads to the clinical phenotype of either spherocytosis or distal RTA remain to be elucidated.[324]

Recessive distal RTA is genetically heterogeneous and occurs with and without sensorineural deafness. Both affected genes encode for subunits of the apical proton pump (H^+-ATPase) in type A intercalated cells. In distal RTA, type Ib (MIM 267300), with sensorineural deafness, B1 subunit gene of the H^+-ATPase is affected by various mutations (ATP6V1B1).

A similar phenotype with milder sensorineural deafness manifested in adulthood, occurs as the result of several mutations in the a4 subunit of the proton pump (ATP6V0A4).[343] Deafness is thought to result from hair cell damage due to changes in the acid−base and electrolyte milieu of the endolymph. Epithelial cells surrounding the endolymphatic space express the H^+-ATPase. The high potassium concentration in endolymph (around 140 mmol/liter) creates a positive endolymph potential that results in passive proton efflux. To maintain pH at around 7.40 active proton transport into the endolymph is necessary. Accordingly, systemic alkali treatment corrects acidosis in these patients but apparently cannot prevent progressive loss of hearing.[50]

Autosomal-recessive distal RTA with normal hearing (distal RTA, type Ic, MIM 602722) is caused by mutations in the ATP6N1B gene, which encodes for an 840−amino acid, kidney-specific isoform of ATP6N1A. The encoded protein constitutes a noncatalytic, accessory subunit of the proton pump.[331]

One reported case of a child with renal and probably intestinal K^+ wasting, distal RTA, renal magnesium wasting may represent the first example of an inherited deficiency in the colonic H^+/K^+-ATPase.[328] However, no genetic analysis is currently available. Acquired forms of classical distal RTA lend further support to the identification of H^+/K_+-ATPase as a candidate gene: vanadate, an inhibitor of H,K-ATPase, but not vacuolar H^+-ATPase, causes hypokalemic distal RTA and decreased H^+/K^+-ATPase activity in rats.[83] Also, vanadate contamination of drinking water has been linked to endemic hypokalemic distal RTA in Thailand.[271] Rat models of distal tubular acidosis induced by urinary tract obstruction or lithium were recently associated with decreased H^+/K^+-ATPase activity in the medullary collecting duct, with enhanced or unchanged activities in the cortical collecting duct.[108] Thus, acquired or congenital defects in H^+/K^+-ATPase may cause classical distal RTA.

Mice lacking the K-Cl cotransporter Kcc4 exhibit deafness and renal tubular acidosis. Apart from the inner ear, Kcc4 is expressed—as are H^+-ATPase and kAE1—in type A intercalated cells of the medullary collecting duct and may be necessary for basolateral chloride extrusion (permitting continued basolateral CL^-/HCO_3^- exchange). A human disorder has not been described, but this finding supports the central role of the alpha-intercalated cells in the pathogenesis of distal RTA and establishes the K-Cl cotransporter Kcc4 as an additional candidate gene for primary, distal RTA.[36]

Secondary Distal Renal Tubular Acidosis

As described previously, distal RTA can lead to hypercalciuria and nephrocalcinosis. However, distal RTA can also result from tubular damage caused by hypercalciuria and nephrocalcinosis of any cause. Reported causes include hyperparathyroidism,[296] hypervitaminosis D,[114] and hyperthyroidism.[185]

Distal RTA occurs frequently in patients with autoimmune diseases. Kidney biopsies often reveal lymphocytic interstitial nephritis,[151] which may be responsible for the acidification defect. This form of RTA occurs in patients with Sjögren syndrome,[111,348] chronic active hepatitis, and primary biliary cirrhosis.[141,285] Lymphocytic cytotoxicity specific to renal tissue and autoantibodies directed to renal collecting duct cells have been identified in several such patients.

Several drugs and toxins can produce distal RTA. Amphotericin B, a cation-selective ionophore and may increase H^+ back leak. Unlike most other forms of distal RTA, the capacity to generate a normal U-B pCO_2 gradient is maintained[103,105,248,340] (see Diagnosis of Proximal and Hypokalemic Distal Renal Tubular Acidosis section). Other drugs and toxins, including toluene,[23,263] analgesics,[338] and cyclamates[384] can produce distal RTA. They probably act through a variety of different mechanisms. Toluene thus causes both distal and proximal tubular acidosis, but organic acidosis by overproduction of hippuric acid resulting from the metabolism of toluene is an additional factor in the genesis of metabolic acidosis.[65]

A variety of tubulointerstitial diseases may produce distal RT. Transplanted kidneys can develop both proximal and distal RTA.[24,32,259,377] Transient proximal RTA occurs frequently in the immediate posttransplant period. Distal acidification defects may occur months to years after the transplant. The distal defect may be secondary to chronic cellular rejection.[259] Batlle et al.[24] studied renal acidification defects in transplant patients and identified a number of pathogenic mechanisms. Multiple defects were also found when distal RTA developed in patients with chronic obstructive uropathy.[20] The abnormalities included intrinsic acidification defects, decreased renin (and aldosterone) production, and renal resistance to aldosterone.

As indicated previously, a form of endemic distal RTA was identified in Thailand[270] that has been linked

to vanadate contamination of drinking water. Affected subjects are at high risk for sudden (nocturnal) death probably caused by cardiac arrhythmias due to potassium depletion. The relatively high prevalence of hypokalemic periodic paralysis in the same population may increase the frequency of severe hypokalemic side effects.[271]

Patients with early or incomplete distal RTA may not manifest the full-blown syndrome. These patients cannot normally acidify their urine and therefore excrete reduced quantities of titratable acid. However, they maintain apparently normal acid–base balance by increasing renal ammonia excretion, decreasing citrate excretion and increasing bone buffering.[55,350] Patients with incomplete distal RTA are often discovered during a family screening when a relative with classic distal RTA is diagnosed. They may also be identified during nephrolithiasis evaluation. These patients are not acidemic, but they are hypercalciuric and have low urine citrate levels. Therefore they develop renal stones and nephrocalcinosis. Oral alkali therapy will increase urine citrate, reduce urine calcium, and decrease stone formation and nephrocalcinosis.

Diagnosis of Proximal and Hypokalemic Distal Renal Tubular Acidosis

A hypokalemic, hyperchloremic, low bicarbonate pattern is consistent with a diagnosis of proximal or hypokalemic distal renal tubular acidosis. Chronic respiratory alkalosis can produce an identical plasma electrolyte pattern as metabolic acidosis and must be ruled out by the history, physical examination, and arterial blood gas analysis. The anion gap provides a differential clue. It tends to be slightly reduced with hyperchloremic acidosis (as a result of proton buffering by albumin, which decreases its negative charge) and slightly increased by respiratory alkalosis (as a result of increased organic acid levels and decreased proton buffering by albumin increasing its negative charge).

If acidosis is confirmed, other forms of hyperchloremic metabolic acidoses, especially acidosis secondary to diarrhea, must be excluded usually by the history. Before embarking on an extensive and expensive evaluation of renal acidification defects and their underlying disease states, it is necessary to determine if the acidosis is of renal or extrarenal origin. In the typical clinical circumstance, there is usually some doubt regarding this classification when the patient is evaluated initially. This major differential diagnostic hurdle can be easily surmounted with a measurement of net acid excretion (NAE): elevated NAE correlates with extrarenal acidosis, and normal or reduced NAE with renal acidosis. In brief, the normal kidney responds to systemic acidosis by increasing NAE.

When RTA is the most likely possibility, the proximal and hypokalemic distal types must be differentiated. Patients with proximal RTA are able to normally acidify the urine once the $[HCO_3^-]p$ is reduced acutely to values below the renal threshold. In contrast, patients with hypokalemic distal RTA cannot normally acidify the urine whether the $[HCO_3^-]s$ is normal or markedly reduced. Therefore, while a UpH of less than 5.5 effectively rules out classic distal RTA, it is still compatible with a diagnosis of proximal RTA.

Diagnostic Tests for Distal RenalTubular Acidosis

Patients with distal RTA have low urine NH_4^+ excretion rates, which is a major reason they develop metabolic acidosis and positive acid balance. Reduced urine NH_4^+ excretion is partly due to decreased collecting duct trapping because of the high urine pH. In addition, the medullary countercurrent NH_4^+ concentration gradient is probably disrupted in many of these patients as a result of tubulointerstitial disease. The urine NH_4^+ excretion rate helps differentiate distal RTA from other forms of chronic hyperchloremic metabolic acidosis. Occasional patients with metabolic acidosis whose renal acidification mechanism is normal have a urine pH above 5.5 despite severe acidemia. Markedly increased renal ammoniagenesis and ammonia excretion in these patients raise the urine pH by virtue of NH_3's property as a diffusible base (Fig. 59.19B). Hypokalemia is an important stimulus to renal ammonia synthesis and excretion.[349] Therefore patients with chronic diarrhea and hypokalemic hyperchloremic metabolic acidosis may develop a high urine pH despite maximal renal acidification.[21] Although the high urine pH suggests a diagnosis of RTA, the high ammonia excretion rate rules out that possibility. The urine anion gap, defined as $UNa + UK - UCl$, estimates the urine $[NH_4^+]$.[142] Patients with metabolic acidosis whose $UCl > UNa + UK$ (i.e., negative urine anion gap) generally excrete more than 80mEq/liter NH_4^+ in the urine, ruling out a diagnosis of distal RTA. When the $UCl < UNa + UK$ (i.e., positive urine anion gap), then urine NH_4^+ excretion is relatively low and a diagnosis of distal RTA is possible.[21,142] However, the interpretation of urine electrolytes and the urine anion gap will be confounded if large quantities of HCO_3^-, or organic anions, such as ketoacid salts, are present in the urine. Bicarbonate should be excluded by measuring urine pH, while ketosalts are excluded by the clinical circumstances and urine dipstick. It must be recalled that the urinary anion gap,

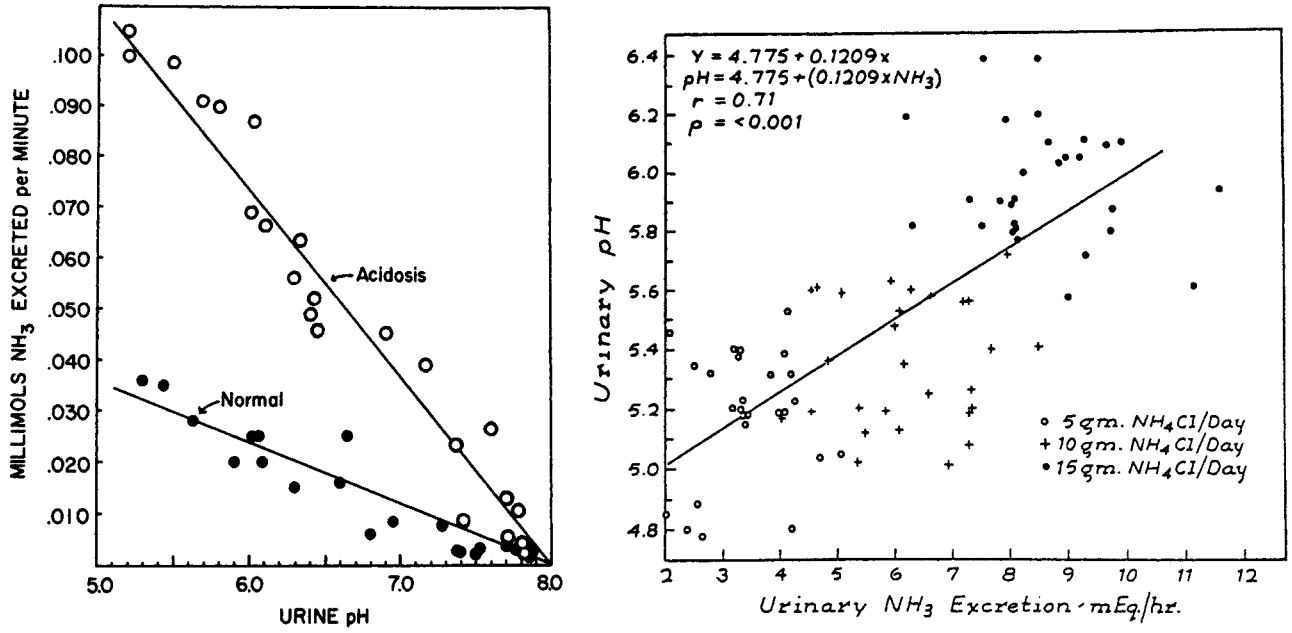

FIGURE 59.19 (A) The relation between urine pH and ammonia excretion in a single animal under conditions of normal acid–base balance in chronic acidosis. Urine pH was varied by the intravenous infusion of sodium bicarbonate. Note that the animal excretes a greater quantity of ammonia at any given urine pH under conditions of chronic acidosis. (*With permission, from Pitts RF. The renal excretion of acid. Fed Proc 1948;7:418.*) (B) The relationship between ammonia excretion and urinary pH during chronic NH_4Cl loads. As the chronic acid load was increased in stepwise fashion, mean urinary ammonia excretion increased. Note that the urine pH also increased progressively as the NH_4Cl load increased from 5 to 10 or 10 to 15 g/day. Thus, more severe chronic metabolic acidosis was associated with a higher urine pH, as well as higher ammonia excretion rates. *(With permission, from Madison LL, Mebane D, Unger RH, Lochner A. The hypoglycemic action of ketones. II. Evidence for a stimulatory feedback of ketones on the pancreatic beta cells. J Clin Invest 1964;43:408–415.)*

although often helpful for clinical diagnostic purposes, gives only crude estimates of renal NH_4^+ excretion.

Patients with incomplete distal RTA always require an acidification test to establish this diagnosis. By definition, these patients are not spontaneously acidemic under basal conditions.[55,110] The acid load should reduce the plasma [HCO_3^-] by 4–5 mEq/liter. The most commonly used, standardized acidification test is ingestion of a single dose of NH_4Cl, 100 mg/kg body weight over 30–40 min. The NH_4Cl may first be dissolved in water to improve its absorption. Following ingestion of the NH_4Cl, sequential urine specimens are collected over six hours. The [HCO_3^-]p is measured prior to and three hours after the oral NH_4Cl load and should decrease by 4–5 mEq/liter to document adequate NH_4Cl absorption and systemic acidification. The normal response to this acidosis is urine acidification with the pH falling below 5.5.

An alternative acidification test may be used when patients cannot tolerate ammonia loads (i.e., patients with hepatic insufficiency who may develop encephalopathy). The ingestion of $CaCl_2$ 2 mEq/kg will generate a metabolic acidosis.[281] Ingested $CaCl_2$ ionizes and within the intestine the Ca^{2+} binds CO_3^{2-} (principally from pancreatic secretions) to form relatively insoluble $CaCO_3$. Ingested Cl^- is absorbed in exchange for secreted HCO_3^-. The net effect of these reactions is the excretion of $CaCO_3$ into the stool and systemic acidification, equivalent to a NH_4Cl or HCl load.

Urinary tract infections and bacteriuria can confound the interpretation of urine pH measurements. Urease from bacteria split urea into CO_2 and NH_3. The NH_3 combines with H^+, which increases the urine pH. A diagnostic work-up for RTA, undertaken in the presence of a persistent urinary tract infection, mandates precautions to mitigate urine stasis by ensuring a rapid urine flow rate. Urine must be promptly collected and analyzed and potent bactericidal agents should be placed in the collection container. The (U-B) pCO_2 gradient can also be a helpful diagnostic tool under such circumstances.[104,105,160]

The gradient between urinary and blood pCO_2 [(U-B) pCO_2] after an intravenous $NaHCO_3$ load is probably proportional to distal tubule proton secretion and can be used as a diagnostic test for distal RTA. Pitts and Lotspeich[291] provided the experimental basis for this test: Bicarbonate loading delivers large quantities of $NaHCO_3$ to the distal tubule and stimulates proton

secretion. Owing to the absence of carbonic anhydrase, the H_2CO_3 that is generated does not rapidly dehydrate and instead is delivered to more distal tubule segments, the ureters and bladder. The H_2CO_3 relatively slowly dehydrates to form H_2O and CO_2 in these structures, where the medullary countercurrent system and surface-to-volume relationship are not favorable to rapid CO_2 dissipation. In consequence, the urine pCO_2 increases. Thus, a high urine−blood (U-B) pCO_2 gradient is accepted as evidence for distal tubule proton secretion.

Since the (U-B) pCO_2 gradient is influenced importantly by urinary pH, nonbicarbonate buffers, and HCO_3 concentration, it is best measured under standardized conditions, that is, during an intravenous $NaHCO_3$ load. $NaHCO_3$, at a concentration of 500 mEq/liter, is infused at 3 ml/min. The pH and pCO_2 of sequential urine specimens are determined. Steady-state urine values are usually achieved 2−4 hours after the infusion is initiated when the urine pH exceeds 7.5. At this time, the (U-B) pCO_2 gradient should be greater than 20−30 mm Hg.[23] Most patients with distal RTA cannot generate a normal gradient, which is consistent with the notion that most cases of distal RTA are caused by defective distal proton secretion. One exception is amphotericin-induced RTA, which likely is due to a H^+ back leak; such patients can generate a normal (U-B) pCO_2 gradient.[105]

Increased distal delivery of Cl^- (by administering furosemide) or SO_4^{2-} (by Na_2SO_4 infusion) can also be used to estimate distal H^+ secretion. Due to the low permeability of these anions in the collecting ducts, a more lumen negative transepithelial potential and thus a stimulus for H^+ (and K^+) secretion are created.[19,24]

In summary, distal RTA is generally confirmed by systemic acidemia, a relatively high urine pH, and a low ammonium excretion rate or—indirectly—a positive urinary anion. Other common features include nephrocalcinosis, nephrolithiasis, hypercalciuria and hypocitraturia.

Diagnostic Tests for Proximal Renal Tubular Acidosis

Patients with proximal RTA are able to normally acidify their urine if their $[HCO_3^-]p$ is adequately reduced. However, as the $[HCO_3^-]p$ is increased, for example, by administering exogenous $NaHCO_3$, urinary pH increases and bicarbonaturia develops while the $[HCO_3^-]p$ is still below the normal range. Intravenous HCO_3^- titration experiments are required to identify accurately proximal RTA. However, a diagnosis can usually be established with oral $NaHCO_3$ administration. Simultaneous measurement of urine and serum bicarbonate and creatinine concentrations permits the fractional bicarbonate excretion rate to becalculated:

$$[HCO_3^-]u \times [Cr]s/[HCO_3^-]s \times [Cr]u \times 100\% = \text{fractional excretion } HCO_3^-$$

Patients with proximal RTA excrete greater than 10−15% of the filtered HCO_3^- load as the $[HCO_3^-]p$ approaches normal.

Although isolated bicarbonate wasting can occur, most patients with proximal RTA have other proximal tubule reabsorptive defects. Glucose, amino acids, uric acid, lysozyme, beta-2-microglobulin, light chains, and other small proteins are abnormally excreted. Decreased phosphate reabsorption results in renal phosphate wasting and hypophosphatemia, which can lead to growth retardation, rickets, and osteomalacia. Detection of increased urinary excretion of these proximally reabsorbed molecules is, therefore, an important clue to the identification of proximal RTA in an acidotic patient. Hypercalciuria and hypocitraturia are uncommon with proximal RTA. In consequence, nephrolithiasis and nephrocalcinosis do not occur with increased frequency.

Treatment of Hypokalemic Distal Renal Tubular Acidosis

The therapy of hypokalemic distal RTA begins with an effort to establish, and if possible remove, an underlying process. Thus, RTA secondary to a drug or toxin is most appropriately treated by its elimination. When an underlying process cannot be eliminated or treated, therapy directed at the chemical abnormalities may be initiated.

Patients with distal RTA cannot completely regenerate that HCO_3^- decomposed by normal acid loads. This leads to hypokalemic hyperchloremic acidosis, ECF volume depletion, secondary hyperaldosteronism, hypercalciuria, and hypocitraturia. The administration of an adequate quantity of oral bicarbonate will reverse most of these abnormalities. Adults generally require between 50 and 100 mEq of HCO_3^- or HCO_3^- precursors.

Larger quantities, up to 15 mEq/kg/day of $NaHCO_3^-$ may be required in children with distal RTA.[250] In these children, an element of proximal HCO_3^- wasting exists in addition to the distal tubule defect. Although it is possible that volume expansion, produced by the administered $NaHCO_3$, has reduced the proximal HCO_3^- reabsorptive rate, careful studies in several patients exclude this possibility. Direct measurement of ECF and renin levels suggests volume contraction.[250] High doses of $NaHCO_3$ therapy are necessary for these children to achieve normal growth

rates. This form of combined distal and proximal RTA has been called type III RTA in the past. However, as these children mature, the HCO_3^- wasting component decreases and classic distal RTA evolves.[250]

The ingestion of adequate quantities of HCO_3^- normalizes the acid–base status of these patients. Furthermore, ECF volume is expanded, reducing renin, angiotensin, and aldosterone levels. This ameliorates the renal K^+ wasting. Early in the course of therapy, HCO_3^- administration may produce profound hypokalemia unless K^+ is aggressively replaced. Once the initial K^+ deficit is corrected, additional potassium supplements are often not required.

Bicarbonate therapy can restore normal growth in children and stop skeletal mobilization in adults.[101,250] Hypercalciuria decreases, urine citrate increases, and renal stone formation and nephrocalcinosis decrease.[149,262]

Some of the available HCO_3^- salts and HCO_3^- salt precursors are listed in Table 59.10. Sodium bicarbonate tablets and baking soda are inexpensive and readily available. One teaspoon (about 4.5 grams) of baking soda contains 50–60 mEq of sodium bicarbonate, and is an adequate daily dose for many adults with distal RTA. The gas generated by oral HCO_3^- may be unpleasant and occasionally diarrhea results from the osmotic load. These side effects are diminished by dividing the doses and limiting each dose to one-half teaspoon (2 to 2.5 grams). An alternative alkali source is Shohl's solution, which contains sodium citrate and citric acid constituted to provide 1 mEq/ml of potential sodium bicarbonate. Shohl's solution does not generate CO_2 gas. Compared with $NaHCO_3$, sodium citrate delivers a smaller osmotic load due to citrate's trivalent charge. One millimole of Na citrate provides 3 mEq of potential HCO_3^- and represents 4 mOsm; an equivalent dose of $NaHCO_3$ delivers 6 mOsm. Shohl's solution is commercially available as Bicitra. However, all citrate compounds markedly enhance the GI absorption of aluminum.[258] Therefore, caution must be exercised when these drugs are prescribed and they should never be used together with aluminum-containing compounds.

Most patients with distal RTA do not require supplemental potassium following initial potassium repletion. However, for the occasional patient who does need additional potassium, potassium-containing alkali salts listed in Table 59.10 may be used. If $NaHCO_3$ salts produce sodium retention and edema, dietary NaCl should be restricted and diuretics may be administered cautiously.

TABLE 59.10 Oral $NaHCO_3$ and Bicarbonate Precursors

$NaHCO_3$ tablets	3.9 mEq/325-mg tablet
Baking soda ($NaHCO_3$)	60 mEq/teaspoon
Shohl's solution: bicitra	
Na citrate	1 mEq/mL
Citric acid	1 mEq/mL
Polycitra	
Na citrate	1 mEq/mL
K citrate	1 mEq/mL
Citric acid	1 mEq/mL
Kaon (K gluconate)	1.33 mEq/mL
	5 mEq/tablet
K-lyte ($KHCO_3$ and K citrate)	25 or 50 mEq/tablet

Treatment of Proximal Renal Tubular Acidosis

The treatment of proximal RTA is most effective when an underlying process can be reversed or eliminated. When this is not possible, treatment may be directed at the biochemical abnormalities. However, proximal RTA is a more difficult disorder to treat than distal RTA. Although exogenous $NaHCO_3$ can increase the $[HCO_3^-]p$, the proximal HCO_3^- reabsorptive capacity is exceeded and bicarbonaturia results. To the extent that administered $NaHCO_3$ expands volume, HCO_3^- wasting will also be worsened. Increased distal $NaHCO_3$ delivery also accelerates renal potassium wasting. Figure 59.20 shows that patients with proximal RTA develop bicarbonaturia and K^+ wasting when exogenous $NaHCO_3$ is administered. By contrast, patients with distal RTA respond to $NaHCO_3$ treatment by reducing renal K^+ excretion.[322]

If alkali salts are administered to patients with proximal RTA, large doses (10–30 mEq/kg/day) will be required. Bicarbonate retention can be improved by modest volume depletion. Thiazide diuretics may be used to contract the ECF volume and increase proximal HCO_3^- reabsorption.[43,292] However, thiazide diuretics may exacerbate renal K^+ wasting. In such cases, potassium-sparing diuretics may be useful. Dietary NaCl restriction is also used to reduce volume. Patients with proximal RTA are in a tenuous state of potassium balance and frequent determinations of serum $[K^+]$ are required to avoid both hypokalemia and hyperkalemia.

When generalized proximal defects result in Fanconi's syndrome, oral phosphate salts and vitamin D metabolites are required to treat the resulting skeletal abnormalities.[4] Modest volume depletion also promotes phosphate retention. Normal growth may be restored with such therapy.

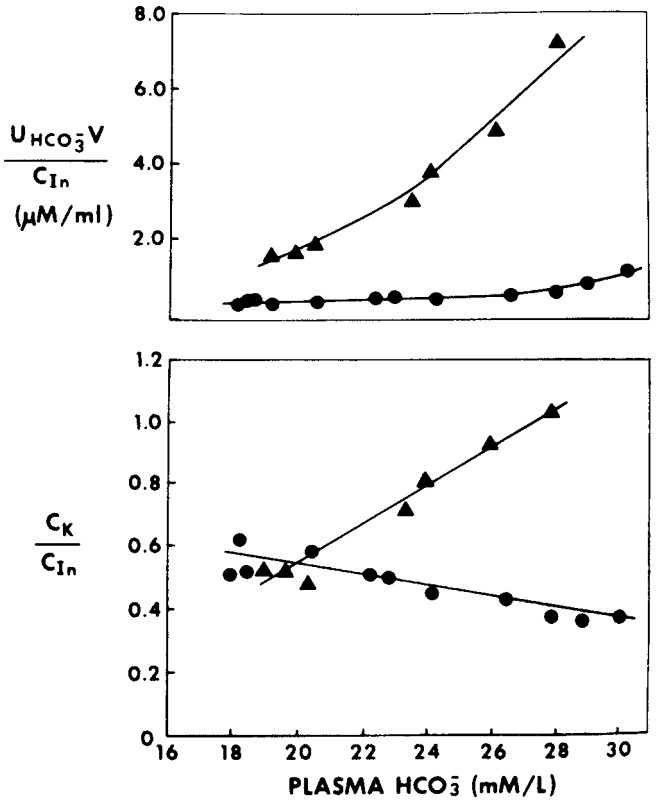

FIGURE 59.20 Fractional excretion of bicarbonate and potassium as a function of the plasma bicarbonate concentration in patients with proximal (triangle) and distal (circle) renal tubular acidosis.

Generalized Distal Tubular Acidosis (Hyperkalemic Renal Tubular Acidosis)

Aldosterone-sensitive tissues include the sweat glands, salivary glands, colon, and distal renal tubule. Aldosterone stimulates sodium reabsorption in the cortical collecting tubule, which usually increases the negative potential difference at this site. This electric potential enhances the secretion of protons and potassium.[241] Potassium deficiency will increase distal tubule H^+ secretion. Aldosterone also stimulates active H^+ secretion via the proton ATPase independent of Na^+ reabsorption.[341]

Decreased aldosterone activity in the distal renal tubule reduces Na^+ reabsorption, K^+ secretion, and H^+ secretion. Salts of decomposed HCO_3^-, which would normally be excreted with NH_4^+ or titratable acid, are instead excreted as sodium salts. This results in a hyperchloremic metabolic acidosis and ECF contraction. In addition to the direct decrease of H^+ secretion secondary to reduced aldosterone activity, the development of hyperkalemia inhibits renal ammoniagenesis and decreases renal NH_4^+ excretion. Decreased NH_4^+ excretion is the major reason these patients develop metabolic acidosis.[347,350]

Animal models show that mineralocorticoid deficiency does not block the capacity to generate a normal pH gradient across an epithelial membrane but does reduce the rate of H^+ secretion. A normally acid urine pH can be achieved despite a rate defect, if urine buffer levels are very low. However, urine pH rises rapidly when buffer is made available. This phenomenon has been documented in mineralocorticoid-deficient animals and in humans.[347]

Szylman and associates[347] suggested the critical role played by hyperkalemia in this form of metabolic acidosis. Reducing the serum potassium concentration with the administration of kayexalate resulted in increased renal ammonia excretion, which correlated with correction of acidosis.[347,349] That study did not establish a role for renal mechanisms in correcting the acidosis, however, because renal net acid excretion was not reported and kayexalate is known to bind to gut NH_4^+ and to increase plasma bicarbonate by that mechanism.[361] Moreover, increased urine ammonia represents additional urine buffer. The rate defect imposed by the low aldosterone activity will increase the urine pH and correspondingly reduce titratable acidity.[183] This sequence is illustrated in Fig. 59.21. Dietary correction of hyperkalemia in hyperkalemic distal RTA with renal insufficiency produced a greater increase in ammonia excretion than the reduction in titratable acid so that metabolic acidosis improved.[238] However, there was a large extrarenal component to the increase in plasma bicarbonate. In adrenalectomized mineralocorticoid deficient dogs with normal kidneys studied following withdrawal of aldosterone, but continuing on physiologic glucocorticoid replacement, the degree of acidosis and magnitude of reduction in NAE was similar whether or not hyperkalemia was prevented by a low potassium intake.[183] When hyperkalemia was permitted, the decrement in NAE was due to reduced NH_4 excretion, whereas with maintained normokalemia, the decrement in NAE was due to reduced titratable acid excretion, suggesting that, without structural renal damage, the aldosterone deficiency-induced H^+ secretory rate defect is sufficient to explain the acidosis and is independent of potassium-induced alterations in buffer (NH_3) availability. Thus, while hyperkalemia is not the critical factor in the pathogenesis in this form of metabolic acidosis, hyperkalemia has the potential to aggravate acidosis by limiting buffer (NH_3) availability in circumstances where alternative urinary buffers (i.e., phosphate) are severely limited.[180]

The various syndromes that reduce aldosterone activity or action are listed in Table 59.11. They are divided into three major categories: (1) defective adrenal gland aldosterone synthesis due to generalized destruction, damage localized to the zona glomerulosa, or enzymatic defects that reduce mineralocorticoid

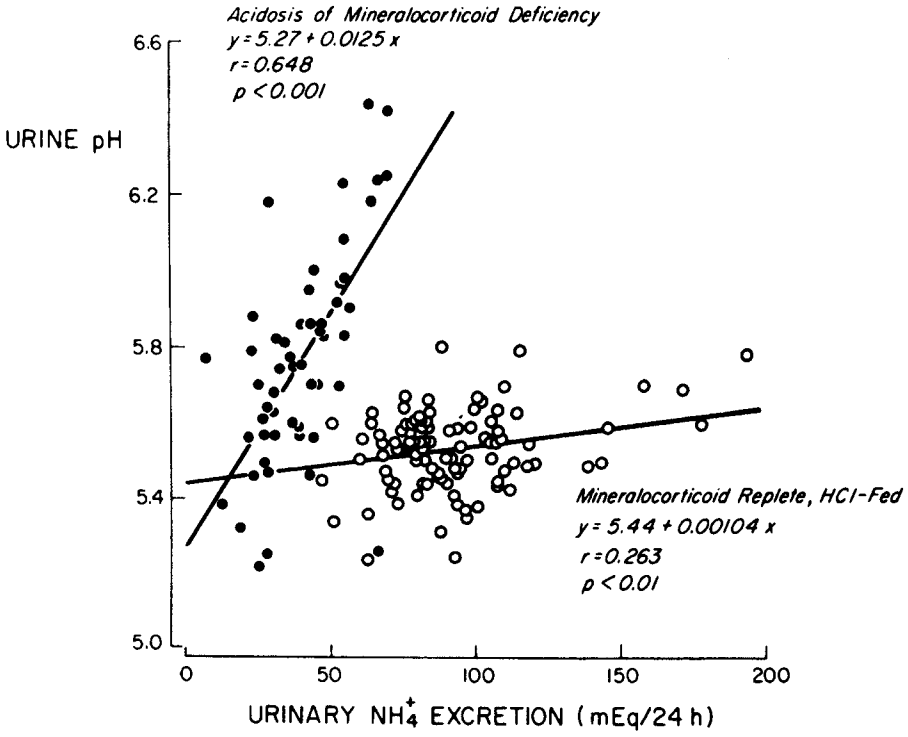

FIGURE 59.21 Urine pH as a function of urine ammonia excretion in two groups of dogs during steady-state metabolic acidosis-fed HCl: mineralocorticoid-deficient dogs (closed circle) and mineralocorticoid-replete dogs (open circle). *(With permission, from Hulter HN, Ilnicki LP, Harbottle JA, Sebastian A. Impaired renal H^+ secretion and NH3 production in mineralocorticoid-deficient glucocorticoid-replete dogs. Am J Physiol 1977;326: F136–F146.)*

synthesis; (2) decreased aldosterone synthesis by a normal adrenal gland as a result of reduced angiotensin II stimulation (hyporeninemic hypoaldosteronism); and (3) genetic or acquired forms of generalized dysfunction of the collecting duct with features of resistance to mineralocorticoid action. These disturbances comprise inherited disorders of aldosterone sensitivity due to either mineralocorticoid receptor defects or disturbances in aldosterone-sensitive Na^+ or Cl^- reabsorption, and acquired forms, that is, generalized destruction of aldosterone-sensitive nephron segments, notably the collecting duct, and pharmacologic interference with mineralocorticoids.

Primary Adrenocortical Deficiency

Destruction of the adrenal cortex by infection, tumor, hemorrhage, or an autoimmune process produces Addison's disease. Severe damage results in combined glucocorticoid and mineralocorticoid deficiencies. The glucocorticoid deficiency produces anorexia, weight loss, GI distress, hypoglycemia, weakness, and inability to mount a normal "stress" reaction. Mineralocorticoid deficiency produces renal salt wasting, hyperkalemia, and metabolic acidosis. Most patients with Addison's disease can be treated adequately without mineralocorticoid replacement despite combined deficiencies. Glucocorticoid replacement and generous quantities of NaCl will maintain acid and K^+ balance. Delivery of large amounts of Na^+ to the distal tubule will stimulate K^+ and H^+ secretion, even in the absence of mineralocorticoid activity. However, electrolyte balance in these patients is precarious. If salt ingestion is limited, or Na^+-rich fluids are lost (i.e., diarrhea), then negative Na^+ balance rapidly develops, ECF volume shrinks, and renal distal tubule Na^+ delivery falls. In the absence of aldosterone, K^+ excretion and H^+ excretion are sharply reduced, leading to hyperkalemia and metabolic acidosis. Therefore, if salt intake is restricted or ECF deficits develop, mineralocorticoid replacement becomes mandatory for maintenance of normal electrolyte balance.

Adrenal Enzyme Defects

Figure 59.22 shows the scheme for adrenal steroid synthesis. Severe proximal enzyme defects block the conversion of cholesterol to progesterone and produce profound neonatal adrenal insufficiency. This disorder is usually rapidly fatal. Patients with partial proximal defects can survive. Defects of more distal enzymes in this metabolic pathway are also compatible with life.

The most common congenital adrenal enzyme defect is 21-hydroxylase deficiency.[266] This disorder is usually inherited with an autosomal recessive pattern. The block can affect both glucocorticoid and mineralocorticoid synthesis or only the glucocorticoid pathway. Although complete 21-hydroxylase deficiency may be fatal unless promptly diagnosed and treated, children

TABLE 59.11 Causes of Mineralocorticoid Deficiency and Resistance

Primary mineralocorticoid deficiency
Combined glucocorticoid and mineralocorticoid deficiencies
Addison's disease
Bilateral adrenalectomy
Bilateral adrenal destruction
Congenital adrenal enzyme defects: 21-hydroxylase deficiency,3-b-OH dehydrogenase deficiency, desmolase deficiency
Isolated mineralocorticoid deficiency
Familial methyloxidase deficiency
Transient mineralocorticoid deficiency of infancy
Chronic idiopathic hypoaldosteronism
Chronic heparin therapy
Hyporeninemic hypoaldosteronism
Diabetic nephropathy
Tubulointerstitial disease
Volume expansion
Prostaglandin inhibitors
Acquired mineralocorticoid resistance
Renal insufficiency: renal disease with disproportionate medullary destruction
Drugs: spironolactone, amiloride, triamterene
Congenital mineralocorticoid resistance
With salt wasting and hypotension: pseudohypoaldosteronism type I
Autosomal-dominant renal form: defect in mineralocorticoidreceptor expression (MLR)
Autosomal-recessive multiorgan form: defects in alpha (SNCC1A), beta (SNCC1B), and gamma (SNCC1G) subunits of ENaC
With salt retention and hypertension: pseudohypoaldosteronism type II (Gordon's syndrome)
Defects in WNK1 and WNK4 kinases

with mild 21-hydroxylase deficiency survive without specific therapy. However, ACTH levels increase markedly in response to relative glucocorticoid deficiency and drive steroid synthesis. The 21-hydroxylase block shifts steroid precursors toward androgen synthesis (Fig. 59.22). This results in the adrenogenital syndrome. The children grow rapidly, and males prematurely virilize while females develop ambiguous genitalia. Exogenous glucocorticoid administration will decrease ACTH production, slow androgen synthesis, and reverse virilization. However, supraphysiologic quantities of glucocorticoids may be necessary to completely normalize androgen levels. These higher doses will produce iatrogenic Cushing's syndrome. Recent work indicates that androgen antagonists should be combined with glucocorticoids to prevent Cushing's syndrome yet reverse virilization.[82]

The 21-hydroxylase step is required for mineralocorticoid synthesis. Different isoenzymes may catalyze this reaction in the zona fasciculata (glucocorticoids) and zona glomerulosa (mineralocorticoids).[332] In some children, the 21-hydroxylase defect principally affects glucocorticoid synthesis in the zona fasciculata while mineralocorticoid synthesis is normal. In others, both the glucocorticoid and mineralocorticoid pathways are affected. When mineralocorticoid synthesis is reduced, variable degrees of salt wasting, hyperkalemia, and hyperchloremic acidosis result. Exogenous mineralocorticoid is usually required to normalize the electrolyte pattern. Generally, these exogenous mineralocorticoid requirements will decrease with time.

21-Hydroxylase deficiency accounts for about 90% of all cases of adrenogenital syndrome. Much less common are 11-hydroxylase deficiency and 17-hydroxylase enzyme deficiency, which also produce adrenogenital syndrome. These enzymes are not required to synthesize mineralocorticoids. Instead, affected children overproduce mineralocorticoids and therefore develop hypertension and metabolic alkalosis.

Final conversion of corticosterone to aldosterone requires sequential oxidations of the 18-methyl group. These oxidations are catalyzed by two methyl oxidase enzymes. Hereditary defects of these oxidases produce aldosterone deficiency, renal salt wasting, hyperkalemia, and hyperchloremic acidosis.[95] These enzymes are also inhibited by chronic heparin administration.[79,220,379] Hyperkalemia and metabolic acidosis may develop with chronic heparin therapy, especially in patients with renal insufficiency.

The salt wasting and volume depletion that occur in these patients will stimulate renin synthesis. However, potassium retention and hyperkalemia will suppress renin synthesis.[320] Therefore, renin levels may be high, normal, or low, depending on the net effect of several offsetting stimuli.

Hyporeninemic Hypoaldosteronism

Most patients with adrenal enzyme defects that lead to mineralocorticoid deficiency have high plasma renin levels as a result of volume contraction. In contrast, patients with hyporeninemic hypoaldosteronism have low renin activity. Presumably, aldosterone deficiency in these patients results from decreased renin secretion and angiotensin generation. The low renin and angiotensin levels may reflect specific juxtaglomerular apparatus damage, generalized renal damage, volume expansion, or pharmacologic inhibition of renin or angiotensin II.

Hyporeninemic hypoaldosteronism most often occurs in elderly individuals with mild renal insufficiency.[310,312] Many also have diabetes mellitus. The single most common biochemical abnormality they develop is asymptomatic hyperkalemia. Hyperchloremic acidosis occurs in about 50%.[90]

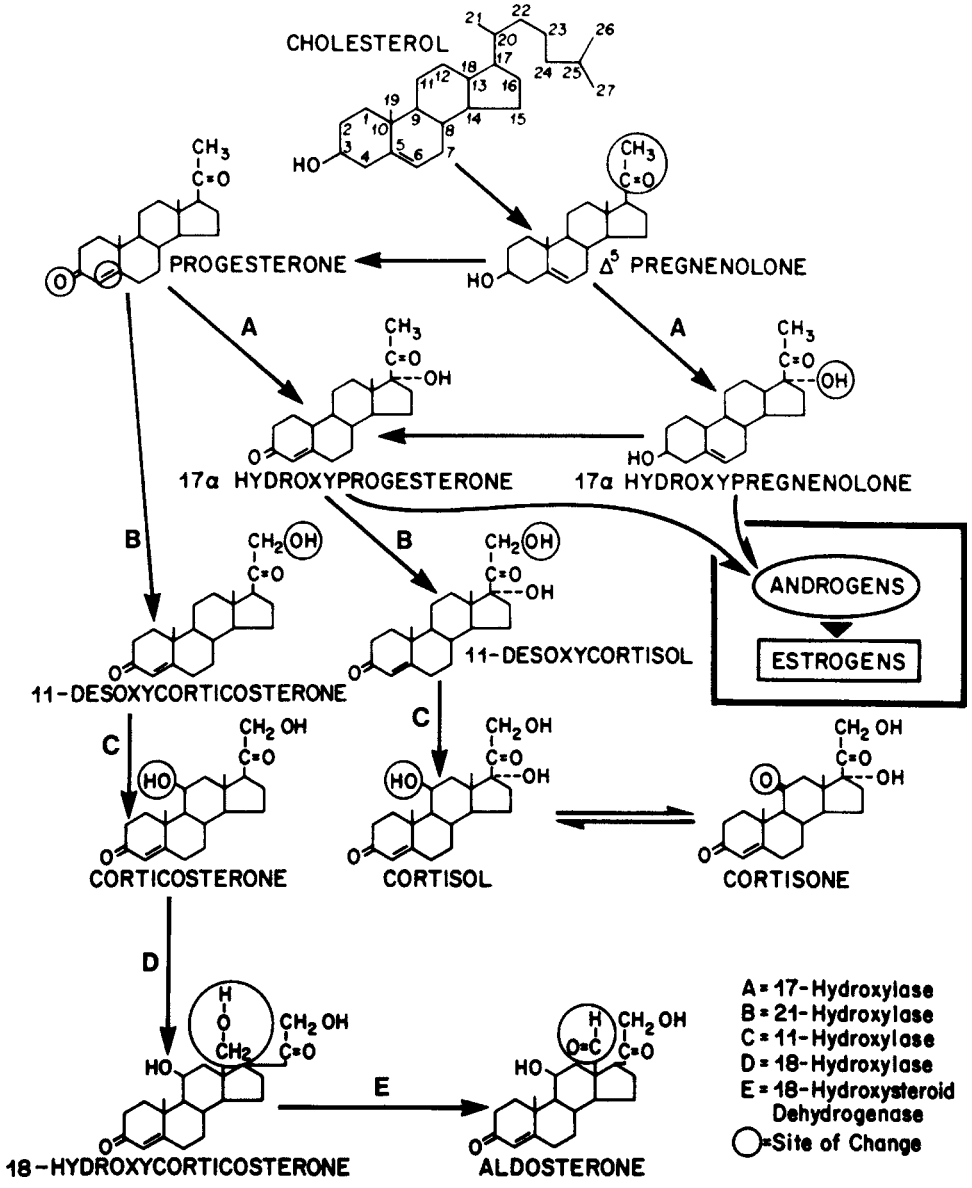

FIGURE 59.22 Adrenal metabolic reactions leading from cholesterol to mineralocorticoids,glucocorticoids, and sex hormones.

Several hypotheses have been advanced to explain the syndrome of hyporeninemic hypoaldosteronism. Multiple defects may exist in different patients or within a single patient. The most widely accepted explanation attributes the syndrome to juxtaglomerular injury resulting from an inflammatory, vascular, or immunologic insult. For example, autonomic neuropathy can suppress renin release. Pharmacologic suppression and physiologic suppression by volume expansion may also occur. Decreased renin secretion reduces angiotensin activation, which in turn decreases aldosterone release. The low aldosterone levels are ultimately responsible for the biochemical and clinical features of the syndrome.

The role of volume expansion in this syndrome remains unsettled. Clinical probes of volume status may be inadequate in these patients. Orthostatic hypotension may signal autonomic insufficiency rather than volume contraction. Edema may develop as a result of hypoalbuminemia rather than volume expansion. If volume expansion is primary, then diuresis should reverse the disorder. Indeed, diuretics are occasionally successful,[277] but more often this approach fails. However, in these patients ECF volume may not have been adequately reduced. Furthermore, chronic suppression of renin and aldosterone synthesis may require a prolonged period of stimulation before an appropriate response can be elicited.

An alternative hypothesis locates the primary lesion in the adrenal gland. Reduced renin levels could then be secondary to hyperkalemic suppression.[320] Several adrenal aldosterone synthetic defects have been described in diabetic patients.[96] Insulin may be necessary for a normal zona glomerulosa response to various stimuli, especially hyperkalemia.[81,90,287] Although aldosterone usually increases in response to angiotensin II infusions in these patients, the magnitude of this response may not be appropriate.[90] However, most patients with well-defined adrenal aldosterone secretory defects (i.e., 21-hydroxylase deficiency) develop high renin levels despite hyperkalemia.

Theoretically, a syndrome of inappropriate ANP secretion would be predicted to produce hyporeninemic hypoaldosteronism, but no such syndrome has been observed yet.

The increased proclivity of diabetics for development of this syndrome has several possible explanations.[364] First, diabetic vascular disease may preferentially affect the juxtaglomerular apparatus. Second, diabetic autonomic neuropathy may reduce neural stimulation of the juxtaglomerular apparatus.[49,287–289,312,357,370] Third, inactive forms of renin, called "big renin," may be released and not generate angiotensin II.[97] Fourth, decreased renal prostaglandin synthesis in these patients may reduce renin generation.[284]

Patients with primary hyporeninemic hypoaldosteronism and mild hyperkalemia do not require specific therapy. Volume contraction should be avoided because reduced renal distal tubule sodium delivery exacerbates both the hyperkalemia and acidosis. If hyperkalemia and/or metabolic acidosis are severe, then medical intervention is necessary. Patients whose ECF volume is expanded often respond to potent diuretics.[90,92] Exogenous mineralocorticoids, such as fludrocortisone, can further mitigate hyperkalemia and acidosis although supraphysiologic doses may be required as a result of relative renal mineralocorticoid resistance.[90,287]

Hyperkalemia will exacerbate markedly the metabolic acidosis. Reduction of potassium levels with mineralocorticoids, Na^+/K^+ exchange resins, or diuretics increases renal NH_4^+ excretion and improves or reverses the hyperchloremic acidosis.[100,243,345]

A number of drugs interfere with at various levels with the renin-angiotensin II-aldosterone axis and may induce hyperkalemic renal tubular acidosis. Inhibition of renal prostaglandin synthesis reduces renin secretion and can produce the syndrome.[272] By blockade of either conversion of angiotensin I to angiotensin II (ACE inhibitors) or the action of angiotensin (angiotensin receptor-1 antagonists), these widely used drugs can decrease adrenal aldosterone secretion. However, these drugs will increase renin levels markedly. The aldosterone deficiency that is produced is not complete. For the ACE inhibitors, an escape phenomenon has been described after prolonged use (i.e., angiotensin II production becomes again renin dependent). The incomplete aldosterone deficiency and the ACE-inhibitor escape phenomenon provide the rationale for combined use of these drugs in heart failure, hypertension and in intervention strategies to retard progression of renal insufficiency. Hyperkalemia and metabolic acidosis do not usually develop when these drugs are administered alone. However, these drugs are clinically important causes of hyperkalemia when given to patients with decreased renal function and when given in combination with other drugs that also interfere with the renin-angiotensin-aldosterone axis and aldosterone action (Fig. 59.23).

Abnormal Cortical Collecting Duct ("Renal Resistance to Mineralocorticoids")

Genetic Causes

Hyperkalemic RTA of genetic origin is most frequently observed in pseudohypoaldosteronism type I occurring in young children without other apparent renal pathology.[12] The disease is characterized by salt-wasting, hyperkalemia and metabolic acidosis in the presence of markedly elevated plasma renin activity and aldosterone concentrations. In the autosomal-dominant form of pseudohypoaldosteronism type I (MIM 177735), mineralocorticoid resistance is limited to the kidneys and is caused by heterozygous mutations in the gene encoding the mineralocorticoid receptor.[137]

In the autosomal-recessive form of pseudohypoaldosteronism type I (MIM 264350) aldosterone resistance is generalized, affecting all major

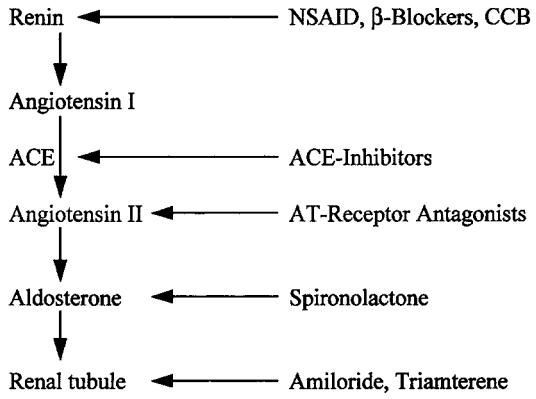

FIGURE 59.23 Commonly used drugs that interfere with synthesis or action of component of the renin-angiotensin-aldosterone axis. NSAID, nonsteroidal anti-inflammatory drugs.

mineralocorticoid-sensitive tissues (kidney, colon, sweat and salivary glands). Aldosterone resistance is due to homozygous, loss of function mutations in the alpha, beta or gamma subunits of the amiloride-sensitive, epithelial sodium channel (ENaC).[68] This recessive form of pseudohypoaldosteronism type I manifests with lifelong severe salt-wasting, while the dominant form is characterized by a milder defect. Renal salt wasting improves with advancing age in these patients. This disorder can be effectively treated with generous exogenous salt supplements. The syndrome usually becomes less severe as these children mature.[99] However, even after electrolytes become normal and salt supplements can be reduced, aldosterone levels remain very high and these individuals remain relatively resistant to mineralocorticoid effects and are very sensitive to any aldosterone blockade.

Another distinct group of mineralocorticoid-resistant patients present with hyperkalemic, hyperchloremic acidosis, expanded ECF volume, hypertension, low to normal renin and aldosterone levels, and a diminished response to the kaliuretic effects of exogenous mineralocorticoids. Renin and aldosterone levels increase when volume is reduced by diuretics or salt restriction. This syndrome was first described in several children by Gordon and co-workers[148] and is called pseudohypoaldosteronism type II or Gordon's syndrome. Schambelan et al.[311] suggested almost 30 years ago that a renal distal tubule "chloride shunt"—that is, increased NaCl reabsorption in the thick limb and early distal tubule leading to impaired K^+ and H^+ secretion—could explain the features of this disorder. Thus, pseudohypoaldosteronism type II exhibits a clinical phenotype directly opposite of Gitelman's syndrome, which is characterized by hypotension, salt wasting, and metabolic alkalosis, and is due to mutations in the thiazide-sensitive NaCl cotransporter NCC. NCC gain of function mutation, a reasonable candidate mechanism for this syndrome, was, however, excluded. Rather, this syndrome was shown to be the consequence of mutations in two of the four known WNK (with no lysine kinases) kinase genes, WNK1 and WNK4 located on chromosomes 12 and 17, respectively.[378] WNK1 and WNK4 are predominantly expressed in the distal convoluted tubule and collecting duct. WNK4 downregulates the activity of ion transport pathways expressed in these nephron segments, such as the apical thiazide-sensitive Na^+-Cl^- cotransporter and apical secretory K^+ channel ROMK (which will become less active), as well as upregulates paracellular chloride transport and phosphorylation of tight junction proteins such as claudins. WNK4 mutations behave as a loss of function for the Na^+–Cl^- cotransporter (which will become more active) and a gain of function with regard to ROMK and claudins. These dual effects of WNK4 mutations fit with proposed mechanisms for developing electrolyte and acid–base abnormalities and hypertension in PHA-II and point to WNK4 as a multifunctional regulator of diverse ion transporters.[132] WNK1, an aldosterone-inducible protein, interacts with WNK4 by mechanisms that are not yet well characterized. The mutation in WNK1 results in gain of function and inhibition of WNK4, thereby activating NCC.[382] WNK1 also stimulates Na^+ transport via EnaC.[113] Via this process, a gain of function mutation would be expected to result in hypertension, but also hypokalemia and metabolic alkalosis, which are not observed in pseudohypoaldosteronism type II. More information on the precise roles and interactions of WNK1 and WNK4 is needed and the results will greatly affect our understanding of the regulation of distal ion and H^+ transport and of blood pressure regulation.

Acquired Forms of Hyperkalemic Distal RTA

Most commonly, renal tubular damage can lead to destruction of mineralocorticoid target cells within the kidney with impaired secretion of potassium and protons.[66,232,264,308,355] Due to the cell damage by a variety of pathological processes, apparent renal mineralocorticoid resistance is present. Patients with systemic lupus erythematosus,[91,204] obstructive uropathy,[20] sickle cell disease,[22,93] allergic drug reactions,[73] and damaged renal transplants[24,288] may develop impaired collecting duct function and renal tubule mineralocorticoid resistance. Many of these patients have multiple distal tubule defects in association with the mineralocorticoid resistance. Juxtaglomerular destruction can produce hyporeninemic hypoaldosteronism in addition to the mineralocorticoid resistance. Classic distal renal tubular acidosis may also coexist with decreased mineralocorticoid responsiveness probably reflecting wide-spread damage to the collecting ducts, both cortical and medullary.

Renal mineralocorticoid resistance may have a pharmacologic basis (Fig. 59.23). The spironolactones, competitive inhibitors of aldosterone, bind to specific receptors and block transport of aldosterone into the cell nucleus. These drugs have a potent effect when the prevailing mineralocorticoid level is high. They are less effective when mineralocorticoids are low and are ineffective in adrenalectomized individuals. Spironolactone reduces Na^+ reabsorption, H^+ secretion, and K^+ secretion in the distal tubule and may generate hyperkalemic hyperchloremic acidosis in those individuals dependent on high mineralocorticoid activity to maintain H^+ and K^+ balance (e.g., patients with cirrhosis).[131,182]

Amiloride and triamterene are diuretics that block distal tubule electrogenic Na^+ transport.[342] However,

their effect is independent of mineralocorticoid activity and the diuretic effect occurs even in adrenalectomized individuals.[228] Amiloride blocks the Na^+ channels on the luminal membrane of distal tubule cells. Reduced electrogenic Na^+ transport decreases the lumen-negative voltage, reducing H^+ and K^+ secretion.[152] Hence a voltage-dependent acidification and K+ secretory defect develops.[152] Triamterene has similar effects although its mechanism of action is not identical to amiloride.

Cyclosporine A is frequently associated with hyperkalemia. Although it was initially believed that this drug produced hyporeninemic hypoaldosteronism, subsequent studies have shown relatively normal aldosterone levels.[5] These patients probably develop renal resistance to the effect of aldosterone. Cyclosporine may also block other steps in the renin-angiotensin-aldosterone axis.[5,336]

Gastrointestinal Hyperchloremic Acidosis

Large quantities of H^+ and HCO_3^- continuously cycle through the gastrointestinal tract. Basal gastric HCl secretion is about 10 mEq/hr (0–50 mEq/liter). Acid secretion can increase to 50 mEq/hr after appropriate stimulation.[119] At this time, the gastric HCl concentration may reach 150 mEq/liter. Most of the HCl secreted by the stomach is neutralized by HCO_3^- secreted by the pancreas and liver. These organs can secrete up to 250 mEq/day of HCO_3^-. Some HCl is also neutralized by small intestine ion transport. The small intestine epithelium contains $Na^+/H+$ cation exchangers, which secrete H^+ and absorb Na^+ from the lumen, and Cl^-/HCO_3^- anion exchangers, which secrete HCO_3^- and absorb Cl^- from the lumen. When these two ion exchangers operate together, the net result is NaCl absorption and H_2CO_3 secretion. However, Na^+/H^+ exchange predominates in the jejunum while Cl^-/HCO_3^- exchange is more active in the duodenum and ileum.[358]

Normally, the small intestine delivers between 600 and 1500 ml/day of relatively HCO_3^--rich fluid to the colon. The colon absorbs most of this fluid and electrolyte load. A Cl^-/HCO_3^- anion exchanger in the colon reduces stool $[Cl^-]$ to low levels. Sodium is absorbed in exchange for H^+ and for K^+. However, the HCO_3^- is largely decomposed by organic acids produced by colonic bacterial metabolism. Acetic, butyric, propionic, lactic, and other acids are produced when these bacteria ferment carbohydrates delivered to the colon. H^+ from these acids combines with HCO_3^- in the lumen to form H_2CO_3 (which dehydrates to H_2O and CO_2). The organic acid anions remain in stool as Na^+ and K^+ salts and represent decomposed HCO_3^-. In consequence, stool water usually has an acid pH reaction.

Diarrhea markedly increases the loss of stool water and stool base. If the sum of stool $[HCO_3^-]$ and decomposed $[HCO_3^-]$ is equal to the $[HCO_3^-]$p, then diarrhea should produce volume depletion without severe acid–base derangements. More commonly, the sum of $[HCO_3^-]$ and decomposed $[HCO_3^-]$ in watery stool is between 30 and 80 mEq/liter.[352] Decomposed $[HCO_3^-]$ usually exceeds $[HCO_3^-]$ and the stool pH is often acid. Despite its acid pH, the large quantity of decomposed HCO_3^- in stool results in a metabolic acidosis.

Diarrhea leads to ECF contraction and stimulation of the renin-angiotensin-aldosterone axis. Hyperchloremic acidosis develops due to the loss of stool HCO_3^- and decomposed HCO_3^- with much less chloride loss. The volume depletion also stimulates dietary chloride retention. Hypokalemia develops due to the large amount of K^+ that is lost in stool (30–65 mEq/liter). Colonic K^+ secretion, which is largely driven by the negative electrical voltage in the colon lumen, is further stimulated by high aldosterone levels.

Under normal circumstances, the kidneys should be able to compensate for stool alkali losses by increasing renal net acid excretion. However, patients with severe diarrhea often also have impaired renal function. In addition to a decreased GFR, low Na^+ delivery to the distal renal tubule due to volume contraction will reduce renal acid excretion. In consequence, reduced renal acid excretion usually contributes to the development of metabolic acidosis in patients with diarrhea.[189]

Many patients with diarrhea also develop a component of anion gap metabolic acidosis. This is usually due to lactic acidosis, which occurs as a result of volume depletion. Volume contraction may also elevate protein and phosphate concentrations, which will elevate the anion gap.[368] Uremic acidosis can occur when vascular collapse produces renal failure.

Hypokalemic hyperchloremic acidosis secondary to diarrhea may generate a relatively alkaline urine pH (>6.0) at a time maximal renal acidification should exist. The reason for the relatively high urine pH is the dramatic increase in renal ammoniagenesis and ammonium excretion that develops in these patients. The dual stimuli of chronic metabolic acidemia and hypokalemia markedly augment ammoniagenesis and renal ammonia excretion. The high urine NH_4^+ levels drive up the urine pH. When a relatively alkaline urine is noted in a patient with hypokalemic hyperchloremic acidosis, this should suggest a diagnosis of renal tubular acidosis. The key differential finding is a high urine $[NH_4^+]$ or a negative urinary anion gap in patients with diarrhea and normal renal acidification and a low $[NH_4^+]$ or a positive urinary anion gap in those with

distal RTA. This issue is further discussed in Diagnosis of Proximal and Hypokalemic Distal Tubular Acidosis.

The [HCO_3^-] in pancreatic and biliary secretions ranges from 50 to 100 mEq/liter. Normally, this HCO_3^- neutralizes gastric HCl or is absorbed by the jejunum, resulting in no net systemic acid–base effects. However, if these secretions are removed from the body, then hyperchloremic acidosis results. This can occur in patients with pancreatic or biliary fistulas. Consequently, patients with pancreas transplants with bladder drainage develop hyperchloremic metabolic acidosis even with normal renal function and require large amounts of base supplements.[268] This and other disadvantages of bladder diversion (reflux pancreatitis, chemical cystitis, hyperinsulinemia) have lead to the increasing use of a more physiologic drainage procedure that is either enteric or portal vein drainage. These procedures eliminate loss of HCO_3^- and metabolic acidosis with comparable perioperative complication rates.[213]

Several compounds can accelerate gastrointestinal HCO_3^- loss and produce hyperchloremic metabolic acidosis. Cholestyramine, a nonabsorbed anion exchange resin used to treat hyperlipidemia, biliary pruritis, and several other disorders, is ingested as a chloride salt. In the GI tract, Cl^- released from the resin exchanges with HCO_3^-. The resin-bound HCO_3^- is excreted in the stool. The chloride released from the resin is absorbed via the Cl^-/HCO_3^- anion exchanger. The modest HCO_3^- loss and Cl^- gain usually produced by cholestyramine ingestion is generally handled by increased renal acid and Cl^- excretion. However, young children and adults with renal insufficiency or reduced renal acid excretion can develop hyperchloremic acidosis when they ingest cholestyramine.[201,304]

As mentioned earlier, ingestion of $CaCl_2$ produces hyperchloremic acidosis[281] and can be used experimentally as an acid load to study renal acidification.

Gastrointestinal–Ureteral Connections

When urine enters the gastrointestinal tract, or a segment of intestine is interposed into the urine stream, hypokalemic hyperchloremic metabolic acidosis often develops. As discussed previously, the small intestine and colon contain Cl^-/HCO_3^- exchangers. When isotonic saline is instilled into the colon, the [Cl^-] progressively falls and [HCO_3^-] increases as a result of this exchange.[84,202] Potassium also diffuses into the colon lumen due to its lumen-negative voltage. Similarly, if chloride-rich urine enters the colon or ileum, the Cl^- is absorbed and HCO_3^- secreted. Urine NH_4^+ will also be absorbed by the intestine either together with Cl^- or in exchange for N_4^+.[109,257] This further reduces the acid load present in urine. Large quantities of ammonia (and HCO_3^-) will be generated in the intestine by bacterial hydrolysis of urea. If this NH_4^+ is absorbed without HCO_3^-, systemic acidification also results. Urea conversion to NH_4^+ and HCO_3^- elevates the pH of the fluid and increases the fraction of ammonia in the NH_3 unionized form. Although absorption of NH_3 will not produce acidosis, it can lead to hyperammonemic encephalopathy in these patients.[202]

Chronic renal insufficiency, resulting from obstructive uropathy and interstitial nephritis, occurs commonly in patients whose urinary tracts are diverted into GI segments. This contributes to the metabolic acidosis that develops. Distal tubule acidification mechanisms may be especially susceptible to such damage.

Ureterosigmoidostomy, one of the earliest forms of surgical urinary diversion, results in prolonged colon exposure to urine. This provides ample opportunity for Cl^-/HCO_3^- exchange, NH_4^+ absorption, and K^+ secretion. Consequently, hypokalemic hyperchloremic acidosis occurs commonly in these patients.[246,337] These electrolyte abnormalities are exacerbated by constipation, which increases urine–colon contact time, and are reduced by incontinence, which decreases contact time. Ureterosigmoidostomy is now only occasionally used and the ureteral anastomosis is then placed into the distal rectosigmoid to minimize contact time.[64]

Isolated loops of ileum, or less commonly jejunum, can be used as urine bladder substitutes. These loops have several advantages in comparison with ureterosigmoidostomy. Fecal contamination of the urinary tract is avoided and intestine–urine contact time is reduced because urine is externally drained into a urostomy bag.[255] However, if a long bowel segment is used, or if stomal stenosis develops, then contact time increases and severe hypokalemic hyperchloremic acidosis can develop.[109,234] Jejunal segments may generate less K^+ wasting than ileal loops.[144] When hypokalemic metabolic acidosis develops, $NaHCO_3$, other $NaHCO_3$ precursors, and potassium salts are used to correct acid–base and electrolyte abnormalities. Recent studies suggest that pharmacologic inhibition of cyclic AMP, an intestinal secretogogue, may reduce the severity of these electrolyte abnormalities. Both nicotinic acid and chlorpromazine have been used in this fashion.[257]

Postchronic Hypocapnia

Posthypocapnic hyperchloremic acidosis develops when patients with chronic respiratory alkalosis stop hyperventilating. Chronic hypocapnia decreases renal NH_4^+ and titrable acid excretion and induces a transient $NaHCO_3$ diuresis. This continues until a new lower steady-state plasma [HCO_3^-] is established when

acid balance is restored. In humans, compensation decreases the plasma [HCO_3^-] by about 0.4 mEq/liter for each 1-mm Hg reduction in CO_2 tension, which results in a near normal arterial pH.[209] The renal compensatory response also generates mild ECF volume contraction and stimulates retention of dietary NaCl.[138] Consequently, hyperchloremia develops. However, the increase in chloride does not equal the HCO_3^- reduction and the difference produces a slight increase in the anion gap,[208] comprised mainly of organic acid anions, especially lactate.

If respiratory alkalosis recedes and the pCO_2 increases toward normal, then renal net acid excretion must increase to normalize acid–base status. Sodium must also be retained together with the HCO_3^-. To the extent that the low [HCO_3^-] and high [Cl^-] persist, this represents a hyperchloremic metabolic acidosis. The resulting metabolic acidosis is transient and probably dependent on the severity of preexisting hypocapnia.[138]

HCl and HCl Precursors

Infusion or ingestion of HCl and compounds that can be metabolized to HCl produces hyperchloremic metabolic acidosis. For example, ingested NH_4Cl is metabolized by the liver to urea and HCl. Similarly, chloride salts of metabolizable organic cations can be converted to HCl. They include basic amino acids such as histidine, arginine, lysine, and hydroxylysine, which are generally prepared as HCl salts. HCl is liberated when the amino acids are metabolized to neutral products, to CO_2 and H_2O, or are incorporated into proteins.[168]

Intravenous hyperalimentation solutions include neutral, acidic, and basic amino acid salts. When the quantities of Cl^-- and Na^+-containing amino acid salts are balanced, their acid–base impact is neutral. However, some synthetic amino acid solutions contain a higher concentration of chloride-containing amino acid salts, which represents a net HCl load. Hyperchloremic acidosis can develop, especially in young children and patients with impaired renal function.[120,168] This hyperchloremic acidosis is efficiently prevented by adding bicarbonate precursors, such as sodium acetate to the currently used solutions. Failure to supply thiamine to parenterally fed patients induced severe lactic acidosis.[363]

Chloride gas inhalation can also produce hyperchloremic acidosis because when Cl2 gas is hydrated it generates HCl.[346]

Dilution Acidosis

Diluting a solution of nonbicarbonate nonvolatile buffers with saline or water proportionately reduces the concentration of the acids and conjugate bases. This has a minimal effect on the solution's pH:

$$pH = pKa + \log base/X\text{: }acid/X = pKa + \log base\text{:}acid$$

where X = water or saline. However, diluting the HCO_3^-/pCO_2 buffer pair in an open system produces a different result. While [HCO_3^-] falls, the pCO_2 is maintained at baseline levels because it is continuously replenished. A fall in [HCO_3^-] with a stable pCO_2 reduces the pH.

Similarly, the pH of separated whole blood, maintained at a pCO_2 of 40 mm Hg, will fall sharply if the blood is diluted with saline.[135] However, the pH reduction produced by dilution is much less when intact animals are expanded to an equivalent degree.[135,302] Stabilization of the pH in the intact animal is due to the interaction of the HCO_3^-/pCO_2 pair with non-HCO_3^- buffers, such as hemoglobin and phosphate, as well as other extracellular and intracellular buffers. These buffers accept H^+ and generate HCO_3^- to prevent a marked reduction in pH:

$$NaB + H_2CO_3 \rightarrow HB + NaHCO_3$$

ECF volume expansion will decrease proximal tubule HCO_3^- reabsorption and this may contribute to development of metabolic acidosis. However, this effect is relatively small in humans. In consequence, the plasma [HCO_3^-] falls only about 2 mEq/liter following ECF volume expansion in humans.[135]

Mild expansion metabolic acidosis could also occur in patients with the syndrome of inappropriate antidiuretic hormone secretion. A proportionate decrease in plasma [Na^+], [Cl^-], and [HCO_3^-] should result in acidosis. However, the [HCO_3^-] generally remains normal in these patients. In part, this is due to the buffer interactions discussed previously. An additional factor is direct stimulation of adrenal aldosterone secretion produced by hyponatremia.[75] The higher aldosterone levels accelerate distal tubular H^+ secretion (HCO_3^- generation) to offset the reduction in [HCO_3^-]. ADH may also modulate renal acid excretory capacity directly by virtue of its inhibitory effect on HCO_3^- reabsorption in the thick ascending limb[146] and its stimulation of sodium reabsorption in the collecting duct.[316]

Summary: Treatment of Metabolic Acidosis

Generally, the metabolic acidoses can be divided into those resulting from a chronic underexcretion of acid (i.e., uremic and distal renal tubular acidosis), chronic wasting of bicarbonate (i.e., proximal RTA or diarrhea), and acute net overproduction of acids (i.e., ketoacidosis, lactic acidosis).

Patients with chronic acidosis owing to decreased acid excretion can often be readily treated with exogenous sodium bicarbonate. The daily bicarbonate requirements should be relatively modest because it would only be necessary to offset normal net acid production rates of 70–100 mEq/day. In addition to normalization of acid–base parameters, the correction of the acidosis will stop skeletal dissolution, reverse hyperventilation, and improve the overall state of well-being. The specifics of therapy in patients with distal renal tubular acidosis, the mineralocorticoid-deficiency states, and uremic acidosis have been discussed in the appropriate previous sections.

When acute or chronic acidosis results from a loss of bicarbonate salts, exogenous sodium bicarbonate may also prove effective. This is apparent in patients with acute and chronic diarrhea, pancreatic fistulas, and various gastrointestinal–ureteral connections. However, patients with proximal RTA are resistant to exogenous bicarbonate therapy and usually require an alternative therapy.

A third category includes those metabolic acidoses associated with an acute accumulation of strong acids that overwhelms normal renal acid excretory capacity. Ketoacidosis, lactic acidosis, and the toxin-associated acidoses fall into this group. In these individuals, bicarbonate therapy is often inappropriate and ineffective. The therapeutic thrust must be directed toward an understanding and reversal of the underlying pathophysiology. With ketoacidosis, insulin and fluid therapy will reverse the acidosis, but bicarbonate administration is ineffective alone and perhaps deleterious. Lactic acidosis reflects a basic underlying disturbance in mitochondrial oxygenation, which mandates immediate therapy. The low bicarbonate and pH do not necessarily require therapy with exogenous bicarbonate unless these levels become very low. In these acidoses, the accumulating anions represent potential bicarbonate; therefore, rebound metabolic alkalosis may occur following exogenous bicarbonate administration.

If the pH is below 7.2, and certainly if it is near 7.0, and the underlying process cannot be reversed immediately, sodium bicarbonate infusion may be necessary to prevent development of fatal acidemia. When the acidosis is severe, reductions in HCO_3^- produce disproportionately large reductions in pH. For example, if the HCO_3^- concentration is 4 mEq/liter and the pCO_2 is 12 mm Hg, the pH will be 7.15. At this point, respiratory compensation is almost maximal. A further reduction in HCO_3^- of only 2 mEq/liter will cause the pH to plummet to 6.84.

To calculate exogenous bicarbonate requirements, a distribution space of approximately 50% body weight is a good first approximation. However, much larger quantities of bicarbonate may be necessary, especially when accumulating acids, such as lactic acid or ketoacids, are rapidly being generated. Under such circumstances, the HCO_3^- distribution space may exceed 100% of body weight. In some patients with chronic lactic acidosis, the lactic acid generation rate may be accelerated by bicarbonate infusions so that no net beneficial effect results.[121] Whenever sodium bicarbonate therapy is used, its adverse effects must be anticipated and, if possible, avoided. Sodium bicarbonate is usually administered as a hypertonic solution that produces hypernatremia, hyperosmolality, ECF volume expansion, and pulmonary congestion. When large quantities of sodium bicarbonate are administered, adequate water must be provided to avoid severe hypertonicity. Although the effects of infused bicarbonate on the plasma potassium concentration are small, physicians should be cautious if hypokalemia already exists. Further reductions in plasma potassium concentrations might produce profound hypokalemia, resulting in muscle weakness or even respiratory muscle paralysis. When sodium bicarbonate is administered to a patient with a high concentration of potential bicarbonate (i.e., lactate or ketoacids), reversal of the underlying disturbance may result in development of a rebound metabolic alkalosis.[372]

Respiratory Acid–Base Disorders

Nicolaos E. Madias[1] *and Horacio J. Adrogué*[2]

[1]Department of Medicine, Tufts University School of Medicine and Steward St. Elizabeth's Medical Center, Boston, Massachusetts, USA

[2]Department of Medicine, Baylor College of Medicine, The Methodist Hospital, Houston, Texas, USA

The physiologic approach to acid–base disorders views blood pH as determined by the prevailing levels of carbonic acid ($PaCO_2$, the respiratory component) and plasma bicarbonate concentration ($[HCO_3^-]$, the metabolic component), as stipulated by the Henderson equation, $[H^+] = 24 \times PaCO_2/[HCO_3^-]$, the equilibrium relationship of the carbonic acid/bicarbonate system.[2] In this equation, the hydrogen-ion concentration of blood is expressed in nEq/liter, the carbon dioxide tension is expressed in mm Hg and the plasma $[HCO_3^-]$ is expressed in mEq/liter.

In this chapter, we discuss those abnormalities of acid–base equilibrium initiated by a change in blood carbon dioxide tension; such abnormalities are referred to as respiratory disorders.

RESPIRATORY ACIDOSIS

Respiratory acidosis, or primary hypercapnia, is the acid–base disturbance initiated by an increase in CO_2 stores (i.e., carbonic acid) and characterized by an increase in CO_2 tension and acidification of body fluids.[8] Life-threatening acidemia of respiratory origin can occur during severe, acute respiratory acidosis or during respiratory decompensation in patients with chronic hypercapnia.

Respiratory acidosis occurs when carbon dioxide excretion by the lungs lags behind carbon dioxide production, thereby increasing whole-body carbon dioxide stores. Because the sum of PCO_2 and PO_2 is constant in alveolar gas in patients breathing room air (~150 mm Hg at sea level), the development of substantial hypercapnia is by necessity accompanied by equivalent hypoxemia. A simplified form of the alveolar gas equation at sea level and while breathing room air (F_IO_2, 21%) is as follows:

$$P_AO_2 = 150 - 1.25\ PaCO_2$$

where P_AO_2 is alveolar O_2 tension (mm Hg). This equation demonstrates that patients breathing room air cannot reach $PaCO_2$ levels much greater than 80 mmHg because the hypoxemia that would occur at greater values is incompatible with life. Therefore, extreme hypercapnia occurs only during O_2 therapy, and severe CO_2 retention is often the result of uncontrolled O_2 administration.

The level of arterial CO_2 tension ($PaCO_2$) is above 45 mm Hg in patients with simple respiratory acidosis (measured at rest and at sea level).[12] An element of respiratory acidosis may still occur with lower $PaCO_2$ in patients residing at high altitude (e.g., 4000 m or 13,000 ft) or patients with metabolic acidosis, in whom a normal $PaCO_2$ is inappropriately high for this condition. Another special case of respiratory acidosis is the presence of arterial eucapnia, or even hypocapnia, occurring together with severe venous hypercapnia, in patients having an acute, profound decrease in cardiac output but relative preservation of respiratory function. This disorder is known as "pseudorespiratory alkalosis".[7,10,11]

PATHOPHYSIOLOGY

The ventilatory system is responsible for maintaining $PaCO_2$ within normal limits by adjusting alveolar minute ventilation to match the rate of CO_2 production. Clinically relevant conditions that alter CO_2 production are listed in Table 60.1. However, if significant amounts of CO_2 are added to the inspired gas because of

TABLE 60.1 Modifiers of Carbon Dioxide Production

Decrease	Increase
Mechanical ventilation, sedation, muscle relaxants (decreased work of breathing)	Severe dyspnea with use of accessory muscles (increased work of breathing)
Inactivity, sleep	Agitation, seizures, exercise
Hypothermia	Hyperthermia
Fat utilization	Carbohydrate utilization
Weight loss	Weight gain
Hypothyroidism	Hyperthyroidism

TABLE 60.2 Pathogenesis of Respiratory Acidosis

Imbalance between the strength of the respiratory pump and the weight of the respiratory loads caused by either of the following:
Impairment of the respiratory pump
Depressed central drive
Abnormal neuromuscular transmission
Muscle dysfunction
Increased respiratory loads
Ventilation/perfusion mismatch (increased dead space ventilation)
Augmented airway flow resistance
Lung stiffness
Pleural/chest wall stiffness
Augmented ventilatory demand (increased carbon dioxide production)
Failure of carbon dioxide transport
Cardiac arrest, circulatory collapse
Pulmonary embolism (thrombus, fat air)

accidental exposure or experimental design, respiratory acidosis can occur despite the presence of even a substantial increase in alveolar ventilation. The main elements of ventilation are the respiratory pump, which generates a pressure gradient responsible for air flow, and the loads that oppose such action. The strength of the respiratory pump can be evaluated by the pressure gradient generated by the diaphragm, which represents the difference between abdominal and pleural pressures.

The determinants of primary hypercapnia, summarized in Table 60.2, include either an imbalance between the strength of the respiratory pump and the weight of the respiratory loads or a failure of carbon dioxide transport from tissues to the lung. When the respiratory pump is unable to balance the opposing load, respiratory acidosis develops. Higher load can be caused by increased ventilatory demand, augmented airway flow resistance, and stiffness of the lungs or the chest wall. A reduction in pulmonary perfusion can also result in CO_2 retention leading to the condition referred to as "pseudorespiratory alkalosis." Respiratory acidosis is categorized into acute and chronic forms, taking into consideration their usual mode of onset and duration. (Table 60.3 and Table 60.4).

In most clinical settings, the development of respiratory acidosis is multifactorial, and recognition of each of the underlying mechanisms of CO_2 retention allows for effective patient management.

Depressed Pump Secondary to Abnormal Central Drive

The $[H^+]$ of body fluids is the main chemical stimulus for pulmonary ventilation acting on the central chemoreceptors (brainstem) and the peripheral arterial chemoreceptors (carotid and aortic bodies) (8). In normal humans there is a linear relationship between arterial PCO_2 and minute ventilation and the slope becomes steeper in the presence of hypoxemia.[55] In contrast, minute ventilation does not increase until arterial O_2 tension (PaO_2) falls below 60 mmHg, with further increases as hypoxemia worsens; yet, the hypocapnia resulting from the hypoxemia-induced hyperventilation blunts the ventilatory response.[55]

Primary disturbances in the CNS comprise the classic forms of hypercapnia that result from an abnormal respiratory control system. Yet, a faulty respiratory drive is also involved in the development of respiratory failure in other clinical settings that are unrelated to a primary disorder of ventilatory control mechanism. The ventilatory response to hypoxia and hypercapnia in the normal population has a wide range, and genetic factors play a role in this variable response. In addition, an experimentally induced increase in the work of breathing caused by both an increased airway resistance and a decrease in thorax/lung compliance alters the ventilatory drive; this change points to a complex interaction between the mechanical load and the brainstem control of the respiratory muscles. Episodes of apnea occurring in patients with status asthmaticus have been linked to this interaction.[12]

The pathogenesis of upper airway obstruction during sleep includes pharyngeal narrowing during both inspiration (caused by subatmospheric collapsing pressure) and expiration (caused by reduced ventilatory motor output due to central hypopnea).[83]

Depressed Pump Secondary to Abnormal Function of Respiratory Muscles

Inadequate ventilation leading to CO_2 retention may occur whenever the respiratory pump fails to adequately propel air through the respiratory conduits, in

TABLE 60.3 Causes of Acute Respiratory Acidosis

Depressed Central Drive	*Failure of Carbon Dioxide Transport*
General anesthesia	Cardiac arrest, circulatory collapse
Head trauma	Pulmonary embolism (thrombus, fat, air)
Cerebrovascular accident	
Obesity hypoventilation syndrome	*Ventilation/perfusion mismatch*
Cerebral edema	*(increased space ventilation)*
Brain tumor	Acute lung injury
Encephalitis	Multi-lobar pneumonia
Brain-stem lesion	
Abnormal neuromuscular transmission	*Augmented airway flow resistance*
High spinal cord injury	Upper airway obstruction
Guillain-Barré syndrome	Coma-induced hypopharyngeal obstruction
Status epilepticus	Aspiration of foreign body or vomitus
Botulism; tetanus	Laryngospasm
Crisis in myasthenia gravis	Angioedema
Familial periodic paralysis	Inadequate laryngeal intubation
Drugs or toxic agents (e.g., curare, succinylcholine, aminoglycosides, organophosphate poisoning)	Lower airway obstruction
	Status asthmaticus
Muscle dysfunction	Exacerbation of chronic obstructive pulmonary disease
Fatigue	
Hyperkalemia	*Lung stiffness*
Hypokalemia	Atelectasis
Enhanced ventilatory demand	*Pleural/chest wall stiffness*
High carbohydrate diet	Pneumothorax
High carbohydrate dialysate (peritoneal dialysis)	Haemothorax
Sorbent-regenerative hemodialysis	Flail chest
Increased dead space ventilation	Abdominal distension
	Peritoneal dialysis

TABLE 60.4 Causes of Chronic Respiratory Acidosis

Depressed Central Drive	*Ventilation/Perfusion Mismatch*
Central sleep apnea	*(increased dead space ventilation)*
Obesity hypoventilation syndrome	Emphysema
Methadone/heroin addiction	Pulmonary fibrosis
Brain tumor	Pulmonary vascular disease
Bulbar poliomyelitis	
Hypothyroidism	*Augmented airway flow resistance*
	Upper airway obstruction
Abnormal neuromuscular transmission	Tonsillar and peritonsillar hypertrophy
High spinal cord injury	Paralysis of vocal cords
Poliomyelitis	Tumor of the cords or larynx
Multiple sclerosis	Airways stenosis postprolonged intubation
Muscular dystrophy	Thymoma, aortic aneurysm
Amyotrophic lateral sclerosis	Lower airway obstruction
Diaphragmatic paralysis	Chronic obstructive pulmonary disease
Muscle dysfunction	
Myopathic disease (e.g., polymyositis)	*Lung stiffness*
	Severe chronic interstitial lung disease
	Pleural/chest wall stiffness
	Kyphoscoliosis
	Thoracic cage disease
	Thoracoplasty
	Obesity

spite of a normal respiratory drive and the absence of lung disease.[12] Primary disorders of the respiratory muscles and of the motor neurons responsible for pulmonary ventilation are classic examples of this pathophysiologic mechanism. However, an even larger and heterogeneous group of patients exists in which fatigue of the respiratory muscles plays a critical role in the development of respiratory acidosis. Such respiratory muscle fatigue is observed with poor nutrition, certain electrolyte disorders (potassium and phosphate depletion), an obligatory high level of ventilation, decreased compliance of the respiratory system, increased resistance to airflow, and alterations in thoracic configuration. Structural and functional changes in the respiratory muscles, as well as depletion of their energy stores, occur with malnutrition.

Increased Load Secondary to Abnormalities in the Lungs, and Pleural/Chest Wall Stiffness

A reduction in the effective alveolar ventilation (V_A) causes respiratory acidosis in the presence of normal or

even increased total minute ventilation (V_E).[8] The defect responsible for this condition is an increased dead space ventilation (V_D) caused by alveoli that remain ventilated but not perfused and from alveoli with excessive ventilation with respect to heir perfusion. In both cases, an increased ventilation to perfusion ratio (V_A/Q) exists. Advanced chronic obstructive pulmonary disease is the most typical condition in which this pathophysiologic defect dominates the CO_2 retention observed. The maintenance of eucapnia in patients with less advanced disease results from an increased minute ventilation, which compensates for the inefficiency of the CO_2 excretion imposed by the V_A/Q mismatch. Should the airway resistance increase, however, (because of bronchial spasm, edema of the bronchial wall, or retention of secretions), or if the minute ventilation needed to maintain eucapnia is too high, the $PaCO_2$ will increase because of respiratory-muscle fatigue. The expanded V_D in patients with advanced pulmonary disease, pulmonary thromboembolism, and shock, results in ratios of V_D/V_E and V_D/V_T (dead space to tidal volume ventilation) that might be twice the normal value of 0.3; such ratios are frequently associated with CO_2 retention. The nearly linear shape of the CO_2 dissociation curve over the physiologic range greatly facilitates the excretion of carbon dioxide in patients with all types of V_A/Q inequalities, because blood leaving areas with low V_A/Q ratio (that has a relatively high PCO_2) is counterbalanced when mixed with blood traversing high V_A/Q units (that has relatively low PCO_2 values).

Increased Carbon Dioxide Production

Overproduction of CO_2 is seldom the sole cause of CO_2 retention because enhanced V_{CO_2} stimulates ventilation thus increasing CO_2 excretion. Yet, patients with marked reduction in pulmonary reserve and those receiving constant mechanical ventilation might develop respiratory acidosis caused by increased CO_2 production. Relevant clinical conditions characterized by an increased V_{CO2} include physical activity, increased work of breathing by the respiratory muscles, seizures, shivering, fever, and hyperthyroidism. The effect of hyperthermia may be substantial because CO_2 production increases by approximately 13% for each 1°C-increase in body temperature above normal. The administration of large carbohydrate loads, orally or parenterally, is a potentially significant cause of enhanced CO_2 production in patients with hypercapnic respiratory failure. In these cases, a larger portion of fat in the diet might properly supplement caloric intake without imposing the CO_2 burden that results from carbohydrates.[15] Additional causes of CO_2 loading include the infusion of bicarbonate-containing solutions, hemodialysis with sorbent regenerative cartridge systems, and insufflation of the peritoneum with CO_2 during endoscopic procedures.

Failure of Carbon Dioxide Transport

A large reduction in cardiac output and pulmonary blood flow caused by hemorrhage or pharmacologic vasodilation in the presence of constant pulmonary ventilation (i.e., fixed mechanical ventilation) leads to a reduction in $PaCO_2$ and end-tidal PCO_2; the latter is indicative of a reduction in pulmonary CO_2 excretion which results in primary hypercapnia (Figure 60.1). In

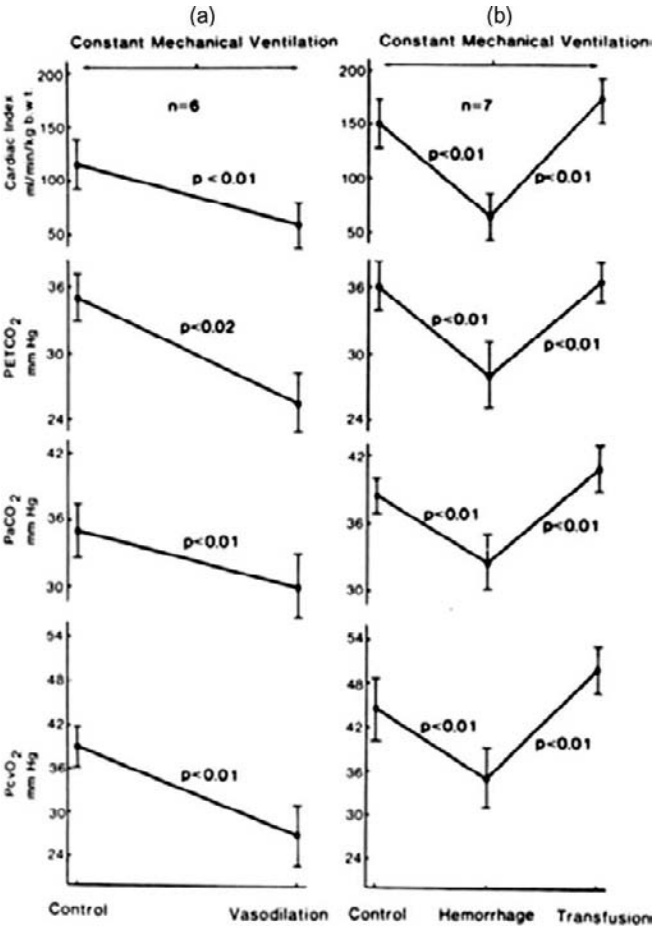

FIGURE 60.1 Reduction in end-tidal PCO_2 ($P_{ET}CO_2$) arterial PCO_2 ($PaCO_2$) and central venous PO_2 ($P_{CV}O_2$) as a result of diminished cardiac index because of pharmacological vasodilation (A) or hemorrahge (B) (changes reversed by transfusion) in the presence of constant pulmonary ventilation in anesthetized dogs. In both cases, arterial hypocapnia occurred in the presence of fixed mechanical ventilation, therefore discounting pulmonary hyperventilation as an obligatory mechanism for its pathogenesis. Moreover, the reduction in $PaCO_2$ was in fact associated with a reduction in pulmonary CO_2 excretion, as indicated by the large and significant decrement in $P_{ET}CO_2$. *(With permission, from Adrogué HJ, Rashad MN, Gorin AB, Yacoub J, Madias NE. Arteriovenous acid–base disparity in circulatory failure: studies on mechanism. Am J Physiol 1989;**257**:F1087–F1093.)*

fact, in states of severe circulatory failure, arterial hypocapnia can coexist with venous and therefore tissue, hypercapnia; however, the body CO_2 stores have been enriched and respiratory acidosis rather than respiratory alkalosis is present. This entity, which we have termed pseudorespiratory alkalosis, develops in patients with profound depression of cardiac function and pulmonary perfusion, but relative preservation of alveolar ventilation, including patients with advanced circulatory failure and those undergoing cardiopulmonary resuscitation.[7,10,11] The severely reduced pulmonary blood flow limits the CO_2 delivered to the lungs for excretion, thereby increasing the venous PCO_2. On the other hand, the increased ventilation-to-perfusion ratio causes a larger than normal decrease of CO_2 per unit of blood traversing the pulmonary circulation, thereby giving rise to arterial eucapnia or frank hypocapnia. A progressive widening of the arteriovenous difference in pH and PCO_2 develops in two settings of cardiac dysfunction, namely, circulatory failure and cardiac arrest. (Figure 60.2).[10] Severe oxygen deprivation prevails in the tissues in these two conditions, and it can be completely disguised by the reasonably preserved arterial oxygen values. Appropriate monitoring of acid–base composition and oxygenation in patients with advanced cardiac dysfunction requires mixed (or central) venous blood sampling in addition to the sampling of arterial blood.[10]

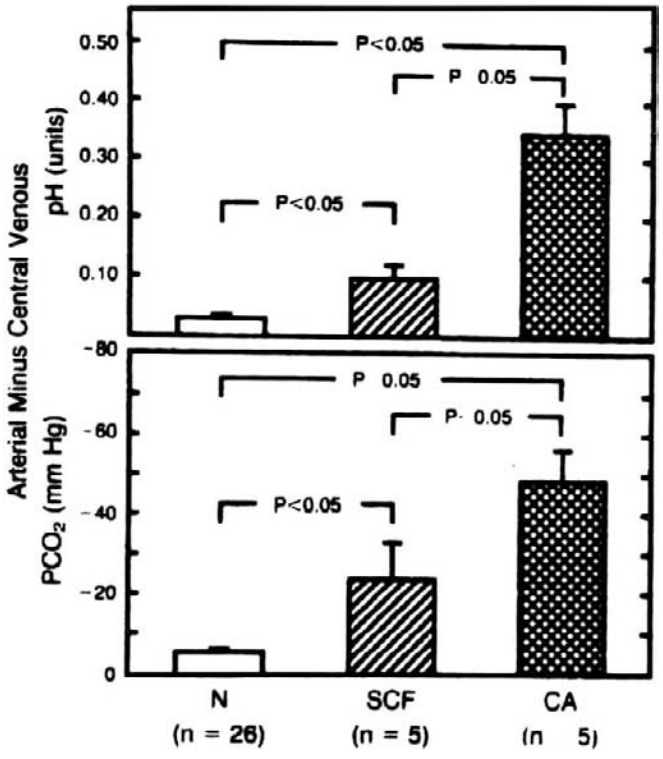

FIGURE 60.2 Arteriovenous differences in pH and PCO_2 in patients with different hemodynamic conditions. Patients with severe circulatory failure or cardiac arrest had a significant widening of the arteriovenous difference in pH and PCO_2. N, normal hemodynamic status; SCF, severe circulatory failure; CA, cardiac arrest in the presence of constant mechanical ventilation. *(With permission, from Adrogué HJ, Rashad MN, Gorin AB, Yacoub J, Madias NE. Assessing acid–base status in circulatory failure: differences between arterial and central venous blood. N Engl J Med 1989;**320**:1312–1316.)*

Secondary Physiologic Response

The secondary increment in plasma $[HCO_3^-]$ observed in acute and chronic hypercapnia is an integral part of the respiratory acidosis.[2] Adaptation to acute hypercapnia elicits an immediate increment in plasma $[HCO_3^-]$ due to titration of non-HCO_3^- body buffers; such buffers generate HCO_3^- by combining with H^+ derived from the dissociation of carbonic acid:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+$$
$$H^+ + B^- \leftrightarrow HB$$

where B^- refers to the base component and HB refers to the acid component of non-HCO_3^- buffers. This adaptation is completed within 5 to 10 minutes from the increase in $PaCO_2$, and assuming a stable level of hypercapnia, no further change in acid–base equilibrium is detectable for several hours.[22] Observations in unanesthetized normal humans studied in an environmental chamber (inspired CO_2 7 and 10%) reveal a mean $\Delta[HCO_3^-]/\Delta PaCO_2$ slope of 0.1 mEq/L per mm Hg. An essentially identical slope is obtained in humans in whom respiratory acidosis is induced by endogenous hypercapnia.[9]

Moderate hypoxemia does not alter the adaptive response to acute respiratory acidosis. However, studies in dogs have shown that pre-existing hypobicarbonatemia (whether it is caused by metabolic acidosis or chronic respiratory alkalosis) enhances the magnitude of the plasma $[HCO_3^-]$ response to acute hypercapnia; this response is diminished in hyperbicarbonatemic states (whether they are caused by metabolic alkalosis or chronic respiratory acidosis) (Figure 60.3).[4,64]

Although the increment in plasma $[HCO_3^-]$ during acute hypercapnia originates virtually exclusively from body buffering, evidence exists for a renal adjustment even during this early phase of the disorder. A fall in urine pH and a small increase in urine NH_4^+ and titratable acid excretion have been observed within minutes after induction of hypercapnia. Moreover, HCO_3^- reabsorption rate in the proximal convoluted tubule increases in response to acute hypercapnia. Sustained hypercapnia causes an additional, larger increase in plasma $[HCO_3^-]$ owing to stimulation of renal acidification.[5,18,65,87] As a consequence, net acid excretion (largely in the form of NH_4^+) transiently

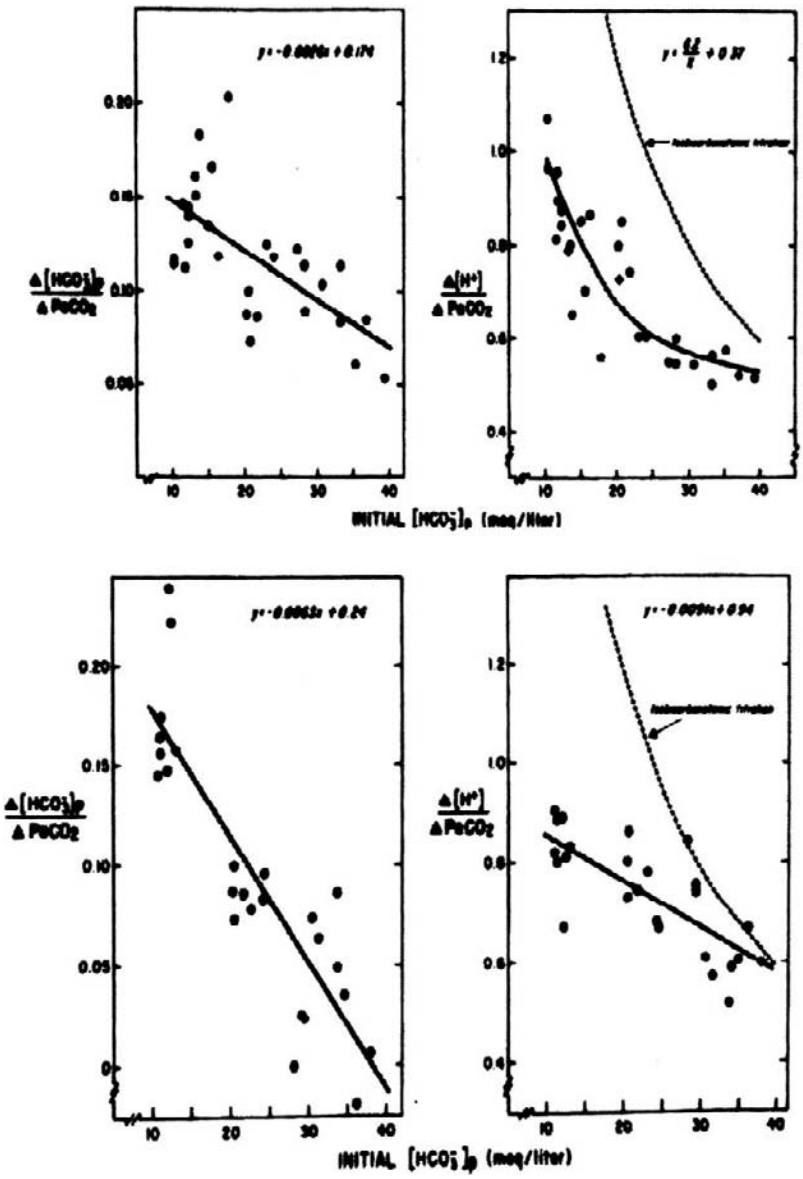

FIGURE 60.3 Influence of chronic metabolic (upper panel) or respiratory (lower panel) acid–base disorders on the acute CO_2 titration curve. Relationship between initial level of $[HCO_3]_P/PaCO_2$ regression line ($\Delta[HCO_3]_P/\Delta PaCO_2$, left) or slope of $[H^+]/PaCO_2$ regression line ($\Delta[H^+]/\Delta PaCO_2$, right) for all acute CO_2 titration studies is shown. Initial level of $[HCO_3]_P$, rather than of $PaCO_2$, is employed as an index of chronic acid–base status of animals with respiratory disorders (lower panel) for reasons of comparison with animals with metabolic acid–base disorders (upper panel). Initial $[HCO_3]_P$ values of 10 and 40 mEq/liter correspond to chronic levels of $PaCO_2$ of about 15 and 100 mm Hg, respectively. Equations describing these functions are shown in respective panels. Slope of each relationship is significantly different from 0. Interrupted line (right), labeled isobicarbonatemic titration, depicts theoretical values for $\Delta[H^+]/\Delta PaCO_2$ that would be obtained if $[HCO_3]_P$ were to remain constant at its chronic level during acute CO_2 titration. *(With permission, from Adrogué HJ, Madias NE. Influence of chronic respiratory acid-base disorders on acute CO_2 titration curve. J Appl Physiol 1985;**58**:1231–1238; and Madias NE, Adrogué HJ. Influence of chronic metabolic acid–base disorders on the acute CO_2 titration curve. J Appl Physiol 1983;**55**:1187–1195).*

exceeds endogenous acid production, effecting negative H^+ balance and generation of new HCO_3^- for the body fluids.[5] Conservation of the new HCO_3^- is ensured by an increased rate of renal HCO_3^- reabsorption, which reflects the hypercapnia-induced increase in H^+ secretory rate. Observations during the provision of exogenous alkali indicate that this increase in renal HCO_3^- reabsorption occurs roughly in parallel with the spontaneous increase in plasma $[HCO_3^-]$. A new steady state emerges for any given level of hypercapnia when the augmented filtered load of HCO_3^- is balanced by the increase in HCO_3^- reabsorption and when net acid excretion returns to the level that offsets daily endogenous acid production. In the new steady state, however, the mix of the net acid constituents differs from the normal baseline: Excretion of NH_4^+ remains increased, but is balanced by increased HCO_3^- excretion and decreased titratable acidity.[5,65] Urine pH is also increased compared to baseline. As HCO_3^- stores are being augmented by the transient increase in net acid excretion, Cl^- stores are correspondingly depleted by a transient increase in renal Cl^- excretion. Chloruresis appears to outstrip net acid excretion during the first 1–2 days of exposure to hypercapnia, the difference being accounted for by an increase in the excretion of Na^+ and K^+. Consequently, some degree of Na^+ and K^+ depletion typically accompanies adaptation to chronic hypercapnia. The hypochloremia that results from the transient chloruresis is sustained by a persistently depressed renal Cl^- reabsorption. In dogs, a new steady state emerges within three to five days. Whether this temporal pattern applies to humans is unknown. In

patients, chronic hypercapnia often reflects gradual deterioration in pulmonary function; consequently, the secondary response might keep pace with the slowing rising $PaCO_2$ without a perceptible delay.[9,65]

Studies in dogs indicate that a highly predictable curvilinear relationship exists between the degree of chronic hypercapnia and the levels at which plasma [HCO_3^-] and blood [H^+] stabilize following full physiological adaptation. Over the range of $PaCO_2$ values between 40 and 90 mm Hg, which would encompass most values encountered clinically, this curvilinear relationship between plasma [HCO_3^-] and $PaCO_2$ is closely approximated by a straight line with a mean $\Delta[HCO_3^-]/\Delta PaCO_2$ slope of 0.3 mEq/L per mm Hg. The corresponding relationship between blood [H^+] and $PaCO_2$ is strikingly linear, [H^+] rising on average by 0.32 nEq/L per mm Hg chronic elevation in $PaCO_2$. Careful observations of patients with chronic hypercapnia as a result of chronic obstructive pulmonary disease allowed estimation of a mean $\Delta[HCO_3^-]/\Delta PaCO_2$ slope of 0.35 mEq/L per mm Hg.[9,23] This slope functions up to a $PaCO_2$ of approximately 70 mm Hg. Beyond that level, the slope of $\Delta[HCO_3^-]/\Delta PaCO_2$ seems to flatten. More recently, a substantially larger slope was reported, but the small number of blood gas measurements, one for each of 18 patients, calls into question the validity of the conclusion reached. Notably, there is no information in humans on the effects of pre-existing metabolic acidosis or metabolic alkalosis on the $\Delta[HCO_3^-]/\Delta PaCO_2$ slope of superimposed chronic hypercapnia. In dogs, the background presence of metabolic disorders alters this slope substantially.

The renal response to chronic hypercapnia is not altered appreciably by dietary Na^+ or Cl^- restriction, moderate K^+ depletion, alkali loading, moderate hypoxemia (PaO_2, 45−55 mm Hg), or adrenalectomy. However, recovery from chronic hypercapnia is crippled by a diet deficient in Cl^-; in this circumstance, despite correction of the level of $PaCO_2$, plasma [HCO_3^-] remains elevated so long as the state of Cl^- deprivation persists, leading to posthypercapnic metabolic alkalosis.[6,26,65,87] On the other hand, moderate potassium depletion does not interfere with full repair of acid−base equilibrium following the return to eucapnia.

Available information implicates essentially the entire nephron and its acidification apparatus in the renal response to chronic hypercapnia. Micropuncture observations in the proximal tubule of the rat indicate that, whereas absolute HCO_3^- reabsorption is increased only mildly in acute hypercapnia, a substantial rise is observed during the chronic phase of the disorder. Total CO_2 absorption was unchanged in microperfused cortical collecting tubules obtained from rabbits exposed to hypercapnia for 3−6 hr, but it was substantially increased in tubules derived from animals that had been exposed to hypercapnia for a 24-hr period. Other microperfusion studies in the rabbit have shown, however, stimulation of acidification in cortical and medullary collecting tubules within 20 min from the onset of hypercapnia. Parallel increases in the rates of the luminal Na^+/H^+ exchanger (presumably the NHE-3) and the basolateral $Na^+/3HCO_3^-$ cotransporter in the proximal tubule have been described; these adaptations reflect an increase in the V_{max} of each transporter but no change in the K_m for sodium.[81] However, other investigators have not been able to reproduce the finding of a stimulated Na^+/H^+ exchanger in chronic hypercapnia.[65] Additionally, several studies have shown that acute or chronic hypercapnia induces exocytotic insertion of H^+-ATPase-containing subapical vesicles to the luminal membrane of both proximal tubule cells and type A intercalated cells of cortical and medullary collecting ducts. Such a redistribution of H^+-ATPase pumps during hypercapnia is not associated with a detectable increase in their quantity in either cortex or medulla. A transient increase in cell calcium appears to be important in this exocytotic event.[85,90] Rat tubule microdissection studies revealed that by 24 hr of hypercapnia, but not at earlier times, the activity of H^+-ATPase along the entire nephron (i.e., proximal tubule, thick ascending limb of Henle, and cortical and medullary collecting tubules) and that of the H^+-K^+-ATPase in the cortical and medullary collecting tubules were increased. Similar increases in the activities of the H^+-ATPase and the H^+-K^+-ATPase were observed in adrenalectomized rats replaced with physiological doses of aldosterone.[41] Further, chronic hypercapnia increases the steady-state abundance of mRNA coding for the basolateral Cl^-/HCO_3^- exchanger (band 3 protein) of type A intercalated cells in rat renal cortex and medulla. Whether this change is translated into increased levels of protein and activity of the exchanger remains unknown.[88]

The signal that triggers the renal acidification response to hypercapnia remains undefined, but present evidence favors the increase in $PaCO_2$ itself rather than the decrease in systemic pH. Indeed, observations in dogs indicate that a decrement in systemic pH is not a prerequisite to the augmentation of renal HCO_3^- reabsorption required for sustaining the secondary hyperbicarbonatemia characteristic of chronic hypercapnia.[65,66] Subsequent *in vitro* studies in rabbit proximal tubule have provided plausible validation of these whole-animal observations. Much more work is required in this area as well as the role of the filtered HCO_3^- load, and that of changes in hemodynamics and hormonal factors (such as stimulated β-adrenergic tone, renin-angiotensin-aldosterone system, cortisol, and arginine vasopressin).

There is currently no information on the impact of graded degrees of chronic renal insufficiency on the

renal acidification response to respiratory acidosis. In a patient with hyporeninemic hypoaldosteronism, hyperkalemia, and an eGFR on the order of 20–25 ml/min/1.73 m^2, the secondary response to chronic hypercapnia was suppressed; correction of the hyperkalemia allowed expression of an essentially normal secondary response. These events were ascribed to the fact that the renal response to chronic hypercapnia largely entails stimulation of ammoniagenesis and increased ammonium excretion, processes that are impaired by hyperkalemia. This case also suggests that in the absence of hyperkalemia, advanced renal insufficiency would be required to adversely impact this response. Obviously, patients with end-stage renal disease cannot mount a renal response to chronic hypercapnia and, thus, they are more subject to severe acidemia. The degree of acidemia is more pronounced in patients receiving hemodialysis rather than peritoneal dialysis because the former treatment maintains, on average, a lower plasma [HCO_3^-].[65]

Plasma Electrolyte Composition during Respiratory Acidosis

Mild hypernatremia ($\Delta[Na^+]$, 2–4 mEq/liter) is typically seen in both acute and chronic hypercapnia.[22] Hypochloremia is a consistent finding in chronic hypercapnia, and it reflects both a shift of chloride into erythrocytes and a loss of chloride in the urine during the adaptive process.[86,87] Plasma potassium concentration increases (by only approximately 0.1 mEq/liter for each 0.1 unit fall in pH) during acute hypercapnia, probably because of a shift of this ion out of cells;[3] plasma potassium does not change appreciably during chronic hypercapnia. Hyperphosphatemia is a characteristic feature of acute hypercapnia and probably reflects a release of phosphate from tissues; a rise in plasma phosphate is not observed during chronic hypercapnia. Consistent changes in plasma calcium and magnesium have not been noted in response to hypercapnia in limited observations in humans. Plasma lactate and pyruvate concentrations fall during acute hypercapnia, but they are not significantly altered by chronic hypercapnia, even in the presence of moderately severe hypoxemia. No appreciable changes in plasma unmeasured anions occur in either acute or chronic hypercapnia.

CEREBROSPINAL FLUID COMPOSITION DURING RESPIRATORY ACIDOSIS

Because carbon dioxide diffuses readily across the blood brain-barrier, increases in $PaCO_2$ are rapidly reflected in the CSF, producing a prompt increase in CSF [H^+].[55] Experimental and clinical studies have demonstrated a narrowed CSF-arterial PCO_2 difference during respiratory acidosis that has been attributed to the associated increase in cerebral blood flow. With persistent hypercapnia, CSF [HCO_3^-] increases progressively, so that the rise in CSF [H^+] is ameliorated. Studies in dogs exposed to 12% CO_2 showed that the steady-state pH decrements were virtually identical in blood and CSF.

Intracellular pH during Respiratory Acidosis

Increases in extracellular PCO_2 both *in vivo* and *in vitro* exert a prompt acidifying effect on intracellular pH.[8,54] Efforts at estimating the magnitude of intracellular acidification during acute hypercapnia using the "whole-body" DMO method have yielded variable results. *In vivo* estimates of intracellular pH of various tissues (using the DMO method or ^{31}P-NMR spectroscopy) have yielded variable responses to acute hypercapnia. Whereas intracellular pH falls in skeletal muscle and kidney by a magnitude similar to that in the extracellular compartment, smaller changes or no changes in intracellular pH have been noted in cardiac muscle, cerebral cortex, and liver (54). Renal intracellular pH returns to the normal level during the chronic phase of respiratory acidosis. There is currently no information regarding the impact of chronic hypercapnia on the intracellular acidity of other tissues.

PATHOPHYSIOLOGIC EFFECTS AND CLINICAL MANIFESTATIONS OF RESPIRATORY ACIDOSIS

Because clinical hypercapnia almost always occurs in association with hypoxemia, it is often difficult to determine whether a specific manifestation is the consequence of the elevated $PaCO_2$ or the reduced PaO_2. Nevertheless, one should bear in mind several characteristic manifestations of neurologic or cardiovascular dysfunction to diagnose the condition accurately and to treat it effectively.

Neurologic

Hypercapnia causes vasodilation and increased cerebral perfusion when autoregulation pathways of cerebral blood flow are intact.[79] This effect amounts to approximately 6% blood flow increase per 1 mm Hg rise in PCO_2, and is less pronounced in women than in men presumably because of differences in prostaglandin levels. Maximal hypercapnic vasodilation occurs at

PCO_2 levels of about 80 mm Hg.[79] Experimental studies in humans demonstrated increases in cerebral blood flow up to 200% in response to hypercapnia. Aging impairs the vasodilatory response, an effect that may be dependent on a lower concentration of oxyhemoglobin or on derangements in the arterial wall.

The precise mechanism of CO_2-induced cerebral vasodilation in humans remains undefined.[24] The increase in cerebral blood flow appears to originate from the associated acidosis, because normalization of pH by administering bicarbonate reverses the vasodilation. Studies in healthy volunteers demonstrated that hypercapnia increased cerebral release of nitric oxide accompanied by an increase in venous-arterial difference for nitrite. In contrast hypoxemia (FiO_2 10 and 12%) caused a net cerebral uptake of nitrite.[76] Release of CNP (C-natriuretic peptide) was also observed in hypercapnia.[76] Animal studies have shown that two mechanisms, namely, activation of K_{ATP} channels in vascular smooth muscle and release of nitric oxide participate in hypercapnic vasodilation.[79] Conversely, some studies in humans have shown that CO_2-induced cerebral vasodilation is independent of nitric oxide.[52] Animal studies have also demonstrated that hypercapnia increases optic disc PO_2 and this effect is prevented with systemic nitric oxide synthase inhibition; thus, nitric oxide seems to mediate CO_2-vasodilation in retinal arterioles.[77]

It is a widely held view that hypercapnia should be avoided in patients suffering from ischemic brain injury because it may lead to uncontrolled intracranial hypertension.[24] However, recently published experimental studies in rats have demonstrated that moderate to severe hypercapnia ($PaCO_2$ 60−100 mm Hg) is neuroprotective after transient global cerebral ischemia-reperfusion injury; this protection was proposed to be mediated by a hypercapnia-induced promotion of survival of neurons by modulating apoptosis-regulating proteins. In contrast, rats exposed to very severe hypercapnia ($PaCO_2$ 100−120 mm Hg) had increased brain injury and more cerebral edema.[93] Whether a similar response occurs in humans remains unknown.[24]

Most of the important clinical manifestations of hypercapnia result from its effects on the central nervous system (CNS).[17,41] Factors that influence the CNS disturbances in respiratory acidosis are the magnitude of the hypercapnia, the rapidity with which it develops the severity of the acidemia, and the degree of attendant hypoxemia. Acute hypercapnia is often associated with marked anxiety, severe breathlessness, disorientation, confusion, incoherence, and combativeness. The alterations in the level of consciousness observed in hypercapnia are accompanied by reductions in brain glutamate and aspartate and increases in glutamine and gammaaminobutyric acid (GABA). In unusually severe hypercapnia, stupor or coma can result.[41] Hypercapnic coma characteristically occurs in patients with acute exacerbations of chronic respiratory insufficiency, who are treated injudiciously with "high-flow" oxygen. Motor disturbances, including tremor, myoclonic jerks, and asterixis, are frequent accompaniments of both acute and chronic hypercapnia. Sustained myoclonus and seizure activity can also develop. Signs and symptoms of increased intracranial pressure (pseudotumor cerebri) are occasionally evident in patients with either acute or chronic hypercapnia, and they appear to be related to the vasodilating effects of CO_2 on cerebral blood vessels.[17,41] Headache is a frequent complaint. Blurring of the optic discs and frank papilledema can be found when hypercapnia is severe.[12] The plantar response can be extensor. It is not surprising, given this broad range of possible CNS findings, that respiratory acidosis often is diagnosed erroneously as a cerebral vascular accident or as an intracranial tumor.

Cardiovascular

Animal studies in cardiac myocytes and in intact isolated hearts have demonstrated that the decrease in tissue pH observed in ischemia, if maintained during reperfusion, may have a protective effect against irreversible tissue injury. The large decrease in tissue pH is accounted for by the combined effects of respiratory and metabolic acidosis in association with hypoxia.[53,57] This protection has been called the "pH paradox" since the rapid correction of acidosis observed during reperfusion precipitates irreversible tissue injury.[21] Correction of ischemia induced-acidosis during reperfusion increases cytosolic free calcium that leads to cellular injury. Administration of inhibitors of Na^+/H^+ exchange have been shown to prevent a rapid rise in tissue pH during reperfusion and this effect ameliorates ischemia/reperfusion injury.[21]

An assessment of myocardial contractility and blood flow in response to short term moderate respiratory acidosis and alkalosis have been reported in anesthetized patients with coronary artery disease. It was concluded that changes in $PaCO_2$ lead to hemodynamic effects largely due to alterations in systemic vascular resistance rather than by alterations in myocardial contractility.[56]

The hemodynamic consequences of respiratory acidosis can reflect a variety of mechanisms, including a depressing effect on myocardial contractility, systemic vasodilation resulting from an action of hypercapnia on vascular smooth muscle, stimulation of the sympathetic nervous system leading to increased plasma catecholamine levels, and blunting of receptor responsiveness to catecholamines.[8] The composite effect of

these inputs is such that acute hypercapnia of mild to moderate degree is usually characterized by warm, flushed skin, a bounding pulse, diaphoresis, increased cardiac output, and normal or increased blood pressure.[12] On the other hand, severe hypercapnia might be attended by decreases in both cardiac output and blood pressure. The vasodilatory effect of acute hypercapnia is most apparent in the cerebral circulation, where blood flow increases in direct relation to the level of $PaCO_2$. Chronic respiratory acidosis is associated with normal cardiac output and blood pressure, unless a complicating disorder such as cor pulmonale supervenes. Cerebral blood flow remains increased in chronic hypercapnia, but the increment appears to be less than that occurring in comparable levels of acute hypercapnia.

Cardiac arrhythmias occur frequently in patients with either acute or chronic hypercapnia, especially those receiving digitalis as therapy for cor pulmonale.[50] Particularly common are supraventricular tachyarrhythmia's with ventricular rates of 120–160 beats/min. Yet the role of the elevated $PaCO_2$ *per se* in the generation of cardiac arrhythmias is unclear. Indeed, remarkably little cardiac irritability occurs in extreme hypercapnia in the absence of accompanying hypoxemia and, by way of contrast, rapid restoration of normal $PaCO_2$ from very high levels is known to trigger cardiac arrhythmias, including those of ventricular origin.[50] Of interest is the reported striking increase in myocardial PCO_2 (e.g., up to 346 mmHg) and $[H^+]$ (e.g., 440 nEq/liter, pH 6.38) after ventricular fibrillation. Such hypercapnia greatly reduces cardiac resuscitability.[78] Because bicarbonate administration can aggravate PCO_2 leading to further circulatory depression, this agent should be used with caution in the presence of respiratory acidosis.

Respiratory

The normally dry alveolar space results from active sodium transport across the epithelial barrier mediated by the Na, K-ATPase.[89] A reduced alveolar fluid reabsorption caused by mechanical stress, endothelial activation, or hypoxia can lead to pulmonary edema. Hypercapnia, independent of acidosis, has been shown to impair alveolar fluid reabsorption by decreasing Na, K-ATPase activity in the alveolar epithelial cells.[89] This CO_2-induced effect results from stimulation of Na, K-ATPase endocytosis. Recent investigations have demonstrated that in rat lungs, hypercapnia leads to extracellular signal-regulated kinase (ERK) activation which in turn may mediate the CO_2-induced Na,K-ATPase down regulation and endocytosis.[92]

Complex shifts in the oxyhemoglobin dissociation curve occur during hypercapnia, because increased $PaCO_2$ tends to shift the curve to the right (Bohr effect), and acidemia (by decreasing intracellular 2,3-DPG) tends to shift the curve to the left.[34,51] Further complexity is introduced if chronic hypoxemia is present, because of an augmented intracellular 2,3-DPG level, which tends to shift the curve to the right. In addition to the effects of hypercapnia on P_{50}, erythropoietin production in response to hypoxia is inhibited by respiratory acidosis.

Contradictory evidence has been obtained about the effects of acute hypercapnia on pulmonary vascular resistance and pulmonary artery pressure; some studies indicate an increase in these parameters, whereas others have failed to demonstrate any significant effect.[12,27] Respiratory acidosis does not significantly influence the pulmonary vasoconstriction in response to hypoxia whereas respiratory alkalosis blunts this response. Diaphragm performance decreases during respiratory acidosis in anesthetized dogs, but such an effect was not observed in other skeletal muscles.

Immune Response

Respiratory acidosis elicits an inhibitory response of the immune system that has been described as a "double-edged sword" since it combines morbid effects as well as potentially salutary actions.[35] Hypercapnia was shown to inhibit bacterial growth but these effects occur at extremely high levels of PCO_2 that are not encountered in clinical practice. A reduction in cytokine signaling between immune cells and of neutrophil and macrophage production of proinflammatory cytokines including TNF-α1, IL-1β, IL-8, and IL-6 occurs in respiratory acidosis; conversely, the complement system is activated.[35]

The impairment in the cellular immune response observed in respiratory acidosis is complex and involves reduction of phagocyte migration, chemotaxis, and adhesion; decreased phagocytic ability; reduction of oxidant-mediated bacterial killing; and altered mechanisms of neutrophil death.[32] It appears that at least some of the effects of hypercapnia on the immune response are dependent on acidemia and not on the level of PCO_2 *per se*.[48]

Whereas the actions described above can be characterized as harmful, the effects of respiratory acidosis on tissue injury caused by infection or inflammation have elements that appear salutary.[31] Animal studies have shown that the severity of lung injury caused by bacterial pneumonia is ameliorated by respiratory acidosis. Similarly, the severity of septic shock and lung injury in systemic sepsis has been shown to be reduced by hypercapnia.[35] Buffering of experimentally induced respiratory acidosis does not have beneficial effects and may worsen tissue injury in bacterial pneumonia.[48]

Renal and Metabolic

Mild to moderate hypercapnia results in renal vasodilation, but acute increments in $PaCO_2$ to levels above 70 mm Hg induce renal vasoconstriction and hypoperfusion. A role for angiotensin II in the renal vasoconstriction observed during acute respiratory acidosis in the company of hypoxemia was documented in conscious dogs. Acute hypercapnia stimulates renin secretion by augmenting β-adrenergic tone and leads to increased plasma cortisol and aldosterone levels. Additionally, acute hypercapnia stimulates antidiuretic hormone release and reduces renal sodium and water excretion as a result of the hormonal changes described and the augmented renal adrenergic activity.[8] Salt and water retention commonly attends sustained hypercapnia, especially in the presence of cor pulmonale. Although metabolic demands may be augmented by the associated sympathetic surge, respiratory acidosis decreases the uptake of glucose in the tissues by inducing insulin resistance and inhibits anaerobic glycolysis by depressing 6-phosphofructokinase activity.[1] This effect can have grave consequences during hypoxia, since glycolysis becomes the main source of energy.

Skeletal

Decreased pH of respiratory or metabolic origin produces net calcium loss from cultured bone, but this response is less intense in respiratory acidosis.[28,29] The relatively mild calcium efflux of respiratory acidosis appears to be mediated exclusively by physicochemical dissolution without involving cell-mediated processes. Conversely, metabolic acidosis produces larger calcium efflux because of the additive effects of inhibition of osteoblastic bone formation and stimulation of osteoclastic bone resorption.[28,29]

DIAGNOSIS OF RESPIRATORY ACIDOSIS

In general, one should never rely on clinical examination alone to assess the adequacy of alveolar ventilation.[12] Whenever carbon dioxide retention is suspected, blood gas determinations should be obtained. Indeed, accurate laboratory data are a prerequisite for establishing the diagnosis of respiratory acidosis. Differentiating between acute and chronic hypercapnia can be a difficult task. Neither the level of hypercapnia nor the magnitude of the associated hypoxemia is particularly helpful. Of course, if the presence of complicating acid–base disorders can be excluded, the acid–base parameters themselves can be of assistance; acute hypercapnia is associated with a lower plasma bicarbonate and blood pH than is chronic hypercapnia of the same magnitude. Nonetheless, the utility of this criterion is limited by the frequent uncertainty about the coexistence of additional acid–base disturbances, the individual variability in the secondary physiologic responses to hypercapnia, and the fact that insufficient time from the onset of hypercapnia might have elapsed for full expression of the adaptive responses. In the end, clinical information must be relied on for distinguishing between acute and chronic respiratory acidosis as well as for establishing the underlying etiology.

MANAGEMENT OF RESPIRATORY ACIDOSIS

As previously noted, carbon dioxide retention, whether acute or chronic, is always associated with hypoxemia in patients breathing room air. In fact, hypoxemia, not hypercapnia or acidemia, is the most critical factor that determines morbidity and mortality of patients with acute or chronic respiratory acidosis. Therefore, the greatest emphasis should be placed on ensuring adequate oxygenation. In addition to the maintenance of appropriate oxygenation, the goals of treatment both of acute and chronic respiratory acidosis should include prevention of severe acidemia and amelioration of the hypercapnia.[6,8]

Administering Oxygen

Since oxygen administration promotes the development of CO_2 retention both in patients with acute and chronic respiratory acidosis, this therapeutic tool must be applied with caution.[16] The primary goal of oxygen therapy is to secure a PaO_2 of 60 to 70 mm Hg or an oxygen saturation of 90 to 93%. Higher levels of PaO_2 achieved with the use of very rich inspired oxygen mixtures increase the risk of worsening hypercapnia without adding significantly to the blood oxygen content.

Venturi masks should be used when possible as they yield a precise fraction of inspired oxygen (FiO_2) and provide a flow that exceeds the full ventilatory requirements.[42] Available Venturi masks deliver an FiO_2 of 24, 28, 31, 35, 40, or 60%. The design of the valve ensures that a specific proportion of oxygen and air are mixed and delivered to the patient. Other methods of oxygen delivery can be used, particularly when higher levels of FiO_2 are required. Nasal cannulae, more comfortable devices that permit oral feedings, can provide flow rates of up to 6 liters/min with an associated FiO_2 of approximately 40%. When using nasal cannula, the oxygen flow rate should be increased by 1 liter/min at a time in most instances

since it is difficult to predict the FiO_2 with this device. Simple face masks using flow rates of 6–10 liters/min can provide FiO_2 of up to 55%, but large fluctuations in FiO_2 are observed. Non-rebreathing masks can provide FiO_2 of up to 90%. The use of positive end expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) can enhance the effect of a given level of oxygen administration in patients with pulmonary edema or diffuse pulmonary disease.

As indicated above, supplemental oxygen may lead to the development or worsening of hypercapnia, and this risk of oxygen therapy is even higher in patients with chronic obstructive pulmonary disease (COPD).[16] The major determinants of CO_2 retention in response to supplemental oxygen in patients with COPD, in order of importance, include an increase in dead space ventilation and ventilation/perfusion (V_A/Q) mismatch due to attenuation of hypoxic pulmonary vasoconstriction, decreased binding affinity of hemoglobin for CO_2 in the presence of increased O_2 saturation (Haldane effect), and decreased minute ventilation caused by depressed respiratory drive.[12,16] Abrupt removal of supplemental oxygen in patients who develop CO_2 retention during oxygen therapy may cause a reduction in PaO_2 to levels lower than that at the start of oxygen administration. Consequently, this practice should be avoided since it can lead to more severe tissue hypoxia and acidemia.

One should always be mindful of the risk of oxygen toxicity, which increases as a function of the level of FiO_2 and the time of exposure. As a rule, the lowest possible FiO_2 that achieves the desired hemoglobin saturation should be used, and oxygen support that results in an FiO_2 greater than 30–40% should be withdrawn as soon as feasible.

Assisted Ventilation

Development or worsening of acidemia (e.g., pH less than 7.20) or marked obtundation during oxygen therapy is an indication for mechanical ventilation, although noninvasive positive pressure ventilation (NPPV) might help avoid the need for endotracheal intubation.

Noninvasive Positive Pressure Ventilation

This form of assisted ventilation consists of the mechanical delivery of breaths via a tightly fitting nasal or full facial mask. The salutary effects of NPPV consist of increasing alveolar ventilation, reducing work of breathing and therefore providing rest to the respiratory muscles, and decreasing the rate of intubation.[12] The ventilator might deliver only inspiratory pressure (i.e., pressure support mode or PSV), or pressure might be applied during the entire respiratory cycle (i.e., bilevel positive airway pressure). The latter has become the preferred mode of NPPV used in COPD patients (the "Bi PAP" ventilator is commonly used for this purpose) because it produces greater improvements in blood gases and reduces the work of breathing more effectively than PSV alone. The high success rate of NPPV is well documented in patients with acute respiratory failure caused by decompensated COPD or acute cardiogenic pulmonary edema. Yet, it appears that NPPV can be effectively used in other conditions, including the immunocompromised patient (in whom intubation carries a higher risk of pulmonary infection), in postoperative respiratory failure, after coronary artery bypass grafting or lung resection, as an adjunct to extubation, and to avoid reintubation of previously mechanically intubated patients. A lower incidence of nosocomial infections, especially pneumonia, in comparison with standard mechanical ventilation likely explains the lower mortality associated with NPPV. Contraindications to the use of NPPV are cardiovascular instability (e.g., hypotension, serious arrhythmias, myocardial ischemia), craniofacial trauma or burns, inability to protect the airway, and the likely need for emergent intubation.

In patients with chronic respiratory acidosis, assisted ventilation should be avoided if adequate oxygenation can be attained by conservative therapy (PaO_2 on the order of 60–70 mmHg and hemoglobin oxygen saturation of 90–93%). As a general rule, if the patient is alert, able to cough, and can cooperate with the treatment program, mechanical ventilation is usually not necessary. Noninvasive positive pressure ventilation is an effective modality for selected patients with acute exacerbations of COPD. Candidates for the use of NPPV are patients with a respiratory rate of 25 per minute or greater accompanied by moderate to severe respiratory distress and acidemia or hypercapnia (pH <7.35 or $PaCO_2 >45$ mm Hg).

Mechanical Ventilation (Invasive, Including Airway Intubation) and Permissive Hypercapnia

Acute respiratory failure accounts for about two-thirds of all patients requiring mechanical ventilation. Causes of acute respiratory failure include ARDS, severe heart failure, fulminant pneumonia, sepsis, trauma, and the postoperative state. The remaining one-third of patients require ventilator assistance because of exacerbations of COPD or neuromuscular disorders, or after developing coma.

The objectives of mechanical ventilation are to reverse progressive respiratory acidosis or life-threatening hypoxemia unresponsive to conservative management and to decrease the work of breathing.

The most widely used mode of mechanical ventilation is assist-control ventilation, in which the ventilator delivers a preset tidal volume when triggered by the patient's inspiratory effort or independently if such an effort does not occur within a preselected time. Another widely used modality is pressure-support ventilation in which 16–30 breaths per minute are delivered to augment the patient's spontaneous respiratory effort by a preset level of pressure (rather than volume).

Traditionally, the goal of treatment with mechanical ventilation had been to restore $PaCO_2$ and arterial blood pH to a level close to the normal values of 40 mm Hg and 7.40, respectively, regardless of the tidal volumes and airway pressures needed.[13] However, it is now clear that large tidal volumes with excessively high airway pressures (e.g., plateau levels higher than 25–35 cm of H_2O) often lead to alveolar overdistension and barotrauma. Therefore, an alternative approach that uses a protective ventilation strategy and allows $PaCO_2$ to rise, called "permissive hypercapnia" (or controlled mechanical hypoventilation), has been introduced.[13,20] In this form of treatment, lower tidal volumes (5 to 7 ml/kg or less) and peak inspiratory pressures are used. As expected, $PaCO_2$ rises but rarely exceeds 80 mm Hg, and blood pH can decrease to as low as 7.00 to 7.10, while blood oxygenation is secured.[20,38] Permissive hypercapnia has been reported to have salutary effects in animal models of cerebral ischemia-reperfusion injury and in lung injury secondary to bacterial infection (see Pathophysiologic Effects and Clinical Manifestations of Respiratory Acidosis).

The increased respiratory drive associated with permissive hypercapnia can cause extreme discomfort, making sedation necessary. Because the patient commonly requires neuromuscular blockade as well, accidental disconnection from the ventilator can cause sudden death. Furthermore, after the neuromuscular blocking agent is discontinued, there might be weakness or paralysis for several days or weeks. There are several contraindications to the use of permissive hypercapnia, including cerebrovascular disease, brain edema, increased intracranial pressure, convulsions, depressed cardiac function, cardiac arrhythmias, and severe pulmonary hypertension. Importantly, most of these entities can develop as adverse effects of permissive hypercapnia itself, especially when hypercapnia is associated with substantial acidemia. In fact, some experimental evidence indicates that correction of acidemia attenuates the adverse hemodynamic effects of permissive hypercapnia.[30] It appears prudent, although still controversial, to keep the blood pH at approximately 7.30 by administering intravenous alkali when controlled hypoventilation is prescribed.[6]

If mechanical ventilation is deemed necessary in patients with chronic respiratory acidosis, the goal should be to increase minute ventilation sufficiently to maintain blood pH and $PaCO_2$ at levels that are close to the patient's chronic baseline values. Because acute alkalemia reduces P_{50}, a rapid increase in blood pH should be avoided in the management of patients with acute exacerbations of chronic respiratory acidosis. Such an alkalemia can be observed with aggressive normalization of $PaCO_2$ via mechanical ventilation or after alkali administration. Because these patients commonly have an associated cardiac or cerebrovascular insufficiency, they cannot augment cardiac output or regional perfusion to overcome the higher oxygen binding affinity of hemoglobin. When employing assisted ventilation, blood gases should be measured frequently to prevent or correct both overventilation and underventilation. In general, as long as adequate oxygenation can be maintained, $PaCO_2$ should be reduced toward the chronic baseline over many hours to a few days.

Improving Pulmonary Function

Measures directed against all possible reversible factors responsible for the respiratory acidosis should be undertaken. Pulmonary infections should be treated aggressively, and direct examination of bronchial secretions and cultures should guide such therapy. Bronchodilators, administered by inhalation, orally, subcutaneously, or intravenously, are the main therapeutic tool for patients with COPD.[69] The most relevant bronchodilators include β-agonists and anticholinergics; theophylline is used less often. Inhaled glucocorticoids, systemic glucocorticoids, and mucoactive agents are often used as adjunct therapy in COPD and other causes of respiratory acidosis. Reversal of the hypercapnia, acidemia, and hypoxemia will usually improve cardiac dysfunction and pulmonary hypertension.[12] Excluding the case of cor pulmonale in association with low cardiac output, administration of digitalis appears to be of no value in the treatment of the depressed cardiac contractility accompanying severe respiratory acidosis. Close monitoring of the patient's fluid status is crucial, because volume overload increases pulmonary capillary pressure and predisposes to the development of pulmonary edema. Diuretics should be used, as needed. In appropriate settings, the use of intermittent ultrafiltration/hemodialysis or continuous arteriovenous or venovenous hemofiltration may be required. Nutritional support is of crucial importance in order to minimize reduction in the strength and endurance of the respiratory muscles and depression in the body's immunity. Administering a larger proportion of nonprotein calories as fat emulsions might aid the weaning process from ventilatory support by decreasing the rate of CO_2 production in comparison with isocaloric amounts of carbohydrate.[15]

Alkali Therapy

The presence of a component of metabolic acidosis has traditionally been the primary indication for alkali therapy in patients with respiratory acidosis. However, in patients maintained on mechanical ventilation, in whom permissive hypercapnia is utilized resulting in blood pH values below 7.20, some clinicians recommend the use of sodium bicarbonate to ameliorate the acidemia.[30] In fact, correction of acidemia attenuates the adverse hemodynamic effects of permissive hypercapnia. As explained before, it appears prudent, although still controversial, to keep the blood pH at approximately 7.30 by administering intravenous alkali when controlled hypoventilation is prescribed.[6]

Alternative forms of alkali, which do not augment CO_2 generation as much as bicarbonate does, but are effective in ameliorating acidemia include Carbicarb® and THAM (Tromethamine).[25,61,63] Carbicarb is an equimolar mixture of sodium carbonate and sodium bicarbonate. Because carbonate is a stronger base, it is used in preference to bicarbonate for buffering hydrogen ions generating bicarbonate rather than carbon dioxide in the process ($CO_3^{2-} + H^+ \rightarrow HCO_3^-$). In addition, the carbonate ion can react with carbonic acid, therby consuming carbon dioxide ($CO_3^{2-} + H_2CO_3^- \rightarrow 2HCO_3^-$). Yet, the interaction of bicarbonate with hydrogen ions still generates CO_2. Thus, Carbicarb limits but does not eliminate the generation of carbon dioxide.[6,19] Clinical experience with Carbicarb is limited, and this product is not yet commercially available for clinical use.

THAM (tris [hydroxymethyl] aminomethane) is a synthetic buffer available as a 0.3-N solution, which at a pH of 7.20–7.40 has a buffer capacity equivalent to that of normal blood.[25] A distinct property of THAM is its capacity to buffer both metabolic acids ($THAM + H^+ \rightarrow THAM^+$) and carbonic acid ($THAM + H_2CO_3 \rightarrow THAM^+ + HCO_3^-$). Because THAM freely penetrates cells it can be an effective intracellular buffer. Indeed, *in vitro* and *in vivo* studies have indicated that both extracellular and intracellular pH rise after THAM administration; *in vitro* studies have shown that THAM exerts a positive inotropic effect on the ischemic myocardium. When used in the experimental treatment of head injury, it reduces brain edema. THAM has been proposed as a substitute for bicarbonate in treating the acidemia of respiratory acidosis because of its theoretical potential to decrease $PaCO_2$.

The effects of THAM in patients with acute respiratory distress syndrome (ARDS) undergoing permissive hypercapnia has been investigated.[91] Permissive hypercapnia of two hours duration and $PaCO_2$ of 80 mm Hg increased cardiac output and decreased systemic vascular resistance. Mean pulmonary artery pressure increased and mean arterial pressure decreased significantly only in the untreated group (pH-uncorrected group). Myocardial contractility decreased in both groups but significantly less (approximately 10%) in the pH-corrected group with THAM.

However, correction of acidemia with this compound leads to CO_2 retention because of pH-mediated depression of ventilation. In addition, serious adverse effects have been reported with the use of THAM, including hyperkalemia, hypoglycemia, and widespread organ necrosis.[6]

In the absence of a complicating element of metabolic acidosis and with the possible exception of the severely acidemic patient with intense generalized bronchoconstriction undergoing mechanical ventilation (see previous discussion), there is no role for alkali administration (i.e., $NaHCO_3$, Carbicarb, THAM) in chronic respiratory acidosis.

MIXED ACID–BASE DISORDERS ASSOCIATED WITH RESPIRATORY ACIDOSIS

Complicating acid–base disorders occur with surprising frequency in patients with acute or chronic respiratory acidosis and often present a considerable challenge to the clinician. What follows is a brief account of the most common mixed acid–base disorders in which respiratory acidosis is a component.

Respiratory Acidosis and Metabolic Acidosis

Clinical examples of this entity include untreated cardiopulmonary arrest, circulatory failure in patients with COPD, severe renal failure associated with hypercapnic respiratory failure, various intoxications, and hypokalemic (or less frequently hyperkalemic) paralysis of respiratory muscles in patients with diarrhea or renal tubular acidosis.[8] In patients with this mixed disturbance, increasing ventilation to reduce $PaCO_2$ can be of great value in rapidly bringing blood pH, and presumably intracellular pH, into a safe range. Therefore, consideration should be given to intubating and mechanically ventilating patients with metabolic acidosis, who retain CO_2, or those with moderate to severe respiratory acidosis, who also develop an element of metabolic acidosis. Despite the potential disadvantages of bicarbonate administration, and considering the profound impact of severe acidemia on cardiovascular function as well as the lack of suitable alternatives, we recommend the judicious administration of sodium bicarbonate in selected patients with metabolic and respiratory acidosis who have a blood pH less than 7.10.[8] However, alkali

therapy must be used with great caution in these patients, because of the substantial risk of further respiratory depression leading to life-threatening hypoxemia and worsened hypercapnia. In patients with metabolic acidosis and respiratory acidosis who also have fluid excess, congestive heart failure, or severe renal failure, administration of any sodium containing alkali might be potentially harmful. Consequently, dialysis utilizing bicarbonate containing dialysate might be a reasonable option. With this treatment modality, not only can large quantities of alkali be delivered, but significant amounts of fluid can also be removed.

Respiratory Acidosis and Metabolic Alkalosis

This combination represents one of the most frequently observed mixed acid–base disorders. Deviation of blood pH toward alkalinity commonly occurs in patients with respiratory acidosis because of several complicating events and medications.[8] Patients with COPD frequently develop gastritis, peptic ulcer disease, or gastrointestinal bleeding as a result of taking xanthines and corticosteroids, and possibly due to the underlying disease itself. Metabolic alkalosis resulting from ingestion of absorbable antacids and/or vomiting is prevalent. Chronic administration of corticosteroids can induce potassium depletion and metabolic alkalosis. Further, prescription of diuretics for treatment of cor pulmonale or other disorders can also generate metabolic alkalosis. Critically ill patients with respiratory failure caused by ARDS and, occasionally, those with profound hypokalemia also might develop this mixed acid–base disorder. Rapid correction of CO_2 retention via mechanical ventilation in patients with long-standing hypercapnia and secondary hyperbicarbonatemia can cause transient alkalemia, a condition commonly referred to as "posthypercapnic metabolic alkalosis." In the absence of the clinical history, simple review of the blood gas values might lead to the erroneous diagnosis of primary metabolic alkalosis. If the patient's chloride intake remains adequate, urinary excretion of the excess bicarbonate will repair the hyperbicarbonatemia in one to three days. On the other hand, unavailability of chloride will perpetuate the state of posthypercapnic alkalosis.

The management of patients with mixed respiratory acidosis and metabolic alkalosis requires a combination of measures aimed at correcting the coexisting disorders. Acetazolamide can produce large bicarbonate losses in the form of the sodium and potassium salt. The pharmacologic effect of acetazolamide substantially diminishes once the elevated plasma [HCO_3^-] is returned toward normal. Plasma potassium should be closely monitored, especially if potassium depletion was initially present, and appropriate supplementation should be provided. On occasion, the administration of an acidifying agent is required. An alternative therapeutic approach in patients with renal failure is the use of either hemodialysis with a "low bicarbonate" concentration in the dialysate or of hemofiltration along with saline replacement. Effective management of the superimposed element of metabolic alkalosis will usually result in a significant decline in the $PaCO_2$ level and improvement of the patient's hypoxemia.

Respiratory Acidosis, Metabolic Acidosis, and Metabolic Alkalosis

This triple disorder might be encountered during cardiopulmonary resuscitation when an element of metabolic alkalosis caused by alkali administration is superimposed on preexisting respiratory acidosis and metabolic (lactic) acidosis. Similarly, this mixed disturbance is observed in severely ill patients with COPD and CO_2 retention, who might develop simultaneously metabolic alkalosis (usually caused by diuretics and a chloride restricted diet) and metabolic acidosis (commonly lactic acidosis caused by hypoxemia, hypotension, or sepsis). The management of this triple acid–base disorder demands application of therapeutic measures aimed at each individual component.

RESPIRATORY ALKALOSIS

The acid–base disturbance initiated by a decrease in CO_2 stores (i.e., carbonic acid) and characterized by a decrease in CO_2 tension is termed respiratory alkalosis, or primary hypocapnia, and entails alkalinization of body fluids.[60] The level of $PaCO_2$ is less than 35 mm Hg in patients with simple respiratory alkalosis, who are at rest and at sea level. An element of respiratory alkalosis can still occur with higher levels of $PaCO_2$ in patients with metabolic alkalosis in whom a normal $PaCO_2$ is inappropriately low for this primary metabolic disorder.

PATHOPHYSIOLOGY

The presence of hypocapnia signifies excessive alveolar ventilation relative to the prevailing CO_2 production, thereby leading to negative CO_2 balance, which may result from increased alveolar ventilation, decreased CO_2 production, or both. Primary hypocapnia might also originate from the extrapulmonary elimination of CO_2, as indicated above. In the vast majority

of cases, however, primary hypocapnia reflects alveolar hyperventilation due to increased ventilatory drive or the use of mechanical ventilation. Increased ventilatory drive might result from signals arising from the lung, peripheral chemoreceptors (carotid and aortic), brainstem chemoreceptors, or influences originating in other centers of the brain.[62] The response of the brainstem chemoreceptors to CO_2 can be augmented by systemic diseases (e.g., liver disease, sepsis), pharmacologic agents, volition, and other influences. Hypoxemia is a major stimulus of alveolar ventilation, but PaO_2 values lower than 60 mm Hg are required to elicit consistently this effect. Not uncommonly, alveolar hyperventilation is the result of maladjusted mechanical ventilators. Further, it is common practice to deliberately induce respiratory alkalosis during general anesthesia in patients with critical elevation of intracranial pressure or brain injury, or in neonatal respiratory failure, especially when pulmonary vascular resistance is exceedingly high. Potential mechanisms of respiratory alkalosis due to decreased CO_2 production in the presence of constant alveolar ventilation (i.e., mechanical ventilation) include a reduction in physical activity (e.g., sedation, skeletal muscle paralysis) or a reduction in the basal metabolic rate (e.g., hypothermia, hypothyroidism). In states of severe circulatory failure, arterial hypocapnia can coexist with venous, and therefore with tissue, hypercapnia; however, the body CO_2 stores have been enriched, and respiratory acidosis rather than respiratory alkalosis is present. This entity, which we have termed pseudorespiratory alkalosis, has been examined in the section on respiratory acidosis.

Respiratory alkalosis is the most frequent acid–base disorder encountered, since it occurs in normal pregnancy and with high-altitude residence. It is also the most common acid–base abnormality in critically ill patients, occurring either as the simple disorder or as a component of mixed disturbances;[7] indeed, in such patients, its presence may represent a grave prognostic sign, especially if $PaCO_2$ levels are below 20–25 mm Hg. Table 60.5 lists the major causes of respiratory alkalosis. Most are associated with the abrupt appearance of hypocapnia, but in many instances the process might be sufficiently prolonged to permit full, chronic adaptation to occur. Consequently, no attempt has been made to separate these conditions into acute and chronic categories.

The mechanisms by which the processes listed in Table 60.5 lead to hyperventilation differ markedly.[62] Hypoxia stimulates ventilation through activation of peripheral chemoreceptors and might result in hypocapnia if CO_2 excretion is unimpeded. Such situations of hypoxia include decreased inspired oxygen tension (e.g., high-altitude residence) and conditions producing increased venous admixture and marked

TABLE 60.5 Causes of Acute Respiratory Alkalosis

ventilation/perfusion inequality (e.g., bronchopulmonary disease, pulmonary edema). A reduction in PaO_2 below 60 mm Hg is required for hyperventilation to develop. Hypotension, especially when associated with sepsis, often causes respiratory alkalosis even in the absence of a reduced PaO_2. This phenomenon occurs because the stimulus to peripheral chemoreceptor activation is decreased oxygen delivery rather than decreased PaO_2. Severe anemia (hemoglobin level lower than 30% of normal) can lead to respiratory alkalosis by the same mechanism. As noted above, severe circulatory failure in the presence of substantial pulmonary ventilation can give rise to "pseudorespiratory alkalosis," a distinct pattern of arteriovenous acid–base disparity characterized by arterial hypocapnia and alkalemia in association with venous (and tissue) hypercapnia and acidemia.[10,11]

Central-nervous-system–mediated hypocapnia can result from a wide variety of causes. Respiratory alkalosis can certainly be produced through voluntary hyperventilation. The anxiety-hyperventilation syndrome can result in severe hypocapnia and alkalemia leading to the development of chest oppression, circumoral numbness, and paresthesias in the extremities. Early recognition is important because appropriate measures might produce prompt relief. Various neurologic diseases of vascular, infectious, traumatic, or neoplastic origin can also produce hypocapnia, presumably by enhancing stimulatory inputs to ventilation or by interrupting normal inhibitory pathways.

A number of pharmacologic agents can induce hyperventilation and respiratory alkalosis.[62] Aspirin and other salicylates in doses exceeding a few grams per day can produce primary hypocapnia by direct stimulation of medullary chemoreceptors. In cases of salicylate intoxication, respiratory alkalosis often coexists with metabolic acidosis that arises from accumulation of organic acids. Nikethamide, a respiratory stimulant acting directly on the respiratory center of the brainstem and, in addition, increasing the center's sensitivity to CO_2 and activating peripheral chemoreceptors, has been used in the treatment of CO_2-retaining disorders; however, the results obtained with this drug as well as other ventilatory stimulants (e.g., ethamivan, doxapram, almitrine, progesterone, and medroxyprogesterone) have been modest at best. Other drugs known to stimulate alveolar ventilation include nicotine, dinitrophenol, xanthines, and pressor hormones (epinephrine, norepinephrine, and angiotensin II).[62] Progesterone and medroxyprogesterone are also respiratory stimulants that are presumed to act centrally. This property of progesterone is most likely responsible for the $PaCO_2$ of normal women being lower by 2–3 mm Hg than that of normal men, and for the chronic hypocapnia characteristic of normal pregnancy (see later discussion). Progesterone is considered to be the basis of the hyperventilation that occurs during the luteal phase of the normal menstrual cycle ($\Delta PaCO_2$ of approximately 3–6 mm Hg) that is attended by a rise in blood pH and a fall in renal acid excretion. In fact, in both pregnant and nonpregnant women, the $PaCO_2$ value is inversely related to the blood progesterone level.

Patients with a variety of pulmonary disorders, including interstitial lung disease, pneumonia, pulmonary embolism, and pulmonary edema, can develop respiratory alkalosis as a result of stimulation of pulmonary receptors that signal the brainstem through ascending pathways in the vagus nerve; these receptors might be triggered by irritants (nociceptive receptors), pulmonary expansion or collapse (stretch receptors), or pulmonary capillary congestion (juxtacapillary or J receptors).[12] Accompanying hypoxemia, acting on peripheral arterial chemoreceptors, might also play a contributory role. Measurable increases in alveolar ventilation appear early in pregnancy and, subsequently, are augmented further. On average, $PaCO_2$ falls to approximately 34 mm Hg in the first trimester, to about 32 mm Hg in the second trimester, and to approximately 28 mm Hg in the third trimester, when circulating progesterone attains its highest levels. The associated changes in plasma bicarbonate and therefore pH are consistent with adaptation to chronic respiratory alkalosis.

Septicemia due to either gram-positive or gram-negative organisms commonly results in respiratory alkalosis. Whereas the concomitant hypoxemia and

circulatory failure might account for the genesis of hypocapnia in gram-positive sepsis, direct stimulation of central chemoreceptors by bacterial toxins has been shown to account, at least in part, for the respiratory alkalosis of gram-negative sepsis.[7]

Hepatic failure represents an important cause of respiratory alkalosis. The specific mechanisms responsible for the hyperventilation remain uncertain, but the extent of hypocapnia correlates best with the level of blood ammonia.

Mechanical hyperventilation might induce respiratory alkalosis if the mechanical apparatus is improperly adjusted.[80] This complication can be avoided only by assessing acid–base status frequently in patients undergoing assisted or controlled ventilation. Abrupt cessation of mechanical hyperventilation, especially in anesthetized patients or those who had received sedatives, might result in critical hypoxemia due to apnea or severe respiratory depression; the prevailing low level of $PaCO_2$ fails to provide a stimulus for ventilatory drive and apnea or depressed respiration will persist until $PaCO_2$ rises sufficiently to stimulate ventilation. This mechanism may account for a substantial number of cardiorespiratory arrests during recovery from general anesthesia. Despite claims to the contrary, cessation of voluntary hyperventilation might also result in severe hypoxemia due to depressed ventilation or apnea.

Heat exhaustion, heat stroke, fever, hyperthyroidism, and delirium tremens might also produce respiratory alkalosis by mechanisms that remain undefined. Finally, a postmetabolic-acidosis hypocapnia can develop following rapid correction of a large bicarbonate deficit by alkali administration; this persistent hyperventilation, which can last for 24–48 hours, is attributed to a delay in correcting the acidity at the central chemoreceptor site.

Secondary Physiologic Response

Hypocapnia elicits adaptive decrements in plasma $[HCO_3^-]$ that should be viewed as an integral part of the respiratory alkalosis and serve to ameliorate the resulting alkalemia.[44,58] An immediate decrement in plasma $[HCO_3^-]$ occurs in response to hypocapnia. This acute adaptation is complete within 5 to 10 minutes from the onset of hypocapnia, and no further detectable changes in acid–base equilibrium occur for a period of several hours, establishing an operational "acute steady state".[9] The acute adaptation is accounted for principally by alkaline titration of the body's non-HCO_3^- buffers and, to a lesser extent, by increased production of organic acids, notably lactic acid. When hypocapnia is sustained, renal adjustments cause an additional decrease in plasma $[HCO_3^-]$ further ameliorating the resulting alkalemia.[44]

The adjustment in acid–base equilibrium following the induction of acute hypocapnia results entirely from nonrenal mechanisms. Evidence indicates that approximately one third of the total buffering response can be ascribed to red cell and extracellular protein buffering, the remainder being attributed to tissue buffering.

Figure 60.4 depicts the 95% confidence limits for plasma $[HCO_3^-]$ and blood $[H^+]$ in uncomplicated acute respiratory alkalosis of graded severity. These limits represent the range of responses within which acid–base equilibrium would be expected to fall if an acute reduction in $PaCO_2$ were the only factor disturbing plasma acidity. The data from which these limits were calculated were obtained during the course of acute "whole body" titration experiments using passive hyperventilation of anesthetized human subjects undergoing minor surgical procedures.[14] The acute, secondary change in plasma $[HCO_3^-]$ is substantially greater in magnitude than that observed during acute hypercapnia of comparable degree, falling by approximately 0.2 mEq/liter for each 1-mm Hg acute decrement in $PaCO_2$; thus, a reduction in plasma bicarbonate of some 3–4 mEq/liter occurs within minutes after $PaCO_2$ is lowered to 20–25 mm Hg. The resulting change in plasma $[H^+]$, however, is strikingly

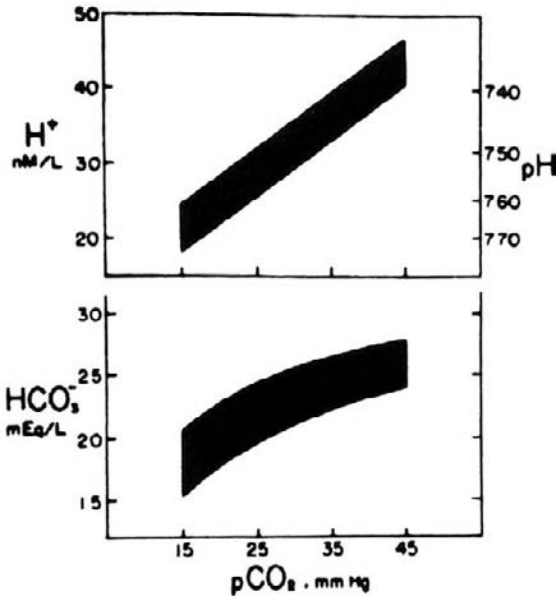

FIGURE 60.4 **Ninety-five percent confidence limits for plasma bicarbonate concentration (lower panel) and plasma hydrogen-ion concentration (upper panel) in acute respiratory alkalosis.** The limits were calculated from data obtained in anesthetized patients who were passively hyperventilated during minor surgical procedures. *(With permission, from Arbus GS, Hebert LA, Levesque PR, Etsten BE, Schwartz WB. Characterization and clinical application of the "significance band" for acute respiratory alkalosis. N Engl J Med 1969;**280**:117–223).*

similar to that observed during acute hypercapnia. On average, plasma [H^+] decreases by approximately 0.75 nEq/liter for each 1-mm Hg acute reduction in $PaCO_2$. Thus, acute adaptation to a $PaCO_2$ of 20 mm Hg in a subject with a normal acid–base equilibrium at baseline will yield, on average, a plasma [HCO_3^-] of 20 mEq/liter and a [H^+] of 24 nEq/liter (pH 7.62).[9]

If hypocapnia persists, plasma [HCO_3^-] falls further as a consequence of renal adaptive responses, which entail a dampening of [H^+] secretion by the renal tubule. As a result, transient suppression of net acid excretion occurs, largely manifested by a fall in ammonium excretion and, early on, by an increase in bicarbonate excretion. Transient bicarbonaturia and a rise in urinary pH occur when hypocapnia develops abruptly but not in response to gradually evolving hypocapnia. These changes in net acid excretion, in turn, lead to positive hydrogen-ion balance and a reduction in the body's bicarbonate stores. Maintenance of the resulting hypobicarbonatemia is ensured by gradual suppression in the rate of renal bicarbonate reabsorption, itself a reflection of the hypocapnia-induced decrease in the tubular hydrogen-ion secretory rate.[44,65]

The adaptive acid retention during sustained hypocapnia is normally accompanied by a loss of sodium into the urine; the resultant extracellular fluid loss is responsible for the hyperchloremia that typically attends chronic respiratory alkalosis. When a new steady state emerges, renal net acid excretion returns to control levels and the altered anionic picture of the extracellular fluid, namely, hypobicarbonatemia and hyperchloremia, is maintained by reduced bicarbonate reabsorption and enhanced chloride reabsorption.

Micropuncture and microperfusion studies have documented suppressed proximal and distal acidification during hypocapnia, including decreased proximal HCO_3^- reabsorption, increased proximal Cl^- reabsorption, and decreased formation and delivery of NH_4^+ and titratable acidity. Reduced proximal HCO_3^- reabsorption has also been demonstrated by micropuncture in chronic hypocapnia, but distal acidification has not been examined with these techniques in the chronic phase of the disorder.[65]

Regarding the cellular mechanisms mediating the down-regulation of renal acidification during chronic hypocapnia, parallel decreases in the rates of the luminal Na^+/H^+ exchanger (Fig 60.5) and the basolateral $Na^+/3HCO_3^-$ cotransporter in the proximal tubule have been found reflecting a decrease in the V_{max} of each transporter, but no change in the K_m for sodium.[49,81] Moreover, hypocapnia induces endocytotic retrieval of H^+-ATPase pumps from the luminal membrane of the proximal tubule cells as well as type A intercalated cells of cortical and medullary collecting tubules.[65] In rat tubule microdissection studies, the

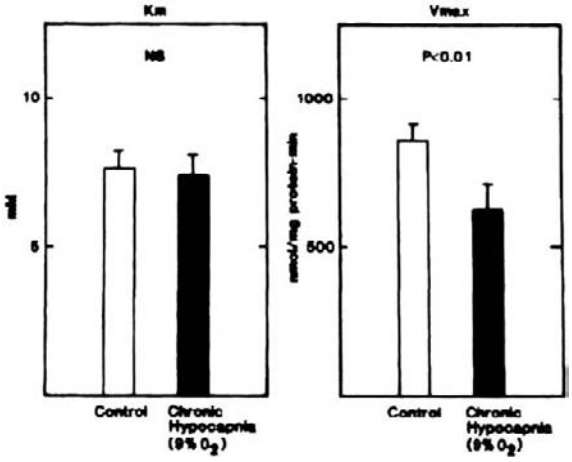

FIGURE 60.5 Kinetic characteristics of rabbit renal cortical brush-border membrane vesicle Na^+-H^+ exchanger in animals adapted to chronic hypocapnia (9% O_2) (shaded bars) or in paired, contemporaneous controls (open bars). Data on Km for sodium are depicted on the left and those on Vmax on the right. Data represent means ± SE for seven paired sets of rabbits. Chronic hypocapnia resulted in a significant decrease in the Vmax of the exchanger, whereas the Km for sodium remained unaltered. *(From ref., 49 with permission).*

activity of the H^+-ATPase along the entire nephron (i.e., proximal tubule, thick ascending limb of Henle, and cortical and medullary collecting tubules) and that of the H^+-K^+-ATPase in the cortical and medullary collecting tubules were decreased by 6 hr of hypocapnia and thereafter. The inhibitory effect of hypocapnia on the H^+-ATPase and the H^+-K^+-ATPase appears to be independent of potassium and aldosterone.[43] No information exists on potential effects of chronic hypocapnia on the basolateral Cl^-/HCO_3^- exchanger (band 3 protein) of type A intercalated cells or the apical Cl^-/HCO_3^- exchanger (pendrin) of type B intercalated cells.

Evidence indicates that the renal adaptation to persistent hypocapnia is mediated not by changes in plasma or "whole-body" intracellular pH but by some direct effect of reduced $PaCO_2$ itself.[33,68] Thus, animals in which plasma [HCO_3^-] had been substantially reduced prior to adaptation to sustained hypocapnia (by means of the chronic administration of a large HCl load) evidenced the same renal response to a primary reduction in $PaCO_2$ as normal, even though the net effect of such adaptation was an overt fall in plasma pH (Fig 60.6).[33]

Approximately two to three days are required for the completion of the renal response to hypocapnia. Limited data in humans (patients subjected to chronic hypocapnia, high-altitude dwellers, volunteers studied at high altitude or at simulated altitude) have indicated that plasma [HCO_3^-] decreases, on average, by approximately 0.4 mEq/liter for each 1-mm Hg chronic

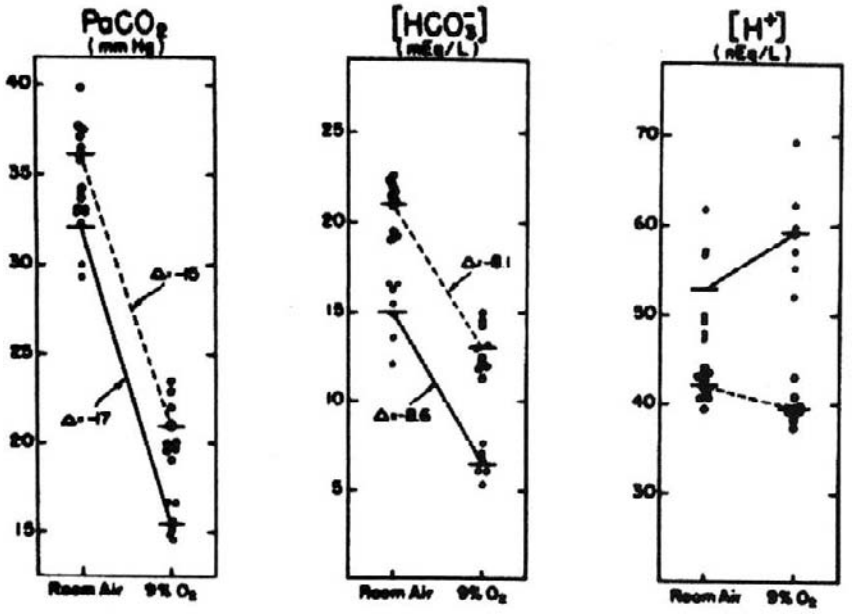

FIGURE 60.6 Changes in plasma bicarbonate concentration and hydrogen-ion concentration during prolonged exposure to hypocapnia in normal dogs (dashed lines) and in dogs with chronic HCL-acidosis (solid lines). Similar decrements in $PaCO_2$ in the two groups produced nearly equivalent reductions in plasma bicarbonate concentration, despite divergent effects on hydrogen-ion concentration. *(From ref., 33 with permission).*

decrease in $PaCO_2$. Despite the similarity in the magnitude of the secondary response of plasma bicarbonate to chronic hypocapnia between dogs and humans, the resultant impact on blood $[H^+]$ is substantially disparate. Whereas in the dog, blood $[H^+]$ falls by only 0.17 nEq/liter for each 1-mm Hg chronic reduction in $PaCO_2$, the corresponding decrease in humans is on the order of 0.4 nEq/liter.[58] The main reason for this discrepancy is the higher baseline level of plasma $[HCO_3^-]$ in humans (24 to 25 mEq/liter vs. 21 mEq/liter in the dog).

Plasma Electrolyte Composition during Respiratory Alkalosis

Mild hyponatremia ($\Delta[Na^+]$, 2–4 mEq/liter) has been noted in acute hypocapnia,[14,58] but plasma sodium concentration remains normal during chronic hypocapnia. Hyperchloremia, a consistent finding in respiratory alkalosis, reflects largely the chloride shift from erythrocytes during the acute state and the volume contraction accompanying the renal response during the chronic stage.[44] Plasma potassium concentration decreases (by approximately 0.1–0.4 mEq/liter for each 0.1-unit rise in pH) during acute hypocapnia.[3] The mechanism of hypokalemia in acute respiratory alkalosis most likely involves both a shift of potassium into the cells and transient kaliuresis accompanying bicarbonaturia that lasts only hours and becomes more evident when hypocapnia develops abruptly.[3] By contrast, a study in normal volunteers with acute respiratory alkalosis caused by voluntary hyperventilation revealed development of mild hyperkalemia that appeared to be mediated by enhanced alpha-adrenergic activity.[59] No appreciable changes in plasma potassium occur during chronic hypocapnia in the dog or in patients at sea level. On the other hand, a persistent reduction in plasma potassium concentration (on the order of 0.5 mEq/liter) was detected in human subjects during chronic hypocapnia induced by exposure to high altitude ($\Delta PaCO_2$ 8 mm Hg). Mild hypophosphatemia is a characteristic feature of acute hypocapnia and reflects translocation of phosphate into cells, but no consistent changes in plasma phosphate have been noted in chronic hypocapnia. Despite the hypophosphatemia, acute respiratory alkalosis decreases the fractional excretion of phosphate, and this response is blunted by β-adrenoreceptor blockers. Mild reduction in ionized calcium occurs in acute hypocapnia because of an alkalemia-induced increase in protein binding of serum calcium. Although this decrease could not account by itself for the tetany and seizures that occasionally attend acute hypocapnia, it might play a contributory role. Serum total calcium and magnesium concentrations remain normal during persistent hypocapnia. A more recent study concluded that chronic hypocapnia induces impaired renal tubular responsiveness to PTH and defective PTH secretion (as defined by the failure of the hormone's levels to rise in response to the prevailing decrease in serum ionized calcium).

A mild and transient elevation in plasma lactate concentration occurs during acute hypocapnia that results from stimulation of 6-phosphofructokinase activity, and there is no appreciable change in plasma lactate during chronic hypocapnia.[44] Plasma unmeasured

anions do not change notably in acute hypocapnia, but small increases (on the order of 3 mEq/liter for a 20-mm Hg chronic reduction in $PaCO_2$) have been observed in chronic respiratory alkalosis; the source of this increase remains unidentified.

Cerebrospinal Fluid Composition during Respiratory Alkalosis

Cerebrospinal fluid (CSF) hydrogen-ion and bicarbonate concentrations fall in parallel with those of arterial blood during induction of acute hypocapnia;[37] the magnitude of the reduction in hydrogen-ion concentration in the CSF of the dog is similar to that observed in the arterial blood. The fall in CSF bicarbonate concentration is accompanied by an increase in CSF chloride concentration that accounts for 75% of the change in the level of bicarbonate, and a mild rise in CSF lactate concentration that accounts for the remaining 25%. Several investigators have noted a widening of the CSF−arterial PCO_2 difference during acute hypocapnia resulting from a lesser fall of PCO_2 in CSF than in blood; this effect is thought to be secondary to the decrease in cerebral blood flow associated with hypocapnia.

Studies of the response of CSF acidity during chronic hypocapnia have shown reductions in CSF hydrogen ion and bicarbonate concentrations similar to those of arterial blood (37).

Intracellular pH during Respiratory Alkalosis

"Whole-body" intracellular hydrogen-ion concentration, as assessed by the DMO (5, 5-dimethyl-2, 4-oxazolidinedione) method, has been found to fall in parallel with extracellular hydrogen-ion concentration when healthy human subjects hyperventilate voluntarily to achieve a $PaCO_2$ of 15−20 mm Hg. Similar results have been obtained from studies in dog and rat muscle and rat brain. On the other hand, ^{31}P-nuclear magnetic resonance (NMR) spectroscopy has revealed much smaller changes in canine heart intracellular pH in response to acute hypocapnia as compared with the extracellular compartment.[55] The response of intracellular acidity to chronic hypocapnia has not been studied.

PATHOPHYSIOLOGIC EFFECTS AND CLINICAL MANIFESTATIONS OF RESPIRATORY ALKALOSIS

Neurologic

A variety of clinical manifestations frequently occur in acute hypocapnia, but these are seldom evident in the chronic phase of the disorder. A rapid decrement in $PaCO_2$ to half normal values or lower is typically accompanied by numbness and paresthesias of the extremities, chest oppression, circumoral numbness, lightheadedness, and mental confusion. Muscle cramps, increased deep-tendon reflexes, carpopedal spasm, and generalized seizures occur infrequently.[62] The neurologic manifestations of acute respiratory alkalosis have been attributed largely to the attendant cerebral hypoperfusion, although additional factors have been implicated, including alkalemia, the pH-induced shift to the left of the oxyhemoglobin dissociation curve, and the decrements in the level of ionized calcium and potassium. Cerebral vasoconstriction and reduced cerebral blood flow have been well documented during acute hypocapnia;[62] in severe cases, cerebral blood flow might reach values lower than 50% of normal. In addition, cerebral vasoconstriction leads to decreases in cerebral blood volume, thereby lowering intracranial pressure. A characteristic electroencephalographic picture consisting of generalized slowing and high-voltage wave forms has been reported. Brain and CSF lactate concentrations have been found to increase by amounts greater than those in the systemic circulation and to remain slightly increased during persistent hypocapnia. Increased synthesis of lactate is consequent to cerebral hypoxia resulting from the intense vasoconstricting effects of hypocapnia and, probably, to alkalemia-induced acceleration of anaerobic glycolysis. Some evidence indicates that cerebral blood flow returns to normal in chronic respiratory alkalosis.

Respiratory alkalosis and hypoxemia are observed in acute mountain sickness (AMS) and high-altitude cerebral edema, conditions characterized by cerebral swelling. Evaluation of self-identified AMS-susceptible and non-AMS-susceptible volunteers demonstrated as early as 40 minutes after development of hypoxemia, increases in cerebral blood volume and brain tissue volume occur, and CSF is shifted into the venous circulation decreasing CSF volume; the latter is a compensatory mechanism to maintain normal intracranial pressure.[40] These findings did not differ in the two study groups. Of note is the clinical observation that administration of acetazolamide ameliorates the central nervous system impairment observed in AMS.

Hypocapnia can have deleterious effects on the brain of premature infants, patients with traumatic brain injury, acute stroke, or general anesthesia, and after cardiopulmonary bypass or sudden exposure to very high altitude.[36,38,45,47,74] The mechanisms of brain injury may include cerebral ischemia; antioxidant-glutathione depletion caused by augmented production of cytotoxic excitatory amino acids; increases in anaerobic metabolism, cerebral oxygen demand,

neuronal dopamine, and brain excitability; and seizure activity.[62] Hypocapnia in premature infants can lead to white-matter damage, including cystic changes, periventricular leukomalacia, and secondary cerebral bleeding. If sepsis is present, the brain damage is enhanced by the release of lipopolysaccharide, interleukin-1β, and tumor necrosis factor α. Long-term neurologic sequelae can develop when immature brains are exposed to $PaCO_2$ levels of less than 15 mm Hg for even short periods.[62] Furthermore, abrupt correction of hypocapnia in these patients leads to cerebral vasodilation, which might cause reperfusion injury or intraventricular hemorrhage.

The effects of acute hypocapnia without hypoxemia to decrease cerebral blood flow and intracranial pressure have been used as a therapeutic tool in reducing brain edema due to a variety of causes, including meningitis, encephalitis, head trauma, and neurosurgical procedures.[70,71,72] Unfortunately, in most instances, the derived benefit is limited in magnitude and short-lived. Hypocapnia had been recommended as a therapeutic measure to produce a favorable redistribution of cerebral blood-flow during focal cerebral ischemia of acute onset. Yet, experimental data suggest that, rather than reducing the area of the critically ischemic brain, hypocapnia might increase the size of the region at risk.[36] Deliberate induction of hypocapnia in patients with traumatic brain injury or acute stroke has actually resulted in worse outcomes; consequently, some experts recommend against this therapeutic approach.

The rationale for the use of hypocapnia (i.e., $PaCO_2$ of 20 to 25 mm Hg) during general anesthesia includes depression of spontaneous ventilation, and reduced requirements of muscle relaxants, analgesics, and sedatives.[62] However, acute hypocapnia during general anesthesia can be followed by impaired cerebral function for up to six days, especially in older patients, and this complication outweighs the potential benefits.

Cardiovascular and Renal

Myocardial contractility assessed in isolated perfused hearts initially increases but rapidly returns to control levels in acute respiratory alkalosis. The switch from the state of augmented contractility is not dependent on the activity of the myocardial Na^+/H^+ exchanger or the Cl^-/HCO_3^- exchanger since blockers of these transporters (amiloride, SITS) did not prevent the biphasic mechanical response. Changes in both cytosolic pH and calcium concentration appear to play a major role in this response.[75] In the isolated rat heart, primary hypocapnia enhances postischemic calcium gain, an effect that is considered nonsalutary. Although acute hypocapnia does not lead to cardiac arrhythmias in normal volunteers, it appears that it contributes to the generation of both atrial and ventricular tachyarrhythmias in patients with ischemic heart disease; such arrhythmias are frequently resistant to standard forms of therapy. Acute respiratory alkalosis impairs myocardial oxygenation by a dual effect that includes increased myocardial oxygen demand and decreased myocardial oxygen supply. The higher oxygen demand is caused by increased contractility and a rise in systemic vascular resistance, whereas the decreased oxygen supply results from reduced coronary flow caused by vasoconstriction as well as increases in platelet count and aggregation.

Chest pain and ischemic ST-T wave changes have been observed in acutely hyperventilating subjects with no evidence of fixed lesions on coronary angiography. The pathogenesis of these manifestations remains unknown, although myocardial ischemia secondary to hypocapnia-induced vasoconstriction and an alkalemia-induced shift to the left of the oxyhemoglobin dissociation curve have been proposed. Indeed, acute hypocapnia has been shown to induce coronary artery spasm and Prinzmetal's angina in susceptible patients.

Hypocapnia produces variable effects on regional blood flows. Acute respiratory alkalosis decreases myocardial, cerebral, dermal, and renal blood flows, but it increases muscle blood flow. Insufficient data exist with regard to the effects of persistent hypocapnia on the distribution of blood flow, but it appears that dermal and renal blood flows remain depressed, whereas muscle and liver perfusion is increased. For reasons that remain unknown, chronic hypocapnia leads to increased responsiveness of the kidney to antidiuretic hormone administration; water retention exceeds that of normocapnic animals, resulting in the rapid development of hyponatremia.

Respiratory

A primary decrease in $PaCO_2$ and the attendant increase in pH characteristic of acute respiratory alkalosis cause a shift to the left in the oxyhemoglobin dissociation curve (Bohr effect), resulting in an impediment of oxygen unloading to the tissues but an enhancement of oxygen loading in the lungs.[52] During chronic alkalosis, however, these effects are offset by a shift of the curve to the right produced by an increased concentration of 2, 3-diphosphoglycerate (2, 3-DPG) in the erythrocytes.[52] In spite of the impediment of oxygen unloading to the tissues in acute hypocapnia, oxygen consumption was found to increase by approximately 12% in anesthetized and paralyzed patients during hyperventilation-induced alkalosis. The mechanism of this response remains undetermined.

Adverse effects of hypocapnia can involve the airways, lung compliance, alveolar-capillary permeability, and pulmonary vasculature.[27,84] Acute respiratory alkalosis causes bronchoconstriction, an increase in airway resistance, and a decrease in lung compliance. Experimental observations have shown that hypocapnia leads to bronchospasm and airway edema; yet the effects of hypocapnia on alveolar-capillary permeability are incompletely defined. Studies utilizing the isolated buffer-perfused rabbit lung have concluded that respiratory alkalosis leads to direct lung injury and also potentiates lung injury induced by ischemia-reperfusion. Additional studies in rats using the isolated perfused lung model have shown that respiratory alkalosis independently of pH level decreases alveolar fluid reabsorption; this effect was associated with decreased Na,K-ATPase activity at the basolateral membrane of distal air spaces.[73] Thus, it appears that hypocapnia increases pulmonary capillary permeability, worsens intrapulmonary shunt and systemic oxygenation, and has a negative effect on acute lung injury.

DIAGNOSIS OF RESPIRATORY ALKALOSIS

Evaluation of the patient's history, physical examination, and ancillary laboratory data, including blood gas determinations, is required to establish the diagnosis of respiratory alkalosis. The presence of respiratory alkalosis, especially the chronic form, is frequently missed; physicians often misinterpret the electrolyte pattern of hyperchloremic hypobicarbonatemia as indicative of normal anion gap metabolic acidosis. If the patient's acid–base profile reveals hypocapnia in association with alkalemia, at least an element of respiratory alkalosis must be present. Yet hypocapnia might be associated with a normal or an acidic pH due to the concomitant presence of additional acid–base disorders. One should also note that mild degrees of chronic hypocapnia leave blood pH within the high normal range. Once the diagnosis of respiratory alkalosis is made, a search for its cause should be carried out. The diagnosis of respiratory alkalosis can have important clinical implications, since it often provides a clue to the presence of an unrecognized, serious disorder or signals the gravity of a known underlying disease.

MANAGEMENT OF RESPIRATORY ALKALOSIS

Accumulated evidence over the past few years indicates that the widely held view that hypocapnia poses little risk to health under most conditions is not accurate. In fact, substantial hypocapnia in hospitalized patients, whether spontaneous or deliberately induced, can be associated with transient or permanent damage in the brain and the respiratory and cardiovascular systems.[36,38,45,46,72,82] Furthermore, rapid correction of severe hypocapnia leads to vasodilation of ischemic areas, resulting in reperfusion injury in the brain and lung. Consequently, severe hypocapnia must be prevented whenever possible, and if present, abrupt correction should be avoided. Severe alkalemia caused by acute primary hypocapnia requires corrective measures that depend on whether serious clinical manifestations are present. Such measures can be directed at reducing plasma [HCO_3^-], increasing $PaCO_2$, or both. Even if baseline plasma [HCO_3^-] is moderately decreased, reducing it further can be particularly rewarding in this setting, as this maneuver combines effectiveness with relatively little risk. For patients with the anxiety-hyperventilation syndrome, in addition to reassurance or sedation, re-breathing into a closed system (e.g., a paper bag) might prove helpful by interrupting the vicious cycle that can result from the reinforcing effects of the symptoms of hypocapnia. Respiratory alkalosis resulting from severe hypoxemia requires oxygen therapy. The oral administration of 250–500 mg of acetazolamide (Diamox) can be beneficial in the management of signs and symptoms of AMS.[47] Of course, patients undergoing mechanical ventilation lend themselves to an effective correction of hypocapnia (whether due to maladjusted ventilator or other causes) by resetting the device.

MIXED ACID–BASE DISORDERS ASSOCIATED WITH RESPIRATORY ALKALOSIS

Respiratory alkalosis is frequently associated with other acid–base disorders. We describe here some of the more common clinical examples of mixed acid–base disturbances in which respiratory alkalosis is a component.

Respiratory Alkalosis and Metabolic Acidosis

This mixed acid–base disorder is commonly encountered during the rapid correction of severe metabolic acidosis. During treatment, plasma [HCO_3^-] often returns toward normal more swiftly than the secondary hypocapnia (originally induced by the acidosis) can abate. As a consequence, the degree of hypocapnia often remains inappropriately large with respect to the then-current decrement in plasma [HCO_3^-] for a period

of several hours or more; blood [H^+] during such intervals is often normal or even frankly low.

Patients with salicylate intoxication commonly manifest elements of both metabolic acidosis and respiratory alkalosis, reflecting the independent effects of the salicylate molecule on both cellular metabolism (uncoupling of oxidative phosphorylation) and ventilation (stimulation of central chemoreceptors). Patients with gram-negative sepsis can also develop this mixed disturbance, reflecting the frequent occurrence of primary hyperventilation, on the one hand, and of lactic acidosis and/or renal failure, on the other. This combination also occurs occasionally in the setting of combined hepatic and renal failure. Additionally, patients undergoing "high-mass-transfer" hemodialysis with acetate dialysate can develop mixed respiratory alkalosis and metabolic acidosis; the former reflects rapid loss of CO_2 into the dialysate, and the latter reflects the removal of bicarbonate by the dialyzer at a rate faster than the body's alkali stores can be replenished by tissue metabolism of the circulating acetate.

It should be noted that patients with sustained respiratory alkalosis of recent onset, in whom renal adaptation to hypocapnia is as yet incomplete (i.e., if hypocapnia has been present for only a day or so), might have acid–base values indistinguishable from those characteristic of patients with this mixed disturbance. Other laboratory data and relevant historical information should serve to differentiate between these alternatives.

Respiratory Alkalosis and Metabolic Alkalosis

Although these two disturbances do not often coexist, when they do, blood [H^+] might, of course, be driven to extremely low levels.[67] Patients with hepatic insufficiency, who frequently have persistent hyperventilation, might develop this combination of acid–base disturbances if they are treated with potent diuretics or if they lose gastric fluid. Pregnant patients who develop metabolic alkalosis from any cause will exhibit this mixed acid–base disorder because they typically feature chronic hypocapnia. Similarly, patients with an underlying metabolic alkalosis might develop such a picture if ventilation is stimulated (e.g., pulmonary embolus, pulmonary edema, sepsis).

Because adaptation to chronic hypocapnia requires renal function, severe alkalemia can develop in patients with end stage renal disease receiving dialysis therapy. Considering that peritoneal dialysis therapy maintains plasma [HCO_3^-] within the normal range regardless of the prevailing $PaCO_2$, patients receiving this treatment are at particular risk of alkalemia.[7]

This mixed disturbance can be diagnosed readily if the level of $PaCO_2$ is less than normal and if plasma [HCO_3^-] is frankly elevated. The disorder should be treated as a medical emergency, because extreme alkalemia carries a grave prognosis.[7] With the exception of patients undergoing mechanical ventilation (and the consequent ability to increase $PaCO_2$ promptly), measures should be taken to rapidly reduce the elevated plasma [HCO_3^-].

Mechanisms and Disorders of Magnesium Metabolism

Karl P. Schlingmann and Martin Konrad

University Children's Hospital, Pediatric Nephrology, Münster, Germany

INTRODUCTION

Body magnesium homeostasis depends on the balanced regulation of intestinal magnesium absorption and renal magnesium conservation. Renal magnesium handling is a filtration–reabsorption process, as there is little evidence of secretion along the nephron segments (Fig 61.1). About 80% of the total plasma magnesium (0.65–1.2 mM) is filtered through the glomeruli. Of the ultrafilterable magnesium (0.5–0.9 mM), 15–20% is reabsorbed by the convoluted and straight portions of the proximal tubule. The thick ascending limb (TAL) of the loop of Henle, specifically the cortical segment, plays a major role in reclaiming filtered magnesium (55–70%), whereas only 5–10% are reabsorbed in the distal convoluted tubule (DCT). However, the DCT provides the selective regulation of magnesium reabsorption and plays an important role in determining the final urinary excretion.[1] About 3–5% of the filtered load normally appear in the urine. Magnesium transport in both the TAL and DCT responds to changes in magnesium to effect sensitive control of magnesium balance.

PHYSIOLOGY OF RENAL MAGNESIUM HANDLING

Glomerular Filtration

Approximately 70% of plasma magnesium is in the ionic form, Mg^{2+}.[2] The remaining magnesium is bound to circulating proteins (essentially albumin) or is complexed with citrate, oxalate, and phosphate anions. About 80% of the total serum magnesium is ultrafilterable through the glomerular membrane that varies with the amount bound to nonfilterable proteins.[3]

Proximal Tubule

Physiology of Proximal Tubule Magnesium Reabsorption

In the adult, proximal tubule magnesium reabsorption rate (15–20%) is considerably less than the fractional reabsorption of sodium and calcium.[3] In neonates, the proximal tubule reabsorbs about 70% of the filtered magnesium that is the same as the fractional reabsorption of sodium and calcium.[4] Clearly, the permeability of the proximal tubule changes during development so that more magnesium is delivered to the loop of Henle in the adult. This maturation in segmental handling of magnesium should be taken into consideration when assessing renal magnesium handling in very young children. Proximal tubule magnesium transport in adults is thought to be active and transcellular in nature, whereas it is probably passive in the immature individual occurring through the paracellular pathway entrained with water movement.

Various hormones alter magnesium reabsorption within the proximal tubule.[5] They do so by influencing salt and water transport, and thus luminal magnesium concentration. Reabsorption is load dependent, so that transport is greater with elevated luminal magnesium concentrations. Extracellular volume expansion or anything that retards salt and water transport results in diminished fluid absorption and greater magnesium delivery into the loop of Henle and the DCT. The increase in distal delivery is normally reclaimed in these nephron segments but may be large enough to cause an increase in urinary magnesium excretion and hypermagnesiuria.[6]

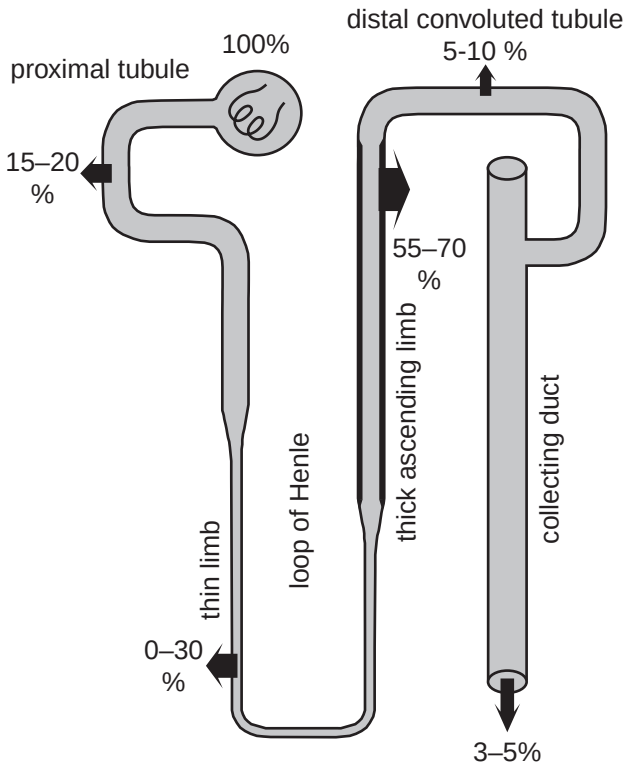

FIGURE 61.1 Summary of segmental magnesium reabsorption along the nephron.

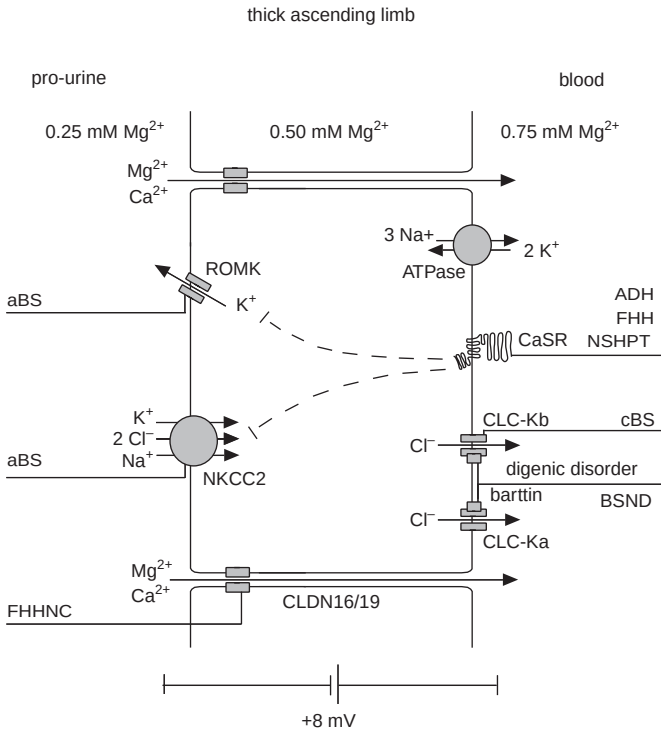

FIGURE 61.2 **Schematic model of magnesium reabsorption in the cTAL of Henle's loop.** The membrane proteins influencing magnesium reabsorption are indicated. Magnesium reabsorption is passive and occurs through the paracellular pathway. Furosemide diminishes Mg^{2+} absorption by inhibiting NKCC2 and transepithelial voltage. Peptide hormones (PTH, calcitonin, glucagon, AVP) enhance magnesium reabsorption in the cTAL by increasing the transepithelial voltage and magnesium permeability of the paracellular pathway.[5] The sites of genetic diseases associated with magnesium reabsorption in the cTAL are indicated: aBS, cBS, antenatal Bartter syndrome with sensorineural deafness (BSND/digenic disorder), FHHNC, ADH, FHH, and NSHPT.

Loop of Henle

Physiology of Loop of Henle Magnesium Reabsorption

The thin descending limb is able to reclaim significant amounts of filtered magnesium. Inference from micropuncture data of the differences in magnesium delivery to the late proximal tubule and the hairpin turn of rat juxtamedullary nephrons indicate that a significant fraction of the filtered magnesium, on the order of 30%, is reclaimed along the descending limb in the concentrating kidney.[7] The amount of magnesium absorption is associated with water transport in the descending limb. Accordingly, magnesium reabsorption is considerably diminished during forced diuresis when water reabsorption is negligible in this segment.[5] The TAL reabsorbs the predominant portion of the magnesium, amounting to some 70% of the filtered load. Moreover, de Rouffignac and colleagues have shown that it is the cortical thick ascending limb (cTAL), not the medullary segment (mTAL), that reabsorbs magnesium.[8] They have further reported that transepithelial magnesium absorption is passive moving from lumen to the interstitial space through the paracellular pathway (Fig 61.2), consistent with earlier observations.[9] The driving force for magnesium movement is the positive luminal transepithelial voltage generated by K^+ recycling across the apical membrane (Fig 61.2). Any influence that alters transepithelial voltage or the permeability of the paracellular pathway will alter magnesium reabsorption in the cTAL.[5] The voltage in the TAL is dependent on apical 70-pS K^+ channel (ROMK) activity and Na−K−2Cl cotransport that control current flow across the apical membrane of the TAL cell. Sodium exits by the basolateral Na−K−ATPase and chloride through basolateral ClC-Ka and ClC-Kb members of the chloride channel family (ClC). Functional expression of ClC-Ka and ClC-Kb channels requires the coexpression of barttin, an essential β-subunit of the channels.[10] As barttin controls ClC-Ka and ClC-Kb activity, it importantly influences salt absorption in the TAL.[11,12] Changes in their transport rates will affect the transepithelial voltage and thus the magnesium absorption. The permeability of the paracellular pathway also plays an important role in determining transepithelial magnesium transport. Paracellular Mg^{2+} movement is influenced by electrostatic charges of

proteins comprising this route.[3] Moreover, there appears to be selectivity of the pathway to divalent cations.[6] Paracellular proteins of the claudin family of tight junction proteins claudin-16 and claudin-19 have been identified in the TAL and are involved in controlling magnesium and calcium permeability of the paracellular pathway.[13,14] This notion is supported by the phenotype resulting from mutations in the encoding genes *CLDN16* and *CLDN19*. Affected individuals present with massive calcium and magnesium wasting due to defective reabsorption in the cTAL.[13,14]

In humans, the claudin family comprises at least 22 proteins with a molecular weight between 20 and 27 kDa. They consist of four transmembrane helices, two extracellular loops, and intracellular N- and C-termini. While the first loop is believed to influence paracellular charge selectivity, the second is probably responsible for the interaction between opposing claudins of adjacent cells. In association with occludin, claudins polymerize into linear fibrils that ultimately alter ion selectivity and permeability of tight junctions.[15] Claudins have been shown to be differentially expressed along the nephron[16,17] and to be regulated by receptor-mediated activation.[18–20]

Control of Loop of Henle Magnesium Reabsorption

HORMONAL CONTROLS

A large number of hormones stimulate magnesium reabsorption in the loop of Henle (Table 61.1). Included are peptide hormones such as parathyroid hormone (PTH), calcitonin, glucagon, and arginine vasopressin (AVP).[5] Adrenergic agonists, isoproterenol, and insulin also increase magnesium transport.[3] Mineralocorticoids stimulate NaCl absorption and in turn transepithelial voltage in the loop and by inference increase magnesium reclamation in this segment.[1] Prostaglandins, on the other hand, diminish both salt and magnesium conservation in the cTAL.[5] All of these hormonal responses are mediated by changes in transepithelial voltage by altering apical K^+ recycling and Na−K−2Cl cotransport and the paracellular permeability by modifying tight junctions proteins.[21]

NONHORMONAL CONTROLS

The extracellular Ca^{2+}-sensing receptor (CaSR) importantly influences divalent cation transport in the TAL.[1,22–24] Activation of the CaSR decreases hormone-dependent cAMP release by inhibition of adenylyl cyclase. CaSR activation has been reported to reduce the activity of the 70-pS K^+ channel, and thus potassium recycling and Na−K−2Cl cotransport leading to diminished transepithelial voltage.[23] Though putatively acting through this mechanism, it does not affect salt reabsorption much.[8,25–27] A number of studies have shown that elevated calcium and magnesium, as well as the multivalent gadolinium and the calcimimetic NPS R-467, inhibit the hormonal stimulation of intercellular calcium and magnesium movement at any given voltage, suggesting that the CaSR may also have an effect on paracellular pathways, again perhaps acting through the modification of tight junctions.[26–28] CaSRs are expressed at the basolateral membrane of both medullary and cortical TALs so that they respond to increases in divalent cation concentrations in the blood/interstitium rather than luminal Ca^{2+} and Mg^{2+}.[29] This explains earlier findings that increases in plasma calcium or magnesium inhibit calcium and magnesium transport but increases in luminal concentrations do not.[6]

Hypermagnesemia and hypercalcemia have long been known to result in diminished divalent cation reabsorption.[30] Using clearance studies, Wong et al. elevated serum magnesium levels in thyroparathyroidectomized dogs and determined the urinary magnesium excretion rates with elevated filtered magnesium.[31] They showed that elevated filtered magnesium concentration was initially associated with increases in magnesium reabsorption until an apparent tubular maximum, Tm, was attained, beyond which any additional filtered magnesium was excreted in the urine. Micropuncture studies showed that this Tm was the result of increased proximal tubule reabsorption and diminished loop transport, and has been extensively used in the clinical assessment of renal magnesium conservation.[32] The cellular basis for these observations, as revealed by Hebert and colleagues, is the CaSR present at the basolateral membrane of the TAL that inhibits transport upon

elevation of either calcium or magnesium.[23] The concept of a Tm as an index of total renal magnesium conservation is still useful as long as the segmental contribution is considered and the plasma magnesium concentration is not extreme.[33]

Dietary magnesium restriction and hypomagnesemia have been reported to stimulate magnesium absorption within the cTAL.[6,34] Wittner et al. have shown that the increase in magnesium transport is due to an increase in the permeability of the paracellular pathway to magnesium, in keeping with the passive nature of magnesium transport within the loop.[34] Interestingly, calcium absorption in the loop is also increased by magnesium restriction, so the response is not selective to magnesium.[34] Again, we assume that these changes in paracellular magnesium transport involve modification of tight junction proteins including claudin-16 and claudin-19. In support of this notion, Efrati et al. have reported that the amount of *cldn16* transcript is increased in mice with dietary-induced hypomagnesemia.[35]

Loop Diuretics

Furosemide and bumetanide diminish the luminal positive voltage by virtue of their effects on the Na−K−2Cl cotransporter. Because of this, the acute furosemide usage leads to enhanced distal delivery and increased urinary excretion of magnesium.[35] However, with chronic furosemide therapy urinary excretion usually returns to near control levels. This is likely due to enhanced reabsorption in the proximal tubule and DCT. Thus, prolonged use of furosemide does not often lead to renal magnesium wasting.

Distal Convoluted Tubule

Physiology of Distal Convoluted Tubule Magnesium Reabsorption

The DCT plays an essential role in determining the final urinary magnesium excretion since little or no magnesium is reabsorbed beyond this segment.[1] Magnesium transport within the DCT is transcellular and active in nature (Fig 61.3). Magnesium enters the cell through selective ion channels across the apical membrane, driven by the transmembrane negative electrical potential.[36] Apical magnesium entry is the rate-limiting step in reabsorption, and many of the hormonal and nonhormonal controls act at this site. Cellular magnesium is actively extruded at the basolateral membrane, possibly by a sodium-dependent exchange mechanism which is still unresolved at the molecular level.[3] Micropuncture studies and experiments with immortalized mouse DCT (mDCT) cells have shown that magnesium transport in the DCT is dependent on luminal magnesium concentration and apical transmembrane voltage.[36]

Though being far from completely understood, our knowledge of magnesium transport in the DCT has greatly evolved over the recent years. First, the divalent cation channel, TRPM6, had been implicated in renal magnesium absorption based on the observation that mutations in the *TRPM6* gene cause autosomal recessive hypomagnesemia with secondary hypocalcemia (HSH).[37,38] HSH is characterized by very low serum magnesium due to diminished intestinal magnesium absorption and renal magnesium wasting (see section IIA6). TRPM6 is a member of the transient receptor potential melastatin (TRPM) family of cation channels.[39] They are characterized by six transmembrane segments, a highly conserved pore-forming region, and a Pro-Pro-Pro motif following the last transmembrane domain. Unlike the other members of the TRPM family, TRPM6 and its close homologue TRPM7 possess a unique structure in that they have an alpha-kinase domain in the C-terminal region.[39–41] Dorovkov and Ryazanov have shown that this alpha-kinase phosphorylates and activates annexin 1.[42] Annexin 1 plays a

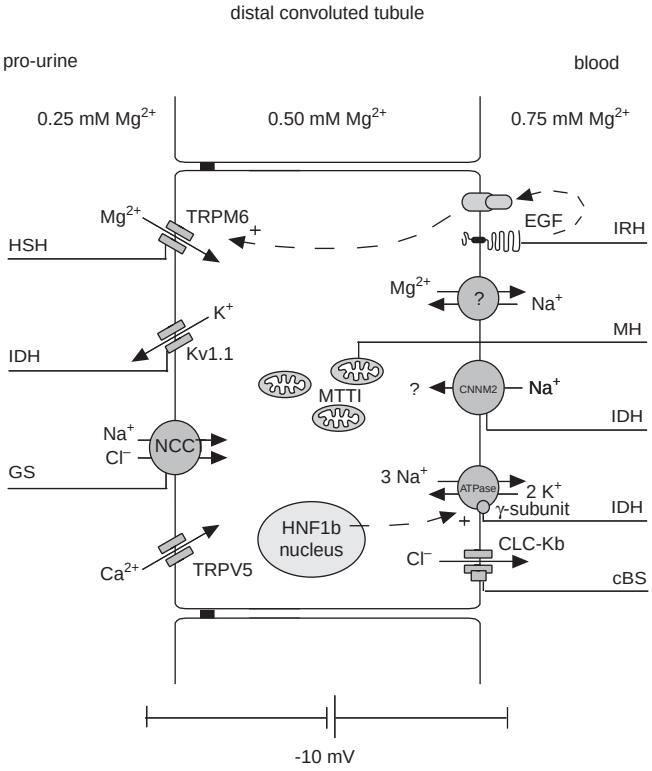

FIGURE 61.3 **Schematic model of magnesium absorption in the DCT.** The membrane proteins influencing magnesium absorption are indicated. Peptide hormones (PTH, calcitonin, glucagon, AVP) enhance magnesium reabsorption in the DCT. The sites of genetic diseases affecting magnesium reabsorption in the DCT are indicated: HSH, IDH, GS, IRH, metabolic hypomagnesemia (MH), cBS.

pleiotropic role in cell proliferation, inflammation, and apoptosis. What this has to do with magnesium transport is not known but Nadler et al. have reported that TRPM7 is essential in cell viability so that it likely plays an important role in cell metabolism.[39] Takezawa et al. have provided evidence that TRPM7 activity is modulated by its own endogenous kinase domain, responding to changes in intracellular levels of cAMP induced by G_i- and G_s-coupled receptors.[43] Earlier it was found that TRPM6 and TRPM7 channels are permeable to calcium and magnesium, are inhibited by increases in intracellular magnesium levels or Mg-ATP,[39] and, although controversial, possibly inactivated by phosphatidylinositol 4,5-bisphosphate hydrolysis.[43,44] TRPM7 is ubiquitously expressed among tissues whereas TRPM6 expression is restricted to few tissues including intestine and kidney.[37] Chubanov et al. have shown that TRPM6 and TRPM7 form heteromultimeric complexes that form functional magnesium permeable channels at the cell surface.[45] Voets et al. have reported that TRPM6 is located along the apical membrane of the small intestine and DCT, transports both magnesium and calcium, and is associated with the divalent cation-binding proteins, parvalbumin, and calbindin-D_{28K}.[46] Whether these binding proteins play a role in regulation of cellular magnesium reabsorption, as they do for calcium, is not known. Several authors have also shown that other divalent ions, such as zinc and cobalt, were also transported by TRPM6, which supports earlier observations demonstrating that TRPM6/TRPM7 are permissive metal ion transporters.[45–47] Nevertheless, magnesium appears to be the preferred substrate so that TRPM6 and TRPM7 are considered as a primary magnesium entry channel.

Control of Distal Convoluted Tubule Magnesium Reabsorption

HORMONAL CONTROLS

A large number of peptide hormones stimulate magnesium absorption within the DCT (Table 61.1). Many of these are the same hormones that influence magnesium transport in the cTAL of Henle's loop. These include PTH, calcitonin, glucagon, and AVP, all of which act through individual receptor-mediated signaling (reviewed in Dai et al.[36]). Renal magnesium conservation seems to be a concerted response to all of these hormones. However, these hormones also stimulate sodium, potassium, and chloride transport in the mTAL, cTAL, and calcium transport in both the cTAL and the distal tubule so that hormonal control is not specific to magnesium.

There is good evidence that vitamin D is important for renal magnesium conservation.[1] Ritchie et al. have demonstrated that $1,25(OH)_2D_3$ increases magnesium entry rates in isolated DCT cells.[48] The response is concentration dependent, involves transcriptional processes necessitating de novo protein synthesis, and does not appear to be related to receptor-mediated cAMP release and stimulation of magnesium uptake.[48] Finally, $1,25(OH)_2D_3$-stimulated magnesium transport is additive to PTH-mediated uptake suggesting that the peptide and steroid hormones regulate magnesium absorption through distinctive intracellular signaling pathways.[36] These studies show that vitamin D_3 metabolites modulate magnesium transport in the DCT independent of other hormonal influences.

Vitamin D_3 administration has often been associated with increases in urinary magnesium and calcium excretion. Vitamin D_3 metabolites increase intestinal absorption of magnesium and calcium so that a positive divalent cation balance may lead to hypermagnesemia and hypercalcemia which in turn diminish magnesium absorption in the loop of Henle through the extracellular CaSR. This may also explain the increase or absence of changes in urinary magnesium excretion following administration of vitamin D_3. The net effect on magnesium balance would thus depend on the relative magnitude of vitamin D_3 actions at the intestinal and renal levels.

Aldosterone enhances hormone-stimulated magnesium entry by potentiating receptor-mediated intracellular signaling, including cAMP formation.[36] Accordingly, acute mineralocorticoids increase magnesium conservation within the DCT in the presence of circulating hormones. Chronic aldosterone administration, on the other hand, generally results in renal magnesium wasting.[36] This has been explained by extracellular volume expansion leading to diminished salt and magnesium reabsorption within the loop of Henle. The potentiation of hormone-mediated magnesium reabsorption in the distal convolute would tend to minimize magnesium loss in hypermineralocorticoidism

Other humoral factors influence renal magnesium conservation such as prostaglandins, insulin, adrenergic agonists, and purinogenic metabolites. Prostaglandin E_2 (PGE_2) is the major arachidonate metabolite synthesized by cyclooxygenase in the mammalian kidney. PGE_2 has a number of diverse actions on the kidney in addition to its ability to influence renal hemodynamics. PGE_2 inhibits salt transport in the mTAL and salt as well as calcium and magnesium absorption within the cTAL and also modulates sodium and water transport in the cortical collecting duct (CCD).[5,49] By its actions in the DCT, prostaglandins may limit magnesium excretion and maintain magnesium balance. Insulin has clearly been shown to have antinatriuretic and antimagnesiuric effects by its actions on the TAL.[5] but insulin also increases magnesium transport in isolated DCT cells.[36] Furthermore, the nephron is richly innervated along its

length from the glomerulus to the collecting tubule. Renal nerve stimulation significantly increases salt and water reabsorption in the proximal tubule, loop of Henle, and distal tubule.[5] Dai and colleagues have shown that isoproterenol increases magnesium transport in DCT cells.[36] It can be concluded from these studies with immortalized mDCT cells that renal nerves and circulating catecholamines play a role in the control of magnesium transport in the DCT.

The interactions of the various peptide and steroid hormones, prostaglandins, and renal innervation are complex.[5] It can be inferred that overall distal magnesium absorption is controlled by all of these influences initiated individually but coming together through shared intracellular signaling pathways.[5] Few studies have been directed at describing these interactions. It is clear that control of renal magnesium handling is orchestrated by many hormones and influences.

The most interesting discovery concerning the hormonal control of tubular magnesium reabsorption stems from the discovery of a mutation in pro-EGF in a family with hereditary magnesium wasting (see below).[50] The mutation impairs the basolateral sorting of epidermal growth factor (EGF) in the DCT. Thereby, binding of EGF to basolaterally expressed EGF receptor (EGFR) is abolished which finally leads to renal magnesium wasting. The supposed mechanism of EGF action is a stimulation of intracellular Src kinase as well as MAP kinase signaling cascades which in turn activate magnesium reabsorption via TRPM6.[51] Thebault and colleagues could show that incubation with EGF leads to an activation of TRPM6-induced currents in HEK293 cells.[51] The authors suggest EGF to be the first selectively acting magnesiotropic hormone as no influence on calcium transport was detected. However, EGF is also known to influence sodium reabsorption in the aldosterone sensitive distal nephron by activation of MAP kinase signaling.[52]

NONHORMONAL CONTROLS

Early in vivo microperfusion studies have demonstrated that elevated extracellular magnesium or calcium also inhibit fractional magnesium transport in superficial rat distal tubules.[6] This has been attributed to the actions of the extracellular CaSR. Riccardi et al. have shown that the CaSR is located on the basolateral membrane of the DCT.[29] Bapty et al. reported that high extracellular magnesium or calcium concentrations inhibit hormone-stimulated magnesium uptake in immortalized mDCT cells.[36,53] These studies clearly indicate that hypermagnesemia and hypercalcemia per se can modify hormone regulation of active, transcellular magnesium transport within the DCT leading to increased magnesium excretion.

The CaSR in the loop of Henle and also in the DCT provides a negative feedback mechanism to mitigate the over exuberant responses of PTH. PTH stimulates calcium and magnesium reabsorption within both nephron segments leading to a rise in serum divalent cation concentrations. Increments in serum calcium and magnesium feedback at the parathyroid gland to inhibit secretion of PTH and at the kidney tubule to inhibit calcium and magnesium transport in the cTAL and the DCT (Fig 61.4). Both extrarenal and intrarenal feedback mechanisms involve the same CaSR located in the parathyroid gland and on renal epithelial cells, respectively. There is evidence that the scenario for PTH feedback may also apply to other calcium- and magnesium-conserving hormones such as vitamin D.[36] Vitamin D metabolites enhance magnesium uptake in isolated DCT cells through a genomic mechanism involving transcriptional/translational processes requiring 2−3 hours following the addition of the hormone.[48] Elevation of extracellular calcium abolishes $1,25(OH)_2D_3$ stimulation indicating that the CaSR may modify gene expression in DCT cells. In order to determine whether elevated extracellular calcium inhibits $1,25(OH)_2D_3$ responses through the CaSR, Dai and coworkers preincubated the cells with a specific antibody to the CaSR protein before treating them with high calcium and $1,25(OH)_2D_3$.[36] The antibody prevented the effect of calcium on $1,25(OH)_2D_3$-induced magnesium uptake, clearly demonstrating a receptor-mediated response.[36] Accordingly, excess $1,25(OH)_2D_3$ increases distal calcium and magnesium transport leading to elevated serum concentrations and activation of the CaSR that provides a negative feedback on divalent cation reabsorption. The CaSR plays an important additional role in mineral metabolism: The CaSR also inhibits water reabsorption in the collecting duct so that excess luminal calcium does not accumulate to form calcareous concretions.[23] There, the CaSR is expressed both at the luminal and basolateral membrane. Therefore, it not only senses interstitial divalent cation concentrations but also intraluminal or urinary cation levels. CaSR activation results in a reduction of autosomal-dominant hypoparathyroidism (ADH)-mediated Aquaporin-2 incorporation into the apical membrane and consecutively a reduced water permeability of the inner medullary collecting duct (IMCD) (citation). The net effect is a concomitant increase in volume flow along with a rise in calcium and magnesium excretion which minimizes the risk of stone formation.[23]

Distal Diuretics

The distal diuretics, hydrochlorothiazide, and amiloride increase magnesium uptake in DCT cells.[36] These agents inhibit sodium chloride cotransport and sodium channels (ENaC), respectively, leading to

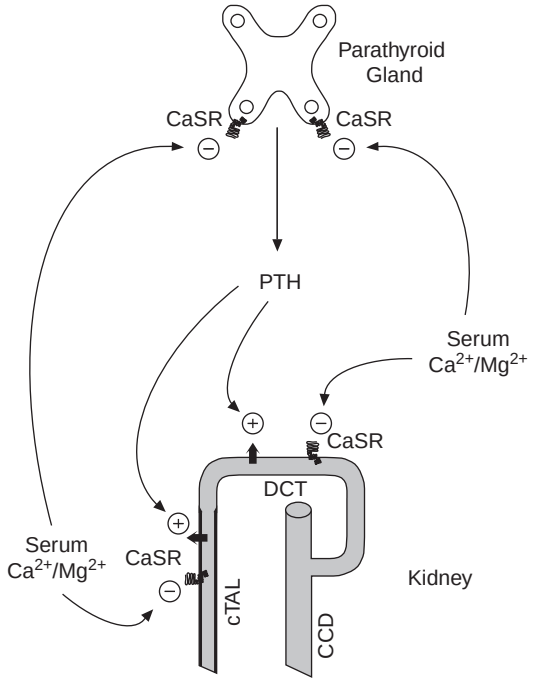

FIGURE 61.4 The extracellular CaSR modulates PTH-stimulated Ca^{2+} and Mg^{2+} reabsorption at renal and extrarenal levels.

diminished intracellular chloride concentration and hyperpolarization of the apical membrane. The increased apical membrane voltage stimulates magnesium entry and transepithelial transport. Although amiloride has clearly been shown to be a magnesium-sparing diuretic, chronic hydrochlorothiazide usage may lead to renal magnesium wasting.[1] The cellular mechanisms for the chronic hydrochlorothiazide effects are unclear but may involve hypokalemia, which can jeopardize renal magnesium conservation.[36,54]

Overall Regulation of Renal Magnesium Handling

In addition to hormonal controls and CaSR-mediated regulation of magnesium reabsorption in TAL and DCT, magnesium transport in these parts of the nephron is regulated in response to altered magnesium status (Table 61.1). A reduction in serum magnesium levels directly results in a decrease in filtered load and consecutively a diminished magnesium flow through the distal nephron. To elucidate the response of the distal nephron to changes in magnesium status, different techniques have been applied including (1) animal studies using magnesium restricted diets and inbred strains with high or low magnesium status, (2) micropuncture and microperfusion studies, and (3) in-vitro experiments with distal tubular cell lines. The discovery of new genes and their encoded proteins involved in paracellular and transcellular magnesium transport in TAL and DCT, respectively, now enables us to investigate the adaptive changes at the molecular level. Classic microperfusion studies in microdissected nephron segments had indicated an increased fractional reabsorption of magnesium in the TAL in rats maintained on a low magnesium diet for only 6 hours, when there is a maximum decline in renal magnesium excretion, but serum magnesium levels are still normal.[55] Calcium and sodium reabsorption rates during this adaptive response remained unchanged. An analogue response was also described for the DCT and furthermore demonstrated in isolated mDCT cells.[56] An inhibition of this adaptive process by pretreatment of cells with cycloheximide, an inhibitor of protein synthesis, implicated genetically controlled mechanisms.[36] More recent studies now identified putative underlying mechanisms of changes in renal tubular magnesium handling in response to magnesium restriction or excess. Efrati and colleagues demonstrated changes in claudin-16 expression in the TAL in mice fed diets with differing magnesium content.[57] Two further studies in mice fed magnesium restricted diets could show that one mechanism underlying the upregulation of renal magnesium conservation in the DCT is an increased expression of TRPM6.[58,59] Contrariwise, Groenestege and colleagues demonstrated that a magnesium enriched diet results in an increase in urinary magnesium, but also calcium wasting.[58] They also found that TRPM6 expression was not dependent on $1,25(OH)_2$-vitamin D or PTH but upregulated by estrogens.[58]

Similarly, hormonal responses are serially organized to regulate magnesium transport in both TAL and DCT. This may be beneficial in that perturbing influences acting in either the loop or distal tubule that can be balanced by homeostatic responses in the other segment. The antenatal Bartter syndrome (aBS) typifies this serial control in magnesium conservation. It results from mutational changes in sodium chloride cotransport in the TAL leading to defective salt absorption (Fig 61.2). Patients with this condition are characterized by volume depletion, hyperreninemia, secondary hyperaldosteronism, hypokalemia, and metabolic alkalosis (see below). Despite defective TAL function, few of these patients demonstrate hypomagnesemia, presumably due to increased reclamation of magnesium in the DCT not affected by the TAL defect.[60–62] In this case, DCT function compensates for diminished TAL reabsorption even though the hormonal controls are similar.

PATHOPHYSIOLOGY OF RENAL MAGNESIUM HANDLING

Genetic Magnesium-Wasting Diseases

Hereditary hypomagnesemia comprises a set of rare genetically determined disorders primarily or secondarily affecting renal magnesium handling. Over the past years, numerous genetic defects in genes encoding components of the renal tubular salt and electrolyte transport machinery or regulating factors have been described (Table 61.2). The spectrum ranges from the most frequent variant, the Gitelman syndrome (GS) with a primary defect in salt reabsorption in the DCT to rare disorders discovered in single patients or families only. The following sections try to summarize essential data from a multitude of research studies published over the last years. Defects primarily or solely affecting renal magnesium handling are preceded by a paragraph on renal salt wasting disorders (Bartter syndrome).

Hypomagnesemia Associated with Abnormal Renal Salt Handling

Tubular salt reabsorption affects the membrane potential of tubular epithelial cells and is involved in the generation of the transepithelial potential, both of which are a prerequisite for the processes of magnesium reabsorption along the different segments of the nephron. Salt-wasting disorders with hypokalemia and metabolic alkalosis, also known as Bartter-like syndromes, impair tubular reabsorption of sodium chloride in different parts of the distal nephron. The renal conservation of magnesium is secondarily affected to a varying extent according to the nephron segment affected in each of the Bartter-like syndromes.

BARTTER SYNDROME

ANTENATAL BARTTER SYNDROME The aBS is caused by mutations either in the furosemide-sensitive Na−K−2Cl cotransporter (NKCC2) or in the ROMK K^+ channel, which cooperate in the apical uptake of sodium chloride in the TAL.[63–66] The defect in sodium chloride reabsorption caused by mutations in either protein reduces the lumen-positive transepithelial voltage and thus impairs passive paracellular reabsorption of calcium and magnesium in this part of the nephron.

aBS is characterized by massive polyuria that manifests in utero with the development of polyhydramnios which in turn results in premature birth in most patients.[67] Postnatally, affected children rapidly develop massive salt wasting and subsequent hypokalemic metabolic alkalosis. In addition, hypercalciuria and nephrocalcinosis occur in virtually all patients. In contrast, disturbances in magnesium homeostasis are not commonly observed in aBS (64). The lack of renal magnesium wasting despite pronounced hypercalciuria is explained by increased distal tubular salt reabsorption, especially via an upregulation of salt reabsorption in the DCT which also leads to enhanced magnesium conservation. The relationship between sodium, calcium, and magnesium handling in the DCT will be discussed in more detail below, as exactly the opposite association is observed in GS, that is, diminished sodium and magnesium transport but increased calcium reabsorption. aBS is characterized by increased prostaglandin E synthesis that might also contribute to an improved magnesium reabsorption in the DCT, as demonstrated in a mDCT cell line.[36]

ANTENATAL BARTTER SYNDROME WITH SENSORINEURAL DEAFNESS The most severe variant of the Bartter-like syndromes is caused by a defect in basolateral chloride extrusion along the distal nephron. Mutations in the activating β-subunit of renal chloride channels ClC-Ka and ClC-Kb or combined mutations of the two chloride channels themselves were identified as the underlying genetic defects.[10,68,69]

Both chloride channels mediate the basolateral extrusion of chloride from tubular epithelial cells in TAL and DCT. In addition, ClC-Ka provides the major route for chloride reabsorption in the ascending thin limb where it is expressed at the apical as well as basolateral membrane. Whereas isolated ClC-Kb defects lead to the clinical picture of classic Bartter syndrome (cBS) (see below), mutations in ClC-Ka have not been described so far in humans. Disruption of ClC-Ka in mice leads to a diabetes insipidus-like phenotype.[70]

Renal salt and water losses are even more severe than in aBS. Patients often require long-term parenteral fluid replacement. The excessive salt wasting is explained by the combined impairment of ClC-Ka- and ClC-Kb-mediated salt reabsorption in both the loop of Henle and in the DCT. Unlike in aBS, hypercalciuria and nephrocalcinosis are uncommon; instead patients often show progressive renal failure of unknown origin.[71]

Serum magnesium levels have been found to be reduced in BSND with values around 0.5 mmol/L.[72] A possible explanation is a combined impairment of paracellular divalent transport in the TAL as well as of active transcellular magnesium reabsorption in the DCT, which results in pronounced renal magnesium wasting and hypomagnesemia. In later stages, however, the impairment of renal function counteracts further magnesium wasting.[72]

CLASSIC BARTTER SYNDROME (CBS) cBS is caused by mutations in the *CLCNKB* gene coding for the chloride channel ClC-Kb.[73,74] The ClC-Kb protein is expressed in the TAL and DCT, where it mediates

chloride efflux from epithelial cells to the interstitium. The clinical picture of cBS varies widely with a spectrum ranging from a phenotype similar to aBS in rare cases to a phenotype almost indistinguishable from GS.[75,76] However, the majority of patients develop hypokalemia, hypochloremia, and failure to thrive during the first year of life, as described by Bartter and coworkers in their initial report.[60] Prenatal onset and nephrocalcinosis as seen in aBS are unusual. A possible explanation for the greater variability in the clinical picture of cBS compared to aBS might be the broad expression pattern of ClC-Kb that appears to be particularly critical for electrolyte handling in the DCT segment.

Hypomagnesemia is detected in up to 50% of affected individuals.[72] Some cBS patients present with combined hypomagnesemia and hypocalciuria, a phenotypic signature of defects in the DCT. Thus, one can assume that in cBS disturbed reabsorption of sodium chloride in distal nephron segments impairs the renal conservation of magnesium.

GITELMAN SYNDROME

The most frequent inherited salt losing tubular disorder affecting renal magnesium handling is the GS. GS is caused by mutations in the thiazide-sensitive sodium-chloride cotransporter NCCT[65,77] which is exclusively expressed at the apical membrane of the DCT. The cardinal features of GS are persistent hypokalemia and metabolic alkalosis with hypomagnesemia and hypocalciuria.[78–81] These findings, which are now considered to be characteristic for disturbances in DCT function, are also seen in other disorders affecting renal magnesium conservation (see below). Although a salt-wasting disorder, salt and water losses in these patients are usually less pronounced than in aBS because the urinary concentrating ability is largely preserved.[76] Patients usually present during childhood or adolescence with symptoms of muscle weakness or overt tetany related to profound hypomagnesemia. However, many "asymptomatic" patients have been reported, and GS is frequently diagnosed following measurement of electrolytes for various other reasons than hypomagnesemia (e.g., preoperative workup). Nevertheless, a large clinical study demonstrated that GS significantly affects quality of life.[82] None of these 50 patients were truly asymptomatic. Salt craving, nocturia, and paresthesia were among the most frequent symptoms.

Mechanisms of enhanced calcium absorption and reduced magnesium transport secondary to disturbed NCCT-mediated salt reabsorption are not fully understood. These features are characteristic for GS but other disorders affecting salt and divalent electrolyte reabsorption in the DCT may result in similar findings (see below). The transport of calcium and magnesium in the DCT is transcellular and active in nature, consisting of an apical entry through a selective ion channel (TRPV5 and TRPM6, respectively) and selective active basolateral extrusion (Fig 61.3). Although Ca^{2+}/Na^{+} exchange has been identified, the molecular nature of the basolateral magnesium transport protein is still unknown, but several studies point to a sodium-coupled exchange mechanism.[1] Paracellular transport of either calcium or magnesium is not observed in the DCT. Accordingly, the notion of Reilly and Ellison is not tenable. They postulated that DCT cells could potentially switch to electrogenic reabsorption of sodium via the apical sodium channel ENaC that would reverse transepithelial voltage to lumen negative that in turn might drive magnesium into the lumen.[83] The hypocalciuria was thought to result from a reduction in NaCl entry into DCT cells leading to hyperpolarization which in turn could increase passive apical calcium entry and basolateral sodium−calcium exchange.

A more satisfying explanation has been advanced by Loffing and colleagues. Immunohistochemical studies in NCCT knockout mice point to the involvement of distinct segments of the distal tubule.[84,85] In NCCT −/− mice, the early portion of the DCT undergoes apoptosis and is almost completely absent with marked decreases in NCCT and TRPM6 expression. In contrast, the late DCT and the connecting tubule (CNT) remain largely intact with retained expression of the epithelial sodium channel ENaC and the epithelial calcium channel TRPV5. Therefore, active transcellular magnesium reabsorption could be impaired simply by loss of early DCT cells in GS patients. Concerning the hypocalciuria, recent studies point to involvement of increased calcium reabsorption upstream to the DCT.[54] The volume contraction in NCCT −/− mice led to a decrease in GFR and an increased fractional reabsorption of sodium, but also calcium already in the proximal tubule where magnesium is poorly reabsorbed. This effect on calcium reabsorption is completely reversed by salt and fluid repletion in these animals. Moreover, Nijenhuis et al. reported that hydrochlorothiazide administration resulted in hypocalciuria in TRPV5 −/− mice showing that active distal tubular calcium reabsorption is not required.[54] As mentioned above, TRPM6 was downregulated in the NCCT knockout mice, which explains the urinary magnesium wasting.[54]

EAST/SESAME SYNDROME

Recently, a complex syndrome combining epilepsy, ataxia, sensorineural deafness, and renal salt wasting was described by two independent groups (for which they introduced the acronyms EAST or SeSAME syndrome).[86,87] Patients present early in infancy with

generalized tonic–clonic seizures, speech and motor delay, severe ataxia, intention tremor, dysdiadochokinesis, severe hearing impairment, and renal salt wasting.

The renal phenotype includes RAAS stimulation, hypokalemic alkalosis, largely preserved urinary concentrating ability, hypomagnesemia and hypocalciuria resembling the above mentioned DCT signature. All patients required high dose potassium and magnesium supplementation (Bockenhauer NEJM),[86] some patients were additionally treated with aldosterone antagonists to narrow potassium losses.[87]

Autosomal-recessive EAST/SeSAME syndrome was shown to be caused by loss-of-function mutations in *KCNJ10*, coding for Kir4.1, a member of the inwardly rectifying potassium channel family.[86,87] Kir4.1 expression was demonstrated in glial cells in several parts of the brain including the spinal cord and in the stria vascularis of the inner ear explaining the observed central nervous phenotype and deafness in affected individuals. In kidney, Kir 4.1 is expressed in DCT, CT as well as in CCD,[88] however its presence was also suggested in TAL.[89] Kir4.1 is localized at the basolateral membrane of distal nephron segments and supposed to function in collaboration with Na–K–ATPase as it allows for a recycling of potassium ions entering the tubular cells in countermove for the extruded sodium.[87] In addition, diminished Kir4.1 function leads to a depolarization of the basolateral membrane and consecutively to a reduction in the driving force for basolateral anion channels as well as sodium coupled exchangers.[90] This decreased basolateral membrane potential could also affect the putative electrogenic Na^+/Mg^{2+} exchanger and possibly explain the observed magnesium wasting in EAST syndrome. Interestingly, the renal phenotype of Kir4.1 −/− mice had not been thoroughly studied until the description of human disease. The re-evaluation of Kir4.1 −/− mice by Bockenhauer and colleagues however clearly demonstrated renal salt wasting leading to significant growth retardation.[86] The concurrent findings of hypomagnesemia and hypocalciuria, also observed in mice, argue for a defect in renal salt reabsorption predominantly in the DCT.

Disorders of Calcium-Sensing Receptor

The extracellular CaSR/Mg^{2+}-sensing receptor (plays an essential role in magnesium and calcium homeostasis by influencing not only PTH secretion in the parathyroid gland but also by directly regulating the rate of magnesium and calcium reabsorption in the kidney. It was first cloned by Brown and colleagues in 1993.[23] Along the distal nephron, the CaSR is expressed basolaterally in TAL and DCT as well as at both the apical and basolateral membrane of the collecting duct.[29] Activation of the CaSR leads to coordinate changes in renal calcium and magnesium excretion and in water diuresis.[23] Dilution of the urine by decreasing aquaporin expression in the collecting duct is thought to minimize the risk of stone formation in the face of an increase in calcium and magnesium excretion. Several diseases associated with both activating and inactivating mutations in the CaSR gene have been described. As alterations in CaSR activity also affect renal magnesium handling, they are presented in this chapter with a special focus on magnesium.

AUTOSOMAL-DOMINANT HYPOPARATHYROIDISM

Activating mutations of the CaSR result in ADH. Patients typically manifest during childhood with seizures or carpopedal spasms. Laboratory evaluation reveals the typical combination of hypocalcemia and low PTH levels, but the majority of patients also exhibit significant hypomagnesemia with serum levels around 0.5–0.6 mmol/L.[91,92] Affected individuals are often given the diagnosis of primary hypoparathyroidism on the basis of inadequately low PTH levels despite their hypocalcemia. Serum calcium levels are typically in a range of 6–7 mg/dL. The differentiation from primary hypoparathyroidism is of particular importance because treatment with vitamin D can result in a dramatic increase in calcium excretion and the occurrence of nephrocalcinosis and impairment of renal function in ADH patients. Therefore, therapy with vitamin D or calcium supplementation should be reserved for symptomatic patients with the aim to maintain serum calcium levels just sufficient for the relief of symptoms.[92]

Activating CaSR mutations lead to a lower set-point of the receptor or an increased affinity for extracellular calcium and magnesium. This inadequate activation by physiological extracellular calcium and magnesium levels then results in diminished PTH secretion and decreased reabsorption of both divalent cations mainly in the cTAL. For magnesium, the inhibition of PTH-stimulated reabsorption in the DCT may significantly contribute to an increased renal loss in addition to the effects observed in the TAL.[36,93] Pronounced hypomagnesemia is observed in patients with complete activation of the CaSR at physiologic serum calcium and magnesium concentrations who also exhibit a Bartter-like phenotype.[94,95] In these patients, CaSR activation inhibits TAL-mediated salt and divalent cation reabsorption to an extent that cannot be compensated in later nephron segments.

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA/ NEONATAL SEVERE HYPERPARATHYROIDISM

Familial hypocalciuric hypercalcemia (FHH)/neonatal severe hyperparathyroidism (NSHPT) result from inactivating mutations present in either heterozygous

or homozygous (or compound heterozygous) state, respectively.[96] FHH patients normally present with mild to moderate hypercalcemia, accompanied by few if any symptoms and often do not require treatment (Table 61.2). Urinary excretion rates for calcium and magnesium are markedly reduced, and serum PTH levels are inappropriately high. In addition, affected individuals also show mild hypermagnesemia.[97] In contrast, NSHPT patients with two CaSR mutations is usually present in early infancy with polyuria and dehydration due to severe symptomatic hypercalcemia. Unrecognized and untreated hyperparathyroidism and hypercalcemia result in skeletal deformities, extraosseous calcifications, muscle wasting, and a severe neurodevelopmental deficit. Early treatment with partial-to-total parathyroidectomy therefore seems to be essential for a favorable outcome.[98] Data on serum magnesium in NSHPT are sparse. However, elevations to levels around 50% above normal have been reported.[99]

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) is caused by mutations in two different members of the claudin family of tight junction proteins, namely claudin-16 and claudin-19.[13,14] Since its first description, at least 80 different patients have been reported, allowing a comprehensive characterization of the clinical spectrum of this disorder and discrimination from other magnesium-losing tubular diseases.[100–103] Due to excessive renal magnesium and calcium wasting, patients develop the characteristic triad of hypomagnesemia, hypercalciuria, and nephrocalcinosis that gave the disease its name. FHHNC patients usually present during early childhood with recurrent urinary tract infections, polyuria/polydipsia, nephrolithiasis, and/or failure to thrive. Signs of severe hypomagnesemia such as cerebral convulsions and muscular tetany are less common. Additional laboratory findings include elevated serum PTH levels before the onset of chronic renal failure (CRF), incomplete distal tubule acidosis, hypocitraturia, and hyperuricemia present in most patients.[104] The prognosis of FHHNC patients is rather poor with progression to CRF early during adolescence. A considerable number of patients already exhibit a markedly reduced GFR (<60 mL/min per 1.73 m^2) at the time of diagnosis. Hypomagnesemia may completely disappear with the decline of GFR due to reduction in filtered magnesium limiting urinary magnesium excretion.

Whereas the renal phenotype is almost identical in carriers of *CLDN16* and *CLDN19* mutations, ocular involvement including severe myopia, nystagmus, or chorioretinitis are much more prominent in patients with *CLDN19* mutations.[14,101,105,106]

In addition to continuous magnesium supplementation, therapy aims at the reduction of calcium excretion by using thiazides to prevent the progression of nephrocalcinosis and stone formation. The degree of renal calcification has been correlated with progression of CRF.[101] However, therapeutic strategies do not seem to significantly influence the progression of renal failure. Supportive therapy is important for the protection of kidney function and should include provision of sufficient fluids and effective treatment of stone formation and bacterial colonization. As expected, renal transplantation is performed without evidence of recurrence because the primary defect resides in the kidney.

Using a positional cloning approach, Simon et al. could identify a new gene (*CLDN16*, formerly *PCLN1*), which is mutated in patients with FHHNC.[13] *CLDN16* codes for claudin-16 or paracellin-1, a member of the claudin family. More than 20 claudins identified so far comprise a family of ~22 kD proteins with four transmembrane segments, two extracellular domains, and intracellular N and C termini. The individual composition of tight junction strands with different claudins confers the characteristic properties of different epithelia regarding paracellular permeability and/or transepithelial resistance. In this context, a crucial role has been attributed to the first extracellular domain of the claudin proteins, which is extremely variable in number and position of charged amino acid residues.[107] Individual charges have been shown to influence paracellular ion selectivity suggesting that claudins positioned on opposing cells forming the paracellular pathway provide charge-selective pores within the tight junction complex.

The C terminus is remarkable for a consensus threonine-X-valine PDZ-binding domain which is possibly involved in protein–protein interactions and targeting of the paracellin-1 protein to tight junction strands. The longest possible open reading frame of the human cDNA encodes a protein of 305 amino acids with a cytoplasmic N-terminus of 73 amino acids. This structure is in contrast to all other claudins, which share a very short N-terminus of only six or seven amino acids. Interestingly, there is a second in-frame start codon within a suitable Kozak consensus sequence at position Met71 that is analogous to the translation start site of all other claudins. Sequence comparison of the human cDNA with other species and the results of mutation analyses, which identified a common insertion/deletion polymorphism (165_166*del*GG*ins*C) that would lead to a shift of the reading frame (R55fs71X), argue for the second translation initiation start site being used in vivo.[102,108]

The majority of mutations reported thus far in FHHNC are simple missense mutations affecting the transmembrane domains and the extracellular loops

with a particular clustering in the first extracellular loop containing the ion selectivity filter. Within this domain, patients originating from Germany and Eastern European countries exhibit a common mutation (L151F) due to a founder effect.[102] Defects in *CLDN16* have also been shown to underlie the development of a chronic interstitial nephritis in Japanese cattle that rapidly develop CRF shortly after birth.[109] Interestingly, affected animals typically show hypocalcemia but no hypomagnesemia, which might be explained by advanced CRF present at the time of examination. The fact that, in contrast to the point mutations identified in human FHHNC, large deletions of *CLDN16* are responsible for the disease in cattle, might explain the more severe phenotype with early-onset renal failure. However, *Cldn16* knockout mice do not display renal failure during the first months of life.[110] In FHHNC patients, progressive renal failure is generally thought to more likely be a consequence of massive urinary calcium wasting and nephrocalcinosis. A study of a large cohort of FHHNC patients showed that the presence of *CLDN16* mutations leading to a complete loss-of-function on both alleles display a younger age at manifestation as well as a more rapid decline in renal function compared to patients with at least one allele with residual claudin-16 function.[111] These findings support the theory that a complete lack of claudin-16 is associated with a more severe phenotype whereas a residual function delays the progression of CRF.

There is evidence from family analyses that carriers of heterozygous *CLDN16* mutations may also present with clinical symptoms. Two independent studies describe a high incidence of hypercalciuria, nephrolithiasis, and nephrocalcinosis in first-degree relatives of FHHNC patients.[101,102] A subsequent study also found a tendency toward mild hypomagnesemia in family members with heterozygous *CLDN16* mutations.[112] Thus, one might speculate that *CLDN16* mutations are involved in idiopathic hypercalciuric stone formation.

Recently, a homozygous *CLDN16* mutation (T303G) affecting the C-terminal PDZ domain has been identified in two families with isolated hypercalciuria and nephrocalcinosis without disturbances in renal magnesium handling.[113] Interestingly, the hypercalciuria disappeared during follow-up and urinary calcium levels reached normal values beyond puberty. Transient transfection of MDCK cells with the CLDN16 (T303G) mutant revealed localization of the mutant paracellin-1 in the apical membrane, whereas wildtype paracellin-1 was correctly targeted. It still remains to be determined why this type of misrouting is associated with transient isolated hypercalciuria without increased magnesium excretion.

Molecular genetic studies in FHHNC patients with a severe ocular involvement lead to the identification of mutations in a second member of the claudin family, claudin-19 (encoded by *CLDN19*).[14] Claudin-19 is expressed together with claudin-16 predominantly in the TAL. Tight-junction strands in this part of the renal tubule also express claudin-10 and claudin-18.[114] These other claudins are able to maintain the barrier function of the tight junction complex also in the absence of claudin-16 and -19; however, claudin-16 and -19 depleted tight junctions displayed a loss in cation permselectivity (Hou et al. PNAS 2009).[114] Unfortunately, it remains an unanswered question so far, if claudin-16 and -19 directly take part in the formation of a paracellular pore structure selective for magnesium and calcium or if they are simply involved in generating the cation selectivity of the tight junction complex required for maintaining the lumen-positive potential in the TAL (Hou, Goodenough 2010).[115] In this context, it is interesting to note that claudin-16 as well as claudin-19 deficient mice also display increased renal losses of sodium as well as potassium in addition to the disturbance in renal magnesium and calcium handling.[114]

Patients with claudin-19 defects display a renal phenotype indistinguishable from patients with defective claudin-16 function,[14] however, the ocular phenotype also observed in patients with claudin-16 defects is much more severe. The molecular basis for the phenomenon is the expression of claudin-19 specifically in different layers of the retina.[14] Patients show a misdevelopment of the optic disc leading to severe visual impairment and the development of horizontal nystagmus.

Hypomagnesemia with Secondary Hypocalcemia

HSH is an autosomal recessive disorder caused by mutations in the *TRPM6* gene coding for TRPM6, a member of the transient receptor potential (TRP) cation channel family.[37,38] Since its first description by Paunier and colleagues in 1968,[116] at least 50 HSH kindreds have been described.[38,117–119] Patients uniformly manifest in early infancy with generalized convulsions refractory to anticonvulsant treatment or other symptoms of increased neuromuscular excitability such as muscle spasms or tetany. Laboratory evaluation at initial presentation reveals severely reduced serum magnesium levels of around 0.2 mmol/L. Severe hypomagnesemia is accompanied by hypoparathyroidism with barely detectable PTH levels and consecutive hypocalcemia with serum calcium levels around 1.6 mmol/L. The unexpected finding of hypoparathyroidism is thought to result from an inhibition of PTH synthesis and secretion in the presence of extreme hypomagnesemia.[98,120,121] In addition, PTH-induced release of calcium from bone is substantially impaired in hypomagnesemia as magnesium depletion interferes with the generation of cAMP in response to PTH.[98] The hypocalcemia is resistant to treatment with calcium or vitamin D.

Treatment in HSH consists of immediate administration of magnesium, usually via the intravenous route at a dose of 0.1 − 0.2 mmol (equivalent to 25-50 mg) per kilogram of body weight, up to a maximum of 8 mmol (equivalent to 2 g).[62,119] Administration of magnesium alone rapidly leads to relief of clinical symptoms, normocalcemia, and normalization of PTH levels. Acute parenteral therapy is followed by lifelong high-dose oral magnesium supplementation.[122] In the majority of patients, organic magnesium salts such as aspartate or citrate are used. Daily requirements of up to 4 mmol/kg of body weight per day (16 times the recommended daily allowance) have been described,[123] although an average daily requirement of around 1 mmol/kg of body weight per day seems to be sufficient in most HSH patients. Whether these large variations reflect different individual requirements or whether they are the consequence of differences in therapeutic strategies remains to be determined. Adolescent patients usually tolerate oral magnesium to a lesser extent than infants and younger children, who on average receive larger amounts per kilogram of body weight. While gastrointestinal complaints are clearly aggravated with rising amounts of oral magnesium in the same patient, the susceptibility to diarrhea shows marked interindividual variability.

The laxative action of magnesium salts administered in therapeutic doses often leads to pronounced gastrointestinal side effects that occasionally necessitate considering alternative routes of administration such as intravenous or subcutaneous injections. Splitting of oral doses can reduce fluctuations of serum magnesium levels and peak urinary excretion and also alleviate diarrhea. Additional intramuscular magnesium injections might be necessary to reduce oral intake. A regimen consisting of daily intramuscular injections given over a 20-year period has been described.[123] Ultimately, the authors used continuous nocturnal administration via nasogastric tube as a therapeutic alternative to improve quality of life. In another HSH patient, hypomagnesemic seizures only ceased after implantation of a subcutaneous pump system that provides continuous magnesium infusions.[124]

Delay in diagnosis may lead to neurological deficits or may even be fatal as seizures are refractory to anticonvulsive treatment. Several HSH patients with severe mental retardation due to recurrent seizures have been reported. The laboratory evaluation of serum magnesium levels should therefore represent an indispensable part of the workup in infantile seizures. After correction of hypomagnesemia, serum levels should be closely monitored to prevent recurrence of symptoms in the presence of hereditary magnesium deficiency.

Contrasting all other known forms of hereditary hypomagnesemia, pathophysiologic studies in affected patients using radioactive magnesium isotopes pointed to a primary defect in intestinal magnesium absorption.[125] The presence of an additional renal phenotype in HSH was controversial until magnesium-loading studies clearly demonstrated a renal magnesium leak.[126] With rising serum magnesium levels during substitution, renal magnesium loss, which is barely detectable at initial presentation, becomes evident demonstrating a decreased renal threshold for magnesium.[38] Despite remaining hypomagnesemic with serum levels around 0.6 mmol/L, HSH patients display inadequately high fractional excretions for magnesium in a range of 2-4%.[37] Assuming intact renal magnesium conservation, fractional excretions rates would be expected to drop below 1% in the presence of hypomagnesemia.[33]

A positional candidate gene approach enabled the identification of mutations in the *TRPM6* gene as the underlying defect in HSH.[37,38] *TRPM6* codes for a member of the TRP family of cation channels. The TRP protein superfamily comprises more than 20 related cation channels playing important roles in a wide variety of physiological processes such as phototransduction, sensory physiology, and regulation of smooth muscle tone.[127] The conventional TRP proteins can be allocated to three subfamilies: TRPC, TRPV, and TRPM. Three additional more distantly related subfamilies—TRPML, TRPN, and TRPP—have been defined more recently.[127] All TRP ion channels share the common feature of six transmembrane domains with a putative pore-forming region between the fifth and sixth transmembrane domain and intracellular N- and C-termini. Four TRP protein subunits assemble to form a functional channel complex.

The TRPM subfamily comprises eight members that exhibit a significant diversity in domain structure as well as cation selectivity and activation mechanisms. Three members—TRPM2, TRPM6, and TRPM7—are set apart from all other known ion channels because they harbor enzyme domains in their respective C termini and thus represent prototypes of an intriguing new protein family of enzyme-coupled ion channels. TRPM6 and TRPM7 contain protein kinase domains in their C termini, which bear sequence similarity to elongation factor 2 (eEF-2) serine/threonine kinases.[40,42]

The functional characterization of TRPM7 demonstrated permeability for various cations, including calcium, magnesium, and several trace metals.[128] TRPM7 gating was shown to be regulated by intracellular magnesium and magnesium-nucleotide complexes.[39] Targeted deletion of TRPM7 in cell lines results in intracellular magnesium depletion and growth arrest.[41] Taken together, these data point to the essential role of

ubiquitously expressed TRPM7 for cellular magnesium homeostasis.

The TRPM6 protein is highly homologous to the TRPM7 ion channel. However, contrasting TRPM7, only one group thus far has succeeded in functional expression of TRPM6 in a mammalian cell line.[46]

The authors were able to show channel properties similar to those observed for TRPM7. In contrast, another group clearly demonstrated that heteromultimerization with TRPM7 is essential for correct membrane targeting of TRPM6.[45] In this study, TRPM7-induced currents were significantly increased by coexpression of TRPM6. Heteromultimerization has been previously described for other members of the TRP family.[129] The detection of TRPM6 expression in the DCT, together with the functional studies in HSH patients that clearly demonstrated a renal magnesium leak, points to an important role of TRPM6 for active transcellular magnesium reabsorption in the DCT.[37,46] Whether TRPM6 alone or in cooperation with TRPM7 constitutes the apical magnesium channel that was physiologically identified in DCT cells remains to be clarified in future studies.

TRPM6 mutations identified in HSH patients comprise the following classes of mutations: stop mutations and frame shift mutations, both leading to premature stops of translation, as well as splice site mutations, which impede proper mRNA synthesis and presumably lead to absence of the corresponding exon and large exon deletions.[37,38] All of the mentioned mutations that are distributed over the entire TRPM6 protein result in truncated TRPM6 proteins. Only few missense mutations, e.g. S141L in the N terminus and P1017R in the putative pore-forming region of the TRPM6 protein, have been identified so far.[37,117,130] The functional analysis of S141L-TRPM6 demonstrated intracellular retention of the mutant protein upon coexpression with TRPM7 and an abrogation of proper tetrameric TRPM6/TRPM7 complex assembly in the endoplasmic reticulum.[45] In contrast, the P1017R mutant shows a preserved trafficking to the plasma membrane, but obviously interferes with channel gating or permeation mechanisms of the functional ion channel tetramer.[130] Therefore, all HSH mutations functionally characterized thus far result in a complete loss of function of the TRPM6 protein. Obviously, complete lack of TRPM6 ion channel function is required for the development of the typical HSH phenotype. It is intriguing to speculate whether minor changes in TRPM6 function by single point mutations might result in a less severe clinical picture or even in subclinical magnesium deficiency.

The mutational analysis of *TRPM6* also supports the data obtained for TRPM7 pointing to an essential role of the C-terminal kinase domain for ion channel function. While abrogation of TRPM7 kinase activity does not impair ion channel function but leads to a decrease in magnesium mediated channel inhibition, structural absence of the kinase domain leads to a complete suppression of ion channel activity.[41] Similarly, truncating mutations of TRPM6 prior to the kinase domain lead to an obvious loss of ion channel function.

How does an impairment of TRPM6 protein function impede epithelial magnesium transport in the intestine and kidney? The observation that in HSH patients the administration of high oral doses of magnesium are successful in achieving at least subnormal serum magnesium levels supports the existing evidence of two independent transport systems for magnesium in the gastrointestinal tract.[131] TRPM6 probably represents a molecular component of active transcellular magnesium transport. An increased intraluminal magnesium concentration achieved by increased oral intake would enable to compensate for the defect of the active transcellular pathway by increasing absorption via the passive paracellular route.[37,132]

Isolated Dominant Hypomagnesemia

FXYD2 (γ-SUBUNIT)

Isolated dominant hypomagnesemia (IDH) was first linked to a mutation in the *FXYD2* gene on chromosome 11q23 which codes for a γ-subunit of Na−K−ATPase.[133] Only two related families with a *FXYD2* mutation have been described so far.[133,134] The index patients of both families presented with generalized convulsions during childhood, at ages 7 and 13 years, respectively. Serum magnesium levels in the two patients at the time of convulsions were approximately 0.4 mmol/L. One index patient was treated for seizures of unknown origin with antiepileptic drugs until serum magnesium levels were evaluated in adolescence. At that time severe mental retardation was evident. Systematic serum magnesium measurements performed in members of both families revealed low serum magnesium levels of around 0.5 mmol/L in numerous apparently healthy individuals. Consequent pedigree analyses of the two families pointed to an autosomal-dominant mode of inheritance. A genome-wide linkage study mapped the disease locus on Chr 11q23.[135] Detailed haplotype analyses identified a common haplotype segregating in the two families which suggested a common ancestor. Indeed, the mutational screening of the *FXYD2* gene demonstrated the identical mutation G41R in all affected individuals of both family branches.

A ^{28}Mg-retention study in one index patient pointed to a primary renal defect.[134] The intestinal absorption of magnesium was preserved and even stimulated in compensation for the increased renal losses. Urinary

magnesium measurements in affected family members revealed daily magnesium excretions of around 5 mmol per day despite profound hypomagnesemia.[134] In addition, urinary calcium excretions were found to be low in all hypomagnesemic family members, a finding reminiscent of patients presenting with GS. But in contrast to GS, no other associated biochemical findings were reported.

The γ-subunit encoded by *FXYD2* is a member of a family of small single transmembrane proteins that share the common amino acid motif F-X-Y-D. Out of the seven members that differ in tissue specificity, FXYD2 and FXYD4—also called CHIF or channel-inducing factor—are highly expressed along the nephron but display an alternating expression pattern.[136] The γ-subunit comprises two isoforms (named γ-a and γ-b) that are differentially expressed in the kidney. The γ-a isoform is present predominantly in the proximal tubule, and expression of the γ-b isoform predominates in the distal nephron, especially in the DCT and CNT.[137] The ubiquitous Na−K−ATPase is a dimeric enzyme invariably consisting of one α- and one β-subunit. FXYD proteins constitute a third or γ-subunit that represents a tissue-specific regulator of Na−K−ATPase and produces distinct effects on the apparent affinity of the Na−K−ATPase for sodium, potassium, and ATP. The FXYD2 γ-subunit increases the apparent affinity of Na−K−ATPase for ATP while decreasing its sodium affinity.[138] Thus, it might provide a mechanism for balancing energy utilization and maintaining appropriate salt gradients.

Expression studies of the mutant G41R-γ-subunit in mammalian renal tubule cells revealed a dominant negative effect of the mutation leading to retention of the γ-subunit within the cell. Whereas initial data pointed to retention of the entire Na−K−ATPase complex in intracellular compartments, more recent data demonstrate an isolated trafficking defect of the mutant γ-subunit while trafficking of the α/β-complex is preserved.[139] The mutant γ-subunit is obviously retarded in the Golgi complex which points to disturbed post-translational processing. The assumption of a dominant negative effect was first substantiated by the observation that individuals with a large heterozygous deletion of chromosome 11q including the *FXYD2* gene exhibit normal serum magnesium levels.[140] Meanwhile, it could be shown that wildtype γ-subunits oligomerise within the cell before trafficking to the plasma membrane. The G41R-mutant was shown to also oligomerise with itself and the wildtype γ-subunit and obviously prevents proper routing of wildtype γ-subunits to the plasma membrane and incorporation into functional ATPase complexes.[141]

Urinary magnesium wasting together with the expression pattern of the *FXYD2* gene indicate a defect of active transcellular magnesium reabsorption in the DCT in affected individuals. But how can a defect of Na−K−ATPase modulation lead to impaired renal magnesium conservation? One possible explanation is based on changes in intracellular sodium and potassium levels. Meij and colleagues have suggested that diminished intracellular potassium might depolarize the apical membrane resulting in a decrease in magnesium uptake.[133] Alternatively, an increase in intracellular sodium could impair basolateral magnesium transport, which is presumably achieved by a sodium-coupled exchange mechanism. Another explanation is that the γ-subunit is involved not only in Na−K−ATPase function but is also an essential component of a yet-unidentified ATP-dependent transport system specific for magnesium. Like for calcium, both a specific Mg-ATPase and a sodium-coupled exchanger might exist. Further studies are needed to clarify this issue.

Interestingly, *Fxyd2* −/− mice are viable and without observable pathology.[142] The authors state that there are no abnormalities in serum magnesium and urinary excretion of magnesium under physiological conditions. However, a deletion of one or both alleles in mice does not necessarily mimick the effect of the dominant mutation observed in human disease. Experiments with purified Na−K−ATPase from these mice revealed a decrease in thermostability as well as an increased affinity of the enzyme lacking the γ-subunit for sodium which is in accordance with previous studies.[138]

An interesting feature of IDH linked to the *FXYD2*-G41R mutation is the finding of hypocalciuria. One could only speculate that, similar to GS, a defect in Na−K−ATPase function and energy metabolism might lead to an apoptotic breakdown of the early DCT responsible for magnesium reabsorption, while later parts of the distal nephron remain intact. In patients with the FXYD2 mutant, there is no evidence for renal salt wasting and no stimulation of the RAAS. The finding of hypocalciuria despite no apparent volume depletion apparently contradicts theories that favor an increase in proximal tubular calcium reabsorption due to volume depletion in the GS. In fact, these findings instead point to contrary changes in magnesium and calcium reabsorption in the DCT or in different DCT segments.

KCNA1

Genetic heterogeneity in IDH was demonstrated by the identification of a dominant-negative missense mutation in KCNA1 encoding the voltage-gated potassium channel Kv1.1.[143] The phenotype of affected patients originating from a large Brazilian family included recurrent episodes of muscle cramps, tetanic

episodes, tremor, and muscle weakness starting in infancy. Laboratory analyses revealed isolated hypomagnesemia <0.4 mmol/L while urinary magnesium excretions were found to be inadequately elevated pointing to a renal magnesium leak. Interestingly, no alterations in renal calcium handling were observed.

Interestingly, *KCNA1* mutations had been identified before in patients with episodic ataxia with myokymia (OMIM 160120), a neurologic disorder characterized by periodical appearance of incoordination and imbalance as well as myokymia, an involuntary, spontaneous, and localized trembling of muscles.[144] In addition to muscle cramps and tetany attributed to magnesium deficiency, these symptoms were also present in members of the above mentioned Brazilian kindred with hypomagnesemia.

By using a genome-wide SNP-based linkage strategy followed by subsequent conventional sequencing of candidate genes identified a heterozygous mutation in the *KCNA1* gene cosegregating with the disease.[143] The mutation (c.A763G) leads to a nonconservative amino acid exchange (p.N255D) in the encoded Kv1.1 potassium channel. Functional voltage-gated potassium channels of the KCNA family are composed of tetramers. Coexpression of the mutant N255D-Kv1.1 with wildtype channel subunits in HEK293 cells resulted in a significant reduction in current amplitudes compatible with a dominant-negative effect of the mutant. The dominant-negative effect rather seems to be the result of an impaired gating of the potassium channel tetramer as trafficking to the plasma membrane is preserved.[145]

Kv1.1 expression was demonstrated in kidney in colocalization with TRPM6 in the DCT, presumably at the apical membrane. Glaudemans and coworkers propose a model in which Kv1.1 allows for a hyperpolarization of the DCT cell membrane potential as a prerequisite for TRPM6-mediated magnesium entry (Fig 61.3). Thereby, the authors, for the first time, linked magnesium reabsorption in the DCT to potassium secretion and identified a new dependency between renal magnesium and potassium handling at the molecular level.[143]

CNNM2

Another form of IDH was described recently in which mutations in *CNNM2* were discovered.[146] *CNNM2* (or ACDP2) had been identified before by differential gene expression microarray analysis of genes upregulated in face of hypomagnesemia in mice.[147] The authors had demonstrated that the CNNM2 protein is able to induce the transport of different divalent cations including magnesium.[147] Furthermore, the *CNNM2* gene locus had been linked to serum magnesium levels in a genome-wide association study.[148]

Stuiver and colleagues screened *CNNM2* as a candidate gene in patients with unresolved magnesium wasting disorders and identified heterozygous mutations in two unrelated families with IDH.[146] In affected patients, clinical symptoms and time of manifestation seem to be highly variable with symptoms ranging from convulsive episodes in early childhood to muscle weakness, vertigo, and headaches during adolescence. Other heterozygous carriers from both families remained asymptomatic. Serum magnesium levels in affected individuals were in the range of 0.4-0.5 mmol/L and failed to normalize under oral magnesium supplementation. All other serum electrolytes were found to be normal. As data on urinary calcium excretions vary between the described index patients, it remains unclear if the finding of hypocalciuria seen in a number of other inherited magnesium wasting disorders (see above) is also a concomitant feature in patients with *CNNM2* mutations.

The *CNNM2* gene codes for CNNM2 or Cyclin M2, a transmembrane protein expressed in kidney at the basolateral membrane of TAL and DCT, but also expressed in other organs especially the brain.[146] CNNM2 is one of four members of a protein family with a conserved domain structure (for which this family was previously named ancient conserved domain proteins or ACDP family) with sequence similarities to the bacterial CorC protein involved in bacterial magnesium transport.[149]

Whereas a truncating frame-shift mutation was identified in one of the described families, affected individuals of the second family carry a point mutation leading to a nonconservative amino acid exchange at a conserved residue of the CNNM2 protein (T568I).[146] Whereas trafficking of the mutant T568I-CNNM2 protein was preserved in HEK293 cells, patch clamp analyses of mutant and wildtype CNNM2 revealed a significant reduction in magnesium-sensitive, inwardly rectifying sodium currents. In contrast to previous experiments in Xenopus oocytes by Goytain and Quamme,[147] the authors did not observe significant magnesium currents upon over-expression of CNNM2 in HEK293 cells.[146] The localization data together with the functional studies lead to the assumption that CNNM2 might represent a basolateral magnesium sensing mechanism in renal tubular cells rather than being a molecular component of the yet uncharacterized basolateral magnesium extrusion machinery itself. As Stuiver and colleagues identified a truncating mutation as well as a missense mutation in their families, they only speculate on a reduced amount of functional protein as a putative mechanism for the dominant mode of inheritance.[146] Therefore, it remains a subject of further studies how exactly CNNM2 is involved in basolateral magnesium transport processes.

Renal Cysts and Diabetes Syndrome

HNF1β

Hepatocyte nuclear factor 1β (HNF1β) is a transcription factor critical for the development of kidney and pancreas. Heterozygous mutations in *HNF1B* have first been implicated in a subtype of maturity-onset diabetes of the young (MODY5) before an association with developmental renal disease was reported. The renal phenotype is highly variable including enlarged hyperechogenic kidneys, multicystic kidney disease, renal agenesis, renal hypoplasia, cystic dysplasia, as well as hyperuricemic nephropathy. The association with both symptom complexes lead to the term renal cysts and diabetes syndrome. *HNF1B* mutations are present in heterozygous state, either inherited or *de novo*, and comprise point mutations as well as whole-gene deletions.[150] Interestingly, around 50% of affected individuals present with hypomagnesemia due to renal magnesium wasting.[150,151] The degree of hypomagnesemia is usually mild to moderate ($\sim$0.65 mmol/L), and the defect in renal magnesium conservation is accompanied by the occurrence of hypocalciuria. The *HNF1B* gene encodes a transcription factor regulating the expression of numerous renal genes including the *FXYD2* gene which contains several HNF1β-binding sites in its promotor region.[151] In accordance with the phenotype and in silico data, Adalat and colleagues could show that HNF1β was able to stimulate the expression of *FXYD2* in vitro. Therefore, defective FXYD2 transcription represents a putative mechanism explaining renal magnesium wasting in patients with *HNF1B* mutations.

Isolated Recessive Hypomagnesemia

Geven and colleagues initially reported a form of isolated hypomagnesemia in a consanguineous family indicating autosomal recessive inheritance.[152] Two affected girls presented with generalized convulsions during infancy. Unfortunately, late diagnosis resulted in neurodevelopmental deficits in both patients. A thorough clinical and laboratory workup at 4 and 8 years of age, respectively, revealed serum magnesium levels of 0.5 − 0.6 mmol/L with no other associated electrolyte abnormalities. A ^{28}Mg-retention study in one patient pointed to a primary renal defect, while intestinal magnesium uptake was preserved.[152] Both patients exhibited renal magnesium excretions of 3−6 mmol per day despite hypomagnesemia which confirmed renal magnesium wasting whereas calcium excretion rates were in the normal range.

Using a homozygosity mapping strategy, Groenestege and colleagues identified a candidate interval on chromosome 4q.[50] A subsequent screening of candidate genes within this region resulted in the identification of a homozygous point mutation (c. C3209T) in the *EGF* gene leading to a nonconservative amino acid exchange (p.P1070L) in the encoded pro-EGF protein (pro-EGF) in the two sisters.[50] It was further demonstrated the the mutation impairs the basolateral sorting of pro-EGF in the DCT. The EGF hormone is thought to act at the basolateral side of DCT cells via binding to its EGFR to stimulate magnesium reabsorption via TRPM6.[51] The mechanism is described in more detail in the paragraph on hormonal controls of DCT mediated magnesium reabsorption (see above). Despite acting in a paracrine fashion in the DCT, the authors speculate on a role of EGF as a selectively acting magnesiotropic hormone.[50]

Mitochondrial Hypomagnesemia

In 2004, a mutation in the mitochondrial isoleucine tRNA gene, tRNA^{Ile}, or *MTTI* [OMIM 500005], has been discovered in a large Caucasian kindred.[153] An extensive clinical evaluation of this family was prompted after the discovery of hypomagnesemia in the index patient. Pedigree analysis was compatible with mitochondrial inheritance as the phenotype was exclusively transmitted by affected females. The phenotype includes hypomagnesemia, hypercholesterolemia, and hypertension. Of the adults on the maternal lineage, the majority of offspring exhibit at least one of the mentioned symptoms; approximately half of the individuals show a combination of two or more symptoms, and around one-sixth had all three features. Serum magnesium levels of family members in the maternal lineage greatly vary, ranging from $\sim$0.8 to $\sim$2.5 mg/dL (equivalent to $\sim$0.3 to $\sim$1.0 mmol/L) with approximately 50% of individuals being hypomagnesemic.

Hypomagnesemic individuals (serum magnesium $<$0.75 mmol/L) showed higher fractional excretions (median around 7.5%) than their normomagnesemic relatives in the maternal lineage (median around 3%) which clearly pointed to renal magnesium wasting as causative for hypomagnesemia. Interestingly, hypomagnesemia was accompanied by decreased urinary calcium levels, a finding pointing to the DCT as the affected tubular segment. These findings again suggest an association of magnesium and calcium transport in the DCT as discussed above.

The mitochondrial mutation observed in the examined family affects the tRNA^{Ile} gene *MTTI*.[153] The observed nucleotide exchange occurs at the T nucleotide directly adjacent to the anticodon triplet. This position is highly conserved among species and critical for codon−anticodon recognition. The functional consequences of the tRNA defect for mitochondrial function remain to be elucidated in detail. As ATP consumption

along the tubule is highest in the DCT, the authors speculate on an impaired energy metabolism of DCT cells as a consequence of the mitochondrial defect which in turn could lead to disturbed transcellular magnesium reabsorption. Further studies in these patients might help to deliver insight into the mechanism of distal tubular magnesium wasting in these patients.

Acquired Renal Magnesium Wasting Disorders

Cisplatin and Carboplatin

The cytostatic agent cisplatin and the newer antineoplastic drug, carboplatin, are widely used in various protocols for the therapy of solid tumors.[154] Among diverse side effects, nephrotoxicity receives most attention as the major dose-limiting factor.[155] Carboplatin has been reported to have less severe side effects than cisplatin.[156–159] Hypomagnesemia following renal magnesium wasting is regularly observed in patients treated with cisplatin.[154,159,160] The incidence of magnesium deficiency is greater than 30% but increase to over 70% have been observed with longer cisplatin usage and greater accumulated doses.[160]

Cisplatin exerts a direct damage to renal tubular cells and causes proximal as well as distal tubular dysfunction.[155] Acute cisplatin toxicity involves defective mitochondrial function, decreased ATPase activity, altered cell cation content, and altered solute transport. In the distal tubule, the reabsorption of salt and particularly of magnesium are compromised. In rodents, cisplatin leads to an impairment of proximal tubular function, whereas in dogs and humans morphological changes appear predominantly in the DCT and the collecting duct.[161–163] Thus, the interpolation from animal studies concerning cisplatin toxicity may be misleading, but the evidence from both clinical and experimental studies indicate that the drug acts on distal tubular magnesium transport. As there is no magnesium reabsorption within the CCDs, it is likely that actions within the DCT are responsible for the renal magnesium leak. Using micropuncture, Mavichak et al. showed that magnesium reabsorption was diminished in the distal tubule of rats receiving cisplatin.[162] The molecular mechanisms for the acute, apparently selective effects on magnesium remain undefined. It would be of interest to determine if amiloride retains its magnesium-conserving actions in these patients.[1] The effects of cisplatin may persist months or years later—long after the inorganic platinum has disappeared from the renal tissue.[164,165] Whatever cellular mechanisms are involved they must include genetic alterations of magnesium transport. The fact that cisplatin exerts its cytotoxicity binding cellular DNA may be relevant.[154,156] The chronic alterations in distal tubular ion transport comprise a clinical picture reminiscent of GS.[166] Morphological studies in humans with cisplatin nephrotoxicity could demonstrate focal tubular necrosis predominantly in the DCT, a feature also observed in NCCT-deficient mice suggestive for DCT cell apoptosis.[84,167] Therefore, fluid repletion and especially magnesium supplementation with sufficient doses should routinely be prompted to prevent acute and chronic cisplatin nephrotoxicity and the risk of adverse effects from hypomagnesemia.

Aminoglycosides

Aminoglycosides, such as gentamicin, induce renal impairment in up to 35% of patients, dependent on the dose and duration of administration. In addition, aminoglycosides cause hypermagnesiuria and hypomagnesemia.[168] As many as 25% of patients receiving gentamicin will exhibit hypomagnesemia.[168] The hypermagnesiuric response occurs soon after the onset of therapy; it is dose dependent and readily reversible upon withdrawal. As with adults, neonates also display an immediate increase of calcium and magnesium excretion after gentamicin infusion.[169,170] Magnesium wasting is associated with hypokalemia and hypercalciuria that may also lead to diminished plasma calcium concentrations.[171] This would suggest that aminoglycosides affect renal magnesium and calcium transport in the tubular segments where both are reabsorbed. Experimental studies with animals support this notion.[172] The cellular mechanisms are not completely understood, but hypermagnesiuria and hypercalciuria are observed in the absence of histopathological changes.[173] Because gentamicin is a polyvalent cation, it was postulated that it may have effects on the CaSR.[36,174–176] Activation of this receptor by polyvalent cations inhibits the passive reabsorption of magnesium and calcium in the TAL and active hormone-mediated transport in the DCT leading to renal magnesium and calcium wasting.

Calcineurin Inhibitors

The calcineurin inhibitors cyclosporine and tacrolimus (FK506) are widely prescribed as immunosuppressants to organ transplant recipients and in numerous immunologic disorders. Under this therapy, patients are at high risk of developing renal injury and hypertension. Tubular dysfunction with subsequent disturbance of mineral metabolism is another common side effect. Both drugs commonly lead to renal magnesium wasting and hypomagnesemia.[177] These drugs also cause modest hypercalcemia with hypercalciuria and hypokalemia.[177] The hypomagnesemic effect is probably attenuated by the fall in GFR and reduction in filtered magnesium, but this defect appears to be specific

for magnesium.[178] Calcineurin inhibitor therapy is associated with an inappropriately high fractional excretion rate of magnesium, suggesting impaired passive reabsorption in the TAL or active magnesium transport in the DCT.[179]

Chang and colleagues have reported that cyclosporine reduces claudin-16 expression in the TAL.[180] Furthermore, cyclosporine and tacrolimus have been shown to inihibit PTH-stimulated magnesium uptake in a mDCT cell line.[181] Accordingly, Ledeganck and colleagues could show that cyclosporine decreases the renal expression of TRPM6, TRPM7, NCC, and EGF.[182] In contrast to the above mentioned study by Chang et al.,[180] these authors did not find a decrease in claudin-16 or claudin-19 expression in their rat model.[182] In an previous animal study, Nijenhuis et al. had demonstrated that tacrolimus induces a decrease in TRPV5, calbindin-D28k, and TRPM6 at the mRNA level.[183] They could also show a decrease in TRPV5 and calbindin-D28k at the protein level. These effects appeared to be specific, as no morphologic features of tubular toxicity were observed. Finally, Ledeganck and coworkers could demonstrate that the EGF-mediated increase in TRPM6 abundance was abrogated by cyclosporine.[182] As mentioned above, cyclosporine, beyond its effect on magnesium transport in the DCT, downregulates the sodium chloride cotransporter NCCT in the DCT resulting in renal salt wasting.[182]

With respect to magnesium, it is interesting to note that TRPM6 expression in the intestine was not changed upon tacrolimus administration. It is not known whether these drugs act through calcineurin, which is the intracellular receptor for these agents. It is speculated that FK506-binding proteins, which are known to bind and regulate the calcium-permeable transient receptor potential-like cation channels, might be involved because tacrolimus disrupts this binding.[184] In analogy, consider that certain FKBPs might also regulate TRPV5 or TRPM6 expression or activity. Hypomagnesemia has been implicated as a contributor to the nephrotoxicity and arterial hypertension associated with calcineurin inhibitors. Mervaala et al. could demonstrate that the adverse effects of cyclosporine in spontaneously hypertensive rats largely depend on dietary sodium and that these adverse effects can be prevented by magnesium supplementation.[184] Magnesium supplementation also had a beneficial effect on cyclosporine nephrotoxicity in a rat model used by Miura and colleagues.[185]

EGF Receptor Antibodies

The EGF hormone axis has been implicated in renal magnesium handling by the discovery of a homozygous mutation in the *EGF* gene in a family with isolated recessive hypomagnesemia (IRH) (see above).[50] The way for these findings was paved by the observation that anticancer treatments with monoclonal antibodies against the EGFR resulted in renal magnesium wasting and hypomagnesemia.[186] Of note, patients treated with EGFR targeting antibodies (cetuximab, panitumumab) for colorectal cancer usually receive a combination therapy with platinum compounds potentially aggravating the effects on serum magnesium levels. A significant number of patients receiving such a chemotherapeutic regimen show decreasing serum magnesium concentrations over time.[186,187] 24 hour urine collections as well as magnesium loading tests in single patients demonstrated a defect in renal magnesium conservation. Together with the genetic findings in IRH due to a pro-EGF mutation, these findings imply a selective effect of EGFR targeting on transcellular magnesium transport in the DCT. There, TRPM6 mediated magnesium uptake into DCT cells is stimulated by basolaterally secreted EGF via its receptor (EGFR).[50] The initial report of Tejpar and colleagues describes oral as well as intravenous magnesium supplementation in patients with different degrees of hypomagnesemia after cetuximab treatment, however with limited success regarding serum magnesium levels.[186] Subsequent studies investigated the development of hypomagnesemia under EGFR targeting therapy in relation to the antitumor effect and outcome of patients.[188,189] They found that the development of hypomagnesemia is correlated with the tumor response rate and outcome. Patients with a reduction of serum magnesium >50% (!) showed a better tumor response rate and a better overall survival.[189] The authors therefore consider serum magnesium as an easily measurable biomarker for efficacy in colorectal cancer patients treated with cetuximab.

Proton-Pump Inhibitors (PPIs)

Over the last 20 years, PPIs for the reduction of gastric acidity have emerged to one of the most widely prescribed classes of drugs worldwide.[190] Due to the large number of patients, even rare side effects could become apparent that remained undiscovered during initial clinical trials. Hypomagnesemia, clinically apparent as muscle cramps, tetany, nausea, vomiting, but also cerebral convulsions, has been observed in a small but significant number of patients receiving PPIs. It is well conceivable that in a substantially larger number of patients, the relationship between low serum magnesium levels and the use of PPIs remained unrecognized. A recent review summarizing the data from previous publications reveals severely lowered serum magnesium levels below 0.4 mmol/L with concomitant hypocalcemia, a laboratory constellation reminiscent of HSH due to TRPM6 defects.[190] A previous report on hypomagnesemia following PPI treatment had already

described suppressed PTH levels during phases of severe hypomagnesemia as a probable cause of hypocalcemia (as in HSH).[191] Although a number of patients additionally receive diuretics, this finding does not explain the extraordinary degree of magnesium deficiency observed in patients receiving PPIs.

What is the mechanism underlying hypomagnesemia in PPI users? Data regarding urinary magnesium excretions in hypomagnesemic PPI are contradictory. Fractional magnesium excretions were reported to be low in face of profound hypomagnesemia pointing to an intact tubular magnesium reabsorption. However, as observed in HSH patients, a renal magnesium leak might only become apparent if serum magnesium levels reach a certain threshold. An alternative explanation could involve a disturbed intestinal reabsorption of magnesium. Unfortunately, the molecular link between proton-pump inhibition and hypomagnesemia remains unclear so far. In regard of the severe degree of hypomagnesemia, possible molecular mechanisms include an inhibition of TRPM6 leading to a combined intestinal and renal defect, but also a disturbance of ATPases or ATPase-subunits other than gastric H^+-K^+-ATPase involved in epithelial magnesium transport.

In any case, it is recommended to monitor serum magnesium levels patients receiving PPIs, particularly those with concomitant cardiac disease and risk for arrhythmia. Contrariwise, attention should be drawn to the medication list of patients presenting with hypomagnesemia and secondary hypocalcemia due to hypoparathyroidism.

Miscellaneous Agents

A number of antibiotics, tuberculostatics, and antiviral drugs may result in renal magnesium wasting.[33,168] The cellular bases by which these agents lead to abnormal magnesium reabsorption are still largely unknown. Many are associated with general cytotoxicity. Amphotericin B may lead to acquired distal tubular acidosis, which in turn reduces renal magnesium reabsorption.[33] Pamidronate used in the treatment of tumor-associated hypercalcemia has been reported to cause transient hypomagnesemia.[192] The cellular mechanisms are difficult to predict since this drug is used in patients with hypercalcemia that may aggravate renal magnesium wasting.

Metabolic Acidosis

It has long been known that systemic acidosis is associated with renal magnesium wasting. Acute metabolic acidosis produced by infusion of NH_4Cl or HCl leads to significant increases in urinary magnesium excretion.[1,33] Chronic acidosis also leads to urinary magnesium wasting which, as with the acidosis itself, may be partially corrected by the administration of bicarbonate.[1] In contrast to metabolic acidosis, acute and chronic metabolic alkalosis consistently leads to a fall in urinary magnesium excretion.[1]

The cellular basis for the acid-base effects on magnesium transport appears to be diverse. Di Stefano et al. perfused isolated mouse cTAL segments harvested from mice maintained on alkaline drinking water (20 mM sodium bicarbonate) for three days.[193] They showed that alkalosis doubled magnesium absorption from control levels without a change in transepithelial voltage. They interpreted these data to indicate that alkalosis changes the permeability of the paracellular pathway so that magnesium moves passively through the pathway to a greater degree resulting in greater magnesium absorption. The effects of metabolic acidosis were not determined in this study.[193] Nevertheless, these data suggest that pH influences the paracellular pathway perhaps through alteration of claudins. Dai et al. have used an mDCT cell line to determine the effects of extracellular pH changes on cellular magnesium uptake.[36] The results of these experiments showed that acute alkalosis markedly enhances magnesium uptake, whereas acidosis diminishes transport.

Metabolic acidosis of any etiology would be expected to lead to diminished magnesium reabsorption in the distal tubule. Diabetic subjects frequently present with hypomagnesemia and cellular magnesium deficiency.[194–196] This is, in part, due to urinary magnesium wasting.[197] In combination, insulin deficiency and ketoacidosis of uncontrolled diabetes diminish magnesium transport in TAL[198,199] and DCT,[36] resulting in exacerbation of renal magnesium wasting.

Phosphate Restriction and Phosphate Depletion

One of the hallmarks of hypophosphatemia and cellular phosphate depletion is the striking increase in urinary calcium and magnesium excretion.[32,33,36] The hypermagnesiuria may be sufficiently large to lead to overt hypomagnesemia.[200] The increase in divalent ion excretion in both human disease and experimental animal models occurs within hours of dietary phosphate restriction. Three mechanisms have been proposed to account for the increased renal excretion: (1) mobilization of calcium and magnesium from bone, (2) suppression of PTH secretion, and (3) disturbed tubular transport.[36]

It is evident from clearance experiments that the urinary excretion of divalent cations in phosphate-depleted human subjects is inappropriate for the plasma concentration, supporting the notion of defective tubular transport.[200]

Dai et al. have shown that cellular phosphate depletion leads to diminished magnesium uptake in mDCT cells.[201] This observation supports the notion that the DCT may be involved, in part, in decreased

magnesium absorption and increased magnesium excretion associated with hypophosphatemia. The reasons why cellular phosphate depletion leads to diminished magnesium reabsorption are not known.

Cellular Potassium Depletion

Hypokalemia and cellular potassium depletion are associated with diminished magnesium absorption within TAL and DCT that may lead to increased magnesium excretion.[1] The increase in urinary excretion of divalent cations may be explained by the effects of potassium depletion on salt absorption in the TAL. Chloride conservation is impaired in potassium-depleted rats, which may be related to altered basolateral Na−K−ATPase activity resulting in impaired apical NKCC2-mediated sodium chloride cotransport.

To date, there is no direct evidence for changes in magnesium absorption in the TAL with potassium depletion. However, as magnesium and calcium are absorbed by passive mechanisms, it is probable that impaired salt transport can lead to diminished divalent cation absorption in this segment.

Studies using isolated mDCT cells suggest that potassium depletion may have additional effects on magnesium transport in the DCT.[202] Cellular potassium depletion results in the inhibition of magnesium uptake into mDCT cells, as determined by microfluorescence. The exact mechanism for the disturbed magnesium entry is not known, but might involve a diminished potassium excretion via Kv1.1 (KCNA1) as suggested by the discovery of mutant Kv1.1 in a dominantly inherited form of hypomagnesemia (see above).[143] The authors propose a model in which Kv1.1 activity is critical for the establishment and maintenance of the DCT cell membrane potential as a prerequisite for magnesium entry via TRPM6. Further studies are required to fully explain the defective magnesium transport in the DCT associated with cellular potassium depletion.

Experimental and clinical data suggest a close association of serum magnesium, potassium, and phosphate levels. Crook et al. reported a twofold increase in the prevalence of hypophosphatemia (plasma phosphate <0.8 mmol/L) and a sixfold increase in hypokalemia (plasma potassium <3.5 mmol/L) in patients with hypomagnesemia (plasma magnesium <0.70 mmol/L).[203] A trilogy consisting of hypomagnesemia, hypophosphatemia, and hypokalemia was also found in 8% of patients with hypomagnesemia and 17% of patients with severe hypomagnesemia (plasma magnesium <0.50 mmol/L). The evidence suggests that hypokalemia and hypophosphatemia may have profound effects on tubular magnesium transport. Many of the syndromes associated with potassium depletion and phosphate depletion are complicated by concurrent alterations in acid-base balance.[203] There is evidence that acid-base changes have different effects on magnesium transport relative to potassium or phosphate depletion, such that the three disturbances may act in an additive manner to compromise renal magnesium conservation.[36]

Calcium Channels

Joost G.J. Hoenderop and René J.M. Bindels

Department of Physiology, Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Centre, The Netherlands

CA^{2+} CHANNELS IN THE KIDNEY

The kidney plays an eminent role in the maintenance of the Ca^{2+} balance by regulating the Ca^{2+} excretion of the body. Renal epithelial cells are unique in their ability to mediate vectorial transport of Ca^{2+} between the luminal and basolateral compartments. The initial step in this process is the Ca^{2+} influx across the luminal membrane. In addition, Ca^{2+} influx is crucial to facilitate Ca^{2+}-dependent signal transduction processes in the renal cell. In general, Ca^{2+} is postulated to enter the epithelial cell via Ca^{2+}-permeable channels present at the plasma membrane under the influence of a steep inwardly-directed electrochemical gradient. In the last decade a series of cation channels, including voltage-dependent and independent channels, has been identified that could facilitate the entry of Ca^{2+} ions in the epithelial cells of the kidney.

Voltage-Dependent Ca^{2+} Channels

Voltage-dependent Ca^{2+} channels have been well characterized in excitable tissues and at least four different types including, L, N, T and P, can be distinguished on the basis of electrophysiological and pharmacological properties.[1] The molecular identity and precise localization of these Ca^{2+} channels along the nephron is not well understood. Previous studies from Yu and colleagues have demonstrated the existence of voltage-dependent Ca^{2+} channels in the kidney (Table 62.1).[2,3] They identified a gene transcript encoding the pore-forming alpha 1-subunit of a Ca^{2+} channel (alpha 1A) in the glomerulus and the distal convoluted tubule (DCT). Skott and coworkers assessed the distribution of the identified alpha(1G)-subunit encoding a voltage-dependent Ca^{2+} channel with T-type characteristics.[4] RT-PCR analysis of microdissected rat nephron segments revealed alpha(1G) expression in DCT, CNT, cortical collecting duct (CCD), and inner medullary collecting duct (IMCD) (Table 62.1). Immunohistochemistry on sections of rat kidneys using an anti-alpha(1G) antibody demonstrated labeling at the apical plasma membrane domains of DCT, CNT and IMCD principal cells. Another study from Bacskai and Friedman examined the parathyroid hormone (PTH)-sensitivity of Ca^{2+} influx in single cultured cells originating from distal renal tubules by measuring the intracellular Ca^{2+} concentration. They found that PTH activates dihydropyridine-sensitive Ca^{2+} channels.[5] Tan and Lau, described a 25 pS, cAMP-sensitive apical Ca^{2+} channel in rabbit kidney CNT cells, that was inhibited by dihydropyridine agonists and depolarization.[6] The properties of these Ca^{2+} channels are largely conferred by their pore-forming alpha1 subunit. In general, voltage-sensitive Ca^{2+} channels are heteromeric, multisubunit proteins, as has been clearly demonstrated for the skeletal muscle and brain channels, and their properties are not only determined by the pore-forming alpha1-subunit itself, but also depend on the presence of regulatory beta subunits. To identify the accessory beta subunit of DCT/CNT Ca^{2+} channels, degenerate primers based on published beta subunit sequences were used to amplify rat kidney cDNA by the polymerase chain reaction (PCR). Alternatively, spliced transcripts of three beta-subunit genes (beta-2,3,4) were identified.[3] Northern blot analysis indicated that beta 4-subunit is preferentially expressed in kidney cortex. Transcripts of all three beta-subunit genes were detected by PCR in microdissected nephron segments, but only the beta 4-subunit was found in DCT/CNT. At present, the physiological significance of these

TABLE 62.1 Characteristics of Ca^{2+} Channels in the Kidney

	Channel Isotype	Selectivity pCa/pNa [125,9]	Segmental distribution
Voltage-dependent Ca^{2+} channels	Alpha 1A	~1000	G, DCT[2]
	Alpha 1G	~1000	DCT, CNT, CD[4]
Other Ca^{2+} permeable channels	TRPC1	1	G, PT, TAL, RV[12,126]
	TRPC3	1.5	G, CD, RV[12,126]
	TRPC4	1.1; 7	G, RV[12,126]
	TRPC5	1.8; 9	G, RV[12,126]
	TRPC6	5	G, CD, RV[12,126]
	TRPV4	6	ATL, TAL, DCT, CNT[29]
	TRPV5	107	DCT, CNT[7]
	TRPV6	130	DCT, CNT, CD[7]
	TRPM3	1.6	CNT, CD[127]
	TRPM6	7	DCT[20]
	TRPP2	5	DCT, CD[128,24]

Ca^{2+} permeable channels that were detected in the kidney are listed in the table. G, glomerulus; PT, proximal tubule; ATL, ascending thin limb of Henle; TAL, thick ascending limb of Henle; DCT, distal convoluted tubule; CNT, connecting tubule; CCD, cortical collecting duct; CD, collecting duct; RV, resistance vessels; n.d., not determined.

voltage-dependent Ca^{2+} channels in transepithelial Ca^{2+} transport remains unclear. Functional Ca^{2+} influx measurements were only performed in non-polarized single cell systems. In addition, pharmacological studies in polarized primary cultures of rabbit CNT and CCD have demonstrated that voltage-dependent Ca^{2+} channel blockers do not inhibit transepithelial Ca^{2+} transport.[7] Additional studies are needed to address the functional relevance of voltage-dependent Ca^{2+} channels in the process of transepithelial Ca^{2+} transport in the kidney.

Other Ca^{2+} Channels

Non-voltage-gated Ca^{2+} channels in the kidney are mainly represented by the transient receptor potential (TRP) superfamily of proteins consisting of Ca^{2+} permeable channels. TRP channels can be divided by sequence homology into at least six subfamilies, designated TRPC (canonical), TRPV (vanilloid), TRPM (melastatin), TRPP (polycystins, PKD-type), TRPA (ankyrin), TRPML (mucolipin), and the more distant subfamily TRPN (no mechano-receptor potential or nomp).[8,7,9,10] Mammalian homologues of the first identified *Drosophila* TRP gene encode a family of at least 20 ion channel proteins (Figure 62.1). Mutations and/or dysfunction of TRP proteins produce many renal diseases, including Mg^{2+} wasting, Ca^{2+}-related disorders and polycystic kidney diseases.

TRPC Channels

TRP channels are widely expressed and facilitate diverse functions, ranging from thermal, tactile, taste, osmolar, and fluid flow sensing to transepithelial ion transport. TRPC1 was the first member of the mammalian TRP family purported to form an ion channel. TRPC channels are ubiquitously expressed in mammalian tissues.[11,9,10] TRPC1, 3, 4, 5 and 6 mRNA and protein expression was detected in freshly isolated rat renal resistance vessels and glomeruli suggesting that these channels may play a role in mediating voltage-independent Ca^{2+} entry to facilitate cellular signal transduction processes.[12] It should be noted that members of the TRPC family are non-selective divalent ion channels (Table 62.1). Interestingly, TRPC1 dysfunction might be important in the development of diabetic nephropathy while TRPC6 seems to be an important target for the treatment of both genetic and acquired glomerular diseases.[13,14] Finally, TRPC3 plays a key role in the influx of Ca^{2+} into principal cells.[15]

TRPM Channels

The discovery and subsequent characterization of members of the TRPM family of cation channels has highlighted new insights into unknown aspects of ion (cellular) homeostasis regulation. The groups of Konrad and Sheffield reported that hypomagnesemia associated with secondary hypocalcemia (HSH) is an autosomal recessive disease that is genetically linked to TRPM6.[16,17] This disease is primarily due to defective intestinal Mg^{2+} absorption and affected individuals show neurologic symptoms of hypomagnesemic hypocalcemia, including seizures and muscle spasms during infancy.[18] Renal Mg^{2+} conservation has been reported to be normal in most patients. In some cases, however, a renal leak has been documented suggesting impaired renal Mg^{2+} reabsorption. Patients studied by Konrad et al. and others showed inappropriately high fractional Mg^{2+} excretion rates with respect to their low serum Mg^{2+} levels.[18] Hypocalcemia is secondary to parathyroid failure resulting from Mg^{2+} deficiency. TRPM6 is a member of the long TRPM family and is similar to TRPM7 (also known as TRP-PLIK[8]), a unique bifunctional protein known as a Mg^{2+} and Ca^{2+}-permeable cation channel with protein kinase activity.[19] TRPM6 has a ~4 fold higher affinity for Mg^{2+} compared to Ca^{2+}, but is clearly permeable for Ca^{2+} (Table 62.1).[20] TRPM6 is exclusively expressed in the early part of the DCT consistent with its role being

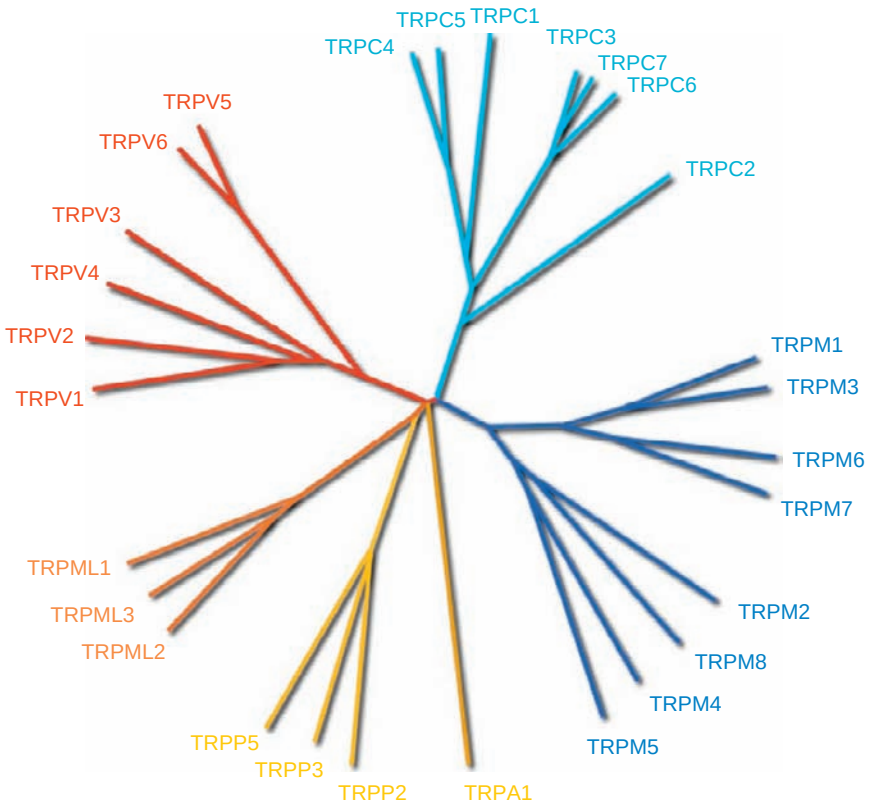

FIGURE 62.1 **Mammalian TRP family tree.** The evolutionary distance between the TRP channels is shown by the total branch lengths in point accepted mutations (PAM) units, which is the mean number of substitutions per 100 residues. The tree was calculated using the neighbor-joining method for human, rat and mouse sequences.[8]

the gatekeeper of active transepithelial Mg^{2+} transport.[18,20] In addition, other TRPM channels have been detected in kidney. Northern and immunoblot analysis demonstrated abundant expression of TRPM3 in human kidney.[21] Functional studies indicated that TRPM3 is permeable for Ca^{2+} and activated by reduction of extracellular osmolarity (Table 62.1).[21] Immunohistochemical localization studies should provide more information about the physiological function of TRPM3 in the kidney.

TRPP Channels

Growing evidence has emerged that polycystins are ion channels or regulators of ion channels. This suggests that autosomal-dominant polycystic kidney disease (ADPKD), which arises from mutations in polycystins, is a form of ion channel disease. ADPKD is a major, inherited nephropathy affecting over 1:1000 of the world wide population.[22,23] The disease is caused by mutations in two genes, PKD1 and PKD2, which encode for the proteins, polycystin-1 and polycystin-2 (TRPP2), respectively. Although disease-associated mutations have been identified in these two proteins, the sequence of molecular events leading to clinical symptoms is still unknown. Polycystin-1 resides in the plasma membrane and it is proposed to function in cell-cell and cell-matrix interactions, whereas TRPP2 is concentrated in the endoplasmic reticulum (Table 62.1). In contrast to the nonselective cation channel TRPP2, TRPP1 is a large, integral membrane protein that structurally resembles a receptor or adhesion molecule. TRPP1 and TRPP2 form a protein complex in cilia, which are microtubule-based organelles that function as cellular mechanosensors. Flow of fluid causes cilia to bend, which in turn results in a TRPP1/TRPP2 complex-dependent increase in intracellular Ca^{2+} levels, directing attention to the regulation of intracellular Ca^{2+} as a possible misstep that participates in cyst formation.[22,23] Immunostaining of human and mouse renal tissues has demonstrated widespread and developmentally regulated TRPP2 expression, with the highest level in thick ascending limb (TAL) and DCT.[24]

TRPV Channels

Plant and colleagues identified TRPV4 as a Ca^{2+}-permeable, non-selective cation channel that exhibits spontaneous activity in isotonic media and is rapidly activated by a decrease in extracellular osmolarity, cell swelling, heat or phorbol esters.[25,26,27] TRPV4 is expressed at high levels in kidney and here subtle changes in osmolarity result in significant changes in the intracellular Ca^{2+} concentration. Here, TRPV4 is candidate for a molecular sensor that confers osmosensitivity.[25,27] Liedtke and Friedman showed that TRPV4

knockout mice have reduced water intake and become more hyperosmolar compared to wild-type littermates.[28] The response to both hyper- and hypoosmolar stimuli was impaired in these knockout mice. Immunohistochemical studies have shown that the expression of this osmotically-responsive cation channel is restricted to water-impermeant nephron segments.[29] The strongest expression of TRPV4 was observed along the basolateral membrane in the ascending thin limb (ATL) and the thick ascending limb (TAL) as was DCT and CNT. TRPV4 was absent from the proximal tubule (PT) and decending thin limb (DTL). These data imply a role for TRPV4 in the response of renal epithelial cells to anisotonicity, particularly in the hypotonic luminal milieu of TAL and DCT, and the potentially hypotonic luminal milieu of the CD.[29]

The most Ca^{2+}-selective channels of the TRP superfamily are the epithelial Ca^{2+} channels TRPV5[30] and TRPV6.[31] These latter channels are predominantly expressed in organs that mediate transepithelial Ca^{2+} transport.[7] Unique properties distinguish them from other TRP channels and studies by several groups have demonstrated that TRPV5 and TRPV6 exhibit all the characteristics being the gatekeepers of active Ca^{2+} transport in kidney and small intestine, respectively. These epithelial Ca^{2+} channels of the TRPV family have been studied in great detail and are, therefore, outlined in the following paragraphs.

EPITHELIAL Ca^{2+} CHANNELS: TRPV5 AND TRPV6

cDNA and Primary Protein Structure

The epithelial Ca^{2+} channel family is restricted to two members and genomic cloning demonstrated that these Ca^{2+} channels are transcribed from distinct genes juxtaposed on human chromosome 7q35, which suggests an evolutionary gene duplication event.[7,32] TRPV5 and TRPV6 are completely conserved in terms of exon size in the coding regions and they share similar intron-exon structures with the other TRP genes. To date, epithelial Ca^{2+} channels have been cloned from several species including pufferfish, rabbit, rat, mouse and human. TRPV5 and TRPV6 exhibit an overall homology of about 75%. Remarkably, several domains in TRPV5/6 are completely conserved within these species including the core structure of the protein consisting of 6 TM segments and the pore region, ankyrin repeats, PDZ motifs and putative protein kinase phosphorylation sites (Figure 62.2).[7] Four TRP-channel subunits will form the functional Ca^{2+} channel. In addition, it was demonstrated that both epithelial channels are high mannose- and complex-glycosylated.[33] PDZ motifs and ankyrin repeat domains are present in a diverse range of receptors and ion channels including other members of the TRPV subfamily. PDZ motifs are recognized by PDZ domains that are modular protein interaction domains playing a role in protein trafficking and protein complex assembly. In general, ankyrins connect ion channels, transporters and cell adhesion molecules to the spectrin-based cytoskeletal elements in distinct membrane domains.[34]

Distribution of TRPV5 and TRPV6

The renal expression profile of TRPV5 has been studied in detail.[7] In different species, it was demonstrated that TRPV5 co-localizes with the Ca^{2+} transport proteins, including calbindin-D_{28K} and the extrusion proteins, the plasma membrane ATPase 1b (PMCA1b) and the Na^{+}-Ca^{2+} exchanger type 1 (NCX1) in the late

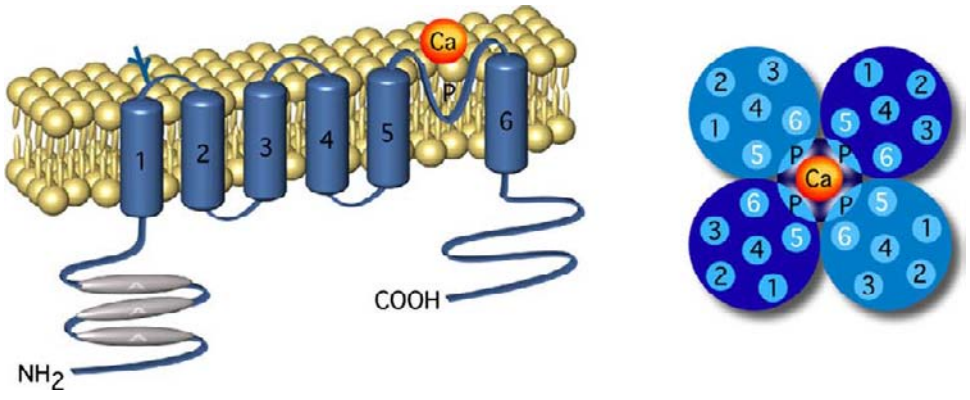

FIGURE 62.2 The epithelial Ca^{2+} channels are ~730 amino acids long with a predicted molecular mass of ~85 kDa. TRPV5 and TRPV6 contain a core domain consisting of 6 TM segments. In addition, a large cytosolic amino- and carboxyl-terminus are present containing ankyrin repeats. Between TM5 and TM6 there is a short hydrophobic stretch predicted to be the pore-forming region of these channels. Four channel subunits will form the functional Ca^{2+} channel.

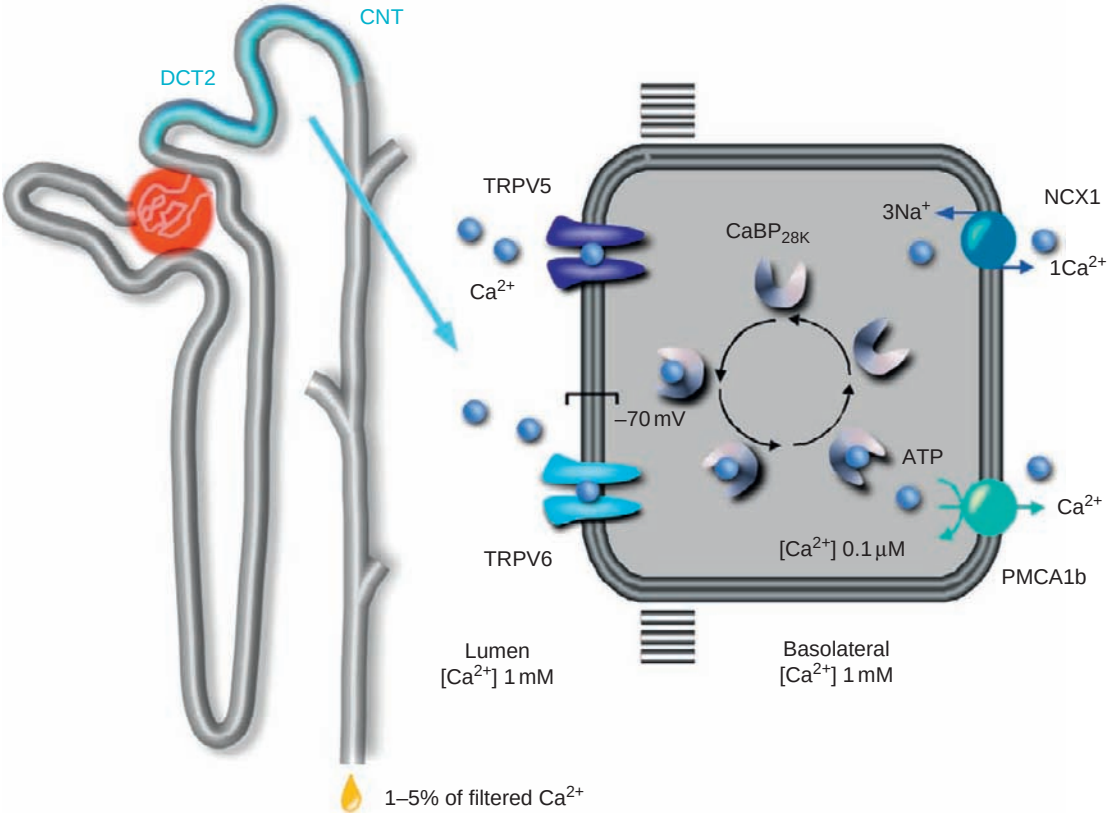

FIGURE 62.3 **Transepithelial Ca^{2+} transport is carried out as a 3-step-process.** Following entry of Ca^{2+} through the (hetero)tetrameric epithelial Ca^{2+} channels, TRPV5 and TRPV6, Ca^{2+} bound to calbindin diffuses to the basolateral membrane. At the basolateral membrane, Ca^{2+} is extruded via a ATP-dependent Ca^{2+}-ATPase (PMCA1b) and a Na^+-Ca^{2+}-exchanger (NCX1). In this way, there is net Ca^{2+} transport from the luminal space to the extracellular compartment. The active form of vitamin D, 1,25-$(OH)_2D_3$, stimulates the individuals steps of transepithelial Ca^{2+} transport by increasing the expression levels of the luminal Ca^{2+} channels, calbindins and the extrusion systems.

DCT (DCT2) and the CNT (Figure 62.3). Transepithelial Ca^{2+} transport is generally envisaged as a three step process consisting of passive entry of Ca^{2+} across the apical membrane, cytosolic diffusion of Ca^{2+} bound to calbindin-D_{28K} and active extrusion of Ca^{2+} across the opposite basolateral membrane via PMCA1b and NCX1. The highest immunocytochemical abundance of TRPV5 was found in DCT2 with a gradual decrease along CNT. A minority of cells along CNT lacked immunopositive staining for TRPV5 and the other Ca_2^+-transporting proteins. These negative cells were identified as intercalated cells.

In contrast to TRPV5, which is mainly expressed in the kidney, TRPV6 shows a more ubiquitous expression pattern. TRPV6 expression was predominantly found in the brush-border membrane of the small intestine where it co-localizes with calbindin-D_{9K} and PMCA1b in agreement with the expected properties being the gatekeeper in active Ca^{2+} absorption.[7,32] Recently, TRPV6 was detected in mouse kidney along the apical domain of DCT2 through inner medullary collecting duct (IMCD). TRPV6 co-localizes with TRPV5 and the other Ca^{2+} transport proteins in DCT2 suggesting a role in Ca^{2+} reabsorption.[35] In addition, the protein is also detected in the intercalated cells and the IMCD that are not involved in transepithelial Ca^{2+} transport pointing to additional functions of TRPV6. Thus, the precise role of this epithelial Ca^{2+} channel in the kidney remains to be established, but given the widespread distribution of TRPV6 throughout the nephron segments functions could include Ca^{2+} reabsorption, Ca^{2+} signaling and others.

Biophysical Properties

In Human Embryonic Kidney (HEK) 293 cells heterogeneously expressing TRPV5, currents through the channel can be activated under conditions of high intracellular Ca^{2+} buffering by hyperpolarizing voltage steps. In divalent cation free solutions, large inward currents are observed, which show a typical time-dependent increase (gating) that remains constant for more than one minute.[36] Outward currents are negligible indicating that the channel is nearly

completely inwardly rectifying. In analogy to voltage-dependent Ca^{2+} channels, permeation through TRPV5/6 can by described by "repulsion" pore models considering a pore consisting of two high affinity binding sites, whereby the double occupation of the two binding sites by either Na^+ or Ca^{2+} provides the "drive" for Ca^{2+} conduction due to mutual repulsion of the two cations or by a three binding-site model in which two low affinity sites flank a high affinity binding site for Ca^{2+}. Importantly, the current through TRPV5 and TRPV6 is carried exclusively by Ca^{2+} at physiological extracellular Ca^{2+} concentrations. In the situation where Ca^{2+} is absent single channel Na^+ currents through TRPV5 can be measured in inside-out patches.[37,38] Given the low conductance of these channels in the presence of extracellular Ca^{2+} reliable single channel measurements are technically not feasible.

A characteristic aspect of currents through the epithelial Ca^{2+} channels is the inactivation at negative membrane potentials. This inactivation is nearly complete if Ca^{2+} is the charge carrier and is significantly delayed when $Ca_2{}^+$ is substituted for Ba^{2+} or other divalents indicating that the process is Ca^{2+}-dependent. Furthermore, currents of monovalent cations through these Ca^{2+} channels do not inactivate. Repetitive stimulation of TRPV5 and TRPV6 currents by short hyperpolarizing pulses consequently result in a decay of the current. The slow recovery from inactivation in divalent cation free solution after the Ca^{2+}-dependent decay is a further typical hallmark of these Ca^{2+} channels. Although the above described structural aspects and basic electrophysiological properties of TRPV5 and TRPV6 are rather similar, some differences exist between these homologous channels including permeability of divalent cations, kinetics of Ca^{2+}-dependent inactivation and recovery from inactivation.[7] For instance, TRPV5 shows a higher permeability for Ba^{2+} compared to TRPV6, e.g., the current ratio I_{Ba}/I_{Ca} is ~0.9 for TRPV5, but only ~0.4 for TRPV6. TRPV6 clearly shows a fast component of inactivation which is less prominent for TRPV5, e.g., time to 10% inactivation at hyperpolarizing steps to−100 mV is ~25 ms for TRPV5 but only ~40 ms for TRPV6. Interestingly, these typical differences could be explained by sequence differences between TRPV5 and TRPV6. Interestingly, the structural determinants of these differences appear not to be located in either the amino- or carboxyl-terminus, but in the intracellular TM2-TM3 linker sequence. Substitution of this TM2−TM3 linker of TRPV6 to TRPV5 confers the kinetic and permeation phenotype of TRPV6 to TRPV5, whereas exchanging the amino- or carboxyl-termini is ineffective.[39] Mutation studies by Suzuki and co-workers demonstrated that a histidine residue at position 587 in the carboxyl-terminus close to TM segment 6 of TRPV6 affect the inactivation behavior of TRPV6.[40] In addition some distinct pharmacological differences exist, e.g., ruthenium red is a 100-fold more potent blocker for TRPV5 than TRPV6 (IC_{50} ~9 μM for TRPV6 but ~100 nM for TRPV5). Furthermore, TRPV5 is approximately four times more sensitive to Cd^{2+} blockage than TRPV6 (IC_{50} ~70 nM for TRPV5 but ~260 nM for TRPV6) .[7]

Ion Selectivity

To date, TRPV5 and TRPV6 are the most Ca^{2+}-selective channels in the TRP superfamily. The unique permeation property in the epithelial Ca^{2+} channels is not conserved in the TRPV subfamily, which shares the highest homology with TRPV5 and TRPV6. TRPV5 and TRPV6 display P_{Ca}/P_{Na} values of more than 100 whereas a permeation sequence of $Ca^{2+} > Ba^{2+} > Sr^{2+} > Mn^{2+}$ has been reported.[41,42,43,36] The permeation profile of monovalent cations is $Na^+ > Li^+ > K^+ > Cs^+$.[41,37,44,43,36]

Nilius and co-workers have demonstrated that the molecular determinants of the Ca^{2+} selectivity and permeation of TRPV5 and TRPV6 reside at a single aspartate residue in the pore-forming region (TRPV5-D542 and TRPV6-D541) (Figure 62.4).[44] Neutralization of these negatively charged amino acid residues affects the high Ca^{2+} selectivity of the epithelial Ca^{2+} channels. These data suggest that high Ca^{2+} selectivity in TRPV5 and TRPV6 depends on a ring of four aspartate residues in the pore region, similar to the ring of four negative residues (aspartates and/or glutamates) in the pore of voltage-dependent Ca^{2+} channels.[45,7,46] Most likely, D542/D541 is the narrowest part of the selectivity filter with a diameter of approximately 5.2 Å and forms part of the high affinity-binding site for Ca^{2+}. A detailed analysis of the structure of the TRPV5 and TRPV6 pores has been recently published (Figure 62.4).[45,46] The amino acid residues facing the pore were determined by cysteine scanning mutagenesis (SCAM). Cysteines introduced in a region preceding D542 for TRPV5, and D541 for TRPV6, displayed a cyclic pattern of reactivity to cysteine reacting agents indicative of a pore helix. This pattern of covalent modification of cysteines supports a KcsA-homology based 3-D model (Figure 62.4). In addition, the pore region of TRPV5 and TRPV6 contains additional negatively charged amino acid residues that only have minor effects on the Ca^{2+} permeation properties. In another study, the role of D542 for blockage of monovalent currents through TRPV5 by Ca^{2+} and Mg^{2+} was supported, however, not for determining Ca^{2+} permeability.[47] However, all of our data including recent findings from concatemers[48] and a detailed

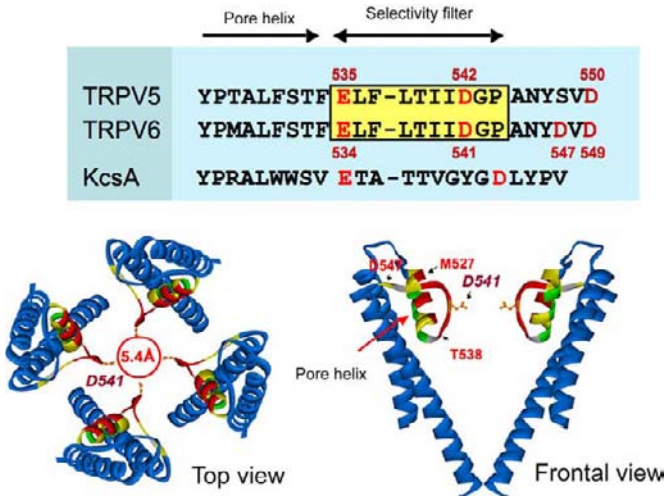

FIGURE 62.4 *Upper part:* Alignment of the pore regions of TRPV5, TRPV6 and the potassium channel KcsA (*NCBI* accession numbers CAB40138 for TRPV5, AAD47636 for TRPV6 and S60172 for KcsA). The boxed sequences represent the putative selectivity filter of the channels. The amino-terminal part of this pore structure likely represents a putative pore helix. *Lower part:* Model for the TRPV6 pore region, based on the KcsA structure. Views of the structure are shown, looking sideways at two opposite subunits (*left*) or looking down from the external solution to the complete homotetrameric channel (*right*). At the narrowest point, formed by the acidic side chain of Asp 541 (orange), the pore has a diameter of 5.4 Å. Blue residues correspond to the residues in TM5 and TM6 (TM1 and TM2 in KcsA), whose accessibility was not tested in this study. Amino acids that were subjected to substituted cysteine accessibility method SCAM analysis (residues P526 to D547) are colored in green, yellow, red or grey: residues in red reacted rapidly to Ag^{+} (reaction rate $>5*10^{6}$ M^{-1} s^{-1}), residues in yellow reacted with Ag^{+} at a rate $<5*10^{6}$ M^{-13} s^{-13}, and residues in green did not show significant reactivity to Ag^{+}. Residues where cysteine substitution resulted in non-functional channels are marked in grey. The figure was prepared using DS ViewerPro 5.0 (Accelrys Inc.), based on the coordinates of KcsA. *Figure adapted from references.*[7,46]

study of TRPV6 pore properties[46] clearly demonstrated that the Ca^{2+} selectivity is determined by D542/D541.

Mechanism of High Ca^{2+} Selectivity

The high Ca^{2+} selectivity of TRPV5 and TRPV6 refers to a mechanism of permeation as proposed previously for voltage-dependent Ca^{2+} channels. In the absence of Ca^{2+}, Mg^{2+} will bind at a site within the pore-region, which is mainly determined by D542/D541. At low driving forces, e.g. less negative membrane potentials, the driving force is not sufficient to displace Mg^{2+} out of the pore and the channel is blocked. At hyperpolarisation, Mg^{2+} will be moved from this high affinity site thereby allowing monovalent cations to permeate the channels. Because of the higher affinity of the binding-site for Ca^{2+} versus Mg^{2+}, Ca^{2+} will outnumber Mg^{2+} at this site and is now blocking the pore for a movement of monovalent cations. If the inward driving force is sufficient enough to remove Ca^{2+} from the high affinity site, a fast inward permeation occurs supported by the low affinity sites, which flank the high affinity Ca^{2+}-binding site. All the data so far support the crucial role of D542/D541 in the channel pore region of TRPV5 and TRPV6 channels.[48]

Rectification and Gating

A predominant inward rectification is a clear hallmark of the TRPV5 and TRPV6 channels besides the high Ca^{2+} selectivity. This inward rectification is only partially due to blockage by Mg^{2+}, which is removed by hyperpolarization. Thus, the most prominent part of rectification remains in the absence of intracellular Mg^{2+} and is not due to blockage by endogenous polyamines. The intrinsic rectification of these channels is, however, dramatically reduced by neutralization of the negatively charged D542/D541 residues indicating that the permeation site is also involved in rectification.[49] In mammalian cells heterogeneously expressing the epithelial Ca^{2+} channels, TRPV5 and TRPV6 are constitutively open at a low intracellular Ca^{2+} concentration and negative membrane voltage.[36] The above described mechanism of removing channel blockage by Ca^{2+} or Mg^{2+} is necessarily part of the gating mechanism.[49] At this moment other mechanisms that might influence gating of TRPV5 and TRPV6 cannot be excluded. Huang and colleagues showed that PIP_2 activates TRPV5 and that activation of TRPV5 by PIP_2 decreases the sensitivity of TRPV5 to inhibition by intracellular Mg^{2+}.[50]

Modulation of the Channel Activity

Intracellular Ca^{2+}

TRPV5 and TRPV6 are controlled by a Ca^{2+}-dependent feedback inhibition. Both Ca^{2+} channels rapidly inactivate during hyperpolarizing voltage steps and this inhibition is reduced when Ca^{2+} is substituted for Ba^{2+} or Sr^{2+} as charge carriers. The inactivation is dependent on the extracellular Ca^{2+} concentration and occurred also in cells buffered intracellularly with BAPTA.[36] In addition, the current disappeared during repetitive activation by short hyperpolarizing pulses. This current decay was significantly diminished when Ca^{2+} was replaced by Ba^{2+} as charge carrier and abolished when extracellular Ca^{2+} was lowered to 1 nM, again indicating that a Ca^{2+}-dependent process inhibits channel activity.[36] Increase of the extracellular Ca^{2+} concentration significantly stimulated the rate of current decay. Ca^{2+} influx is a prerequisite for this phenomenon because the Ca^{2+}-impermeable D542A mutant lacks a monovalent current decay in response

to repetitive stimulation.[44] These findings suggest that the TRPV5/6 channels are down-regulated by Ca^{2+} influx through the channel and thus likely by increasing the Ca^{2+} concentration in a micro-domain near the pore region, thereby inducing feedback inhibition of the channel. This could be a crucial mechanism for the regulation of TRPV5 and TRPV6 under physiological conditions. The inhibition is highly Ca^{2+}-sensitive with calculated affinity values around 100 nM. Considering the high affinity mechanism of Ca^{2+}-dependent TRPV5/6 inhibition, the presence of intracellular Ca^{2+} buffering proteins, such as calbindins, will ultimately determine the channel activity.[51]

Pharmacology

Ruthenium red and econazole are the most effective blockers of the epithelial Ca^{2+} channels identified so far. The inorganic polycationic dye ruthenium red, which binds to phospholipids, inhibits TRPV5 and TRPV6 in a voltage-dependent manner. Transepithelial Ca^{2+} transport in primary cultures of immunodissected rabbit CNT and CCD are inhibited in the same concentration range.[52] Antimycotic imidazoles such as econazole and miconazole are highly effective inhibitors with IC_{50} values of the micromolar range. These compounds block the channels, however, voltage-independently.[53] In addition, TRPV5 and TRPV6 are efficiently blocked by inorganic cations according to the following profile: $Pb^{2+} = Cu^{2+} = Gd^{3+} > Cd^{2+} > Zn^{2+} > La^{3+} > Co^{2+} > Fe^{2+} >> Fe^{3+}$ with IC_{50} values between 1 and 10 μM. Blockers of store-operated Ca^{2+} entry channels (SOC), e.g., SKF965 and 2-aminoethoxydipheny borate (2-APB), are nearly ineffective for TRPV5 and TRPV6.[53,54,55] Another SOC blocker, the adenylcyclase inhibitor MDL 12330A, exerts half-maximal inhibition of TRPV5 at ~20 μM.[53] Xestospongin, a noncompetitive inositol (1,4,5)-trisphosphate receptor antagonist seems, however, to block TRPV6.[56] Blockers of protein tyrosine kinases such as tyrphostin B46 and genistein, CaM antagonists calmidazolium R24571 and trifluoperazine, and voltage-dependent Ca^{2+} channel blockers such as mibefradil, quinidine, nifedipine, niflumic acid and verapamil, have only small or no effects on TRPV5 activity.[53] Interestingly, blockage by ruthenium red and Cd^{2+} is much more sensitive for TRPV5 than TRPV6 which can, therefore, be used to differentiate both Ca^{2+} channels.[33]

pH

Previous studies indicated that acidification of the apical medium inhibits transepithelial Ca^{2+} transport across primary cultures of rabbit CNT and CCD cells.[57] $^{45}Ca^{2+}$-uptake in TRPV5-expressing *Xenopus laevis* oocytes was inhibited by acidification of the incubation medium.[30] Extracellular acidification reduced currents through TRPV5 carried by either monovalent or divalent cations,[58] which was confirmed by Peng and colleagues[59] Additionally, extracellular pH also affected current kinetics, extracellular Mg^{2+} blockage and Ca^{2+} affinity. The gating component of monovalent cation currents through TRPV5 was delayed at alkaline pH and as well as blockage by extracellular Mg^{2+}. For voltage-dependent Ca^{2+} channels and cyclic nucleotide-gated channels, it was found that protonation of a single glutamate residue in the pore region is responsible for the dramatic changes in divalent cation affinity by extracellular pH. A similar mechanism might be applicable for TRPV5 and TRPV6 in which a single aspartate residue in the pore determines the Ca^{2+} permeation and Mg^{2+} blockage of the channel.[44] Extrapolating these findings to the *in vivo* situation, the pH influence could at least in part provide the molecular basis of acidosis-induced calciuresis. Interestingly, the molecular mechanism of TRPV5 blockage by protons is mechanistically understood taking into account the pore structure described above.[45,46] Mutation of the glutamate residue at position 522 to glutamine preceding the pore helix decreased the inhibition of the channel by extracellular protons.[60] Thus, pH sensitivity is mainly mediated by glutamate at position 522 and may act as the "pH sensor" of TRPV5.

Molecular Structure

The molecular architecture of TRPV5 and TRPV6 channels has recently been unraveled.[48] Co-immunoprecipitations and molecular mass determination of TRPV5 and TRPV6 complexes using sucrose gradient sedimentation showed that these channels form homo- and heterotetrameric channel complexes (Figure 62.2).[48] Niemeyer and co-workers identified the third ankyrin repeat being a stringent requirement for physical assembly of TRPV6 subunits.[61] It was proposed that the third ankyrin repeat initiates a molecular zippering process that proceeds past the fifth ankyrin repeat and creates an intracellular anchor that is necessary for functional subunit assembly. Subsequent studies by Chang et al. confirmed the importance of the ankyrin repeats in TRPV5 assembly. Functional studies have shown that ankyrin repeat 1 fulfills a predominant role in the oligomerization of TRPV5.[62]

Interestingly, several studies indicated that certain tissues co-express TRPV5 and TRPV6 which allows oligomerization of these channels *in vivo*. Immunohistochemical studies demonstrated co-expression of TRPV5 and TRPV6 in DCT. Heteromeric complex formation can modify the activity of members of

the TRP family.[63,64] Likewise, hetero-oligomerization of TRPV5 and TRPV6 might influence the functional properties of the Ca^{2+} channel. Because TRPV5 and TRPV6 exhibit different channel kinetics with respect to Ca^{2+}-dependent inactivation, Ba^{2+} selectivity and sensitivity for inhibition by ruthenium red, the influence of the heterotetramer composition on channel properties was investigated.[33] Concatemeric channels were constructed consisting of four TRPV5 and/or TRPV6 subunits configured in a head-to-tail fashion. Differences in the ratio of TRPV5 and TRPV6 subunits in these concatemers showed that the phenotype resembles mixed properties of TRPV5 and TRPV6. Thus, regulation of the relative expression levels of TRPV5 and TRPV6 may be a mechanism to fine-tune the Ca^{2+} transport kinetics in kidney or other TRPV5/6-co-expressing tissues.[33]

The tetrameric organization of TRPV5 and TRPV6 resembles that of the voltage-dependent Ca^{2+} channel and the Shaker potassium channel that are composed of four tandemly associated homologous domains. Clustering of four subunits is assumed to construct an aqueous pore-region centered at the four-fold symmetry axis. This tetrameric architecture of TRPV5/6 implies that four of the aspartic residues (D542, D541) form a negatively charged ring structure that functions as a selectivity filter for Ca^{2+} in analogy with voltage-dependent Ca^{2+} channels.[45,48,46] Protein crystallography of these channels will be the most challenging approach to determine the three-dimensional structure in the near future.

REGULATION OF THE EPITHELIAL Ca^{2+} CHANNELS

Vitamin D

Independent studies consistently demonstrated that the expression of TRPV5 and TRPV6 is tightly controlled by 1,25-$(OH)_2D_3$.[7] First evidence for this vitamin D-sensitivity was observed in vitamin D_3-depleted rats.[65] Decreased 1,25-$(OH)_2D_3$ levels in these animals were supplemented, which was accompanied by normalization of the plasma Ca^{2+} concentration and an increase in renal TRPV5 mRNA and protein expression. In addition, Nijenhuis et al. addressed the 1,25-$(OH)_2D_3$-dependent regulation of TRPV6.[35] Intraperitoneally injection of 1,25-$(OH)_2D_3$ in mice resulted in an increase in TRPV6 mRNA and protein expression in the kidney, however, the effect of this hormone on TRPV5 expression was more robust. The observed vitamin D-dependent regulation of TRPV5 and TRPV6 was further substantiated using many different cell lines and animal knockout models including vitamin D receptor (VDR), 1α-OHase and TRPV5 knockout mice.[66,67,68,69]

Wood and coworkers studied the vitamin D-sensitivity of TRPV6, calbindin-D_{9K} and PMCA1b in Caco-2 cells, which are generally used as model of duodenal cells.[70] A tight correlation between the 1,25-$(OH)_2D_3$-induced expression of TRPV6, calbindin-D_{9K}, PMCA1b and transepithelial Ca^{2+} transport was established in this intestinal cell line. In contrast, Barley et al. could not confirm the generally observed vitamin D-dependent sensitivity of TRPV6 in duodenal biopsies from 20 normal volunteers.[71] However, there was a 10-fold variation between the lowest and the highest level of TRPV6 expression in the human tissues. In addition, the subjects used were a mixed population of men and women of age 25−71 years, which made it difficult to disclose a relationship between TRPV6 expression and vitamin D metabolites. Likewise, cell lines and primary cultures have been established from the distal part of the nephron including DCT and CNT. Measurements of calbindin-D_{28K} expression in control and 1,25-$(OH)_2D_3$-treated renal epithelial cells indicated a direct relationship between 1,25-$(OH)_2D_3$-induced calbindin expression and transepithelial Ca^{2+} transport.[72]

In addition, several genetically modified mouse models including VDR and 1α-OHase knockout mice, in which the vitamin D system has been inactivated, have been created to systematically dissect the genetic regulation of Ca^{2+} transport genes and their functional consequences on transepithelial Ca^{2+} transport. Two groups independently generated 1α-OHase knockout mice that represent a unique animal model for pseudo-vitamin D-deficiency rickets (PDDR) since these mice display undetectable 1,25-$(OH)_2D_3$ concentrations, hypocalcemia, secondary hyperparathyroidism and failure to thrive.[66,68] In addition, the 1α-OHase knockout mice developed distinct histological evidence of rickets and osteomalacia. Interestingly, there was a correlative relationship between the expression level of TRPV5, calbindin-D_{28K} and NCX1 proteins in kidney, TRPV6, calbindin-D_{9K} and PMCA1b in duodenum and the serum Ca^{2+} concentration. Normalization of the plasma Ca^{2+} concentration by 1,25-$(OH)_2D_3$ was associated with a restoration of the expression level of the Ca^{2+} transporters confirming the essential role of these proteins in active 1,25-$(OH)_2D_3$-mediated Ca^{2+} (re)absorption. The concerted regulation of TRPV5/6 and the other Ca^{2+}-transporting proteins guarantees sufficient capacity during high transport rates. Calbindin-D regulates the Ca^{2+} influx across the apical membrane by buffering intracellular Ca^{2+} and thus controlling feedback inhibition of TRPV5/6 channel activity. Analogous observations were made from experiments performed with VDR knockout mice.

Taken together, vitamin D-deficient animal models and epithelial cell lines demonstrated unequivocally the 1,25-$(OH)_2D_3$-sensitivity of TRPV5 and TRPV6. Analysis of putative promoter regions of human and murine TRPV5/6 genes revealed potential vitamin D response elements (VDREs) in line with the previously observed functional data.[65] However, promoter studies are still lacking to further substantiate the existence of functional VDREs in these genes.

Parathyroid Hormone

The parathyroid glands play a key role in maintaining the extracellular Ca^{2+} concentration through their capacity to sense minute changes in the level of blood Ca^{2+}. Early studies using micropuncture and cell preparations demonstrated that PTH stimulates active Ca^{2+} reabsorption in the distal part of the nephron via a dual signaling mechanism involving PKA- and PKC-dependent processes.[73,74] van Abel et al. demonstrated that PTH upregulates TRPV5 expression, which increases active Ca^{2+} reabsorption via a long-term manner. Parathyroidectomized rats displayed a downregulation of TRPV5 protein expression, whereas long-term PTH supplementation restored the expression.[75] In addition, PTH exerts also a short-term effect by rapidly elevating TRPV5 channel activity. Activation of the PTH receptor initiates a signaling pathway, involving cAMP and PKA that rapidly phosphorylates threonine-709 of TRPV5, increasing the channel's open probability and thus promoting Ca^{2+} reabsorption.[76] Altogether, these results suggest that TRPV5 is the molecular target for the short- and long-term PTH-induced stimulation of active Ca^{2+} reabsorption in the distal part of the nephron.

Klotho

Characterization of a mouse that showed a phenotype comparable to human aging led to the identification of the hormone klotho.[77] Klotho is a type-I (single-pass) membrane protein predominantly expressed in tissues involved in Ca^{2+} homeostasis, such as kidney, choroid plexus, and the parathyroid gland. Indeed, there is a growing body of evidence that klotho controls active Ca^{2+} reabsorption in the kidney. Here, klotho is exclusively expressed in DCT2 and CNT, where following extracellular domain shedding, it is secreted into the circulation and the pro-urine. Subsequently, extracellular klotho hydrolyses oligosaccharide chains of N-glycosylated TRPV5, causing channel retention at the plasma membrane and a subsequent increase in TRPV5-mediated Ca^{2+} influx.[78,79] Cha et al. observed a klotho-mediated removal of terminal sialic acids from the N-glycan in TRPV5.[80] This cleavage exposed the underlying galactose-N-acetylglucoseamine disaccharides in TRPV5, so that it can directly interact with a membrane-bound galectin-1, explaining the subsequent plasma membrane retention of TRPV5. Interestingly, treatment with PNGaseF to hydrolyze the entire N-glycan of TRPV5 mimicked the stimulatory effect of klotho, suggesting additional mechanisms besides binding to membrane galectin-1.[78] Thus, there is compelling evidence that klotho is a novel calciotropic hormone that, amongst others, can exert its stimulatory effect on TRPV5 cell surface retention from the pro-urine in the DCT2 and the CNT.[81]

Estrogens and Androgens

Estrogen deficiency after menopause results in bone loss, which is associated with a rise in plasma and urinary Ca^{2+}. *In vivo* studies showed that estrogen deficiency is associated with increased renal Ca^{2+} loss, which can be corrected by estrogen replacement therapy.[82,83] Furthermore, estrogen receptors also reside in proximal and distal tubules within the nephron. However, the underlying mechanism by which estrogen may act on Ca^{2+} reabsorption is still poorly understood. It was demonstrated that estrogen upregulates the expression of TRPV5 in kidney in a 1,25-$(OH)_2D_3$-independent manner.[84] In ovariectomized 1α-OHase knockout mice 17β-estradiol replacement therapy resulted in upregulation of renal TRPV5 mRNA and protein levels, leading to normalization of plasma Ca^{2+} levels. Recent findings suggest that also TRPV6 expression is regulated by estrogen, as duodenal expression of TRPV6 mRNA of 1α-OHase knockout mice and ovariectomized rats is upregulated after 17β-estradiol administration. Van Cromphaut and coworkers reported that renal TRPV5 and duodenal TRPV6 expression is reduced in estrogen receptor alpha (ERalpha) knockout mice and upregulated by estrogen treatment.[85] Furthermore, in lactating mice renal TRPV5 mRNA and duodenal TRPV6 expression levels increased 2 and 13 times, respectively. It is clear that the expression of both epithelial Ca^{2+} channels is influenced by the estrogen status. The mechanism of estrogen-controlled upregulation of epithelial Ca^{2+} channel mRNA remains to be elucidated. Interestingly, Weber et al. recently described an estrogen-responsive element in the promoter sequence of the mouse TRPV6 gene, which was absent in the mouse TRPV5 gene.[86] Finally, it was shown that estradiol can also exert a rapid stimulatory effect on intracellular Ca^{2+} concentration in renal cells involving TRPV5.

Androgens contribute significantly to sex differences observed in renal Ca^{2+} handling by inhibiting the expression of renal Ca^{2+} transport proteins as demonstrated by several experimental findings. Male mice have a greater urinary Ca^{2+} excretion compared to

females, a feature accompanied by a reduced renal expression of Ca^{2+} transport proteins.[87] In addition, orchidectomy (ORX) induced hypocalciuria in male mice, thus resembling a female-like phenotype on renal Ca^{2+} reabsorption. Moreover, testosterone supplementation of ORX mice caused a normalization of their urinary Ca^{2+} excretion, accompanying a decreased expression of renal TRPV5 and calbindin-D_{28K}.[87] Importantly, serum 1,25-$(OH)_2D_3$, PTH, and estrogen levels did not differ between the sham-operated, ORX and testosterone-supplemented ORX mice, suggesting that androgens may directly affect the transcription of the renal Ca^{2+} transporters.

Furthermore, it was demonstrated that TRPV6 expression is suppressed by androgen and was induced by a specific androgen receptor antagonist in human prostate cancer cell line cells, suggesting that the gene is negatively regulated by androgen. TRPV6 was shown to be strongly upregulated in advanced prostate cancer.[88,89] Also in carcinomas of other tissues, such as breast, thyroid, colon and ovary, TRPV6 expression is increased.[90] Thus, TRPV6 might be a marker for tumor progression. Indeed, northern blot analysis, in situ hybridization experiments and immunohistochemistry clearly demonstrated that TRPV6 is highly expressed in prostate cancer cells, whereas in healthy prostate epithelia little or no expression is was found.[91,89] The appearance of TRPV6 correlates positively with tumor grade and TRPV6 might, therefore, be a promising target for the development of drugs against prostate cancer.

Thus, both testosterone and estrogen have opposing regulatory properties in terms of renal transcriptional expression of Ca^{2+} transporters.

Kallikrein

In kidney, tissue kallikrein is secreted into the pro-urine, where it mediates the formation of bradykinin that binds to the type 2 bradykinin receptor. In primary cultures of rabbit CNT cells it has been shown that kallikrein stimulates transcellular Ca^{2+} transport.[92] This stimulatory effect of TK was mediated by the apical bradykinin receptors signaling through the phospholipase C/diacylglycerol/PKC pathway, resulting in phosphorylation of TRPV5 and subsequent delay in its retrieval from the plasma membrane. Additionally, mice lacking tissue kallikrein waste a large amount of Ca^{2+} without any significant alterations in plasma Ca^{2+}, PTH, and vitamin D_3 levels or any detectable changes in the expression of Ca^{2+} transporters in the DCT2 and CNT.[93] These observations together highlight the importance of the regulation of the TRPV5 channel abundance in the plasma membrane by the pro-urine tissue kallikrein.

Dietary Ca^{2+} Content

Several studies described above provide evidence that the epithelial Ca^{2+} channels are regulated by 1,25-$(OH)_2D_3$, it is, however, difficult to distinguish the effects of hypocalcemia from those of vitamin D-deficiency. Therefore, studies were performed in VDR and 1α-OHase knockout mice fed a normal and high rescue Ca^{2+} diet. These mice models are ideal to study the role of dietary Ca^{2+} in the regulation of TRPV5 or TRPV6 independent of 1,25-$(OH)_2D_3$. Intriguingly, the reduced expression level of renal TRPV5 in the 1α-OHase knockout mice was restored by high dietary Ca^{2+} intake and accompanied by normalization of the plasma Ca^{2+} concentration.[94] Importantly, this effect was observed in the absence of 1α-OHase-activity. In contrast, the Ca^{2+}-enriched rescue diet reduced the expression of renal TRPV5 in wild-type mice that exhibit normal serum vitamin D and Ca^{2+} levels. It is known that under physiological conditions, plasma Ca^{2+} acts via a negative feedback mechanism which eventually leads to suppression of the 1α-OHase-activity that decreases Ca^{2+} reabsorption and expression of Ca^{2+} transport proteins. Identical observations were made in VDR knockout mice where TRPV5 and TRPV6 mRNA levels were upregulated by dietary Ca^{2+}.[95] Studies in these knockout mice models revealed that Ca^{2+} supplementation can upregulate gene transcription encoding for Ca^{2+} transporters in the absence of circulating 1,25-$(OH)_2D_3$, but the molecular mechanism of this vitamin D-independent Ca^{2+}-sensitive pathway remains elusive.[94]

Regulation by Auxiliary Proteins

Calmodulin

Calmodulin (CaM) plays a pivotal role as Ca^{2+} sensor in Ca^{2+}-dependent inactivation, thereby facilitating both activation and inactivation of ion channels, including voltage- and ligand-gated Ca^{2+} channels and members of the TRP superfamily. Ca^{2+} binding to CaM is highly cooperative with Ca^{2+} binding first to the carboxyl-terminal EF-hands, which have the highest affinity for Ca^{2+}, followed by Ca^{2+} binding to lower affinity sites located in the amino-terminus. Niemeyer et al. showed that CaM binds to the carboxyl-terminus of human TRPV6 in a Ca^{2+}-dependent manner.[96] In addition, Nilius et al. indicated that the rabbit TRPV5 C-terminal region is also important for the Ca^{2+}-dependent inactivation process.[97] Recently, CaM was shown to bind to the C- and N- tails of TRPV5 and TRPV6 as well as the transmembrane domain of TRPV6 in a Ca^{2+}-dependent fashion (Figure 62.5).[98] Furthermore, electrophysiological measurements of HEK293 cells heterologously co-expressing Ca^{2+}-insensitive CaM

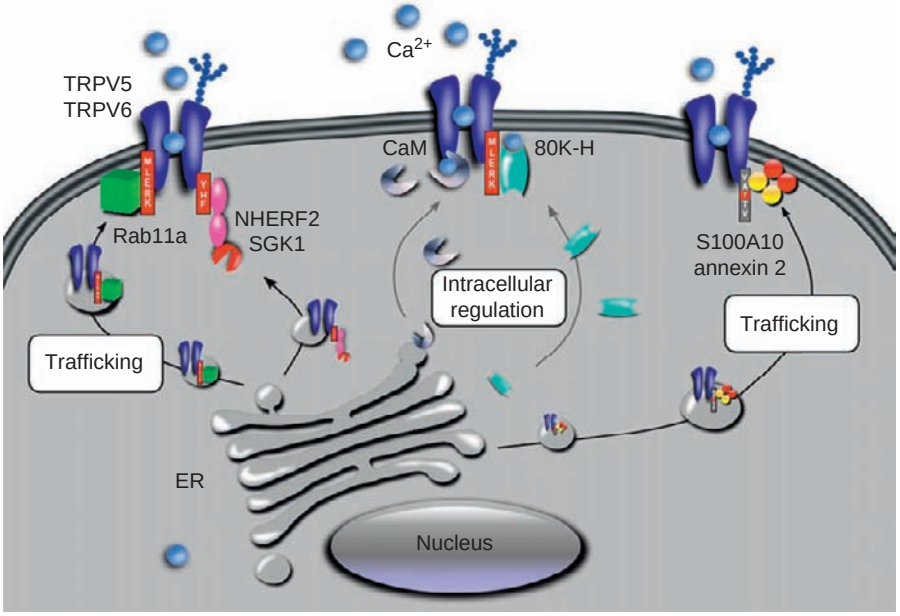

FIGURE 62.5 Integrated model about the regulation of the epithelial Ca^{2+} channels (TRPV5 and TRPV6) by associated protein complexes including calmodulin (CaM), S100A10-annexin 2, Na^+/H^+ exchanger regulating factor 2 (NHERF2), 80K-H, Rab11a. See text for further explanation.

mutants and TRPV6, revealed a significantly reduced inward Ca^{2+} current, whereas no effect of the mutants was demonstrated on currents of TRPV5-expressing cells. It remains, therefore, to be established whether CaM is the general Ca^{2+} sensor or that other processes play a role in the Ca^{2+}-dependent inactivation of TRPV5. Moreover, the high affinity EF-hand Ca^{2+}-binding sites of CaM were demonstrated to contribute primarily to the observed CaM effect upon TRPV6 activity. The C-terminal CaM-binding site of TRPV6 is identical between mouse and rat, but not similarly present in human TRPV6, which might explain the previous observation that CaM binding to human TRPV6 is localized to a different region. Together, these results suggest that CaM positively affects TRPV6 activity.

S100A10-Annexin 2

S100A10 was identified as an associated protein of TRPV5 and TRPV6 by screening a kidney cDNA library using the yeast two-hybrid system. S100A10, which specifically associates with the carboxyl-termini of these epithelial Ca^{2+} channels, is a 97 amino acid protein member of the S100 superfamily that is present in a large number of organisms including vertebrates, insects, nematodes and plants. Several members of the S100 protein family form heteromeric complexes with annexins and S100A10 is often found tightly associated with annexin 2 to form a tetrameric complex. Van de Graaf and co-workers provided evidence of a regulatory role for the S100A10-annexin 2 heterotetramer in TRPV5 and TRPV6 functioning.[52] The association of S100A10 with TRPV5 and TRPV6 was restricted to a short conserved peptide sequence VATTV located in the carboxyl-termini of these channels. The first threonine of this interaction motif was identified as a crucial determinant for binding and channel function. Malfunctioning of these mutant channels was accompanied by a major disturbance in their subcellular localization, indicating that the S100A10-annexin 2 heterotetramer facilitates the translocation of TRPV5 and TRPV6 channels towards the plasma membrane (Figure 62.5). The importance of annexin 2 in this process was demonstrated by a siRNA-based downregulation of annexin 2 that significantly inhibited the currents through TRPV5 and TRPV6 indicating that annexin 2 in conjunction with S100A10 is crucial for TRPV5 activity. Taken together, these findings show that the S100A10-annexin 2 complex is a significant component for the trafficking of the epithelial Ca^{2+} channels and, therefore, the Ca^{2+} homeostasis.

Na^+/H^+ Exchanger Regulating Factor 2

Embark and coworkers recently demonstrated that TRPV5 activity in *Xenopus laevis* oocytes is increased upon co-expression with the Na^+/H^+ exchanger regulating factor 2 (NHERF2) and the serum glucocorticoid inducible kinase (SGK1).[99] In analogy, co-expression of SGK1 with NHERF2 stimulates the activity of the ROMK1, a K^+ channel involved in renal K^+ handling.[100] Coexpression of SGK1 and NHERF2 results in a stabilization of ROMK1 in the plasma membrane, leading to an increased ROMK activity.[101] Whether this mechanism is identical for TRPV5 remains to be established. Using GST pull-down and overlay assays, we demonstrated the specific interaction of NHERF2 with the last three amino acids in the carboxyl-terminus of

TRPV5 (van de Graaf et al., unpublished results). This suggests that the NHERF2/SGK1 protein pair affects TRPV5 in a direct fashion, via protein-protein interaction (Figure 62.5). The last three amino acids of TRPV5 resemble a PDZ motif, which allows binding to a PDZ domain-harboring protein like NHERF2. The concerted action of the NHERF2 and SGK1 proteins increased TRPV5 activity. It is tempting to speculate that the stimulatory effect on TRPV5 trafficking to the plasma membrane reflects SGK1-mediated phosphorylation of TRPV5, but this remains to be demonstrated experimentally.

80K-H

Gkika and colleagues identified 80K-H as a protein involved in the Ca^{2+}-dependent regulation of TRPV5.[102] This latter study demonstrated a specific interaction between 80K-H and TRPV5, co-localization of both proteins in the distal part of the nephron and similar transcriptional regulation by 1,25-$(OH)_2D_3$ and dietary Ca^{2+}. The interaction of 80K-H was localized to a conserved α-helical region of only ~30 amino acids. The interaction between 80K-H and TRPV5 was lost when 5 amino acids (MLERK) at the C terminal end of this region were removed by truncation or mutation into glycines. Furthermore, 80K-H directly bound Ca^{2+} and inactivation of its two EF-hand structures totally abolished the Ca^{2+} binding. Electrophysiological studies using 80K-H mutants showed that three domains of 80K-H (two EF-hand structures, the highly acidic glutamic stretch and the His-Asp-Glu-Leu sequence) are critical determinants for TRPV5 channel activity. Importantly, inactivation of the EF-hand pair reduced the TRPV5-mediated Ca^{2+} current and increased the TRPV5 sensitivity to intracellular Ca^{2+}, accelerating feedback inhibition of channel activity. None of the 80K-H mutants altered the plasma membrane localization of TRPV5 nor the association of 80K-H with TRPV5, suggesting that 80K-H has a direct effect on TRPV5 activity. Taken together, 80K-H act as a novel Ca^{2+} sensor controlling TRPV5 channel activity (Figure 62.5).

Rab11a

Rab11a, a small GTPase involved in trafficking via recycling endosomes, was recently identified as a novel TRPV5- and TRPV6-associated protein.[103] This small GTPase co-localized with TRPV5 and TRPV6 in DCT and CNT. Importantly, the Ca^{2+} channels and Rab11a were here present in vesicular structures underlying the apical plasma membrane. Using a combination of GST pull-down and co-immunoprecipitation assays a direct interaction between Rab11a and the epithelial Ca^{2+} channels (Figure 62.5) was shown, hinting at a novel mechanism of Rab11a-mediated trafficking. Furthermore, it was demonstrated that TRPV5 and TRPV6 preferentially interact with Rab11a in its GDP-bound conformation. Expression of a mutant Rab11a protein, locked in the GDP-bound state, resulted in a marked decrease of channels at the cell surface, indicating a direct role of Rab11a in the trafficking of the Ca^{2+} channels towards the plasma membrane. The interaction of Rab11a was localized to the conserved MLERK domain in the carboxyl-terminus of TRPV5 and TRPV6. 80K-H binding was localized to the same region, suggesting a possible common binding site in TRPV5 and TRPV6 for these two distinct proteins.[102] Mutagenesis of these 5 amino acids abolished channel activity at the plasma membrane by impairing the trafficking to the cell surface. Interestingly, Zobiack and coworkers have demonstrated that the annexin 2-S100A10 complex controls the distribution of Rab11-positive endosomes.[104] Furthermore, annexin 2 was enriched in these endosomes. This suggests that two crucial pathways controlling the cell surface expression of TRPV5 and TRPV6 coincide.

Indeed, the mechanisms underlying TRPV5 endocytosis have been investigated in several studies.[103,105] After reaching the cell surface, the TRPV5 channel was internalized through dynamin- and clathrin-dependent processes. First, TRPV5 appeared in numerous small vesicles, before entering larger vesicles, where it co-localized with Rab11a, a marker for recycling endosomes.[105] The majority of internalized TRPV5 entered the recycling pathway, whereas only a minor part was degraded. TRPV5 channels present in recycling endosomes were able to reach the plasma membrane again through direct interaction with Rab11a. Moreover, the presence of a large and stable recycling pool of TRPV5 channels was demonstrated, as blocking protein biosynthesis did not reduce TRPV5-mediated Ca^{2+} influx. Altogether, the continuous endosomal recycling of internalized TRPV5 channels enables TRPV5 reappearance at with many the plasma membrane providing a synthesis-independent pathway for the apical influx of Ca^{2+}.

WNK

WNK3 and WNK4, members of the With No Lysine (K) family of protein serine/threonine kinases, are also positive regulators of the epithelial Ca^{2+} channels TRPV5 and TRPV6 through enhancing the membrane expression level of the functional channel proteins via a kinase-dependent pathway.[106,107] The kinase domain of WNK3 appeared sufficient to exert the positive effect on TRPV5. Since these WNKs are expressed in the distal part of the nephron, where TRPV5 and TRPV6 are expressed, they might positive regulators of the active Ca^{2+} reabsorption pathway in the kidney.

Regulation by Immunosuppressives and Diuretics

Tacrolimus

Tacrolimus (FK506) is a widely prescribed immunosuppressant drug and is known to induce significant side effects on mineral homeostasis, including increased bone turnover, a negative Ca^{2+} balance and hypercalciuria.[108,109] The kidney plays an essential role in the maintenance of the Ca^{2+} homeostasis by providing the main excretory route. In theory, downregulation of Ca^{2+} transporter proteins in the distal part of the nephron may be involved in the pathogenesis of hypercalciuria during drug treatment. Previous reports showed reduced calbindin-D_{28K} levels during FK506 treatment, suggesting that FK506 could affect active Ca^{2+} transport.[110] In addition, it was demonstrated that FK506 treatment significantly increased urinary Ca^{2+} excretion, accompanied by a down-regulation of the renal mRNA and protein expression of TRPV5.[111] The fact that serum Ca^{2+} concentrations and the glomerular filtration rate did not differ from control animals confirmed that impaired Ca^{2+} reabsorption rather than an increased filtered load caused the hypercalciuria. This data supported the hypothesis that FK506 induces a primary defect of renal active Ca^{2+} reabsorption by specifically down-regulating the proteins involved in active Ca^{2+} transport. The molecular mechanism underlying the downregulation of the epithelial Ca^{2+} channel by FK506 remains elusive. In previous studies, plasma 1,25-$(OH)_2D_3$ was either unaltered or moderately increased, while plasma PTH levels were not affected by similar doses of FK506, which excludes that the reduced Ca^{2+} transport protein expression levels are secondary to decreased circulating levels of calciotropic hormones.

Furosemide

Diuretics such as furosemide are frequently used in the clinical practice. Furosemide is usually administered over a long period of time and is known to disturb Ca^{2+} reabsorption leading to various symptoms including alterations in structure and stability of bone. The molecular mechanism underlying its action on Ca^{2+} reabsorption includes the following events. Furosemide inhibits the Na^+—K^+—$2Cl^-$ (NKCC2) transporter present in the apical membrane of the TALH resulting in a reduction in NaCl reabsorption and K^+ recycling across the apical membrane. This action diminishes the lumen-positive potential that drives the paracellular reabsorption of Ca^{2+} explaining the hypercalciuric action of furosemide. As a consequence the delivery of Ca^{2+} to DCT and CNT is enhanced, which are the primary sites of active Ca^{2+} reabsorption.[7] Indeed, furosemide treatment increased the abundance of the Ca^{2+} transport molecules including TRPV5, TRPV6, calbindin-D_{28K} and calbindin-D_{9K}, in the DCT that could represent a solute load-dependent effect in response to increased calcium delivery and, therefore, serves as a compensatory adaptation in the downstream segment.[112]

Thiazide Diuretics

Thiazide diuretics have, in contrast to loop diuretics, the unique characteristic of decreasing Na^+ reabsorption, while increasing Ca^{2+} reabsorption. In addition, mutations in the thiazide-sensitive Na^+-Cl^- cotransporter (NCC) have been shown to cause Gitelman's syndrome. These patients suffer from hypovolemia, hypokalemic alkalosis, hypomagnesemia and hypocalciuria.[113] Intriguingly, the molecular mechanisms responsible for the hypocalciuria and hypomagnesemia of thiazide administration and Gitelman's syndrome remain elusive. Two hypotheses exist with respect to the Ca^{2+}-sparing effect of thiazides.[7] First, renal salt and water loss due to thiazide treatment result in contraction of the extracellular volume (ECV), which triggers a compensatory increase of proximal Na^+ reabsorption. This would in turn enhance the electrochemical gradient driving passive Ca^{2+} transport in proximal tubule tubular segments.[113,114,115] Early studies by Weinman and Eknoyan already demonstrated that the escape from the chronic effects of chlorothiazide is due to a decrease in the glomerular filtration rate and to an increase in fractional reabsorption in the proximal tubule.[116] Subsequently, Nijenhuis et al. showed in rats that the hydrochlorothiazide (HCTZ)-induced hypocalciuria was accompanied by a significant decrease in body weight compared to controls, illustrating that ECV contraction occurred.[117] Since Na^+ depletion resulted in a similar hypocalciuria, it is likely that the ECV contraction by itself is responsible for the thiazide-induced hypocalciuria. This is further supported by the finding that Na^+ repletion during HCTZ treatment, thereby preventing the ECV contraction, normalized the calciuresis. Second, microperfusion experiments suggested that acute administration of thiazides in the tubular lumen stimulates Ca^{2+} reabsorption in DCT.[118] Subsequently, several molecular mechanisms were postulated to explain this latter stimulatory effect. These included hyperpolarisation of the plasma membrane resulting in increased apical Ca^{2+} entry through TRPV5 and, alternatively, enhanced basolateral Na^+/Ca^{2+} exchange due to a decreased intracellular Na^+ concentration.[114] This last hypothesis was based on substantial co-localization in DCT of

NCC and the proteins involved in active Ca^{2+} transport. However, immunohistochemical studies demonstrated only minor overlap, whereas the Ca^{2+} transporters (i.e., TRPV5, calbindin-D_{28K}, NCX1 and PMCA1b) completely co-localized.[7] Interestingly, it was demonstrated that in the DCT epithelium the Ca^{2+} transport proteins including TRPV5, calbindin-D_{28K} and PMCA1b were decreased in animals treated with high thiazide dosis. In addition, the localization of the NCC protein was shifted from the luminal membrane to the basal membrane. Furthermore, Schultheis et al. generated NCC knockout mice exhibiting hypocalciuria and hypomagnesemia, representing a valuable animal model explaining Gitelman's syndrome.[119] In these mice Ca^{2+} reabsorption was unaltered in the DCT and CNT as indicated by real-time reverse transcription-PCR, Western blotting, and immunohistochemistry for TRPV5 and NCX1 and micropuncture experiments.[120] Micropuncture data indicated that a reduced glomerular filtration and enhanced fractional reabsorption of Na^+ and Ca^{2+} upstream of the DCT provide compensation for the Na^+ transport defect in the DCT and contribute to the hypocalciuria.[120] Taken together, these data support the hypothesis that enhanced proximal tubular Na^+ transport as a consequence of ECV contraction stimulates paracellular Ca^{2+} transport and comprises the molecular mechanism explaining thiazide-induced hypocalciuria. Furthermore, thiazide-induced hypocalciuria could still be elicited in TRPV5 knockout mice, in which active Ca^{2+} reabsorption is virtually abolished.[121] Additional experiments investigating the time dependency of the thiazide effects demonstrated that Ca^{2+} excretion is unaltered during the natriuretic response following HCTZ administration, again indicating that direct stimulation of active Ca^{2+} reabsorption by inhibition of NCC does not occur. In contrast, a profound decrease in urinary Ca^{2+} excretion followed the initial natriuresis and, importantly, paralleled a reduced net Na^+ excretion.[121] Taken together, a long-standing question in physiology and medicine seems resolved indicating that enhanced proximal tubular Na^+ transport as a consequence of ECV contraction, stimulates paracellular Ca^{2+} transport and constitutes the molecular mechanism underlying thiazide-induced hypocalciuria.

Characterization of TRPV5 Knockout Mice

TRPV5 knockout mice have been generated by genetic ablation of TRPV5 to investigate the requirement of TRPV5 functioning in renal and intestinal Ca^{2+} (re)absorption.[67] Interestingly, analysis of 24-hour urine demonstrated that TRPV5 knockout mice exhibit a major calciuresis, since significantly more Ca^{2+} was excreted in the urine compared to wild-type littermates. The urinary Ca^{2+} concentration of the knockout mice reached 20 mM compared to 6 mM for control littermates. Serum analysis demonstrated that TRPV5 knockout mice are normocalcemic, but have significantly elevated 1,25-$(OH)_2D_3$ levels compared to TRPV5 wild-type mice.

As indicated TRPV5 knockout mice display hypercalciuria from impaired active Ca^{2+} reabsorption, but also hyperphosphaturia, polyuria and increased urinary acidification.[67] The latter two adaptations seem highly beneficial because they facilitate the excretion of large quantities of Ca^{2+} by reducing the potential risk of Ca^{2+} precipitations. It has been postulated that a high luminal Ca^{2+} concentration activates the Ca^{2+}-sensing receptor in the apical membrane of the IMCD.[122] The consistent polyuria in hypercalciuric TRPV5 knockout mice, noted by a substantial decrease in urinary osmolality, is caused by downregulation of renal AQP2 water channels, possibly a result of activating the Ca^{2+}-sensing receptor along the luminal membrane of the CD.[123] Furthermore, gene ablation of the collecting duct-specific B1 subunit of H^+-ATPase in TRPV5 knockout mice abolishes enhanced urinary acidification, which resulted in severe tubular precipitations of Ca^{2+}-phosphate in the renal medulla.[123] Thus, in TRPV5 knockout mice, activation of the renal Ca^{2+}-sensing receptor promotes H^+-ATPase-mediated H^+ excretion and downregulation of AQP2, leading to urinary acidification and polyuria, respectively.

To identify the exact defective Ca^{2+} reabsorption site along the nephron in TRPV5 knockout mice *in vivo* micropuncture studies were performed that combine classical and new research tools in a way that promises to yield important new insights into single-nephron function. Quantitative free-flow collections of tubular fluid revealed unaffected Ca^{2+} reabsorption in TRPV5 knockout mice up to the last surface loop of the late proximal tubule. In contrast, mean Ca^{2+} delivery to puncturing sites within the DCT and CNT was significantly enhanced in TRPV5 knockout mice. Because K^+ secretion occurs along these nephron sites the distal luminal potassium concentration was used as an indicator of the distal collection site. Based on the shape of the relationship between distal luminal K^+ concentration and fractional Ca^{2+} delivery it is evident that in contrast to TRPV5 wild-type mice, fractional Ca^{2+} delivery increases with an increased K^+ concentration indicating a defective Ca^{2+} reabsorption in the DCT and CNT which is consistent with the localization of TRPV5.

Remarkably, inactivation of the TRPV5 gene was accompanied by a decrease in the renal calbindin-D_{28K} and NCX1 mRNA expression. Because transepithelial

Ca^{2+} transport in DCT and CNT was abolished in TRPV5 knockout mice, the simultaneous decrease in calbindin-D_{28K} and NCX1 mRNA levels, in the presence of elevated 1,25-$(OH)_2D_3$ levels, suggests a regulatory mechanism primarily controlled by TRPV5. This means that TRPV5 or the Ca^{2+} influx through TRPV5 possibly controls the transcription of the other Ca^{2+} transport genes including calbindin-D_{28K} and NCX1. Although down-regulation of renal calbindin-D_{28K} is secondary to TRPV5 ablation in the TRPV5 knockout mice, the reduced calbindin-D_{28K} level may further augment the severity of the hypercalciuria. In this respect, it is interesting to compare the hypercalciuria in calbindin-D_{28K} and TRPV5 knockout mice. Calbindin-D_{28K} knockout mice fed a regular Ca^{2+} diet displayed a ~2 fold increase in the urinary Ca^{2+} excretion compared to wild-type littermates,[124] whereas TRPV5 knockout mice fed the same Ca^{2+} diet excreted ~6 times more Ca^{2+} in the urine compared to controls.[67] These findings underscore the gatekeeper function of TRPV5 in the process of Ca^{2+} reabsorption.

In general, $Ca_2{}^+$ hyperabsorption by the small intestine is favored as compensation for renal Ca^{2+} wasting. Ca^{2+} absorption was assessed by measuring serum $^{45}Ca^{2+}$ at early time points after oral gavage. A significant increase in the rate of $^{45}Ca^{2+}$ absorption was observed in TRPV5 knockout mice compared to wild-type mice indicating a compensatory role of the small intestine. In addition, TRPV6 and also calbindin-D_{9K} expression levels were significantly up-regulated in TRPV5 knockout mice consistent with this increased Ca^{2+} absorption. These intestinal adaptations likely result from the elevated 1,25-$(OH)_2D_3$ levels observed in TRPV5 knockout mice.

In addition to kidney and intestine, also bone showed a clear phenotype in TRPV5 knockout mice. Microcomputed tomography analyses of the femur demonstrated that trabecular thickness in the femoral head of TRPV5 knockout mice was significantly reduced compared to wild-type mice. Trabecular bone volume, tissue volume and bone fraction were not different between the genotypes. This could not be explained by a difference in trabecular number. Alternatively, it is possible that the trabeculae are longer, i.e., protrude further into the bone marrow cavity and thereby compensate for reduced trabecular thickness. Analyses of the diaphysis showed that cortical bone volume, cortical volume fraction and cortical bone thickness were reduced in TRPV5 knockout versus wild-type mice.

These data from TRPV5 knockout mice unequivocally established that TRPV5 is the gatekeeper in active Ca^{2+} reabsorption. Ablation of the TRPV5 gene seriously disturbs renal Ca^{2+} handling, causing increased 1,25-$(OH)_2D_3$ plasma levels, Ca^{2+} hyperabsorption and reduced bone formation. These deficiencies in Ca^{2+} handling have been reported frequently in patients with idiopathic hypercalciuria, in which TRPV5 dysfunction could contribute to the pathogenesis. Finally, the increased 1,25-$(OH)_2D_3$ levels and effects on bone structure indicate that alterations in TRPV5 may have implications for age-related bone disorders, including osteoporosis.

Cell surface sensors for extracellular Ca^{2+} and Mg^{2+}[51] provide an important mechanism for the regulation of diverse physiological processes by extracellular divalent mineral ions.[53,190,402] These ion sensors function as "calciostats" for Ca^{2+} and/or Mg^{2+} that not only regulate divalent mineral metabolism at the level of the whole organism but also control a variety of other cellular processes (e.g., salt and water handing in various epithelia and cell proliferation-differentiation) in terrestrial and aquatic animals, as well as in plants.[51,177,301] This chapter will focus on the role of the extracellular calcium-sensing receptor (CaSR) in the mammalian parathyroid, kidney, and other tissues participating in divalent mineral ion homeostasis. The unique properties of the mammalian CaSR include: (1) Having extracellular Ca^{2+} and Mg^{2+} as its primary physiological ligands, establishing that ions can function as first messengers. (2) Responding with a millimolar EC_{50}, close to the normal plasma ionized Ca^{2+} concentration, but several orders of magnitude higher than that for ligands of other G protein–coupled receptors. (3) Possessing a remarkable ability to detect small deviations from the normal ionized calcium concentration of 1.1–1.3 mM, making it an ideal sensor for Ca^{2+}, functioning as a "calciostat."

The identification of inherited disorders due to activating or inactivating mutations of the CaSR, basic research in CaSR biology, the development of CaSR-active compounds (calcimimetics), and the results from clinical trials of calcimimetics have established the biological roles of this receptor in mineral ion homeostasis and have suggested roles of the CaSR in several non-Ca^{2+} homeostatic processes,[1,147,201] (also see reviews[147,402]). The reader is referred to Chapter 65 and other chapters in the section, "Regulation and Disorders of Calcium Homeostasis," for additional information and background.

LIGAND BINDING: THE CaSR IS A Ca^{2+}/Mg^{2+} AND AN "EXTRACELLULAR ENVIRONMENT" SENSOR

The CaSR is a member of class C of the G protein–coupled receptor (GPCR) superfamily. Class C receptors include the extracellular Ca^{2+}-sensing receptors (CaSRs and perhaps GPRC6A), the metabotropic glutamate receptors, the GABAB receptors, the V3R pheromone receptors, the T1R taste receptors, and several orphan receptors (RAIG1, GPRC6B-5D, and GABABL).[40]

CaSR Agonists

The CaSR can be activated by Ca^{2+}, Mg^{2+} and certain other polycations (e.g., Gd^{3+}, polylysine, polyarginine, and neomycin[49,52,349]). These agonists are referred to as type I agonists as they can directly and independently activate the receptor (Fig. 63.1). CaSR activity can also be modulated by other substances or conditions that function by modifying the EC_{50} for extracellular Ca^{2+} (up or down); allosteric activators of the CaSR of this type are referred to as type II allosteric activators (Fig.63.1). Thus, type II activators require the presence

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00063-X

of extracellular Ca^{2+} and function as allosteric modifiers of Ca^{2+} affinity. Currently identified physiological type II agonists include polyamines (e.g., spermine),[349] L-amino acids (especially aromatic amino acids),[90] extracellular pH,[347] and extracellular ionic strength, primarily changes in NaCl concentration in a physiological context.[192,301,348] Increases in polyamine[349] or amino acid concentrations,[89] or isosmotic reductions in ionic strength[301,348] reduce the EC_{50} (increase the affinity) for extracellular Ca^{2+}. At a constant ionized Ca^{2+} concentration, these changes in the concentrations of type II agonists will increase activation of the CaSR. As a consequence, CaSR responses to changes in concentrations of divalent minerals or type I agonists must be viewed in the setting of a specific "extracellular environment" (i.e., presence or absence of polyamines and L-amino acids, pH, and ionic strength). Interestingly, the CaSR appears to have initially evolved as a salinity sensor in marine species where these organisms used the effects of ionic strength (salinity) on activation of the receptor by the Ca^{2+}/Mg^{2+} present in salt water to regulate tissue responses for salinity adaptation.[301] With the evolution of land-based tetrapods and the loss of the ocean reservoir of Ca^{2+}/Mg^{2+}, we see the first appearance of the parathyroid glands and parathyroid hormone (PTH), which are required for divalent mineral regulation of the internal "ocean" represented by the extracellular fluids (ECFs) of terrestrial organisms. Currently identified CaSR-active small molecules (calcimimetics and calcilytics) are used in the treatment of certain disorders of calcium homeostasis. They function as allosteric activators and antagonists, respectively, of the CaSR via the type II mechanism and therefore, require extracellular Ca^{2+} to act (Fig. 63.1).[46,307]

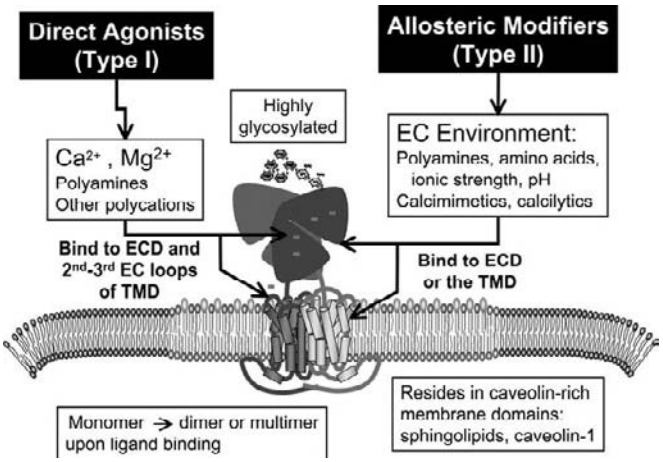

FIGURE 63.1 Schematic representation of the dimeric calcium-sensing receptor (CaSR) localized to caveolin-rich membrane domains. ECD, extracellular domain; TMD, transmembrane domain containing 7 α-helical membrane-spanning segments. Activators/agonists of the receptor can either be type I, which don't require the presence of Ca^{2+} to activate the CaSR, or as type II allosteric modifiers that potentiate the action of Ca^{2+}, which must be present at a concentration of ~1 mM for a type II agent to activate the receptor. Polyamines, such as spermine, act primarily in the type II mode, but can also serve as weak type I agonists. See text for discussion.

Ligand Binding to the CaSR

Class C GPCR receptors have a large (hundreds of residues) N-terminal extracellular domain (ECD) that is joined to the canonical 7-transmembrane (7-TM) domain typical of GPCRs. The ECDs of the class C-related metabotropic glutamate receptors[242,410] or the distantly related bacterial periplasmic nutrient-binding proteins (e.g., the maltose-binding protein (MBP))[397] form a bilobed structure that has a ligand binding region within the central cleft between these lobes (Fig. 63.2A). Following ligand binding, there is a

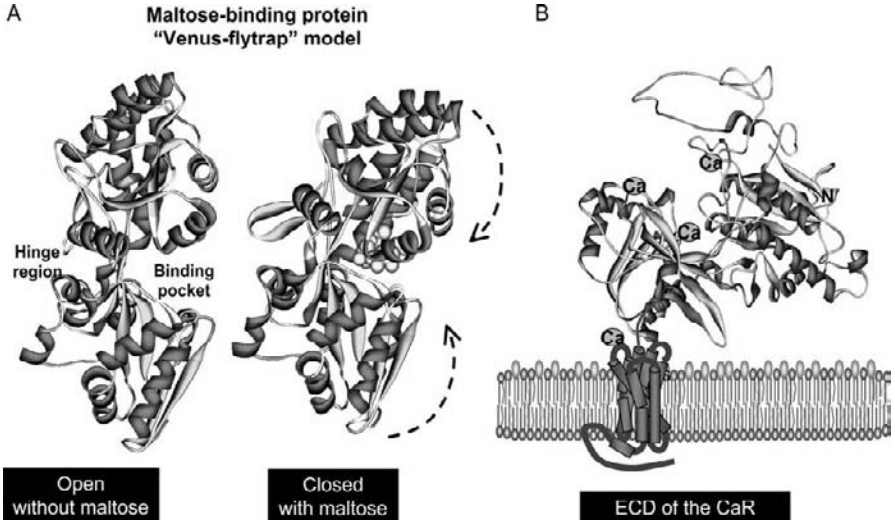

FIGURE 63.2 The Venus flytrap model of the extracellular domain of one monomer of the calcium-sensing receptor (CaSR). A: Structures of the bacterial periplasmic maltose-binding protein in the absence and present of ligand (yellow structure). Note the closing of the lobes around the ligand upon ligand binding (dashed arrows). B: Structural model of the human CaSR made by threading the human sequence through the extracellular domain of mGluR. Note the bilobed structure that is similar to the bacterial maltose-binding protein. Potential calcium interacting sites are shown. The best characterized of these is in the crevice between the two lobes of the VFT, which faces upward and to the left at about 10 o'clock. Structure colors: red = α helices; blue = β strands.

conformational change in the ECD, which results in the two lobes moving toward one another to enclose the ligand (Fig. 63.2A, Venus-flytrap model). This molecular motion in the ECD is thought to be translated into conformational changes in the 7-TM domain, leading to G-protein activation.[242,410]

The ligand-binding sites on class-C receptors, including the CaSR, are located on the ECD and, to a lesser extent, in the 7-TM domains.[39,242,410] While an x-ray crystal structure of the ECD of the CaSR has not been obtained, the ECD can be modeled[207,213,331] on the basis of the known structure of several metabotropic glutamate receptors.[410] This structural model is shown in Fig. 63.2B with the location of potential Ca^{2+}-interacting regions composed of negatively charged amino acid residues. In addition, three serine residues (S-147, S-169, and S-170) and proline-823 in the ECD are crucial for maximal responsiveness to extracellular Ca^{2+}.[205,389,451] Receptor activation by Ca^{2+} is greatly reduced by removal of the ECD, emphasizing the importance of negatively charged acidic (and other) residues in the ECD for the binding of polyvalent cations.[39,176,183,204,205,357,410] Additional acidic residues in the second and third extracellular loops in the 7-TM domain have also been suggested to participate in Ca^{2+}-binding interactions.[176,183,205,206,353] In contrast, the response to calcimimetics is retained when the ECD is removed from the CaSR,[183] indicating that these type II activators bind at a different site than does Ca^{2+}. Observations indicate that the critical sites for interaction of calcimimetics with the CaSR are located in the 7-TM domain, primarily the TM6−TM7 region,[206,331,353] with Glu837, at the outer end of TM7, serving as an "anchor" by binding the amino group in the aliphatic linker between the two hydrophobic ends of the molecule. In addition, negative allosteric modulators of the CaSR (calcilytics) have been identified that exhibit a binding site in the 7-TM domain of the CaSR that overlaps with but is not identical to that for the calcimimetics.[331]

The Concept of Superagonism for Agonist Binding to the Class C Receptors

As described previously, type II agonists (including calcimimetics) of the CaSR can act as allosteric enhancers or positive allosteric modulators.[339,382] It is clear that most GPCRs possess allosteric binding sites that can be recognized by small-molecule ligands.[279] GPCR class-C receptors, including the CaSR,[11,218,430] form dimers (or even multimers), and this intermolecular interaction is believed to play an important role in allosteric activation.[40,339] Type I ligand binding enhances dimerization of the CaSR associated with formation of intermolecular disulfide linkages.[13,155,352,430] Thus, most of the receptors on plasma membranes of cells are in the dimeric (and multimeric) form,[14] since cell surface CaSRs are exposed to millimolar concentrations of extracellular Ca^{2+}. Although the intermolecular disulfide links between ECDs are not essential for dimerization,[452] they play an important structural role and help to maintain the receptor in its inactive state in the absence of agonist. Initial dimerization takes place in the endoplasmic reticulum, and this interaction may be necessary for the receptor's transport to the cell surface.[337] Once on the cell surface, intermolecular interactions between CaSR monomers are essential for normal function of this receptor.[15] Specifically, in the presence of agonist, dimerization of the CaSR and other class C receptors appears to enhance downstream cellular signaling, providing "superagonism".[382] This dimer-driven superagonism, which can also be thought of a positive cooperativity, likely accounts for the ability of type II agonists (e.g., L-amino acids) to activate the receptor by an allosteric mechanism[298] and the remarkable ability of this receptor to detect small changes in ionized Ca^{2+} from the normal plasma Ca^{2+} of 1.1-1.3 mM (Ca^{2+}-Ca^{2+} allosteric enhancing effect). Given that the Hill coefficient of the dimeric CaSR is 3−4, it is likely that there are at least 2 binding sites for calcium on each of the two monomers,[213] resulting in the substantial degree of positive cooperativity needed for the receptor's exquisite sensitivity to small changes in Ca^{2+}. An intact COOH-terminus on the CaSR is also required for cell surface expression.[68,351]

Complex Signaling: the Receptor is Promiscuous

CaSR coupling to G-protein has been referred to as promiscuous, since type I ligands activate one or more of several G proteins (e.g., $G\alpha_{q11}$, $G\alpha_{i2-i3}$).[53,210,429] As with most GPCRs, the COOH-terminal tail of the CaSR and one or more intracellular loops are crucial for signal transduction.[68,351] The CaSR-generated cytosolic signal is a complex of phospholipase activation (PLC, $cPLA_2$, PLD) and the generation of diverse cellular second messengers (see[201,210,429] for reviews), $G\alpha_{q11}$–mediated PLC activation $\rightarrow\uparrow IP_3\rightarrow\uparrow$cytosolic Ca^{2+} concentration ($Ca^{2+}{}_i$) and $Ca^{2+}{}_i$ oscillations as well as $\rightarrow\uparrow DAG\rightarrow\uparrow PKC$; $G\alpha_i$-mediated $\rightarrow\downarrow$cAMP; $\uparrow$intracellular $Ca^{2+}\rightarrow\uparrow$phosphodiesterase (PDE)$\rightarrow\downarrow$cAMP; cytosolic (c)$PLA_2$ activation$\rightarrow\uparrow$arachidonic acid (AA)$\rightarrow\uparrow P_{450}\rightarrow\uparrow$20-HETE; phosphatidylinositol 3-kinase (PI3K)$\rightarrow PIP_3$; MAP kinases, such as ERK1/2, c-Jun activated N-terminal kinase (JNK), and p38 MAPK; filamin scaffolding of $G\alpha_q\rightarrow\uparrow$Lbc RhoGEF$\rightarrow\uparrow$Rho A GTPase leading to activation of a serum response element (SRE) and $G\alpha_{12/13}\rightarrow\uparrow$PLD$\rightarrow\uparrow$phosphatidic acid

(PA).[42,150,178,195,208,229,230,285,336,441,448] It remains unclear in many cases how this second messenger "soup" and related intracellular signaling pathways integrate to modulate cellular functions, such as PTH secretion or renal responses to extracellular Ca^{2+}. The ability of the CaSR to be modulated by such a wide variety of agonists and extracellular conditions likely accounts for its multifunctional nature in regulating divalent mineral balance as well as in modulating diverse cellular functions seemingly unrelated to mineral homeostasis. Examples of the latter include CaSR effects on salt and water transport by the kidney[186] and gastrointestinal epithelia.[147] The CaSR also provides proliferation-differentiation-apoptosis signals to certain epithelial cells (e.g., keratinocytes in the skin, mammary gland cells and colonocytes).[26,50,222]

BINDING PARTNERS OF THE CaSR

Several proteins have been shown to interact with the CaSR and can exert important effects on its function or trafficking. The receptor-activity-modifying proteins (RAMPs), RAMP-1 and RAMP-3, participate in the translocation of the CaSR to the plasma membrane in some cell types.[37] The CaSR on the cell surface exhibits little desensitization when exposed repeatedly to elevated levels of Ca^{2+}_o, at least in parathyroid cells. This resistance to desensitization is the consequence, at least in part, of its interaction with the large, actin-binding scaffold protein, filamin-A,[450] and is likely important to make sure that the CaSR is expressed at sufficient levels on the cell surface to enable it to continuously monitor and maintain a constant level of Ca^{2+}_o. Additional binding partners of the CaSR comprise the K^+ channels, Kir4.1 and Kir4.2, caveolin-1, and the E3 ubiquitin ligase, dorfin.[209] The functional consequences of these interactions remain to be fully elucidated, but Kir4.1 and Kir4.2 colocalize with the CaSR in the basolateral membrane of the distal nephron, and co-expression of the CaSR with these two channels in *X. laevis* oocytes decreases channel activity.[211] Dorfin likely participates in regulating the proteasomal degradation of the receptor.[209]

REGULATION OF CaSR GENE EXPRESSION

Several factors upregulate the expression of the CaSR gene; these include elevated levels of Ca^{2+}_o[447] and calcimimetics,[287] both of which act by stimulating the CaSR, $1,25(OH)_2D_3$ (through vitamin D responsive elements (VDRE) in the CaSR's two promoters, which reside within alternatively spliced regions of the first exon (exons 1A and B)),[60] the cytokines interleukin-1β[308] and interleukin-6,[61] and the chemokines MCP-1 and SDF-1α (which likely traffic intracellular receptor to the cell surface in the short term).[315] Because the CaSR also upregulates the VDR gene and activation of each gene upregulates its own expression,[268,287] there potentially could be synergistic interactions between the VDR and CaSR. For example, activation of the CaSR upregulates its own expression and that of the VDR; upregulation of the latter could potentiate vitamin D signaling via increased VDR occupancy (even without a change in the level of $1,25(OH)_2D_3$), thereby further stimulating CaSR expression and action, and so forth. Factors that downregulate CaSR gene expression include PTH and a high phosphate diet.[361] A reduction in CaSR expression also occurs in both primary (1°) hyperparathyroidism (HPT) and secondary (2°) HPT (e.g., in the setting of renal insufficiency) through incompletely defined mechanisms,[92,119,122,233,398] although a reduction in circulating $1,25(OH)_2D_3$ levels likely contributes in the setting of chronic kidney disease by decreasing CaSR gene expression.

OVERVIEW OF THE CaSR'S ROLE IN Ca^{2+} HOMEOSTASIS

The response of the Ca^{2+}_o homeostatic system to hypocalcemia illustrates the tightly integrated functions of the three key elements of the Ca^{2+}_o homeostatic system: (1) the CaSR, the principal sensor of Ca^{2+}_o, (2) the tissues that mediate the fluxes of Ca^{2+} into and out of the extracellular fluid (ECF) (e.g., bone, kidney and intestine), and (3) the calciotropic hormones regulating these fluxes (PTH, $1,25(OH)_2D_3$ and Ca^{2+}_o itself, serving its "hormone-like" role via the CaSR). Further details can be found in chapter 65. Hypocalcemia evokes PTH secretion by the parathyroid glands. The hypocalcemia-induced increase in the circulating PTH level exerts three key homeostatic actions on the kidney: (1) enhancing distal tubular reabsorption of Ca^{2+}, (2) promoting phosphaturia, and (3) stimulating the synthesis of 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) from its largely inactive precursor, 25-hydroxyvitamin D_3. Hypocalcemia also directly stimulates $1,25(OH)_2D_3$ production in the proximal tubule by an action that is likely CaSR-mediated.[409,433] The stimulation of renal Ca^{2+} retention by PTH takes place both in the cortical thick ascending limb of Henle's loop (CTAL)[186] and in the distal convoluted tubule (DCT),[10,139] as described in detail later.[43,104] Consequently, there is a "resetting" of Ca^{2+} reabsorption by the kidney, producing a shift to the right in the curve relating serum to urinary Ca^{2+} concentration so that more Ca^{2+} is reabsorbed at any given level of Ca^{2+}_o.[323] Elevated circulating

concentrations of $1,25(OH)_2D_3$ enhance: (1) gastrointestinal absorption of Ca^{2+}, (2) reabsorption of Ca^{2+} in the DCT,[199,200] and (3) release of skeletal Ca^{2+} in conjunction with the bone resorptive action of PTH. $1,25(OH)_2D_3$ also inhibits PTH production and its own synthesis in the proximal tubule via the VDR, as noted earlier.[48,300] The resultant translocation of Ca^{2+} into the extracellular fluid from GI tract and bone, combined with greater renal tubular reabsorption of Ca^{2+}, will, except when there is severe Ca^{2+} deficiency, restore Ca^{2+}_o to normal.

A more recently discovered hormone that regulates both calcium and phosphate homeostasis as well as the interactions between these homeostatic systems is fibroblast growth factor (FGF)-23. It is released principally by osteocytes (osteoblasts encased in bone during bone formation) in response to $1,25(OH)_2D_3$ and hyperphosphatemia,[221,384,387] and its exerts a potent phosphaturic action on the proximal tubule. FGF-23 inhibits both $1,25(OH)_2D_3$ production and PTH secretion, providing negative feedback control of $1,25(OH)_2D_3$ synthesis and the phosphaturic action of PTH. This rapidly developing field is reviewed elsewhere in this volume and in recent reviews.[221,384,387]

CaSR FUNCTION IN PARATHYROID

As just noted, the regulation by Ca^{2+}_o of PTH secretion by the parathyroid chief cells is a key component of the Ca^{2+}_o homeostatic system.[48,190] The molecular mechanism by which Ca^{2+}_o performs this feat was deduced by the cloning of the CaSR in 1993 in the laboratories of Brown and Hebert.[51] The CaSR senses the extracellular ionic activity of the divalent minerals, Ca^{2+} and Mg^{2+}, and translates this information, via the complex array of cellular signaling pathways described previously, to modify PTH secretion,[196,307] preproPTH mRNA levels via changes in its stability,[248,302] and parathyroid gland hyperplasia.[88,419] Genetic studies have demonstrated that the activity of this receptor determines the steady-state plasma calcium concentration in humans by regulating key elements in the calcium homeostatic system.[310,383]

CaSR Regulates PTH Secretion

The level and constancy of plasma ionized Ca^{2+} are set in large part by regulating the release of Ca^{2+} from bone via the actions of secreted PTH and $1,25(OH)_2D_3$ as well as by modulation of the Ca^{2+} excretion by the kidney, and, indirectly via the action of $1,25(OH)_2D_3$, intestinal calcium absorption, as noted above.[48,190] Figure 63.3 shows the typical inverse relationship between PTH secretion and plasma Ca^{2+}. In contrast there is a direct relationship between urinary Ca^{2+} excretion and plasma Ca^{2+} (Fig. 63.4). These effects of plasma ionized Ca^{2+} on PTH secretion and renal Ca^{2+} excretion are mediated by the CaSR. The role of the CaSR in divalent mineral homeostasis has been established by the identification and characterization of inherited hyper- or hypocalcemic disorders that result from CASR gene mutations (the official designation of the gene for the human CaSR is in all capital letters and italicized) (chromosome 3q13.3–21; Fig. 63.5).[48,174,182,324,404] *In vitro* studies in mammalian cells expressing normal or mutant CaSR proteins have confirmed that these receptor mutations alter the Ca^{2+} EC_{50} of the CaSR (CaSR

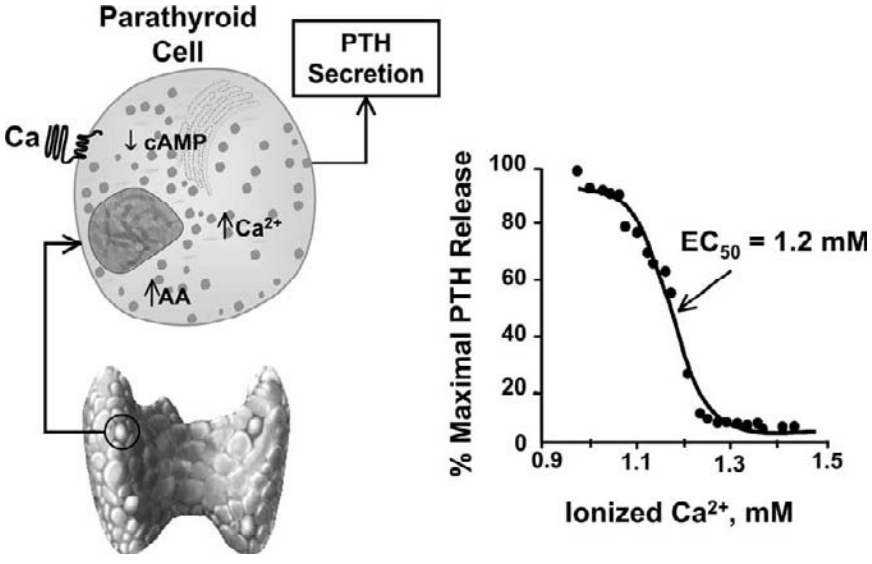

FIGURE 63.3 Inverse relationship between ionized serum calcium and parathyroid hormone (PTH) secretion. PTH secretion is maximal at low ionized calcium; raising calcium reduces secretion via several intracellular signaling pathways, including decreased levels of cAMP and increases in the products of PLA_2 and PLC action. Ionized calcium sensing by the parathyroid gland is mediated by the calcium-sensing receptor (CaSR). The EC_{50} for calcium-sensing by the gland is shown (1.2 mM Ca^{2+}_o); at normal ambient levels of Ca^{2+}_o, the gland is about 70–75% suppressed.

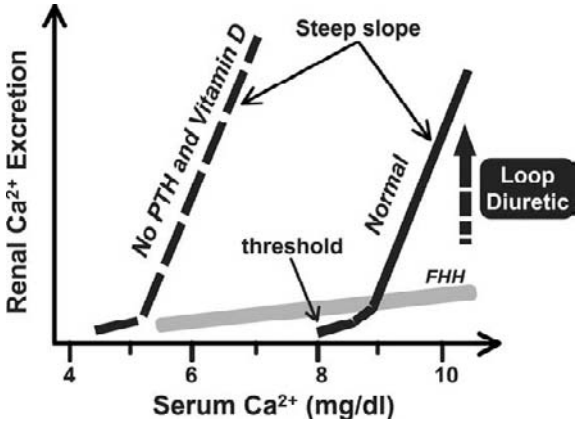

FIGURE 63.4 Direct relationship between serum calcium and renal calcium excretion demonstrating the calcium-sensing ability of the nephron (solid black curve). Note the steep relationship after reaching a threshold serum calcium concentration. In individuals with calcium-sensing receptor (CaSR)—inactivating mutations (FHH, familial hypocalciuric hypercalcemia), the relationship (solid gray line) is flatter than normal. This defect in the relationship is not due to a disturbance in calcium transport function of the thick ascending limb since loop diuretics can markedly increase calcium excretion in FHH. In the absence of parathyroid hormone and vitamin D, the threshold of serum calcium at which calcium excretion begins is reduced but the steep relationship between serum calcium and renal calcium excretion remains. The latter is due to the action of the CaSR.

refers to the CaSR protein).[13,252,292,325] Loss-of-function mutations in one or both of the CASR alleles result in hypercalcemic disorders due to upward resetting of the CaSR EC_{50} for ionized Ca^{2+} in both the parathyroid gland and kidney.[48,83,404] Autosomal dominant hypercalcemia, in which one CASR allele has an inactivating mutation, typically presents as a benign hypercalcemic disorder called familial hypocalciuric hypercalcemia (type 1 FHH; OMIM 145980, known as HHC1) or as symptomatic hypercalcemia in neonatal hyperparathyroidism (NHPT).[326] Two phenotypically similar conditions (HHC2, OMIM 145981; and HHC3, OMIM 600740) are linked to the long[256] and short arms of chromosome 19,[185] respectively, but the responsible genes have not yet been identified. Neonatal severe hyperparathyroidism (NSHPT) results from consanguineous unions in FHH families in which both alleles have inactivating mutations[48,274] or, occasionally, in families in which the two parents have different inactivating mutations (i.e., producing a compound heterozygous infant).[237] Infants with NSHPT exhibit severe hypercalcemia frequently necessitating total parathyroidectomy.[48,404] The hypercalcemia in these loss-of-function CaSR disorders is usually associated with reduced renal Ca^{2+} excretion,[246,275] rather than the increased Ca^{2+} excretion that is observed in other hypercalcemic states (e.g., 1° HPT and malignant hypercalcemia).[403] The abnormal renal response in FHH demonstrates the important role of the CaSR in the hypercalciuric response to hypercalcemia.

Homozygous CaSR knockout mice exhibit marked parathyroid hyperplasia and hyperparathyroidism and die soon after birth due to severe hypercalcemia (Fig. 63.5).[196] Support for the role of PTH in causing the severe and lethal hypercalcemia came form the observations that the lethal mouse phenotype can be rescued by knocking out the PTH gene[238] or by deletion of the *Gcm2* gene, which is the "master gene" needed for development of the parathyroid glands.[412] Studies carried out in the mice with knockout of PTH and/or the CaSR have documented the crucial role of CaSR-regulated PTH secretion as a "floor" preventing hypocalcemia, while the CaSR-mediated upregulation of renal Ca^{2+} excretion and stimulation of calcitonin secretion are an effective "ceiling" limiting increases in serum calcium in response to dietary or other forms of calcium load.[225] Indeed, the PTH knockout mice defend against hypercalcemia just as well as the wild type mice, even though they lack PTH and the ability to suppress it while hypercalcemic.

Autosomal dominant, gain-of-function (activating) mutations in the CaSR result in an opposite shift in plasma ionized calcium (i.e., hypocalcemia) due to downward resetting of the receptor EC_{50} (autosomal dominant hypocalcemia (ADH); OMIM 146200).[341] In some individuals with severe activating mutations, a renal salt wasting disorder with hypercalciuria has been observed that mimics the hyperprostaglandin E_2 syndrome (type V Bartter syndrome).[415,432] The latter confirms the important role of the CaSR in regulating renal Ca^{2+} handling and clearly demonstrates the importance of the CaSR in regulating salt transport in the thick ascending limb (TAL).[187] CASR gene polymorphisms also appear to contribute to the normal variation in steady-state plasma ionized Ca^{2+} concentration, at least in certain populations.[87,383] CaSR-activating or -inhibiting autoantibodies can result in autoimmune hypoparathyroidism[227,231] or an acquired syndrome mimicking FHH, called autoimmune hypocalciuric hypercalcemia, respectively.[232,270,317] Mice with an activating mutation in the CaSR exhibit a phenotype similar to that in patients with ADH.[203] All these various lines of evidence convincingly document the key role of the CaSR in mediating the effects of Ca^{2+} on PTH secretion.

In addition to reducing the secretion of PTH, activation of the CaSR increases the degradation of full length, biologically active PTH1-84 to PTH7-84 and smaller carboxyterminal fragments, thereby decreasing the secretion of intact PTH further still during hypercalcemia and, conversely, increasing it in the setting of hypocalcemia.[413]

CaSR Regulates Expression of the preproPTH Gene

Elevated levels of Ca^{2+}_o and calcimimetics not only inhibit PTH secretion but also decrease the levels of the mRNA encoding preproPTH;[302,365] this action of the calcimimetics proves the mediatory role of the CaSR in regulating preproPTH gene expression. The CaSR-mediated alteration in the level of preproPTH mRNA is the result of a change in preproPTH mRNA stability rather than in gene transcription per se. $1,25(OH)_2D_3$, in contrast, acts by a direct inhibitory action on the transcription of this gene.[391] Naveh-Many, Silver and coworkers have clarified the molecular mechanisms by which Ca^{2+}_o and the CaSR control the stability of preproPTH mRNA. Exposing parathyroid cells to elevated levels of Ca^{2+} activates the CaSR and, through a pathway that involves stimulation of calmodulin (CaM) and protein phosphatase 2B, post-translationally modifies and reduces the binding of the preproPTH mRNA stabilizing factor, AU-rich factor (AUF-1), to an AU-rich element in the 3′ untranslated region (UTR) of the preproPTH mRNA.[248] The loss of AUF-1 from this binding site permits a second, destablizing protein, K-homology splicing regulator protein (KSRP), to bind to the same site. KSRP subsequently interacts with and is activated by the peptidyl-prolyl isomerase, Pin-1, and, pari passu, recruits the endoribonuclease, PMR1, which is part of the RNA-cleaving exosome. PMR-1 then degrades prepro-PTH mRNA by cleaving it internally.[303,304]

CaSR Regulates Parathyroid Cellular Proliferation

Studies in humans with NSHPT[115] or in mice homozygous for knock out of the *Casr* gene (the symbols for mouse genes are italicized with only the first letter capitalized)[196] have proven the CaSR's importance in regulating parathyroid cellular proliferation. In both cases, marked parathyroid cellular proliferation and glandular enlargement ensue despite severe hypercalcemia, documenting that the CaSR has an essential role in tonically inhibiting parathyroid cellular proliferation. Studies in uremic rat models[94,95] have illuminated the mechanisms by which high dietary intake of Ca^{2+}, acting via the CaSR, controls parathyroid proliferation. Induction of the cyclin dependent kinase inhibitor, $p21^{WAF1}$, and downregulation of the growth factor, TGF-α, and its receptor, the epidermal growth factor receptor (EGFR), both of which are upregulated in this setting, are key components of this mechanism.[95] 1,25 $(OH)_2D_3$ appears to act in a similar way to inhibit parathyroid cellular proliferation in similar experimental models.[96] An additional mechanism that may participate in stimulation of parathyroid growth during hypocalcemia is an endothelin-1-mediated stimulation of parathyroid cellular growth.[217] Similar studies are difficult to perform in non-uremic animals owing to their much slower rate of parathyroid proliferation, but it seems likely that similar mechanisms participate. Reduced expression of p21 and another cyclin dependent kinase inhibitor, p27, may also participate in the dysregulation of parathyroid growth in both primary (1°) and secondary (2°) hyperparathyroidism (HPT).[57] The second messenger pathway(s) that link the CaSR to the regulation of parathyroid proliferation have not yet been clarified.

Interactions of Vitamin D and the CaSR in the Regulation of Parathyroid Function

A large body of data has stressed the importance of vitamin D in reducing expression of the preproPTH gene and parathyroid proliferation. What is the relative importance of the VDR and CaSR in controlling parathyroid function? The CaSR clearly regulates the secretion of PTH over a time frame from seconds to minutes or longer and is the dominant regulator of acute changes in secretory rate. Over a longer time frame of three weeks, vitamin D deficiency and hypocalcemia both modulate preproPTH mRNA levels in the rat, although hypocalcemia of ~6 mg/dl more powerfully stimulates preproPTH gene expression than does vitamin D deficiency.[300]

Recent studies utilizing mouse knockout models, however, have provided surprising results regarding the relative importance of the VDR and CaSR in controlling parathyroid gland function *in vivo*. As noted before, homozygous knock out of exon 5 of the CaSR causes striking hyperparathyroidism with marked elevations in both PTH and parathyroid gland size, which clearly cannot be compensated by the remaining VDR gene.[196] This mouse model, if anything, likely underestimates the consequences of loss of the CaSR on parathyroid function, since knock out of exon 5 of the CaSR produces, in some tissues, an alternatively spliced CaSR that lacks exon 5 (which encodes part of the CaSR ECD) and can seemingly still signal.[370] Thus the VDR apparently has limited ability to offset loss of the CaSR in this animal model. In contrast, studies of mice with knockout of the VDR[250] have demonstrated that the CaSR effectively compensates for loss of the vitamin D receptor with regard to the control of parathyroid function. That is, while VDR-/- mice develop strikingly elevated levels of PTH and marked parathyroid enlargement on a standard diet,[156] administering a calcium-rich "rescue" diet normalizes both serum Ca^{2+} and PTH levels.[156,250] Thus hypocalcemia *per se* rather

than vitamin D deficiency is seemingly the dominant contributor to the elevated PTH levels. In addition, if the rescue diet is begun early in life, it completely prevents the parathyroid enlargement in the VDR-/- mice, showing that hypocalcemia per se rather than loss of the VDR was also a critical contributor to parathyroid growth in this setting. Subsequently, Meir, et al. created mice with knockout of the VDR only in the parathyroid glands.[286] In this way, the actions of the VDR on the parathyroid could be separated from systemic alterations in mineral ion homeostasis, e.g., owing to loss of the VDR in kidney and intestine. The mice with parathyroid-specific VDR ablation manifest only modest (~30%) elevations in serum PTH but do not exhibit any change in the number of proliferating parathyroid cells and have normal serum calcium concentrations.[286] Thus, while administering exogenous $1,25(OH)_2D_3$ clearly suppresses preproPTH gene transcription and parathyroid proliferation *in vivo* and *in vitro*, vitamin D seemingly has only a limited role in regulating parathyroid function *in vivo* under normal physiological conditions. These results should not be taken, however, to mean that $1,25(OH)_2D_3$ has no useful therapeutic role, especially in the 2° HPT of renal insufficiency (see below and elsewhere in this volume). Finally, it would be interesting to investigate CaSR signaling efficiency in the parathyroid in mice with deficient VDR signaling to determine to what extent compensatory alterations in the CaSR and/or its downstream signaling components contribute to the phenotypes observed with global or parathyroid-specific knockout of the VDR.

CaSR AND C-CELL FUNCTION

Studies in CaSR knock out mice have documented the mediatory role of the receptor in high Ca^{2+}_o-stimulated CT secretion by showing blunting of high Ca^{2+}-induced CT secretion in response to elevated levels of Ca^{2+}_o in CaSR +/− mice[141] and near total loss of Ca^{2+}-elicited CT secretion in CaSR-/-PTH-/- mice.[225] A plausible model for how the CaSR stimulates CT secretion[281] involves CaSR-induced activation of a nonselective cation channel, which causes cellular depolarization, thereby stimulating voltage-sensitive calcium channels and causing the increase in Ca^{2+}_i that activates exocytosis. Although CT is a potent hypocalcemic hormone in rodents, it has a much more modest, if any, hypocalcemic action in normal humans.

CaSR AND KIDNEY FUNCTION

The kidney plays key roles in Ca^{2+} and Mg^{2+} homeostasis by providing the major route for divalent mineral excretion from the body. Thus, it should not be surprising that variations in serum Ca^{2+} and Mg^{2+} affect many aspects of renal function. For instance, an increase in serum Ca^{2+} reduces glomerular filtration rate, inhibits renin secretion by the juxtaglomerular ^{JG} cells,[137] and induces renal vasoconstriction.[136] The kidney regulates the renal excretion of Ca^{2+} and Mg^{2+} by modulating the tubular reabsorption of these divalent cations along the nephron. The cellular mechanisms mediating mineral ion transport across the various nephron segments from proximal tubule (PT) to collecting duct (CD) are detailed elsewhere in this book (see Chapter 65). The cellular distribution of the CaSR in the kidney coincides with crucial aspects of Na^+, water and divalent mineral transport along the nephron that enables this receptor to modify a range of transport process key to the "safe" excretion of these minerals (i.e., in the absence of stones or nephrocalcinosis). The CaSR is apical in the PT[359] and inner medullary collecting ducts (IMCDs)[379] and basolateral in the TAL,[359] distal convoluted tubule (DCT),[359] and macula densa cells.[359] This differential cellular polarization of the CaSR permits $Ca^{2+}{}_o$ to be sensed in the initial glomerular filtrate in the PT and the final urine in the IMCD, while concurrently responding to changes in serum Ca^{2+} in segments critical for regulated Ca^{2+}/Mg^{2+} absorption (TAL and DCT).[186]

Evidence of a role for plasma Ca^{2+} concentration in determining renal Ca^{2+} excretion comes from examining the relationship between these parameters. Beyond a specific threshold of plasma Ca^{2+}, urinary Ca^{2+} excretion rises steeply with increasing serum Ca^{2+} concentrations (Fig. 63.4) (for reviews see[186,243,244]). Calciotropic hormones, such as PTH and calcitonin, as well as vitamin D, do not modify the steep relationship between plasma Ca^{2+} and urine Ca^{2+} excretion, but instead shift the threshold for the curve to the right such that urinary Ca^{2+} loss occurs at a higher than normal plasma Ca^{2+} Fig. 63.4.[243,244] The steepness of the relationship between urinary Ca^{2+} excretion and plasma Ca^{2+} is, however, lost when the function of the CaSR is impaired as happens in individuals with inactivating mutations of this receptor.[8] The most compelling evidence supporting the role of the CaSR in sensing Ca^{2+}_o and regulating urinary Ca^{2+} excretion comes from such genetic "experiments-in-nature." As discussed earlier in this chapter, individuals heterozygous for inactivating mutations in the CaSR (FHH) are hypercalcemic but have absolute or relative hypocalciuria (i.e., inappropriately low for the prevailing serum calcium concentration).[115,275,403] In contrast, individuals with activating mutations (ADH) are hypocalcemic but exhibit relative or absolute hypercalciuria.[48] Abnormal Ca^{2+}_osensing by the kidney CaSR can account for these abnormal patterns of renal Ca^{2+} excretion.[403]

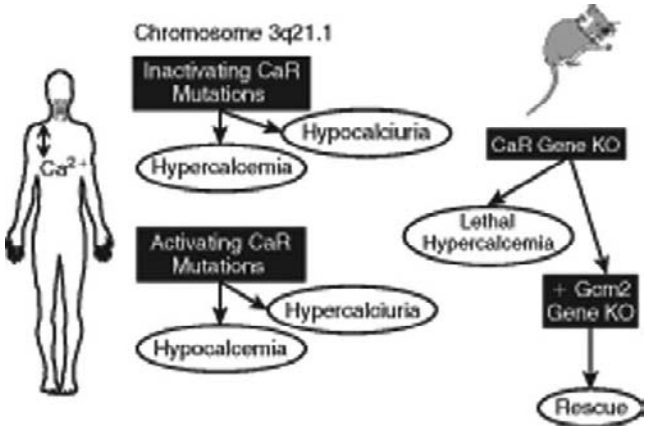

FIGURE 63.5 A: Mutations of the calcium-sensing receptor (CaSR) on chromosome 3q13.3-21 alter the steady-state serum ionized calcium concentration and the calcium-sensing ability of the kidney (serum calcium−urine calcium excretion relationship; Fig. 63.4). Receptor inactivating mutations give rise to hypercalcemia and hypocalciuria while activating mutations result in the opposite phenotype. B: In mice, knocking out the Casr gene results in a lethal phenotype from severe hypercalcemia and hyperparathyroidism within a few days after birth. The severe phenotype can be rescued by deleting the Gcm2 gene, which is required for development of the parathyroid gland. These double-knockout mice have low circulating levels of PTH that is secreted from thymus but is not under the control of the CaSR. See text for discussion.

While our understanding of the function of the CaSR in the kidney is still advancing (see[10,186,358] for reviews), some aspects of CaSR function have been determined for several nephron segments actively involved in the reabsorption of Ca^{2+} and Mg^{2+} as well as Na^+ and water. The reabsorption pattern of Ca^{2+} and Mg^{2+} and the localization of the CaSR along the nephron are shown in Fig. 63.6. In the following sections, we provide a summary of our understanding of the CaSR's functions in specific nephron segments.

CaSR in the Proximal Tubule

For some time, there has been both *in vivo*[409,433] and *in vitro*[30] evidence that Ca^{2+}_o directly modulates the 1-hydroxylation of 25-hydroxyvitamin D_3 in the PT. To avoid the confounding impact of Ca^{2+}_o-induced alterations in circulating PTH levels *in vivo*, Treschel et al. and Weisinger et al. used thyroparathyroidectomized rats infused with PTH to "clamp" the circulating PTH level.[409,433] Changes in $1,25(OH)_2D_3$ levels were then assessed during alterations in serum Ca^{2+}. The steep inverse sigmoidal relationship between Ca^{2+}_o and $1,25(OH)_2D_3$ levels that was observed[433] was reminiscent of the relationship of PTH to Ca^{2+}_o *in vivo* and *in vitro*. Similar results were obtained *in vitro* utilizing an SV40-transformed human PT cell line, that is, enhanced $1,25(OH)_2D_3$ synthesis at low Ca^{2+}_o and inhibition at high Ca^{2+}_o.[30] Recent data supports the CaSR's role in mediating the direct effects of Ca^{2+}_o on the 1-hydroxylation of 25-hydroxyvitamin D_3. Maiti and Beckman utilized the PT cell line, HK-2G, in which high Ca^{2+}_o inhibits CYP27B1 expression,[17] to show that high Ca^{2+} upregulates VDR expression[268] by a p38 MAPK-dependent mechanism.[269] Knocking down the CaSR with siRNA obviated the high Ca^{2+}_o-elicited increase in VDR, showing the latter was CaSR-mediated.[269] However, use of siRNA to document that the CaSR mediated the concomitant inhibition of CYP27B1 expression was not reported.[17] It has also not yet been shown that the high Ca^{2+}_o-induced, CaSR-mediated increase in VDR expression in the PT by itself can account for the reduced expression of CYP27B1.

Furthermore, $1,25(OH)2D_3$ regulates CaSR expression in the kidney: One study in vitamin D−deficient rats found a 90% increase in CaSR expression in the kidneys of $1,25(OH)2D_3$-replete animals,[45] and vitamin D replete rats showed a similar increase in response to $1,25(OH)2D_3$.[60] Vitamin D-responsive elements (VDREs) in the CASR and *Casr* genes and provide a mechanism whereby $1,25(OH)2D_3$ upregulates CaSR expression in parathyroid, thyroid C-cell, and kidney.[60] As noted earlier, since $1,25(OH)2D_3$ upregulates its own expression as well as that of the CaSR, and the CaSR upregulates its own expression and that of the VDR, there could be synergistic interactions between the effects of Ca^{2+}_o, acting via the CaSR, and $1,25(OH)_2D_3$ on the PT and elsewhere in the kidney. CaSR expression in the PT is reduced by PTH and dietary phosphate loading.[361]

Transcripts for the CaSR are present in the regions where PTH/PTHrP mRNA is expressed in the proximal convoluted (PCT) and straight tubule (PST) (as well as in glomerulus, CTAL, DCT and cortical CD).[360] High Ca^{2+}_o inhibits PTH-induced cAMP accumulation in the PCT and CTAL.[278,399] This action could explain, at least in part, the inhibition by the CaSR of PTH-stimulated phosphate excretion. Thus the CaSR directly modulates the action of PTH on the PT (and of renal Ca^{2+} reabsorption in the TAL) in addition to its central, inhibitory effect on PTH secretion. The CaSR protein is in the subapical compartments of the PT,[359] where it mediates some of the effects of high Ca^{2+} on PTH-induced cAMP production.[278] We have hypothesized a role for the receptor in the transport of phosphate and/or in the regulation of a local ionic homeostasis, bypassing systemic levels of calciotropic hormones (see following paragraphs).[358]

McKinney and coworkers[283] reported that luminal and peritubular perfusion of rabbit PCT with high Ca^{2+}_o (5 mM) modulated water and HCO_3^- reabsorption. Because a large fraction of Na^+ transport in PT

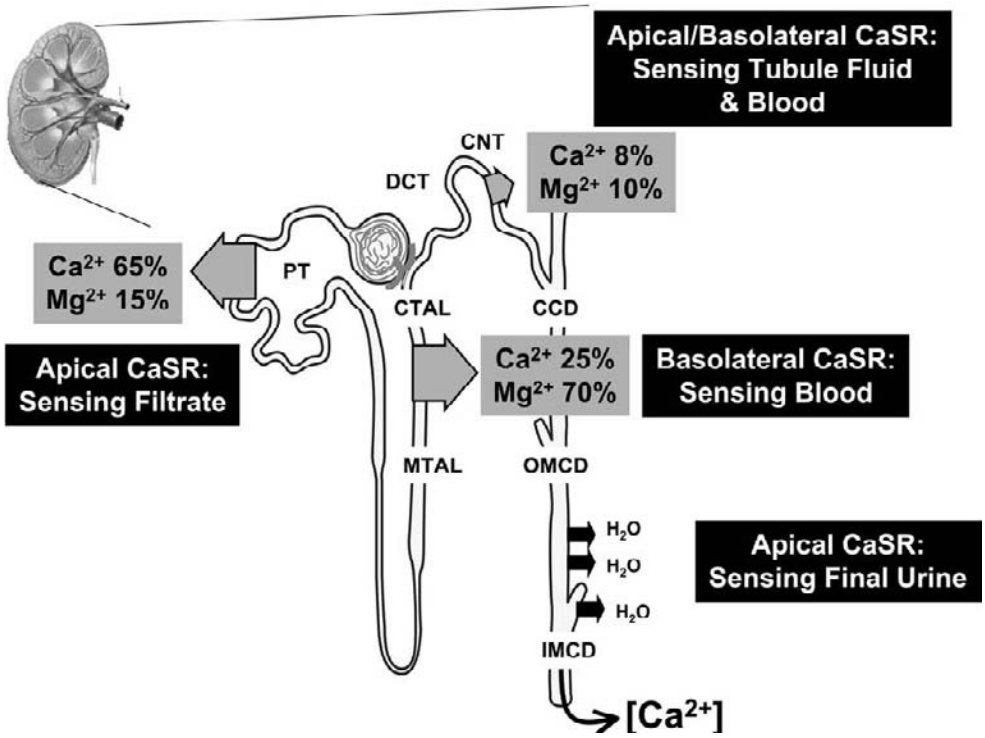

FIGURE 63.6 Schematic representation of fractional reabsorption of calcium and magnesium along the nephron together with the localization of the calcium-sensing receptor (CaSR). The CaSR not only responds to calcium in the blood–interstitium (basolateral localization), but in many nephron segments, the receptor may be modulated by calcium/magnesium in the tubule fluid (apical localization). See text for discussion.

depends on basolateral Na^+, K^+-ATPase (NKA), NKA activity provides an index of solute reabsorption. Preliminary studies by Hebert's group have suggested that increases in Ca^{2+}_o reduce NKA activity by 20 to 35% in a rabbit PT cell line. This magnitude of NKA inhibition is similar to that observed with dopamine, a known regulator of PT solute and volume transport. Modulation of PT NKA by CaSR activation would enable filtered (i.e., luminal) Ca^{2+} to regulate Ca^{2+} delivery to distal nephron segments. In contrast, since only 15% of filtered Mg^{2+} is reabsorbed in the PT (in contrast to the 50–60% of Ca^{2+} reabsorbed proximally), activation of the CaSR in the PT would be expected to have little effect of Mg^{2+} homeostasis.

CaSR in the Thick Ascending Limb of Henle

About 25% of filtered calcium is reabsorbed along the TAL (Fig. 63.6).[139] It is well established that increases in extracellular Ca^{2+} and Mg^{2+} inhibit Cl^- transport in TAL.[100,108,109,344,345] Increases in plasma, but not urinary, Ca^{2+} (or Mg^{2+}) concentrations directly modulate NaCl and mineral ion transport in the rat loop of Henle,[105,344,345] consistent with CaSR expression on basolateral membranes of the TAL.[359,360] Since most divalent mineral reabsorption mediated by the TAL occurs in CTAL,[105,138,140,271] the effect of plasma Ca^{2+} on renal Ca^{2+} (Mg^{2+}) handling relates to changes in interstitial ionized Ca^{2+} and Mg^{2+} surrounding the CTAL. In medullary thick ascending limb (MTAL) and CTAL the lumen-positive transepithelial voltage generated by NaCl reabsorption[58] drives most divalent mineral reabsorption via the paracellular route in mouse,[105,109] rat,[271] and rabbit.[36,104] In addition, a portion of Ca^{2+} absorption in the CTAL (at least in the mouse) may also traverse the transcellular route (see Chapter 65).[140] A number of hormones (e.g., vasopressin, parathyroid hormone, glucagon, calcitonin), coupled to Gαs-linked receptors, increase cellular cAMP accumulation[103,104,189] thereby stimulating NaCl and divalent mineral reabsorption through both paracellular and transcellular routes.[103,104] As we shall see in the following paragraphs, the CaSR uses a variety of mechanisms and second-messenger pathways to modulate NaCl reabsorption, and thereby divalent mineral absorption, in the TAL.

Both genetic experiments-of-nature and acquired disorders have established that the CaSR is a significant regulator of functionally coupled salt and divalent mineral transport in the TAL. Activating mutations of the CaSR are generally associated with autosomal

dominant hypocalcemia (see preceding sections)[341]; however, certain activating mutations of the CaSR have been found in individuals presenting with the phenotypic picture of Bartter syndrome combined with the typical hypocalcemic hypercalciuria present with activating CaSR mutations.[415,432] Bartter syndrome is a set of renal salt- and Ca^{2+}- and Mg^{2+}-wasting disorders due to low or absent ion transport in the TAL.[355] Mutations in several salt transporter genes or in genes encoding transporter regulatory proteins in the TAL cause Bartter syndrome.[187] It is now clear that the CaSR is one of these regulatory proteins. In addition, an acquired Bartter-like phenotype has also been observed in certain individuals receiving the aminoglycosides, gentamicin or amikacin,[82] likely reflecting aminoglycoside antibiotic-induced activation the CaSR in the TAL.[284,431]

At least three second-messenger pathways appear to be involved in CaSR-mediated regulation of transport in the TAL:[16,139,189,358] (1) the CaSR→↑PLA_2→↑AA →↑P_{450} →↑20-HETE pathway; (2) the CaSR→↓AC/↑PDE→↓cAMP pathway; and (3) the CaSR→↑TNF →↑COX-2→↑PGE_2 pathway. A second-messenger pathway commonly coupled to CaSR stimulation is $G\alpha_q$ activation of phospholipase C, release of IP_3 and a rise in Ca^{2+}_i via release of Ca^{2+}_o from internal stores (CaSR→↑PLC→↑IP_3→↑Ca^{2+}_i pathway).[13,51,229] Increasing Ca^{2+}_o does lead to rises in Ca^{2+}_i in the rabbit, rat, and mouse TAL[67,107,320,427] but there are divergent data regarding whether this increase in Ca^{2+}_i is functionally coupled to the $G\alpha_{q/11}$→↑PLC pathway.[107,427] The rise in intracellular Ca^{2+} appears to take place via extracellular entry in the rabbit,[107] but in the mouse CTAL CaSR agonists do induce a rise in Ca^{2+}_i from a thapsigargin-sensitive pool.[320] In the rat, increases in Ca^{2+}_o produce a concentration-dependent increase in IP_3 implicating the classical CaSR→↑PLC→↑IP_3→↑Ca^{2+}_i pathway.[102] Regardless of the mechanism, an important conclusion is that CaSR activation in the TAL gives rise to an increase in Ca^{2+}_i.

The CaSR→↑PLA_2→↑AA→↑P_{450}→↑20-HETE pathway couples CaSR activation to regulation of apical K^+ channels in the TAL (Fig. 63.7).[427,428] Since the apical 30-pS and 70-pS recycling K^+ channels are crucial for maintaining NaCl transport by both the CTAL and MTAL,[168,189,191] inhibition of this channel would decrease NaCl, Ca^{2+} and Mg^{2+} transport. Ca^{2+}_o and the other CaSR agonists, activate phospholipase A2 (PLA_2) releasing arachidonic acid (AA), which can be metabolized by a CYP4A P_{450}-hydroxylase to generate 20-HETE (the CaSR→↑PLA_2→↑AA→↑P_{450}→↑20-HETE pathway).[127,137,426,427,428] 20-HETE inhibits the 70-pS (but not the 30-pS) apical K^+ channel in inside-out membrane patches.[426] In contrast, AA can inhibit the 30-pS (ROMK1) K^+ channel activity independently of

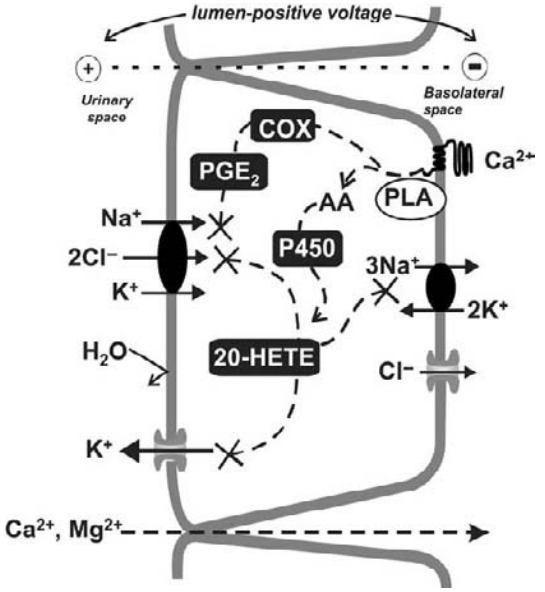

FIGURE 63.7 The PLA_2→↑AA→↑P_{450}→↑20-HETE and the CaSR→↑TNF→↑COX-2→↑PGE_2 pathways couple calcium-sensing receptor (CaSR) activation to regulation of salt and divalent mineral handling in the thick ascending limb. See text for discussion.

the generation of AA metabolites.[263,264] Thus, both the 30-pS and 70-pS K^+ channels in the apical membranes of TAL can be inhibited by components of the CaSR→↑PLA_2→↑AA→↑P_{450}→↑20-HETE pathway. This pathway has also been implicated in the inhibition of salt transport in the CTAL by angiotensin II (Ang II)[161,262] and bradykinin.[170] This effect of Ang II is mediated, at least in part, by P_{450}→↑20-HETE–mediated inhibition of the 70-pS K^+ channel.[262] In addition, this pathway has been implicated in the effect of a K^+-deficient diet to reduce apical 70-pS K^+ channel activity.[172] In fact, K^+ depletion enhances the Ca^{2+}_o-induced inhibition of the 70-pS K^+ channel.[173] Finally, exogenous AA can inhibit adenylate cyclase activity in CTAL by a pertussis toxin–sensitive mechanism[130]; this would modulate the effects of Gαs-coupled hormones on NaCl transport, and thereby divalent mineral absorption.

The CaSR→↓AC/↑PDE→↓cAMP pathway also couples CaSR activation to regulation of salt transport in the TAL (Fig. 63.8). Increases in Ca^{2+}_o reduce vasopressin-stimulated cAMP production in isolated mouse[399,400] and rat[100] TAL segments by inhibiting adenylate cyclase (AC) activity and increasing nucleotide degradation in the TAL.[100,101] Small increases in Ca^{2+}_o (0.5 to > 1.5 mM) produce a modest decrease in cAMP production but a major increase in phosphodiesterase (PDE)-dependent cAMP degradation. Studies on cyclic nucleotide-generating secretagogues in rat and mouse colon support the potent effect of the CaSR to increase PDE activity and suggest that a rise in Ca^{2+}_o

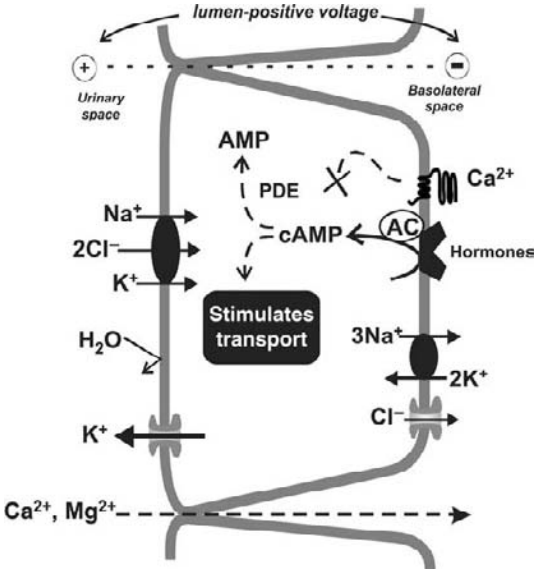

FIGURE 63.8 The CaSR→↓cAMP/↑PDE→↓cAMP pathway couples CaSR activation to regulation of salt and divalent mineral transport in the thick ascending limb (TAL). See text for discussion.

is crucial for activation of PDE.[146] Larger (non-physiological) increases in Ca^{2+}_o (> 1.5 mM) produce an even greater decrease in cAMP production in the TAL.[101] The CaSR agonist-induced rise in Ca^{2+}_i is also crucial for the latter, probably by modulating a Ca^{2+}-inhibitable adenylate cyclase isoform in the TAL (AC types 5 and 6).[64,65,100,193] The mechanism for CaSR-mediated modulation of cAMP has been studied in detail in HEK cells,[150] where CaSR stimulation reversed or prevented cAMP accumulation by activating a pertussis-sensitive $G\alpha_i$ and by increasing Ca^{2+}_i. Low-frequency, but not high-frequency, Ca^{2+}_i oscillations correlated with CaSR-mediated reductions in cAMP. Certain hormones, like PTH, also may enhance the paracellular permeability for Ca^{2+} and Mg^{2+}, at least in mouse CTAL.[439] The CaSR regulates both the active transcellular and passive paracellular reabsorption in mouse CTAL.[297] It should be noted that in bovine parathyroid cells extracellular Ca^{2+} decreases cAMP accumulation by a pertussis toxin-sensitive mechanism, implicating functional coupling of the parathyroid CaSR to $G\alpha_{i2}$.[76] However, in rat TAL, pertussis toxin has no effect on cAMP accumulation induced by increasing Ca^{2+}_o to 2.5 mM.[101]

The CaSR is also expressed in MTAL where it regulates NaCl reabsorption and alters the countercurrent mechanism crucial for urinary concentrating ability. This CaSR effect in MTAL could be important for regulating the concentration of divalent minerals in the final urine, ensuring that divalent minerals are excreted in a less concentrated urine, and thereby, reducing the risk of stone formation or nephrocalcinosis.[190] Information on the effects of CaSR agonists on transport processes in MTAL is inferential. It seems likely that the CaSR in MTAL also functions via the CaSR→↑PLA_2→↑AA→↑P_{450}→↑20-HETE pathway as well as by reducing cAMP,[128] based on a number of studies in MTAL showing that 20-HETE inhibits salt transport[120,121,282,453] by reducing Na^+-K^+-$2Cl^-$ cotransport,[6,282] Na^+-K^+-ATPase,[63,121,282] and apical 70-pS K^+ channel activities.[426]

The CaSR→↑TNF→↑COX-2→↑PGE_2 pathway also participates in CaSR-mediated regulation of salt transport by the TAL (Fig. 63.7). CaSR agonists increase cyclooxygenase-2 (COX-2) expression and COX-2−dependent synthesis of prostaglandin E_2 (PGE_2) in primary cultured MTAL cells.[126,128] CaSR-mediated increases in TNF production in rat MTAL cells depend on activation of PLC and a downstream calcineurin- and NFAT-(nuclear factor of activated T cells) dependent pathway.[423] The increase in COX-2 associated with CaSR stimulation depends, at least in part, on a rise in TNF levels and a TNF autocrine feedback on MTAL cells.[126,128,423] Since PGE_2 reduces NaCl transport by TAL,[97] this CaSR-linked, cytokine-mediated mechanism may contribute to regulating NaCl and divalent mineral handling by CTAL and MTAL. PGE_2 also inhibits the 70-pSK^+ channel in TAL by reducing vasopressin-stimulated cAMP accumulation and by a PKC-dependent pathway.[255] It has been suggested that variations in the local interstitial ionic Ca^{2+} concentration could influence COX-2 activity and PGE_2 production along the TAL from outer medulla to cortex[127] A clinical consequence of the CaSR→↑TNF→↑COX-2→↑PGE_2 pathway can be seen in chronic hypercalcemia where high urinary PGE_2 excretion results from upregulated COX-2 expression.[272] The influence of Ca^{2+}_o on salt transport in TAL via the CaSR→↑TNF→↑COX-2→↑PGE_2 pathway also provides one mechanism for the PGE_2-dependent renal polyuria and salt loss occurring in chronic hypercalcemia.[330]

The integrated effect of stimulation of the CaSR→↑TNF→↑COX-2→↑PGE_2, CaSR→↑PLA_2→↑AA→↑P_{450}→↑20-HETE and CaSR→↓AC/↑PDE→↓cAMP pathways in TAL is a "loop diuretic"−like effect of activation of the CaSR by its agonists. This diuretic effect likely accounts for the observation that increasing serum ionized Ca^{2+} concentration in healthy men by ~25% results in about a 1.5-fold increase in Na^+ excretion[117] and the diuresis and natriuresis that accompanies hypercalcemic states. Chronic hypercalcemia, induced in rats either by PTH[425] to vitamin D,[424] also downregulates several Na^+ transporters, including the Na^+-K^+-$2Cl^-$ cotransporter. While it seems likely that the CaSR mediates these effects, at least in part, this has not been studied experimentally. These

latter two studies also point out that reduced expression of Na^+ transporters in several nephron segments, in addition to TAL, may contribute to the solute and volume depletion observed in some hypercalcemic patients. In addition, this integrated effect of CaSR activity on the TAL and its consequent loop diuretic-like effect may participate in the influence of calcium intake on blood pressure.[171,280,394] The possible impact of molecular variations in the CaSR in Na^+ balance, blood pressure and other processes, such as colonic neoplasia, are currently under investigation.[181,220]

Reabsorption of Ca^{2+} in MTAL and CTAL through the paracellular pathway is accompanied by little water flow since this tubular epithelium has a low water permeability due to the lack of apical aquaporins.[189,309] Thus, we might anticipate that the resultant rise in Ca^{2+} concentration at the basolateral surface of the TAL would activate the CaSR and immediately reduce further NaCl and Ca^{2+} reabsorption. The CaSR, however, has a built in mechanism (Fig. 63.9), whereby increasing ionic strength reduces the receptor's sensitivity (increases the EC_{50}) to extracellular Ca^{2+} by an allosteric mechanism.[188,348] The reduction in CaSR activation at higher ionic strength (NaCl concentration) translates to less inhibition of ion reabsorption. The obvious advantage is that both Na^+ and Ca^{2+} contribute toward their final reabsorption and accumulation at the basolateral membrane of this nephron segment via regulated activity of the CaSR.

As discussed previously, Ca^{2+} and Mg^{2+} reabsorption by the TAL are coupled. This might seem

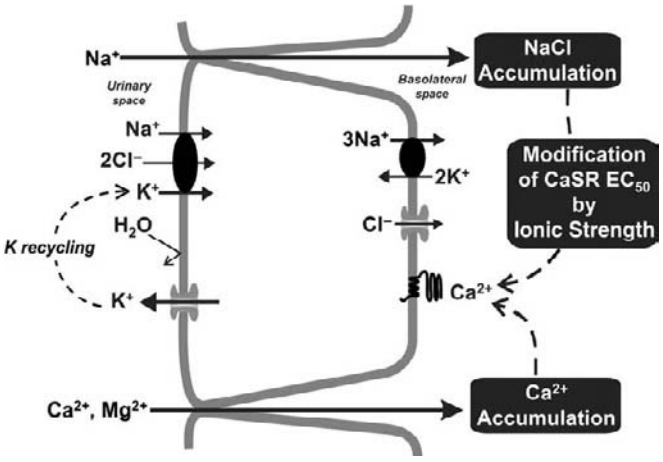

FIGURE 63.9 Role of the allosteric modifying effect of ionic strength in modulating calcium-sensing receptor (CaSR) function in the medullary thick ascending limb. Both Na^+ and Ca^{2+} contribute to their final reabsorption and accumulation at the basolateral membrane of this nephron segment via regulated activity of the CaSR. See text for discussion.

contradictory since normal plasma concentrations of Mg^{2+} are well below the EC_{50} values for CaSR activation by these divalent cations *in vitro*. However, genetic diseases in humans in which the CaSR gene is mutated indicate that the CaSR is also involved in Mg^{2+}_o homeostasis (i.e., serum Mg^{2+} is high-normal or mildly elevated in FHH). While it is still unclear how this is achieved, Mg^{2+}_o might enhance receptor sensitivity to Ca^{2+}_o (a calcimimetic-like effect).[53] However, the tubule Mg^{2+} concentration at TAL can be twice that in the initial glomerular filtrate, owing to the limited reabsorption of Mg^{2+} in the PT compared with other ions such as Na^+, Cl^-, and Ca^{2+}. This increase in Mg^{2+} concentration and delivery to the TAL would enhance Mg^{2+} reabsorption via the paracellular pathway and give rise to higher interstitial Mg^{2+} concentrations near the basolateral membrane. The high basolateral Mg^{2+} concentration may be sufficient to activate the basolateral CaSR in CTAL and suppress reabsorption of further magnesium.

The EC_{50} for Ca^{2+} stimulation of the CaSR can be modified by extracellular pH,[347] suggesting that the receptor might also act as a pH sensor along the nephron. An analogous role for the CaSR has recently be documented in the stomach.[125,158] Thus, not only Ca^{2+}_o, but also the state of acid–base balance could influence salt and water transport along the nephron by modulating the CaSR's activity. Although direct evidence is not available, several mechanisms responsible for NH_4^+ or HCO_3^- transport could be affected by the CaSR, which could, therefore, alter acid-base balance. The TAL actively reabsorbs NH_4^+[160,234,235,236] by transcellular and paracellular pathways.[110] The bulk of transcellular absorption depends on Na^+-K^+(NH_4^+)-$2Cl^-$ cotransporter activity where NH_4^+ instead of K^+ is transported with Na^+ and Cl^-.[160] Paracellular NH_4^+ transport depends on the transepithelial voltage just like the transport of Ca^{2+} or Mg^{2+}. Similar to the influence of the CaSR on divalent mineral absorption, stimulating CaSR (high Ca^{2+}_o and/or pH) may reduce NH_4^+ absorption by the TAL. Therefore, the activity of the CaSR could influence net urinary acid excretion by modulating the accumulation of ammonium/ammonia in the renal medulla. The TAL also reabsorbs HCO_3^- and this transport can be inhibited by angiotensin II via the $PLA_2 \rightarrow \uparrow AA \rightarrow \uparrow P_{450} \rightarrow \uparrow$20-HETE pathway.[161] Similarly, activation of this same pathway by the CaSR would likely reduce HCO_3^- absorption.

Finally, macula densa cells express substantial CaSR immunoreactivity on their basolateral side.[359] Although the receptor's function in this region has not been investigated, indirect evidence suggests that the CaSR could sense changes in Ca^{2+}_o and, accordingly, regulate tubuloglomerular feedback.

CaSR in the DCT

The DCT reabsorbs about 10% of filtered Ca^{2+} by an active transcellular mechanism, as Ca^{2+} movement through the intercellular spaces is negligible because of the markedly low permeability of the tight junctional membranes to Ca^{2+} (see Chapter 65).[138,139] In this nephron segment, Ca^{2+} absorption is inversely proportional to Na^+ absorption[54,93] and strongly regulated by calciotropic factors (PTH, vitamin D). Ca^{2+} absorption is a three-step process. First, apical Ca^{2+} entry occurs down its electrochemical gradient through the Ca^{2+}-selective channel, TRPV5 (see Chapter 65).[197] Second, Ca^{2+} must diffuse across the cell, presumably bound to the Ca^{2+}-binding proteins, calbindins D_{9K} and D_{28K}. Finally, basolateral efflux of Ca^{2+} into the bloodstream is uphill and requires energy achieved by means of a plasma membrane Ca^{2+}-ATPase (PMCA) and the $Na+/Ca^{2+}$ exchanger (NCX1).[28,138,139,257,266] 1,25 $(OH)_2D_3$ acts in the DCT to increase active Ca^{2+} reabsorption by upregulating the expression of the key molecules participating in transcellular Ca^{2+} transport, including TRPV5, calbindins-D_{9K} and D_{28K}, NCX1, and PMCA1B. The role of vitamin D in regulating this pathway was shown unequivocally using 1 α(OH)ase-/- mice, which lack any endogenous 1,25$(OH)_2D_3$.[198] Repleting these mice with 1,25$(OH)_2D_3$ increases the expression of TRPV5, calbindin-D_{28K}, calbindin-D_{9K}, NCX1 and PMCA1B.

The CaSR is expressed basolaterally, intracellularly, and occasionally apically in a punctate, vesicle-like pattern in DCT.[359,360] What role does it play in modulating Ca^{2+} transport in this nephron segment? Interestingly, restoring normocalcemia and normophosphatemia in the 1 α(OH)ase$^{-/-}$ mice with a high Ca^{2+} high phosphate, lactose-containing "rescue" diet upregulated the expression of TRPV5, calbindin D_{28K}, NCX1 and PMCA1b.[198] These effects of Ca^{2+} supplementation likely reflect direct actions of Ca^{2+} on the same cell type(s) upon which 1,25$(OH)_2D_3$ acts in the DCT. In fact, earlier studies[118] had shown that 1,25$(OH)_2D_3$ and/or elevated medium Ca^{2+}upregulated the expression of calbindin-D_{28K} in primary chicken kidney cells, likely by acting upon the same calbindin-D_{28K}-containing cells. The rescue diet, however, did not fully normalize renal Ca^{2+} handling in the VDR-/- mice, as urinary Ca^{2+} excretion in the VDR-/- mice was twice that in normal mice ingesting the same rescue diet.[251] Therefore, dietary Ca^{2+}-induced upregulation of several components of the transcellular pathway for Ca^{2+} absorption does not completely compensate for loss of the VDR.

A recent study demonstrated that raising Ca^{2+}_o enhanced Ca^{2+} reabsorption in DCT, in contrast to the CaSR-mediated inhibition of Ca^{2+} reabsorption in CTAL.[407] In this study, the CaSR and TRPV5 were co-expressed in the same cells, and activating the CaSR on the apical membrane increased TRPV5 activity, with a resultant rise in Ca^{2+}_i by means of a PKC-dependent phosphorylation of amino acid residues S299 and S654 in TRPV5. This stimulation of the activity of TRPV5 was suppressed by a dominant negative CaSR, proving the receptor's involvement. What is the purpose of a CaSR-dependent stimulation of Ca^{2+} reabsorption in DCT? Topala, et al.[407] suggested that this provides a local feedback mechanism for adjusting Ca^{2+} reabsorption in DCT as a function of the prevailing urinary Ca^{2+} concentration, perhaps mitigating the risk of Ca^{2+}-containing stones when the urine reaching the DCT has an excessively high Ca^{2+} concentration.

The DCT, along with the CTAL, is also an important nephron segment for Mg^{2+} conservation, which occurs through TRPM6, an apical Mg^{2+} channel homologous to TRPV5.[153] The CaSR is expressed in the mouse DCT cell line, MDCT, and cAMP production stimulated by hormones signaling through Gαs activation (PTH, AVP, calcitonin and glucagon) is inhibited by CaSR agonists.[18,19] Moreover, aminoglycosides can inhibit PTH-stimulated Mg^{2+} uptake in these cells likely by activating the CaSR.[224] Additionally, the ability of 1,25 $(OH)_2D_3$ to stimulate Mg^{2+} uptake into MDCT cells is abrogated by elevated Ca^{2+}_o and Mg^{2+}_o.[362] This latter effect of divalent minerals is abolished by pretreatment with CaSR antibodies or antisense CaSR mRNA oligonucleotides.

CaSR in Collecting Duct

Cortical Collecting Duct (CCD)

In the CCD, CaSR protein is cytosolic and at the basolateral membrane of some, but not all, α-intercalated cells,[359] suggesting a potential role for extracellular divalent minerals in preventing stone formation by regulating urinary acidification when tubular Ca^{2+} concentrations are critically high (see below). Indeed, in a recent elegant study performed utilizing the hypercalciuric TRPV5 knockout mouse model, homozygous knockout of TRPV5 produced the expected hypercalciuria, but it was not accompanied by kidney stones.[356] However, the mice manifested marked urinary acidification and increased urine flow. Moreover, when TRPV5-/- mice were bred with mice lacking the B1 subunit of the H^+-ATPase, they exhibited severe nephrocalcinosis, which was lethal within the first 3 months of life, suggesting that urinary acidification was a compensatory mechanism ensuring adequate solubility of urinary Ca^{2+}. Exposing outer medullary collecting ducts from TRPV5-/- mice to the CaSR agonists, Ca^{2+} and neomycin, stimulated H^+ secretion via H^+-ATPase, accompanied by downregulation of aquaporin-2

(AQP2),[356] resulting in not only acidification but also polyuria. The latter would reduce the urinary Ca^{2+} concentration by diluting it in a greater volume. The further CaSR-mediated inhibition of urinary concentrating ability that occurs in the IMCD is described below. These actions of the CaSR on urinary acidification were not observed in the double knockout TRPV5-/-/B1-/- mice. These experiments show that CaSR activation promotes urinary acidification and a reduction in water reabsorption in the TRPV5-/- mice, two mechanisms reducing the urinary concentration and increasing the solubility of the calcium salts, primarily calcium-phosphate salts, that caused nephrocalcinosis in the TRPV5-/-/B1-/- mice. It should be noted that the solubility of calcium oxalate stones, the most common type of stone in humans, has less pH dependence than do calcium-phosphate stones, and urinary acidification mediated by the CaSR in the setting of hypercalciuria might have less impact on calcium oxalate stone formation. Nevertheless, the elaboration of more dilute urine would be beneficial in the latter setting.

Inner Medullary Collecting Duct

In the IMCD, the CaSR is expressed in the same endosomes in which the vasopressin-activated AQP2 water channels reside[379] (Fig. 63.10). Vasopressin-activated V2 receptors on the basolateral membrane of IMCD cells produce cyclic AMP accumulation in these cells. Cyclic AMP activates protein kinase A (PKA), which, in turn, phosphorylates AQP2 (and certainly other proteins) leading to movement of these endosomes to the apical plasma membrane.[142,226] The increase in water permeability of the apical membrane enhances transtubular movement of water driven by the interstitium-to-luminal osmotic gradient. The result of these events is an increase in final urine osmolality. Since the AQP2-containing endosomes also contain CaSR protein, insertion of these endosomes into the apical membrane increases surface expression of both AQP2 and CaSR. Activation of the CaSR by increases in tubular Ca^{2+} concentrations reduces vasopressin-stimulated increases in water permeability in the *in vitro*-perfused IMCD,[379] presumably due to reduced trafficking of AQP2 to the luminal membrane during CaSR activation.[343] Since CaSR stimulation can reduce cAMP accumulation in TAL cells, a similar CaSR-mediated reduction in cAMP in IMCD might account for the reduction in water permeability. Vasopressin-enhanced water permeability in the IMCD is also virtually absent in dihydrotachysterol-induced chronic hypercalcemia.[378] A reduction in AQP2 protein expression and activation of the CaSR contribute to this effect.

A consequence of these effects of CaSR stimulation in the IMCD is regulation of the concentration of ionized Ca^{2+} in final urine. Since the EC_{50} for Ca^{2+}_o stimulation of the CaSR is modified by pH, ionic strength, polyamines, and amino acids (a calcimimetic-like effect, see[402] for review), many tubule fluid constituents in the IMCD can influence receptor activity and its consequences on IMCD water permeability. Ca^{2+} solubility in the tubule fluid or crystal growth may be influenced by many factors altering the CaSR's EC_{50} for Ca^{2+} (see Chapter 68). Moreover, Ca^{2+} delivery to the IMCD is increased whenever the CaSR is stimulated in the TAL. If luminal Ca^{2+} increases in the terminal IMCD above a certain level determined by the integration of factors influencing the CaSR, the enhanced CaSR stimulation in IMCD will alter reabsorption to limit further increases in Ca^{2+} concentration. This influence of Ca^{2+} on water transport in IMCD provides an example of physiological "trade-off" where water conservation is sacrificed to ensure uneventful excretion of divalent cations in a soluble form in terrestrial vertebrates.

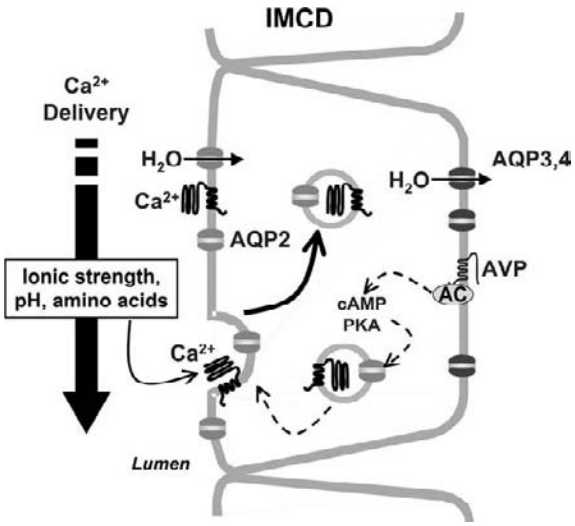

FIGURE 63.10 In the inner medullary collecting duct (IMCD), the calcium-sensing receptor (CaSR) is expressed in the same endosomes in which the vasopressin-activated aquaporin-2 (AQP2) water channels are expressed. Activation of the CaSR by increases in tubular fluid Ca^{2+} concentrations reduce vasopressin-stimulated increases in water permeability by modulating the trafficking of AQP2. Since the EC_{50} for Ca^{2+}_o stimulation of the CaSR is modified by pH, ionic strength, polyamines, and amino acids, many constituents of the tubule fluid in the terminal collecting duct can influence receptor activity and its consequences on IMCD water permeability. See text for discussion.

CaSR and Renin Secretion

Renin plays important roles in sodium, volume and blood pressure homeostasis: Hypovolemia is sensed by the juxtaglomerular (JG) cells of the afferent arteriole in

the kidney, which, in turn, increases renin secretion. Renin converts circulating angiotensinogen to angiotensin II, a potent endogenous pressor that also increases production of the sodium-retaining hormone, aldosterone, by the adrenal zona glomerulosa.[180] The elevation in blood pressure stimulated by angiotensin II combined with the sodium retention promoted by aldosterone tends to normalize sodium and volume homeostasis. It has been known for several decades that elevating Ca^{2+}_o inhibits renin release by the JG cells.[137] Only more recently, however, has it been demonstrated convincingly that the CaSR is expressed by JG cells[316] and mediates the inhibition of renin release by high Ca^{2+}_o.[267] The role that CaSR-mediated regulation of renin secretion plays in normal blood pressure and volume homeostasis is not currently understood. The capacity to modulate renin secretion pharmacologically, e.g., using a CaSR antagonist, could potentially be of therapeutic benefit in high renin forms of hypertension.

Developmental Regulation of Renal CaSR Expression

In the newborn, reduced responsiveness of the kidney to vasopressin and PTH could potentially reflect effects of the CaSR on these aspects of renal function. In the developing rat kidney, there is little prenatal expression of the CaSR, except in large tubules and branching ureteric buds of developing nephrons.[73] CaSR mRNA and protein increase markedly during the first postnatal week, principally due to expression of the receptor in the developing TAL and, to a lesser extent, in the CD. The receptor's level of expression remains nearly constant after postnatal day 14. Thus it is possible that some of the previously described changes in renal handling of divalent cations and water in the perinatal and immediate postnatal periods are related, in part, to the increasing levels of CaSR expression and its resultant inhibitory effects on the actions of PTH and antidiuretic hormone on the developing nephron.

CaSR AND THE SKELETON

Our understanding of the CaSR's roles in bone and cartilage has lagged behind that in parathyroid and kidney, as a result, in part, of controversy as to whether the receptor is actually present in cartilage and bone cells, to say nothing of its biological relevance there. Some studies have provided unequivocal evidence for the receptor's presence in cartilage or chondrocytic cell lines[69,70] and/or in bone,[70] as well as in osteoblastic cell lines, osteoclasts and related cell lines. Others, however, have not (for review, see[405]). The following discussion is a summary of the current state of this field, which ultimately may be relevant to bone disease encountered in patients with kidney disease and the therapy thereof. While the CaSR-related, class C GPCR, GPRC6A,[240,434] which responds to extracellular Ca^{2+}, amino acids (especially basic amino acids), and calcimimetics,[84,85,240,333,435] has been suggested to participate in extracellular Ca^{2+}-sensing in bone,[334] additional study will be required to establish its importance, if any, in bone and to determine if GPRC6A and CaSR interact in these cells

The CaSR in Cartilage

The chondrocytic cell line, RCJ3.1C5.18, expresses easily detectable levels of CaSR mRNA and protein.[72] When these cells are incubated with elevated levels of Ca^{2+}_o, there is suppression of the early differentiation marker, aggrecan, and enhanced expression of several markers of terminal differentiation, namely osteopontin, osteonectin and osteocalcin, as well as increased synthesis of cartilagenous matrix, another indication of enhanced differentiation.[72] Several of these effects of the CaSR were potentiated by overexpressing the wild type CaSR or inhibited by transfecting the cells with a CaSR with defective signaling capacity, suggesting a mediatory role for the receptor. Growth plate cartilage also expresses the CaSR.[70] Initial studies of cartilage in mice with homozygous knock out of exon 5 of the CaSR revealed rickets,[145] suggesting that the receptor might be required for normal cartilage development. However, when these severely hyperparathyroid mice were "rescued" by knock out of the PTH gene (CaSR-/-PTH-/-)[238] or of the key parathyroid transcription factor, Gcm-2 (CaSR-/-Gcm-/-),[412] there was no apparent cartilage phenotype, and the CaSR's role in cartilage, if any, was questioned.

Additional studies at about the same time, however, demonstrated that keratinocytes from CaSR-/- mice could generate a variant CaSR with exon 5 spliced out.[411] This finding raised the possibility that skeletal expression of the "exon 5-less" CaSR in the original CaSR-/- mice might, in fact, possess biological activity capable of rescuing the CaSR-/-PTH-/- and $CaSR^{-/-}$Gcm-/- mice from any skeletal consequences of losing the full length CaSR. In fact, chondrocytes from CaSR-/- mice had the same cellular responses to Ca^{2+}_o seen in wild type chondrocytes,[370] presumably owing to the presence of a biologically active CaSR lacking exon 5. However, it has not yet been possible to directly document biological activity of the exon 5-less CaSR when it is expressed in heterologous cell systems.

To study further the biological actions of the CaSR in bone using knock out mouse models, Chang, et al. developed mice in which exon 7 of the CaSR was "floxed" by inserting loxP sites flanking this exon.[71] Mating of these mice with mice expressing the Cre recombinase only in a particular tissue of interest owing to the recombinase being driven by a suitable promoter specific for that tissue, results in recombinase-mediated excision of the floxed exon and recombination of the ends of the remaining gene. As a result, transcription and translation now produces a truncated CaSR protein lacking exon 7. Mice with exon 7 of the CaSR floxed were mated with mice expressing the Cre recombinase only in chondrocytes to examine the consequences of knocking out the CaSR in cartilage. Exon 7 encodes the entire CaSR transmembrane domain and C-tail, and when the CaSR gene lacks exon 7, it can only generate the CaSR's ECD in a soluble form, which would be released extracellularly and presumably be incapable of signaling.[71] Chondrocyte-specific CaSR deletion resulted in death of embryos by day 13,[71] an unexpectedly severe phenotype in view of the multiple hormonal or other factors regulating chondrocyte development and function. Subsequent use of an inducible Cre recombinase made it possible to delete exon 7 of the CaSR on days 16–18 of embryonic life, i.e., subsequent to when the embryos died in the previous model. This maneuver produced viable embryos, which nevertheless displayed delayed development of their growth plates. These data suggested, therefore, a critical, non-redundant role(s) for the CaSR in cartilage development.

The CaSR in Osteoblasts

Initially, some,[70,442,443] but not all,[335] studies found the CaSR in intact bone, primary osteoblasts in culture and osteoblastic cell lines (for review, see[405]). In osteoblastic cells expressing the CaSR, high Ca^{2+}_o has actions that would be expected to stimulate bone formation. These include promoting proliferation of pre-osteoblasts,[75] enhancing expression of the mRNAs that encode osteoblast differentiation markers, such as Cbfa-1, osteocalcin, osteopontin, and collagen 1, and stimulating mineralized nodule formation.[113]

Studies in the mice with global knock out of exon 5 of the CaSR revealed, in addition to the rickets alluded to above, severe hyperparathyroid bone disease resulting from loss of the CaSR in the parathyroid, which complicated interpretation of the impact of losing the CaSR on osteoblast function per se. Studies in "rescued" CaSR-/-PTH-/-[238] and CaSR-/-Gcm-/-[412] mice, however, showed little or no difference in their bone histology and histomorphometry from that observed in control mice, suggesting that the CaSR does not have an important role in the formation and turnover of the skeleton. However, conditional knock out of exon 7 of the CaSR in osteoblasts utilizing osteoblast-specific Cre's produced mice exhibiting poor postnatal growth and skeletal development, with small poorly mineralized skeletons.[71] Most of these mice experienced long bone and rib fractures and died by 3 weeks of age. Their bones had reduced levels of both early and late markers of osteoblast differentiation, including type 1 collagen, insulin-like growth factor-1 (IGF-1, a key osteoblast growth factor), alkaline phosphatase, and osteocalcin. There was also a higher than normal rate of osteoblast apoptosis. These results suggest key roles for the CaSR in promoting proliferation, differentiation and survival of osteoblasts as well as in enhancing mineralization of the skeleton.[71] They also have the important implication that a calcimimetic with some specificity for osteoblasts might have potential utility as a bone anabolic agent.

The CaSR in Osteoclasts

As with osteoblasts, some studies failed to detect the CaSR in osteoclasts,[385] while others found it in cell lines considered to be models of osteoclast precursors (e.g., RAW 264.7),[288] in multinucleated osteoclasts differentiated from these precursors *in vitro* and in at least some mature osteoclasts in bone sections.[113] Available evidence suggests that while the CaSR serves a permissive role in osteoclastogenesis *in vitro*, high Ca^{2+}_o concentrations also directly suppress osteoclast activity and enhance their apoptosis.[288] Therefore, if the CaSR has similar actions *in vivo*, a calcimimetic targeting both osteoblasts and osteoclasts specifically might not only stimulate bone formation but also inhibit bone resorption, although an *in vitro* investigation that did not detect CaSR transcripts in osteoclasts or their precursors did not observe any functional effect of a calcimimetic on these cells.[385] Clearly more work is necessary to determine the CaSR's role, if any, in osteoclasts *in vivo*. The effects of Ca^{2+}_o on osteoclast function have also been suggested to result from an entirely different Ca^{2+}_o-sensing mechanism (for review,[449]).

THE CaSR AND THE GASTROINTESTINAL TRACT

Roles of the CaSR in the Stomach

In the stomach, the CaSR is expressed in the mucus-secreting surface epithelium,[291,376] the parietal cells in the gastric crypts,[78,148,291] and in the gastrin-secreting G-cells.[55,56] It directly stimulates acid secretion[148] and

also does so indirectly by stimulating gastrin secretion,[55] which, in turn, promotes secretion of histamine from gastric ECL cells. The latter acts directly on parietal cells to stimulate gastric acid secretion.[147] Although gastric acid secretion might not seem relevant to Ca^{2+} homeostasis, both calcium carbonate and calcium phosphate salts are more soluble under acidic conditions ($CaCO_3$ will not dissolve above pH 5.0). Therefore, an acidic environment in the stomach will promote the availability and, subsequently in the small intestine, the absorption of free luminal Ca^{2+}.[147] Recent work has suggested that the CaSR in the stomach senses not only Ca^{2+} but also amino acids and pH.[125,159] Thus the receptor likely integrates several types of signals that impact its functions in the stomach. The response to amino acids may promote the secretion of acid needed to stimulate the gastric phase of protein digestion, while the response of the CaSR to pH could represent, at least in part, the long-sought pH sensor needed for the feedback regulation of acid secretion, stimulating it when pH is high and inhibiting it when pH is low.

Roles of the CaSR in the Small Intestine

The CaSR is present in the small intestine,[74] likely in the same cells expressing the VDR (although this has not yet been formally proven) as well as in cell lines of intestinal origin.[143] However, its functions in the intestine are incompletely characterized. Available data suggest that it can act together with vitamin D to enhance the expression of the various components of the transcellular calcium transport system or substitute, at least in part, for the actions of $1,25(OH)_2D_3$ in certain instances. For example, in organ cultures of fetal rat duodenum, not only $1,25(OH)_2D_3$ but also elevated levels of Ca^{2+}_o increase the expression of the mRNA for calbindin-D_{9K}.[41] Subsequently, van Abel, et al. demonstrated that administering the rescue diet described earlier to 1α(OH)ase-/- mice normalized serum Ca^{2+} concentration concomitant with statistically significant, >10-fold increases in the intestinal expression of TRPV6 and calbindin-D_{9K},[414] similar to the effect of dietary rescue in the kidneys of these mice. While not formally proven, these actions of calcium are likely to be CaSR-mediated. Thus elevated levels of Ca^{2+} can apparently substitute, at least partially, for a lack of vitamin D in maintaining sufficient levels of expression of key elements of the intestinal transcellular Ca^{2+} transport system, suggesting a vitamin D-independent role for Ca^{2+}_o in regulating its own absorption in the intestine. An additional function of the CaSR in the small intestine may be to promote digestion via the capacity of cholecystokinin (CCK)-secreting endocrine cells to secrete CCK in response to calcium[247] or upon exposure to peptides[299] or aromatic amino acids.[194] The secreted cholecystokinin, in turn, would stimulate pancreatic enzyme secretion and enhance small intestinal digestion of ingested nutrients.

Roles of the CaSR in the Colon

Although the proximal small intestine is often thought of as the predominant site for intestinal calcium absorption, substantial absorption also occurs in the cecum of the large intestine by a vitamin D-responsive mechanism.[124] The cloning of the apical intestinal calcium uptake channel, TRPV6, provided a molecular basis for regulated calcium absorption in the cecum, as this channel was expressed at robust levels in this segment of the large bowel.[328] An additional function of the CaSR in the large intestine, which is apparently uninvolved in calcium homeostasis per se, is to inhibit the secretion of fluid by the crypts, particularly when stimulated by cAMP.[146] This action has been suggested to represent a potential target for the treatment of diarrheal disease, such as cholera (e.g., with a calcimimetic).[146] Finally, the CaSR expressed in the colon regulates the growth and differentiation of cells within the colonic crypt, promoting cellular differentiation and inhibiting cell growth.[329,438] It does so by mechanisms that include: (1) upregulation of cyclin-dependent kinase inhibitors such as p21, (2) promotion of E-cadherin expression and suppression of beta-catenin expression,[66] (3) increased local levels of $1,25(OH)_2D_3$[329] (which also enhances differentiation and inhibits proliferation), and (4) reduction in c-myc expression.[222] These actions of the CaSR may contribute to the reduction in the risk of colonic adenomas[181] or colon cancer observed with increased dietary intake of calcium in many but not all studies[20,144,223] (for reviews, see[329,395]).

MODULATION OF THE CaSR IN 2° HPT

The ability of ionized Ca^{2+} to modulate PTH secretion is reduced in secondary hyperparathyroidism (2° HPT).[53,163,167,371] Unlike primary hyperparathyroidism (1° HPT), there is no major right shift in the set point for extracellular Ca^{2+} in 2° HPT during the phase when there is diffuse hyperplasia, although an elevated set-point can occur in severe 2° HPT or 3° HPT (i.e., when hypercalcemia supervenes, which often requires parathyroidectomy).[163] Moreover, no inactivating mutations in the CaSR have been identified as is the case for FHH.[106,202] However, CaSR mRNA and protein expression are significantly

reduced in all forms of hyperparathyroidism, including in 2° HPT.[123,154,184,233,445,446] The magnitude of the decrease in CaSR expression is associated with the degree of parathyroid proliferation[445]: The larger the parathyroid gland, the lower the CaSR protein expression.[59]

In the rat 5/6 nephrectomy model, parathyroid gland hyperplasia is also associated with a reduction in CaSR expression,[293] and both parathyroid hyperplasia and the change in CaSR expression and function are abrogated by a low-phosphate diet.[44,364] While a significant negative correlation between CaSR mRNA expression, glandular weight and PTH secretion has been observed in the rabbit,[21] gland proliferation precedes downregulation of the CaSR.[363] Nevertheless, the CaSR knockout mouse exhibits marked parathyroid gland hyperplasia, showing that the CaSR can indeed influence chief cell proliferation.[196] However, it is clear that the interplay among serum PTH, CaSR expression, and gland hyperplasia is complex since the elevated PTH level in 5/6 nephrectomy rats is reversed after an isogenic kidney transplant without upregulation of CaSR mRNA.[249]

Calcimimetics are Type II Allosteric Enhancers: Role in 2° HPT

Calcimimetics are small, lipophilic organic molecules that function as allosteric enhancers (superagonists) of the CaSR. Thus, calcimimetics are type II agonists that left-shift the ionized Ca^{2+}-PTH secretion curve in parathyroid glands (lower the EC_{50} for ionized Ca^{2+}) without affecting the minimal or maximal responses (Fig. 63.1). As type II agonists, calcimimetics have no effect on PTH secretion in the absence of extracellular Ca^{2+}. In 5/6 nephrectomized and normal rats, calcimimetics cause a dose-dependent decrease in serum PTH and ionized Ca^{2+}.[88,134,306] A first-generation calcimimetic, NPS R-568, was shown to reduce PTH secretion *in vitro* and *in vivo*,[7,133] but it was entirely metabolized by the hepatic P_{450} system and exhibited suboptimal pharmacokinetics in certain individuals. Second-generation calcimimetics (e.g., cinacalcet HCl) overcame this problem in metabolism of the drug (see following sections). Calcimimetics have been shown to reduce PTH secretion in 1° HPT,[321,388,392] 2° HPT,[31,164,165,254,314,346] and parathyroid carcinoma.[393] While calcimimetics can produce a transient increase in calcitonin secretion from thyroidal C cells,[131,306] the dose of calcimimetic that suppresses PTH secretion is at least 10-fold lower than required to alter calcitonin secretion.[131] This apparent specificity of calcimimetics for parathyroid as opposed to other cell types examined to date is an important factor enabling targeted therapy of various forms of hyperparathyroidism.

Calcimimetics reduce plasma Ca^{2+}.[132,321,392,393] The fall in plasma Ca^{2+} is clearly not due to increased renal excretion of Ca^{2+}, given that it occurs in nephrectomized rats,[131] but instead results from the left shift in the relationship between serum Ca^{2+} and PTH. In mild 1° HPT calcimimetics acutely and chronically lower serum PTH and normalize serum Ca^{2+} without increasing urine Ca^{2+} excretion in most patients.[321,392] Activation of the kidney CaSR would be expected to increase urinary Ca^{2+} excretion at any given level of serum Ca^{2+}, and thus the lack of effect of calcimimetics on renal Ca^{2+} excretion in 1° HPT suggests that at doses that reduce the parathyroid set-point, these agents do not exert a calciuric effect owing to their direct renal action. In 1° HPT, a reduced filtered load of Ca^{2+}, decreased bioavailability of the drug in the kidney, or lower calcimimetic sensitivity of the renal, relative to the parathyroid, CaSR have been suggested as the causes of any apparent effect of calcimimetics on the kidney.[131] However, like parathyroidectomy, the calcimimetic NPS R-467 prevents furosemide-induced nephrocalcinosis in rats,[319] suggesting that the reduction in PTH is an important indirect factor in the modulation of renal Ca^{2+} handling in this model. The calcimimetic, cinacalcet HCl (also known as AM 073, KRN 1493, NPS 1493; Cinacalcet HCl, Sensipar in the United States; Mimpara in the European Union), which exhibits good bioavailability and pharmacodynamics,[241,306] lowers serum PTH and serum Ca^{2+} in hemodialysis[31,165,253,254,314,346] and peritoneal dialysis[254] patients with 2° HPT. On the basis of findings from randomized, double-blind studies, cinacalcet HCl was approved for the treatment of secondary HPT.[31,86,112,134,162,305,366]

In the 5/6 nephrectomy model of chronic renal failure in the rat, calcimimetics prevent parathyroid hyperplasia when given at the time of renal mass reduction[419,422] and reduce gland mass when given after the development of diffuse hyperplasia.[88,293,294] These changes in parathyroid gland mass are associated with an increase CaSR and VDR expression[287,372] as well as a reduction in parathyroid cell proliferation.[418] The effects of extracellular Ca^{2+} on parathyroid cell proliferation in culture have been variable[421]; however, parathyroid cells in culture can exhibit a rapid decrease in CaSR expression complicating interpretation of these studies.[290] R-467 suppressed DNA synthesis by 35% in one study,[375] while Ca^{2+} had the opposite effect in cultured parathyroid cells derived from uremic patients that continue to express the CaSR.[374] While the mechanisms for the disparate effects of extracellular Ca^{2+} and calcimimetics remain to be defined,[111,375,421] the downstream mediators of CaSR action on parathyroid gland proliferation–differentiation are under investigation.[91,390] The

CaSR-mediated activation of the mitogen-activated protein kinases (MAPKs; ERK1/2) appears to be linked to the inhibition of PTH secretion.[91,230]

Calcimimetics, the Ca × Pi Product, and Cardiovascular Risk in Dialysis Patients

The elevation of the serum calcium × phosphate product (Ca × Pi) commonly occurring in dialysis patients predisposes them to vascular and tissue calcification and contributes importantly to their increased risk of cardiovascular events.[29,166] Also, plasma PTH levels, as well as those of Pi and calcium, impact on patient survival. As a "uremic toxin",[276,277] the effects of PTH are believed to occur through an alteration in myocardial function and of microvessel thickness.[4,5,33,34] In addition, high Pi concentrations increase vascular calcification,[151,295] an effect that is exacerbated by an elevation in serum calcium concentration.[444] These events are of relevance if one considers that, until the calcimimetics became available, all maneuvers aimed at reducing PTH levels yielded an increase in plasma ionized calcium and of the Ca × Pi product. Indeed, treatment of 2° HPT with $1,25(OH)_2D_3$ or its analogues, while generally initially effective in reducing serum PTH, the calcemic and the phosphatemic effects of vitamin D can ultimately enhance the abnormal mineral metabolism and exacerbate vascular calcification, although retrospective studies have suggested a reduction in overall mortality with vitamin D therapy.[401] In contrast, cinacalcet HCl generally lowers serum Ca^{2+}, serum phosphate, and the serum Ca × Pi product modestly (by ~15%)[32,253,254,346] and decreases both vascular and soft tissue calcification in uremic rats treated with calcitriol,[259] suggesting that this calcimimetic could potentially lower morbidity and mortality due to cardiovascular complications. In the rat uremic model, NPS R-568 treatment has been shown to diminish cardiovascular changes associated with chronic renal failure (cardiac interstitial fibrosis, capillary length density, and arteriolar wall thickness).[312] It is unclear whether calcimimetics reduce cardiovascular risk in animal models by lowering plasma PTH and/or through a direct effect on blood vessels. Evidence that the CaSR is present in rat and porcine blood vessels and that activation of the receptor by high calcium or calcimimetics results in vasodilatation has been demonstrated.[313,437] Also, in uremic rats, but not in sham-operated animals, the calcimimetic R-568 causes a marked and sustained antihypertensive effect.[311] While these animal studies support the potential for a beneficial effect of calcimimetics on cardiovascular risk in chronic renal failure in humans, this latter possibility is currently under investigation. A small meta analysis of four randomized, double-blind, placebo-controlled clinical trials utilizing cinacalcet or placebo in patients who were already being treated with vitamin D and phosphate binders assessed the impact of cinacalcet therapy on end-points other than serum mineral ions and PTH.[98] The results indicated that, relative to patients not receiving cinacalcet who were receiving standard care, patients treated with cinacalcet had a >90% decrease in the rate of parathyroidectomy and about a 40% reduction in hospitalizations for cardiovascular events. The study was not sufficiently powered, however, to determine the effect of the drug on "hard" cardiovascular end-points, such as myocardial infarction or death. Two randomized controlled studies have recently been completed that address this latter point, the ADVANCE ("A randomized study to evaluate the effects of cinacalcet plus low dose vitamin D on vascular calcification in subjects with chronic kidney disease (CKD) receiving hemodialysis") and EVOLVE studies (EValuation Of Cinacalcet HCl Therapy to Lower cardioVascular Events).[79] The results of the ADVANCE trial showed that Cinacalcet produced modest but statistically significant reductions in some indices of vascular (e.g., volume of coronary artery calcification) and valvular (i.e., aortic valve) calcification.[350a] The second of these has as its primary end-points all-cause mortality and first nonfatal cardiovascular event in 3800 chronic dialysis patients treated with a flexible regimen of traditional therapies, and, in addition, receiving either cinacalcet or placebo.[79] While not yet published, the initial results from the EVOLVE trial did not show any reduction in overall cardiovascular mortality in the Cinacalcet-treated patients (www.amgen.com/media/media_pr_detail.jsp?releaseID=1703773).

The severity of osteitis fibrosa is directly proportional to the severity of the 2° HPT and the magnitude of PTH overproduction. While high and sustained elevations in serum PTH in hyperparathyroidism cause osteitis fibrosa, smaller and transient increases in PTH, e.g., those produced by a subcutaneous injection of PTH1-34 or PTH1-84 for the treatment of osteoporosis, have a net anabolic effect on bone.[152] PTH secretion in healthy individuals exhibits complex fluctuations—a circadian rhythm as well as an ultradian rhythm of several PTH pulses per hour.[381] These serum PTH rhythms are generally preserved in chronic renal failure and correlate with serum Ca^{2+}, serum phosphate, and bone metabolism.[135,381] Chronic suppression of PTH secretion with vitamin D analogues in 2° HPT is associated with inhibition of the ultradian and circadian rhythms of PTH, which may contribute to the low bone turnover disease of chronic renal failure.[381] However, while calcimimetics appear to induce a circadian rhythm in serum PTH, interestingly, they do not increase bone mass in ovariectomized rats.[289] In the rat 5/6 nephrectomy model of 2° HPT, NPS R-568 halts the

progression of, and reverses osteitis fibrosa cystica.[420] This response of bone is consistent with the PTH-lowering effect of calcimimetics.[88,132,306] In the rat uremic model, daily intermittent NPS R-568 induces an exaggerated circadian fluctuation in PTH and stabilizes cortical and cancellous bone mass.[215,289]

OTHER APPLICATIONS OF CALCIMIMETICS IN CKD

Recurrent HPT after Parathyroidectomy for Severe 2° or 3° HPT in Patients with End Stage Renal Disease

Some dialysis patients progress from severe 2°, albeit normocalcemic, HPT to a state called "tertiary" (3°) HPT, in which there is frank PTH-dependent hypercalcemia, as noted above.[179,214,340] The progression from 2° to 3° HPT usually occurs coincident with a transition from polyclonal parathyroid hyperplasia to nodular hyperplasia, in which each nodule represents a separate monoclonal growth, behaving functionally like a parathyroid adenoma.[110] Nodular parathyroid glands show an increase in set-point similar to that observed with adenomas in 1° HPT. There is reduced expression of both the CaSR and VDR in this setting, which likely contribute to the associated functional abnormalities.[110] The genetic defects in the parathyroid nodules of patients with 3° HPT, however, usually differ from those seen in parathyroid adenomas.[9,214]

In dialysis patients with 2° or 3° HPT who cannot be adequately controlled by phosphate binders and vitamin D analogues or develop hypercalcemia, subtotal parathyroidectomy may be necessary (or, in some centers, total parathyroidectomy with reimplantation of a small amount of the patient's own parathyroid tissue).[340] Even following initially successful surgery, however, there is a risk of recurrence of HPT ranging from about 10% at three years to 30% after seven years. Cinacalcet might provide a non-surgical approach to the problem of recurrent HPT. In one off-label study (i.e., using the drug in an application not yet formally approved by the FDA) utilizing the drug in this setting in a small number of patients (N = 6), there were substantial reductions in mean PTH (1388 to 435 pg/ml), serum calcium (9.6 to 8.3 mg/dl), serum phosphorus (5.5 to 31.3 mg/dL) and Ca × Pi product (53 to 31 mg^2/dL^2).[258] In additional case reports, cinacalcet has effectively lowered serum calcium to or toward normal in this setting. While the results to date are encouraging, additional experience in CKD patients with recurrent HPT after prior parathyroid surgery is clearly needed to further validate the application of calcimimetics to these patients.

Patients with CKD Prior to the Institution of Dialysis Therapy

There are very limited data on the use of cinacalcet in patients with CKD not yet requiring dialysis.[81] In an off-label, placebo-controlled investigation of 404 patients (75% taking cinacalcet and 25% placebo), cinacalcet reduced PTH by 43% (vs −1.1% in controls) and serum calcium by 8.9% (vs +0.8%), and elevated serum phosphorus by 21% (vs +6.8%), producing a 21% rise in the Ca × Pi product. However, the Ca × Pi product also increased (by 17%) in the placebo group and was 40 mg^2/dL^2 or less in both groups, well within the National Kidney Foundation (NKF) guidelines for this parameter guidelines.[81] There is currently no consensus with regard to whether the drug should be used in this setting. However, given the capacity of cinacalcet to inhibit parathyroid cellular proliferation, it might limit parathyroid hyperplasia in this group; of patients, especially if it were possible to accurately measure parathyroid volume non-invasively. Moreover, in patients with stage 3 and 4 CKD having unusually large elevations in serum PTH, it might make it possible to lower PTH to levels within the NKF guidelines (35–70 pg/mL in stage 3 and 70–110 pg/mL in stage 4). Finally, further studies could determine whether cinacalcet slows the progression of renal failure in stages 3 and 4 CKD, as it does in experimentally-induced renal insufficiency in animal models.[312,338]

Hypercalcemia and HPT Following Renal Transplantation

Renal transplantation is followed by the development of PTH-dependent hypercalcemia in about 10% of patients[22] and persistent, albeit normocalcemic, HPT in additional patients. Hypercalcemia and/or an elevated Ca × Pi product following renal transplantation have been associated with increased mortality and elevated risk of losing the transplanted kidney.[116] Owing to the limited capacity of hyperplastic parathyroid glands to involute, ~50% of patients who are hypercalcemic immediately following transplantation remain so after 12 months. Several studies have utilized cinacalcet to treat hypercalcemia in the post renal transplant period. The largest study carried out to date used the drug off-label in 48 transplant patients who were hypercalcemic or had persistent 2° HPT,[157] but this study did not have an untreated control group. 91% of the hypercalcemic patients became normocalcemic and 70% of the initially normocalcemic patients reached a target PTH of 75 to 125 pg/mL. 10 patients developed hypocalcemia. In several other studies, comparable decrements in PTH and serum calcium were observed

in frankly hypercalcemic patients following renal transplantation.[260]

Some studies have reported hypercalciuria in this setting in patients treated with cinacalcet,[35] which has the potential to damage the transplanted kidney, or the development of modest decreases in renal function.[239] Most reports, however, have not encountered hypercalciuria, and, in those describing reductions in renal function, they were modest (~10% increase in serum creatinine) and were reversible after discontinuing the drug.[239] Increases in bone mineral density have taken place during treatment of patients with cinacalcet following renal transplantation (e.g., in the femoral neck[408]). While this effect of the drug would be very beneficial in such patients, caution is warranted in ascribing this effect to cinacalcet, as control groups were lacking in these two studies.

One study reported that 8 of 9 hypercalcemic renal transplant patients whose serum calcium normalized during treatment for 12 months with cinacalcet remained normocalcemic after cessation of the treatment.[239] Given the absence of a control group, it's unclear whether cinacalcet improved the outcome in these patients, although spontaneous resolution of hypercalcemia in this situation has been estimated to be only ~50%. Thus the drug has the potential to hasten resolution of hypercalcemia and reduce the need for parathyroidectomy post-renal transplant, but further studies are needed in this regard. A recent investigation found that discontinuing cinacalcet therapy before renal transplantation did not adversely impact graft survival.[216] This finding and the stable renal function seen in most patients receiving cinacalcet post renal transplantation are noteworthy, since parathyroidectomy following renal transplantation can be associated with reduction in graft function.[216]

OTHER APPLICATIONS OF CALCIMIMETICS

Parathyroid Carcinoma

Silverberg et al. utilized cinacalcet to treat 29 hypercalcemic patients with inoperable parathyroid cancer.[393] This use of the drug and its application to treating patients with severe hyperparathyroidism who are unable to undergo parathyroid surgery are the only FDA-approved uses of Cinacalcet, in addition to treatment of 2° HPT in stage 5 CKD, in the U.S. The drug has been approved for treatment of 1° HPT in Europe. The mean serum Ca^{2+} in these patients decreased from 14.1 mg/dL to 12.4 mg/dL, with 62% of the patients demonstrating a 1 mg/dL or greater reduction.[393] The patients with the highest initial serum Ca^{2+} showed the largest reduction in serum Ca^{2+} during treatment. While the proportion of patients achieving normocalcemia during treatment with cinacalcet was not explicitly stated, the graphical depiction of the data suggests it to be about 10%.

Serum PTH concentrations, which were measured before the first daily dose of the drug in the morning, did not decline significantly (−4.6%). This observation may reflect the fact that the circulating half-life of cinacalcet is such that serum PTH has increased from its nadir at 2-4 hours following the most recent dose to a level approaching the baseline PTH value by 12-24 hours following the last dose of the drug.[321] Ideally, while measuring the area under the PTH curve over a 24-hour period would provide a more accurate reflection of the integrated impact of cinacalcet on parathyroid function, this is impractical in routine clinical practice. Treatment with cinacalcet did not produce any alteration in quality of life as measured with the SF-36 instrument. Thus at least some biochemical control of hypercalcemia is achievable with cinacalcet in the majority of patients with parathyroid cancer over a time frame of months or longer, but the drug's impact in the longer-term management of this disease, including survival, is not clear at present.

Other Forms of 1° HPT

Cinacalcet has been utilized off-label in patients with 1° HPT in two settings: (1) Mild 1° HPT, as an approach to lowering the serum Ca^{2+} and/or PTH concentrations,[322] and (2) persistent, "intractable" 1° HPT in subjects with a history of failed parathyroid surgery or in those in whom parathyroid surgery is contraindicated.[273] Prior the development of calcimimetics, no medical therapy was available that effectively reduced serum Ca^{2+} on a long-term basis in 1° HPT. In most instances, the CaSR in 1° HPT does not contain the inactivating mutations that are the cause of FHH; thus the calcimimetics are acting upon an inherently normal CaSR.

A placebo-controlled study examined the consequences of treatment with cinacalcet for up to 5 years in patients with mild 1° HPT.[322] After one year, 73% of the patients treated with cinacalcet showed normalization their serum Ca^{2+} concentration, compared with 5% in the placebo group. PTH declined modestly in the cinacalcet-treated group (−7.6%), although the level achieved was significantly lower than in the placebo group. Patients who have undergone successful surgery for 1° HPT demonstrate an increase of ~10% in their BMD over the one to two years after surgery[322]; In contrast, BMD in patients treated with cinacalcet did not rise, although it remained stable over the five years of the study. Thus the drug does not bring about a

true "medical parathyroidectomy".[322] Approximately 20–30% of the patients treated with cinacalcet withdrew from the study during the first year, and an additional 25% withdrew during the last four years, at least in part due to nausea and vomiting, which was present in ~30% of patients; 16% of the placebo group experienced nausea during the first 12 months.[322]

Seventeen patients with intractable 1° HPT, which was of considerably greater severity than in the study just described (mean serum Ca^{2+} of 12.7 mg/dL vs. 10.7 mg/dL, respectively), were treated for a mean of 270 days with cinacalcet. The drug brought about a 1 mg/dL or greater reduction in serum Ca^{2+} in 88% of the patients, and 53% achieved normocalcemia.[273] Cinacalcet has recently been approved for use in treating such patients when they are not candidates for surgery. In summary, off-label treatment of 1° HPT with cinacalcet is costly (several hundred dollars per month depending on the dose) and cannot be considered to be the equivalent of a surgical parathyroidectomy, at least with regard to the skeleton. Furthermore, follow-up of these patients on a regular basis, with the related medical expense, would be required. Therefore, the drug's role in the treatment of 1° HPT other than in patients with parathyroid cancer and those with severe 1° HPT remains unclear. Most likely its use in the United States in mild 1° HPT will be limited to off-label use in subjects unable or unwilling to undergo parathyroidectomy.

Other Forms of Hyperparathyroidism

Cinacalcet has demonstrated some efficacy in several other types of PTH-dependent hypercalcemia. All of these exhibit an elevation in set-point for $Ca^{2+}{}_o$-regulated PTH release, which normalizes or, or returns toward normal, during treatment with calcimimetic, with an associated reduction in serum Ca^{2+}.

One such condition is lithium-induced hypercalcemia. PTH-dependent hypercalcemia occurs in 10–20% of patients being treated with lithium for psychiatric disorders, principally bipolar disorder, although the prevalence of this complication differs widely from <10% to >50% in different series.[380] Lithium-treated patients consistently exhibit an increase in set-point for Ca^{2+}_o-regulated PTH release when studied *in vivo*,[175,350] which likely reflects some direct, but as yet unknown, pharmacological effect of the drug on the parathyroid gland.[47] Some subjects with lithium-induced hyperparathyroidism harbor a parathyroid adenoma if they are subjected to parathyroid surgery, while others have multigland parathyroid hyperplasia. Lithium also decreases renal Ca^{2+} excretion, and can produce a clinical and biochemical presentation of acquired, hypocalciuric, PTH-dependent hypercalcemia resembling FHH.

The therapy of lithium-induced hypercalcemia/hyperparathyroidism can be challenging, because psychiatrists are often reluctant to stop lithium treatment in patients who develop hypercalcemia, which is accompanied by some risk of aggravating the underlying psychiatric disorder. Many such patients have relatively mild hypercalcemia and can be followed expectantly without surgery in a manner similar to that proposed for the follow up of asymptomatic 1° HPT.[27] Several individual case reports or small case series have described off-label treatment of lithium-induced HPT with cinacalcet. Serum calcium concentration declined from an average of 10.8 to 10.0 mg/dL in three patients in one study[169] and from 10.9 to 10.1 in two additional patients.[396] Thus, in subjects with lithium-induced HPT in whom parathyroid surgery is indicated, but the patient refuses or surgery is contraindicated for other reasons, cinacalcet potentially provides an additional mode of treatment.

Familial Hypocalciuric Hypercalcemia

FHH is in most cases a benign clinical condition without long-term sequellae, as noted earlier. Occasional families with FHH, however, exhibit a more severe clinical picture, including neonatal hyperparathyroidism combined with overt bone disease, hypercalcemia that is more severe than the norm in FHH, pancreatitis, or even renal stone disease.[12,182,327] Some such patients have undergone parathyroid surgery,[62,327] providing a rationale for using a calcimimetic as a alternative, medical therapy in these atypical cases. Most FHH mutations demonstrate some capacity for "rescue" of their function by a calcimimetic *in vitro*, providing a rationale for the drug having a Ca^{2+}_o-lowering effect *in vivo*.[212,261,451] There are several reports of FHH being treated off-label with cinacalcet. In one, the drug reduced serum calcium concentration from ~11.4 mg/dL to an average of 9.7 after 12 months of therapy.[406] In another, treatment reduced serum PTH from 148 to 32 pg/ml (normal 7–75) and serum ionized calcium from 1.48 to 1.23 (normal 1.13–1.34).[3] Therefore, the use of a calcimimetic in unusually severe or atypical cases of FHH could: (1) help to assess whether symptoms (such as pancreatitis) are related to the hypercalcemia, and (2) provide an alternative to surgery in the rare case in which the latter was felt to be indicated.

Phosphate-Wasting Disorders

A novel application of treatment with cinacalcet is to alleviate the hypophosphatemia occurring in patients with excessive circulating levels of the phosphaturic hormone, FGF-23.[23,221,228,296] The hypophosphatemia, principally by decreasing the Ca × Pi product, reduces

the structural integrity of bone, producing the characteristic bowing of the lower extremities and other bony abnormalities that are characteristic of the rickets that occurs in the growing skeleton of children.[245] In adults who develop phosphate wasting after growth of the skeleton is complete, hypophosphatemia produces osteomalacia (poorly mineralized bone), in association with bone pain and, in some cases, fractures.[25] Two diseases caused by FGF-23 excess are X-linked hypophosphatemia (XLH) and tumor-induced osteomalacia (TIO).[24,221,367,440] The first is caused by inactivation of the gene encoding PHEX (phosphate-regulating gene with homologies to endopeptidases on the X-chromosome), an endopeptidase whose substrate in unknown, but by an unknown mechanism increases production of FGF-23 by osteocytes.[114,221,436] TIO results from increased synthesis of FGF-23 by tumors of mesenchymal origin, usually benign, which are currently called phosphaturic mesenchymal tumors of the mixed connective tissue type.[219]

Treating patients with either XLH and TIO involves phosphate supplementation combined with administration of $1,25(OH)_2D_3$.[38,221] The latter increases gastrointestinal phosphate absorption and mitigates the 2° HPT caused the transient hypocalcemia that follows administration of phosphate. In spite of treatment with $1,25(OH)_2D_3$, however, 2° (and rarely 3°) HPT may develop, exacerbating the hypophosphatemia owing to PTH-induced phosphaturia.[368] It is the latter complication that prompted the utilization of cinacalcet off-label in XLH[2] and TIO.[149] Administering a single dose of cinacalcet and 20 mg/kg phosphate to eight subjects with XLH produced a decrease in serum PTH (from 34 to 23 pg/ml) and a substantial increase in TmP/GFR (tubular maximum for phosphate corrected for GFR) from 1.7 to 2.5.[2] Chronically administering cinacalcet to two patients with TIO greatly decreased PTH (from 20 to <10 pg/ml in one patient and 24 to <10 pg/ml the other),[149] substantially improved serum phosphate (from 2.8 to 3.7 mg/dL and from 2.8 to 3.4 mg/dL, respectively) and permitted a lowering of the dose of phosphate administered.[149] Thus these preliminary studies suggest a possible role for calcimimetics as an adjunct to supplementation with phosphate and $1,25(OH)_2D_3$ in patients with XLH or TIO, thereby mitigating 2° HPT, enhancing renal phosphate reabsorption, increasing serum calcium $\times$ phosphate product and leading to improved mineralization of bone.

Calciphylaxis

Calciphylaxis (sometimes called calcific uremic arteriolopathy) is a rare but potentially life-threatening condition encountered predominantly in patients with chronic renal insufficiency, particularly those with end stage renal disease receiving dialysis treatment.[99,265,373] Patients present with cutaneous necrosis of variable extent that is painful and can progress and become life-threatening. There is thrombosis of the small cutaneous blood vessels in association with calcification of the media of the vessel wall, which causes skin necrosis.[99,265,373] One of the strongest predictors of the development of calciphylaxis is hyperphosphatemia, associated with the high Ca $\times$ Pi product characteristic of patients with ESRD. While an elevated level of PTH per se is not thought to be a risk factor for calciphylaxis (e.g., the very low incidence of calciphylaxis in PHPT), some consider it a tissue sensitizer predisposing to development of the condition in the presence of other factors initiating the disease, i.e., in ESRD.[99,265,373]

Therapy of calciphylaxis is empiric and suboptimal. In addition to local care of skin ulcers, measures designed to reduce serum phosphorus (and the Ca $\times$ Pi product) using non-calcium-based phosphate binders are a cornerstone of treatment.[99,265,373] Bisphosphonates and the administration of sodium thiophosphate have improved healing of skin lesions in some cases, by an uncertain mechanism(s). Some reports have found that parathyroidectomy prolongs life in individuals with calciphylaxis,[373] providing a rationale for therapy with cinacalcet off-label as a pharmacological approach to lowering serum PTH. This use of cinacalcet has been described in about a dozen articles, mostly single case reports {for example, see[318,342,354,369,386,416]}. While uncontrolled, these studies have shown some efficacy of cinacalcet in treating calciphylaxis, although the use of several other therapies (e.g., bisphosphonates, sodium thiosulfate) concurrently makes it difficult to definitively attribute the observed therapeutic benefit to the calcimimetic. Regardless, the apparent benefit of cinacalcet in these cases affords a rationale for its use in additional patients in this difficult-to-treat condition with its substantial morbidity and mortality.

SUMMARY AND PERSPECTIVES

The field of Ca^{2+}_o-sensing and the CaSR has progressed rapidly since the cloning of the CaSR in 1993. Three major areas of investigation have been: (1) clarifying the CaSR's role in maintaining Ca^{2+}_o homeostasis, (2) identifying and characterizing disorders of Ca^{2+}_o-sensing, and (3) developing CaSR-based therapeutics, especially calcimimetics. Much has been learned about how the CaSR regulates PTH secretion, preproPTH gene expression, and parathyroid cellular proliferation. There is also much greater understanding of how the receptor

regulates the functions of various nephron segments, especially those that relate to the kidney's diverse, key roles in mineral ion homeostasis. The latter include CaSR-mediated control of the 1-hydroxylation of 25-hydroxvitamin D and phosphate handling in the proximal tubule, control of monovalent and divalent cation transport in the TAL, modulation of Ca^{2+} reabsorption in the DCT, regulation of acid secretion, especially in the CCD, and modulation of water reabsorption in both the CCD and IMCD. The relevance of these latter two actions to calcium metabolism have only been elucidated with the recognition that the receptor integrates tubular Ca^{2+} reabsorption with acid secretion and urinary concentration to ensure safe passage of Ca^{2+} salts during their journey through the distal segments of the nephron. Previously unsuspected roles of the CaSR have also emerged in other tissues participating in Ca^{2+}_o homeostasis, especially in bone and intestine. In the former, the CaSR now appears to play critical non-redundant roles of the development, growth and turnover of the skeleton and arguably plays a more fundamental role than vitamin D and the VDR, since loss of the VDR can be compensated nearly completely by provision of normal circulating levels of mineral ions. Finally our understanding of the CaSR's roles in the GI tract is rapidly evolving. The receptor not only promotes the availability of Ca^{2+} in a soluble, readily absorbable form in the stomach, but its ability to sense other components of the ECF, especially pH and amino acids, likely permit it to integrate signals related not only to Ca^{2+} per se but also to other nutrients, especially proteins, and to facilitate the digestion of the latter.

The identification and characterization of inherited diseases of Ca^{2+}_o-sensing, such as familial hypocalciuric hypercalcemia and neonatal severe hyperparathyroidism, as the consequences of inactivating CaSR mutations and autosomal dominant hypoparathyroidism, with or without the features of Bartter's syndrome, as the result of activating CaSR mutations has both clarified the pathophysiology of the CaSR and formally proven its biological relevance. Subsequent studies have uncovered a variety of acquired abnormalities of Ca^{2+}_o-sensing involving the CaSR and its downstream signaling pathways, inactivating or activating antibodies to the CaSR, and alterations in the expression/function of the receptor in 1°, 2° and 3° HPT. The existence of disorders of Ca^{2+}_o-sensing led naturally to the recognition that such disorders might be amenable to treatment with CaSR-based therapeutics, especially the "calcimimetic", allosteric CaSR activators. The first such agent to reach the clinic was cinacalcet HCl, which has been so far only been approved in this country for the treatment of severe 2° HPT in patients receiving dialysis therapy for end stage renal disease, for the therapy of severe hypercalcemia in parathyroid cancer, and for treating severe 1° HPT when surgery is not an option. However, there are a number of currently "off-label" applications where the drug may be useful, such as for treating: (1) hypercalcemia post-renal transplant, (2) recurrent severe hyperparathyroidism after parathyroidectomy in patients with renal failure, (3) lithium-induced hypercalcemia, (4) "severe" or complicated cases of FHH, and (5) the phosphate wasting and iatrogenic 2° HPT in patients with FGF-23 excess.

Although touched on only briefly here, one largely uncharted areas for future investigation are the CaSR's roles in tissues seemingly totally uninvolved on Ca^{2+}_o homeostasis. The receptor regulates myriad cellular processes, a few examples being the growth, differentiation and apoptosis of a variety of cells types[53,129,417] and a variety of processes in the central and peripheral nervous system.[77,80,332,377,417] Further clarification of these roles with not only elucidate important biological questions but may also offer new applications of CaSR-based therapeutics.

CONFLICT OF INTEREST

E.M.B. is an inventor on patents related to the calcium-sensing receptor and calcium receptor active compounds and is receiving royalties on calcimimetics. J.P.G. and D.R. have grants from Amgen.

Renal Calcium Metabolism

José F. Bernardo[1] *and Peter A. Friedman*[2]

[1]Renal-Electrolyte Division, Department of Medicine, University of Pittsburgh, Pittsburgh, USA
[2]Department of Pharmacology and Chemical Biology, University of Pittsburgh, Pittsburgh, USA

INTRODUCTION

Calcium supports diverse physiological roles as a structural element in bone and as a molecular trigger for second messenger signaling. To achieve this, homeostatic mechanisms regulate intracellular calcium at submicromolar levels, whereas extracellular calcium is in the millimolar range. The fact that intricate regulatory processes have evolved than enable ion concentrations to be maintained over several orders of magnitude underscores the importance of the varied biological functions of calcium in signal transduction, cell permeability, excitation-secretion and excitation-contraction coupling, and cell fertilization on the one hand, and maintenance of skeletal integrity on the other.

CALCIUM CHEMISTRY

An adaptable coordination sphere, which facilitates binding to the irregular geometry of proteins, makes calcium particularly well suited for its biological roles. The ability to cross-link two proteins requires an ion with a high coordination number (which dictates the number of electron pairs that can be formed) and is generally six to eight for calcium.[1] Such cross-linking of osseous structural proteins is enhanced at the relatively high calcium concentrations that are found in extracellular fluid. The variable bond length of the calcium ion permits formation of more extensive cross-linking involved in membrane stabilization by facilitating lipid polymorphism and formation of hexagonal arrays. Moreover, unlike disulfide or sugar-peptide cross-links, calcium linking is readily reversible. Despite these virtues, were intracellular free calcium (Ca^{2+}_i) of the same order as its extracellular concentration, the proper functioning of a variety of proteins and macromolecules would be impaired. Thus, from an evolutionary perspective, it is advantageous to maintain low concentrations of intracellular calcium.

The corollary of the benefits accruing from the physical characteristics of calcium at high extracellular concentrations defines a nearly ideal set of attributes that are desirable at submicromolar intracellular concentrations. By virtue of its low intracellular levels, changes of calcium activity can function as first or second messengers to activate effector targets. The fact that calcium can be rapidly bound and released, together with the high affinity and selectivity of many proteins for calcium, enhance its ability to regulate ion channels, calcium-dependent enzymes, and so on. Another advantage of low free intracellular calcium concentrations is that microcrystallization and precipitation of calcium phosphate is avoided. The evolution of high-energy phosphate compounds such as ATP may be selectively favored because they circumvent the microcrystallization and precipitation of calcium phosphate.

Serum Calcium

In adult humans, the calcium concentration of extracellular fluid averages 10 mg/dl (=5 mEq/l, 2.5 mM). Plasma calcium exists as three distinct chemical forms: protein-bound, complexed (but diffusible), and ionized. The relations between the various forms of calcium are shown schematically in Fig. 64.1. Forty percent of the serum calcium is bound to plasma proteins, with albumin accounting for some 90% of this.

DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00064-1

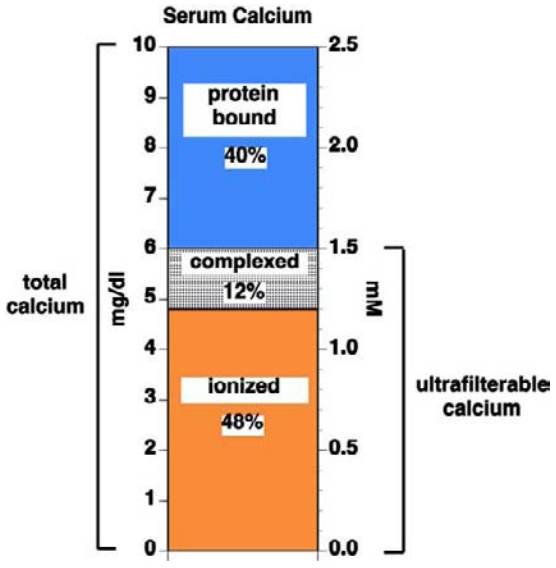

FIGURE 64.1 **Chemical forms of calcium in serum.** Calcium concentrations are expressed as mg/dl on the left-hand axis and as mM on the right. The total serum calcium concentration, 10 mg/dl or 2.5 mM, can be divided into three pools, protein-bound, that complexed with small anions, and ionized calcium. The latter two moieties, i.e., complexed and ionized, represent the calcium that is filtered at the glomerulus and subject to tubular reabsorption as it passes through the nephron.

Smaller percentages are bound, though with greater affinity, to ß-globulin, α_2-globulin, α_1-globulin, and γ-globulin. Ten percent of the serum calcium is complexed with small polyvalent anions. Calcium complexes are formed by ion pairing with phosphate and citrate and, to a lesser extent, with bicarbonate, and sulfate. The degree of complexation depends upon the concentrations of ionized calcium, the complexing anion, and the ambient pH. The different moieties of calcium are important because only diffusible calcium, i.e., the free plus complexed calcium, is filtered at the glomerulus and crosses cell membranes. A comprehensive discussion of the biologically relevant forms of calcium and their interrelations is available elsewhere.[2]

The ultrafilterable, or ionized fractions, of calcium as summarized above are affected by changes in the total serum calcium concentration, blood pH, plasma protein concentration, and the concentration of complexing anions. Increases in total serum calcium concentrations are usually accompanied by concomitant elevations in the concentration of ultrafilterable calcium, at least up to a total concentration of about 4 mM. Above this concentration, the ultrafilterable fraction declines such that increases of ultrafilterable calcium no longer parallel elevations of total calcium concentration. Reduction in calcium ultrafiltration with hypercalcemia has been postulated to result from the formation of insoluble $Ca_3(PO_4)_2$ protein complexes. This idea is supported by the finding that ultrafilterable phosphate concentrations also decline.[3] Conversely, hypocalcemia is generally associated with a fall in calcium ultrafiltration.[4]

Changes in the concentration of serum proteins are usually accompanied by parallel changes in the total serum calcium concentration so that the ultrafilterable fraction remains constant.[5,6,7] In severe hypoproteinemia, however, the ultrafilterable fraction increases.[4,8]

The concentration of ionized Ca^{2+} varies inversely with blood pH. Acidemia increases ionized Ca^{2+} concentrations, whereas alkalemia causes decreases.[5,7,8] Increases in the serum concentration of complexing anions, such as phosphate, citrate, sulfate, or bicarbonate, reduce the ionized Ca^{2+} concentration by sequestering Ca^{2+}.

The amount of calcium in the extracellular fluid represents a dynamic balance between intestinal absorption, renal reabsorption, and osseous resorption. Symptoms of hypocalcemia vary in relation to the ionized serum calcium concentration. Mild reductions of calcium are associated with paresthesias and muscle cramps; more severe decreases of calcium may induce seizures. Increases of plasma calcium, on the other hand, have been implicated in attenuation of the renal effects of parathyroid hormone (PTH), the antidiuretic action of vasopressin, and reduced renal concentrating capacity. A schematic representation of calcium balance, for an adult human, is shown in Fig. 64.2. Assuming a daily dietary calcium intake of 1,000 mg, net intestinal absorption amounts to about 200 mg, with the remaining 800 mg excreted in the feces. In balance, net intestinal absorption is matched by urinary excretion, while calcium accretion and loss from bone are equal. Thus, approximately 200 mg of calcium are excreted daily. In adults, net calcium balance is effectively zero, suggesting that in the absence of a calcium challenge such as lactation, the kidneys represent the dominant regulatory site of calcium metabolism.[9,10]

The renal responses to alterations of extracellular calcium are transduced by the calcium-sensing receptor (CaSR), which is expressed prominently at the sites of PTH and vasopressin action in the kidney.[11,12]

CALCIUM TRANSPORT ALONG THE NEPHRON

General Considerations, Calcium Clearance

Maintenance of extracellular calcium balance requires the daily urinary excretion of 200 mg of

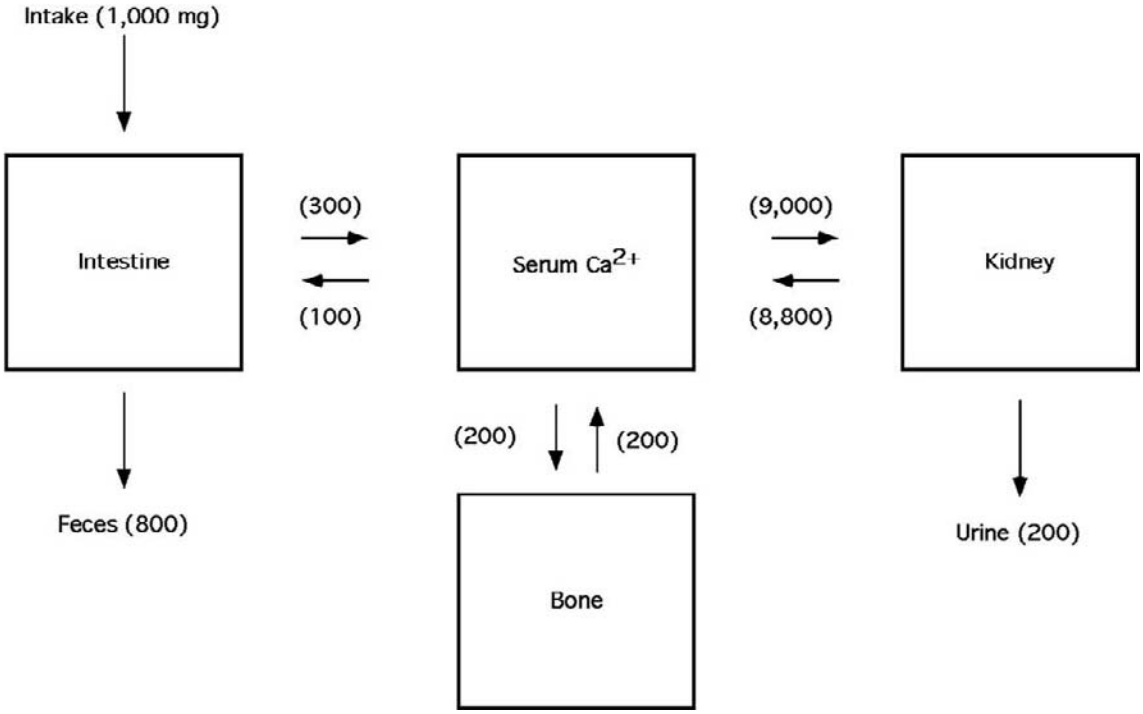

FIGURE 64.2 **Extracellular calcium balance in the adult human.** Numeric values for calcium intake, excretion, and fluxes are in mg/day, approximated for a 70 kg individual, original data from ref. [254].

calcium. The amount of calcium excreted equals the difference between that filtered and reabsorbed:

calcium excreted = filtered load − calcium reabsorbed

or,

$$U_{Ca^{2+}}V = (GFR \times P^{uf}_{Ca^{2+}}) - TCa^{2+}$$

where $U_{Ca^{2+}}$ is the concentration of calcium in the urine, V is the rate of urine flow, GFR is the glomerular filtration rate, $P^{uf}_{Ca^{2+}}$ is the concentration of ultrafilterable calcium in plasma (filtered load being the production of GFR and plasma ultrafiltrable calcium), and $T_{Ca^{2+}}$ is the rate of net Ca^{2+} reabsorption.

Unlike phosphate or magnesium, which exhibit saturable reabsorptive kinetics (i.e., a tubule reabsorption maximum, T^m), most studies[9,13–15] suggest that calcium does not display such behavior. However, some evidence for a calcium $T^m(T^m_{Ca^{2+}})$ has been advanced.[16,17] The $T^m_{Ca^{2+}}$ is conventionally determined by measuring calcium excretion as a function of the plasma calcium, or ultrafilterable calcium, concentration. Two explanations have been proposed for the apparent failure of calcium excretion to saturate at elevated serum calcium concentrations. It has been argued that, *in vivo*, only a limited excursion of ultrafilterable plasma calcium concentrations can be tolerated and that within this range the filtered load of calcium may be less than the $T^m_{Ca^{2+}}$.[14] It has also been postulated that since the bulk of calcium absorption is passive and may be accomplished by a combination of diffusion and solvent drag, no $T^m_{Ca^{2+}}$ exists.

Calcium is reabsorbed throughout its passage along the nephron. As detailed below and shown schematically in Fig. 64.3, 60–70% of the filtered calcium is reabsorbed by proximal tubules, an additional 20% by thick ascending limbs, and 5–10% by distal tubules. Final adjustments of calcium excretion are achieved in collecting ducts, where transport may be absorptive or secretory. The net result of these processes is that only 0.5–1.5% of the filtered calcium is normally excreted in the voided urine.

The interested reader is referred to several excellent monographs for more comprehensive treatments of calcium homeostasis and clearance[2,18] micropuncture[19] and isolated tubule studies[20] of renal calcium transport.

Glomerular Filtration

The renal disposition of calcium begins with its ultrafiltration across the capillaries of the glomerulus. The ultrafilterable forms of calcium include ionized Ca^{2+} and calcium complexed to small anions. Calcium bound to plasma proteins is not filtered. The calcium

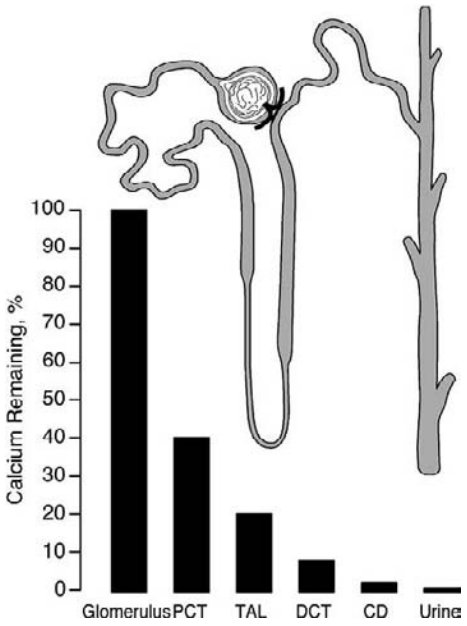

FIGURE 64.3 **Renal calcium absorption.** The figure represents a stylized view of the nephron and the graph depicts the percentage of filtered calcium remaining at the glomerulus, proximal convoluted tubule (PCT), thick ascending limb (TAL) of Henle's loop, distal convoluted tubule (DCT), collecting duct (CD), or in the final urine.

concentration in the ultrafiltrate, measured by directly sampling tubular fluid from Bowman's space is 1.31 mM, or 63% of that in plasma.[21–23] This value compares favorably to that of ultrafiltrate prepared with artificial membranes.[8,23–25]

Glomerular ultrafiltration is a passive process, driven by the net hydraulic and osmotic pressure gradient across the capillary membranes. The glomerulus is generally not considered a site of regulation of calcium absorption or homeostasis. However, it should be borne in mind that PTH depresses the glomerular ultrafiltration coefficient K_f, which may thereby diminish single nephron filtration rates and contribute to the hormone's calcium-sparing action (cf. Hypercalcemia[26,27]). mRNA transcripts for the type 1 PTH receptor (PTH1R)[28,29] and type 2 PTH receptor (PTH2R) are expressed in glomeruli.[30,31]

Proximal Convoluted Tubule

Following its ultrafiltration across the glomerular capillaries, calcium is reabsorbed throughout the nephron. As shown in Fig. 64.3, the majority of the filtered calcium is recovered by the proximal tubules. The proximal nephron of both superficial and juxtamedullary tubules consists of three ultrastructurally distinct segments: S_1, S_2, and S_3.[32] Operationally, however, calcium transport has been characterized in the microscopically recognized proximal convoluted tubules, corresponding primarily to the S_1 segment, and to a lesser extent in superficial proximal straight tubules (*pars recta*), S_2 segments.

Sixty to Seventy percent of the filtered calcium is absorbed by the end of the proximal convoluted tubule. Using *in vivo* micropuncture techniques, Lassiter and colleagues,[22] and subsequently others,[33,34] demonstrated that two-thirds of the filtered calcium is reabsorbed by the end of the accessible proximal convolution in the rat. Somewhat less complete absorption, 37–45%, obtains in the rabbit.[35,36] Remarkably, in the hamster, which exhibits the most robust calcium-sparing effect of PTH, calcium absorption by proximal tubules is negligible.[37] This observation underscores the primacy of distal segments in regulating final calcium excretion.

In general, random collections of proximal tubule fluid samples under control conditions result in tubular fluid to glomerular filtrate calcium ratios, $(TF/GF)_{Ca^{2+}}$ between 1.0 and 1.2. Based on these findings it is commonly held that the concentration of calcium within the proximal tubular fluid remains essentially identical to that of glomerular filtrate or ultrafilterable plasma (UF) calcium,[22,38] i.e., that calcium transport along the length of the proximal convoluted tubule proceeds essentially as an isoosmotic process. These observations, in turn, have been interpreted as indicating that the bulk of calcium absorption is energetically passive. However, a detailed examination of calcium absorption along the length of the accessible superficial proximal tubule revealed that $(TF/GF)_{Ca^{2+}}$ increases from a value close to unity at the earliest micropuncture locations to a value of about 1.2, still relatively early in the nephron, and stayed constant for the remaining accessible portions of the proximal nephron.[39] The cause of the elevated $(TF/GF)_{Ca^{2+}}$ ratios is unclear but may have its origin in molecular sieving of calcium at the luminal pole of the tight junctions as calcium absorption lags behind that of water. Alternatively, the presence of nontransported, anionically complexed calcium within the lumen might contribute to or account for the elevated values of $(TF/GF)_{Ca^{2+}}$. Inasmuch as the proximal tubule transepithelial voltage is about −2.5 mV, these findings are consistent with the idea that a component of proximal calcium transport may be energetically active since it proceeds against an electrochemical gradient.

Proximal Straight Tubule

Because proximal straight tubules (*pars rectae*) do not extend to the surface of the kidney and are not amenable to conventional micropuncture techniques, calcium

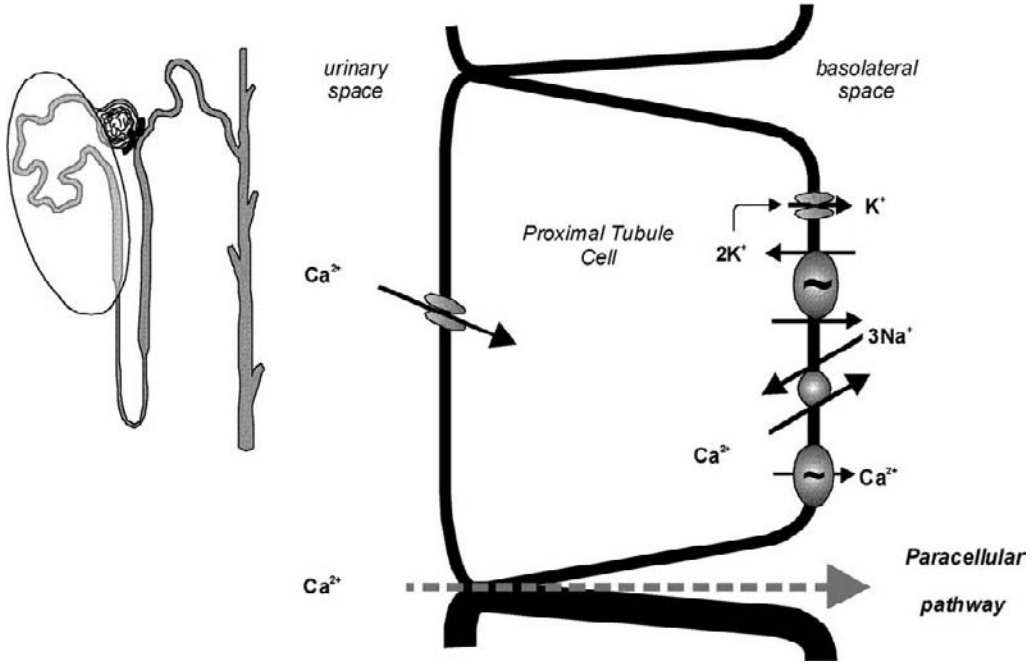

FIGURE 64.4 **Model of proximal tubular calcium absorption.** The inset shows the portion of the nephron referred to in the cell model. In proximal tubules, the majority of calcium is absorbed by passive mechanisms through the paracellular pathway. Evidence supports the presence of a small component of active, transcellular calcium transport.

transport by this segment has been less thoroughly studied than in proximal convoluted tubules. Indirect estimates of calcium reabsorption derived from the difference between the calcium concentration of fluid samples obtained from late proximal convoluted tubules and those from the tip of the loop of Henle suggested that 10% of the filtered calcium is recovered by proximal straight tubules.[22,40,41] This approach necessitates obtaining proximal samples from a superficial nephron, while the samples from the loop of Henle are taken from the tip of a juxtamedullary nephron. Nonetheless, direct *in vitro* microperfusion studies of proximal straight tubules substantiated the conclusion that proximal straight tubules absorb 10% of the filtered calcium.[42,43]

Mechanisms of Proximal Tubule Calcium Transport

Calcium absorption by proximal tubules may be mediated by a combination of passive and active transport mechanisms. The transepithelial absorption of calcium can be conceptually described by the following relation:

calcium absorption = passive transport + active transport

where passive absorption is the sum of diffusion and solvent drag. These relations can be expressed formally as:[44]

$$J_{Ca^{2+}} = \underbrace{\frac{P_{Ca^{2+}}\left(\Delta C_{Ca^{2+}} + \frac{Zi}{RT}\overline{C}_{Ca^{2+}}\Delta\psi\right)}{\text{diffusion}}}_{} + \underbrace{\frac{(1-\sigma_{Ca^{2+}})\overline{C}_{Ca^{2+}}J_v}{\text{solvent drag}}}_{} + \underbrace{\frac{J^{active}_{Ca^{2+}}}{\text{active transport}}}_{}$$

where, $P_{Ca^{2+}}$ is the apparent calcium permeability, $\Delta C_{Ca^{2+}}$ is the transepithelial calcium concentration difference ([lumen-to-bath] − [bath-to-lumen]), z_i is the valence, R the gas constant, T the absolute temperature, $C_{Ca^{2+}}$ is the average transmural calcium concentration across the tubule ([lumen-to-bath + bath-to-lumen]/2), $\Delta\Psi$ is the transepithelial voltage, σCa^{2+} is the reflection coefficient for calcium, J_v is the net fluid absorption, and $J\{^{active}_{Ca^{2+}}\}$ is the metabolically active, transcellular calcium transport.

Most evidence suggests that proximal tubule calcium transport is passive, i.e., energetically independent, and occurs primarily by diffusion and solvent drag. These mechanisms imply that calcium absorption proceeds primarily by the paracellular route (Fig. 64.4) through the lateral intercellular space between adjoining cells. By contrast, active transport is a two-step process, wherein calcium enters the cell across apical plasma membranes and is then extruded across basolateral plasma membranes. Basolateral efflux occurs against a steep electrochemical gradient and is powdered by the hydrolysis of ATP by the Na-K-ATPase. A general schematic representation of

these processes in proximal tubules is shown in Fig. 64.4.

It should be noted that, although small by comparison with paracellular calcium absorption, active cellular absorption by proximal tubules amounts to some 20 μmol/min,[45] which, in fact, is approximately twice that of the distal nephron, where calcium absorption is entirely cellular.

The mechanism of calcium transport by the S_2 segment of the proximal straight tubule resembles that of the proximal convoluted tubule. Studies using isolated perfused rabbit S_2 proximal tubules, under experimental conditions designed to minimize net fluid movement and the electrochemical gradient for Ca^{2+}, generally are consistent with the idea that passive driving forces are the major determinant of calcium absorption.[42,46] However, evidence for a significant amount of active calcium transport has been reported.[43] Sacks and Bourdeau[47] showed that when passive driving forces across isolated S_2 segments of rabbit proximal straight tubules were experimentally manipulated, the direction and rate of net calcium flux were predicted by the magnitude of the imposed electrochemical gradient. Thus, passive diffusion appears to be the major mechanism of transport in proximal straight tubules.

The presence of active, transcellular calcium absorption by proximal tubules, no matter how slight its magnitude, necessitates specific transport proteins in apical plasma membranes to admit calcium and others in basolateral membranes to mediate its extrusion. As far as is presently known, cellular calcium entry is mediated by calcium channels. Support for the presence of such channels takes the form of electrophysiological[48–51] and pharmacological[51–60] evidence. The molecular identity of such proximal tubule calcium channels is unknown but appears not to be TrpV5 or TrpV6.[61] Basolateral calcium efflux in energetically dependent. Two proteins capable of mediating such transport are the plasma membrane Ca^{2+}-ATPase (PMCA) or the NCX Na^+/Ca^{2+} exchanger. Proximal tubule cells express PMCA1 and PMCA4 isoforms, which may serve as the primary mechanism of cellular Ca^{2+} efflux.[62] Proximal tubules also express the NCX1 Na^+/Ca^{2+} exchanger.[63] The relative contribution of NCX1 and PMCA1/4 to cellular calcium absorption is not known.

In summary, proximal tubules exhibit high calcium permeability and low transepithelial electrical resistance. Most calcium absorption proceeds through passive mechanisms and traverses the paracellular pathway (Fig. 64.4). The majority of passive absorption is diffusive, with an additional slight contribution by solvent drag. The active component constitutes 20% of the total calcium absorption and proceeds through a transcellular pathway that involve entry through apical membrane calcium channels and exit across basolateral membranes that is mediated by isoforms of the plasma membrane Ca^{2+}-ATPase and/or the Na^+/Ca^{2+} exchanger.

Descending and Ascending Thin Limbs

Limited information is available on calcium transport and permeability of thin descending limbs of Henle's loop. The few studies failed to uncover evidence for net calcium movement (absorptive or secretory) (summarized in [39]). When single rabbit descending thin limbs were perfused *in vitro*, (TF/UF) Ca^{2+} and (TF/P) inulin increased proportionately.[41] This would allow calcium to accumulate in the tubular fluid. Furthermore, these studies revealed a remarkably low permeability to calcium; about one-tenth that of proximal convoluted tubules.

Thin ascending limbs of Henle's loop also exhibit low calcium permeability and are not a site of net calcium transport.[64] The low permeability of thin ascending limbs is particularly striking in view of its comparatively high permeability to sodium and chloride.[65] In single, microperfused thin ascending limbs of the hamster, removal of luminal calcium had no effect on the concentration of intracellular free calcium,[66] consistent with the low permeability.

In summary, calcium transport by thin descending limbs and thin ascending limbs contributes little to the overall reabsorptive process because of the low Ca^{2+} permeability and absence of active calcium transport by these segments.

Thick Ascending Limb

Approximately 20–25% of the filtered calcium is reabsorbed by thick ascending limbs of Henle's loop. Thick ascending limbs are comprised of medullary and cortical portions. This division is relevant because appreciable functional and species differences attend calcium transport and its hormonal regulation by these nephron segments. Calcium is absorbed by both medullary and cortical portions of thick ascending limbs, though to differing degrees. It is unclear if the gradual changes in cellular architecture between medullary and cortical portions of the thick ascending limb are related to differences in the mechanism or magnitude of calcium transport. The distinguishing feature of calcium transport in thick ascending limbs is the presence of parallel paracellular and cellular transport pathways (Fig. 64.5). Under resting conditions, calcium absorption is energetically passive and proceeds through the paracellular pathway driven primarily by the lumen electropositive transepithelial voltage resulting from

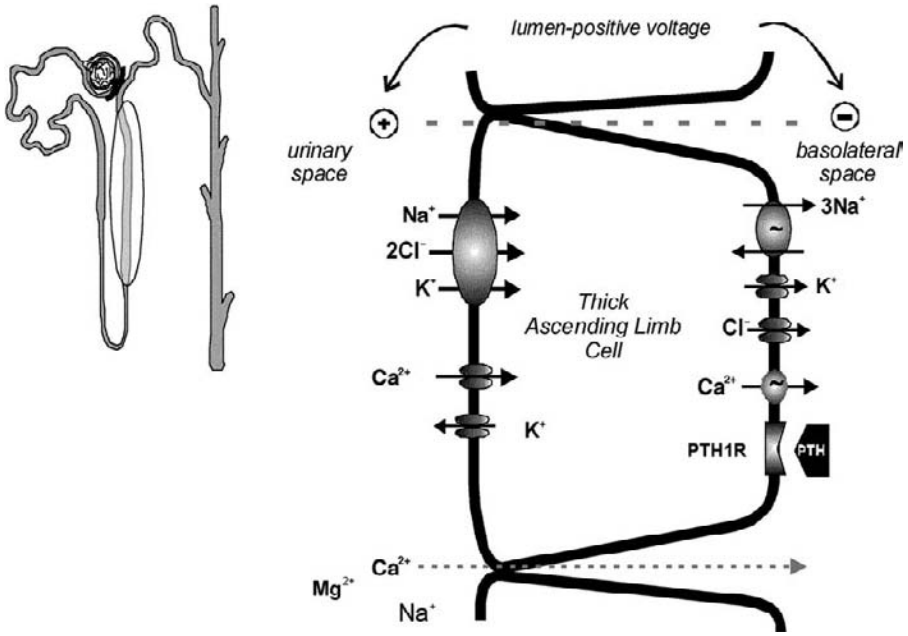

FIGURE 64.5 **Model of calcium absorption in thick ascending limbs.** The inset shows the portion of the nephron referred to in the cell model. Calcium absorption proceeds through both an active, transcellular pathway and by passive mechanisms through the paracellular pathway. Resting, i.e., basal absorption is passive and is driven by the ambient electrochemical gradient for calcium. Calcitropic hormones such as PTH and calcitonin (not shown) stimulate active cellar calcium absorption in cortical and medullary thick ascending limbs, respectively, as detailed in the accompanying text. Other hormones, such as vasopressin, that stimulated Na^+ absorption by the Na-K-2Cl cotransporter, cause parallel elevations of calcium absorption by increasing the transepithelial voltage and the driving force for passive calcium absorption. Conversely, the loop diuretics bumetanide and furosemide, by inhibiting Na-K-2Cl cotransport, decrease the transepithelial voltage and diminish passive calcium absorption with an attendant increase in calcium excretion.

the absorption of Na^+. The greater the rate of Na^+ absorption, the larger the voltage, and the consequent rate of Ca^{2+} absorption. Conversely, lower rates of Na^+ absorption, following the administration of loop-acting diuretics, for instance, the lower the extent of Ca^{2+} absorption. Thus, in the absence of hormonal stimulation, Ca^{2+} and Na^+ absorption parallel one another in thick ascending limbs as they do in proximal tubules.

The pattern of parallel Ca^{2+} and Na^+ absorption is disrupted, however, by PTH and by calcitonin. Thick ascending limbs express the parathyroid hormone receptor and the calcitonin receptor. The distribution of these receptors, as deduced by the ability of their respective ligands to induce cAMP accumulation,[67] varies importantly between medullary and cortical ascending limbs and across species. Table 64.1 summarizes representative findings for humans and the mouse. Direct studies of the effect of PTH and calcitonin on calcium transport by isolated cortical and medullary thick limbs established that these peptides stimulate active, transcellular calcium absorption.[39] Thus, resting calcium absorption proceeds through the paracellular pathway through tight junctions, and active calcium absorption follows a transcellular route.

TABLE 64.1 PTH and Calcitonin Receptor Distribution in Thick Ascending Limbs

Species	Segment	PTHR	CTR
Human	CAL	++	+++
	MAL	++	++
Mouse	CAL	++++	+
	MAL	0	0

Distribution and abundance of parathyroid hormone receptor (PTHR) and calcitonin receptor (CTR) are scaled based on relative stimulation of adenylyl cyclase.[255,256]

Moreover, whereas passive calcium transport in thick limbs parallels Na^+ movement, active calcium cellular calcium transport is inversely related to cellular sodium absorption. The reason for this is that apical membrane calcium influx is voltage dependent. Cellular Na^+ entry depolarizes the cell, thereby reducing the driving force for Ca^{2+} entry, and conversely decreased Na^+ influx hyperpolarizes the transmembrane voltage and increases Ca^{2+} influx. These complex relations between voltage and paracellular vs. cellular calcium movement makes it difficult to assess

the relative contribution of cellular and paracellular calcium transport to the net absorption, especially under physiological conditions or in clinical settings.

Notably, other peptide hormone receptors, including those for ADH and glucagon, are also expressed in thick ascending limbs. Their activation is not accompanied by changes of calcium absorption. This may be explained by the requirement for activation of both adenylyl cyclase and phospholipase C, which occurs with PTH and calcitonin but not ADH or glucagon, for stimulation of cellular calcium transport in cortical ascending limbs.[68]

Bartter's Syndrome and Calcium Transport by Thick Ascending Limbs

Mutations in the *Slc12a1* (Na-K-2Cl cotransporter),[69] the *KCNJ1* (ROMK apical K^+ channel),[70] and *CLCNKB*, (the human homolog of the ClC-K2 basolateral Cl^- channel)[71] genes have been described in a number of families with Bartter's syndrome. The syndrome is characterized by salt wasting, hypokalemic alkalosis and, in the classic and antenatal variants, accompanied by hypercalciuria.[72] Loss of Na-K-2Cl cotransporter function by gene mutation results in a clinical presentation similar to that of inhibition of cotransporter activity by loop diuretics, viz., salt wasting, volume depletion, hypokalemic metabolic alkalosis, and hypercalciuria. These findings underscore the parallel nature of sodium and calcium absorption by thick ascending limbs.

Distal Convoluted Tubules

Distal convoluted tubules absorb 8–10% of the filtered calcium. Although modest in overall magnitude, distal tubules are the most important site for renal calcium economy because they are the site of the key regulatory influence of PTH on calcium absorption. Calcitonin, and 1,25$(OH)_2D_3$ also participate in regulating calcium absorption by distal tubules. The other notable feature of calcium absorption by distal tubules is that it proceeds entirely through a transcellular pathways (Fig. 64.8) and is inversely related to sodium absorption. Thus, thiazide diuretics dissociate calcium and sodium movement by inhibiting sodium transport, thereby promoting calcium absorption.

The superficial distal nephron is composed of three tubule segments, the distal convoluted tubule, the connecting tubule, and the cortical collecting tubule, each composed of distinct cell types.[73] The distal convoluted tubule begins at the macula densa and, in most species, ends gradually as a transition to connecting tubules.[74] Although it is generally thought that distal convoluted tubules consist of a single cell type, the distal convoluted tubule cell, intercalated cells may be found, particularly in the later one-third of the tubule. In humans, intercalated cells may be present throughout the distal convoluted tubule.[75] Distal convoluted tubule can be functionally divided in to DCT1 and DCT2 portions. The former expresses the NaCl cotransporter, whereas the latter expresses both the NaCl cotransporter and the epithelial Na channel, ENaC.[76] Connecting tubules consist of connecting tubule cells and intercalated cells. The cortical collecting duct is comprised of principal and of alpha or beta intercalated cells. These different cell types and relevant when considering calcium transport and its hormonal regulation. The distribution of calcium-transporting or regulating proteins in mouse distal nephron sites has been elegantly analyzed.[77] The findings are included in the relevant following sections.

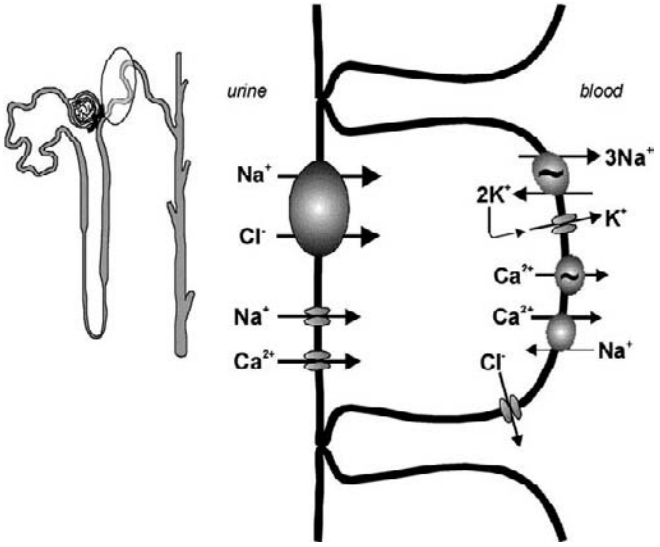

FIGURE. 64.6 **Calcium and sodium absorption by distal convoluted tubules.** The inset highlights this portion of the nephron. The cell model shows two apical membrane Na^+ entry mechanisms, the thiazide-diuretic-inhibitable Na-Cl cotransporter and the amiloride-blockable, epithelial Na channel, ENaC. Calcium enters the cell across apical membranes through dihydropyridine-sensitive calcium channels. Basolateral calcium efflux is thought to be mediated by the plasma membrane Ca^{2+}-ATPase (PMCA) and the Na^+/Ca^{2+} exchanger. In distal convoluted tubules, both basal and stimulated calcium absorption follows a transcellular path.

Pioneering stop-flow studies first demonstrated that calcium was absorbed by distal tubules. Direct examination of calcium transport along the length of the accessible surface distal tubule confirmed these conclusions.[22] 10% of calcium delivered to distal convoluted tubules is absorbed by the end of the accessible surface portion of distal tubules. Since the $(TF/UF)_{Ca2+}$ ratio is less than unity and the transepithelial voltage is lumen-negative,[78,79] calcium

absorption proceeds against both chemical and electrical gradients and, hence, is active. Detailed information on permeability coefficients and related biophysical parameters of distal calcium transport can ben found in previous editions.[39]

Cellular Mechanisms of Distal Tubule Calcium Transport

Calcium absorption by distal convoluted tubules proceeds entirely by active, transcellular absorption (Fig. 64.7). In this regard it is conspicuously different from proximal tubule calcium absorption, which is primarily if not entirely passive and paracellular in nature, or calcium absorption by thick ascending limbs, which is mediated by hybrid transcellular and paracellular mechanisms.

The salient features of cellular calcium transport by distal convoluted tubule cells are summarized schematically in Fig. 64.6. Entry across apical cell membranes occurs through calcium channels[80–84] and basolateral efflux is mediated by a combination of Na^+/Ca^{2+} exchange and Ca^{2+}-ATPase. It is now generally accepted that TrpV5 calcium channels are responsible for apical calcium entry (see Chapter 62, Calcium Channels).[85] TrpV5, was cloned and localized to apical membranes of distal convoluted tubules.[77,86,87] TrpV5 is a homotetramer that is constitutively active, has a 77 pS single channel conductance.[88] Some aspects of the biology of TrpV5 remain to be resolved. For instance, TrpV5 is insensitive to dihydropyridine or phenylalkylamine calcium channel blockers[89,90] that have been shown to inhibit calcium absorption by distal convoluted tubules and DCT cells.[91,92] Recent findings suggest that PTH stimulates Ca^{2+} entry by PKA-mediated phosphorylation of TrpV5.[93] The mechanism whereby thiazide diuretics inhibit calcium entry by TrpV5 channels is uncertain. A heteromeric, dihydropyridine sensitive calcium channel that incorporates ß$_3$-subunits[94,95] has also been described. It is stimulated by PTH,[91] thiazide[96] and amiloride[97] diuretics, but is refractory to furosemide.[95] Its molecular identity is unknown.

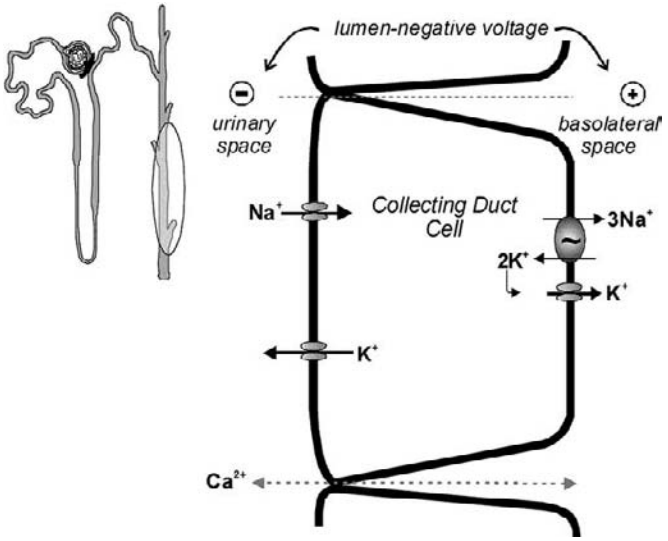

FIGURE 64.7 **Calcium transport by collecting ducts.** This nephron segment is shown in the shaded area of the inset. Collecting ducts are not thought to be a primary site of calcium transport. Studies suggest that calcium movement is small in magnitude and thermodynamically passive. Transport may be absorptive or secretory, driven by the lumen-negative transepithelial voltage.

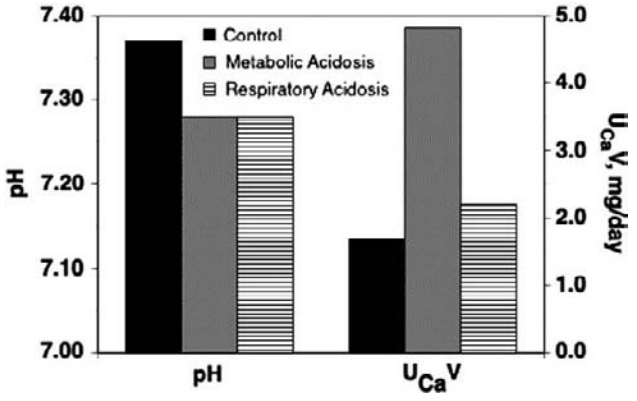

FIGURE 64.8 **Effects of metabolic or respiratory acidosis on serum pH and urinary calcium excretion in rats** *(Redrawn from ref. [171]).*

TRPV5-null mice exhibit a comparable hypocalciuric response to thiazides as do wild-type normal mice.[98] Because the pharmacological site of thiazide action is the distal nephron, Nijenhuis concluded that thiazide diuretics indirectly stimulate paracellular proximal tubular calcium reabsorption by contracting the extracellular fluid volume. The clinical implication of this finding is that patients with recurrent kidney stones must restrict dietary sodium to enhance the volume-depleting action of thiazides to maximize the hypocalciuric effect.

The Klotho gene encodes a type I single-pass transmembrane protein that is associated with TrpV5. Secreted Klotho, a beta-glucuronidase, hydrolyzes extracellular sugar residues on TRPV5, thereby inhibiting internalization of TRPV5 and increasing the abundance of TRPV5 on the cell surface.[99] The net result of this action is to increase TRPV5-mediated calcium influx and renal calcium absorption. Klotho-deficient mice exhibit higher calcium excretion than do wild-type mice.[100]

Distal convoluted tubules express several isoforms each of the Ca^{2+}-ATPase[101,102] (PMCA) and the Na^+/Ca^{2+} exchange (NCX).[103–106] NCX1 is

extensively expressed on basolateral membranes of DCT1 of mouse[107] and DCT2 of rat[108] distal convoluted and connecting tubules. PMCA isoforms display a comparable pattern of distribution.[103] NCX1 operates in forward and reverse modes. In the forward direction, NCX1 mediates calcium efflux that is coupled to sodium influx in a ratio of 3 Na^+ exchanged for 1 Ca^{2+} ion. Operating in this fashion, NCX1 is thus electrogenic.[109] Other exchanger modes and stoichiometries have been reported.[110] Given the membrane hyperpolarization induced by PTH,[91,111] it would be expected that calcium extrusion mediated by NCX1 would be accelerated in response to PTH action, thereby coordinating symmetric increases of apical calcium entry and basolateral efflux, accounting to the hypercalcemic actions of PTH.

The $K_m^{Ca^{2+}}$ for renal Na^+/Ca^{2+} exchange is 0.1–10 μM, within the range of free intracellular Ca^{2+} (Ca_i^{2+}) stimulated by PTH, calcitonin, and thiazide diuretics.[96–112] The K_m is comparable to that of the PMCA,[113–116] whereas the V_{max} of the PMCA is 20–40 times greater than that for Na^+/Ca^{2+} exchange. Assuming that $[Na^+]_i$ is 17.5 mM[117] and Ca_i^{2+} is 120–300 nM,[118] the Na^+/Ca^{2+} exchanger operates in the forward direction at no more than 4–10% of its maximal velocity. Under the same conditions, the PMCA functions at 30–70% of its V_{max}. Thus, under resting conditions, PMCA activity would account for 85% of basolateral calcium efflux and Na^+/Ca^{2+} exchange would mediate only 15%. Based on these considerations, it is reasonable to imagine that resting calcium efflux is mediated by the PMCA and that in response to PTH, thiazide or amiloride diuretics that hyperpolarize distal tubules, the rate of forward electrogenic Na^+/Ca^{2+} exchange increases and accounts for the bulk of calcium efflux.

Gitelman's Syndrome and Distal Tubule Calcium Transport

Gitelman and Welt[119] described a variant of Bartter's syndrome exhibiting salt wasting, hypokalemia, and hypermagnesuria but that was uniquely associated with decreased calcium excretion.[119,120] Gitelman's syndrome is due to inactivating mutations of the apical membrane Na-Cl cotransporter gene, *Slc12a3*, which is located on human chromosome 16. The hypocalciuria of Gitelman's syndrome can be understood from the model of distal tubular calcium absorption depicted in Fig. 64.6. Since the direction and magnitude of sodium and calcium absorption are inversely related in distal convoluted tubules, impaired or diminished apical Na-Cl cotransport enhances calcium absorption. Thus, the disordered mineral ion metabolism accompanying Gitelman's syndrome reinforces the conclusions drawn regarding the cellular mechanisms of distal calcium absorption and the inverse relations between calcium and sodium transport by distal tubules.[109]

Connecting Tubules

Connecting tubules represent a structural and functional transition from distal convoluted tubules to collecting ducts. In superficial nephrons, connecting tubules are short and connect distal convoluted tubules to collecting ducts. Connecting tubules of deep nephrons form an arcade before draining into a collecting duct. The ratio of superficial to deep connecting tubules varies between species (cf. Chapter 20). Notably, whereas distal convoluted tubules consist of a single cell type, the principal cell, connecting tubules are comprised of principal cells and intercalated cells. As in distal convoluted tubules, principal cells mediate calcium absorption. α-intercalated cells secrete protons by a combination of the vacuolar H^+-ATPase and by the gastric-type H/K-ATPase.[121–123] Operationally, cellular calcium absorption is similar to that in distal convoluted tubules: it proceeds by a transcellular route and is stimulated by PTH and thiazide diuretics. Calcium movement by connecting tubules has recently been reviewed in depth.[124] The presence of calcium-transporting principal cells and proton-absorbing intercalated cells may be responsible for the association of hypercalciuria and metabolic acidosis, which has been traced to connecting tubules.[125]

Experimentally metabolic acidosis induced by NH_4Cl or acetazolamide decreased renal TRPV5 and calbindin-D_{28K} mRNA and protein expression in wild-type but not in TRPV5-null mice.[126] Thus, downregulation of renal calcium transport proteins may be the mechanism responsible for hypercalciuria associated with metabolic acidosis. Conversely, chronic metabolic alkalosis increased the expression of calcium transport proteins accompanied by diminished calcium excretion in wild-type mice. This effect persisted in TRPV5-null animals. Additional factors may also contribute to the hypocalciuric effect of metabolic alkalosis.

Collecting Tubules

Cortical collecting tubules only modestly participate in overall calcium homeostasis. Calcium transport is small in magnitude and may be absorptive or secretory. Calcium flux varies directly with the magnitude and direction of the transepithelial voltage.[127] At spontaneous transepithelial voltages (−40 to −50 mV), a

small net secretory flux is observed. Secretory calcium transport could play a role in regulating calcium excretion when long-term changes of transepithelial voltage occur, for instance, as an adaptive response to changes in mineralocorticoid status.[128] A conceptual model of calcium transport by collecting tubules is shown in Fig. 64.7.

Inner medullary collecting ducts absorb calcium and may be responsible for recovery of as much as 1.4% of the filtered load.[129] Calcium absorption by inner medullary collecting ducts is insensitive to PTH. Other reports failed to find evidence to support measurable calcium transport by this nephron segment.[130,131]

TABLE 64.2 Factors Regulating Renal Calcium Transport

Tubule Segment	Fractional Reabsorption	⇓Calcium Reabsorption	⇑Calcium Reabsorption
Proximal Tubule	61%	Volume contraction, phosphate loading,	Volume expansion, phosphate depletion, hypercalcemia, PTH, acetazolamide
Descending thin limb	9%		osmotic diuretics
Thick ascending limb	20%	PTH, calcitonin	furosemide, bumetanide
Distal convoluted tubule	5%	PTH, calcitonin, thiazide diuretics, amiloride, phosphate loading, alkalosis, mineralocorticoid depletion	acidosis
Collecting duct	3%		
Excreted in Urine	<1%		

REGULATION OF RENAL CALCIUM TRANSPORT

A variety of physiological, pathological, hormonal, and pharmacological factors influence tubular calcium reabsorption. The most important of these are enumerated in Table 64.2 and considered below.

Parathyroid Hormone

PTH is the most important physiologic regulator of renal tubular calcium transport, and its actions are covered in detail in Chapter 65. PTH increases renal calcium reabsorption and lowers urinary calcium excretion. In the complete absence of the hormone or in PTH deficiency states, there is diminished tubular reabsorption and hypercalciuria. The stimulatory effect of PTH on calcium transport is limited to distal nephron segments. Paradoxically, PTH decreases calcium absorption by proximal tubules; the calcium-sparing action is due entirely to its effects on cortical thick ascending limbs, distal convoluted tubules, and, in some species, connecting tubules.

Mechanism of PTH Effects on Renal Calcium Transport

It was long held that the calcium-sparing action of PTH was mediated exclusively by the adenylyl cyclase–cAMP–protein kinase A (PKA) axis. This conclusion was based on the following evidence: PTH enhanced the urinary excretion of cAMP formed *de novo* in the kidney (nephrogenous cAMP); administration of exogenous cAMP analogs or forskolin mimicked the effect of PTH in a variety of preparations; and the nephron locations at which PTH activates adenylyl cyclase correlated well with the sites of its physiologic actions. We know now that PTH effects on renal calcium transport, at least in distal tubules, require activation of both PKA and protein kinase C (PKC).[68] It should be borne in mind that PTH-induced formation of nephrogenous cAMP occurs in proximal tubules, where the hormone has little effect on calcium absorption, and is mainly related to the phosphaturic action of PTH. The discrepancy between the necessity and sufficiency of PKA in activating renal calcium transport may be due to non-specific, crossover effects that occur upon addition of high concentrations of forskolin or of exogenous cAMP analogues.[132,133] cAMP-dependent but PKA-independent actions of PTH in some instances may be mediated by EPAC,[134] an exchange protein that is cAMP-dependent and activates PKC.[135]

Functional studies[136] and the molecular cloning of the PTH receptor[137,138] revealed that in addition to activating adenylyl cyclase, PTH activates phosphatidylinositol specific phospholipase C (PI-PLC). PTH stimulation of distal calcium absorption requires activation of PKA and PKC.[68] It should be mentioned that emerging evidence points to the ability of PTH receptors to activate additional signaling pathways involving phospholipase A_2,[139,140] phospholipase D,[68,141] and MAP kinase.[142–144]

The PTH receptor mediates the effects of both PTH and of the PTH-related peptide (PTHrP) and is

therefore designated the Type 1 PTH/PTHrP receptor (PTH1R). A second Type 2 PTH receptor (PTH2R), which responds uniquely to PTH and not PTHrP has also been identified.[145,146] The PTH2R is not thought to be expressed in renal tubular epithelial cells but in vascular cells of the kidney and has not yet been implicated in renal calcium transport.

The PTH1R may activate PKA and PKC. In some cases occupancy of the PTH1R activates only one signaling pathway. For instance, in keratinocytes,[147–149] cardiac myocytes,[150,151] lymphocytes[152–154] and vascular smooth muscle cells[155] reasonable evidence suggests that the PTH1R activates phospholipase C and PKC, PLC but not adenylyl cyclase and PKA. Under certain circumstances, one pathway may be preferentially activated at low concentrations of PTH, while both pathways are stimulated at higher concentrations.[156] These and other cell-specific signaling pathways initiated upon activation of the PTH1R appear to be determined by Na/H exchanger regulatory factor, a cytoplasmic adapter protein.[157]

Extracellular Fluid Volume

Extracellular volume expansion increases calcium excretion, whereas extracellular volume contraction decreases calcium excretion. These effects are brought about indirectly through alterations of proximal tubule function. Calcium transport in proximal tubules is passive and coupled to sodium and water absorption; changes in proximal salt and water absorption cause parallel changes of calcium transport. Hence, by reducing proximal salt absorption, extracellular fluid volume expansion inhibits calcium absorption and increases calcium excretion, whereas volume contraction augments proximal salt absorption, thereby enhancing calcium absorption and decreasing calcium excretion.[130,158] Because of the sheer magnitude of proximal solute absorption, even slight alterations of extracellular fluid volume exert profound effects on calcium absorption. These are commonly ignored or misconstrued when explaining the calcium-sparing actions of drugs such as thiazide diuretics, which reduce extracellular fluid volume. Nonetheless, a number of studies[159,160] provide evidence that the natriuretic effects of volume expansion can only be partially explained by diminished proximal solute reabsorption and point to the presence of distal effects of volume expansion.

Acute extracellular volume expansion decreases ionized calcium concentrations in plasma, with an attendant stimulation of PTH secretion.[161] Increased serum PTH levels, in turn, by directly stimulating calcium absorption by distal convoluted tubules, further reduce calcium excretion.

Acid–Base Balance

Metabolic acidosis increases calcium excretion,[125,162–165] whereas metabolic alkalosis decreases calcium excretion[166–168] at any given plasma calcium concentration. By displacing calcium bound to albumin, acidosis increases the ionized and ultrafilterable calcium in plasma, without affecting the total calcium concentration.[169] Chronic acidosis does not alter resting PTH levels. Further, the changes of renal calcium transport do not require the presence of the parathyroid glands[125,170]and, thus, are not due to secondary changes in serum PTH levels.

The hypercalciuria associated with metabolic acidosis is thought to be caused by reduced distal tubule calcium absorption. The effect is specific for calcium and dissociates the normal parallel relations between renal sodium and calcium absorption, a hallmark of distal tubular regulatory actions. The decline of proximal bicarbonate reabsorption associated with the acidosis decreases fractional calcium reabsorption and augments calcium excretion. Administration of bicarbonate can reverse decreased distal tubule calcium transport.[125,164] The mechanism by which this occurs is uncertain but may be indirect and involve increasing bicarbonate delivery to distal tubules, where bicarbonate is not absorbed and may complex calcium, resulting in greater excretion. However, the effect of bicarbonate to augment distal tubule calcium absorption may also be direct and proceed independent of systemic acid–base status.[125,163]

The effects of respiratory acid–base disturbances on calcium excretion are not as well studied as those of metabolic origin. Respiratory acidosis variably affects renal calcium excretion. As shown in Fig. 64.8, for a comparable fall of blood pH, calcium excretion was unchanged with chronic respiratory acidosis, whereas calcium excretion increased during chronic metabolic acidosis.[171] These findings imply that reductions of pH, per se, do not account for the changes in urinary calcium excretion that accompany chronic metabolic acidosis. In contrast, Chronic respiratory acidosis increased fractional urinary calcium excretion in the dog.[172] Here, serum pH declined to 7.2 after one week of breathing 10% CO_2, while serum PTH and ionized calcium were unchanged but absolute and fractional calcium excretion rose by 50 and 75%, respectively, in the absence of a change in the filtered calcium.

Phosphate Depletion

Chronic phosphate depletion causes striking increases in calcium excretion.[173–175] Although hypophosphatemia, per se, reduces PTH levels, which

contributes to the diminished calcium absorption, the effect of phosphate depletion is independent of PTH.[176] Proximal tubule absorption of both sodium and calcium is reduced proportionately,[177] and calcium absorption is impaired in thick ascending limbs or early distal tubules.[178,179] Acute phosphate infusion reduced calcium excretion to control levels without affecting proximal tubular absorption.[177] In another study,[179] PTH or phosphate infusion partially corrected the renal calcium wasting. Thus, the distal calcium absorptive defect was sensitive to phosphate infusion but was independent of PTH since infusion of PTH failed to alter urinary calcium excretion. It is not known how phosphate augments distal calcium transport.

Hypercalcemia

Hypercalcemia has several effects on the renal calcium handling. It has been noted repeatedly that calcium infusion reduces GFR.[26,180,181] Hypercalcemia causes a fall in the glomerular ultrafiltration coefficient, K_f, resulting in a decrease in both single-nephron and whole-kidney GFR;[26,27,182] these effects do not occur in the absence of PTH. Both the PTH1R and PTH2R are expressed on glomerular cells.[29,31,183] It would be attractive to attribute the calcium-dependent effects of the calcium-sensing receptor (CaSR). However. immunolocalization studies of the CaSR failed to detect protein expression[184] even though cDNA transcripts were reported[28] in the rat glomerulus.

Calcium infusion increases both calcium and sodium excretion,[185] in part due to inhibition of isoösmotic solute absorption by proximal tubules.[180] However, urinary calcium excretion increases to a greater extent than does sodium excretion, suggesting both a specific inhibitory effect of hypercalcemia on calcium transport and, by inference, that this effect occurs in distal tubules, where calcium and sodium absorption can be dissociated. Evidently, in intact animals, elevations of serum calcium are accompanied by suppression of PTH secretion,[180] which decreases calcium absorption at hormone-sensitive sites in cortical thick ascending limbs and particularly distal convoluted tubules. However, hypercalcemia also directly inhibits calcium absorption by thick ascending limbs of Henle's loop.[186,187]

Hypercalcemia suppresses PTH-stimulated cAMP formation specifically in thick ascending limbs. Increasing extracellular calcium from 1 to 5 mM inhibited cAMP production in response to PTH and calcitonin in dissected cortical thick ascending limbs of Henle, but not in proximal convoluted tubules.[188] High calcium also inhibited cAMP production stimulated by forskolin. The mechanism of this inhibitory effect was unclear at the time. It is now appreciated that these effects are mediated by the CaSR.

CaSR

Significant insights in to the regulation of calcium metabolism followed the cloning of the extracellular calcium-sensing receptor (CaSR) by Brown et al.[11] The CaSR is located mainly in the parathyroid glands and on renal tubules. In the parathyroid glands, calcium binding activates the receptor and inhibits PTH secretion. The CaSR colocalizes with the PTH1R in cortical thick ascending limbs and distal convoluted tubules,[184] suggesting a regulatory role on the effects of PTH. Consistent with these observations, graded elevations of extracellular calcium progressively inhibit PTH-stimulated cAMP formation by mouse cortical thick limb and distal convoluted tubule cells. Raising basolateral, but not luminal calcium concentration directly suppressed PTH-stimulated cellular and paracellular calcium absorption by single perfused cortical thick ascending limbs.[189] The CaSR is also expressed at other nephron sites, where it participates in regulating proximal phosphate transport[190] and vasopressin-dependent hydroösmsis in collecting ducts.[191]

The clinical relevance of the CaSR to renal calcium transport has been established by identifying hyper- and hypocalcemic disorders resulting from CaSR mutations: familial hypocalciuric hypercalcemia and neonatal severe hyperparathyroidism result from inactivating CaSR mutations, while an autosomal dominant form of hypocalcemia is caused by activating mutations.[192,193] In addition to effects of mutations on CaSR activation or inactivation, an acquired form of hypocalciuric hypercalcemia and multiple autoimmune disorders arising from the presence of specific antibodies against the CaSR.[194] In ESRD patients, Rodriguez et al. assessed the role of the CaSR in the pathogenesis of secondary hyperparathyroidism.[195] CaSR expression was reduced by 60% in hyperplastic glands as compared with normal parathyroid tissue and it was worst in patients with nodular hyperplasia, a condition associated with refractory secondary hyperparathyroidism.

Clinical Hypercalcemia

Primary hyperparathyroidism accounts for the majority of hypercalcemia seen in the outpatient setting.[196] Epidemiological data point to a decreasing prevalence of primary hyperparathyroidism.[197] The overall age and gender-adjusted rate declined from 82.5 per 100,000 person-years in 1974–1982 to 21.6 per 100,000 from 1993–2001. This trend over several

decades suggests a change in the epidemiology of the disease. The authors speculate that a factor besides the introduction of automated serum calcium testing explains the peak incidence in the 1970s. They hypothesize that the factor could have been the previous widespread use of x-rays in the 1940–1950s as diagnostic and therapeutic tool (head and neck radiation) for acne and thymic enlargement.

Surgery remains the preferred choice for adenoma-related primary hyperparathyroidism. Minimally invasive parathyroidectomy is a procedure that evolved as a result of the technological advance in preoperative and intraoperative localization tools to guide parathyroid surgery and is now commonly performed at several centers. Based on review of medical charts of 352 patients that underwent parathyroidectomy for primary hyperparathyroidism, an intraoperative PTH level 10-min after gland excision with a 50% decrease from the pre-incision PTH levels provided the most reliable evidence of a successful surgical procedure, while avoiding unnecessary parathyroid exploration.[198] The calcium sensing receptor mimetic cinacalcet (Sensipar) is available for patients for whom parathyroidectomy is not an option. Patients with primary hyperparathyroidism treated with cinacalcet for five years maintained normal serum calcium levels with reduced plasma PTH, increased serum phosphate and alkaline phosphatase.[199] No significant effects were noted on bone mineral density. Although not presently approved by the FDA for routine treatment of primary hyperparathyroidism, these and other positive outcomes will likely result in approval.

Humoral hypercalcemia of malignancy (HHM) related to PTH-independent factors such as PTH-related protein (PTHrP) is the other major etiological origin of hypercalcemia.[200] Recently, severe hyperparathyroidism has been described in association to ectopic production of PTH by a metastatic neuroendocrine pancreatic tumor.[201,202] This is an extremely rare cause of HHM, and in several cases there was clear demonstration that the tumor cell expressed the PTH gene as a mechanism of hypercalcemia. In the report of VanHouten there was hypomethylation and increased expression of an otherwise normal PTH gene, leading to the suggestion that the tumor cell expressed a transcription factor capable of interacting with a portion of the PTH gene promoter and then activate PTH gene expression.[202] This biological presentation also has been described in a patient with hepatocellular carcinoma, where the tumor cell secreted intact bioactive PTH.[203] Notably, these extremely rare presentations should not alter the clinical evaluation of patients with humoral hypercalcemia of malignancy.[204]

A secondary and often overlooked cause of hypercalcemia is Milk Alkali Syndrome.[205] Milk Alkali Syndrome consists of hypercalcemia, metabolic alkalosis, and renal insufficiency. Although originally described in middle-aged men consuming milk and antacids for treatment of peptic ulcer disease, it is now most commonly found in older women taking calcium supplements for osteoporosis. Increasing numbers of pregnant women with Milk Alkali Syndrome have been reported. The pathogenesis of the hypercalcemia is complicated and includes various components including excessive calcium intake combined with a failure to suppress $1,25(OH)_2$-vitamin D levels, and other factors.[206] Hypercalcemia and alkalosis generally resolve quickly upon cessation of calcium intake. Ancillary treatment with furosemide, bisphosphonates, or calcitonin is no longer recommended.[205]

Renal Osteodystrophy

The therapeutic control of hyperparathyroidism and bone health, unfortunately, may induce hypercalcemia and vascular calcification in patients with chronic kidney disease. Cardiovascular disease causes more than 60% of deaths among patients with end stage renal disease (ESRD); and the annual cardiovascular mortality rate is significantly higher (by more than an order of magnitude) than in the non-ESRD population, especially among individuals younger than 70.[207] Hyperphosphatemia, hypercalcemia, and the calcium-phosphorus (Ca x P) product are associated with increased mortality, particularly to cardiovascular causes. Goodman et al.[208] reported a high prevalence of coronary artery calcification among young adults receiving dialysis, especially those who were on supportive dialysis for longer than 10 years. More recent findings reveal that vascular calcification itself, as evaluated with x-ray films or ultrasound, is linked to aortic stiffness and reduced patient survival.[209]

A persistent question remains as to whether the use of calcium-based phosphate binders and/or vitamin D to prevent hyperparathyroidism leads to a high calcium burden and vascular calcification. To this end, non-calcium based agents such as Sevelamer and lanthanum salts have been added to the therapeutic armamentarium.

Diuretics

All diuretics, with the notable exception of the thiazides, increase calcium excretion. The magnitude of the calciuric effect varies with the nephron site of action of the particular agent and its associated efficacy. At one extreme, drugs such as acetazolamide that act on proximal tubules have little effect on net calcium excretion. At the other extreme, loop diuretics, the most efficacious diuretics, exert profound effects on calcium

excretion. By contrast, thiazide diuretics decrease calcium excretion. The actions of diuretics on renal calcium excretion and transport are considered below in some detail.

Carbonic Anhydrase Inhibitors

Acetazolamide and related carbonic anhydrase inhibitors block proximal tubule bicarbonate absorption by producing a limiting intra-luminal pH gradient, against which H^+ ions cannot be exchanged for Na^+. Acetazolamide increases urinary sodium excretion with slight, if any, effect on calcium excretion.[210–214] Acetazolamide elicits similar reductions of proximal tubule sodium and calcium absorption.[210] However, although sodium excretion increased while urinary calcium excretion was unchanged, calcium absorption by thick ascending limbs and distal tubules must have been enhanced in a compensatory manner. This would be consistent with the load dependence of calcium transport by thick limbs and especially distal tubules. It is not known whether acetazolamide increases calcium absorption directly or whether the effect is secondary to increased bicarbonate delivery to distal tubules.[125] Nonetheless, acetazolamide caused a relatively greater increase of sodium than of calcium excretion in the isolated perfused dog kidney.[214] These results would favor a direct action of acetazolamide on renal calcium transport.

Loop Diuretics

The major diuretics acting in the loop of Henle are furosemide, bumetanide, piretanide, torsemide, which are sulfamyl anthranilic acid derivatives, and ethacrynic acid, a phenoxyacetic acid,[215] which is now infrequently used. Loop diuretics block sodium absorption by thick ascending limbs, thereby diminishing the driving force for calcium absorption and an attendant and substantial increase of urinary calcium excretion. The magnitude of the natriuresis generally, but not always,[214,216–219] parallels the calciuresis. These deviations may arise from the PTH status at the time the diuretic was administered or other events that regulate calcium or sodium transport at more downstream nephron sites.

Loop diuretics block apical membrane Na-K-2Cl cotransport by thick ascending limbs, where calcium absorption is largely passive, and driven by the lumen-positive transepithelial voltage[187,220] (Fig. 64.5). The positive voltage arises from the secretion of cellular K^+ into the tubular lumen and from the cation permselectivity of the tight junctions. By inhibiting Na-K-2Cl cotransport, loop diuretics decrease intracellular chloride and sodium.[221] The basolateral membrane possesses Cl^- and K^+ conductances,[222] which determine the membrane voltage. Hence, upon blockade of chloride entry, the cytosolic Cl^- activity falls to its equilibrium level[221] and both apical and basolateral membranes hyperpolarize.[223] Thus, the hyperpolarization of both cell membranes upon administration of furosemide is accompanied by depolarization of the transepithelial voltage. These oppositely oriented changes of the transepithelial voltage and the cell membrane potential may exert complicated offsetting effects on calcium transport by thick ascending limbs. The variable effects on calcium and sodium excretion caused by loop diuretics may be related to the magnitude and balance of the inhibitory action of the diuretics on passive calcium absorption and the stimulatory effect on active calcium absorption. The net effect of these competing actions is determined by the relative magnitude of paracellular vs. cellular transport pathways and the extent of drug-induced blockade of Na-K-2Cl cotransport in medullary thick ascending limbs, where there is no cellular calcium absorption, and cortical thick ascending limbs, where the aforementioned considerations suggest that cellular calcium transport may mitigate the degree of blockade of passive paracellular calcium absorption. It should be borne in mind that the passive route clearly dominates overall calcium absorption by thick ascending limbs,[220,224] consistent with the view that furosemide administration usually does not dissociate urinary calcium and sodium excretion.

Thiazide Diuretics

About 5–7% of the filtered sodium and calcium is reabsorbed by distal convoluted tubules. Thiazide diuretics, which block Na-Cl cotransport in distal convoluted tubules, have the unique characteristic of concomitantly decreasing calcium excretion while increasing sodium excretion. The hypocalciuric effect of thiazide diuretics forms the basis for their usefulness in treating idiopathic hypercalciuria.

A model incorporating the generally accepted cellular mechanisms responsible for NaCl and Ca^{2+} absorption by distal convoluted tubule cells is shown in Fig. 64.6. Two sodium entry mechanisms coexist in distal convoluted tubules; an electroneutral Na-Cl cotransporter that is found in early (DCT1) and late (DCT2) distal convoluted tubules and the amiloride-sensitive epithelial Na^+ channel (ENaC) that is restricted to DCT2.[77,225–228] The transport of each Na^+ by the Na-Cl cotransporter is coupled in an electroneutral fashion to the influx of one Cl^- ion. Thiazide diuretics inhibit NaCl reabsorption in distal convoluted tubules.[229–231] As discussed earlier, Ca^{2+} entry in distal convoluted tubules is mediated by TrpV5 and perhaps other calcium-permeable channels that are activated by membrane hyperpolarization. Maneuvers that inhibit

Na^+ entry hyperpolarize the membrane, augmenting the driving force of Ca^{2+} entry.

Initial thiazide administration may not decrease calcium excretion proportionally to the increase in sodium excretion. However, with chronic administration, thiazides cause a sustained reduction in calcium excretion,[213,232–234] that is accompanied by a modest but persistent increase of serum calcium.[213,232,234] The mediating role of PTH on the calcium-sparing effect of thiazide diuretics has been disputed. On balance, it seems that the acute hypocalciuric effects of thiazide diuretics require adequate PTH levels.[235] However, it has been noted that circulating PTH levels actually fall, rather than rise, during thiazide administration.[236,237] Furthermore, acute thiazide administration to thyroparathyroidectomized rats[231,238] or humans[239] produces comparable dissociation of calcium and sodium clearances as in normal subjects. Prolonged administration of polythiazide to thyroparathyroidectomized rats diminished calcium excretion without changing sodium excretion or body weight. Conversely, a permissive role for PTH in the stimulatory effect of thiazide diuretics on rabbit connecting tubules has also been noted.[240] Studies of direct action of thiazide diuretics on calcium absorption by distal convoluted tubules[241] and immortalized distal convoluted tubule cells[96] establishes that chlorothiazide directly stimulates calcium transport. Thus, the stimulatory effect of thiazide diuretics on calcium transport is both direct and independent of PTH.

Extracellular fluid volume contraction may contribute to thiazide-induced decreases of calcium excretion by enhancing proximal tubule solute absorption. This is pointedly illustrated by recent studies in TrpV5-null mice[98] as described earlier.

Potassium-Sparing Diuretics

The mechanism of Na^+ reabsorption by principal cells of cortical collecting ducts is shown in Fig. 64.7. Na^+ enters the cell across the apical plasma membrane down its electrochemical gradient through highly selective epithelial Na^+ channels (ENaC). These channels are inhibited by two chemically distinct drugs; amiloride and triamterene. Amiloride is a pyrazinoylguanidine derivative, whereas triamterene is a chemically unrelated aryl pteridine; both are weak organic bases. As a consequence of their ability to block ENaC, they hyperpolarize the cell. By contrast, spironolactone, an aldosterone analogue that is also a potassium-sparing diuretic, has an entirely different mechanism of action, and depolarizes the cell.[242] The ability of amiloride and triamterene to hyperpolarize the luminal membrane of cells expressing ENaC and possessing apical Ca^{2+} channels activated by hyperpolarization may augment calcium absorption and diminish calcium excretion. Spironolactone, which depolarizes the membrane potential, would not be expected to exhibit such an effect.

Like thiazides, the K-sparing diuretics amiloride[243–250] and triamterene[246] dissociate sodium and calcium excretion. The calcium-sparing actions of amiloride and thiazides are additive in dogs[246] and humans,[244] a likely consequence of their separate sites[229] or mechanisms[96,97] of action on the distal tubule. Amiloride directly stimulates calcium transport by distal convoluted tubules.[97] In the aforementioned studies, amiloride blocked Na^+ entry and hyperpolarized the membrane voltage, which activated calcium entry through dihydropyridine-sensitive Ca^{2+} channels. As far as is presently known, TrpV5 channels are not affected and do not mediate the calcium-sparing action of these drugs.

Triamterene also blocks ENaC[251] and, therefore, should exhibit a calcium-sparing action. However, whereas amiloride decreased fractional calcium excretion in the dog, triamterene did not,[246] i.e., the dissociation of sodium and calcium clearances by triamterene was due to its effect on sodium elimination. In humans, however, triamterene increased calcium excretion[252,253] with a concomitant fall in sodium elimination.[253] In another study, triamterene had no effect on calcium excretion but increased magnesium excretion.[218] Thus, there is uncertainty as to whether triamterene affects renal calcium excretion with no obvious explanation for the difference with amiloride.

INTRODUCTION

Calcium plays a vital role in several biological processes.[1] It is an important constituent bone mineral,[2] and is necessary for normal neuromuscular transmission, muscular contractility, cellular signaling, enzyme function, and blood coagulation. Hence, the appropriate control of calcium homeostasis is vital to the well-being of the organism. A persistently negative calcium balance results in hyperparathyroidism and bone demineralization and contributes to the pathogenesis of osteomalacia and the development of osteoporosis with attendant vertebral and appendicular fractures.[3,4] Severe calcium deficiency results in tetany and, in extreme cases, grand mal seizures. The deposition of excess calcium at ectopic sites occurs in several diseases such as nephrolithiasis, arteriosclerosis, valvular calcification, and calciphylaxis.[3] Therefore, an appreciation of how calcium is normally absorbed, excreted and regulated is important in understanding the pathophysiology of disease.

Calcium homeostasis is a tightly controlled process involving several tissues, hormones, and proteins. The hormones 1α,25-dihydroxyvitamin D (1α,25$(OH)_2$D), parathyroid hormone (PTH), and calcitonin contribute to the regulation of calcium metabolism.[5–7] These three hormones have specific roles in several tissues including the intestinal mucosa, bone, and renal tubular cells. They work in concert with each other through complex interactions to maintain extracellular fluid calcium concentrations in the normal range. In this chapter, we will discuss the physiological role of each of these hormones in calcium homeostasis.

CALCIUM BALANCE

Many tissues are dependent on the maintenance of extracellular calcium concentrations within the physiological range for proper function. If extracellular calcium concentrations are significantly altered or disrupted, tissue and organ dysfunction may result (see above). Bone is the major reservoir of calcium, containing about 99% of total body calcium stores, and provides a significant buffer to maintain extracellular calcium concentrations within the normal range if calcium intake declines or calcium losses occur.[2] The maintenance of serum calcium concentrations in the face of significant overall deficits in calcium balance occurs at the expense of bone integrity. Serum calcium concentrations (range 8.9–10.1 mg/dL in adults) are age dependent, and small differences in circulating concentrations occur as a result of gender.[3,8] Table 65.1 shows normal serum calcium concentrations in males and females measured at the Mayo Clinic. Serum calcium is comprised of protein-bound calcium (40%); complexed calcium, i.e., calcium complexed to ions such as citrate, sulfate, and phosphate (13%); and ionized calcium (47%).[9,10] Total serum calcium concentrations are dependent upon circulating concentrations of albumin and to a smaller extent upon circulating concentration of globulins.[11–17] The biologically active fraction of serum calcium is ionized (normal range 4.8–5.7 mg/dL in adults) and, at a normal serum pH of 7.4, is approximately 47% of total serum calcium. The percentage of ionized calcium changes with pH—an alkaline pH causing a reduction in free ionized

TABLE 65.1 Concentrations at Mayo Clinic

Serum Calcium Concentrations			
Males		Females	
Age (years)	Concentration (mg/dL)	Age (years)	Concentration (mg/dL)
1–14	9.6–10.6	1–11	9.6–10.6
15–16	9.5–10.5	12–14	9.5–10.4
17–18	9.5–10.4	15–18	9.1–10.3
19–21	9.3–10.3	≥19	8.9–10.1
≥22	8.9–10.1		
Age- and Sex-Specific Serum Ionized Calcium Concentrations			
1–19	5.1–5.9	1–17	5.1–5.9
≥20	4.8–5.7	≥18	4.8–5.7

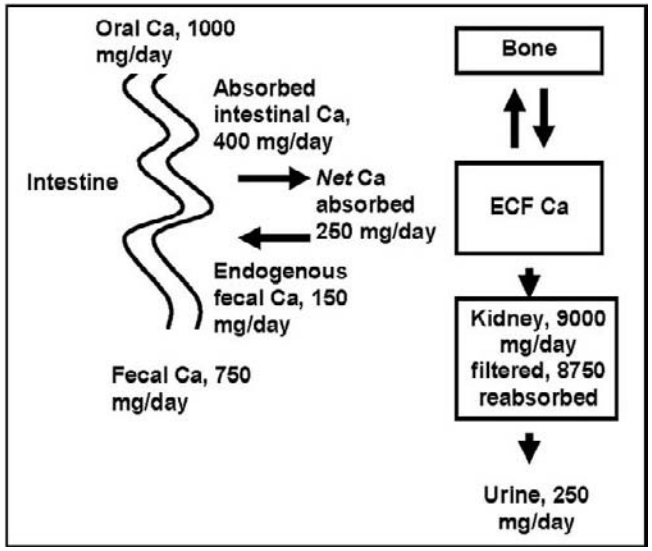

FIGURE 65.1 **Calcium homeostasis in a normal human adult.**

calcium concentrations and an acid pH causing an increase in ionized calcium concentrations. The relationships between ionized calcium, total calcium, albumin and pH are defined by the following equation:[9]

$$[\text{CaProt}] = \{0.2111[\text{Alb}]\} - \left\{(0.42)\frac{[Alb]}{47.3}(7.42 - \text{pH})\right\}$$

$$\text{CaProt} = \text{protein} - \text{bound calcium, mmoles/L.}$$

A 1-gram/deciliter change in serum albumin concentration is associated with a 0.8-milligram/deciliter change in total serum calcium. Since globulins bind calcium less avidly than does albumin, a 1-gram/deciliter change in globulins results in a 0.16-milligram/deciliter change in total serum calcium.[11–17] It should be noted that changes in the concentrations of serum proteins are generally not associated with changes in the percentage of ionized calcium present in the circulation. Also, it is worth remembering that the amount of calcium filtered at the glomerulus of the kidney is a sum of the ionized calcium concentration and the complex calcium concentration (approximately 60% of total serum calcium concentration).

Under normal circumstances of neutral calcium balance in the adult human, net intestinal absorption of calcium is equal to urinary calcium (Figure 65.1).[18] Calcium flux into and out of bone is well balanced with equal amounts of calcium being deposited and resorbed. Over a 24-hour period, a typical human adult ingests about 1000 mg of elemental calcium. Approximately 40% of ingested calcium is absorbed in the intestine and enters the bloodstream. Both active and passive processes are involved in the absorption of calcium from the intestine.[19] When the intestinal lumen calcium concentrations are <10 millimoles/liter, active processes play a major role in calcium absorption.[19,20] However, when calcium concentrations in the intestinal lumen exceed 10 millimoles/liter, passive processes become operative in the absorption of calcium.[21] About 150 mg of calcium are excreted into the gastrointestinal tract each day, predominantly in pancreatic and intestinal secretions ("endogenous fecal calcium"),[22] for a net calcium absorption of about 250 mg per day. The kidney filters about 9000 mg of calcium each day in the glomeruli and reabsorbs the majority of filtered calcium in the proximal and distal nephron, resulting in a net loss of about 250 mg from the kidney in the urine.[23–26] A majority of calcium is reabsorbed in the proximal tubule along with sodium (approximately 70 to 85%). The remainder of filtered calcium is reabsorbed in the thick ascending limb of the loop of Henle and in the distal convoluted tubule, largely as a result of the activity of the sodium-calcium exchanger and plasma membrane calcium pump (PMCA). In states of calcium balance, urinary calcium approximates the amount of calcium absorbed in the intestine.

The following sections will describe how the vitamin D endocrine system, PTH, and calcitonin alter calcium homeostasis in various tissues including the intestine, kidney, and bone.

VITAMIN D ENDOCRINE SYSTEM

Nomenclature

The synthesis of the active form of vitamin D, 1α,25-dihydroxyvitamin D, requires sequential metabolic processing of precursor sterols in several tissues such as the skin, liver and kidney. The term vitamin D refers to both vitamin D_2 and vitamin D_3 (Figure 65.2).[27]

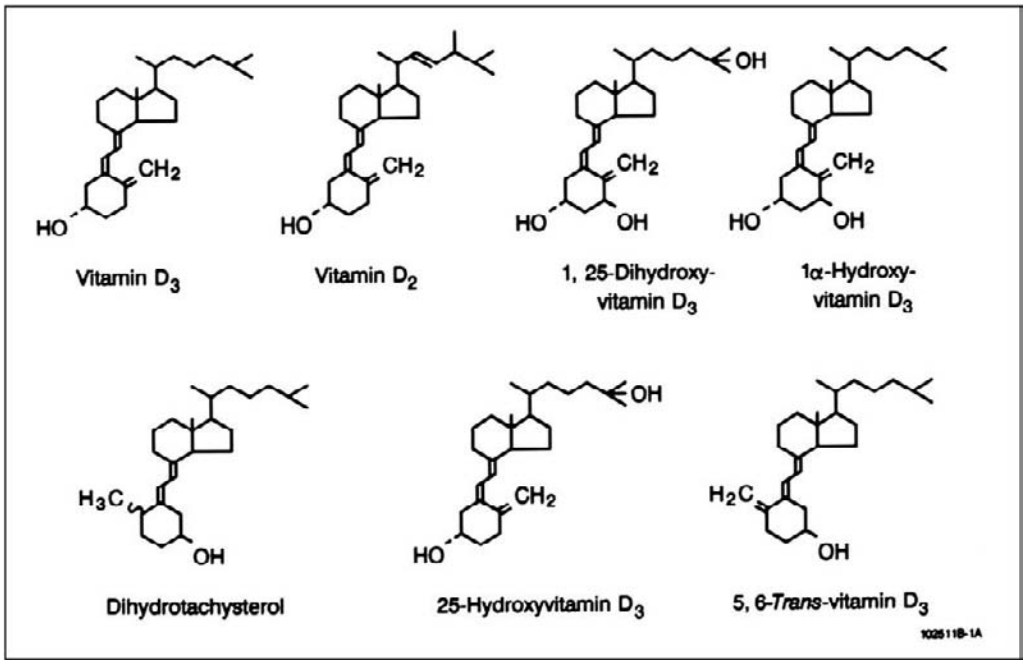

FIGURE 65.2 **Structures of vitamin D_3, vitamin D_2 and other vitamin D metabolites and analogs.**[27]

The metabolic processing of both these forms of vitamin D is similar for practical purposes in mammals, although vitamin D_2 is considerably less active in birds than is vitamin D_3. For the purposes of this chapter, it is appropriate to assume that the metabolic transformations that occur with vitamin D_3 also occur with vitamin D_2. Vitamin D_2 is derived from the plant sterol, ergosterol, whereas, vitamin D_3 is derived from 7-dehydrocholesterol, a byproduct of steroid metabolism. In non-vitamin D supplemented individuals, a majority of circulating vitamin D is in the form of vitamin D_3 or cholecalciferol. Medicinal vitamin D preparations available in the United States today may contain either vitamin D_2 or vitamin D_3. Individuals taking large amounts of vitamin D_2 supplements have elevated concentrations of vitamin D_2 and its 25-hydroxylated metabolite, 25-hydroxyvitamin D_2.[3]

Formation of Vitamin D

In the early 1900s, Huldshinsky[28] and Chick[29] in Vienna showed that exposure of rachitic children to ultraviolet light cured their bone disease. Steenbock and Hart showed that ultraviolet irradiation of animals would put them into positive calcium balance.[30] Later, Steenbock and Black clearly demonstrated that ultraviolet light-induced antirachitic activity in the fat-soluble portion of foods and skin.[31] Hess and Weinstock made similar observations.[32] Building on these observations, Askew and his coworkers isolated vitamin D_2.[33] Windaus and his colleagues showed that 7-dehydrocholesterol was converted to vitamin D_3, and subsequent work showed that this process occurred *in vivo* in normal skin.[34–39] 7-dehydrocholesterol is not directly converted to vitamin D_3 in the skin but rather is first converted to pre-vitamin D_3 that undergoes thermal isomerization to vitamin D_3 (Figure 65.3). Several other, biologically inert, side-products such as lumisterol and tachysterol are produced during the photolysis of 7-dehydrocholesterol. Vitamin D_3 has a higher affinity for the vitamin D binding protein (VDBP) than does pre-vitamin D_3, and the binding of vitamin D_3 to VDBP following its formation in the skin facilitates the removal of the vitamin from skin.[40] Vitamin D_2 and vitamin D_3 are converted in the liver to 25-hydroxyvitamin D_2 and 25-hydroxyvitamin D_3 by the hydroxyvitamin D 25-hydroxylase without significant product inhibition of the enzyme, and consequently circulating 25-hydroxyvitamin D concentrations reflect the amount of vitamin D ingested and the amount of vitamin D formed in the skin. In accord with the earlier observation showing that sunlight exposure enhanced the formation of vitamin D_3 in the skin, several groups have shown that serum 25-hydroxyvitamin D_3 concentrations are lower during and immediately after the winter months than in the summer.[41–51] In the absence of dietary vitamin D supplementation, exposure to ultra-violet B radiation plays an essential role in vitamin D production.

Following conversion of 7-dehydrocholesterol to vitamin D_3 in the skin, vitamin D_3 is transported in the plasma bound to VDBP.[52–54] Any vitamin D_2 ingested

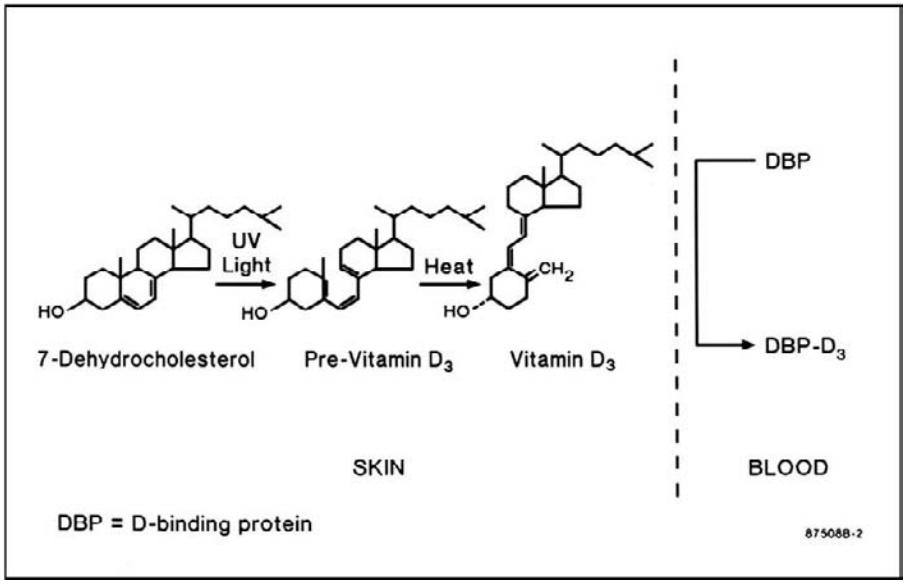

FIGURE 65.3 **The photolysis of 7-dehydrocholesterol to vitamin D_3 via the intermediate, pre-vitamin D_3.**

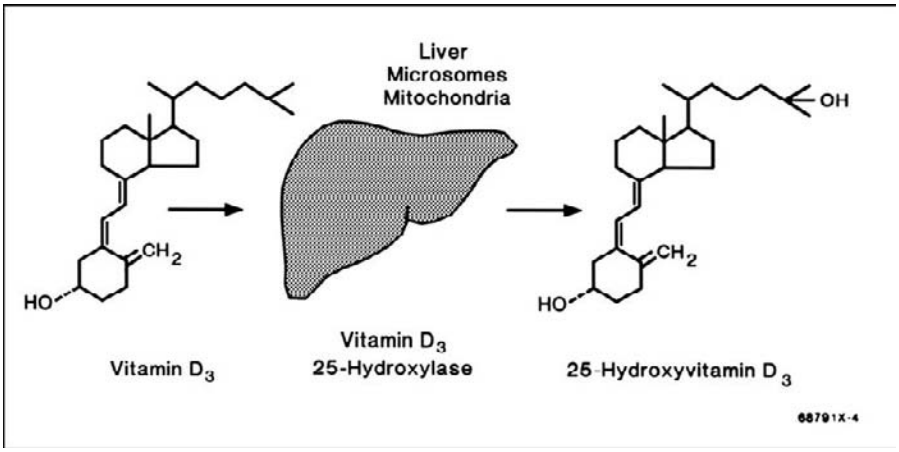

FIGURE 65.4 **The conversion of vitamin D_3 to 25-hydroxyvitamin D_3 in the liver.**

in the diet is also bound to VDBP following absorption in the intestine. Vitamin D_2 and vitamin D_3 are delivered to the liver for hydroxylation by the multicomponent, cytochrome P-450 containing enzyme, vitamin D 25-hydroxylase, which is present in the liver microsomes as well as in mitochondria[55–73] (Figure 65.4). Hepatic conversion of vitamin D_3 to 25-hydroxyvitamin D_3 is not tightly regulated due to a lack of product inhibition of the microsomal vitamin D_3 25-hydroxylase. Several cytochrome P-450s have been cloned and shown to metabolize vitamin D_3 to 25-hydroxyvitamin D_3, including several microsomal cytochrome P-450s and one mitochondrial cytochrome P-450.[74–80] 25-hydroxyvitamin D is the serum metabolite generally measured to determine vitamin D sufficiency or insufficiency in an individual. Accurate determinations of both 25-hydroxyvitamin D_2 and 25-hydroxyvitamin D_3 are obtained using high-performance liquid chromatography methods and mass-spectrometry based methods and such methods are preferred to those using protein binding or antibody binding assays.[81–88]

25-Hydroxyvitamin D_3 is not biologically active except in large concentrations, and it must be metabolized further in the kidney to the bioactive form of vitamin D, 1α,25-dihydroxyvitamin D_3[61,89–98] (Figure 65.5). The 25-hydroxyvitamin D_3-1α-hydroxylase, the enzyme responsible for the conversion of 25-hydroxyvitamin D_3 to 1α,25-dihydroxyvitamin D_3, is a multicomponent, cytochrome P-450 containing enzyme in the mitochondria of renal proximal tubular cells.[99–106] Although the kidney is the primary site of 25-hydroxyvitamin D_3-1α-hydroxylase activity, several other cell types have been shown to have 1α-hydroxylase activity.[107–117] It had previously been thought that the proximal tubule epithelial cells were the only renal cells with 25-hydroxyvitamin D_3 1α-hydroxylase activity. However, several investigators have clearly shown that this enzyme is present and active in several

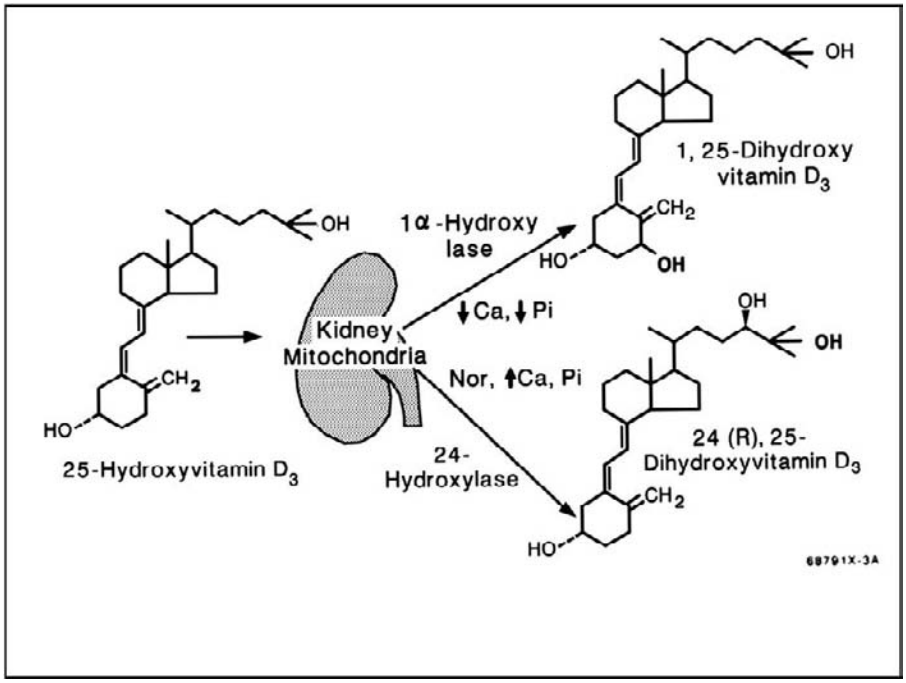

FIGURE 65.5 **The metabolism of 25-hydroxyvitamin D_3 to 1α,25-dihydroxyvitamin D_3 in the kidney.**

segments of the renal tubule.[118–120] The key factors regulating 25-hydroxyvitamin D-1α-hydroxylase production and activity are depicted in Table 65.2. Parathyroid hormone is a potent stimulator of 25-hydroxyvitmain D-1α-hydroxylase and is discussed in detail in the subsequent sections.[6,119,121] In addition to parathyroid hormone, low serum calcium, and low serum phosphorus also stimulate 25-hydroxyvitamin-1α-hydroxylase activity. 1α,25-dihydroxyvitamin D_3 provides a negative feedback through the vitamin D receptor (VDR). VDR-knockout mice have very high concentrations of 1α,25-dihydroxyvitamin D_3.

Recently, other proteins referred to as "phosphatonins" that induce renal phosphate loss have been shown to inhibit renal 25-hydroxyvitamin-1α-hydroxylase activity and 1α,25-hydroxyvitamin D_3 production.[122–126] Two such proteins include fibroblast growth factor 23 (FGF23) and secreted frizzled related protein 4 (sFRP4). Both of these proteins are able to inhibit renal tubule phosphate reabsorption which leads to hypophosphatemia. Despite the hypophosphatemia, which is a potent stimulator of 25-hydroxyvitamin-1α-hydroxylase activity, FGF23 and sFRP4 are capable of preventing the conversion of 25-hydroxyvitamin D_3 to 1α,25-dihydroxyvitamin D_3.[127] FGF23 and sFRP4 are over-expressed in tumors that cause oncogenic osteomalacia, a condition characterized by hypophosphatemia, hyperphosphaturia, and inappropriately low serum 1α,25-dihydroxyvitamin D_3 concentrations.[128] These biochemical abnormalities, including the low 1α,25-dihydroxyvitamin D_3 levels, completely resolve after removal of the offending

tumor.[129] These proteins appear to play an important role in mineral and vitamin D metabolism.[130]

Mechanism of Action of Vitamin D in Intestine

Calcium is absorbed by the intestine (predominantly in the duodenum and proximal small intestine) by two mechanisms, a passive paracellular mechanism and an active transcellular one. The movement of calcium across the apical border of the intestinal cell into the cell is down a concentration gradient (the interior of the intestinal cell has a calcium concentration in the high nanomolar range) and an electrical gradient (the interior of the cell is electronegative relative to the lumen). It does not require the expenditure of energy. However, the movement of calcium out of the intestinal cell at the basolateral membrane is against an electrical and concentration gradient and requires the expenditure of energy (Figure 65.6). Essential to the process of active calcium transport are several vitamin D dependent proteins, each with a specific function. Vitamin D-dependent calcium transport proteins found in the intestinal epithelial cells include the epithelial calcium channel (ECaC), calbindin D_{9K}, and the plasma membrane calcium pump (PMCA). These proteins work in concert to transport calcium from the intestinal lumen, through the brush border membrane, across the intracellular space to the plasma membrane surface and finally out of the cell into the extra-cellular fluid and plasma (Figure 65.7).

The actions of vitamin D in the intestine play an integral role in the maintenance of plasma calcium concentrations within a narrow range in the face of wide fluctuations in dietary calcium intake. When there is an abundance of dietary calcium, a substantial portion can be absorbed passively through the paracellular route. However, when dietary calcium intake declines and plasma calcium concentrations fall, several adaptive responses occur including the production and release of PTH from the parathyroid gland (Figure 65.8). The parathyroid gland is able to sense and respond to slight changes in extracellular calcium concentrations through the calcium sensing receptor (CaSR).[131,132] In addition to the direct effects on calcium homeostasis in bone and the kidney (discussed below), PTH enhances intestinal calcium absorption indirectly by increasing 1α,25-dihydroxyvitamin D_3 production in the proximal tubule cells of the kidney. Bland et al. have also demonstrated that, in vitro, 25-hydroxyvitamin D-1α-hydroxylase activity is regulated by extracellular calcium concentrations independent of PTH.[133] They showed that human proximal tubule cells cultured in a low calcium environment resulted in a significant increase in 1α-hydroxylase activity and this activity was significantly reduced when cultured in a high calcium environment.

The response in the intestine to low dietary calcium intake is to increase the proportion of ingested calcium

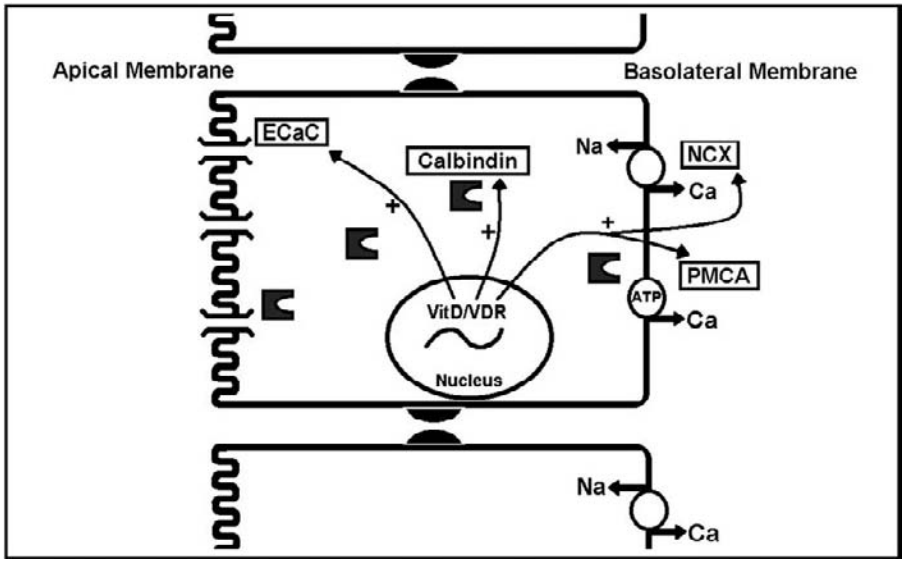

FIGURE 65.7 **Diagram of Epithelial Calcium Transport.** Transcellular transport of calcium ions proceeds from the lumen (intestinal or renal tubular) through the epithelial calcium channel (ECaC) in the apical membrane, across the cytoplasm bound to Calbindin D_{28K} (kidney) or Calbindin D_{9K} (intestine), and subsequently passes through the basolateral membrane through the sodium-calcium exchanger (NCX) or the plasma membrane calcium ATP-ase (PMCA).

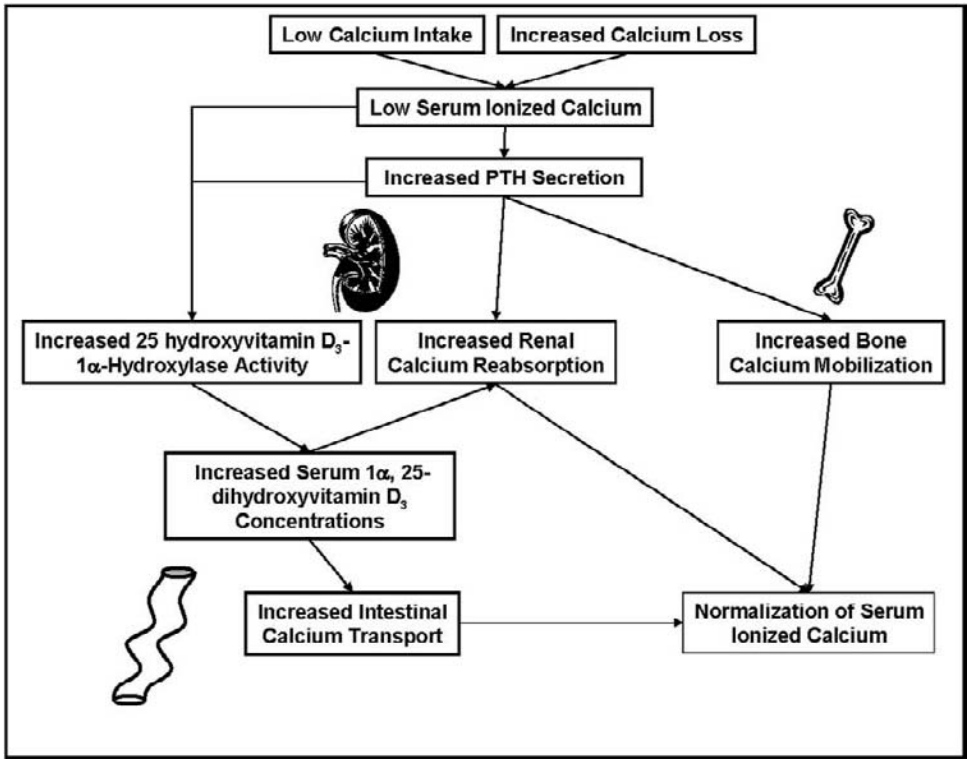

FIGURE 65.8 **Physiological response to hypocalcemia.**

that is subsequently absorbed. This is accomplished by increasing the synthesis and activity of several vitamin D responsive calcium transport proteins in the intestinal epithelial cell. The first step of calcium entry from the intestinal lumen to the interior of the cell is accomplished by the ECaC located on the apical surface of the intestinal brush border epithelium.[134–137] When present in the apical cell wall, ECaC facilitates the entry of calcium ions into the intracellular space. Two forms of ECaC ($ECaC_1$ and $ECaC_2$) are found in the intestine and both are vitamin D responsive. Vitamin D enhances ECaC mRNA expression through the vitamin D receptor (VDR).[138–140] Bouillon et al. has demonstrated in VDR-KO mice that the VDR is necessary for effective regulation of several proteins involved in intestinal calcium transport including ECaC.[140,141] Van Abel et al. have shown that 25-hydroxyvitamin D_3 1α,25-hydroxylase-KO mice also

have lower expression of ECaC than wild-type mice which was corrected with the administration of 1α,25-dihydroxyvitmain D_3.[142] Although the stimulatory effect of vitamin D on calcium transport protein production in the intestine is clear, it is unclear what the direct effect of calcium may be on ECaC expression.[141,142] Regardless of the difference in response to a high calcium diet between the VDR-KO and 25-hydroxyvitamin D_3 1α-hydroxylase-KO mice, these studies would suggest that ECaC expression is regulated by vitamin D-dependent and vitamin D-independent mechanisms.

After calcium ions have entered the enterocyte, they must be transported across the cell to the basolateral membrane, where they will subsequently be transported out of the cell. This is accomplished by the calbindins which are found both in intestinal epithelial cells and in renal tubule cells. In humans, calbindin D_{9K} is responsible for transcellular transport in the intestine and calbindin D_{28K} in the renal epithelium.[143–148] Human calbindin D_{9K} is a 79 amino acid protein encoded on the X chromosome.[145] Hisham at al. identified a putative vitamin D response element in the 5′-flanking region of the calbindin D_{9K} gene in the rat.[149] It has clearly been shown that calbindin D_{9K} mRNA and protein expression is diminished in the face of vitamin D deficiency and that 1α,25-dihydroxyvitamin D_3 administration will increase this expression in various animal models of vitamin D deficiency.[150–152] Basal expression and response to 1α,25-dihydroxyvitamin D_3 treatment changes with age in both rats and humans.[147,148,150,153] Basal expression is lower and the increase in calbindin D_{9K} in response to a given amount of 1α,25-dihydroxyvitamin D_3 is diminished. Although 1α,25-dihydroxyvitamin D_3 appears to be the major stimulus for calbindin D_{9K} in the intestine, dietary calcium may have a direct effect on its expression.[140,152]

The increased expression of ECaC and calbindin D_{9K} likely enhance the capacity of the enterocyte to transport calcium from the intestinal lumen to the intracellular space and subsequently to the basolateral membrane. However, their ability to increase calcium absorption in the face of low dietary calcium intake is dependent on the plasma membrane calcium pump (PMCA). The PMCA represents the final step in active calcium transport across the intestinal mucosa and is the single vitamin D responsive protein in the intestine that is energy dependent. Because it is energy dependent, the PMCA is able to transport calcium across the basolateral membrane against a concentration and electrical gradient. Without the PMCA, calcium absorption through the intestinal epithelial cell could not take place in a state of low calcium intake and low intestinal lumen calcium concentrations. Several isoforms of the protein have been identified with PMCA-1 being the major form found in the human duodenum.[154,155] The PMCA is found in the basolateral membrane and actively transports calcium ions out of the cell into the interstitial space against a concentration gradient.[156] Several investigators have shown that PMCA expression is decreased in the absence of, or increased by, the addition of 1α,25-dihydroxyvitamin D_3.[157–162]

Vitamin D plays an integral role in the absorption of calcium across the intestinal mucosa. Several key proteins involved in this process are directly regulated by 1α,25-dihydroxyvitamin D_3 as demonstrated by numerous experimental conditions and in many species. VDR-KO and 25-hydroxyvitamin D 1α-hydroxylase-KO mice have proven to be useful animal models in elucidating the role of vitamin D in intestinal calcium transport. In both of these models, significantly lower concentrations of all three transport proteins when compared to their wild-type counterparts have been described. In addition, intestinal calcium transport is lower in these KO models, demonstrating their importance in calcium transport. Lending further evidence to the importance of 1α,25-dihydroxyvitamin D_3 in intestinal calcium transport is the excellent correlation between increased ECaC, calbindin D_{9K}, and PMCA expression with improved calcium absorption in vitamin D deficient animals when 1α,25-dihydroxyvitamin D_3 is replaced. This is an effect that is apparent in young as well as older animals. However, the effects of 1α,25-dihydroxyvitamin D_3 on transport protein expression are blunted with age. This may at least partly explain the age-related decline in intestinal calcium absorption.

Mechanism of Action of Vitamin D in Kidney

Calcium handling in the kidney is similar to that in the intestine. There are both vitamin D-dependent and vitamin D-independent mechanisms at work. Reabsorption can take place through a passive paracellular route or an active vitamin D dependent transcellular route. About 55% of plasma calcium is ultra-filterable with about 98% being reabsorbed in the tubule.[163] The kidney plays a unique role in the hormonal regulation of calcium in that it is the primary site of conversion of 25-hydroxyvitamin D_3 to the active form of the hormone 1α,25-dihydroxyvitamin D_3. This was first discovered by Fraser and Kodicek when 1α,25-dihydroxyvitamin D_3 production was noted to be diminished after nephrectomy.[94,164] Although the kidney is the major site of 25-hydroxyvitamin D_3 1α-hydroxylase activity, several other cell types are capable of converting 25-hydroxyvitamin D_3 to 1α,25-dihydroxyvitamin D_3.[108,109,112,117,165] It has been known for some time that the proximal tubule epithelial cell exhibited 25-hydroxyvitamin D_3 1α-hydroxylase

activity.[166–170] However, the presence of 25-hydroxyvitamin D-1α-hydroxylase mRNA and protein has more recently been described by Zehnder et al. in more distal portions of the tubule including the distal convoluted tubule, cortical collecting duct, thick ascending limb of loop of Henle, and Bowman's capsule.[119,120] The significance of 25-hydroxyvitamin D-1α-hydroxylase expression and activity in these distal portions of the nephron is not completely known. One could speculate there is a paracrine effect of vitamin D in these portions of the tubule since vitamin D-dependent calcium transport takes place in the distal nephron.

As previously mentioned, a state of hypocalcemia will lead to increased 1α,25-dihydroxyvitamin D_3 production in the kidney that is stimulated by higher PTH concentrations and probably by the hypocalcemia itself. Several vitamin D responsive proteins that are essentially analogous to those described in the intestine are present in the renal tubule cells. The up-regulation of these proteins by vitamin D helps defend against hypocalcemia and the maintenance of plasma calcium within the normal range in the face of low calcium intake or increased bone or soft tissue calcium deposition.

The first step in renal calcium transcellular transport involves the epithelial calcium channel. ECaCs have been described by Hoenderop et al. in the renal tubule apical membrane[136] and are felt to be responsible for uptake of luminal calcium ions to the intracellular compartment. Of the two forms of ECaCs, ECaC-1 expression appears to be limited to the kidney whereas ECaC-2 is found in several other tissues.[171–174] Human ECaC-1 is encoded on the long arm of chromosome 7 and has several putative vitamin D response elements.[175] ECaC mRNA and protein is up-regulated in vitamin D deficient animals after supplementation with 1α,25-dihydroxyvitamin D_3.[137–139,176,189] When measured by quantitative PCR in the VDR-KO mouse model, ECaC-1 concentrations are decreased in the kidney when compared to wild-type littermates.[174] However, in the same study, Weber et al. demonstrated that ECaC-1 could be increased by giving the animals a high calcium rescue diet. This would suggest that renal ECaC-1 is regulated by vitamin D dependent and vitamin D independent mechanisms.

Extensive work has been done regarding the role and regulation of the calcium binding protein calbindin D_{28K} in the kidney. It is felt that calbindin D_{28K} acts as an intracellular calcium transporter from the apical membrane to the basolateral membrane similar to the action of calbindin D_{9K} in the intestine. Calbindin D_{28K} is expressed not only in the kidney but also in neural tissue.[144,177] However, only renal concentrations seem to be impacted by exposure to 1α,25-dihydroxyvitamin D_3.[177] Within the renal tubule, calbindin D_{28K} is found mainly in the distal portions of the nephron and co-localizes with other vitamin D responsive proteins involved in transepithelial calcium transport.[23,178,179] In contrast to the ECaC and PMCA which are located in the apical and basolateral membranes, respectively, calbindin D_{28K} is found in the cytosolic compartment.[180] Several groups have clearly shown that renal calbindin D_{28K} is regulated by vitamin D.[150,177,181–191] Vitamin D deficient or replete animals given 1α,25-dihydroxyvitamin D_3 significantly increase the expression of calbindin D_{28K} mRNA and protein. This effect is also seen in vitro when cultured renal tubule epithelial cells are exposed to 1α,25-dihydroxyvitamin D_3.[180–184] Although 1α,25-dihydroxyvitamin D_3 is a potent stimulator of renal calbindin expression, changes in calcium, phosphorus, and magnesium also impact its expression. Huang and Christakos showed a lack of effect of a high calcium diet in vivo in vitamin D deficient animals on mRNA levels of calbindin D_{28K}.[190] However, Clemens et al. showed that 1α,25-dihydroxyvitamin D_3 induction of calbindin D_{28K} was enhanced by exposure of the cells to a higher calcium concentration.[184] Renal calbindin production also appears to be increased when exposed to a low phosphorus diet and decreased when exposed to a diet rich in magnesium.[177,190–193]

When plasma calcium concentrations are low, the filtered amount of calcium in the glomerulus is also diminished, and the kidney must increase the proportion of calcium that is reabsorbed in order to maintain normal calcium balance. This process cannot take place without the ATP-dependent PMCA. Multiple forms of the PMCA have been described with ubiquitous distribution.[194–198] As in the intestine, the renal PMCA localizes to the basolateral plasma membrane.[196] Along with the sodium-calcium exchanger (NCX), the PMCA is responsible for transporting calcium ions out of the renal epithelial cell into the interstitial space and eventually into the blood. The NCX itself cannot transport calcium across a concentration or electrical gradient as can the PMCA. Renal PMCA mRNA and protein are up-regulated by exposure to 1α,25-dihydroxyvitamin D_3 in vivo and in vitro.[189,199,200] Hoenderop et al. performed an experiment comparing homozygous 25-hydroxyvitamin D_3-1α-hydroxylase knock-out mice with heterozygotes (controls).[189] When on a normal calcium diet, homozygous mice had lower levels of ECaC-1, calbindin D_{28K}, and NCX concentrations when measured by real time PCR. However, PMCA concentrations were not different between the two groups. When given 1α,25-dihydroxyvitamin D_3, both the homo- and heterozygous mice increased expression of all of the calcium transporting proteins including PMCA. This would suggest that 1α,25-dihydroxyvitamin D_3 may not be necessary for basal mRNA levels to

be present but the protein is highly responsive to 1α,25-dihydroxyvitamin D_3.

PARATHYROID HORMONE

Endocrine System

Parathyroid hormone is an 84 amino acid peptide produced and secreted by the parathyroid glands and is an important regulator of extracellular calcium concentrations. PTH secretion from the parathyroid gland is stimulated by hypocalcaemia and inhibited when exposed to elevated calcium levels. In turn, PTH regulates serum calcium concentrations through direct mechanisms in the kidney (enhanced calcium reabsorption) as well as in bone (release of mineral from bone). Since PTH is a potent stimulator of 1α-hydroxylase activity resulting in higher 1α,25-dihydroxyvitamin D_3 concentrations, it also exerts its effects on calcium metabolism indirectly through the vitamin D endocrine system described above. The following section will outline the regulation of PTH synthesis and secretion as well as its effects on calcium homeostasis in the kidney and in bone.

Regulation of Parathyroid Hormone

SYNTHESIS AND SECRETION

The chief cells of the parathyroid gland are responsible for the synthesis, storage, and release of parathyroid hormone. PTH is the product of a larger molecule, pre-pro-parathyroid hormone. The pre-sequence is cleaved in the endoplasmic reticulum resulting in pro-PTH. The pro-sequence is subsequently removed in the Golgi apparatus, leaving the final 84 residues that constitute the secreted and active form of PTH.[201] The release of preformed PTH from secretory vesicles is most acutely affected by extracellular calcium concentrations. Figure 65.9 depicts the steep inverse sigmoidal relationship between calcium concentrations and PTH release. A minimal increase in extracellular ionized calcium will inhibit PTH release. Likewise, a slight decrease in plasma ionized calcium is a potent stimulus for PTH synthesis and secretion.[202–209]

The parathyroid cell is able to detect these small changes in calcium concentrations by means of the calcium sensing receptor (CaSR) located on the cell surface.[131,132,210] The CaSR is not only expressed on the surface of parathyroid cells but also in the kidney, bone, intestine, and several other tissues.[211–231] Mutations in the CaSR have contributed to our understanding of its importance in normal calcium homeostasis. In humans, both activating and inactivating mutation is the CaSR have been described.[232–244] Inactivating mutations result in the condition Familial Hypocalciuric Hypercalcemia (FHH) in which serum calcium levels are increased as a result of a higher calcium set point required to inhibit PTH secretion. Similar clinical features have been described in patients with acquired disease due to inactivating antibodies against the CaSR.[191,246] In both of these diseases, the CaSR has become less sensitive to the effects of extracellular calcium and thus higher concentrations are required to inhibit PTH secretion. The opposite scenario has also been described in which activating mutations in the CaSR or antibodies against the CaSR result in inherited or acquired hypoparathyroidism, respectively.[247,248] These are conditions in which the CaSR is more sensitive to extracellular ionized calcium concentrations and PTH secretion is inhibited at lower calcium levels.

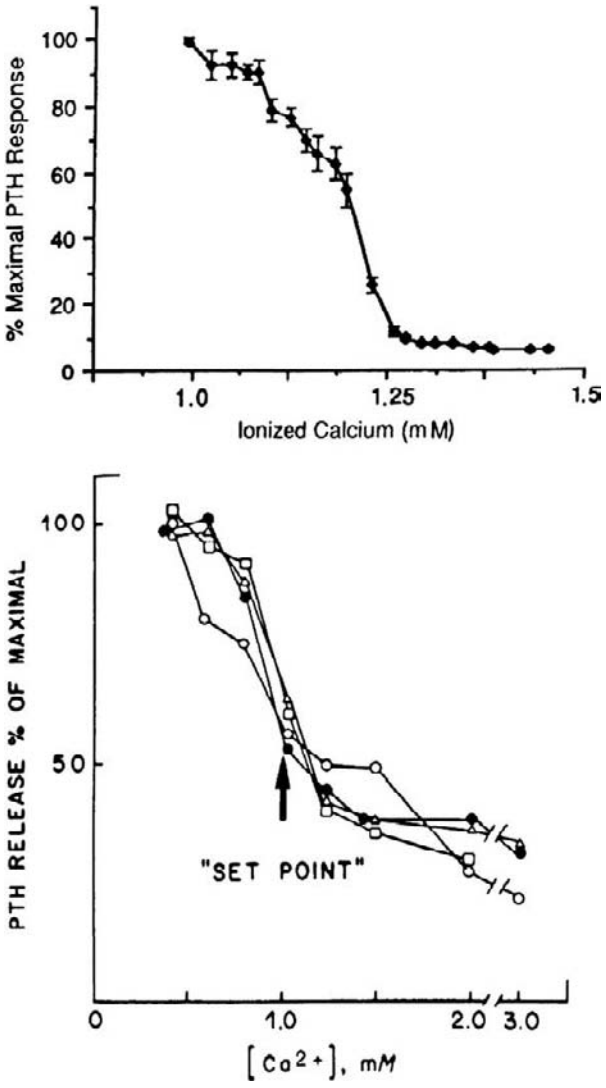

FIGURE 65.9 **Relationship between ionized calcium concentration and parathyroid hormone secretion.** *Reprinted with permission (From Brown, E.M.[202]).*

Several investigators have also shown that cells from parathyroid adenomas and hyperplastic parathyroid glands in patients with primary and secondary hyperparathyroidism have fewer detectable calcium sensing receptors than normal parathyroid tissue.[249] These clinical scenarios point to the critical role of the CaSR in the regulation of PTH secretion in response to calcium concentrations in humans.

Parathyroid hormone secretion is also regulated by 1α,25-dihydroxyvitamin D_3 through the VDR.[250–255] The response to vitamin D on PTH secretion is not as rapid as the acute changes seen with fluctuations in extracellular calcium concentrations detected by the CaSR. Vitamin D acts as a negative feedback on PTH secretion as a means to prevent hypercalcemia. When faced with hypocalcemia, preformed PTH is rapidly secreted from the parathyroid cell and acts in the kidney to increase 1α-hydroxylase activity. The result is increased conversion of 25-hydroxyvitamin D_3 to 1α,25-dihydroxyvitamin D_3. Vitamin D response elements (VDRE) have been identified in the 5′ flanking region of the parathyroid gene and serve to inhibit PTH gene transcription resulting in decreased hormone synthesis.[253,256] In addition to inhibiting PTH secretion by means of the CaSR, extracellular calcium concentrations also influence PTH secretion indirectly by altering VDR expression. Brown et al. fed three groups of rats a vitamin D deficient diet along with either a low, normal, or high calcium diet. Parathyroid tissue VDR mRNA concentrations were approximately sixfold higher in the vitamin D deficient rats fed a high calcium diet.[257] Up-regulation of the VDR in parathyroid cells by higher extracellular calcium concentrations has been observed by others, both *in vivo* and *in vitro*, showing the integrated control of PTH secretion by calcium ion concentration and vitamin D.[258] These findings would suggest that the negative feedback of vitamin D on the parathyroid gland is augmented by higher calcium concentrations, adding yet another layer of control in the regulation of normal calcium homeostasis.

Several other factors also play a role in PTH secretion including serum phosphorus concentrations, magnesium and certain amino acids.[259–271]

Parathyroid Hormone and Kidney

The parathyroid hormone receptor (PTHr) is a G-protein coupled receptor found in a diverse array of tissues including the kidney and bone where it plays an integral part in calcium homeostasis.[272–282] Using RT-PCR and in-situ hybridization techniques, the PTHr has been identified in several portions of the nephron including the glomeruli, proximal convoluted tubule, proximal straight tubule, medullary and cortical thick ascending limb, and the distal convoluted tubule.[283–285] PTH serves different functions in mineral metabolism along the nephron including decreasing phosphate reabsorption (primarily in the proximal portion), facilitating calcium reabsorption (distal portion), and enhanced conversion of 25-hydroxyvitamin D_3 to 1α,25-dihydroxyvitamin D_3.

The direct effect of PTH on transcellular reabsorption of filtered calcium takes place primarily in the distal nephron and uses some of the same machinery as vitamin D regulated calcium transport. Calcium entry into the renal tubule epithelial cell through calcium channels is enhanced in the presence of PTH.[286–290] Friedman et al. demonstrated that this process is dependent on both protein kinase A (PKA) and protein kinase C (PKC) signaling pathways and calcium transport could be prevented with specific inhibitors of PKA or PKC.[288]

Using a murine distal convoluted tubule cell line, Gesek and Friedman demonstrated a dose-dependent calcium uptake by PTH that was inhibited by a dihydropyridine calcium channel blocker.[291] They also demonstrated in the same study that hyperpolarization of the cell was responsible for the calcium uptake and the hyperpolarization was due to chloride efflux. They proposed that the principal mechanism by which PTH induced calcium reabsorption in the distal tubule was through activation of chloride channels that resulted in epithelial cell hyperpolarization. This hyperpolarization sets up a favorable gradient for transcellular calcium transport, thereby facilitating its reabsorption from the distal tubule.

In addition, it has also been shown that distal tubule cells exposed to PTH have increased sodium dependent calcium transport.[292,293] These findings demonstrate the synergistic effects of PTH and vitamin D on calcium reabsorption in the kidney. As outlined in the sections above, there are several vitamin D dependent calcium transport proteins in the distal portions of the nephron. Several of these proteins are utilized or their activity is up-regulated in the presence of PTH.

PTH not only has direct effects on renal tubular calcium transport but also exerts indirect effects through the vitamin D system. PTH is a potent stimulator of 25-hydroxyvitamin D_3 1α-hydroxylase activity in the kidney leading to higher 1α,25-dihydroxyvitamin D_3 concentrations.[245,294–297] Using a luciferase reporter, Brezna et al. demonstrated that PTH stimulates 1α,25-dihydroxyvitamin D_3 production through a promoter in the 1α-hydroxylase gene.[298] Vitamin D then serves to increase extracellular calcium concentrations by the mechanisms describe above.

In states of renal dysfunction, the effects of PTH on the kidney can be dramatically reduced. Its ability to promote phosphate loss in the proximal tubule and reabsorb calcium in the distal tubule can be diminished

despite high circulating levels of PTH. The up-regulatory effect of PTH on 25-hydroxyvitamin D_3 1α-hydroxylase activity is significantly reduced in renal failure.[299] These findings in renal failure are probably (at least partially) due to the decreased number of PTHr found in renal tubular cells in humans and in animal models of chronic renal insufficiency.[300–303]

Parathyroid Hormone and Bone

Calcium metabolism in bone regulated by PTH is complex and involves both osteoblasts and osteoclasts. The effects of PTH on osteoclasts had been thought to be primarily indirect since they do not normally contain PTH receptors. However, osteoclasts from patients with secondary hyperparathyroidism do express PTHr mRNA and protein suggesting a possible direct effect of PTH on ostoeclasts in the disease state.[276] In addition, Dempster et al. have demonstrated increased bone resorption by normal human osteoclasts derived from peripheral monocytes grown on bone slices when exposed to PTH.[304] This effect was seen in the absence of osteoblasts.

When discussing the role of PTH on calcium homeostasis, the main effect in bone is to release calcium ion into the extracellular compartment to maintain normal ionized calcium concentrations. Osteoclasts are the cells responsible for bone resorption and release of mineral. The stimulation of osteoclastogenesis by osteoblasts is by way of the receptor activator of nuclear factor-κB ligand (RANKL), osteoprotegerin (OPG), RANK system (Figure 65.10). RANKL production by osteoblasts is stimulated by PTH and OPG is inhibited by PTH.[305] RANKL induces osteoclast differentiation and activation through the RANK receptor.[306,307] OPG acts by binding to RANKL thus inhibiting osteoclast activation through the RANK receptor.[308,309] Since PTH has positive and negative effects on the production of RANKL and OPG, respectively, its effects on resorption are through two separate yet integrated mechanisms. Once osteoclasts have been activated by PTH through this indirect mechanism, bone resorption ensues and calcium is released.

It should be noted, though, that the type of exposure to PTH (intermittent vs. continuous) will determine the net calcium flux in bone. It is clear that continuous exposure to elevated concentrations of PTH, as in primary hyperparathyroidism, results in a net flux of calcium out of bone resulting in decreased bone mineral content and hypercalcemia. This effect can be reversed with parathyroidectomy.[310–313] In contrast, osteoporotic patients treated with intermittent daily doses of PTH 1-34 have substantial increases in bone mineral content.[314–316] Despite daily treatment with PTH 1-34,

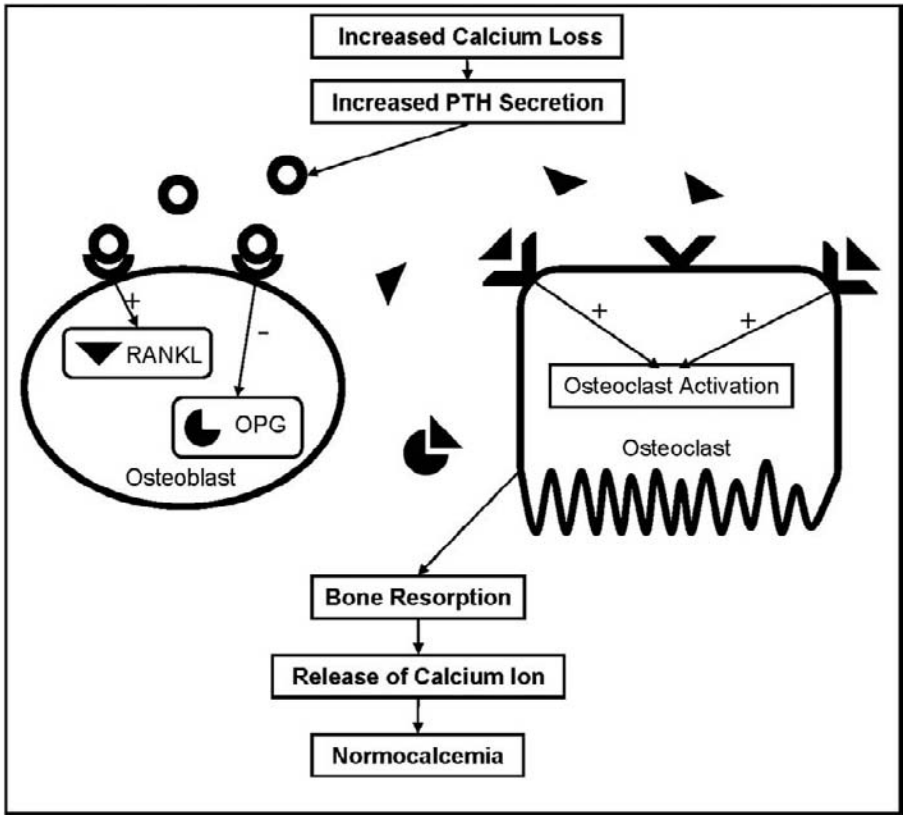

FIGURE 65.10 **Activation of bone resorption by parathyroid hormone.** Parathyroid hormone stimulates the release of calcium from bone indirectly through the osteoblast. When PTH receptors on the osteoblast are activated, they stimulate the production of receptor activator of nuclear factor-κB ligand (RANKL). Osteoprotegerin (OPG) production in the osteoblast is inhibited by PTH. OPG acts to antagonize the action of RANKL by serving as a decoy receptor for RANKL. This allows RANKL to bind its receptor, RANK, which in turn activates the osteoclast thus initiating bone resorbtion and calcium release.

these patients are generally not hypercalcemic and, if so, only transiently. The reason for the discrepancy in the effect on bone metabolism between continuous versus intermittent exposure to PTH is not completely understood.

CALCITONIN

Calcitonin is a 32 amino acid protein encoded on the short arm of chromosome 11 found in the C-cells of the thyroid gland.[317,318] While calcitonin has been used pharmacologically to treat hypercalcemia and osteoporosis, its role in normal calcium physiology is not clear. Under experimental conditions, calcitonin clearly has been shown to affect several aspects of calcium homeostasis. However, in disease states in which calcitonin concentrations are significantly altered, there appears to be little if any effect on calcium metabolism.

The release of calcitonin is stimulated by hypercalcemia and is regulated by extracellular calcium concentrations detected by the CaSR. The presence of the CaSR on the C-cells of the thyroid gland has been clearly demonstrated.[319–321] Fudge and Kovacs used a CaSR heterozygous knock-out mouse to study the effects of calcium administration on calcitonin levels. Despite higher calcium concentrations, the calcitonin levels were lower in the CaSR heterozygous knock-out mice than wild-type mice providing evidence of the importance of the CaSR in the secretion of calcitonin.[322]

The actions of calcitonin are mediated through the calcitonin receptor encoded on chromosome 7q21.3.[323] The calcitonin receptor is found in many tissues including the kidney and bone.[324–331] Under experimental conditions, calcitonin has been shown to have several effects in the kidney that may directly or indirectly affect calcium metabolism. Calcitonin is a known stimulator of 25-hydroxyvitamin D_3 1α-hydroxylase activity thus increasing 1α,25-dihydroxyvitamin D_3 concentrations which will have independent effects on calcium metabolism.[299,332] Several studies also show a direct effect of calcitonin on calcium uptake in renal distal tubule cells. Calcium uptake is enhanced through similar mechanisms as PTH dependent calcium reabsorption. Hyperpolarization due to increased chloride conductance and activation of the NCX appear to play an important role.[333–336] The relative effect of calcitonin on vitamin D production and calcium reabsorption in the kidney is likely minimal in comparison to PTH.

In bone, calcitonin exerts its effects primarily on the osteoclast. In mouse bone marrow culture, calcitonin dose dependently reduced the number of tartrate-resistant acid phosphatase positive cells suggesting that osteoclastogenesis can be inhibited by calcitonin.[337] Osteoclastic bone resorption and release of calcium can be inhibited by exposure of these cells to calcitonin.[338,339] This anti-osteoclast activity of calcitonin can be transient, likely due to a rapid and sustained decrease in calcitonin receptor abundance after calcitonin exposure.[340,341] This calcitonin receptor down-regulation is at least be partially abrogated by exposure of the cells to 1α,25-dihydroxyvitamin D_3.[342]

Despite these findings, the importance of calcitonin in normal calcium homeostasis is uncertain. Patients undergoing thyroidectomy or radioiodine ablation of the thyroid gland for Graves' disease have lower basal and calcium stimulated calcitonin concentrations but no difference in bone mineral density.[343] Another study of patients post thyroidectomy suggested a decrease in bone density in men but reported normal concentrations of calcium, PTH, and osteocalcin.[344] The commonly seen transient hypocalcemia after thyroidectomy has been postulated to be due to a transient rise in calcitonin shortly after surgery. However, there is conflicting evidence as to whether or not the rise in calcitonin is coincident with, or after, the fall in calcium is seen.[345,346] The fall in serum calcium frequently seen after thyroidectomy is more likely due to transient hypoparathyroidism. It has also been noted that patients with medullary thyroid cancer and significantly elevated calcitonin concentrations are not hypocalcemic. Hurley et al. performed a study comparing patients with medullary thyroid cancer (MTC) to patients post thyroidectomy. At baseline and after calcium infusion, calcitonin concentrations were significantly higher in the MTC group compared to the thyroidectomy and control groups. However, there were no differences in serum calcium, phosphorus, or PTH concentrations.[347]

When used in pharmacologic doses or under experimental conditions, calcitonin appears to be involved in calcium homeostasis through several different mechanisms including increased vitamin D production, renal calcium reabsorption, and inhibition of osteoclast function.

CONCLUSION

Most tissues in the body are dependent on calcium for normal function. If extracellular calcium concentrations are not maintained within the normal range, significant pathology may result depending on the duration and severity of the abnormality. Perturbations in calcium homeostasis can result in severe morbidity including osteoporotic fractures, renal failure, and seizures. Due to the consequences associated with abnormalities in calcium metabolism, it is not surprising there are several highly integrated mechanisms in place to defend against hypocalcemia and hypercalcemia.

Assuming there is adequate vitamin D intake or exposure to UVB radiation, the hormonal regulation of calcium is able to maintain eucalcemia despite wide fluctuations in dietary calcium intake. Vitamin D, PTH, and calcitonin work in concert in the intestine, kidney, and in bone to assure normal calcium balance.

INTRODUCTION

An adult human contains about 1000 g of calcium, the majority of which (~99%) is found in bone.[1] Calcium serves two principal physiologic functions. The first involves the production of calcium-phosphate hydroxyapatite crystals that bind to organic matrix and provide the unique mineralized structure of bones and teeth. The calcified nature of these tissues allows for mastication and enables bones to protect internal organs, to bear weight, and to function as the levers on which muscles act during locomotion. The second function is metabolic. Soluble calcium ions in the extracellular fluid (ECF) and cytosol are critical for a large number of enzymatic reactions, signaling cascades, and electrical membrane potentials that are necessary for normal cellular functions. Only 1% of total body calcium is contained within the ECF and soft tissues. Of the total circulating calcium, the ionized fraction is generally estimated to be approximately 50%, with the remainder of the total serum calcium bound to serum proteins, primarily albumin, and to a lesser extent complexed with anions, such as citrate or sulfate.[1] Only the ionized fraction of total serum calcium is physiologically important, and this component is regulated on a minute-to-minute basis. Clinical laboratories can measure either total serum calcium or ionized calcium routinely. However, accurate measurement of ionized calcium requires that the specimen be obtained anaerobically and analyzed promptly. Therefore, total serum calcium is most often used as an indirect assessment of the ionized calcium fraction.

The two functions of calcium described in the previous paragraph are interrelated, as skeletal calcium exchanges with ECF calcium. In this way, bones serve as a sink for excess calcium as well as a reservoir of calcium for metabolic needs. Given the large quantitative differences in the size of the two calcium pools, only about 1% of skeletal calcium is in active equilibrium with the ECF at any given time under normal physiologic conditions. A complicated homeostatic system involving multiple organs and hormones regulates the calcium concentration of the ECF as well as the calcium content of the skeleton. The organs involved include the parathyroid glands, the kidneys, the skeleton, and the gut. The hormones that coordinate the calcium regulating functions of these organs are parathyroid hormone (PTH), vitamin D, PTH-related protein (PTHrP) and calcitonin. Abnormalities in these organs, the hormones, or their receptors can all cause disturbances in calcium metabolism and lead to either hypercalcemia or hypocalcemia. In this chapter, we first review the individual components contributing to the regulation of circulating calcium levels. Second we examine the integrated control of calcium homeostasis. Finally, we discuss the most common causes of hypercalcemia and hypocalcemia.

REGULATORS OF CALCIUM HOMEOSTASIS

The Calcium Sensing Receptor

The maintenance of calcium homeostasis requires that a variety of cells within the body have the ability to measure the extracellular ionized calcium concentration of the ECF. This is accomplished primarily through the actions of a 7 transmembrane-spanning G protein-coupled receptor (GPCR) known as the calcium sensing receptor (CaSR).[2–5] The CaSR is a member of subfamily C of GPCRs and is related to the

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00066-5

metabotropic glutamate, pheromone and taste receptors. Evolutionarily, it is descended from periplasmic binding proteins in bacteria that serve as nutrient receptors.[3,6] The human *CaSR* gene is located on chromosome 3q13.3−21 and consists of 7 exons and two distinct promoter regions.[3,5] Expression of the *CaSR* gene is widespread although it is highest in organs that are involved in the regulation of calcium homeostasis, such as the parathyroid glands, the C-cells of the thyroid gland, kidney and bone. The regulation of CaSR mRNA production has not been as extensively studied as other aspects of its physiology, but gene expression has been shown to respond to calcium, vitamin D and cytokines such as interleukin 1β and interleukin 6.[7−10] Regulation of the CaSR and vitamin D receptor are interrelated. Calcium and vitamin D both upregulate *CaSR* gene expression.[11−13] Activation of the CaSR also upregulates expression of the vitamin D receptor (VDR), which, in turn, amplifies the effects of vitamin D on CaSR expression.[12,14] These interactions may be particularly important in the parathyroid to allow for synergistic activity of calcium and vitamin D in regulating PTH gene expression and secretion.

In humans, the mature CaSR encompasses 1078 amino acids. It has a large extracellular domain of 612 amino acids that is heavily glycosylated and serves as the calcium-binding domain.[3−5] The CaSR operates as a homodimer, which forms as the result of disulfide bonds between cysteines 129 and 131 of each monomer.[11,15] The resulting extracellular portions of the complex have been suggested to approximate a Venus flytrap based on molecular modeling derived from the crystal structure of the related metabotropic glutamate receptors. Binding of calcium to clusters of acidic residues within the extracellular domain causes closure of the extracellular "flytrap" motif and this leads to conformational changes that activate intracellular signaling.[6,16] The intracellular portion of the receptor has been shown to couple to $G_{q/11}$, G_i, $G_{12/13}$ and in some instances to G_s.[3,11,17,18] Most commonly, the receptor has been described to activate intracellular calcium transients and MAPK signaling cascades.[3,11] The CaSR also interacts with several other cytoplasmic and/or membrane proteins, including caveolin, filamin, potassium channels (Kir4.1 and Kir4.2) and receptor activating proteins (RAMP) 1 and 3, all of which can modulate downstream receptor signaling.[19] Finally, the receptor has been shown to heterodimerize with several metabotropic glutamate receptor isoforms and GABA receptor isoforms to generate unique hybrid receptors.[20,21] Therefore, like other GPCRs, the CaSR can signal through a variety of pathways and there is likely to be considerable cell type-specific variation in its signaling.

In addition to calcium, the CaSR binds and signals in response to a variety of other cations and positively charged organic molecules such as magnesium, gadolinium, polyamines and aminoglycoside antibiotics.[3,5,11] These molecules can activate the receptor in the absence of calcium and are known as Type 1 ligands. Other ligands, known as Type 2 agonists, have no activity independent of calcium, but instead can modify the sensitivity of the receptor to calcium. These include L-amino acids and small-molecule, allosteric activators and inhibitors known as calcimimetics or calcilytics.[3,5,11] L-amino acids bind to the extracellular domain of the receptor in physiologic concentrations and may help to coordinate protein and calcium metabolism.[22] Calcimimetics and calcylitics bind to the transmembrane domain of the receptor and stabilize the active or inactive conformations of the receptor respectively.[23,24] These compounds have been developed as drugs; cinacalcet (Sensipar) is commercially available for the treatment of hyperparathyroidism in chronic kidney disease (CKD) while calcilytics are currently in clinical trials.[25,26] The CaSR has also been shown to respond to alterations in pH, osmolality and salinity.[3] Therefore, although its actions are critical to the regulation of calcium homeostasis, the CaSR actually is a multifunctional sensor for varied alterations in the extracellular milieu.

The CaSR is expressed widely throughout the body. It has been implicated in a variety of actions including calcium and other ion transport, the regulation of cellular proliferation and differentiation, and hormone secretion. We will limit our discussion to its functions in the three tissues of greatest importance to calcium homeostasis, the parathyroid gland, the kidney and bone. The reader is referred to other more comprehensive reviews for discussion of its many other functions.[3,5]

Parathyroid Gland: The parathyroid gland expresses high levels of the CaSR, which regulates three important aspects of parathyroid physiology: *parathyroid hormone* (*PTH*) gene expression, PTH secretion and parathyroid cell proliferation.[4,27] Signaling from the CaSR leads to a reduction in PTH mRNA.[27,28] This effect may, in part, be indirect and mediated by changes in the sensitivity of suppression of *PTH* gene expression by vitamin D. However, there is also a specific calcium response element in the *PTH* gene promoter located 3.6 kB upstream from the transcription start site that acts to inhibit transcription.[27] In addition, as described in more detail in the Section on PTH, CaSR signaling destabilizes PTH mRNA and shortens its half-life.[28] Both effects result in a reduction of PTH synthesis.

The predominant effect of CaSR activation on PTH production is inhibition of PTH secretion.[3,4,27] Activation of the CaSR leads to a prompt suppression of PTH

release, an effect that involves coupling to $G_{q/11}$ and G_i, and the generation of intracellular calcium transients after receptor activation.[3,27] The control of PTH secretion by extracellular calcium is reviewed in more detail in the section on PTH, but genetic experiments in mice have shown that the coupling of PTH secretion to changes in extracellular calcium is completely dependant on the presence of the CaSR on parathyroid cells.[29,30] Furthermore, the number of functional receptors defines the dose-response relationship between extracellular calcium and PTH secretion by parathyroid cells. Reduced numbers of receptors are found in some patients with familial hypocalciuric hypercalcemia as well as in chronic kidney disease (CKD) and in parathyroid adenomas.[4,27,29,30] In each instance, the parathyroid cells become partially resistant to the ability of extracellular calcium to suppress PTH secretion properly.

The CaSR also regulates parathyroid gland mass, and null mutations in the *CaSR* gene result in parathyroid hyperplasia.[4,27,29,30] Part of this effect is indirect and is mediated by the ability of CaSR signaling to enhance parathyroid sensitivity to vitamin D. However, experiments in mice deficient in the VDR or 1 α-hydroxylase (CYP27B1) have demonstrated a direct effect of CaSR signaling on parathyroid hyperplasia as well.[31,32] The molecular details of how CaSR affects cell proliferation and/or hypertrophy are not yet well described.

The Kidney: Experiments performed prior to the identification of the CaSR had suggested that extracellular calcium had direct effects on renal calcium handling that were independent of any effects of PTH.[33] However, the identification of the CaSR and the recognition of its expression throughout the renal tubule have led to the elucidation of an integrated and intrinsic response of the kidney to changes in circulating calcium levels. In fact, recent experiments in mice have suggested that CaSR-mediated alterations in renal calcium handling may be the principal defense against hypercalcemia, while PTH-mediated responses have a more potent effect on the correction of hypocalcemia.[34] When activated by hypercalcemia, the CaSR affects different portions of the nephron to increase calcium excretion, and to acidify the urine and impair renal concentrating ability in order to protect against nephrocalcinosis or nephrolithiasis in the face of the resulting hypercalciuria.

The CaSR promotes renal calcium excretion through several actions. In the thick ascending loop of Henle (TAL), the CaSR is expressed on the basolateral surface and activation of the receptor leads to inhibition of paracellular and transcellular NaCl and divalent cation reabsorption.[11] These effects are primarily mediated by inhibition of the activity of the renal outer medullary potassium channel (ROMK) and the apical Na^+-K^+-$2Cl^-$ cotransporter, NKCC2, which reduces the net lumen positive charge and lowers the electrochemical driving force for paracellular calcium, sodium and magnesium transport.[35,36] In addition, CaSR signaling results in the degradation of claudin 16, which promotes paracellular transport of calcium and magnesium.[37] Activation of the CaSR also inhibits PTH-mediated calcium reabsorption in the CTAL by inhibiting uptake of calcium across the apical membrane and in the CTAL and distal convoluted tubule by inhibiting the activity of the basolateral calcium pump, PMCA1b, which is necessary for extrusion of calcium from the cell into the ECF.[11,38,39]

Concurrent with its effects on calcium excretion, the CaSR also increases acid and water excretion by the kidney, both of which help to maintain the solubility of calcium salts in the urine and prevent the precipitation of the excreted calcium. Activation of the CaSR in the collecting ducts leads to inhibition of the H^+-ATPase, which results in increased acid secretion.[40] Recent genetic studies have underscored the importance of urine acidification in protecting against stone formation in response to hypercalciuria, at least in mice.[40] Hypercalcemia is also well known to inhibit renal concentrating ability.[11] Stimulation of apical membrane CaSRs in the inner medullary collecting duct inhibits vasopressin induced aquaporin 2 (AQ2) insertion into the apical membrane and reduces the transcellular reabsorption of water.[41] In chronic states of hypercalcemia, the CaSR also downregulates AQ2 expression via post-transcriptional mechanisms.[42]

In addition to the direct effects of the CaSR on renal calcium handling, it also inhibits CYP27B1 activity in the proximal tubule.[11,12] This results in lower levels of 1,25 $(OH)_2$-vitamin D (the active form of the hormone), which will also inhibit calcium absorption from the diet, the release of calcium from bone and calcium reabsorption in the distal tubule, all of which would help to lower circulating calcium concentrations.

The Skeleton: Studies in cell lines and in genetically altered mice suggest that the CaSR also affects bone cells independent of its effects on PTH secretion or 1,25 $(OH)_2$-vitamin D production.[29,43] Osteoclasts, osteoblasts, osteocytes, growth plate chondrocytes and bone marrow immune cells have all been found to express the CaSR.[3,5] Selective knockout of the receptor in osteoblasts has been shown to have profound effects on bone growth and mineralization due to impaired osteoblast activity.[29] Studies in cell culture suggest that CaSR signaling may affect both osteoblast proliferation and differentiation.[44] Low levels of CaSR signaling appear to promote osteoclast differentiation but high levels of calcium have been found to inhibit osteoclast function and cause osteoclast apoptosis.[45,46] The regulation of bone cell function by the CaSR is an evolving

issue and, at present, it is unclear whether the actions the CaSR on osteoclasts and osteoblasts are important in the acute regulation of systemic calcium metabolism. It is certainly possible that the CaSR might regulate the mobilization of calcium from the bone interstitial fluid in ways reminiscent of its actions on ion transport in other sites.

Parathyroid Hormone

The principal regulator of the minute-to-minute calcium concentration is parathyroid hormone. PTH is secreted by the four parathyroid glands, which arise from the third and fourth branchial arches during embryogenesis and normally reside near the posterior capsule of the four poles of the thyroid gland. However, extra or ectopic parathyroid glands or small rests of parathyroid tissue are commonly found from the angle of the jaw to the mediastinum, along the path of embryonic migration of the thymus and parathyroid glands. This can be an important consideration in hyperparathyroid states that require surgical intervention (see below).

Human PTH is encoded by a single gene located on chromosome 11 (11p15). The gene contains three exons; the first codes for the 5′ untranslated portion of the mRNA, the second encompasses most of the pre-pro sequences and the third encodes the actual protein sequence of the secreted hormone.[47–49] The *PTH* gene is a member of a small gene family that also includes the *parathyroid hormone-related protein (PTHrP)* and the *tubuloinfundibular peptide of 39 amino acids (TIP39)* genes.[48] Each of these genes has a similar exon/intron structure and all three bind related receptors with overlapping specificities (see below).[50] The *PTH* and *PTHrP* genes likely arose from a common ancestor and lower vertebrates have multiple *PTH* and *PTHrP* genes.

PTH is initially synthesized as pre-pro-parathyroid peptide and undergoes post-translational modification to produce the active hormone. The 25-residue pre-sequence and the 6-residue pro-sequence are cleaved during the initial production of PTH, yielding the mature, 84-amino acid, full-length protein (PTH 1-84).[51] Full-length PTH is the biologically active form of the hormone. It has a very short half-life (minutes) in the circulation and is degraded by the liver and kidney, which generates circulating carboxy-terminal (C-terminal) fragments. These fragments are cleared by the kidney but may accumulate in the circulation in renal failure.[52]

Three factors, calcium, 1,25 dihydroxyvitamin D and phosphate, have been shown to modulate PTH mRNA levels and/or PTH secretion.[53] Parathyroid cells express high levels of the CaSR, which allow them to respond to small changes in the circulating calcium concentration.[54] Changes in extracellular calcium lead to reciprocal changes in PTH secretion (see below) and gene expression.[53,54] The mechanisms through which CaSR signaling affects *PTH* gene expression are not well described. Although a negative calcium regulatory element has been identified in the *PTH* gene promoter region, it is currently thought that the primary effect of CaSR signaling is post transcriptional.[53] PTH mRNA contains AU-rich elements in the 3′ untranslated region (UTR), which regulate its stability. In the setting of low extracellular calcium concentrations, specific proteins bind to these elements and protect the mRNA from degradation. Activation of CaSR signaling displaces these factors and shortens the half-life of PTH mRNA.[55]

A steep inverse sigmoidal relationship exists between PTH secretion and the extracellular ionized calcium concentration and is defined by four parameters (Figure 66.1). The first is the maximum secretory rate of the parathyroid glands. The second is the slope of the curve at the midpoint. The third is the parathyroid gland's "set point," or calcium concentration at which PTH secretion is half maximal. The final parameter is the basal, nonsuppressible rate of PTH secretion. The steep part of the curve encompasses the physiologic range for extracellular calcium, over which small changes in the concentration of ionized calcium elicit dramatic changes in the rate of PTH secretion.[56] Because of this steep slope, ionized calcium concentrations are maintained in a very narrow physiologic range. A great deal of data in both genetically altered mice and in humans with genetic disorders of calcium sensing have demonstrated the primary importance of the CaSR in controlling PTH secretion.[3,56] For example, mice with either global deletion or parathyroid-specific disruption of the *CaSR* gene have very high levels of circulating parathyroid hormone, which are not suppressed by severe hypercalcemia.[29,30] The same is true of humans with null mutations in the *CaSR* gene.[57] Furthermore, in both mice and humans, heterozygous disruption of the *CaSR* gene results in a milder form of hyperparathyroidism, demonstrating a dose effect between parathyroid CaSR levels and the sensitivity of PTH to calcium-mediated suppression.[29,30,57] Conversely, humans with activating mutations in the *CaSR* gene present with hypoparathyroidism characterized by a failure to secrete PTH in response to hypocalcemia.[58]

The molecular mechanisms by which CaSR signaling inhibits PTH secretion are not completely understood. Binding of calcium to the CaSR activates downstream signaling pathways that, in turn, suppress PTH secretion.[3,56] It is clear that activation of both $G\alpha_q$ and $G\alpha_{11}$ is necessary for suppression of PTH secretion since parathyroid specific disruption of the genes for

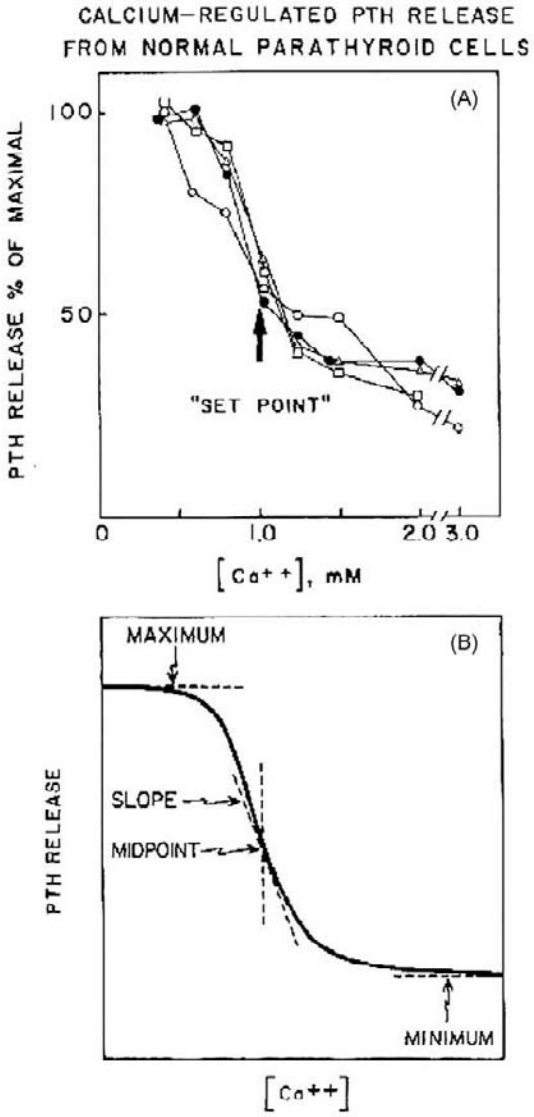

FIGURE 66.1 (A) The inverse sigmoidal relationship between increasing concentrations of extracellular calcium and PTH secretion from dispersed normal parathyroid cells in culture. (B) This relationship can be defined by the maximal rate of PTH secretion, the slope of the curve at the mid-point, the set point (point at half-maximal PTH secretion) and the minimal rate of PTH secretion. *(Reproduced with permission from Brown, EM. 1983. Four-parameter model of the sigmoidal relationship between parathyroid hormone release and extracellular calcium concentration in normal and abnormal parathyroid tissue. J Clin Endocrinol Metab 56:572–581.)*

both of these G-proteins phenocopies the disruption of the *CaSR* gene itself.[59] However, it is not clear how specific signaling events downstream of these G-proteins actually inhibit the secretion of PTH.

Vitamin D will be discussed in more detail below. The active form of vitamin D, 1,25 $(OH)_2$ vitamin D, acts on parathyroid cells to inhibit PTH production, both by increasing circulating calcium levels and by inhibiting *PTH* gene transcription directly.[51,53] This effect is thought to be a result of reduced transcription of the *PTH* gene due to the binding of 1,25 dihydroxyvitamin D to the vitamin D receptor (VDR), which in turn binds to vitamin D response elements in the 5′ flanking region of the *PTH* gene.[60] Vitamin D receptors are abundant in parathyroid tissue and their levels are modulated by calcium and 1,25 $(OH)_2$ vitamin D itself.[53] Activation of the CaSR increases the expression of the VDR in parathyroid cells and 1,25 $(OH)_2$ vitamin D increases the expression of the CaSR, thereby mutually sensitizing the parathyroid glands to negative feedback in states of vitamin D or calcium excess. In CKD and in parathyroid adenomas, expression of both the VDR and the CaSR is reduced, likely contributing to increased PTH production.[61–63]

Phosphate stimulates PTH production and hyperphosphatemia is an important contributor to the development of secondary hyperparathyroidism in patients with chronic kidney disease.[61,64] Some of these effects may be related to the drop in ionized calcium that attends any increase in circulating phosphate, but phosphate also exerts independent effects on PTH mRNA stability.[64] Similar to the effects of low calcium, elevations in serum phosphate lead to the binding of a protein complex to the 3′UTR of PTH mRNA that inhibits its degradation.[55,64] Changes in serum phosphate may also affect PTH indirectly via the actions of fibroblast growth factor 23 (FGF-23), which is secreted from osteocytes (see Chapter 68). The parathyroids respond to FGF-23 but, somewhat paradoxically, FGF-23 has been described to reduce PTH gene expression and secretion,[65–67] even though it also lowers circulating phosphate levels. Therefore, it is possible that the actions of FGF-23 on the parathyroid cells may counterbalance the direct effects of phosphate on PTH gene expression. As discussed in Chapters 69 and 91, FGF-23 levels are elevated in CKD, although it is not known whether these elevated levels contribute to the dysregulation of PTH secretion in these patients. Our understanding of the regulation of parathyroid function by FGF-23 is an evolving area that will require further research for clarification.

PTH binds and activates the Type 1 PTH/PTHrP receptor (PTH1R), a GPCR that is shared with PTHrP.[50,68] It is a member of the B subfamily of GPCRs, which also includes the secretin and calcitonin receptors.[50,69] Two other PTH receptors are also included within this group. The PTH2R is primarily a receptor for TIP39. PTH can bind weakly to this receptor and activate it, but it is not known if this represents a physiological interaction.[50,69] PTHrP cannot activate the PTH2R. There is also a third PTH receptor (PTH3R) documented in zebra fish, but it does not appear to be present within the human genome.[50,69] Thus, as with the PTH peptide family, it appears that evolution has reduced the diversity of PTH receptors.

The amino-terminal portion of PTH [PTH(1–34)] is necessary and sufficient for full activation of the PTH1R. Amino acids in the C-terminal portion of this PTH fragment are thought to bind to the extracellular, amino-terminal portion of the PTH1R, while the amino-terminus of PTH(1–34) binds to the juxtamembrane portion of the PTH1R in order to activate downstream signaling (Figure 66.2).[69,70] The PTH1R has been shown to activate both the cAMP/protein kinase A (PKA) pathway and the phospholipase C/protein kinase C/calcium transient pathway. There is also evidence that the receptor activates phospholipase D and MAPK signaling.[50,69] MAPK activation can occur either through a PLC/PKC-dependant pathway or via a G-protein independent pathway that involves arrestins.[71,72] Many of the classic biological functions of PTH appear to be mediated to a great extent by the cAMP/PKA pathway, which requires the first two amino acids of PTH for activation.[50,69] Less is known about the biological role of the other signaling pathways.

The PTH1R is highly expressed within the skeleton and kidney, the two classic target organs for PTH action. However, it is also widely expressed in many other cells throughout body.[50,69] The receptor at these sites may primarily serve as a PTHrP receptor. However, circulating PTH could theoretically activate these receptors and may therefore affect physiological processes other than calcium and bone metabolism, especially in the setting of hyperparathyroidism.

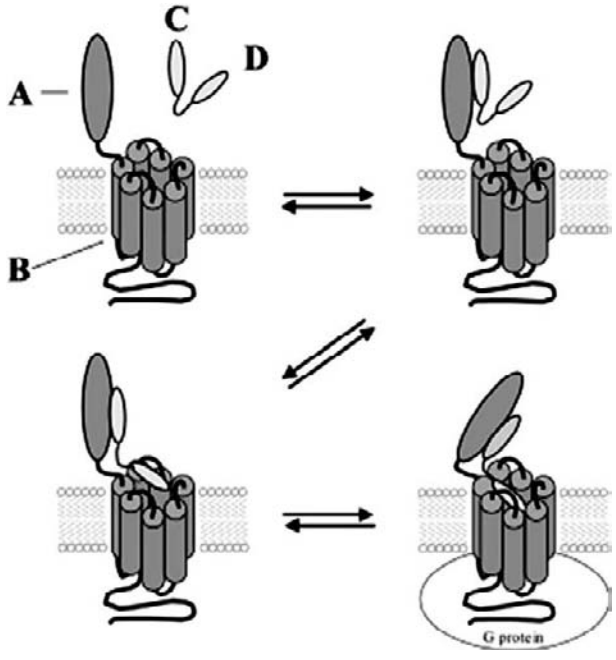

FIGURE 66.2 Model for binding of amino-terminal PTH to the PTHR1. The C-terminal end of PTH (1–34) (C) binds first to the extracellular N-terminal portion of the receptor (B). Subsequently, the amino-terminal portion of PTH 1–34 (D) binds to the J-domain of the receptor. This results in a conformational change of the receptor such that it takes on a more closed shape, which increases its affinity for G-proteins and leads to their activation. *(Reproduced with permission from Potts JT. 2008. Parathyroid hormone: past and present. J Endocrinol 187: 311–325.)*

PTH is the principal hormone that coordinates calcium homeostasis on a minute-to-minute basis. It does this through its actions on the kidney and on bone cells. Below, we discuss the actions of PTH on these two organs in detail.

Kidney: PTH regulates the renal handling of calcium, phosphate, sodium and hydrogen ions.[73] It also regulates the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D.[73] The PTH1R is expressed at different sites along the nephron, including the glomerulus, proximal tubules, the cortical ascending limbs and the distal convoluted tubules. In the proximal and thick ascending limbs the receptor is expressed on both the basolateral surface and the luminal surfaces of cells.[74,75]

PTH was originally recognized for its actions to promote urinary phosphate excretion.[73] Approximately 90% of plasma phosphate is filtered by the glomerulus and 80% is actively reabsorbed, primarily by the proximal convoluted tubules. The regulated step in phosphate reabsorption is entry of phosphate across the luminal membrane of the proximal tubule cells though two related sodium-phosphate co-transporters known as NPT2a and NPT2c.[73,76] PTH inhibits phosphate uptake into these cells by triggering the withdrawal of NPT2a from the apical membrane into intracellular vesicles, which leads to proteolytic degradation of the transporter.[73,77–80] Interestingly, activation of the luminal or basolateral PTH1R pool appears to stimulate different signaling pathways, yet both cause internalization of NPT2a. The basolateral receptors increase intracellular cAMP. At the luminal surface, the PTH1R is associated with a scaffolding protein known as NHERF1, which favors the activation of the PKC pathway over the cAMP pathway.[81,82] NHERF1 has also been shown to bind to NPT2a and it has been suggested that dissociation of NHERF1 from NPT2a is necessary to allow internalization of NPT2a in response to PTH.[73,83,84]

PTH increases calcium reabsorption by the kidney. This occurs through the stimulation of active transcellular calcium transport across epithelial cells in the cortical segment of the thick ascending loop of Henle and in the distal convoluted tubule.[73] In distal tubule cells PTH stimulates cAMP/PKA signaling and phospholipase D, both of which are necessary to mediate calcium transport.[85–90] These signaling cascades lead to hyperpolarization of the membrane potential, which stimulates the entry of calcium across the apical membrane as well as its extrusion via sodium/calcium exchange across the basolateral membrane.

PTH acts on the proximal tubule to stimulate the conversion of 25 (OH) vitamin D to 1,25 $(OH)_2$ vitamin D, which is the active form of vitamin D.[50,51,73,91] In this way, PTH indirectly stimulates calcium absorption from the gut and activates bone cell activity. The increase in 1,25 $(OH)_2$ vitamin D is the result of stimulation of both *CYP27B1* gene expression and activity (the enzyme responsible for hydroxylation of vitamin D at the C-1 position).[73,92,93] The effects of PTH on CYP27B1 activity are opposed by the CaSR and by 1,25 $(OH)_2$ vitamin D itself.[12,94,95] PTH also inhibits the degradation of 1,25 $(OH)_2$ vitamin D by decreasing CYP24A1 (24-hydroxylase) activity in the proximal tubule and thus inhibiting vitamin D catabolism.[96,97]

PTH inhibits acid secretion in the proximal tubule and can produce a mild compensated hyperchloremic acidosis.[73] This is the result of phosphorylation of the Na^+/H^+ exchanger (NHE3) by PKA downstream of the PTH1R.[80,98] While this results in reduced bicarbonate and sodium reabsorption by the proximal tubule, the distal tubules compensate by increasing both sodium and bicarbonate absorption. As a result, there is little change in serum bicarbonate concentrations or pH, although chronic elevations in PTH can be associated with mild hyperchloremia.

The skeleton: PTH increases bone turnover although the net effect on bone depends on the pattern of PTH exposure. Continuous PTH exposure causes net bone catabolism, which is seen in states of hyperparathyroidism. In contrast, intermittent PTH exposure has an anabolic effect on the skeleton, which has been exploited pharmacologically in the treatment of osteoporosis. Below, we will discuss the actions of PTH on the three main cell types in bone, osteoclasts, osteoblasts and osteocytes.

PTH stimulates bone resorption due to an increase in the production of new osteoclasts as well as an increase in the activity of existing osteoclasts.[51,73,99,100] Neither osteoclasts nor their precursors express the PTH1R, so these effects result from paracrine interactions between osteoclasts and cells within the osteoblast lineage, which do express the PTH1R. Osteoclast differentiation, activity and survival are regulated by two cytokines, colony-stimulating factor 1 (MCSF, CSF1) and receptor-activator of NFκB ligand (RANKL).[101,102] CSF1 is produced by stromal/osteoblast cells and acts through its receptor c-fms to induce early monocyte/macrophage precursors to enter the osteoclast lineage.[101,102] RANKL is also produced by cells in the stromal/osteoblast lineage and acts through its receptor, receptor-activator of NFκB (RANK) to promote the differentiation of osteoclast precursors into mature osteoclasts, to increase the bone-resorbing activity of mature osteoclasts and to lengthen the life-span of active osteoclasts.[73,100–102] RANKL can also be bound by a secreted decoy receptor known as osteoprotegerin (OPG), which inhibits osteoclast formation and activity, and promotes osteoclast apoptosis.[73,100–102] Therefore, the RANKL/OPG ratio is an important determinant of osteoclastic activity. PTH increases the secretion of CSF1 and RANKL, and suppresses the secretion of OPG raising the RANKL/OPG ratio.[73,99–103] These alterations in local cytokines increase osteoclast numbers and activity, and stimulate bone resorption.

The direct effects of PTH on osteoblast function are complicated and vary depending on the duration of exposure to PTH as well as the state of differentiation of the cells. The reader is referred to more in-depth reviews for a detailed discussion of the specific effects of PTH on osteoblasts.[73,99–104] Continuous and intermittent PTH both increase osteoblast numbers and rates of bone formation *in vivo*.[73,99–104] This does not appear to be due to cell proliferation as most data suggest that PTH inhibits the proliferation of committed osteoblast precursors and mature osteoblasts.[100,105–107] Intermittent exposure to PTH favors the commitment of mesenchymal precursors to the osteoblast lineage and stimulates osteoblast differentiation.[73,100,108–111] In addition, intermittent PTH administration may convert previously quiescent bone lining cells into active osteoblasts.[112] In contrast, prolonged, continuous exposure to PTH inhibits full osteoblast differentiation.[73,91,100] These alternative effects on osteoblast differentiation may help to explain why net anabolic activity differs between continuous and intermittent PTH exposure.

The PTH1R is expressed on osteocytes and PTH inhibits osteocyte apoptosis and suppresses osteocyte production of sclerostin, an important inhibitor of Wnt signaling in bone.[104,113–116] Experiments in mice suggest that activation of the osteocyte PTH1R influence the activity of osteoblasts and osteoclasts on bone surfaces, demonstrating that these cells may help to coordinate bone turnover in response to PTH.[115] C-terminal fragments of PTH also affect osteocytes by binding to a specific, although as yet uncharacterized, C-terminal PTH receptor. Activation of this receptor may antagonize PTH1R actions, which could theoretically contribute to the skeletal resistance to PTH described in CKD, since decreases in GFR increase the concentration of circulating C-terminal PTH fragments.[116]

Vitamin D

Vitamin D is a steroid hormone that contributes to the development and maintenance of cartilage and bone as well as the regulation of calcium and phosphate metabolism. It exerts a myriad of other effects, including the regulation of the immune response, the control of epithelial cell proliferation and the regulation

of cell differentiation. Here we will limit our discussion to its actions on calcium homeostasis.

The biological activity of vitamin D is mediated by 1,25 $(OH)_2$ vitamin D3, which circulates in pM concentrations.[117] The production of active vitamin D is tightly regulated and is the net result of a series of photochemical and enzymatic steps that involve several tissues throughout the body. The first step in vitamin D synthesis is the formation of pre-vitamin D3 from 7-dehydrocholesterol. This reaction occurs in the plasma membrane of keratinocytes and is catalyzed by ultraviolet B light between the wavelengths of 290 and 315 nM.[118] Previtamin D3 is thermodynamically unstable and in a temperature dependant fashion is converted into vitamin D3, which is shed into the ECF and binds to vitamin D binding protein (DBP) in the circulation.[117] The quantity of vitamin D3 formed in the skin depends on the duration and intensity of sunlight exposure and is inhibited by sunscreen, clothing and skin pigmentation. Thus, people with darker skin and those living at latitudes farther from the equator synthesize less vitamin D, and in the Northern hemisphere, there is less vitamin D synthesis in winter months.[119–122] These racial, geographical and seasonal factors all contribute to the patterns of vitamin D deficiency observed in the human population.

Vitamin D3 can be stored in fat and in the liver. As noted above, it circulates bound to DBP and it is hydroxylated at the C-25 position in order to form 25 (OH) vitamin D.[117] This reaction occurs in the liver and is the sum of the actions of several cytochrome p450 enzymes, although the most important appears to be the microsomal enzyme, CYP2R1.[123] Production of 25 (OH) vitamin-D is controlled by substrate availability, so the measurement of circulating 25 (OH) vitamin D is the most reliable clinical indicator of total body vitamin D stores. 25 (OH) vitamin D circulates in nM concentrations, and is also bound to DBP.[117]

The active hormone, 1,25 $(OH)_2$ vitamin D is formed in the kidney under tight regulation by PTH, phosphate, FGF-23 and calcium concentrations.[117] 25 (OH) vitamin D is filtered into the urine and is reabsorbed together with DBP by megalin and cubulin, which are found in the apical membrane of the proximal tubule cells.[124,125] Hydroxylation of 25 (OH) vitamin D is catalyzed by CYP27B1, which is a cytochrome P450 enzyme found within the inner mitochondrial membrane.[126–128] The proximal tubule also expresses 24 hydroxylase activity mediated by CYP24A1 which generates 24, 25 $(OH)_2$ vitamin D and calcitroic acid, the main inactive metabolites of 25 (OH) vitamin D and 1,25$(OH)_2$ vitamin D, respectively.[129,130] CYP24A1 antagonizes the actions of CYP27B1 both by shunting away its substrate and by inactivating its product. The synthesis of 1,25 $(OH)_2$ vitamin D is regulated primarily by altering the expression of CYP27B1 and CYP24A1 in a reciprocal fashion. PTH, low calcium, low phosphate and calcitonin act to stimulate 1,25 $(OH)_2$ vitamin D production, while high calcium, high phosphate, FGF23 and 1,25 $(OH)_2$ vitamin D, itself, inhibit production.[117] In tissues outside the kidney, CYP27B1 and CYP24A1 expression, and 1,25 $(OH)_2$ production are also regulated by a number of growth factor and cytokine pathways as well as by toll-like receptor signaling.[117]

Vitamin D acts as a classical steroid hormone and regulates gene expression by binding to the vitamin D receptor (VDR), a ligand-activated transcription factor that is a member of the large superfamily of steroid hormone receptors.[117,131,132] The active receptor is a heterodimer between the VDR and the retinoic acid X (RXR) receptor. Like other steroid hormone receptors the activated VDR recruits a number of co-factors to specific sequences within target genes in order to form a multiprotein complex that includes chromatin remodeling activity and transcriptional activators or repressors.[131,132] The activity of vitamin D and the VDR depends on the particular makeup of this protein complex and, like other steroid hormone/receptor complexes, is cell-type and target gene specific. We will not review the details of gene regulation by the VDR further. The interested reader is referred to more comprehensive discussions of this topic.[117,131,132]

Vitamin D acts on all the components of calcium homeostasis and controls the acquisition of calcium from the environment as well as modulating the sensitivity of several organs to calcium and PTH. Below, we review the actions of vitamin D on calcium-regulating organs.

The Intestine: Vitamin D deficiency and genetic disruption of the vitamin D receptor cause hypocalcemia, secondary hyperparathyroidism, rickets, osteomalacia, and growth retardation.[117] All of these disturbances can be rescued by the administration of a high calcium and lactose diet that increases vitamin D-independent gut calcium absorption or by selective, transgenic replacement of intestinal VDR expression in VDR-knockout mice.[133,134] Therefore, it has become clear that the dominant actions of vitamin D on calcium and bone metabolism are to support the absorption of calcium and phosphorus from the diet. Calcium is absorbed from the intestine through a saturable, transcellular process that is prominent in the proximal small intestine and a non-saturable, paracellular process that is more prominent in the ileum and colon.[135] Vitamin D has its greatest effects on increasing transcellular transport, although it can also increase paracellular calcium absorption. Vitamin D has traditionally been thought to increase transcellular calcium transport in enterocytes by increasing the production of proteins involved

in calcium entry across the apical membrane (TRPV6), calcium translocation through the cytoplasm (calbindin D_{9k}, calbindin D_{28k}) and calcium extrusion across the basolateral membrane (PMCA1b).[136–143] However, recent knockout mouse models of TRPV6 and calbindin D_{9k} have suggested that the standard model of vitamin D-mediated transcellular calcium transport may be overly simplistic.[144–146] Vitamin D signaling also upregulates the expression of claudin 2 and claudin 12, both of which modulate the permeability of tight junctions to calcium and, thus, likely regulate paracellular calcium transport.[147]

It should be noted that vitamin D also increases intestinal phosphate absorption.[135] This is caused by increases in the apical expression of NPT2b, a sodium-phosphate co-transporter related to the phosphate transporters expressed in the proximal renal tubule.[148,149] However, the exact molecular mechanisms by which vitamin D regulates NPT2b expression and phosphate absorption remain to be defined.

The kidney: In addition to serving as the site of 1,25 $(OH)_2$ vitamin D synthesis, the kidney is also a target of vitamin D actions.[117,150] The VDR is expressed at highest levels in distal tubule cells but is also expressed at lower levels in the proximal tubule.[151] The net effect of vitamin D on the kidney appears to be the regulation of its own synthesis in a short feedback loop in the proximal tubule and the enhancement of calcium reabsorption in the distal convoluted tubule. In the proximal tubule Vitamin D inhibits the production of CYP27B1 and enhances the production of CYP24A1 acting to inhibit further production of 1,25 $(OH)_2$ vitamin D.[117,150] As in the intestine, vitamin D acts on the distal tubule to regulate the production of several proteins involved in transcellular calcium reabsorption. It upregulates the expression of TRPV5 and TRPV6, the two apical calcium entry channels; Calbindin D_{9k} and Calbindin $_{28k}$, which are involved in cytoplasmic calcium translocation; and PMCA1b, which transports calcium out of the cell across the basolateral membrane.[150] It also has been shown to increase PTHR1 expression in the distal tubule and to enhance the effects of PTH on distal tubular calcium reabsorption.[150]

Bone: The vitamin D receptor is expressed in cells of the osteoblast lineage but not in mature osteoclasts. The classic presentation of vitamin D deficiency in children is growth retardation and rickets, while in adults it can result in osteomalacia.[117] However, as noted previously, when VDR-knockout mice were treated with a high calcium "rescue" diet that normalized calcium, phosphate and PTH levels, these bone phenotypes disappeared, suggesting that the dominant effects of vitamin D on bone were indirect.[133] However, a close examination of $VDR^{-/-}$, $CYP27B1^{-/-}$ and double knockout, $VDR^{-/-}$, $CYP27B1^{-/-}$ mice on rescue diets demonstrated that loss of vitamin D function reduced the numbers of osteoblasts and osteoblast progenitors *in vivo*, which is consistent with many studies *in vitro* that have documented effects of vitamin D on osteoblast gene expression, osteoblast proliferation and osteoblast differentiation.[32,117] However, in the presence of adequate amounts of dietary calcium and phosphate, the direct effects of vitamin D on osteoblast function are subtle and may differ depending on the stage of osteoblast differentiation. The indirect effects of vitamin D on osteoclasts are more straightforward. 1,25 $(OH)_2$ vitamin D increases osteoblast expression of RANKL and decreases the production of OPG by osteoblasts.[152,153] By increasing the RANKL/OPG ratio, vitamin D increases the production of osteoclasts and of bone turnover. This effect of vitamin D is clinically apparent in states of 1,25 $(OH)_2$ vitamin D overproduction or in the setting of excess ingestion of vitamin D, where bone resorption is excessive despite the suppression of PTH secretion.

Parathyroid gland: The parathyroid glands are rich in VDR expression and 1,25 $(OH)_2$ vitamin D inhibits transcription of the PTH gene.[60,154–156] This appears to be a direct effect of the VDR on the PTH gene promoter. Vitamin D also regulates PTH production indirectly by increasing CaSR expression in the parathyroids and by increasing systemic calcium levels.[9] As noted previously, CaSR signaling increases VDR expression in the parathyroids, so vitamin D and calcium act synergistically to suppress PTH secretion.[53] Therefore, states of vitamin D deficiency may sensitize the gland to low calcium levels and increase the PTH response to hypocalcemia. This may contribute to the development of parathyroid hyperplasia and secondary hyperparathyroidism in CKD. However, in mice, it appears that calcium remains the most important factor regulating parathyroid gland growth and PTH secretion. Meir and colleagues disrupted the VDR specifically in parathyroid cells and found that while CaSR levels were decreased, PTH secretion was only modestly increased and that serum calcium levels remained normal.[157] These data suggest that the VDR may have a limited role in regulating parathyroid function at baseline.

Parathyroid Hormone-Related Protein

The *PTHrP* and *PTH* genes share structural elements and sequence homology suggesting that they arose through duplication of a common ancestor.[158–161] The portion of both genes encoding the amino-terminal segments of PTH and PTHrP are highly conserved such that the peptides share 8 of the first 13 amino acids and a high degree of predicted secondary structure over the next 21 amino acids. Beyond this, however, the two

genes share little similarity. PTHrP mRNA is expressed in almost every organ at some time during its development or functioning. Many different hormones and growth factors regulate PTHrP mRNA levels. As with PTH, the CaSR regulates *PTHrP* gene expression in many different cell types.[162,163] Another common observation is that mechanical forces induce *PTHrP* gene expression in many sites.[159]

Like PTH, PTHrP binds to and activates the PTH1R. Most studies *in vitro* suggest that this receptor binds PTHrP and PTH with equal affinity and that both peptides trigger identical signaling events.[50,159] However, the human PTH1R may respond somewhat differently to PTH and PTHrP. It appears that PTH and PTHrP demonstrate differences in their ability to stabilize alternate conformational states of the receptor, so that the duration of cAMP production is shorter for PTHrP (1–36) than for PTH (1–34).[164] This may explain why human subjects subjected to continuous infusion of the two peptides for 72 hours, were found to become hypercalcemic with lower doses of PTH 1–34 than PTHrP (1–36) and had lower 1,25 $(OH)_2$ vitamin D production when infused with PTHrP.[165] These studies may also help to explain differences in the biochemical profiles of HHM and hyperparathyroidism (see below).

In addition to being secreted, PTHrP can also be transported into the nucleus of many different cell types.[166,167] The function(s) of nuclear PTHrP is unclear, but replacement of the endogenous mouse PTHrP gene with a mutant version encoding a protein that cannot enter the nucleus causes widespread cellular senescence, growth retardation and early death.[168] This experiment suggests that nuclear PTHrP is of fundamental importance in many cell types.

PTHrP has been suggested to have many functions. The reader is referred to more comprehensive reviews for a complete discussion.[159,169] Here, we will highlight two areas where PTHrP has been documented to have physiological effects in intact organisms.

Cartilage and bone: A series of genetic experiments in mice and genetic disorders in humans have demonstrated that amino-terminal PTHrP acts through the PTH1R to coordinate the rate of chondrocyte differentiation in order to maintain the orderly growth of long bones during development.[170–173] PTHrP is produced by immature chondrocytes at the top of the growth plate in response to another molecule known as Indian Hedgehog (IHH) secreted by differentiating hypertrophic chondrocytes. PTHrP, in turn, acts on its receptor located on proliferating and prehypertrophic cells to slow their rate of differentiation into hypertrophic cells. Therefore, IHH and PTHrP define a local negative feedback loop that regulates the rate of chondrocyte differentiation (see Figure 66.3).[173] PTHrP is also found in other cartilaginous sites such as the costal cartilage and the hyaline cartilage lining the joint space, where it appears to prevent the inappropriate encroachment of bone into these structures.[174,175]

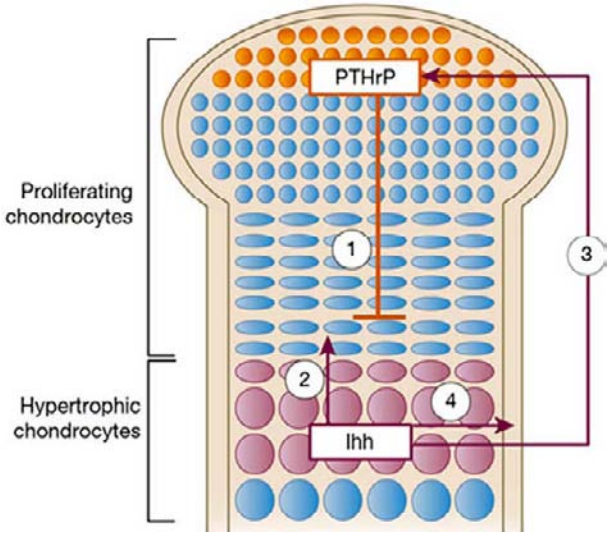

FIGURE 66.3 PTHrP and Indian hedgehog (Ihh) act as part of a negative feedback loop regulating chondrocyte proliferation and differentiation. The chondrocyte differentiation program proceeds from undifferentiated chondrocytes at the end of the bone, to proliferative chondrocytes within the columns and then to prehypertrophic and terminally differentiated hypertrophic chondrocytes nearest the primary spongiosum. PTHrP is made by undifferentiated and proliferating chondrocytes at the ends of long bones. It acts through the PTH1R on proliferating and prehypertrophic chondrocytes to delay their differentiation, maintain their proliferation and delay the production of Ihh, which is made by hypertrophic cells (1). Ihh, in turn, increases the rate of chondrocyte proliferation (2) and stimulates the production of PTHrP at the ends of the bone (3). Ihh also acts on perichondrial cells in order to generate osteoblasts of the bone collar (4). *(Reproduced with permission from Kronenberg HM. 2003. Developmental regulation of the growth plate. Nature 423:332–336.)*

PTHrP also affects bone cells *in vivo*. Heterozygous PTHrP-null mice develop osteopenia with increasing age.[176] In addition, selective deletion of the PTHrP gene from osteoblasts causes decreased bone mass, reduced bone formation, reduced mineral apposition and a reduction in the formation and survival of osteoblasts.[177] These data suggest that PTHrP acts as an important local anabolic factor in the skeleton.

Mammary gland: PTHrP has important functions during breast development, it is involved in regulating systemic calcium metabolism during lactation and it contributes to the pathophysiology of breast cancer.

The mammary gland forms as a bud-like invagination of epidermal cells that grow into a specialized mesenchyme.[178] The epithelial cells of the embryonic mammary bud produce PTHrP, which interacts with the PTH1R expressed on surrounding mesenchymal cells. This interaction is necessary for the outgrowth of the duct system.[179] In both mice and humans,

disruptions of PTHrP signaling cause a failure of breast development past this early bud stage.[180]

PTHrP is also produced by breast epithelial cells during lactation and large quantities are secreted into milk.[181,182] The function of PTHrP in milk is unknown, but it is secreted from the lactating breast into the circulation, where it participates in the regulation of systemic calcium metabolism. The maternal skeleton is an important source of calcium for milk production and the lactating breast secretes PTHrP into the circulation to increase bone resorption.[182] This is the only time in which PTHrP exerts a documented systemic endocrine effect on normal calcium and bone metabolism.

CALCITONIN

Calcitonin is produced by the C-cells of the thyroid gland in humans and by the ultimobranchial body in other animal species. Calcitonin is encoded by the *CALC1* (also referred to as *CALCA*) gene, a member of a family of genes that also encode islet amyloid protein, calcitonin gene related peptide (CGRP), and the precursor of adrenomedullin. Alternative splicing of the CALC1 transcript also yields a homologous peptide, calcitonin gene-related peptide (CGRP), which is produced in the nervous system.[183] Similar to parathyroid cells, C-cells express the CaSR on their cell surface and are sensitive to small changes in extracellular fluid calcium concentrations. Increases in serum calcium levels within the normal physiologic range lead to the secretion of calcitonin.[184]

The calcitonin receptor is a GPCR[185] that is expressed at high levels on osteoclasts. Activation of the calcitonin receptor inhibits osteoclast motility, causes their retraction from the bone surface, and acutely inhibits their ability to resorb bone.[186–188] However, these effects are short-lived, because calcitonin signaling causes a reduction in the number of calcitonin receptors and rapid development of calcitonin resistance.[189] In humans, calcitonin does not appear to be essential for minute-to-minute calcium homeostasis, but it may contribute to the conservation of total body calcium, especially with aging and/or during periods of calcemic stress such as pregnancy or lactation.[190] Experiments in knockout mice suggest that the disruption of calcitonin signaling results in an impaired ability to recover from hypercalcemia, and excessive bone loss during lactation.[191,192]

INTEGRATED REGULATION OF CALCIUM METABOLISM

The various hormones and organ systems discussed in the previous sections all cooperate in order to regulate the ECF ionized calcium concentration and maintain it in a relatively narrow physiologic range. As mentioned previously, it has been suggested that increases in PTH secretion from the parathyroid gland serve as the principal defense against hypocalcemia but that the direct effects of calcium on the kidney CaSR may be more important in returning calcium to the normal range in the face of hypercalcemia. However, this construct has not been validated in human subjects. Even, if this is the case, it is clear that the entire interconnected homeostatic system responds to either hypocalcemia or hypercalcemia.

As illustrated in Figure 66.4, a fall in the ECF calcium level below the physiologic range is rapidly sensed by the parathyroid gland CaSR. Reduced signaling from this receptor then leads to the secretion of more PTH from the parathyroid glands, which, in turn activates the release of calcium and phosphate from the skeleton. There is a rapid release of calcium and phosphate from the bone interstitial fluid followed by an increase in bone resorption that releases calcium

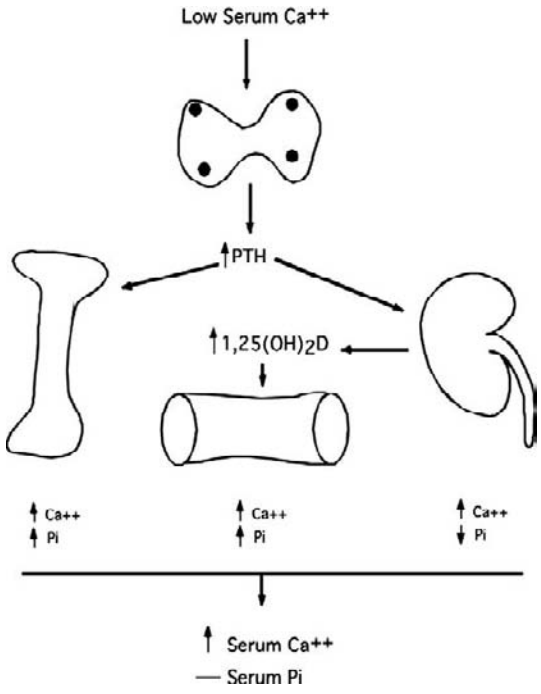

FIGURE 66.4 Integrated response to hypocalcemia. A decrease in the ionized calcium concentration in the ECF is sensed by the CaSR on the parathyroid glands, which leads to increased secretion of PTH. In turn, PTH causes release of calcium from bone and reclamation of calcium from the urine. If the hypocalcemic stimulus is prolonged, PTH induces an increase in the production of 1,25 OH_2 vitamin D from the kidney, which increases calcium absorption from the GI tract. While PTH leads to an increase in the release of phosphate from the skeleton and an indirect increase in GI absorption from the diet, it causes renal excretion of phosphate allowing an increase in the serum calcium levels without changing systemic phosphate levels.

and phosphate from stores within the mineralized portion of bone. In the kidney, PTH increases the reabsorption of calcium from the urine but decreases the reabsorption of phosphate. Presumably, this serves to dispose of the phosphate released from the skeleton and prevents any rise in serum phosphate, which could otherwise inhibit a rise in serum calcium by inducing the precipitation of calcium phosphate salts in soft tissues. In addition to the actions of PTH, reduced CaSR signaling within the kidney also leads to an increase in net calcium reabsorption independent of changes in PTH. Combined, these alterations in parathyroid, skeletal and kidney function return the calcium concentration back to normal and feedback to restrict further PTH release. When hypocalcemia is prolonged, PTH also stimulates the renal production of 1,25 $(OH)_2$ vitamin D, which increases intestinal calcium absorption. When hypocalcemia is no longer present then the system can reset back to its baseline activity. However, if there is a chronic hypocalcemic stress, then long-term elevations in PTH and 1,25 $(OH)_2$ vitamin D may be required to maintain the calcium level within the normal range.

In the presence of hypercalcemia, the various components in the system react in an opposite fashion in order to lower ECF calcium levels. A rise in the ionized calcium level acts on the CaSR in the kidney to trigger an increase in calcium excretion in the urine. As noted previously, this is associated with increased water excretion as well. Increased activation of the parathyroid CaSR suppresses PTH secretion, which, in turn, leads to a reduction in bone resorption and reduced production of 1,25 $(OH)_2$ vitamin D. Hypercalcemia also increases the catabolism of 1,25 $(OH)_2$ vitamin D. When calcium levels return to normal, these various adaptations are reversed and calcium excretion is halted. Normal renal function is critical for the system to be able to maintain a normal calcium in the setting of a chronic excess of calcium entering the ECF, for example in vitamin D excess or in states of pathological bone resorption. If renal function declines and the ability to excrete calcium in the urine is compromised, hypercalcemia will persist.

HYPERCALCEMIA

A list of disorders causing hypercalcemia is provided in Table 66.1. Although there are many potential causes of an elevated calcium level, most patients with hypercalcemia (>90%) are afflicted with either primary hyperparathyroidism or by malignancy-associated hypercalcemia (MAHC).[193,194] Therefore, we will discuss these disorders at some length and only briefly describe the other causes. It is important to keep

TABLE 66.1 Causes of Hypercalcemia

Hyperparathyroidism
Idiopathic primary hyperparathyroidism (PHP)
Familial
MEN type 1 or MEN type 2a
ESRD/tertiary hyperparathyroidism
Familial hypocalciuric hypercalcemia (FHH)
Malignancy associated hypercalcemia (MAHC)
Osteolytic metastases (LOH)
PTHrP and other humoral mediators (HHM)
Endocrinopathies
Adrenal insufficiency
Hyperthyroidism
Acromegaly
VIPoma
Pheochromocytoma
Medications
Vitamin D intoxication
Vitamin A intoxication
Thiazides
Lithium
Milk–alkali syndrome
Excess thyroid hormone
Tamoxifen
Growth hormone
Aminophylline
Granulomatous disease
Sarcoidosis
Tuberculosis
Silicone-induced granulomas
Disseminated candidiasis
Disseminated cytomegalovirus
Pneumocystis carinii pneumonia
Miscellaneous causes
Immobilization
Dehydration
Aluminum toxicity
William's syndrome
Rhabdomyolysis recovery
Idiopathic hypercalcemia of infancy
Jansen's metaphyseal chondrodysplasia

in mind that elevations in the total calcium level can occur in the absence of changes in ionized calcium levels. This is defined as *pseudohypercalcemia*, and occurs in the setting of abnormalities in serum proteins or severe thrombocytosis (platelet counts >700,000).[195] In these setting an ionized calcium level should be obtained to confirm the diagnosis of hypercalcemia before other diagnostic tests are performed.

Clinical Presentation of Hypercalcemia

Patients with mild hypercalcemia (<1 mg/dL above normal) are usually asymptomatic unless they have preexisting cerebral dysfunction. The severity of hypercalcemic symptoms is related both to the degree of elevation in the ionized calcium level and to the rapidity with which the calcium level rises. The higher the calcium and the faster its level rises, the more severe will be the symptoms. When present, symptoms are caused by dehydration secondary to urinary losses of calcium, water, and other electrolytes and to an increase in membrane potential caused by the elevation in ECF ionized calcium concentration (see Table 66.2). Dehydration develops because an increase in the filtered load of calcium leads to hypercalciuria, which is associated with the loss of sodium, anions and water. In addition, as discussed previously, hypercalcemia causes nephrogenic diabetes insipidus due to the stimulation of the CaSR in the collecting ducts of the kidney.[196] Consequently, patients with hypercalcemia frequently report symptoms of polyuria and polydipsia. If significant dehydration ensues, hypercalcemia can worsen quickly because any impairment of glomerular filtration reduces the ability of the kidneys to excrete excess calcium. Patients with moderate to severe hypercalcemia often complain of nausea and vomiting, symptoms likely related to dehydration as well as to the effects of the hypercalcemia on central nervous system function. Because hypercalcemia tends to hyperpolarize membranes, a range of neurologic and neuromuscular signs and symptoms can occur. Patients with mild hypercalcemia often complain of fatigue, depressed affect, and asthenia. With further increases in serum calcium, these complaints progress to impaired concentration and memory, difficulty with cognitive function, stupor, and coma. Muscle weakness can be seen, which can occasionally progress to flaccid paralysis if hypercalcemia becomes severe.[197] Gastrointestinal motility is impaired; this commonly results in constipation and likely contributes to nausea and vomiting. Occasionally, pancreatitis may be the cause of abdominal pain in patients with hypercalcemia.[198,199] Finally, cardiovascular function can be impaired, as manifested by bradycardia and sensitivity to the effects of digitalis. Electrocardiographic changes include shortening of the QT interval, varying degrees of atrioventricular block, and bradyarrhythmias or tachyarrhythmias if the hypercalcemia is severe.[200,201]

TABLE 66.2 Symptoms and Signs of Hypercalcemia

Signs and Symptoms	Acute	Chronic
Gastrointestinal	Anorexia	Dyspepsia
	Nausea	Constipation
	Vomiting	
Cardiac	Bradycardia	Hypertension
	Short QT interval	Digitalis sensitivity
	First degree atrioventricular block	Increased mean carotid intima-media thickness
		Cardiac calcifications,
		Ventricle hypertrophy
		Diastolic dysfunction
Renal	Polyuria	Nephrolithiasis
	Polydipsia	Nephrocalcinosis
Neurologic and psychiatric	Irritability, Psychosis	Depression
	Confusion, Disorientation,	Insomnia
	Forgetfulness	Decreased deep tendon reflexes
	Lethargy, Stupor, Coma	
Musculoskeletal	Bone pain	Hyperuricemia
	Weakness	Gout
	Arthralgia	Pseudo gout
		Pathologic fractures

Primary Hyperparathyroidism

Primary hyperparathyroidism (PHP) is caused by excess production of PTH by the parathyroid glands and is characterized by simultaneous elevations in circulating calcium and PTH levels. Most commonly it is caused by benign adenomas of one or sometimes two parathyroid glands. Less commonly, it is caused by diffuse parathyroid hyperplasia in the setting of the familial endocrine neoplasia syndromes (MEN1 and MEN2). Rarely, it is caused by primary disorders of calcium sensing or by parathyroid carcinoma. Primary hyperparathyroidism is currently estimated to have an incidence between 1 in 500 and 1 in 1000 persons.[202] After the age of 50 years, women are more frequently

affected then men; the female-to-male ratio in that age group is 3:1.[203] Although the onset of hyperparathyroidism can occur at any age, it is more common in older individuals, and the peak incidence is in the sixth decade.[204] Apart from the genetic disorders mentioned above, the only other known risk factor is exposure to external neck irradiation during childhood.

The most common cause of primary hyperparathyroidism is the growth of single or multiple adenomas (more than 75–80%).[205] The typical parathyroid adenoma appears as a collection of chief cells surrounded by a rim of normal tissue at the outer perimeter of the gland. These are clonal neoplasms, whose size and degree of PTH secretion tend to remain remarkably stable over multiple years.[206] One of the features of the neoplastic cells is blunted feedback of PTH secretion by calcium as compared to normal parathyroid cells. The cells in an adenoma have reduced expression of both the CaSR and the VDR as compared to normal cells and the degree of loss of feedback inhibition has been suggested to correlate with the degree of loss of CaSR and/or VDR expression.[207,208] However, it is unclear whether these alterations in VDR and CaSR are drivers of the abnormal proliferation of the original clone of abnormal cells or whether they occur secondary to proliferation of the cells. Approximately 20 to 40% of adenomas have been reported to overexpress cyclin D1, a cell-cycle regulatory protein that can act as a dominant oncogene.[209] An additional 25 to 30% of sporadic adenomas have been reported to have somatic mutations in the multiple endocrine neoplasia 1 (MEN1; menin) tumor suppressor gene on chromosome 11.[210] Approximately 15% of patients with hyperparathyroidism have diffuse enlargement of all four parathyroid glands caused by chief cell hyperplasia.[211] The most common cause of four-gland hyperplasia is long-standing CKD, which leads to chronic hypocalcemia, hyperphosphatemia, and low serum $1,25(OH)_2$ vitamin D levels, all of which stimulate parathyroid cell growth.[212] This hyperplasia can eventually lead to hypercalcemia, so-called tertiary hyperparathyroidism. Most cases of inherited parathyroid hyperplasia result from one of the two MEN syndromes. Hyperparathyroidism is a prominent feature of the MEN1 syndrome, which is caused by mutations in the menin gene, a tumor suppressor.[213] In contrast, hyperparathyroidism associated with the MEN2 syndrome is usually mild and occurs in fewer affected individuals. MEN2 has been shown to be caused by mutations in the *ret* proto-oncogene.[214,215] Both syndromes have an autosomal dominant mode of inheritance. Hyperplasia in these syndromes can be asynchronous, with unequal enlargement of the individual glands over time that gives the misimpression of single-gland disease.[216] Approximately 0.5% of all patients with hyperparathyroidism have parathyroid carcinoma. Typically, these patients have severe hypercalcemia and hyperparathyroidism that recurs following initial therapy.[217] It can be very difficult to distinguish a parathyroid carcinoma from an adenoma by pathologic evaluation alone, but local tissue invasion, local lymph node involvement, and the presence of mitotic figures are clues to the diagnosis. Parathyroid carcinoma occurs with increased frequency in a rare genetic syndrome known as *hyperparathyroid jaw-tumor syndrome*, which is characterized by primary hyperparathyroidism in association with mesenchymal tumors of the mandible.[218] This syndrome was found to be caused by mutations in the *HRPT2* gene encoding the tumor suppressor, parafibromin, and emerging data suggest that mutations in this gene may also cause a significant proportion of sporadic cases of parathyroid carcinoma.[219]

Clinical presentation: The clinical manifestations of primary hyperparathyroidism are variable. They include the characteristic symptoms of hypercalcemia (see Table 66.2) as well as the variable occurrence of skeletal, renal and other organ complications. Historically primary hyperparathyroidism was a rare, severe disease with significant morbidity and mortality. However, as general biochemical screening became popular, it was appreciated that most patients with this disorder had very mild symptoms and many were asymptomatic.[206]

Von Recklinghausen first described osteitis fibrosa cystica in 1891.[220] In the early twentieth century it was linked to hyperparathyroidism when Mandl reported clinical improvement after removal of a parathyroid adenoma from a patient with severe bone disease.[221] The skeletal involvement seen in primary hyperparathyroidism results from a generalized increase in osteoclastic bone resorption, which is accompanied by fibrovascular marrow replacement and increased osteoblastic activity. On radiography, osteitis fibrosa cystica is defined by the following features (see Figure 66.5): (1) generalized demineralization of bone, with coarsening of the trabecular pattern; (2) Subperiosteal resorption, most evident in the phalanges of the hands, resulting in an irregular, serrated appearance to the subperiosteal cortex or even extensive cortical resorption; (3) Bone cysts containing a brownish serous or mucoid fluid predominantly in the central medullary portions of the shafts of the metacarpal bones, pelvis and ribs, which may expend into and disrupt the overlying cortex; (4) Osteoclastomas composed of numerous multinucleated osteoclasts ("giant cells") admixed with stromal cells and matrix, found frequently in trabecular portions of the jaw, long bones, and ribs forming so called "brown tumors;" and (5) Pathologic fractures. Classic osteitis fibrosa cystica is

FIGURE 66.5 Osteitis fibrosa cystica. Hand films from a patient with primary hyperparathyroidism showing the typical findings of parathyroid bone disease. Note the general appearance of osteopenia as well as the erosion of the periosteal surface most prominently seen in the first digit. Also note the cystic dilatation of the distal metacarpals and the mottled appearance of the 5th metacarpal.

now uncommon, occurring in less than 5% of patients. However, primary hyperparathyroidism can also cause more typical osteoporosis and recent data suggest that over 50% of otherwise asymptomatic patients with hyperparathyroidism eventually develop progressive bone loss and are at risk for osteoporosis.[222] Thus, bone mineral density should be measured in all patients with hyperparathyroidism. Cortical bone is more sensitive to the effects of hyperparathyroidism, so bone mineral density in the distal forearm and hip is typically more severely affected than is bone mineral density in the spine.

Up to 20% of patients with primary hyperparathyroidism present with kidney stones, which makes this the most common complication.[223] Primary hyperparathyroidism accounts for fewer than 5% of all calcium kidney stones, but these patients are more likely to have recurrent or severe stone disease. Nephrocalcinosis, or the diffuse deposition of calcium phosphate complexes in the renal parenchyma, is seen less commonly. The most common stone type seen in hyperparathyroidism is calcium oxalate.[224] However, stones of mixed chemical composition (calcium oxalate and calcium phosphate) are often observed. The risk factors for stone disease in patients with hyperparathyroidism are hypercalciuria (>4 mg/kg calcium excretion over 24 hours), which results from hypercalcemia and the increased filtered load of calcium, which triggers the kidney CaSR and overrides the increased distal absorption of calcium mediated by the continuous PTH stimulation.[11] PTH also inhibits bicarbonate reabsorption in the proximal renal tubule resulting in a mild hyperchloremic metabolic acidosis and relatively alkaline urine. Precipitation of calcium phosphate is favored under alkaline conditions, which likely contributes to the formation of calcium phosphate stones and nephocalcinosis. Classically, severe hyperparathyroidism is associated with progressive renal impairment, but it is unclear whether mild hyperparathyroidism directly impairs GFR. In the majority of patients followed conservatively renal function remains stable.

In addition to complications involving bone and the kidney, primary hyperparathyroidism has been associated with a variety of other conditions, which may be related to either hypercalcemia or elevated PTH levels. These are listed in Table 66.3. The issue of whether primary hyperparathyroidism increases the risk for peptic ulcer disease and pancreatitis remains controversial.[225] Peptic ulcer disease was part of the original description of hyperparathyroidism, although this may have represented patients with undiagnosed MEN1 and Zollinger-Ellison syndrome. Although hyperparathyroidism is associated with a higher risk of hypertension, successful surgery does not often correct blood pressure. However, a series of studies have

TABLE 66.3 Potential Complications of Primary Hyperparathyroidism

Renal	Nephrolithiasis
	Nephrocalcinosis
	Impairment of renal function: - decreased creatinine clearance
	Impaired concentrating and acidifying ability
Skeleton	Osteitis fibrosa cystica
	Osteopenia/Osteoporosis
	Increased fracture risk
Cardiovascular	Hypertension
	Left Ventricular Hypertrophy
	Abnormal cardiac calcifications
	Increased cardiac mortality
Malignancy	Increased risk in severe cases

offered suggestive findings that primary hyperparathyroidism is associated with an overall increase in cardiovascular disease.[226]

Diagnosis: The diagnosis of hyperparathyroidism is made by documenting simultaneous elevations in the circulating levels of calcium and PTH in a patient with normal renal function. Plasma intact PTH concentrations, as measured by immunoradiometric assay, will be above the normal range in 90% of cases. In the remaining 10%, the PTH will be inappropriately normal for the degree of hypercalcemia.[227] Plasma 1,25 $(OH)_2$ vitamin D concentrations are increased or normal in most cases of primary hyperparathyroidism. Low 1,25 $(OH)_2$ vitamin D levels may be seen with coexisting vitamin D deficiency or in cases of severe hypercalcemia.[228] Patients with hyperparathyroidism also may have slightly low or low−normal serum phosphorus concentrations, and mild hyperchloremic metabolic acidosis. Alkaline phosphatase levels can be elevated in patients with overt bone disease. Once hyperparathyroidism is diagnosed, patients should be screened for end-organ complications. Renal ultrasonography or spiral computed tomography scans should be used to determine whether the patient has kidney stones. Bone mineral density measurements should be done to detect skeletal disease, preferably using dual energy x-ray absorptiometry, at the spine, hip, and wrist. A 24-hour urine collection should be performed to determine whether hypercalciuria is present.

Management of primary hyperparathyroidism: Surgery is the only curative therapy available for patients with primary hyperparathyroidism. All symptomatic patients or patients with complications of primary hyperparathyroidism such as renal stones or fractures should be referred to an experienced parathyroid surgeon for consideration of parathyroidectomy. Parathyroidectomy is successful and curative for 90−97% of patients when performed by an experienced surgeon.[229] Traditionally, this involved bilateral neck exploration, during which the surgeon identified all four parathyroid glands before resecting the abnormal gland. However, minimally invasive parathyroidectomy has been replacing traditional neck exploration. This requires preoperative localization of the adenoma. Technetium-99 m−sestamibi scans, ultrasonography, 4-dimensional CT scans and magnetic resonance imaging can all be used as preoperative localization studies.[229] A minimally invasive approach is not appropriate for parathyroid hyperplasia because the surgeon must remove either three and one half parathyroid glands or all four glands with autotransplantation of some parathyroid tissue to the forearm. Complications of parathyroid surgery include damage to the recurrent laryngeal nerve and permanent hypoparathyroidism.[230] Activity of the unaffected parathyroid glands is suppressed by the hypercalcemia associated with hyperparathyroidism, and the remaining glands take several days to recover normal secretory activity after removal of the adenoma. This can result in postoperative hypocalcemia in the first 24 to 48 hours. If significant bone disease is present, the influx of calcium into the skeleton as it heals following parathyroidectomy can lengthen the duration and increase the severity of hypocalcemia. This phenomenon is known as the hungry bones syndrome.

The widespread use of routine biochemical screening has led to the increased detection of asymptomatic primary hyperparathyroidism in which patients present with mild hypercalcemia, minimal or no symptoms and no end-organ damage. Studies examining the natural history of long-standing mild, asymptomatic primary hyperparathyroidism have suggested that most patients remain stable and do not develop progressive disease over the course of 10 years. However, the most recent studies suggest that up to 59% of initially asymptomatic patients developed more than a 10% decline in bone mineral density at one or more sites between 10 and 15-years of observation.[231] In addition, concern lingers over the possibility of excess vascular disease and cancer in these patients as well as over the subtle neurocognitive effects ascribed to hyperparathyroidism in some studies. However, it should be noted that the results of three different randomized trials of surgery versus medical follow-up in this patient population have not shown a definitive improvement in neurocognitive symptoms after surgery.[232−234] Therefore, there is much debate over the proper treatment of these patients since it is not clear that surgical correction of their hyperparathyroidism will provide clear benefit. Given ongoing uncertainty about this topic, a group of international experts met in 2008 to review and update guidelines for parathyroidectomy first formulated by an NIH consensus conference in 1990.[235] Table 66.4 lists the criteria for surgery in otherwise asymptomatic patients, and Table 66.5 provides the guidelines for managing nonsurgical patients as suggested by the 2008 International Workshop. These guidelines are not rigid, and each patient must be approached with his or her unique circumstances in mind. In addition, patients who do not undergo surgical treatment should have annual measurements of serum calcium and serum creatinine and should have bone density measurements every year or every other year. If patients demonstrate worsening of hypercalcemia, deterioration of renal function, or progressive bone loss, they should be referred for surgery.

There are no proven medical treatments for primary hyperparathyroidism, but several adjunct medical

TABLE 66.4 Guidelines for Surgery in Asymptomatic Primary Hyperparathyroidism from 2008 International Consensus Conference

Serum calcium (> upper limit of normal) 1.0 mg/dl (0.25 mmol/liter)
Creatinine clearance (calculated) reduced to <60 ml/min
BMD decrease with T-score < − 2.5 at any site and/or previous fracture fragility
Age less than 50 years
Uncertain prospects for adequate medical monitoring

TABLE 66.5 Non-Surgical Management of Primary Hyperparathyroidism

Monitor serum calcium and creatinine annually and bone density (hip, spine, and forearm) every one to two years.[248,246]
In patients with osteopenia and risk factors for fracture or with frank osteoporosis, who are not candidates for surgery, medical therapy with bisphosphonates to preserve bone mass is recommended.[349,246]
Avoid factors that can aggravate hypercalcemia, including thiazide diuretic and lithium carbonate therapy, volume depletion, prolonged bed rest or inactivity, and a high calcium diet (>1000 mg/day).
Encourage physical activity to minimize bone resorption.
Promote adequate hydration to minimize the risk of nephrolithiasis.
Maintain a moderate calcium intake (1000 mg/day). Calcium restriction (eg, <800 mg/day) is probably warranted when the serum calcitriol concentration is high.[248]
Maintain moderate vitamin D intake (400 to 600 IU daily) and treat coexisting vitamin D deficiency with careful monitoring of urinary calcium excretion.[350]

therapies can be useful for patients in need of treatment but who are not considered surgical candidates due to substantial comorbidities, or for those who opt not to proceed with definitive surgery. Maintenance of hydration and physical activity are important in all patients. Bisphosphonates and estrogen replacement therapy have been shown to prevent bone loss and even increase bone mass in patients with hyperparathyroidism. Finally, cinacalcet has been shown to lower serum calcium levels in patients with primary hyperparathyroidism. This drug is an allosteric activator of the CaSR and directly inhibits PTH release by parathyroid adenomas. Cinacalcet demonstrated efficacy in controlling serum calcium in a 1-year randomized clinical trial in patients with this disease.[236] Normalization of serum calcium continued for up to 5 years of therapy in an open-label extension of this trial.[237] However, cinacalcet does not normalize PTH levels or prevent bone loss, so it should not be considered a routine long-term treatment for patients who should otherwise have surgery.

Familial Hypocalciuric Hypercalcemia

Familial Hypocalciuric Hypercalcemia (FHH), also called familial benign hypercalcemia is another form of PTH-dependant hypercalcemia that results from abnormalities in calcium sensing. FHH is caused by loss-of-function mutations of the *CaSR* gene and is inherited in an autosomal dominant pattern in families.[57] The mutations cause a shift in the parathyroid cell's set point for calcium, such that higher than normal levels of blood calcium are needed to suppress PTH secretion. Likewise, abnormal function of the CaSR in the kidney impairs renal calcium excretion and results in hypocalciuria, despite chronic hypercalcemia. Heterozygosity for the mutated *CaSR* gene results in a mild clinical disorder, but homozygotes or compound heterozygotes with two mutant CaSR alleles present with severe primary hyperparathyroidism at birth and require prompt parathyroid surgery for survival. This entity is known as neonatal severe hyperparathyroidism.[57] Finally autoimmune hypocalciuric hypercalcemia (AHH) can be caused by auto antibodies directed against the CaSR that interfere with its function.[238,239]

Clinically, FHH is characterized by lifelong hypercalcemia, which is usually mild but can be as high as 12 mg/dl in some patients. The PTH level is usually slightly elevated or in the upper half of the normal range. The patients are usually asymptomatic and do not manifest end-organ complications of primary hyperparathyroidism. However, in rare instances there have been reports of chondrocalcinosis and pancreatitis in certain families.[240] Phosphate measurements are low, as in primary hyperparathyroidism and magnesium levels are high—normal or slightly elevated. Urine calcium is usually low, although there is much overlap with patients with mild primary hyperparathyroidism. It can be challenging to distinguish between primary hyperparathyroidism and FHH in individual patients. However, the distinction is important since patients with FHH are not helped by surgery. In fact, recurrent hypercalcemia in the first week after surgery is a clinical clue to the correct diagnosis. The most valuable clue to differentiate between the two diagnoses is the occurrence of hypercalcemia in first-degree relatives that is consistent with an autosomal dominant pattern. Documentation of prior normal calcium in the patient under consideration strongly argues against FHH. Finally the ratio of calcium clearance (ClCa) to creatinine clearance (ClCr) has been used to differentiate patients with FHH from those with primary hyperparathyroidism. Calculation can be made using the following formula: Clca/Clcr = [CAu x CRs]/[CAs x CRu]. A ratio of 0.01 or less suggests FHH and separates FHH from primary hyperparathyroidism with modest overlap. However, since primary

hyperparathyroidism is much more common than FHH, most patients with values near the cutoff ClCa/ClCr ratio of 0.01 have primary hyperparathyroidism and not FHH.

The mainstay of therapy for FHH is to prevent the patient from having an unnecessary parathyroidectomy. With the exception of rare patients with pancreatitis, long-term studies suggest that these patients have a benign course.[241]

PARATHYROID-INDEPENDENT HYPERCALCEMIA

This category of disorders represents a heterogeneous collection of causes of hypercalcemia not directly involving the parathyroids. As expected, PTH secretion is appropriately suppressed in response to an elevated ionized calcium level. By far the most common group of affected patients have malignancy-associated hypercalcemia, which will be discussed in some detail. The other causes are found in Table 66.1, only some of which will be discussed below.

Malignancy-Associated Hypercalcemia

Hypercalcemia is a common complication of malignancy, occurring in up to 20 to 30% of patients with cancer sometimes during the course of their disease. Most episodes of hypercalcemia occur with advanced disease and patients with malignancy-associated hypercalcemia (MAHC) usually have a poor prognosis with some studies suggesting up to 50% 30-day mortality.[242] There are two generally recognized forms of this disorder, one in which hypercalcemia is the result of tumor secretion of a humoral factor (usually PTHrP) and one which is the result of extensive bone metastases. Effective pharmacologic therapy has improved the short-term management of these disorders but only effective treatment of the underlying neoplasm can completely resolve the hypercalcemia and significantly influence the long-term prognosis. Although mechanisms in given patients may be varied, in all cases, excessive bone resorption plays a pivotal role in the pathogenesis.

The more common of the two types of MAHC is humoral hypercalcemia of malignancy or HHM. This syndrome generally occurs in patients with few or no bone metastases and resembles primary hyperparathyroidism. Patients with HHM have high blood calcium levels, low blood phosphate levels, and high urinary cAMP levels but suppressed iPTH levels. In 1941, Fuller Albright first proposed the existence of a PTH-like humoral factor and work in the 1980s led to the identification of PTHrP as the cause of HHM.[243] As discussed earlier, PTHrP normally does not circulate, but in patients with cancer, it enters the bloodstream and acts on the PTH1R in bone and kidney to increase bone resorption and cause hypercalcemia. As compared to patients with primary hyperparathyroidism, patients with HHM have low 1,25 $(OH)_2$ vitamin D levels and low levels of bone formation.[244] However, acute infusions of PTHrP into animals increase CYP27B1 activity and increase osteoblast activity, so these differences in HHM still remain unexplained.[245] They may be related to the secretion of other factors by the tumors, to the elevated calcium levels or to differences in how the human PTH1R is activated by PTHrP as compared to PTH. In addition to PTHrP, some non-Hodgkin's lymphomas (usually of B cell origin), produce large amounts of 1,25 $(OH)_2$ vitamin D and can cause hypercalcemia due to activation of bone resorption by vitamin D.[246,247]

The second form of MAHC is due to excessive peritumoral bone resorption in the setting of extensive skeletal metastases and is referred to as local osteolytic hypercalcemia (LOH). LOH occurs most commonly in patients with multiple myeloma and breast cancer. This syndrome is caused by the recruitment and activation of normal osteoclasts that surround the tumor cells and cause local osteolysis. This is though to be the result of secretion of paracrine factors by the tumor cells that stimulate osteoclast differentiation and activity.[248] Myeloma cells secrete numerous cytokines and chemokines that are capable of stimulating bone resorption, including MIP1, lymphotoxin (TNF-β), and interleukins 1β, 3, and 6.[249,250] These factors lead to increased expression of RANKL by marrow stromal cells and osteoblasts and to stimulation of osteoclast formation and activity.[251] Myeloma cells also secrete inhibitors of the Wnt signaling pathway, which also suppresses bone formation.[252] Breast cancer cells secrete PTHrP in quantities that may not reach the circulation to cause HHM, but instead increase local osteoclast activity, again by activating the RANKL/RANK system.[253] Breast cancer cells have also been shown to secrete IL-8 and IL-11, both of which may contribute to local osteoclast activity.[254]

Granulomatous Disease

Hypercalcemia has historically been associated with sarcoidosis, but can also occur in other granulomatous conditions such as tuberculosis, silicone-induced granulomas, and disseminated candidiasis. Approximately 10–20% of patients with sarcoidosis will develop hypercalcemia and 50% will experience hypercalciuria.[255] In patients with the acquired immune

deficiency syndrome (AIDS), hypercalcemia due to granuloma formation has been reported in disseminated cytomegalovirus (CMV) infection and in *Pneumocystis carinii* pneumonia.[256,257] Hypercalcemia in these conditions appears to be vitamin D mediated, since activated macrophages in granulomatous tissue express CYP27B1 and have been shown to be an extra renal source of 1,25 $(OH)_2$ Vitamin D.[258] Increased intestinal absorption of calcium seems to be a major cause of the hypercalcemia. The affected patients may be especially likely to develop hypercalcemia after (1) sunlight exposure, which increases the production of 25 (OH) Vitamin D; or (2) diets enriched in vitamin D and calcium, which increase intestinal absorption of calcium. Glucocorticoids are effective in the treatment of this type of hypercalcemia due to their effects to inhibit gastrointestinal calcium absorption and to suppress production of 1,25 $(OH)_2$ Vitamin D by the granulomas.[259]

Milk-Alkali Syndrome

A study from the University of Oklahoma reported that milk-alkali syndrome due to calcium carbonate ingestion had become the third most common cause of hypercalcemia in hospitalized patients, representing 16% of hospital admissions for hypercalcemia over a 3-year survey.[260] This syndrome results from the ingestion of large amounts of calcium and absorbable alkali. It was first described in the 1930s as a complication of ulcer therapy that consisted of large quantities of milk together with sodium bicarbonate. It continued to be seen commonly in the era before the introduction of H_2-blockers when peptic ulcer disease was often treated with up 20–60 grams of calcium carbonate per day. With the introduction of nonabsorbable antacids and then H_2-blockers and proton pump inhibitors, this syndrome became rare. However, it has become more common again due to the increasing use of calcium carbonate to treat or prevent osteoporosis.

The classic triad defining milk-alkali syndrome consists of hypercalcemia, systemic alkalosis and renal insufficiency. Hypercalcemia is often severe and symptomatic, with presenting values commonly between 15–20 mg/dl. Renal dysfunction can vary from mild to severe and nephrocalcinosis often exists if the syndrome has been present for some time. Other sites of soft tissue calcification, as evidenced by band keratopathy, are common as well. In the older literature, patients were generally reported to be hyperphosphatemic, but in more recent series, phosphate levels have been reported to be normal or low. This most likely reflects the shift from milk, which has a high phosphate content, as a source of calcium to calcium carbonate, which does not. Although some confusion existed in the original literature, recent measurements using modern assays have documented that PTH levels are suppressed.[260,261] The diagnosis of the syndrome requires a careful history especially of over-the-counter medication use.

The pathophysiology of milk-alkali syndrome is not fully understood, but most likely represents a viscous cycle set up by the ingestion of large amounts of calcium in the setting of volume contraction, systemic alkalosis and progressive renal insufficiency. It is unclear what the threshold for the induction of hypercalcemia from oral calcium is, but it may be as low as 2–3 grams of calcium daily. This varies with renal function and also between different subjects. By suppressing PTH and leading to volume contraction, hypercalcemia can limit the kidney's ability to excrete bicarbonate. In turn, systemic alkalosis can impair the renal excretion of calcium and favors the precipitation of calcium phosphate in the kidney and other soft tissues. The development of nephrocalcinosis then leads to progressive renal dysfunction that contributes to the inability to excrete calcium and bicarbonate. Because of volume contraction and the induction of systemic alkalosis, vomiting can precipitate the syndrome. Likewise, the use of thiazide diuretics is a risk factor due to these drugs' ability to interfere with calcium excretion and to cause volume contraction. The biochemical abnormalities are usually reversible with the discontinuation of oral calcium and alkali, and with rehydration followed by forced saline diuresis. If renal failure is severe, making vigorous hydration difficult, hemodialysis against a low calcium bath has also been effective in lowering calcium levels. If the syndrome is acute, hypercalcemia and renal dysfunction resolve promptly and completely. In this setting, there can be rebound hypocalcemia and secondary hyperparathyroidism. In more chronic cases, especially if severe nephrocalcinosis is present, recovery takes longer and renal function may not completely normalize.[262]

Endocrine Disorders

Hypercalcemia occurs in endocrine conditions other than hyperparathyroidism. Mild elevations in circulating calcium can be seen in patients with hyperthyroidism, adrenal insufficiency and pheochromocytoma. Thyroid hormone and catecholamines can stimulate osteoclastic bone resorption directly.[263] In addition, pheochromocytomas often secrete PTHrP.[264] The mechanism for hypercalcemia in adrenal insufficiency is uncertain. In all instances, hypercalcemia resolves with successful treatment of the underlying disorder.

Immobilization

Immobilization due to prolonged bed rest or weightlessness is associated with disordered calcium homeostasis. All immobilized patients develop hypercalciuria but hypercalcemia only occurs in those with a preexisting state of high bone turnover. This is most commonly seen in adolescents with a growing skeleton, particularly those with spinal cord injuries and quadriplegia. Immobilization-associated hypercalcemia in adults is associated with Paget's disease, thyrotoxicosis, primary hyperparathyroidism, and malignancy. Hypercalcemia occurs because of increased osteoclastic bone resorption and decreased osteoblastic bone formation. Prolonged immobilization can lead to osteopenia and nephrolithiasis. Serum PTH and 1,25 $(OH)_2D_3$ concentrations are suppressed, and hypercalcemia and hypercalciuria resolve with resumption of weight bearing.[265] Several studies have reported success in decreasing hypercalcemia and hypercalciuria with the use of bisphosphonates and calcitonin.[266]

Medication-Induced Hypercalcemia

Hypercalcemia is a common complication of therapy with vitamin D preparations. Hypercalcemia of vitamin D intoxication appears to be multifactorial, resulting primarily from a combination of increased GI absorption of calcium and increased bone resorption.[267] Classically, patients with vitamin D intoxication present with hypercalcemia, hyperphosphatemia, and markedly elevated levels of 25 (OH) vitamin D. Because PTH levels are appropriately suppressed, and because vitamin D and hypercalcemia both exert negative feedback on CYP27B1 in the proximal tubules, 1,25 $(OH)_2$ vitamin D levels are usually either normal or only slightly elevated.[268] The amount of vitamin D required to produce hypercalcemia has been estimated to be in excess of 25,000 to 50,000 IU per week. Therefore, it is unusual to see vitamin D intoxication from over-the-counter nutritional supplements. However, there have been reports of hypercalcemia due to poor quality control in the manufacture of these supplements.[269] There have also been outbreaks of vitamin D intoxication resulting from the accidental over supplementation of vitamin D into cow's milk by commercial dairies. Nevertheless, the majority of cases of hypercalcemia occur in patients treated with pharmacological doses of vitamin D or its analogues for the therapy of hypoparathyroidism, malabsorption or renal osteodystropy. The most frequent setting in which vitamin D use leads to hypercalcemia remains the treatment of secondary hyperparathyroidism complicating renal osteodystrophy. Treatment of vitamin D intoxication involves discontinuation of the vitamin D compound, volume expansion and calciuresis. If hypercalcemia is severe or refractory to the above, treatment with glucocorticoids and/or bisphosphonates may be necessary. The duration of hypercalcemia after the withdrawal of the vitamin D source depends on the biological half-life of the compound used.

Chronic lithium therapy is associated with modest increases in parathyroid gland size, which can lead to elevated levels of PTH and calcium.[270] Usually, after lithium therapy is stopped, the blood calcium and PTH levels normalize within several months. Rarely, however, persistent hyperparathyroidism may require parathyroidectomy. Lithium has been described to interfere with the function of CaSR and it increases the set point for PTH secretion in isolated parathyroid cells *in vitro*.[271]

Thiazide diuretics increase proximal tubular calcium reabsorption and may exacerbate hypercalcemia from other causes, such as primary hyperparathyroidism, sarcoidosis, or any other cause of a high, fixed calcium load.[272] Thiazides usually do not cause hypercalcemia in isolation.

Excess ingestion of vitamin A (retinol) results in a syndrome of dry skin, pruritus, pseudotumor cerebri, bone pain, and occasionally hypercalcemia.[273] Hypercalcemia occurs only with the ingestion of 10 times the Recommended Dietary Allowance (RDA) of 5000 IU/day. It can also result from ingestion of isotretinoin (13-cis-retinoic acid [Accutane]) and tretinoin (all-trans-retinoic acid [Retin-A]), which are used to treat acne and acute promyelocytic leukemia. Bones can show characteristic periosteal calcification on radiographs. The hypercalcemia is probably caused by the action of retinoids to stimulate bone resorption.[274]

Renal failure: Hypercalcemia can occur in acute and chronic renal failure but by different mechanisms. Hypercalcemia has been described during the diuretic phase of acute renal failure associated with rhabdomyolysis.[275] In most cases, hypocalcemia occurs during the acute phase of renal failure, and as renal function improves, hypercalcemia occurs. Although the mechanism responsible for the increase in serum calcium in patients with acute rhabdomyolysis is unknown, there are a number of theories. During the early phase of acute rhabdomyolysis the increase in serum phosphorus due to impaired glomerular filtration will lead to a fall in the serum calcium. As serum phosphorus falls during the diuretic phase of acute renal failure, calcium and phosphate salts that have been deposited in soft tissues may be liberated, causing transient hypercalcemia. Alternatively, excessive release of 25 (OH) vitamin D from injured muscle occurs as a result of acute rhabdomyolysis and may lead to increased substrate available for conversion to 1,25 $(OH)_2$ vitamin D as the

kidneys recover. Llach et al. have suggested that the hypercalcemia during the early diuretic phase was due to 1,25$(OH)_2$ vitamin D, which, in turn, was due to increased circulating PTH concentrations.[275]

Hypercalcemia is a common occurrence in patients with chronic renal failure on hemodialysis and can result from hyperparathyroidism, vitamin D intoxication, calcium antacid over ingestion, immobilization, aluminum toxicity or combinations of these factors. In addition, hypercalcemia is particularly common in the first year following renal transplantation. Renal bone disease and related disorders of mineral homeostasis are discussed in greater detail in Chapter 91.

Treatment of Hypercalcemia

The effective treatment of hypercalcemia requires the identification and correction of the underlying pathophysiology. Thus, the treatment for symptomatic primary hyperparathyroidism is surgical removal of the adenoma, and the treatment for malignancy-associated hypercalcemia is the eradication of the underlying neoplasm. Likewise, drugs implicated in hypercalcemia should be discontinued, endocrinopathies should be treated and immobilized patients should be mobilized. However, it is not always possible to fully correct the underlying condition and, sometimes, acute elevations in calcium can be life threatening. Therefore, here we review treatments that can be used to lower circulating calcium levels.

Moderate to severe elevations in serum calcium (above 12−13 mg/dl) usually are symptomatic and acute elevations above 15−16 mg/dl are often associated with an altered level of consciousness progressing to coma and multiple organ dysfunction. In addition, pre-renal azotemia caused by volume depletion can lead to rapidly escalating serum calcium levels in these situations. Therefore, treatments to lower calcium levels acutely should be instituted promptly once serum calcium reaches 13 mg/dl or higher. Principles of management include volume repletion, enhancement of renal calcium excretion, and inhibition of bone resorption.

As reviewed earlier, hypercalcemia leads to renal solute and water losses and all patients with significant hypercalcemia are volume contracted. Dehydration, in turn, limits the ability of the kidney to dispose of excess calcium. Therefore, restoration of the ECF deficit with 0.9% saline should be the first treatment for moderate to severe hypercalcemia. In severe hypercalcemia, this can require the infusion of isotonic saline at rates of 200 to 300 mL/hour, and it should be accompanied by close monitoring of electrolytes and cardiovascular status.[276] Once volume depletion is corrected, treatment with loop diuretics can be initiated to induce natriuresis, which further increases renal calcium excretion. Rehydration and forced saline diuresis can result in lowering of the serum calcium up to 1 to 1.5 mg/dL. In addition, this therapy helps to prevent progressive renal insufficiency and prevents calcium from rising further due to impairments in renal calcium excretion. It also is necessary to garner the full therapeutic effect of therapies directed at inhibiting bone resorption.

Increased bone resorption is a major contributing mechanism responsible for the hypercalcemia of primary hyperparathyroidism and most malignancies. Therefore, inhibition of bone resorption is an effective way to decrease the extracellular calcium concentration before disease-specific therapy is established. The advent of powerful bisphosphonates and more recently therapies directed against the RANKL/RANK cytokine system, has improved the treatment of hypercalcemia significantly, and in the setting of malignancy has enabled the chronic outpatient treatment of MAHC in at least some patients.

Calcitonin is the most rapidly acting antiresorptive agent. It acts directly on osteoclasts to inhibit bone resorption and also lowers renal calcium reabsorption. It can be given in doses of 4 to 8 IU/kg subcutaneously or intramuscularly every 6 to 12 hours.[276] This treatment can lower serum calcium by 1 to 2 mg/dL within several hours, but tachyphylaxis to calcitonin occurs within 24 to 48 hours, probably due to downregulation of calcitonin receptors. Calcitonin use can be particularly effective in the setting of severe hypercalcemia while waiting for the more sustained hypocalcemic effect of administered bisphosphonates to occur. In this regard, it has been shown that calcitonin use with bisphosphonates lowers calcium concentrations more quickly and effectively than either alone.[277]

Bisphosphonates are analogs of pyrophosphates. They have a high affinity for hydroxyapatite and concentrate at the bone surface in areas of high bone turnover. All bisphosphonates inhibit osteoclast function.[278] Non-nitrogen containing compounds, such as etidronate, tiludronate, and clodronate, do so by producing toxic analogs of ATP that cause cell death. Nitrogen-containing compounds, such as pamidronate, alendronate, risedronate and zoledronate, interfere with protein prenylation by inhibiting farnesyl pyrophosphatase, an enzyme in the HMG-CoA reductase pathway.[279] Bisphosphonates, in general, are poorly absorbed and are most effective in treating hypercalcemia when given intravenously. Pamidronate can be given as an intravenous infusion of 60 or 90 mg, which begins to lower serum calcium after 24 to 72 hours and leads to a nadir of calcium within five to six days.[276] Up to 70% of patients with MAHC given Pamidronate

achieve a normalization of calcium lasting up to 18 days. Zoledronate is the other bisphosphonate commonly used to lower calcium levels acutely. Intravenous infusions of 4 to 8 mg of zoledronate result in the normalization of calcium within three to five days in approximately 90% of patients with MAHC, with a duration of response lasting for up to 32 days. In a head-to-head trial, zoledronate resulted in more rapid and more durable remission of hypercalcemia in patients with MAHC than did pamidronate.[280]

Activation of the RANKL/RANK signaling pathway is a final common mechanism for most conditions of excess bone resorption. Therefore, as one might expect, pharmacological blockade of this pathway is particularly effective at inhibiting bone resorption and lowering calcium levels. Denosumab is a fully humanized monoclonal antibody that binds to RANKL and blocks its ability to interact with the RANK receptor. In this manner it mimics the actions of OPG, the natural inhibitor of RANKL signaling. While Denosumab is not formally approved specifically for the treatment of hypercalcemia, it has been shown to reduce the incidence of skeletal related events (including hypercalcemia) when given prophylactically to patients with established bone metastases.[281] Given that it is currently the most potent anti-resorptive agent available, it is likely to be quite effective for the treatment of hypercalcemia and may be especially useful in patients with underlying renal disease, given the potential renal toxicity of intravenous bisphosphonates.[282]

In addition to the above agents, two other classes of drugs can be useful in specific instances. Calcimimetics such as Cinacalcet have been successful in reducing hypercalcemia in trials of patients with primary hyperparathyroidism.[283] Medical therapy in this setting may be helpful in preparation for surgery or in patients that are not surgical candidates. Also, Cinacalcet has been documented to reduce calcium levels in patients with parathyroid carcinoma.[25,284] Glucocorticoids can be effective in hypercalcemic patients with hematologic malignancies, such as multiple myeloma or lymphoma, as well as in patients with granulomatous disorders such as sarcoidosis. They most likely are effective due to their ability to suppress local cytokine and 1,25 $(OH)_2$ vitamin D production.

HYPOCALCEMIA

Hypocalcemia is defined as a total serum calcium concentration of less than 8.4 mg/dl (2.1 mmol/liter) or an ionized calcium concentration of less than 4.48 mg/dl (1.12 mmol/liter). It is important to remember that the total calcium in serum includes both the free and the protein bound fraction. The most common cause of a low total calcium level in hospitalized patients is a reduction in the serum albumin level and, in those patients, ionized calcium levels are normal. Therefore, to make a diagnosis of hypocalcemia based on a total serum calcium level, one must have access to a concurrent measurement of serum albumin. Total serum calcium levels can be corrected for low albumin levels using the following simple formula:

Corrected Calcium Level $= (0.8 \times (4.0\ g/dL - Serum\ Albumin) + Serum\ Calcium$. However, this correction is not always accurate in individual patients, especially those with critically illness. Therefore, if the diagnosis of hypocalcemia is clinically important, an ionized calcium level should be measured to confirm the diagnosis.

Clinical Presentation of Hypocalcemia

The clinical presentation of hypocalcemia depends on the degree and the duration of the low calcium levels. Mild hypocalcemia (within 1 mg/dl below the normal range) is usually asymptomatic. More severe degrees of hypocalcemia can cause varying degrees of neuromuscular irritability, including perioral paresthesias, tingling of the fingers and toes, and spontaneous or latent tetany. Tetany can be elicited by percussion of the facial nerve, which results in contractions of the ipsilateral facial muscle (Chvostek's sign), or by inflating a blood pressure cuff for three to five minutes, which results in carpal spasm (Trousseau's sign). Alterations in membrane potential can present as electrocardiographic abnormalities, which include prolonged QT intervals and marked QRS and ST-segment changes that may mimic acute myocardial ischemia or conduction abnormalities. In severe hypocalcemia or during rapid changes in serum calcium, grand mal seizures or laryngospasm also are possible.[1]

Chronic hypocalcemia is often associated with a milder presentation and may be asymptomatic. However, if chronic hypocalcemia is accompanied by hyperphosphatemia as in PTH deficiency, calcification of the basal ganglia and occasional extrapyramidal disorders may be found. Similar types of calcium deposits can also occur in the lens and lead to cataract formation. When long-standing hypocalcemia is associated with hypophosphatemia as in vitamin D deficiency, growth plate abnormalities (rickets) can occur in children and defects in the mineralization of new bone (osteomalacia) can occur in both adults and children.

Causes of Hypocalcemia

Table 66.6 lists the numerous causes of hypocalcemia. These disorders can be divided into two broad

TABLE 66.6 Causes of Hypocalcemia

Inadequate PTH production/hypoparathyroidism
Iatrogenic
• Neck irradiation • Surgically induced
Infiltrative/Destructive Diseases
• Hemochromatosis • Sarcoidosis • Iron overload due to transfusion dependence in thalassemia • Wilson's disease • Amyloidosis • Metastatic carcinoma
Neonatal
• 2° to maternal hyperparathyroidism • 2° to maternal FHH
Autoimmune
Genetic or developmental disorders
• DiGeorge Syndrome • Activating calcium-sensing receptor mutation • Hypoparathyroidism, Deafness, and Renal Anomalies Syndrome (HDR) • Hypoparathyroidism-Retardation-Dysmorphism (HRD) • Mitochondrial gene defects
Functional hypoparathyroidism
• Magnesium depletion • Magnesium excess • Pseudohypoparathyroidism
Inadequate vitamin D production and action
• Nutritional deficiency • Lack of sunlight exposure • Malabsorption • Post-gastric bypass surgery • End-stage liver disease and cirrhosis • Chronic kidney disease • Vitamin D-dependent rickets type 1 and type 2
Miscellaneous Etiologies
Neonatal hypocalcemia
Hyperphosphatemia
• Phosphate retention in acute or chronic renal failure • Excess phosphate absorption caused by enemas, oral supplements • Massive phosphate release caused by tumor lysis or crush injury
Drugs
• Foscarnet • Intravenous bisphosphonate therapy—especially in patients with vitamin D insufficiency or deficiency
Rapid transfusion of large volumes of citrate-containing blood
Acute critical illness
"Hungry bone syndrome"
• Post-thyroidectomy for Grave's disease • Post-parathyroidectomy
Osteoblastic metastases
Acute pancreatitis
Rhabdomyolysis
Mitochondrial gene defects

groups: (1) those in which hypocalcemia is the result of lack of parathyroid hormone or resistance to parathyroid hormone; and (2) those in which the hypocalcemia occurs despite a normal parathyroid response. The most common cause of hypocalcemia is CKD, especially when creatinine clearance decreases below 30 ml/minute. Progressive renal insufficiency is associated with a complex of metabolic derangements including hyperphosphatemia, low 1,25 $(OH)_2$ vitamin D levels and skeletal resistance to the action of PTH, that lead to chronic hypocalcemia.[285,286] The development of metabolic bone disease in CKD is discussed in more detail in Chapter 91. Below, we will discuss a subset of the disorders listed in Table 66.6 found in patients without a history of CKD.

Hypoparathyroidism

Hypoparathyroidism may be caused by inherited or acquired diseases of the parathyroid gland that result in the impaired synthesis and/or secretion of PTH. Pseudohypoparathyroidism refers to PTH resistance which results in functional hypoparathyroidism, a phenomenon that can also be caused by magnesium deficiency.

Congenital or genetic disorders causing hypoparathyroidism: Congenital hypoparathyroidism has been associated with specific mutations in the signal peptide sequence of the PTH gene, which prevents the appropriate processing and secretion of prepro-PTH.[287] Congenital hypoparathyroidism can also present as part of a syndrome including renal dysplasia and sensorineural hearing loss (HDR), which has been related to mutations in the GATA3 gene.[288–291] Hypoparathyroidism due to defective embryogenesis or parathyroid gland agenesis becomes evident in the neonatal period and is often associated with other branchial cleft abnormalities. The most common of these is the DiGeorge syndrome, which can include absence of the thymus with immunodeficiency, facial abnormalities, and major vascular and cardiac defects.[292,293] Mutations in the glial cell missing B

(GCMB) gene can cause isolated parathyroid gland agenesis.[294–296] Mutations in the CaSR gene can also result in hypoparathyroidism.[297–301] Autosomal dominant hypocalcemia (ADH) is a mirror image of FHH and is caused by activating mutations in the CaSR gene.[275,302] Patients with ADH present with mild to moderate hypocalcemia, hyperphosphatemia, high renal calcium excretion and a low (but measureable) PTH level. Patients with ADH often also present with hypomagnesemia and hypermagnesuria. Some kindreds also present with a picture consistent with Type V Barters (hypokalemia and alkalosis) thought to be due, in part, to the effects of the CaSR on sodium absorption in the thick ascending limb of the Loop of Henle.[303]

Hypoparathyroidism can also develop as the result of autoimmune attack on the parathyroid glands. This can occur in the context of the polyglandular autoimmune syndrome type I. Polyglandular autoimmune (PGA) syndromes are constellations of multiple endocrine gland insufficiencies. PGA Type I is an autosomal recessive disorder with a minor female predominance caused by mutations to the autoimmune regulator (*AIRE*) gene, which codes a nuclear transcription factor involved in the deletion of self-reactive T-cells in the thymus.[304,305] Hypoparathyroidism in PGA type I most commonly occurs in childhood or adolescence and is associated with chronic mucocutaneous candidiasis and primary adrenal insufficiency. Primary hypogonadism, diabetes mellitus, pernicious anemia, vitiligo and autoimmune thyroid disease also occur in this syndrome, although usually after the onset of hypoparathyroidism.

Acquired hypoparathyroidism: Autoimmune hypoparathyroidism can also occur later in life without other autoimmune manifestations. The pathophysiology of this entity is not well understood although autoantibodies against the CaSR are present in almost 30% cases of acquired hypoparathyroidism. How, or if these autoantibodies contribute to the destruction of the parathyroid glands is not known.[306,307]

Most commonly acquired hypoparathyroidism is the result of thyroid, parathyroid, or radical neck surgery.[287] It may be transient, intermittent or permanent. Transient hypoparathyroidism may be due to changes in blood supply to or removal of one or more parathyroid glands during surgery, whereas intermittent hypoparathyroidism is due to decreased parathyroid reserve. Transient hypoparathyroidism may also occur after removal of a parathyroid adenoma as a result of temporary suppression of the remaining parathyroid tissue by the chronically elevated calcium levels caused by the adenoma. It resolves as the remaining glands resume normal function. Some patients with severe hyperparathyroidism develop "hungry bone syndrome" after parathyroidectomy.[308] This syndrome can cause prolonged hypocalcemia and results from the combination of the large influx of calcium and phosphate into healing bones and the relative hypoparathyroidism induced by the preexisting hypercalcemia and/or surgical manipulation of the parathyroid glands. Permanent hypoparathyroidism occurs in patients in whom all parathyroid glands are inadvertently removed/damaged during surgery. They typically become hypocalcemic within 24 hours and remain hypoparathyroid for the duration of their lifetime. Whereas transient hypoparathyroidism occurs in up to 20 percent of patients after surgery for thyroid cancer, permanent hypoparathyroidism occurs in only 0.8 to 3.0 percent of patients after total thyroidectomy.[309]

Acquired hypoparathyroidism can also occur as a result of infiltrative diseases such as hemochromatosis or Wilson's disease.[287] The parathyroid glands can also be destroyed by metastatic tumors and by external radiation to the neck or radioactive iodine therapy for Graves' disease.

Severe magnesium deficiency is a cause of functional hypoparathyroidism as it impairs PTH secretion and causes resistance to the action of PTH in bone and kidneys. Interestingly severe hypermagnesemia can also lead to hypocalcemia due to inhibition of PTH secretion. Parathyroid function is corrected by the return of magnesium levels into the normal range.[310–312]

Diagnosis and treatment: Hypoparathyroidism is suspected in patients with hypocalcemia and hyperphosphatemia in the setting of normal renal function. The diagnosis is confirmed by the finding of a low or low-normal PTH level. Patients will usually also have a low 1,25 $(OH)_2$ Vitamin D level. The presence of cataracts or basal ganglia calcification suggests that the hypocalcemia has been long-standing.

Most patients with hypoparathyroidism require lifelong calcium and vitamin D supplementation. The goals of therapy in patients with hypoparathyroidism are to relieve symptoms and to raise and maintain the serum calcium concentration in the low-normal range. The main complication of treatment for hypoparathyroidism is the development of hypercalciuria and nephrocalcinosis or nephrolithiasis, which put the patient at risk for renal insufficiency.[313] This is the result of the loss of distal tubular calcium reabsorption in the absence of PTH. A large rise in the urinary calcium excretion in the setting of therapy for hypoparathyroidism should raise the possibility of ADH, since chronic activation of the CaSR in the renal tubule will make patients intolerant of the usual therapy with vitamin D and calcium.[287] Therefore, the careful monitoring of urinary and serum calcium are essential and the dose of calcium and vitamin D should be reduced if

urinary calcium excretion is elevated (≥4 mg/kg in 24 hours) or if the serum calcium level is within the normal range. The use of a thiazide diuretic, can also help to decrease urinary calcium excretion in some patients.[272] Ongoing studies suggest that recombinant human PTH or PTH analogues may provide better correction of serum calcium levels without the same risk of hypercalcuria.[314] However, the use of PTH for this purpose has been hampered by its short half-life and expense. In addition, the long-term safety of PTH has not been established, particularly in growing children who may be at greater risk of osteosarcoma. Nevertheless, multiple daily injections of PTH 1-36 have been reported to be helpful in the short-term management of patients with post-operative hypocalcemia that has been difficult to treat with standard therapy.[315,316]

Pseudohypoparathyroidism

Pseudohypoparathyroidism (PHP) is a heterogeneous syndrome characterized by functional hypoparathyroidism, increased serum PTH concentrations and peripheral resistance to the biologic actions of PTH.[317] In 1998, a Japanese epidemiologic study estimated the prevalence of pseudohypoparathyroidism to be 3.4 cases per 1 million people.[318] No information is available regarding the prevalence of PHP in the rest of the world. PHP occurs approximately twice as frequently in females as in males. Patients with PHP often have a number of somatic abnormalities, which are referred to collectively as Albright's hereditary osteodystrophy. These include short stature, round facies, thick neck, barrel chest, subcutaneous ossifications, bradydactyly with disproportional shortening of the fourth and fifth metacarpals/metatarsals, obesity and mild mental retardation.[319] Several variants of PHP have been identified, which result from different abnormalities in the imprinting and tissue-specific expression of the *GNAS1* gene encoding the alpha subunit of the stimulatory G protein ($G\alpha_s$). The three different forms of the disease are PHP type 1a, pseudopseudohypoparathyroidism (pseudo-PHP) and PHP type 1b.[320]

Pseudohypoparathyroidism type Ia is caused by heterozygous loss-of-function mutations in the *GNAS1* gene. This presents as an autosomal dominant disorder but *GNAS1* is an imprinted gene and the presentation of this disorder is determined by whether the subject inherits the mutation from his or her mother or father.[321] Patients who inherit the mutant *GNAS1* gene from their father present with pseudo-PHP and patients who inherit it from their mother exhibit PHP. This is because expression of the paternal allele of GNAS is silenced, or imprinted, in a variety of tissues including the proximal renal tubule. Therefore, if a patient inherits a GNAS mutation from his or her mother, then he or she will have only the paternal allele to rely on. However, as a result of imprinting, many tissues will inactivate that allele and effectively be *GNAS*-null. These patients will present with AHO (Albright's hereditary osteodystrophy), which results from reduced GNAS expression during development, biochemical hypoparathyroidism and PTH resistance. These patients classically have a decreased response of the proximal tubule to PTH, which can be characterized by a diminished nephrogenous cAMP response to PTH administration.[322] In addition, due to the importance of $G\alpha_s$ and cAMP signaling downstream of many peptide hormones, patients with pseudohypoparathyroidism type 1a often manifest mild resistance to other hormones such as TSH, LH and FSH as well.[323] In contrast, if the patient inherits a GNAS mutation in the paternal allele, he or she will still suffer from AHO because of the developmental consequences of having only one normal *GNAS* allele. However, imprinting of the mutant allele will leave other adult tissues with their normal complement of one normal *GNAS* allele. These patients do not manifest PTH or other hormone resistance, they have normal serum calcium and phosphate levels and they have a normal nephrogenous cAMP response to PTH. These patients are referred to as having pseudo-pseudohypoparathyroidism.[324]

Patients with pseudohypoparathyroidism type Ib lack the phenotype of AHO and exhibit hormone resistance that is limited to the action of PTH in the kidney. These patients have been described to carry mutations in far upstream regulatory elements of the GNAS gene that are thought to be involved in the control of paternal GNAS gene methylation and its silencing in the kidney.[325,326] Because the PTH resistance is limited to the kidney, these patients are at risk for skeletal complications (osteoporosis or osteitis fibrosa cystica) due to chronic elevations in PTH, despite their biochemical profile of hypoparathyroidism and renal PTH resistance.[327]

Another less well-defined group of patients present with biochemical hypoparathyroidism and an insufficient phosphaturic response to PTH, but have an appropriate nephrogenous cAMP response to PTH and normal $G\alpha_s$ activity. This disorder is termed pseudohypoparathyroidism type II and may be due to intracellular resistance to the effects of cAMP, most likely caused by a defect in cAMP-dependent protein kinase.[328,329]

Laboratory findings in patients with PHP are similar to those seen in patients with hypoparathyroidism and include hypocalcemia, hyperphosphatemia, and a decreased serum $1,25(OH)_2D_3$ concentration. The important feature that distinguishes PHP from hypoparathyroidism is an increased instead of decreased

serum PTH concentration. The Ellsworth-Howard test can be used to classify the type of pseudohypoparathyroidism.[330] PTH is administered to the fasting patient after control serum and urine samples are obtained. Serum and urine are then collected during the first and second half-hours, and the second and third hours after the PTH infusion. Samples are analyzed for cAMP, phosphorus and creatinine. In normal subjects and in hypoparathyroid patients PTH induces a 10- to 20-fold increase in urinary cAMP excretion. In patients with pseudohypoparathyroidism type I (a and b) the response is markedly diminished. Patients with pseudohypoparathyroidism type II have a normal cAMP response, but an abnormal phosphaturic response to PTH. Classification of the type of pseudohypoparathyroidism has no impact on therapy. Management of the hypocalcemic PHP patient is similar to that of the hypoparathyroid patient and involves the administration of calcium and vitamin D. However, due to the intrinsic defects in PTH response, treatment with PTH will not be effective in raising calcium or lowering phosphate levels.

Vitamin D–Related Disorders

Vitamin D deficiency is common in the general population and is especially prevalent in patients without much exposure to sunlight, for example in institutionalized patients, the elderly, shut-ins, and those with chronic medical illness. In fact, one survey of inpatients in Boston suggested that up to 57% of patients admitted to a general medical ward were vitamin D deficient.[331] Even in a random sample of healthy adolescents, vitamin D deficiency was present in more than 24% of subjects.[332]

As discussed previously, levels of vitamin D vary with the season so that the prevalence of vitamin D deficiency is elevated in winter months. The prevalence of vitamin D deficiency is also greatly affected by the definition of a normal vitamin D level. This has been a controversial topic for several years.[333] Historically, the lower end of the normal range had been defined by the presence of secondary hyperparathyroidism and was set at a circulating 25 (OH) vitamin D level of 15 ng/ml. However, based on a series of epidemiological studies examining parameter such as fracture rates, PTH levels and falls, it was suggested that vitamin D levels should be over 30 ng/ml.[334] However, a recent review of this literature by the Institute of Medicine suggested that 20 ng/ml was a more accurate reflection of the lower end of the normal range.[335] This conversation will undoubtedly continue, but most patients with mild vitamin D deficiency do not demonstrate frank hypocalcemia, presumably because the serum calcium level is supported by increased PTH secretion. Overt hypocalcemia due to vitamin D deficiency is unlikely to occur in patients with levels over 15–20 ng/ml, unless they are also severely calcium deficient or they are on medications that lower bone resorption such as bisphosphonates.[336]

When it does occur, the primary mechanism of hypocalcemia in vitamin D deficiency is decreased intestinal absorption of calcium. In distinction to hypoparathyroidism, vitamin D deficiency is accompanied by hypophosphatemia and increased renal phosphate clearance as a result of secondary hyperparathyroidism. That compensatory response is a consequence of the hypocalcemic stimulus to PTH secretion as well as the stimulation of PTH gene expression and parathyroid cell proliferation by low vitamin D levels. The secondary hyperparathyroidism results in increased calcium mobilization from the skeleton, increased renal reabsorption of calcium, and increased renal 1α-hydroxylation of 25 (OH) vitamin D. Therefore, in all but the most severe vitamin D deficiency, circulating 1,25 $(OH)_2$ vitamin D levels are actually normal or elevated even though 25 (OH) vitamin D levels are low.[337]

Most patients with hypocalcemia and Vitamin D deficiency suffer from a deficiency of vitamin D synthesis and/or malabsorption. Malabsorption is an important cause of vitamin D deficiency in all age groups. Fat malabsorption from any cause or short-bowel syndrome can result in enteric losses of vitamin D. Fat malabsorption should be ruled out in patients with very low 25 (OH) vitamin D levels (<10–15 ng/dL). A number of medications cause vitamin D deficiency. Anticonvulsant medications and antituberculosis therapy are classic examples of medication that accelerate the hepatic inactivation of vitamin D.[338]

Impaired 1-alpha hydroxylation of 25(OH) vitamin D: The most common cause of a defect in 1 alpha-hydroxylase activity is CKD. Impaired 1α-hydroxylation is observed once the creatinine clearance decreases to approximately 30 to 40 mL/minute. Deficiency of 1,25 $(OH)_2$ vitamin D as a result of CKD most likely contributes to the disordered mineral metabolism and parathyroid hyperplasia that are characteristic of longstanding CKD.[339,340] This topic will be discussed in more detail in Chapter 91.

A form of congenital rickets can result from autosomal recessive, loss-of-function mutations in the *CYP27B1* gene.[127] This disorder is known as pseudovitamin D deficiency Rickets or Vitamin D-Dependent Rickets Type 1. Biochemically, this disorder is characterized by hypocalcemia and secondary hyperparathyroidism. The only metabolic abnormalities that differentiate it from dietary vitamin D

deficiency are the presence of normal or elevated levels of 25 (OH) vitamin D and very low levels of 1,25 $(OH)_2$ vitamin D, despite the elevated PTH levels. The disease is inherited in an autosomal recessive fashion and patients present in infancy with rickets, osteomalacia, and seizures, which resolve with therapeutic replacement of 1α-hydroxylated metabolites of vitamin D.[341]

Target organ resistance to 1,25-dihydroxyvitamin: Hereditary vitamin D-resistant rickets (HVDRR, also known as vitamin D-dependent rickets, Type 2) is characterized by resistance to biological effects of calcitriol due to inactivating mutations in the VDR gene.[342,343] This disorder is inherited in an autosomal recessive fashion and patients present with hypocalcemia, hypophosphatemia, secondary hyperparathyroidism and elevated levels of 1,25 $(OH)_2$ vitamin D. The presentation varies but most patients with HVDRR present in infancy or in adolescence with hypophosphatemia, rickets, seizures and, in some families, alopecia totalis.[344,345] Patients require lifelong therapy with large doses of vitamin D3, 1,25 $(OH)_2$ vitamin D and calcium. Therapeutic efficacy is variable and depends on the amount of residual VDR function contained within the mutant receptor. If loss of VDR activity is complete, than calcium infusions along with high doses of oral calcium are necessary to provide enough calcium to heal the rickets and/or maintain adequate bone mineralization.[346]

A variety of other conditions can cause mild to moderate hypocalcemia and these are listed in Table 66.6.

Treatment of Hypocalcemia

A calcium concentration, corrected for albumin, of less than 7.5 mg/dl in a patient with or without symptoms is an indication for treatment. The serum calcium should be increased back into the range (>7.5–8.0 mg/dl) in which symptoms and complications do not occur. Long term objectives are to prevent skeletal deformity and osteomalacia and to resolve secondary hyperparathyroidism while preventing hypercalciuria and hypercalcemia. When treating a pediatric population, the normal growth and development of bones is the priority with the same careful follow up to avoid complications.

Acute management: Severe hypocalcemia may be associated with life-threatening symptoms, in which case urgent treatment with parenteral calcium is indicated.[1] Patients who require immediate attention may exhibit a positive Chvostek's or Trousseau's sign, seizures, papilledema, hypotension, and prolonged ST segment and QT intervals on EKG. This is most likely to occur when the onset of hypoparathyroidism is abrupt. It may also occur in the patient with widespread osteoblastic metastases, tumor lysis, acute pancreatitis, or hungry bone syndrome. In any of those settings, the hypocalcemia is usually of acute onset and associated with significant symptoms. Hence, the calcium concentration should be corrected rapidly. In the case of overt tetany, 10 to 20 ml of calcium gluconate (90 mg of elemental calcium in 10 ml), diluted in 50 to 100 ml of 5% dextrose should be infused intravenously over 10 minutes. Continuous cardiac monitoring is important particularly if the patient is receiving digoxin as serious cardiac arrhythmias may occur. When managing recurrent symptomatic hypocalcemia, a continuous infusion of calcium gluconate should be instituted to provide 10 to 15 mg/kg of elemental calcium over approximately six to eight hours. Calcium chloride can also be used but is more irritating at the site of venous access. If hypocalcemia is likely to persist, therapy should be initiated early with oral calcium supplements (1 to 2 grams of elemental calcium) and calcitriol (0.5 to 1.0 micrograms) daily. Hypomagnesemia, if present, should be corrected with magnesium sulfate intramuscularly or intravenously. Intramuscular injections may be painful, in which case a continuous infusion of 48 mEq of magnesium for 24 hours may be administered. Magnesium therapy should continue for several days in order to restore intracellular magnesium and should be extended as long as the cause of hypomagnesemia is present. The dose of magnesium should be reduced by 50% in patients with renal insufficiency, and the serum magnesium concentration should be followed closely.

Chronic treatment: Most patients with chronic hypocalcemia will require both calcium (1 to 2 g elemental) and vitamin D to maintain a serum calcium concentration in the low normal range. A variety of vitamin D preparations are available and they vary in biologic activity, cost, and duration of effect. Calcitriol can be used for treatment of all chronic hypocalcemic states as it is the biologically active form of vitamin D. The principal advantages of calcitriol are its rapid onset and short duration of action, which minimizes the risk and duration of hypercalcemia in case of unintentional overdose. Calcitriol is the optimal modality in patients with hypoparathyroidism, pseudohypoparathyroidism, and renal failure, as these states are characterized by a deficiency of 1,25 $(OH)_2$ vitamin D. Nevertheless, treatment with high doses of cholecalciferol, ergocalciferol, or calcifediol can increase serum concentrations of 25-hydroxyvitamin D sufficiently to act directly on the vitamin D receptor. Calcidiol binds to the vitamin D receptor, but with far lower affinity than that of 1,25 $(OH)_2$ vitamin D3. These preparations also have a longer duration of action than calcitriol and can result in

prolonged hypercalcemia should overdosage occur.[347] In patients with vitamin D malabsorption causing the hypocalcemia, it would be appropriate to treat with the parent vitamin D compound, ergocalciferol. In severe liver disease, since the formation of 25-hydroxyvitamin D is impaired, calcifediol may be used. Vitamin D requirements may change as a consequence of concomitant administration of anticonvulsants, thiazide diuretics, oral contraceptives, and antacids, or the presence of electrolyte disturbances such as hypomagnesemia or hyperphosphatemia. Requirements may also change during pregnancy due to increased levels of DBP and the production of calcitriol by the placenta.[348] 1 to 2 g of elemental calcium given together with vitamin D should be sufficient to meet the goals of therapy in most patients. As discussed before, the dose of calcium should be adjusted to maintain the total serum calcium concentration in the low normal range (8.0 to 9.0 mg/dl) with the 24-hour urinary calcium excretion not to exceed 4 mg/kg/day to prevent hypercalciuria, nephrolithiasis, nephrocalcinosis and renal impairment. In patients with hypoparathyroidism, addition of a thiazide diuretic may decrease vitamin D requirements by decreasing urinary excretion of calcium, especially when used in combination with moderate salt restriction. Diet recommendations are also important to facilitate achieving treatment objectives. Foods that are high in phosphate, such as dairy products, should be limited to avoid hyperphosphatemia, which may cause soft tissue calcification and impair the efforts to raise serum calcium levels.

Pathogenesis and Treatment of Nephrolithiasis

Fredric L. Coe[1], *Andrew Evan*,[2] *and Elaine Worcester*[1]

[1]University of Chicago School of Medicine, Chicago, Illinois, USA

[2]Indiana University, Indianapolis, Indiana, USA

Stone forming patients are labeled by the stones they form. The largest group form calcium stones (calcium oxalate (CaOx), calcium phosphate (CaP), or a mixture of both); others form stones containing primarily uric acid (UA), struvite (infection stones), or cystine. The pathogenesis of each stone type differs; clinical evaluation, therefore, begins with analysis of all available stones. A large fraction of the common calcium stone formers have no systemic disease but do excrete more calcium than the average person, an inherited trait (idiopathic hypercalciuria, IH) that probably reflects the simple fact that risk of calcium stones increases with rate of urine calcium excretion. These "idiopathic" calcium stone formers (ICSF) produce stones mainly of CaOx crystals, and are by far the most common kind of patient a physician will encounter in practice. All ICSF studied thus far exhibit the same renal histopathology and surgical anatomy, and appear to form their stones via a single highly defined pathway, and therefore represent what amounts to a well-defined specific disease. By contrast, idiopathic calcium stone formers whose stones contain over 50% CaP (IPSF) have renal histopathology, surgical anatomy, and mechanisms of stone production that differ radically from those of ICSF, though they share IH as a common physiological trait. Patients with calcium stones due to systemic diseases such as primary hyperparathyroidism, distal renal tubular acidosis (RTA), ileostomy, small bowel resection, and obesity bypass procedures exhibit renal histopathologies, mechanisms of stone production, and treatments that are specific to the underlying disease. Despite their heterogeneity, all stone diseases share formation of unwanted solid phase crystals that produce similar clinical syndromes. As well, crystals nucleate and grow according to natural laws one can use in clinical practice.

STONES, CLINICAL PRESENTATION, AND NATURAL HISTORY

Crystals form in urine of virtually all healthy people, but among those destined for stone disease they are coarser and larger, and cause a syndrome of pain and hematuria which often eludes diagnosis for some time, the crystals being dispersed or not looked for. As perhaps a second stage, though the continuity may be more apparent than real, crystals become so large and dense they form a gravel or sand-like material whose passage is gritty and evident. Such attacks of gravel with or without bleeding are usually recognized by patients and diagnosed as a kind of stone problem. Certainly the conventional passage of a formed stone is a step beyond gravel, if only because the formed stone may lodge along the urinary tract and demand a procedure to remove it. Pain is usual though not invariant, as is bleeding. Finally, stones and plaques of crystal may form along the calyces and papillary tips, forming the radiographic pattern of nephrocalcinosis that may or may not be associated with stone passage, gravel, or crystalluria with hematuria. Thus is stone disease divided into at least four great divisions as seen by patients and doctors, though all arise in similar ways.

Nature of Stones and Crystals

Formed stones are a complex of proteins interlaid with crystals, like a kind of disordered mineralized

tissue. The matrix proteins include Tamm-Horsfall protein (THP), osteopontin, albumin, prothrombin fragments, and other urine proteins. The crystals are most often CaOx, monohydrate (COM) or dihydrate (COD)[1,2,3] (Table 67.1), often admixed with CaP species such as apatite (APA) and brushite (BR), less often admixed with UA. In a smaller number of patients (12% of 2011 patients seen in the University of Chicago Kidney Stone Clinic with stone analyses), stones are predominantly or completely composed of CaP[4,5]; CaP stones are more common in women. In another 7% of our patients, stones were predominantly UA. Uncommon stones (each seen in fewer than 2% of patients) include those of cystine, struvite, ammonium acid urate, and drugs (Table 67.1). Because each kind of stone crystal evidences a particular disorder of urine supersaturation, stone analysis is the bedrock of clinical practice. Repeated stones all deserve analysis, as urine chemistry changes with time, and a change in composition may signal a need for change of treatment.

Clinical Presentation

Renal Colic

The pain from passage of a stone begins as a discomfort, often not called a pain, and progresses over 30 minutes or so to a plateau of extreme severity, which remains constant thereafter unless medications are given or the stone moves. The pain of a stone in the renal pelvis and upper ureter is over the lateral and anterior abdomen on one side, in a broad band from the ribs downward, and is not well localized. As the stone moves down, the pain moves in parallel, toward the bladder, and a downward moving pain is sure evidence of stone movement. At the uretero-vesical junction, stones often lodge and produce urinary frequency and urgency, dysuria, and hematuria, the complex easily misdiagnosed as urinary infection if symptoms begin there. This latter is common with small stones that easily pass the upper ureter but stick at the bladder junction, and give their first symptoms there. When the stone passes into the bladder, obstruction is relieved and pain disappears on the instant, with a speed unlike any other known pain.

The character of colic is not describable. All attest to severity surpassing any other pain that afflicts humankind, but poets and writers alike fall silent when asked to describe it. What little we have been offered suggests a deep boring and hot sensation, but no more detail than that. Colic is diagnosed by its curious timing, progress, peculiar intensity, and magical disappearance. On the left side, colic can resemble diverticulitis, except the latter causes constipation, whereas colic causes diarrhea and vomiting. On the right it mimics biliary colic, but is too lateral, too severe, too detached from eating, and unnatural in its downward progress. We[6] have constructed long lists of differential diagnosis, but find the problem pointless, because no one mistakes renal colic, for long, as anything other than what it is.

Radiography of Stones

CaOx and CaP stones tend to be small (1–10 mm), bright, and circumscribed. UA stones are famously radiolucent on routine radiography, but can be easily visualized by computed tomography (CT) scan done without contrast infusion. Cystine stones are only faintly visible on routine x-rays, so that we often underestimate size, but CT is ideal for them. A struvite stone, being an amalgam of magnesium ammonium and calcium phosphate crystals and much protein that is made by waves of bacterial overgrowth, naturally appears like a gnarled root. Ultrasound detects stones, but is less sensitive for small stones and does not show anatomy well compared with CT.[7] Because noncontrast CT gives an excellent view of the renal pelvis and of whether there is obstruction, it is our preferred mode of visualization. Protocols using lower doses of radiation are under investigation to evaluate their diagnostic accuracy, and may become preferred in order to limit radiation exposure.

Stones pass in inverse proportion to their size,[8] although time to passage may require four to six weeks.[9] Below 5 mm, passage is common, while ureteral stones greater than 7 mm in diameter pass spontaneously less than 50% of the time. Above 10 mm, passage is unlikely. Stones in the distal ureter are more likely to pass than those located more proximally. Large stones in the renal pelvis grow at leisure and can gradually fill up the collecting system. Such behavior is

more usual for struvite, UA and cystine stones, but CaOx stones do attain such stature occasionally. A stone that fills at least two calyces is called a stag horn stone, although this old and picturesque name is better reserved for stones that fill all of the calyces, and have the shape of a stag's horns.

Urinalysis

Given that crystals are coarse and often symptom producing, one might think that urinalysis is valuable in clinical practice of stone prevention, but our experience is the opposite. It is true that one can teach urine crystal morphology in a stone clinic, and the appearances of crystals under the microscope are beguiling, especially under polarized light, but the impact on diagnosis is modest. In addition, a single sample of urine may not represent the daily average. However, at least one study shows that persistent crystalluria in a first morning urine while on treatment is correlated with relapse.[10]

COM crystals are small dumbbell shapes that can superficially resemble red blood cells. The more dramatic COD is bipyramidal, as shown in all usual atlases. UA forms a reddish dust, because it absorbs uricine, a bilirubin metabolite and is an indication of low urine pH. Calcium phosphates are often small, and called "amorphous," though they are in fact crystalline if seen under higher magnification. Calcium phosphates form whenever urine pH is much above 6.5, and may be irrelevant to stone formation or not depending on how well the spot urine pH represents that of the average 24-hour urine. Crystals occur in casts, and such casts have no established significance. Cystine crystals are found in urine of most cystinuric patients, and have little significance as the cool temperature of the room as compared with the body can allow crystals that are not present *in vivo*. Of course, they may be the first clue as to the correct diagnosis. Perhaps the most valuable finding is a urine pH above eight, which suggests infection with urea hydrolyzing bacteria, and requires follow up with urine culture. Overall, we hesitate to seem skeptical of urinalysis, given its preeminence in nephrology, but in the stone clinic it is more of aesthetic visual than clinical interest.

NATURAL HISTORY

Epidemiology

In the United States, 11% of men and 5.6% of women will report having formed a stone by their seventh decade; the risk is about three times higher in whites compared with African Americans, but has increased in both groups as well as both sexes over the past three decades.[11] Although this may reflect, in part, improved radiologic detection of asymptomatic stones, a true increase in stone formation seems likely based on hospitalization rates. Obesity is associated with increased risk for stone formation, which rises with body mass index and waist circumference, especially in women.[12]

Stone formation is associated with an increased risk of chronic kidney disease, although the mechanism is not known.[13] There also appears to be an increased risk of hypertension among stone formers,[14] and an attendant increase in risk of cardiovascular disease.[15]

There is a significant genetic component to stone formation. In studies comparing stone rates in male twins, the concordance rate for stones was 32% in monozygotic compared with 17% in dizygotic twins.[16] Similarly, in a longitudinal cohort of adult men, those with a family history of stones were 2.5 times more likely to form a first stone over eight years of follow-up than those without.[17] A number of rare monogenic diseases are known which predispose to stone formation.[18] However, most of the genetic predisposition appears to be polygenic, and is strongly influenced by environmental triggers, as seen in diseases such as hypertension and diabetes.

Recurrence

Following a first stone you may confidently predict that 50% of patients will form at least one more stone after eight years and 75% will recur by 15 years.[19] In those with more than one stone, recurrence occurs sooner; approximately 45% of such ICSF will have a new stone within three years. Once recurrent, stones maintain a one- to two-year interval between themselves in the average patient, although the spread is very wide. We have tried in vain to properly characterize high-velocity stone formers.[20] When we have analyzed the stone history of patients with many stones we find the rate of stones per year surprisingly constant and that stone number increases pari passu with how long people wait from their first stone to obtaining preventative treatment. On the other hand, we find many patients in whom a single stone episode will yield a collection of dozens or perhaps hundreds of small stones passed within hours or days, whereas for most people an episode is no more than a single stone. We have never understood how batches of stones are made and passed within a day's span.

PRIMARY PROCESS OF CRYSTALLIZATION

Solid phase begins as the association of ions or molecules in solution reduce the energy of bonds with

water molecules so much that they leave the solution as so-called solid-phase nuclei. For calcium and oxalate, or calcium and phosphate, the association involves formation of dissolved salts; for uric acid and cystine, the molecules associate with themselves, mainly by hydrophobic forces. In either case, for practical purposes, one finds that nuclei form as some critical concentration is reached.

The Notion of Supersaturation

An ideal formal statement of the critical concentrations for nucleation is to compare salt or molecular concentrations of a solution to those at the solubility, any excess being called the supersaturation (SS), and implying the solution is carrying more than it can hold. This naive idea gives the right sense of SS, in begging the question of what is meant by "more than it can hold." If crystals of a salt are incubated for some time, usually 48 hours, with a solution that is initially free of the salt, the concentrations of salt in solution will increase until the crystals no longer dissolve. This concentration is called the solubility and is empirically determined, being otherwise unknowable. A solution that contains the solubility concentration is called saturated. Values for CaOx, calcium monohydrogen phosphate (BR) (a commonly measured initial phase of calcium phosphate), and undissociated UA are (in μM/l) 6.2, 0.39, and 520, respectively.

If one slowly adds calcium and oxalate to a saturated solution it will remain clear. The salt concentration will rise above solubility, and the solution is called supersaturated. The level of SS may be expressed as the ratio of the concentration of the dissolved salt to its solubility. The solution is metastable in that the extra salt, CaOx, for example, will crystallize out and bring the solution to solubility given any of a number of perturbations. The most obvious is to add seed crystals of, for example, CaOx, which will grow until equilibrium is restored. Seeds of CaP, or UA, which are "heterogeneous," will also promote formation of CaOx nuclei on their surfaces and deplete the system back to solubility. The same is true for cell debris and aggregated proteins. If one continues to add calcium and oxalate, but not a solid seed, SS will rise to a critical point called the upper limit of metastability (ULM),[21] which is an empirical limit at which CaOx nuclei will form spontaneously, and bring the solution back down to solubility.

Actual values for SS and the ULM can be determined in human urine (Fig. 67.1). For CaP (Fig. 67.1, open circles) the SS values of normal urine range from 0.1 to 5, versus 2 to 20 for CaOx (Fig. 67.1, stars). The ULM can be determined by adding sodium oxalate to aliquots of the urine, to achieve a CaOx ULM, or calcium chloride, to obtain the CaP ULM. Among healthy individuals, the ULM is strongly dependent upon, but considerably above, the SS,[22] as shown by the position of all points above the line of identity. ULM values range from two- to 11-fold above SS for CaP and 11- to 50-fold for CaOx. How ULM varies with SS is not understood, but that it does so reflects a highly protective set of mechanisms that appear to be aimed at defense against renal crystallization.

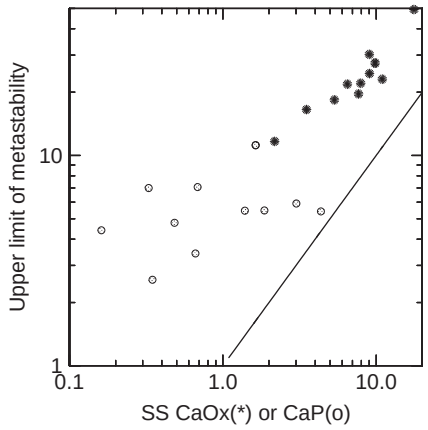

FIGURE 67.1 Relationship between upper limit of metastability (ULM, y-axis) and urine supersaturation (x-axis) for calcium oxalate (stars) and calcium phosphate (open circles). The diagonal line is the line of identity. ULM rises with supersaturation for both phases. Values are from normal individuals.

Relationship of Supersaturation to Stone Composition

As measured clinically SS represents two or three days of urine measurement out of a lifetime, and one wonders to what extent such a slim sampling can be useful in predicting formation of solid phases over the months to years that stones begin and grow in the renal collecting system. In fact, SS appears to be a very robust measure of long-term crystallization forces. Among men and women whose stones were predominantly CaOx (Fig. 67.2), COM SS was above corresponding same-sex normal values, whereas CaP and UA SS values were not. Among patients whose stones were predominantly CaP (Fig. 67.2), CaP SS was above same-sex normal values, whereas COM SS was not. Naturally, because higher urine pH favors CaP SS and reduces UA SS, UA SS is lower than normal in this group. Among patients with UA stones, UA SS is above normal and COM SS is not. Overall, even when measured only a few times, urine SS reflects at least the main components of stones, and therefore one must conclude that renal physiology acts to maintain SS at a reasonably stable level in most stone formers,

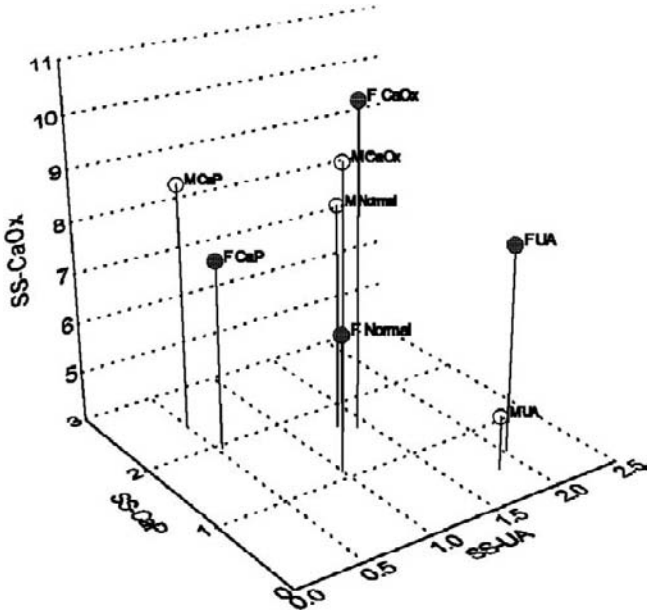

FIGURE 67.2 Supersaturation (SS) versus stone composition. SS for calcium oxalate (CaOx) (z-axis), calcium phosphate (CaP) (y-axis) and uric acid (UA) (x-axis) in females (closed symbols) are low for normals and correspond to stone composition in stone forming females. For males (open symbols), the same is true except that healthy individuals are more similar to stone-forming patients. *(Reprinted with permission from ref.[23])*

and that a few urine samples give a strong insight into long-term, stone-forming tendencies of a patient.

The normal values we used to compare with patient data show a marked sex difference. Whereas healthy women have urine COM SS below that of stone-forming women (Fig. 67.2), COM SS in urine of men is nearly at the levels of patients and is much higher than among healthy women. This occurs mainly because, being larger, men have higher traffics of calcium and oxalate into urine than women, but share with them virtually the same daily urine volume.[23] The finding accords well with the epidemiological observation that male stone formers outnumber female stone formers, and further support the value of even sparse SS measurements to characterize the stone forming impulse of an individual.

Given the general rule that stone composition follows SS, one may ask about the exceptions. When individual urine samples fail to show SS corresponding to stone composition, or show SS not reflected in stone composition, can one use such a discrepancy clinically? We[24] found two types of exception. Sometimes SS elevation is present but the predicted mineral phase is absent from all analyzed stones (Type 1). This occurs mainly when urine volumes are very low and multiple SS values are high. The phenomenon suggests some important renal mechanisms that reduce crystallization. Type 2 discrepancies are solid phase in stones without a relevant SS in the urine. Here, we have found very high urine volume is the rule, and assume that matters have changed with the patients after passing a stone, so that fluid intake increased and a past SS was abolished. These exceptions are a kind of sporadic accent on a general backdrop of correspondence, and we propose that a break in correspondence has clinical use in pointing to increased urine volume, especially, which may not hold long term.

CONTROL OF SUPERSATURATION

Given that SS is the driving force for crystallization, and that direct experiments document a strong link between SS measurements made clinically and stone mineral composition, as well as gender differences in stone forming potential, the regulation of SS and the factors that influence it are clearly at the center of stone pathophysiology. One might at this point illustrate SS values from healthy men and women, and how they vary with factors such as urine volume, pH and mineral traffic, but our interest is what happens among patients with stones. The following figures are therefore made from our measurements of three 24-hour urine samples obtained prior to any treatment among 4500 patients with documented stone formation. As best is possible, they convey some sense of what one encounters in such a population.

Effects of Water Reabsorption

For CaOx, reduced urine volume raises SS markedly (Fig. 67.3), although even at the highest urine flows SS remains above 1, indicating near universal SS in human urine samples over 24 hours. Put another way, crystals of CaOx are unlikely to dissolve in human urine once formed, and anything that provokes nucleation of CaOx is apt to cause a stone to grow given enough time and provided other defenses do not prevent such from happening. For CaP (Fig. 67.4), volume also matters, but the tilt of the graph and spread of the points make clear how much less dramatic the effect. Also note that levels of SS for CaP in urine are much lower than for CaOx, and half of all samples are below one, indicating that CaP phases need not persist even if initially formed. For UA volume effects are also quite marked (not shown). As in the case of CaP, over half of urines are under-saturated. Overall, urine volume of two liters is a useful point to observe. Above this point, further reduction of SS is possible, but the number of urines thins, because one reaches the limits of plausible behavior. Below one liter, high SS is the rule and increase becomes very important. This supports the

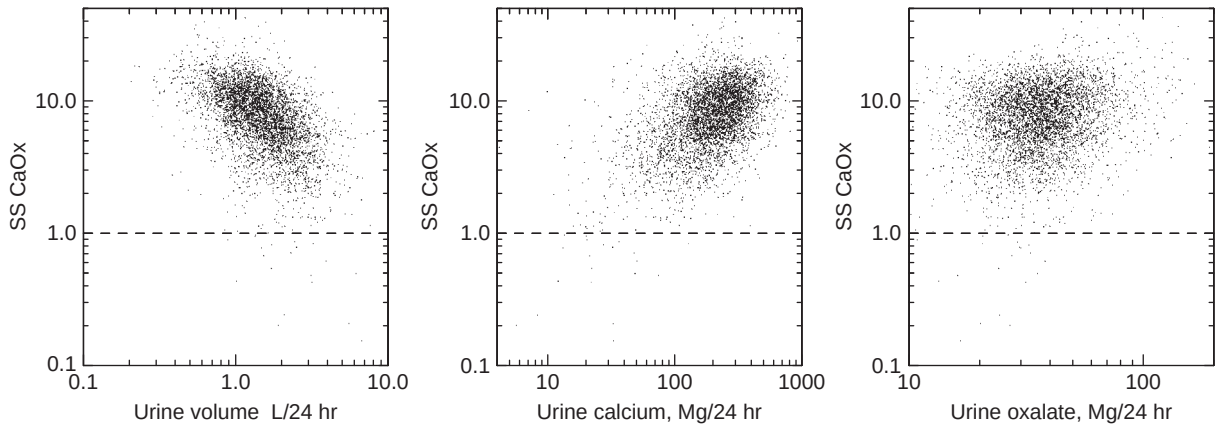

FIGURE 67.3 Determinants of urine calcium oxalate (CaOx) supersaturation (SS). Calcium oxalate SS, y-axis of each panel, varies strongly with urine volume (left panel), moderately with urine calcium excretion (middle panel), and modestly with urine oxalate excretion (right panel). Each point is a single 24-hour urine sample from a patient with nephrolithiasis.

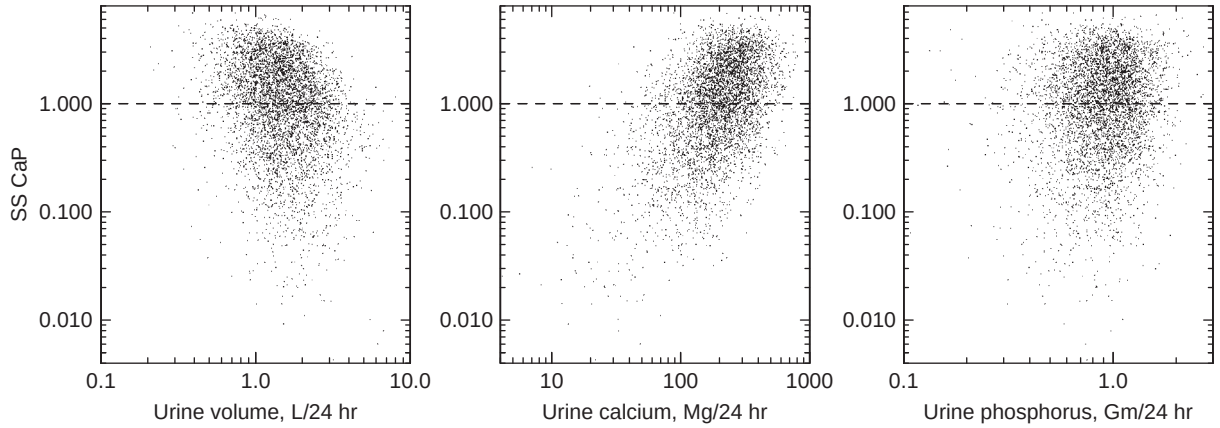

FIGURE 67.4 Determinants of urine calcium phosphate (CaP) supersaturation (SS). Same as Fig. 68.3 except SS values are for calcium phosphate, and urine phosphorus is shown in the right panel in place of urine oxalate excretion.

clinical maxim of two l/day as a goal for urine volume, while less than one l/day is a serious problem. Of interest, the normal person has a urine volume of 1.4 ± 0.05 liters as an average,[25] yet does not make stones. Urine volume obviously varies over the course of the day, and is lowest overnight, which is the time of day associated with the highest levels of SS.[26] This should be kept in mind when advising patients to increase fluid intake.

Effects of Relevant Urinary Solute Traffic

For CaOx, urine calcium excretion is a main controller of SS (Fig. 67.3); therefore, it should be unsurprising that hypercalciuric states are the most prevalent clinical causes of stone disease. Rather than using hard cut-points for diagnosing hypercalciuria, urine calcium should be thought of as a graded risk factor more like blood pressure, and like blood pressure in relation to stroke, higher is worse than lower.[27] As well, and perhaps like the stroke analogy, the spread of SS about any urine calcium point shows how many other factors must be interacting. One is volume, and the rest are not defined on this presentation. Urine oxalate excretion (Fig. 67.3) has none of the effect of calcium, the graph being almost spherical. This fact is incontrovertible, yet *in vitro*, and for theoretical reasons, urine oxalate concentration ought to exert a controlling influence equal to that of calcium.[28] The reason is that the range of oxalate excretion is modest, and the effects offset by other factors such as volume and calcium. For CaP matters are similar but with less sharpness (Fig. 67.4). Urine calcium excretion has a striking effect, as for CaOx; volume affects SS modestly, and urine phosphorus excretion virtually not at all. For UA, volume influences SS rather more than for CaP and a bit less dramatically than for CaOx, and UA excretion is utterly without effect.

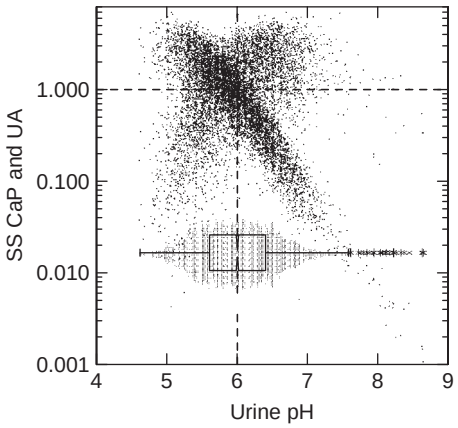

FIGURE 67.5 Relationship between urine pH and supersaturation (SS) for uric acid (UA) and calcium phosphate (CaP). The dashed horizontal line represents the border between supersaturated (above 1) and undersaturated urines. The figure provides evidence for a natural pH optimum to minimize UA (points descending downward to the right) and CaP (points ascending upward to the right) SS. The two SS data sets pass through a dual minimum at about pH 6; the median of the pH distribution for all urine samples in the set is precisely at the dual minimum (dashed vertical line). The horizontal notched box is a nonparametric representation of the median and one quartile on either side of the distribution of urine pH values shown as an oval of tiny dots about the notched box.

Effects of Urine pH on Supersaturation

What really matters in the case of CaP and UA SS is urine pH (Fig. 67.5); in a sense the link between SS and mineral content of these two solid phases reflects stability of 24-hour average urine pH. Above pH 6, virtually no urine is supersaturated with UA, and below 5.3 virtually all are supersaturated. For CaP, the effect is less exacting, perhaps because calcium concentration plays an important role, but SS does not occur below pH 5.3. For CaOx, pH has little effect on SS. That it has any reflects increasing calcium complexation with phosphorus and citrate at higher pH levels, so urine calcium ion falls. As noted before, virtually all urines are supersaturated with CaOx.

Regulation of Urine pH in Relation to Supersaturation

We have no desire to duplicate here detailed materials elsewhere in this volume concerning acid excretion and control of renal acid base balance. However, we have something to add of potential value, offering a perspective usually not considered. Constraints of solubility must have affected renal adaptation to water conservation and mechanisms for maintenance of blood pH, because the solubility laws are prebiological. More compelling, a urine pH near 6 would seem almost a necessary choice for the normal state, because the human design includes excretion of both considerable amounts of calcium, phosphorus, and UA. When plots of CaP and UA SS as a function of urine pH are combined as in Fig. 67.5, a pH about 6 is clearly near a double SS minimum. Among our samples, the mean and median pH were 6.005, a value that represents the actual compromise reached between net acid excretion, ammonium ion excretion, and reabsorption of filtered organic anions such as citrate. This pH effectively removes UA SS as a characteristic of the 24-hour urine.

Daily acid production, from formation of sulfuric acid during protein metabolism, is balanced by proton titration of urine phosphorus, and ammonium excretion. The amounts of urine phosphorus are set mainly by diet intake, although acid loading leads to bone mineral resorption with extra phosphorus availability. Titration of urine phosphorus to the dihydrogen form removes phosphorus from interaction with calcium, which is how low pH lowers CaP SS. Falling pH titrates urate to the dihydrogen form (pK 5.35), which has a limited solubility of 98 mg/l in urine. To keep urine pH near 6, as clearly occurs, ammonia formation in response to acid load must be nicely balanced with phosphorus excretion and proton secretion, otherwise urine pH would run too high or too low. We presume evolution has favored this compromise pH, and suggest the subject may be worth serious experimental attention.

Organic anion reabsorption is increased by acid loading and depressed by alkali loading so that response to alkaline ash diet by the kidney need not result in as great an increase of urine pH as would be required by excretion of bicarbonate as the sole response. Citrate, the most well known of the urine anions, binds urine calcium in a soluble salt, so that increase of pH that does occur is offset by reduced calcium ion activity.[29] The effects of other urine anions on calcium complexation and urine free calcium ion activity are not known. Acid loading lowers urine anions and therefore favors calcium ion activity increase, but abolishes calcium phosphate SS through titration of monohydrogen phosphate to the dihydrogen form. The total response of urine anions to acid-base balance change strongly suggests an evolved defense against CaP crystallization.

Other Effects

Urine SS is influenced by the free-ion activities of the relevant ligands that make up the stone-forming material. As such, it is reduced by high ionic strength that reduces activity coefficients, and therefore very low urine sodium and potassium concentrations raise SS, all other factors being held constant. Oxalate forms

salts with magnesium, sodium, and other urine ions, and the ion activities of each of its ligands affect CaOx SS. Likewise, calcium forms phosphate, sulfate, oxalate, citrate, and other salts, so its free-ion activity also varies with multiple ligand concentrations. Even so, the effects of raw calcium excretion are dramatic, and clinically evident, whereas effects of magnesium and sodium are usually not so because the range of values encountered in clinical practice is too narrow to permit important effects. This is a critical point. Clinical reality concerns what actually happens. Some uncommon patients, for example, because of bowel disease, have almost no urine sodium, or magnesium; among their ranks are a few in whom sodium administration or magnesium loading will lower SS and improve stone prevention. We have emphasized volume, pH, and excretion of calcium because they act generally, and with considerable effect, in most patients.

Relationships between Supersaturation and Upper Limit of Metastability

As first described, the ULM would seem a property of solution, as is SS, and between them no obvious connections come to immediate mind. However, we have already shown how among healthy people ULM and SS seem linked (Fig. 67.1), and this also occurs in patients with stones[30,31] but to a lesser extent than in non-stone formers. Among healthy women and men, ULM for CaP and for CaOx rises with SS, as seen in Fig 67.1. Among patients with stones the distance above the line of identity, which essentially gauges the defense against crystal formation, is reduced compared with that of healthy individuals. That the ULM to SS distance is smaller for CaP than CaOx, in healthy individuals and patients, suggests that CaP is more likely to form as an initial phase, making a starter template on which CaOx can overgrow.

INHIBITORS OF CRYSTALLIZATION AND CELL CRYSTAL INTERACTIONS

Urine certainly slows formation and growth of CaOx and CaP crystals, and we presume that at least late nephron tubule fluid must do the same. We do not know which molecules are primarily responsible for this phenomenon or if defects of inhibition cause stone disease. Perhaps the best evidence for a pathogenetic role of reduced inhibition is the low ULM to SS distance already alluded to in stone formers versus healthy individuals, and the molecules responsible for that effect are unknown. Presently we do not use measurements of individual inhibitors or of urine inhibition in clinical practice. If a commercially practical ULM measurement could be produced, this type of assay might be found useful in predicting the course of treated stone formers, perhaps, but that is mere speculation. At the moment, and when we first wrote this chapter, the whole matter of inhibitors is of mainly theoretical interest.

Calcium Oxalate Molar Ratio

We have found that the calcium/oxalate molar ratio correlated strongly with the ULM for CaOx.[22] However calcium and oxalate molarity both correlate strongly with SS and therefore with ULM so we are concerned that inferences from regression analysis may be misleading.

Citrate

Because it binds calcium in a soluble complex, citrate is clearly a protection against stone formation, and low citrate a risk factor for stones. At urine concentrations of mM levels, citrate can reduce crystal aggregation.[32] *In vitro*, citrate inhibits CaOx growth by 33% at 0.5 mM, and inhibits CaP crystallization at concentrations between 0.5 and 2 mM.[33] Adding 2 to 3 mM of citrate to urine decreases the number and size of crystal particles that form when calcium and oxalate are added to increase SS. In urine, citrate increases the ULM for CaP.[34] These data support the role of citrate as a treatment for calcium stones in patients with hypocitraturia.

Pyrophosphate and Phytate

A long and complex history of unfulfilled promise shadows these small and potent molecules. At 16 μM, pyrophosphate inhibits growth of CaOx crystals *in vitro*, and urine levels of it average 20 to 40 μM.[35] Urine levels of pyrophosphate can vary over a 10-fold range, as well, so clinical events could arise from its deficiency. On the other hand, dialysis of urine does not much reduce growth inhibition effects, suggesting extreme molecular redundancy, and efforts to raise urine pyrophosphate by giving oral orthophosphate supplements do not reduce stone formation significantly. Another small molecule of related character, phytate, inhibits brushite and apatite crystallization; but whereas pyrophosphate inhibited apatite most effectively, phytate inhibited brushite crystallization most effectively.[36] Perhaps modern methods for quantifying these molecules could be important in understanding why some patients with CaP stones produce apatite, others brushite crystals.

Macromolecules and Small Molecules Combined

In addition to the small molecules described above, urine contains a variety of macromolecules, including proteins and glycosaminoglycans, which are active against crystals, and could, in the aggregate, explain the extraordinary ability of urine to prevent crystal growth, aggregation, and nucleation. Presently we recognize at least 10 molecules that have anti-crystal properties, but the links between them and clinical stone disease are tenuous and suggestive: THP,[32,37] chondroitin sulfate,[38] citrate,[39] calgranulin,[40] osteopontin,[41,42] bikunin (inter-α-trypsin inhibitor),[43] prothrombin F1 fragment,[44] heparan sulfate,[45] the complement inhibitor CD59,[46] and inorganic pyrophosphate.[47] These molecules can inhibit to various degrees the nucleation, growth and aggregation of CaOx and CaP crystals, and their ability to bind to cells, at concentrations found in urine. A few studies suggest impaired inhibition may play a role in certain stone formers.

Such a system implies extreme redundancy, perhaps an intentional result of evolutionary biology, perhaps fortunate chance. We omit discussion here of the specialized molecular structures involved in crystal inhibition, but recent work using cystine crystals suggests that understanding the molecular basis of crystal inhibition may eventually lead to the ability to design effective inhibitors for some types of stones.[48]

DISORDERS OF CALCIUM STONE FORMATION

Idiopathic Calcium Stones: Metabolic Abnormalities

Most calcium stone formers have no systemic disease, and most diagnostic evaluation and treatment concerns urine abnormalities that can increase SS, the established driving force for crystal nucleation and growth: high calcium and oxalate excretions, low citrate excretion, high urine pH and low volume. Calcium excretion of patients (Fig. 67.6, upper right panel) frequently exceeds the upper 95th percentiles for normal women (indented) and normal men. Deviations are less marked but still obvious for oxalate and citrate excretions (lower panels). Urine volume of patients overlaps with normals (upper middle panel). Urine pH of CaP stone formers exceeds normals, that of UA stone formers (discussed in a later section) is below normal.

Idiopathic Hypercalciuria (IH)

Pathogenesis

The common definition of IH is urine calcium excretion (mg/day) above 250 in women and 300 in men, values at about the 80th percentiles for healthy

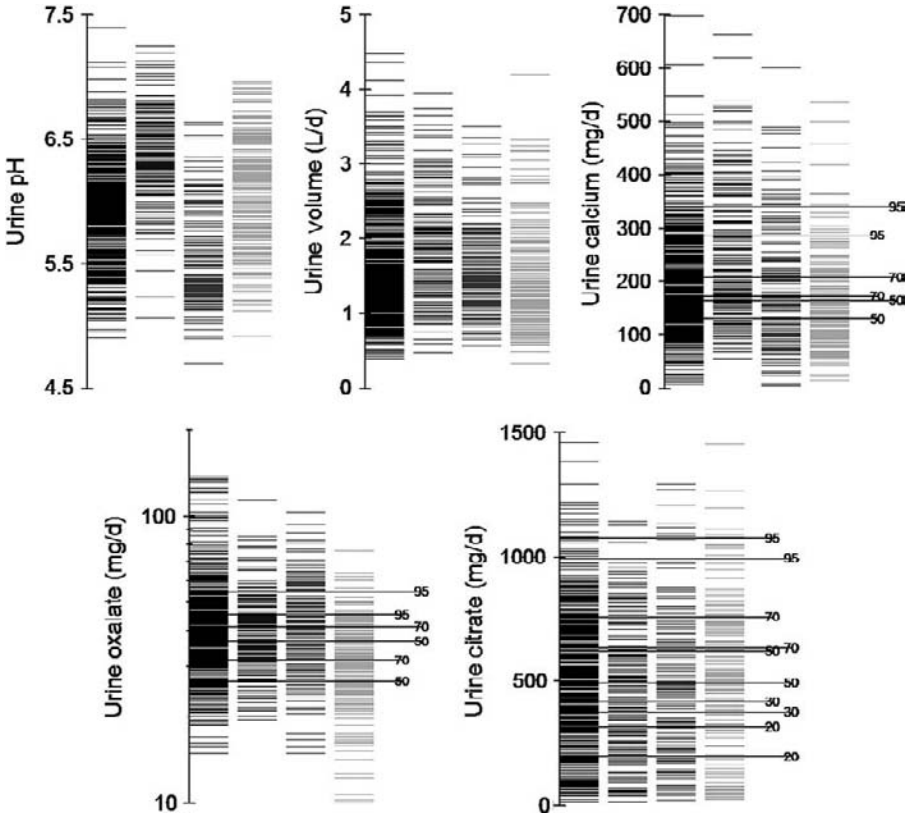

FIGURE 67.6 Urine stone risk factors. Values among normal subjects (right bar in each panel), and (from right to left) uric acid, calcium phosphate, and calcium oxalate stone formers. Percentiles for normal women (indented pins) and men are shown for reference. Each horizontal stripe represents one person.

individuals (Fig. 67.6); serum calcium is not elevated, and known causes of hypercalciuria such as hyperthyroidism, Cushing's syndrome, excess vitamin D intake, sarcoidosis, glucocorticoid use or other systemic diseases are absent. IH is found in 30–60% of ICSF.

Like hypertension, IH is familial, being found in about 50% of first-degree relatives of probands for both sexes.[49] Although IH is clearly genetic, studies of the monogenic hypercalciuric states, in which nephrocalcinosis and/or stones may be found, have not cast much light on pathogenesis of IH, although they offer intriguing clues.[50] Dent's disease appears to drive hypercalciuria via increased calcitriol levels, as in IH. Bartter syndromes involve defects of thick ascending limb calcium transport. Autosomal dominant hypocalcemic hypercalciuria arises from a gain of function mutation in the cell surface calcium receptor (CaSR), and stones and hypercalciuria are abetted mainly by vitamin D and calcium repletion to control hypocalcemia. Familial hypomagnesemia is caused by defects of paracellin-1. However, studies of patients with IH have not found a significant contribution to pathogenesis by mutations in these genes, nor by mutations in the vitamin D receptor (VDR), or the distal tubule apical calcium channel TRPV5. Patients with IH represent one end of the natural distribution of calcium excretion, and hypercalciuria results from the interplay of genetic endowment with environmental triggers.

The extra urine calcium in IH comes from diet, bone or both. In five studies (Fig. 67.7, left panel), one of them containing three separate comparisons[51] calcium absorption by IH patients exceeded normal.[51–55] High levels of serum calcitriol are common in IH (Fig. 67.7, right panel),[53,54,56–64] and this hormone could raise calcium absorption rates. However, many patients with IH have high gut calcium absorption rates with normal calcitriol levels. In this, they resemble an inbred rat colony whose members absorb calcium at high rates because of an over expression of the VDR by intestine.[65] By inference, some human IH could arise in such a way, and one study presents evidence supporting this mechanism.[60]

Another feature of IH compatible with calcitriol stimulation of target tissues is a tendency for bone mineral to be lost during low-calcium diet challenge.[59] In both normal subjects and patients with IH, urine calcium rises as gut calcium absorption (calculated as [diet calcium-fecal calcium]) increases,[66] but patients with IH excrete more calcium than do normal subjects at any level of net calcium absorption, and their urine calcium often exceeds the amount of dietary calcium absorbed. This latter is of great clinical importance, since it means that bone mineral is being lost in the urine, and implies that renal calcium conservation must be impaired. Administration of oral calcitriol to normal subjects can replicate features of IH, particularly the tendency to go into negative calcium balance on a low calcium diet.[67]

Numerous cross sectional studies have found that bone mineral density (BMD) is often decreased in IH[57,68] and BMD correlates inversely with the level of urine calcium.[56] In a prospective study, 46 subjects with hypercalciuria had BMD re-measured after three years of follow-up, and urine calcium excretion was predictive of the change in femoral z score—the higher the urine calcium excretion, the greater the drop in femoral neck mineral density.[69] Risk of fracture is increased in IH as well, as documented by a 19-year

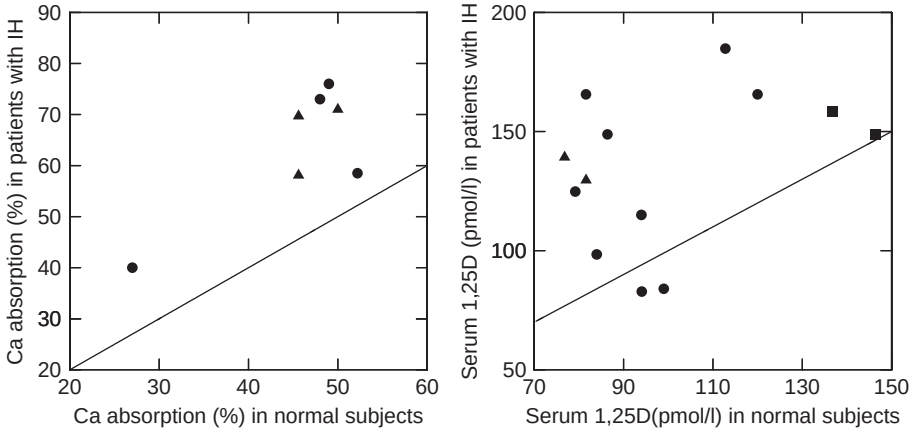

FIGURE 67.7 Intestinal calcium absorption (left panel) and serum calcitriol levels (right panel) in patients with idiopathic hypercalciuria (IH) and healthy individuals. Each solid point is a study and represents a plot of the mean of patients with IH against the mean of healthy individuals in that same study. Triangles and squares depict multiple patient group comparisons within a single publication. The clustering of points above the diagonal lines of identity illustrates the elevation of absorption and calcitriol among IH patients versus normal subjects. Triangles in the left panel are from,[51] circles are from.[52–55] In the right panel, triangles are from,[54] squares are from,[56] circles are from the remaining references in the text.

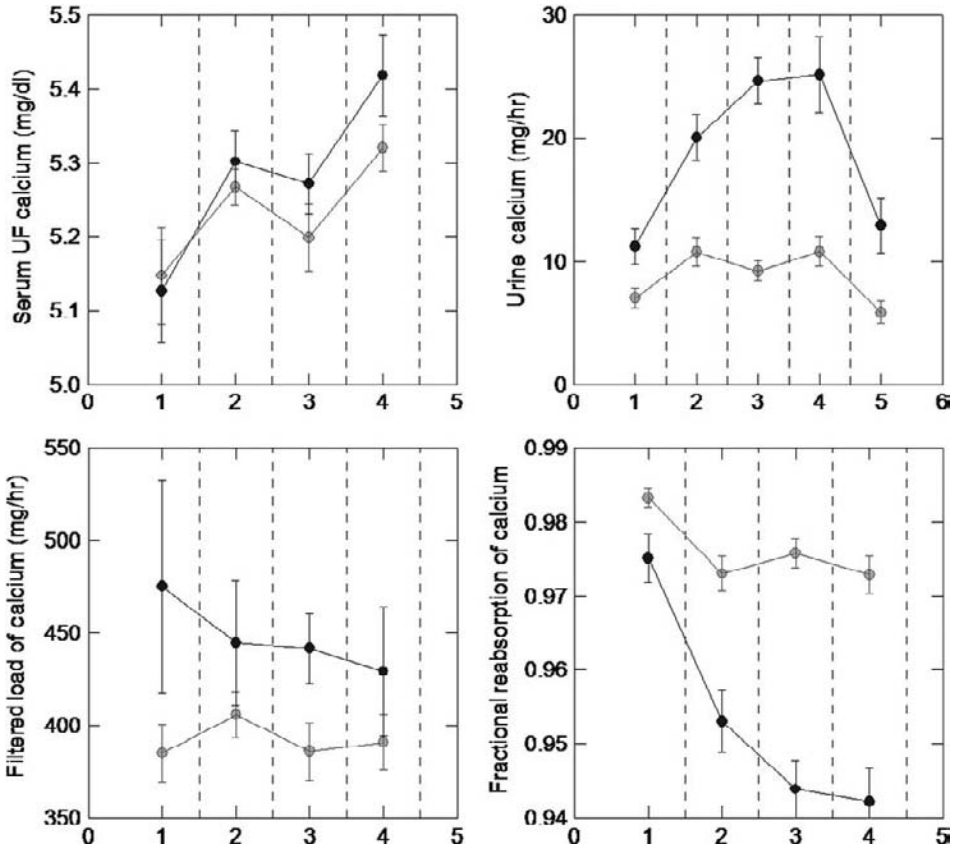

FIGURE 67.8 Calcium handling in patients with idiopathic hypercalciuria (IH) (black circles) and controls (grey circles) fasting and with meals. Serum ultrafilterable calcium increased with meals, but values did not differ between IH and control (upper left panel); neither did the filtered load of calcium (lower left panel). Urine calcium of IH increased far more than control (upper right panel), and fractional calcium reabsorption of IH was significantly less than control (lower right panel). Therefore, response of IH to feeding was an abnormally marked decrease in tubule calcium reabsorption. *(Reprinted with permission from ref.[73])*

follow-up of a cohort in Rochester, Minnesota, which found a four-fold increase in vertebral fractures among stone formers.[70] Abnormal bone histomorphometry has been found in eight studies of IH to date, with generally increased resorption, low bone formation, and a mineralization defect.[71] The mechanisms are still unclear, but a recent report[72] found increased bone expression of receptor activator of nuclear factor kappaB ligand and osteoprotegerin in patients with IH versus control subjects.

How the extra calcium gets into the urine is now reasonably well known. Potential models were increased filtered load from post-prandial increase of serum calcium, reduced renal tubule calcium reabsorption, or both; in fact, reduced tubule reabsorption mediates hypercalciuria.[73] Fasting and with meals, fractional excretion of calcium by IH exceeds controls, but ultra-filterable calcium concentrations and calcium filtered loads do not differ (Fig. 67.8). Using endogenous lithium clearance as a marker, proximal tubule (PT) reabsorption falls with meals more in subjects with IH than in normal subjects,[74] and the delivery of calcium out of PT is crudely proportional to the magnitude of urine calcium excretion (Fig. 67.9); the increased sodium (Na) delivered out of PT is quantitatively reabsorbed distally, so that no difference was seen in Na excretion on the controlled diet. Whether

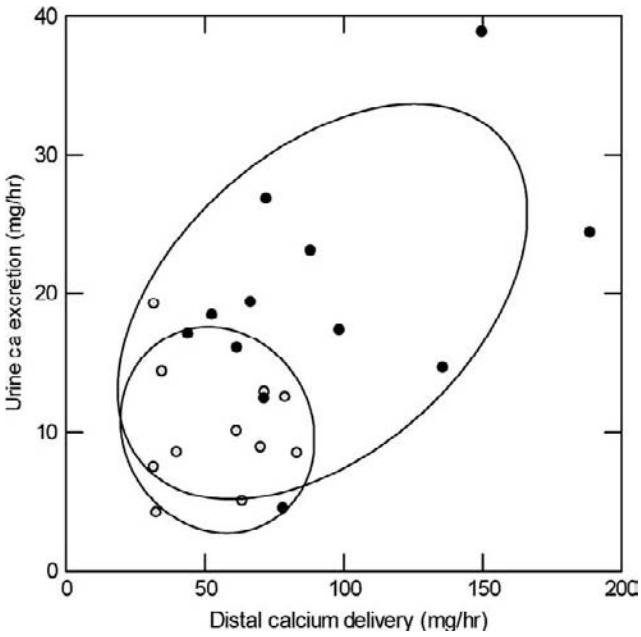

FIGURE 67.9 Relationship between distal calcium delivery and absolute urine calcium excretion in stone formers with IH (black symbols) and controls (gray symbols). Distal delivery is higher in subjects with IH, and calcium excretion rises with distal delivery, but excretion is higher in IH versus controls at comparable deliveries. *(Reprinted with permission from ref.[74])*

other tubule sites also participate in the decreased calcium reabsorption seen in IH is still unknown. This work sheds light on the mechanisms for two successful treatments for recurrent calcium stones; both low sodium diet and thiazide, which reduce urine calcium in IH, could work, in part, by raising PT reabsorption.

Although IH involves accelerated calcium transport in gut, kidney and bone, diet plays a role in promoting calcium loss in these subjects. For example, feeding 100 gm. of glucose reduces renal calcium reabsorption to a much greater extent in IH than in normal subjects, contributing to the negative calcium balance in these patients.[75] High salt intake is also associated with increased calcium in the urine.[76] However, higher dietary calcium intake was associated with decreased risk of stone formation in epidemiologic studies.[77] Because of that, and the risk of bone mineral loss on low calcium intakes,[59] low calcium diet is no longer used for treatment of kidney stones.

Treatment

Having said what one can about pathogenesis and how much is left to discover, therapy is rather well developed and well tested. Most current treatments to prevent stones have as their goal lowering urine SS. A general consensus exists that, in the absence of systemic disease, a first calcium stone can be treated conservatively with increased fluid. A randomized trial in such patients showed a significant decrease in recurrent stones in those patients who increased urine output to over two liters daily.[78] Water is the optimal beverage, but a variety of fluids can be used, if those that are high in sugar or sodium are avoided.

In patients who relapse, additional therapy should be added to fluid intake. Diet modification is one strategy. A randomized trial tested the hypothesis that a diet with a normal calcium intake (30 mmol/day) but low in sodium (50 mmol) and animal protein (52 gm/day) would prevent stones better than a low calcium-low oxalate diet in hypercalciuric men.[79] After 5 years of follow up, significantly fewer men on the normal calcium diet had recurrent stones compared to those on low calcium diet (20 vs. 38%, $p = 0.04$). A second trial of low protein diet for stone prevention was negative, but sodium was not restricted in that study.[80] A diet study has not been done in women, or replicated in other sites. In the United States, the DASH-sodium diet, originally created to lower blood pressure, has many of the features of the study diet used to prevent stones, after elimination of nuts, and was associated with fewer stone episodes in epidemiologic studies,[81] but no trial has validated it as a method of stone prevention.

As a kind of byproduct of their original design, thiazide-type diuretics reduce urine calcium loss and stone recurrence. The mechanism of the reduced calcium loss is probably increased PT calcium reabsorption, with shunting of re-absorbed calcium into bone, as opposed to urine[82] and the effect lasts as long as the drug is taken. Three prospective controlled trials of thiazide have been carried out for three years each (Fig. 67.10)[83–85] and yielded the same result: placebo-treated patients (open symbols) relapsed at a higher rate than corresponding thiazide-treated patients (closed symbols), the effect reaching statistical significance by the end of year three. Being protective of bone in a disease that can deplete bone of its mineral, and protective against stones in recurrent stone formers, thiazide is the primary treatment for IH. Our preference is for chlorthalidone, because it is long acting and used once daily, although hydrochlorothiazide and indapamide have also been used successfully. Very low doses of 12.5 mg can be effective, and we often begin there; 25 mg is effective for most people. Kaliuresis with potassium depletion is staved off with reduced sodium (100 mEq daily is a good goal) and increased potassium intake, or with amiloride 5 to 10 mg every morning or a potassium supplement.

We are often asked what to do when someone who is in need of stone prevention from IH cannot take thiazide. Use of the diet detailed above, with careful follow-up to ensure compliance, can be helpful. Amiloride alone will not work. Since oral glucose raises urine calcium in IH, avoidance of sugar loads is prudent. Often thiazide side effects arise from too high a dose. Sometimes "drug allergies" are a myth or may be overcome by change to another molecular variant.

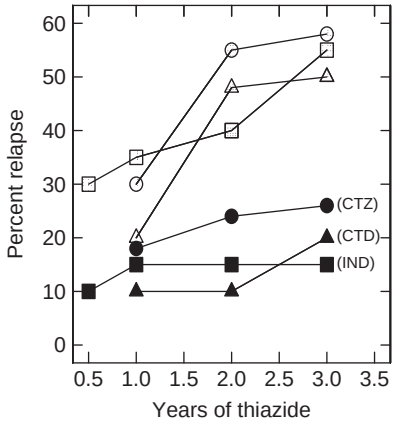

FIGURE 67.10 Three trials of thiazide for reduction of calcium stone recurrence. The percentage of patients with relapse (y-axis) was much reduced in those receiving active drug (filled symbols) vs placebo (open circles). All three trials were randomized, double blind, and prospective. CTZ, hydrochlorothiazide, 25 mg twice daily;[85] CTD, chlorthalidone 25 or 50 mg daily;[84] IND, indapamide, 2.5 mg daily.[83] All three trials showed significant differences between controls and active drug treatment.

Low Urine Citrate

Stone formers, especially females, excrete less citrate than healthy people of the same sex[86] (Fig. 67.6). Citrate inhibits nucleation and growth of calcium crystals, and binds calcium in a soluble complex[39] thereby reducing SS values. The administration of alkali may also have beneficial effects on the skeleton,[87] and can lower urine calcium,[88] although long term data on these effects in stone formers is absent.

The cause of hypocitraturia is usually not apparent. Urine citrate excretion is positively correlated with net GI alkali absorption,[89] which in most cases is provided by fruits and vegetables, and inadequate intake of these foods results in hypocitraturia in some idiopathic stone formers. Filtered citrate is mainly reabsorbed in PT, and citrate in urine is that which escapes reabsorption.[29] Reabsorption is decreased by alkali and increased by acid loads[90] and potassium depletion.[91] Administration of potassium citrate results in metabolism of most of the absorbed citrate to bicarbonate, which allows more filtered citrate to escape reabsorption in PT; urine pH also rises. If only citric acid is administered, a transient increase in urine citrate will occur as citrate that escaped metabolism in the liver is filtered, but metabolized citrate will titrate the ingested proton and no net gain of alkali will occur. Therefore, potassium citrate or bicarbonate will raise urine citrate, but citric acid will not. This may account for the inconsistent results with administration of lemon juice as a substitute for potassium citrate.

Treatment

What is the best course of action for physicians? We propose measuring citrate as part of every 24-hour urine analysis for stone diagnosis, and raising it when it is low, using a potassium citrate salt. Two trials[92,93] document efficacy of supplemental potassium citrate in reducing stone recurrence in hypocitraturic calcium stone formers (Fig. 67.11). Dosing should be about 2/3 of urine ammonia excretion. Care should be taken to monitor urine pH, and avoid raising it significantly above 6.2, as CaP SS may increase, and lead to worsened, not improved, stone formation. When thiazide is used for hypercalciuria, and the inevitable fall occurs in blood potassium, urine citrate will fall, and a small but useful trial[94] has shown that potassium citrate snuffs out the otherwise stubborn recurrences of stones, presumed to form because of urine citrate deficiency. Given a reasonable action, no physician needs to despair at the incomplete understanding evident in this tiny area of science. Nor, given better science, is a better treatment likely to be found.

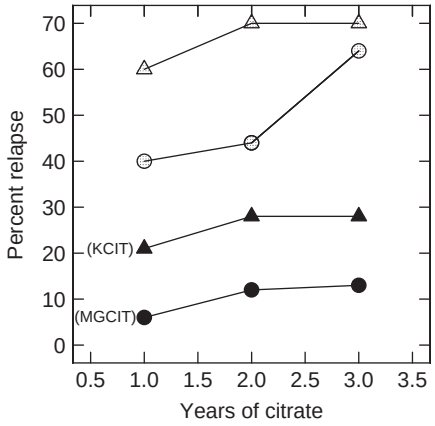

FIGURE 67.11 Two trials of citrate for reduction of calcium stone recurrence. The percent of patients with relapse (y-axis) was much reduced in those receiving active drug (filled symbols) vs placebo (open circles). The two trials were randomized, double blind, and prospective. KCIT, potassium citrate 20 mEq three times daily;[92] MGCIT, potassium-magnesium citrate, two tablets twice daily.[93] Both trials showed significant differences between controls and active drug treatment.

High Urine Oxalate

Urine oxalate may arise from endogenous production in the liver, as an end-product of glyoxalate, amino acid and ascorbic acid metabolism, and from GI absorption of preformed oxalate.[95] Dietary oxalate is absorbed mainly in the colon, and normally about 10% of ingested oxalate is absorbed. Oxalate from both sources has only one fate—renal excretion. Under ordinary circumstances, approximately half of urine oxalate is derived from the diet, and the other half is endogenously produced.[96] Recent experiments using mice in whom the oxalate transporter SLC26A6 was knocked out have led to the understanding that oxalate is also secreted into the gut,[97] and increased urine oxalate may also result from a drop in gut secretion; this has not yet been documented in humans.

Higher urine oxalate values are often encountered in stone formers versus normal subjects (Fig. 67.6) and should be given proper attention. Mild hyperoxaluria (values from 40 to 60 mg/d) may result from a diet high in oxalate[98] or more commonly from a diet low in calcium,[99] as well as from protein loads. Ascorbic acid intake may also contribute significantly to urine oxalate. Oxalate degrading bacteria are normally present in the gut, and absence of such flora may also lead to increased gut oxalate absorption.[100]

Recent work suggests that renal oxalate handling may differ between stone formers and normal subjects.[101] In calcium stone formers on a low oxalate diet, urine oxalate was higher than among a group of normal subjects on the same diet. Plasma oxalate levels did not differ between the two groups, but while

oxalate reabsorption was seen in the normal subjects, oxalate secretion was frequently seen in the stone patients, at similar levels of plasma oxalate. This suggests that control of oxalate transport in the kidney may provide stability of plasma oxalate levels.

Very high levels of urine oxalate, of 80 mg/d or more, occur because of small bowel malabsorption or primary oxalate over-production (see below). These are very serious conditions that can damage kidneys and demand a high level of clinical attention.

This strangely combative area of nephrolithiasis hardly deserves the attention it has had if one maintains a purely clinical perspective. The idea that changes in urine oxalate influence CaOx SS more than corresponding changes in urine calcium has been shown to be incorrect.[28] As we have shown, the range of urine oxalate excretions is much smaller than that for urine calcium or volume so oxalate increase as a cause of stones is modest in practice.

Treatment

Patients with dietary hyperoxaluria should restrict dietary oxalate sources, avoid ascorbic acid supplementation, and ensure a normal calcium intake (800–1200 mg/day) from food. A recent three month pilot study showed that in a group of stone patients with mild hyperoxaluria, urine oxalate fell significantly more with a low sodium, low animal protein, normal calcium (1200 mg) diet compared with a low oxalate diet.[102] This is consistent with findings that stone patients do not appear to have higher oxalate intakes than normal subjects.[103]

High Urine Uric Acid

One of us was not altogether wrong in 1973 describing a tendency toward high urine uric acid excretion (750 and 800 mg/d, women and men, respectively) among patients who formed calcium stones.[104] High levels of uric acid in urine salt out CaOx salts[105] and reduce their solubility. This could foster CaOx overgrowths on Randall's plaque. Allopurinol, in one prospective controlled trial,[106] reduced CaOx stone recurrence, adding a critical support to a supposed pathogenetic mechanism.

Treatment

The source of the extra urine uric acid is usually diet that contains above a pound of beef, chicken and fish—combined—daily. Treatment could be as simple as reducing the total to two-thirds pound, not what one would imagine as a low-protein diet. No diet trial has been undertaken. Allopurinol is effective by trial, but can cause toxic epidermolysis. If stones are persistent and surgically active, diet is of no avail, and high urine uric acid is the main problem, then 100 to 300 mg of the drug daily is reasonable.

IDIOPATHIC CALCIUM STONES: PATHOLOGY

Idiopathic Calcium Oxalate Stone Formation: Role of Interstitial Plaque

These most common stone formers have so distinctive a pattern of clinical presentation, altered physiology, renal histopathology and mechanisms for stone formation they deserve a special place and an extensive presentation. No other kind of patient shares their distinctive features. Like all idiopathic calcium stone formers they have no systemic disease, and display a high prevalence of IH. Their stones are predominantly CaOx in composition and form as overgrowths on the renal papillae.

During percutaneous nephrolithotomy (PNL) or ureteroscopy (URS) stones are found firmly attached to the papillary tips over regions of interstitial apatite plaque, which appear visually as white sub-urothelial deposits (Fig. 67.12, panels A and B). Plaque forms in the basement membranes of thin limbs of Henle's loop[107] (Fig. 67.12, panel C) as micro-particles within which alternating lamina of crystal and an organic matrix form a tree-ring pattern (Fig. 67.12 panels D and E). Particles fuse together in the papillary interstitium to form a syncytium (Fig. 67.12, panel D) in which islands of crystals float in an organic sea. The material accumulates beneath the basement membranes of inner medullary collecting ducts (IMCD) (Fig. 67.12, panel F) and Bellini ducts (BD), and under the urothelium, where it appears as white plaque. The plaque crystal is biological apatite, and the organic layers contain osteopontin[108] and the third heavy chain of the inter alpha trypsin inhibitor,[109] both known inhibitors of CaOx and CaP nucleation and growth. In 30 consecutive ICSF, minute inspection of serial sections from papillary biopsies revealed no crystals in any epithelial compartment, only interstitial plaque.[110]

In a large prospective trial, all stones of sequential ICSF were identified during PNL and classified as being attached or not to the papillary surface.[111] For all attached stones, intra-operative imaging (Fig. 67.13) was used to test if the attachment was on plaque. The results, allowing for unattached stones, and some variation in ascertainment, showed that 75.4% (95% CI = 58–93%) of stones were attached to plaque. Since plaque occupies only 5–10% of total papillary area this is a very large deviation from chance. When studied via IR spectroscopy and digital image reconstruction, virtually all unattached stones showed evidence of having grown attached to plaque: an apatite

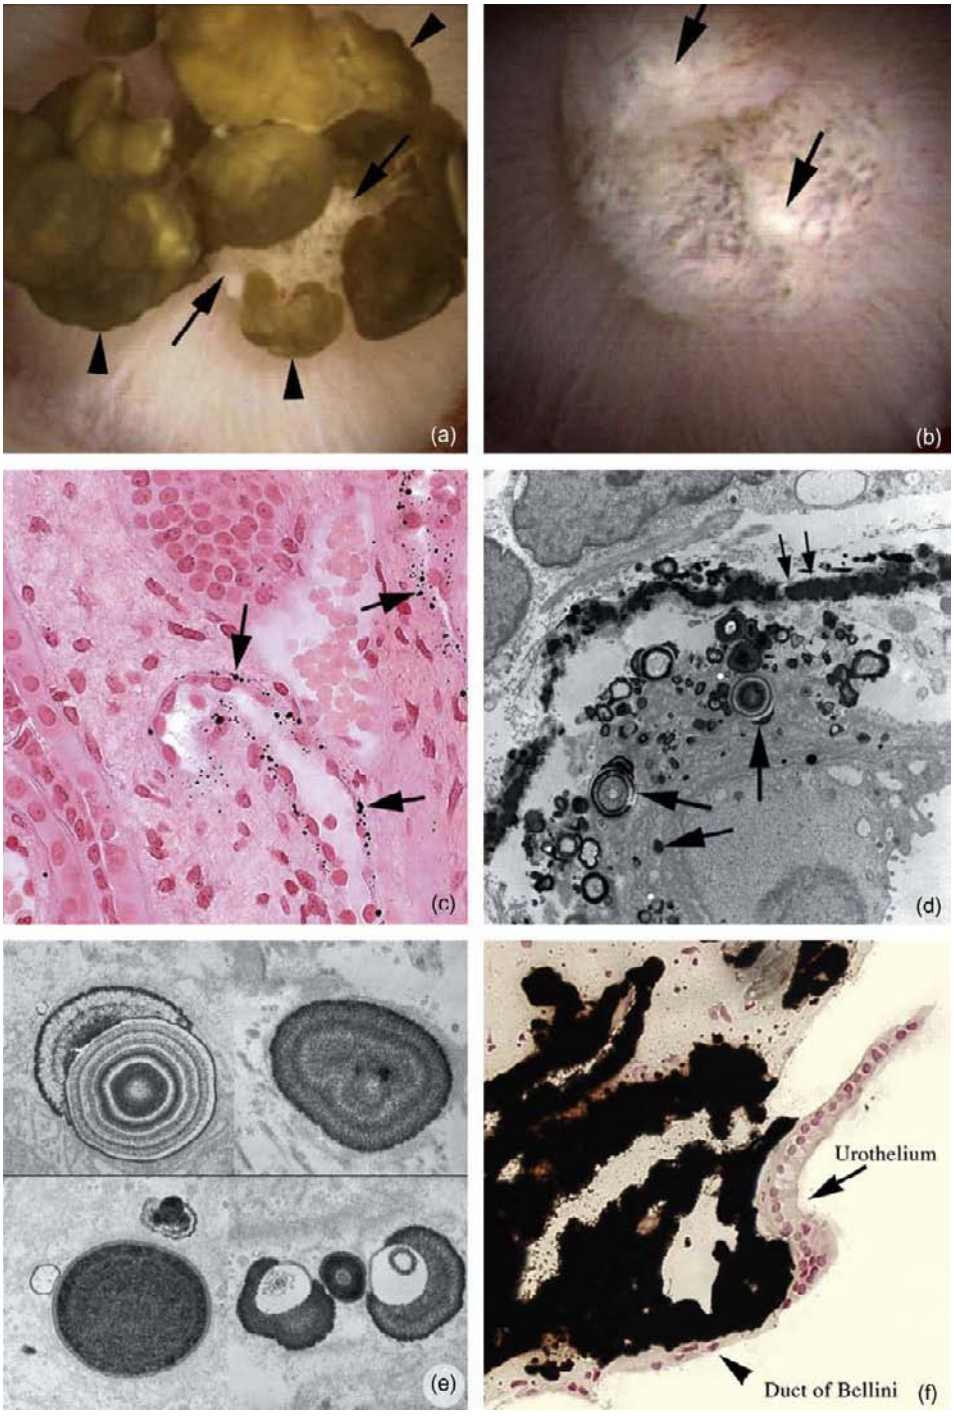

FIGURE 67.12 Digital endoscopic and histologic characteristics of sites of Randall's plaque in ICSF. Panel A is an example of a papilla from an ICSF patient video recorded at the time of stone removal by percutaneous nephrolithotomy revealing a number of small CaOx stones (arrowheads) attached to the tip of the renal papilla. These stones are near or upon regions of irregular whitish plaque material (arrows), more easily seen following removal of the stones (panel B, arrows). These sites of plaque are sub-urothelial in location and represent mineral deposits that first appear as very small spherical structures embedded in the basement membranes of the thin loops of Henle (arrows, panel C) and nearby interstitial space. Because of the location of these crystalline structures, they are termed interstitial deposits or Randall's plaque. By transmission electron microscopy (TEM), the interstitial deposits are seen as individual multilayered spherical structures of varying sizes (arrows, panel D) embedded in the basement membranes of the thin loops of Henle while forming a syncytium in which islands of crystals float in an organic sea (double arrow, panel D). Higher magnification TEM micrographs (panel E) reveal each deposit to be made of alternating light (crystalline material) and electron dense (matrix material) rings. Extensive accumulation of crystalline deposits around the loops of Henle spread into the nearby interstitial space extending to the urothelial lining of the urinary space (panel F).

attachment site often with adherent tubule fragments.[112] In ICSF, the amount of papillary surface covered by plaque correlates strongly with numbers of stones formed, corrected statistically for age and duration of stone disease.[113]

Growth on Plaque

A 0.5 mm CaOx stone (Fig. 67.14, panel (A)) was excised during surgery en bloc with its underlying attachment site (Fig. 67.14, panel (B)).[114] The urinary surface of the stone attachment site occupies the upper half of panel C and the left upper quadrant of panel (D) of Fig. 67.14. Presumably, and via an unknown sequence of events, the integrity of the urothelium was breached at this region of the papillum (Fig. 67.14, panel (C), arrow), exposing sub-urothelial plaque to urine. The exposed surface of plaque, where the stone was attached, is covered by a ribbon of alternating

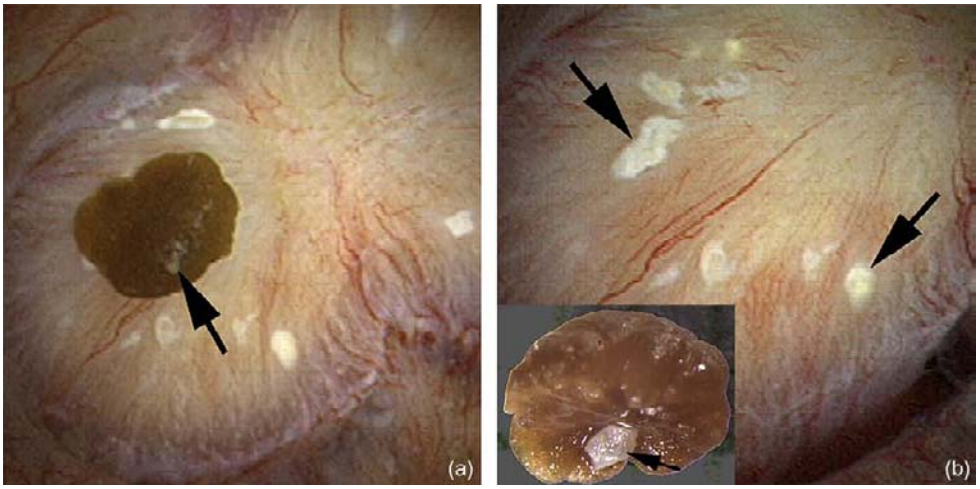

FIGURE 67.13 An attached stone before and after removal. A 3-mm stone (arrow, panel A) lying on an upper pole lateral papillum of an ICSF patient is visualized by a digital endoscope before removal and after removal (panel B). The region where the stone was attached contains sites of interstitial plaque (arrow, panel B). The removed stone has a white patch (arrow, insert to panel B) on its tissue or attachment surface.

organic (black) and crystal (white) layers (Fig. 67.14, panel (D)). The inner boundary layer covering where plaque was exposed (Fig. 67.14, panel (D)) contains Tamm Horsfall protein (Fig. 67.14, panel (F)) and is therefore of urine origin; osteopontin (Fig. 67.14, panel (E)) is also present. The inset at upper right in panel d shows, at higher magnification, crystals oriented perpendicular to the plane of the organic layers. On the outer boundary of the ribbon (*) large rafts of crystals have grown out of the ribbon plane into what was the urinary space and extend outward forming the base of the stone. A double arrow points to large crystals just beneath the ribbon boundary.

From this picture, one infers that following exposure of plaque to urine the plaque surface was covered with organic molecules of urine origin—the inner boundary layer. Driven by urine SS, crystals nucleated in this layer and were covered by more matrix in which new nuclei formed; this process was repeated to make the lamination of the ribbon. Eventually, crystallization escaped from matrix control and expanded to form the base of a new stone.

The crystal in the ribbon and stone base is apatite, not CaOx. In the stone itself, one finds no CaOx until about 70 microns into the stone body, quite remote from the base. This means that CaOx stone formation depends upon deposition of plaque, exposure of plaque to urine via disruption of urothelium, a presumably spontaneous covering of the exposed plaque surface by urine molecules adsorbed onto the matrix of the plaque, nucleation of apatite driven by urine CaP SS, and subsequent waves of matrix covering, apatite nucleation, and eventually escape from the ribbon to form the apatite stone base. More apatite accumulates but eventually, perhaps because of the balance of urine SS values, CaOx comes to predominate. As an alternative, formation of apatite may eventually reduce local pH in the stone interior, favoring CaOx; this idea has no support as yet from experiments. Presently we have no information about what causes urothelial disruption, but the processes of apatite nucleation and plaque formation have been studied reasonably well.

Apatite Nucleation

It would appear that formation of CaOx stones depends upon nucleation and growth of apatite driven by urine CaP SS, so one might ask if CaP SS of ICSF exceeds normal. In fact it does. In a GCRC controlled study (Fig. 67.15) CaP SS (lower right panel) of ICSF (grey bars) exceeds normal (cross hatched bars).[26] Normal controls did not achieve SS values above 1, whereas the SF invariably exceeded 1 (dashed line on graph). Surprisingly, the highest CaP SS values were overnight. Urine calcium molarity of ICSF (upper left panel) far exceeded controls; this difference reflects IH in ICSF coupled with virtually identical urine volumes between the groups (lower middle panel). Urine pH values (lower left panel) and urine phosphate excretions (not shown) did not differ. The critical role of an initial apatite deposit over exposed plaque coupled with the ability of IH to produce marked CaP SS means that clinicians need to control both CaP and CaOx SS in ICSF, a hitherto non-intuitive idea.

The importance of apatite nucleation also raises a possible link between urine citrate levels and CaOx stone formation. Citrate inhibits nucleation and growth of apatite at concentrations of 0.5 to 2 mM/l, levels found in normal urine. If indeed the primary nucleation over exposed plaque is apatite, low urine citrate excretion could foster CaOx stone formation by

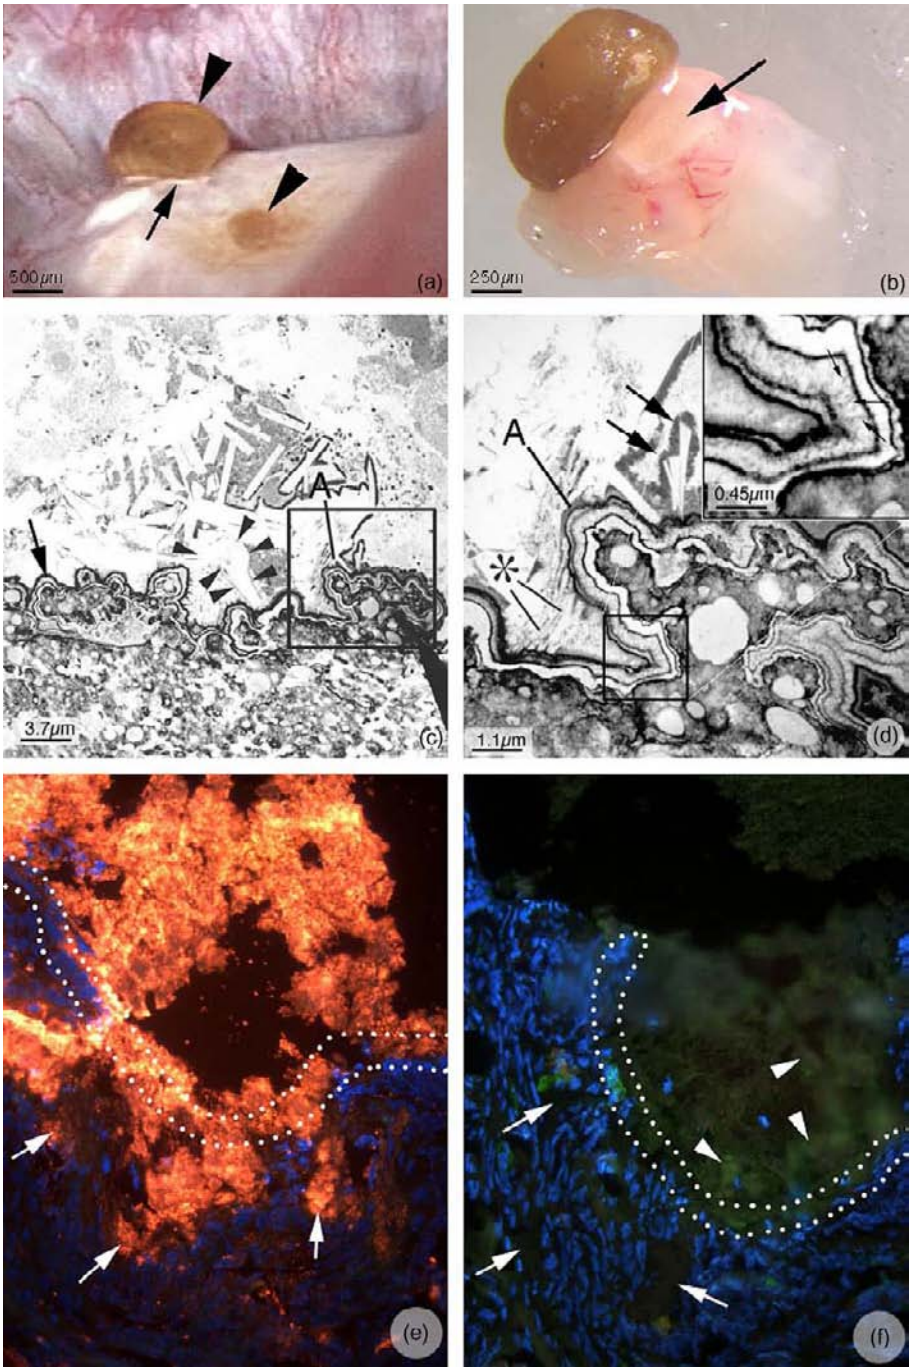

FIGURE 67.14 Endoscopic and ultrastructural analysis of a stone from an ICSF patient. By digital intraoperative endoscopy, small stones (arrowheads) are seen adhered to a papillum (panel A). A distinct region of Randall's plaque is visible just under the stone at the tip of the arrow. During PNL, the larger of the two stones seen in panel A was removed with a biopsy instrument such that the stone-plaque-tissue complex remained intact (panel B, arrow pointing to Randall's plaque region seen in panel A). Panel C is a TEM micrograph at the stone-plaque-tissue interface. The upper portion of the micrograph shows the stone while the lower portion shows interstitial plaque within the papillary tissue. An arrow marks the plaque boundary which has the unique appearance of a multilayered ribbon. Rafts of large crystals (always coated with matrix material) appear to grow out of the ribbon and into what was the urinary space (now the base of a stone). One particular crystal (outlined in arrowheads) is seen attached to the outer matrix layer of the ribbon. Panel D is a higher magnification image of the square seen in panel C. The ribbon-like structure is clearly seen as nine separate layers. The inset (upper right hand corner) reveals five thin black organic lamina that alternate with four white lamina. In the thickest of the white lamina, one can see tiny thin spicules that run perpendicular to the ribbon and have the appearance of multiple voids that contain tightly packed crystals (small arrows, inset). Small (asterisk) and large (arrows) coated crystals are seen inserted into the outer matrix layer of the ribbon. By immuno-histochemistry (panel E) osteopontin was detected in both the stone and interstitial plaque (white arrows) while sites of Tamm-Horsfall protein (panel F) were only seen in the stone (white arrowheads). The dotted white line delineates the interface region. See color plate section at the back of the book.

removing an important inhibitor. Likewise, increase of citrate by potassium alkali administration could reduce CaOx stone formation presuming that increase of urine pH did not offset the benefits of increased citrate inhibition.

Apical Collecting Duct Calcium Receptor (CaSR) Does Not Protect Against Supersaturation

That urine volume can be the same in the ICSF and controls, especially overnight when calcium molarity in ICSF reaches nearly 6 mM/L (Fig. 67.15, compare upper left and lower middle panels), does not accord with the concept, arising in rodents, that the apical collecting duct CaSR protects against stones by reducing water reabsorption when calcium excretion rises.[26] But our data are perfectly predictable from what is otherwise known. The human CaSR, *in vitro*, has an EC50 of about 6 mM/l at the pH and ionic strength of urine.[115] At a total concentration of 6 mM/L, urine contains only about 3 mM/l of calcium ion, the remaining

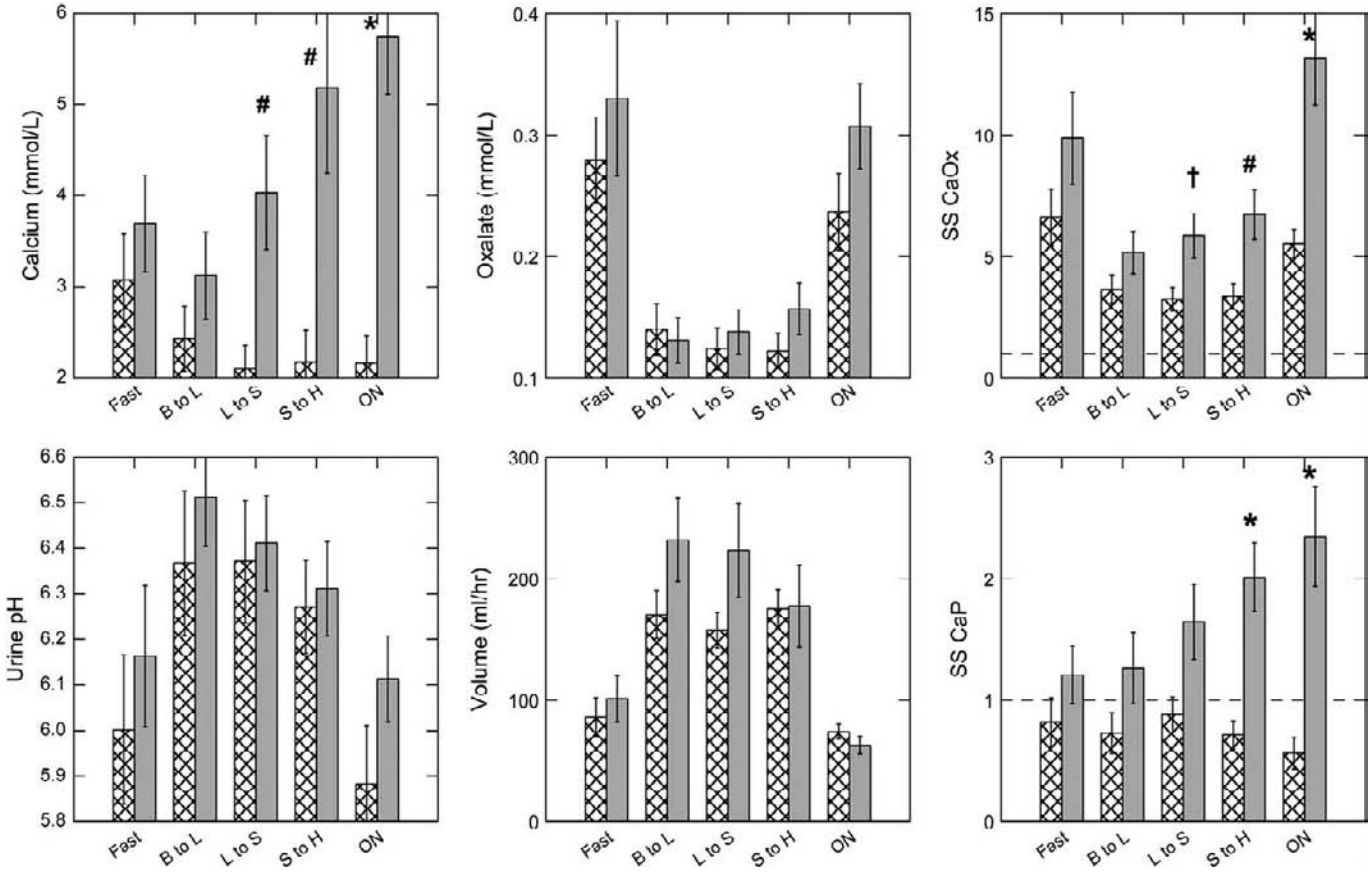

FIGURE 67.15 Urine SS for CaOx and CaP throughout the day in IH and normals. CaOx SS (*top right*) and CaP SS (*bottom right*) are shown during fasting and in the periods from breakfast to lunch (B to L), lunch to supper (L to S), supper to home (S to H), and overnight (ON). Horizontal lines indicate SS of 1. Concentrations of urine calcium (*top left*) and oxalate (*top middle*), as well as urine pH (*bottom left*) and urine flow rate (*bottom middle*), during the same periods are indicated. Cross-hatched bars, normal subjects (N); gray bars, IH. Values are means ± SE adjusted for repeated measures. Significant differences between IH and N by time period: $^{*}P < 0.001$, $^{\#}P < 0.01$, $^{\dagger}P < 0.05$. *(Reprinted with permission from ref. [15])*

calcium being complexed with phosphate, oxalate, sulfate, citrate and other anions. Possibly, the CaSR of stone formers is less sensitive than normal, because reduction of urine calcium excretion in enuretic children with IH may reduce nocturnal urine volume,[116] but this matter has not been addressed. For the moment one may suggest that modest nocturia might be valuable in treatment of very active stones in ICSF.

How Plaque Forms

The fraction of papillary surface covered by plaque (Fig. 67.16) varies directly with urine calcium excretion and inversely with urine volume and pH;[117] a multivariate score using all three variables accounts for much of the variation. How these three variables link mechanistically to plaque is a research matter, but one mechanism is well supported enough to warrant presentation.

Plaque forms in the basement membranes of thin limbs, which are mingled with capillaries in the papilla in a ratio of 4:1, capillaries predominant (Fig. 67.17). Thin limb fluid, in all animal micro-puncture studies, has a high SS with respect to CaP,[118] because water extraction raises calcium concentration above blood levels, and phosphate and bicarbonate to or above blood level. But because the epithelium has very low calcium permeability, entry into the basement membrane from the lumen could be easily over-balanced by diffusive losses into the interstitium.

Such losses are reduced by calcium delivery from the capillaries. The descending vasa recta pass downward through the inner stripe of the outer medulla (OM) in bundles surrounded by a ring of thick ascending limbs (Fig. 67.17) that enrich the OM interstitium with calcium by reabsorbing calcium without water. The descending vas carries this extra calcium down into the papillum, where counter-current trapping helps to keep it there. Vasopressin regulates medullary thick ascending limb (mTAL) reabsorption, therefore low 24 hour urine volumes, which must reflect correspondingly higher vasopressin levels, and more

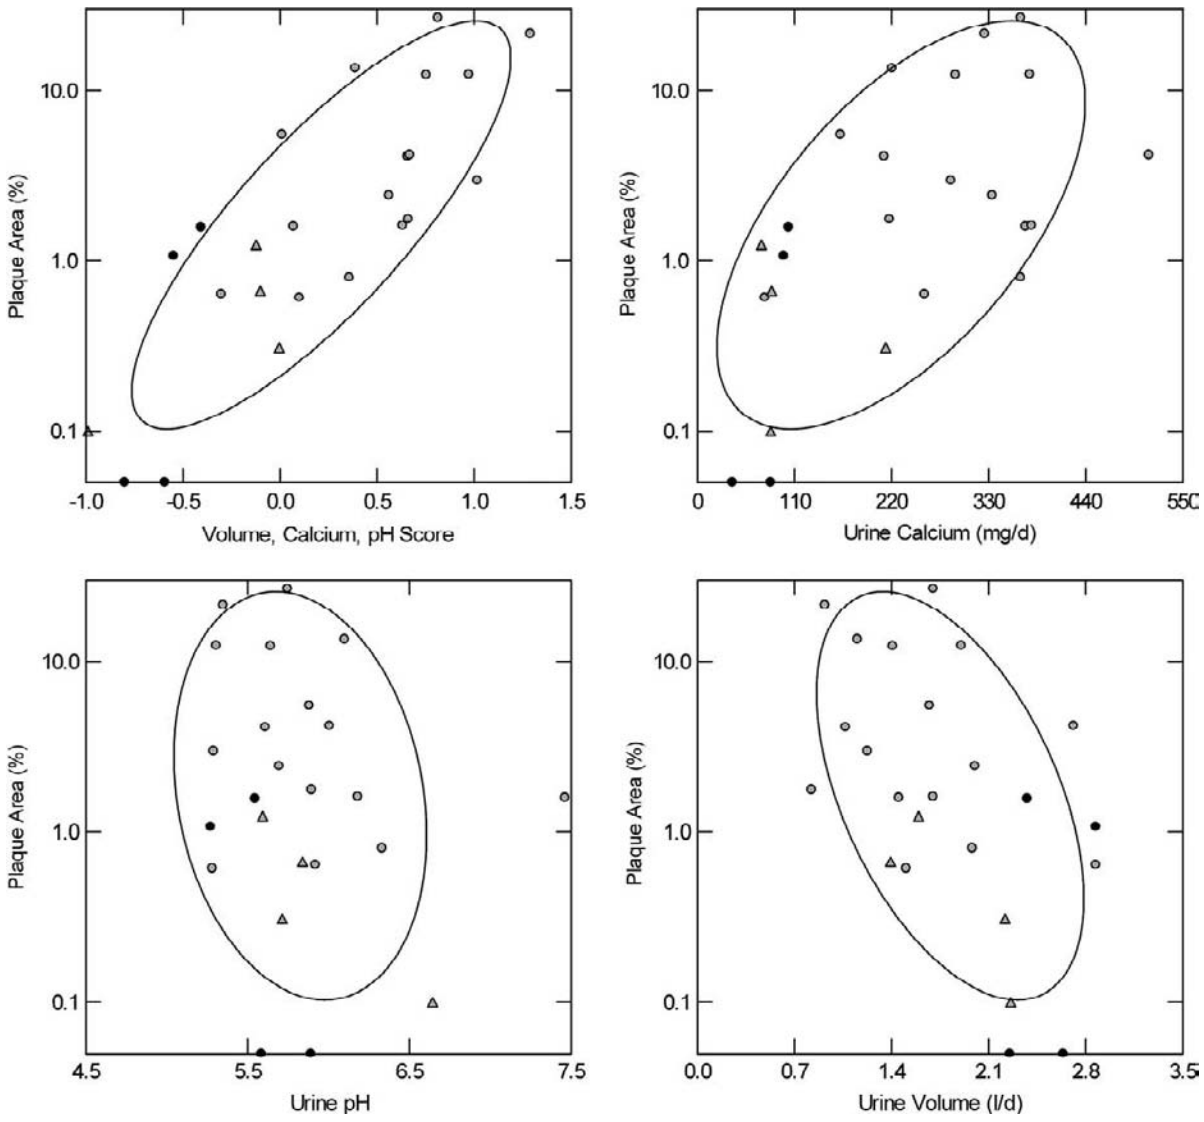

FIGURE 67.16 Relationships between plaque surface coverage and urine composition. Fraction of papillary surface covered by plaque, as determined from intra-operative digital imaging (y-axis of all 4 panels), varies with urine calcium (upper right panel), and inversely with urine pH and volume (bottom panels). A multi-variable score using all three variables accounted for much of the variation in plaque coverage (upper left panel). ICSF are open circles, controls (N) are closed circles; triangles are patients with obesity bypass procedures. *(Redrawn from ref.[117])*

efficient solute trapping, would correlate with plaque abundance. The fact that a few 24 hour urine volumes can correlate so well as they do with plaque that accumulates over years suggests that fluid intake must be strongly habitual and reasonably constant in any one person.

IH increases delivery of calcium out of PT (Fig 67.9), and thin loop segments reabsorb negligible amounts of calcium, so this increase of delivery reaches the mTAL which reabsorbs calcium mainly via electro-chemical equilibria. An increase of delivery will therefore increase absolute calcium reabsorption into the medullary interstitium and thence into the blood in the descending vas recta bundles. They in turn will carry a more calcium-enriched blood than normal down to the capillaries of the papillary tips, directly opposite to the thin limb basement membranes. The result will be increased plaque via local increase in CaP SS, and a tendency for plaque abundance to parallel urine calcium.

The implications of vas "wash down" of calcium into the papillary interstitium are clinically meaningful. Low sodium diet and thiazide might be expected to reduce plaque formation as well as stones because they can increase PT reabsorption. Reduced protein intake, by reducing endogenous acid load from oxidation of sulfur on methionine and cystine, would also increase PT reabsorption. High water intake will not only reduce urine SS but will reduce vasopressin levels and

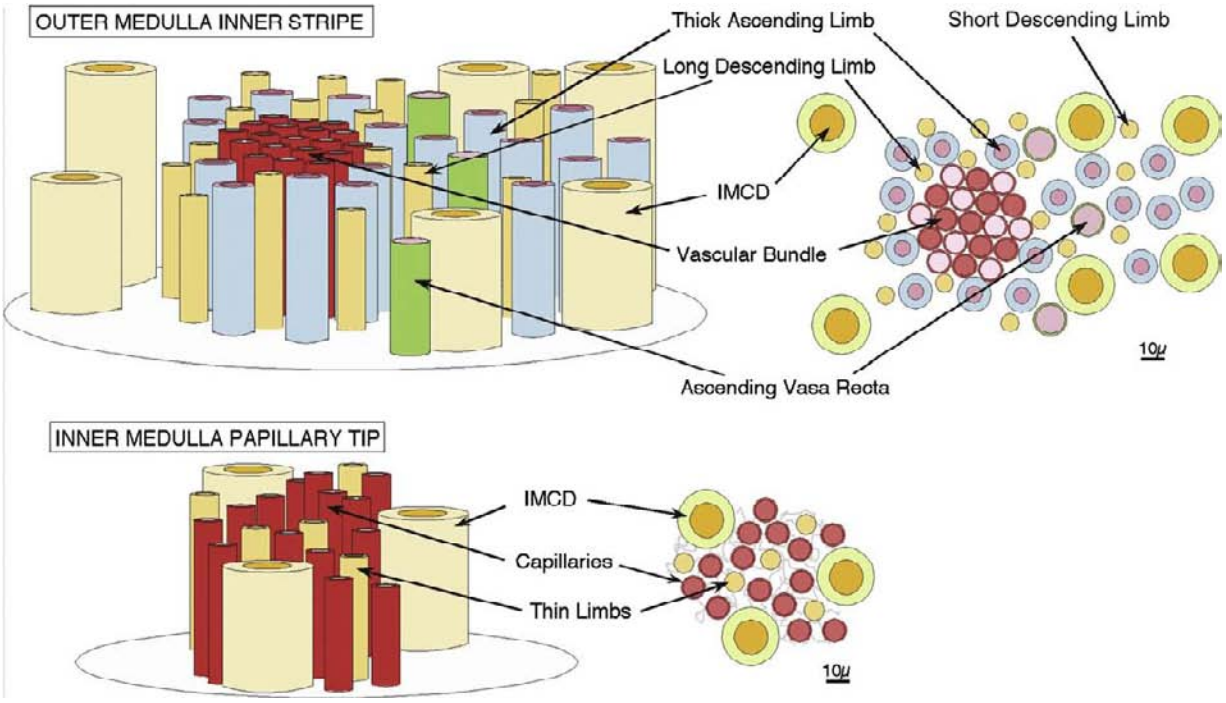

FIGURE 67.17 Physiology of vas wash-down for plaque formation. In the inner stripe of the OM (upper panel), vascular bundles (descending are solid circles, ascending are clear) are surrounded by medullary thick ascending limbs of the long nephrons (mTAL) which reabsorb NaCl and calcium without water. In IH PT can deliver more calcium than normal to mTAL with each meal, raising the absolute rate of mTAL calcium reabsorption above normal. Running downward inside the ring of mTAL, vas blood will be enriched in calcium, and increase inner medulla interstitial [Ca] in the region of thin loops favoring apatite nucleation there. Counter current trapping will help retain the extra calcium. mTAL CaSR is down-regulated by the high ionic strength in OM so it does not shut off continued reabsorption. Short descending thin limbs from mid and outer cortical nephrons travel downward within medullary rays, whose basic unit is a quartet of IMCD with an internal loose bundle of short descending limbs. This arrangement removed water reabsorption by short limbs from diluting the interstitium around the descending vas recta bundles.

therefore mTAL reabsorption and, to the extent that vas wash-down is true, plaque formation.

The Idiopathic CaOx Stone Former as a Unique Clinical Phenotype

The ICSF phenotype is so distinctive as to be unique. Apart from IH, which is not a disease, but merely a selection of people from the high tail of human calcium excretion, there is no systemic illness. Stones are over 50% CaOx. In over 30 instances thus far, kidneys always reveal a singular appearance: normal papillae except for interstitial plaque; no crystals in any epithelial compartments. Stones grow on the outside of the papillae, over regions of interstitial plaque that have been exposed to the urine via disruption of the urothelial membrane. The process of overgrowth begins with an initial apatite layer. Plaque itself forms in basement membranes of thin limbs of Henle's loop and the mechanism appears to involve the basic physiology of IH itself coupled with the peculiar anatomy of the inner stripe of the outer medulla. This physiology and anatomy links plaque formation to the magnitude of IH via changes in PT calcium reabsorption, and to urine volume via both effects of high urine flow to wash solutes out of the deep medulla, and reduction by high water intakes of vasopressin, that drives mTAL calcium reabsorption in the inner stripe.

No other kind of stone former observed thus far manifests the clinical and histopathological characteristics of the ICSF, and we believe, therefore, that ICSF should be set apart into their own category. Because the links between the final disease, stones, and the physiology and histopathology of the condition are reasonably well understood, because treatments to prevent the stones are effective and act through reasonably well defined pathways of pathogenesis, and because the prime mover, IH, is established as heritable, ICSF appear to satisfy all the criteria of a unique disease of stone formation.

Idiopathic Calcium Phosphate (Brushite, BR) Stone Formers

Clinical and Histopathological Features

Like ICSF in their metabolic derangements except for a tendency for high urine pH, the stones they form

contain above 50% CaP. They produce significant amounts of interstitial (white) plaque, but also have a second type of plaque (yellow plaque) which represents plugging of IMCD with apatite crystal.[119] Yellow plaque is seen on the papillary surface as linear yellow streaks, very different from the white plaque of the ICSF (Fig. 67.18, arrows, panel c). Scattered IMCD and BD are massively dilated with apatite plugs (Fig. 67.18, panel a). Epithelial cells of plugged IMCD and BD are mostly dead (Fig. 67.18, panel b) and interstitial fibrosis is severe (Fig. 67.18, panels e and f). Here and there plugs extend out of hugely dilated BD into the urinary space (Fig. 67.18, panels a and b). The papillae are distorted and abnormal, pitted, scarred, and flattened (Fig. 67.18, panel a).

The plugs and stones appear to have a common cause in an elevated urine pH. Among a large series of stone formers for whom stone composition has been determined, the fraction of stone crystal that is CaP rises in synchrony with the urine pH (Fig. 67.19).[4] The higher pH increases CaP SS and therefore the risk of CaP crystallization. Once the process of apatite plugging and consequent cell injury begins, lumen pH of individual IMCD could rise creating a vicious cycle, and if wide-spread the process would further increase urine pH.

Even as new research tests these ideas about pathogenesis, we will be left with the problem of what comes first. The phosphate content of kidney stones in the United States has been rising for decades,[4] and during that time use of extracorporeal shockwave lithotripsy (ESWL) and of potassium alkali for stone treatment both have become common practice. In fact, the number of ESWL procedures per patient, corrected for number of stones, age, sex, and duration of stone disease, rises progressively with the number of ESWL procedures.[4] Possibly, terminal IMCD and BD injury from ESWL or increase of urine pH from potassium citrate treatments initiate CaP crystallization, which then leads to a cycle of further cell injury and crystal plugging. Obstructive uropathy can reduce acidification, and stones are nothing if not a cause of recurrent obstruction. Possibly high urine pH is like IH, an hereditary trait. In patients who converted from making stones composed mainly of CaOx to those composed of CaP, urine pH was significantly higher when they were still making CaOx stones, compared with patients who did not convert.[120] The increased urine pH in patients with idiopathic CaP stones is not accompanied by abnormal serum pH or bicarbonate, although some such patients have abnormalities of acidification on provocative testing with ammonium chloride.[121] This appears to be part of the incomplete RTA syndrome.

How Brushite Stones Form

At surgery mature stones are not often found attached to protruding apatite plugs, nor are they found on the rather scanty plaque. They are usually free in the renal pelvis and calyces. The plug extensions into the urine are like nascent stones in that their further growth is dependent entirely on urine SS and inhibitors, and plugs could break off and grow into clinically relevant stones. This is untested. Possibly stones form in free solution.

Idiopathic Calcium Oxalate and Calcium Phosphate Stone Formers in Practice

As clinicians, we take heed of stone analysis with brushite or CaP even above 20%, because the kidneys can be involved in a significant tubular disease. In such patients we are liberal with thiazide and water, and reduced diet sodium and protein, but stingy with potassium alkali which could increase urine pH and CaP SS. We need a trial of potassium alkali in CaP stone formers, because this reasonable approach may be wrong. Citrate inhibits CaP crystallization, so alkali could be more beneficial than harmful.

PNL and URS are increasingly being used for stone removal, and during such procedures urologists can observe if papillae are affected with plaque alone, or with ductal plugging and papillary retraction. The former implies that water, reduced salt and protein, thiazide and potassium alkali all are reasonable treatment measures. The latter implies that alkali may not be ideal and that measures to prevent stone recurrence should be, perhaps, more urgent and aggressively pursued, as the disease may be more damaging. While not as yet accepted practice, use of observations during stone surgery to guide medical intervention is reasonable and practical in many cases, and can be recommended as an adjunct to medical stone prevention.

CALCIUM STONES ARISING FROM SYSTEMIC DISEASES

In these patients, stones are a manifestation of a systemic disease that, itself, warrants diagnosis and treatment. In each case where we have adequate information, the systemic disease has produced a specific renal histopathology and set of urine stone forming abnormalities which arise from disease-specific and often complex pathophysiology. The whole approach to patients with systemic stone forming disease differs radically, therefore, from that used for idiopathic stone formers.

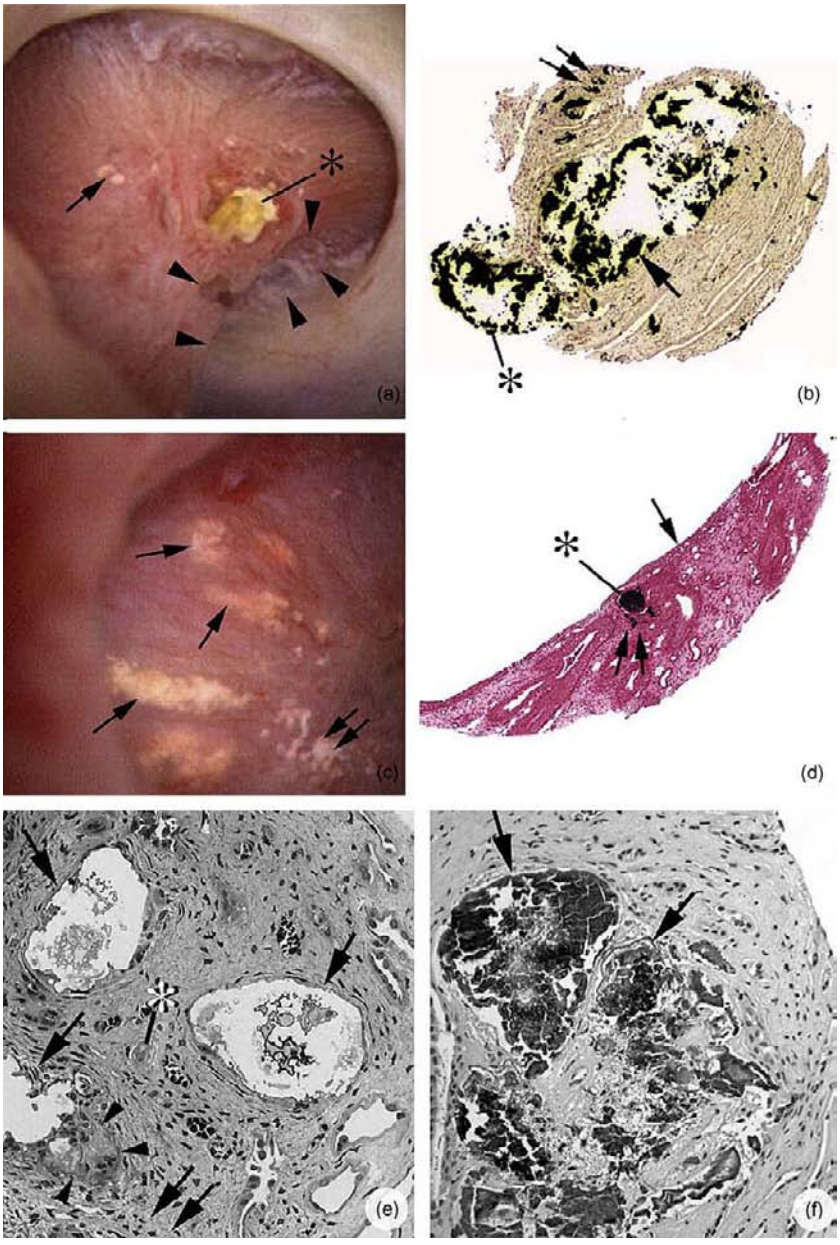

FIGURE 67.18 Endoscopic and histologic images from brushite (BR) stone formers. Panel a shows an example of a papillum from a BR patient that was video recorded at the time of stone removal. Papillae from BR patients often showed depressions (arrowheads) near the papillary tip and flattening, a phenomenon not seen in CaOx stone formers. Like CaOx patients, the papilla from BR stone formers possessed sites of Randall's plaque (arrow), though less in amount. In addition, these papillae possessed sites of yellowish crystalline deposits at the openings of ducts of Bellini (asterisk). The ducts were usually enlarged and occasionally filled with a crystalline material that protruded from the duct that might serve as a site for stone attachment. Panel b shows crystal deposition in a papillary biopsy stained by the Yasue method. Note crystal deposits protruding from the duct of Bellini (*) and in the lumens of an associated inner medullary collecting duct (IMCD) and of a nearby loop of Henle (arrows). The crystal deposits greatly expanded the lumen of these tubules and induced cell injury to complete cell necrosis of the tubular epithelium. A cuff of interstitial inflammation and fibrosis accompanied sites of intra luminal deposition. Panel c shows sites of yellow plaque on the papillum of a BR stone former. Yellowish mineral deposition (single arrows) was found within lumens of IMCD just beneath the urothelium; these deposits are called yellow plaque. Deposits ranged from large areas of crystal deposition in collecting tubules that formed a spoke and wheel-like pattern around the circumference of the papilla to small, single sites of yellowish material in focal regions of a collecting duct lumen. Histologic analysis of sites of yellow plaque (panel d) confirms that these crystal deposits are in IMCD (asterisk) positioned just beneath the urothelial lining (arrow). The double arrow shows a site of interstitial plaque like that seen in idiopathic CaOx stone formers. Light micrograph in panel e shows extensive interstitial fibrosis (double arrow), tubular atrophy (asterisk), loss of tubular lining cells (single arrows) and giant cell formation (arrowheads), while panel f shows a region of heavy mineral deposition (single arrows) at the site of extensive tubular injury and fibrosis. These changes were never seen in CaOx stone formers. See color plate section at the back of the book.

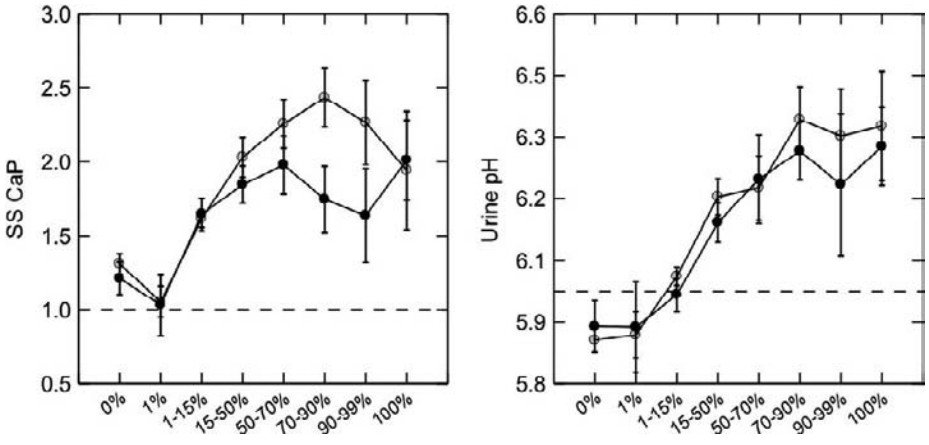

FIGURE 67.19 Correspondence beween percentage of CaP in stones and urinary CaP SS and pH. As expected, CaP SS rose with stone CaP percent (left panel, y- and x-axis, respectively), among men (gray circles) and women (black circles). Values are mean ± SEM. Urine pH also rose progressively (right panel) which would increase CaP SS. *(Reprinted with permission from ref.[4])*

Primary Hyperparathyroidism (PHPT).

Pride of place goes to this disease, even though only 5% of stone patients have it.[25] Before most other causes were known about, PHPT was recognized as a curable cause, and surgeons in the better centers were regularly performing curative neck dissections. The disease arises from neoplasia of one or more parathyroid glands, leading to solitary adenoma in 85% of patients and multiple gland enlargements in the remainder. Malignant neoplasm of the parathyroid glands is rare as a cause of stones. Here, we focus specifically on the stone disease and factors producing stones, leaving details of parathyroid hormone regulation and actions to the appropriate chapters.

Because the main actions of parathyroid hormone (PTH)—increased renal production of calcitriol, increased bone mineral turnover, and increased renal tubule calcium reabsorption—all raise serum calcium, an elevated blood calcium level is always found, if one looks for it properly. The problem is that the elevation can be mild, and because normal values for serum calcium depend on the analytical methods used to measure it, and the methods in use are numerous and variable, the true normal may often not be known by a physician.

PHPT is easily confused with IH because hypercalciuria is prominent and hypercalcemia subtle, often below 11 mg/dl. Although serum phosphorus is generally low, because PTH reduces renal phosphate reabsorption, this trait is also common in ICSF, for unknown reasons. The PTH elevation may also be subtle, but the failure of PTH to be suppressed by elevated serum calcium strongly suggests PHPT. The high urine calcium raises SS with CaOx and CaP, which are the proximate mechanism for stone formation. The hypercalciuria is a direct effect of increased calcium absorption by intestine, driven by calcitriol excess, and bone mineral loss, driven by PTH. One often hears that stones in this disease are more enriched with calcium phosphate salts than is usual, but our patients for whom we have complete stone analysis show only a subtle increase, and only in men.[25]

The renal histopathology of primary hyperparathyroidism combines that of ICSF and IPSF (Fig. 67.20).[122] CaOx stones grow on plaque, and many BD are plugged with apatite crystals (Fig. 67.20). Because PHPT is a marked hypercalciuric state, plaque is not a surprise, although the exact pathophysiology is not defined as yet. Likewise, that urine pH and CaP SS are somewhat higher in PHPT than ICSF,[25] presumably accounts for plugging. Observed at PNL or URS, the combination of apatite tubule plugging with CaOx stones growing on plaque can be of diagnostic use, and suggest the correct diagnosis when hypercalcemia is subtle and PHPT might be mistaken for ICSF or IPSF. Although this combined pathology also occurs in bowel diseases, their presence is almost always obvious.

Given distinctive hypercalcemia and hypercalciuria, PHPT is not difficult to diagnose. Serum PTH is reduced by all hypercalcemic states due to vitamin D excess, primary bone mineral loss from tumor invasion or rapidly progressive osteoporosis, or mediated via the PTH-related peptide found in malignant neoplasms, so one asks not whether PTH levels are high but simply whether PTH levels are not subnormal. If normal or high, PTH values confirm the presence of PHPT in a person with both hypercalcemia and hypercalciuria, and little more needs be done before curative surgery.

Given normal or low urine calcium, however, the possibility exists of familial hypocalciuric hypercalcemia (FHH), a hereditary disorder of the calcium receptor in parathyroid and renal tubule cells. Such patients may have stones and come to attention for them, but should not be considered for parathyroid surgery. Stones will be due to another condition. Family

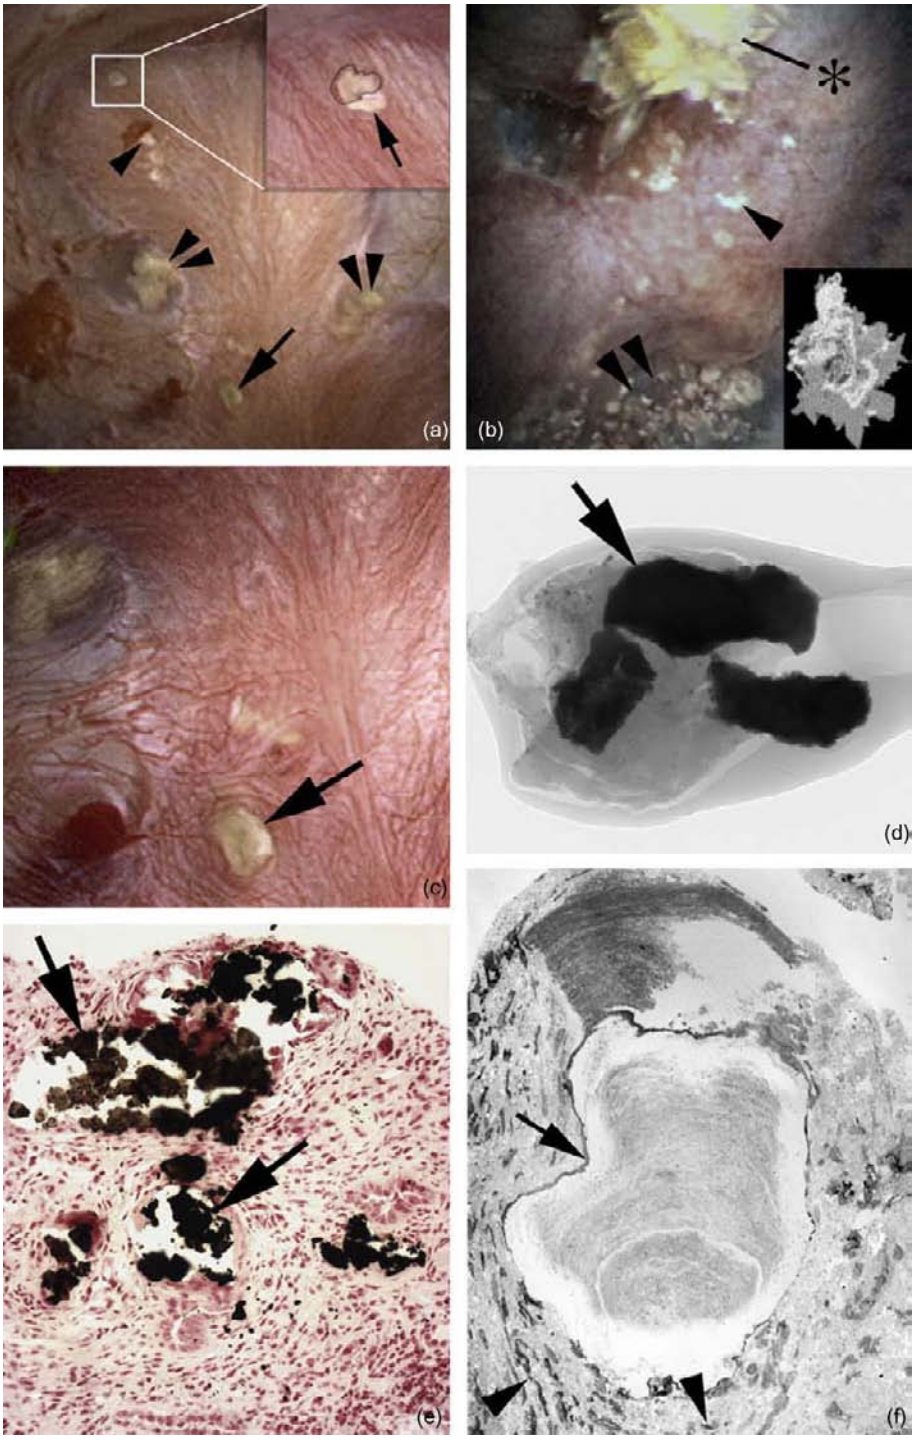

FIGURE 67.20 Endoscopic and histologic images of stone-forming patients with primary hyperparathyroidism (PHPT). Digital endoscopic and histopathologic characteristics of renal papilla from patients with PHPT include a combination of features seen in ICSF and IPSF patients. Patients may have attached stones (see small stone within white outlined square in panel A and enlarged insert where stone is outlined and region of white plaque indicated by arrow; also see asterisk in panel B) at sites of Randall's plaque (single arrowheads, panels A & B) and dilated openings of ducts of Bellini with protruding plugs (single arrow, panel A and C) on the same papilla. Attached stones were composed of CaOx and apatite (see micro-CT insert in panel B). Suburothelial yellow plaque was noted across the papilla and varied in size from small to rather large deposits (double arrowheads, panels A & B). The very large size of some of the intraluminal deposits was confirmed by micro-CT (arrow, panel D). Yasue stained sections and TEM micrographs revealed the massive sites of intraluminal plugs filling the lumens of IMCD (arrows, panels E & F) associated with a loss of all lining cells. A cuff of interstitial fibrosis (arrowheads, panel F) surrounds the plugged tubules. See color plate section at the back of the book.

members can be screened for hypercalcemia as the trait is autosomal dominant with 100% penetrance. Guise and Mundy offer a convenient formula for evaluating urine calcium to diagnose FHH.

Other confusions may arise from lithium treatment, which can induce a state of parathyroid over activity, and use of thiazide, which may raise blood calcium yet leave incompletely treated an independent hypercalciuric state, thus creating a factitious semblance of PHPT. Distinguishing sporadic hyperparathyroidism and its familial forms from the multiple endocrine neoplasia syndromes is usually unnecessary, as stone patients tend to have simple hyperparathyroidism. However, the details of the multiple endocrine neoplasia (MEN) syndromes are discussed in other chapters and may be of interest.

Surgical excision of the abnormal gland(s) is curative for stones, in our work as well as that of others. Postoperatively, serum calcium returns to normal, and urine calcium falls markedly, although it may remain mildly elevated, for unknown reasons. SS for both CaOx and CaP drops and stone formation decreases. The surgery is never intended to confirm the diagnosis, which can be made using serum calcium, urine calcium, and PTH values, but to cure the disease. Proper surgery identifies all parathyroid glands in the neck, to ensure that all abnormal tissue is removed, leaving normal glands untouched. If all parathyroid tissue is removed, creating hypoparathyroidism, a new and difficult stone-forming condition may be produced, because patients lose the effects of PTH to raise renal calcium reabsorption. When supplemental calcium is given by mouth to raise blood calcium to an acceptable level, urine calcium levels rise steeply, and stones form.

Renal Tubular Acidosis

Inherited or acquired forms of distal RTA (Type I RTA) raise urine pH and urine calcium, decrease urine citrate, and produce CaP stones. At surgery, interstitial plaque is not above normal abundance and stones are not found growing on what little is present (Fig. 67.21).[123] Tubule plugging is very widespread (Fig. 67.21) with attendant fibrosis and tissue damage. As in IPSF and PHPT the origin of the CaP stones is not clear: detachment of protruding plugs or free solution crystallization. Diagnosis is from reduced serum bicarbonate with alkaline urine pH, and often hypokalemia showing the importance of blood screening for all stone formers. Treatment with potassium citrate can correct acidosis and reduce hypercalciuria, but careful follow-up is required to ensure that urinary SS for CaP falls. Persistent hypercalciuria after acidosis has been corrected can be treated as for IH, with thiazide.

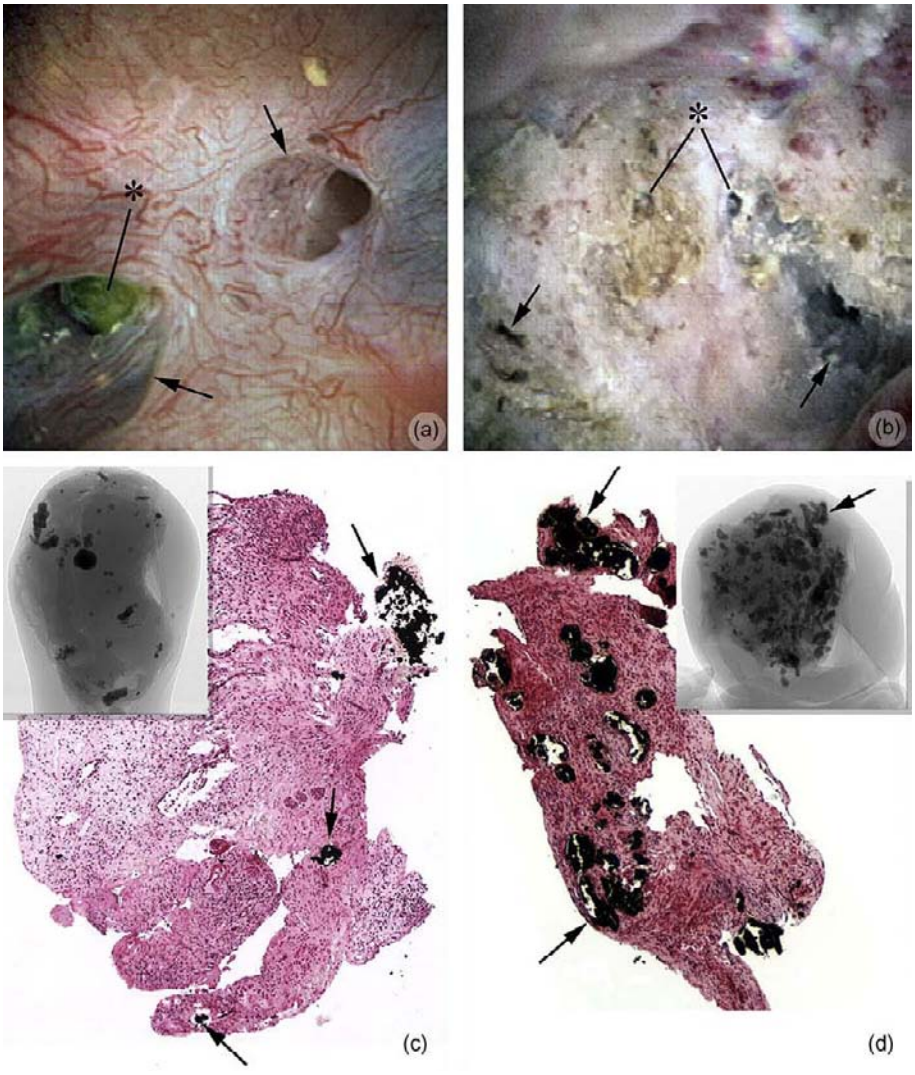

FIGURE 67.21 Endoscopic and histologic images of stone-forming patients with distal tubular acidosis (dRTA). These stone-forming patients have a range of papillary abnormalities. Papillae may be normal apart from an occasional dilated duct of Bellini (arrows, panel A) and yellow plaque representing apatite mineral plugs (asterisk, panel A) within IMCD. Panel B shows the most extensive papillary damage with retraction, loss of normal architecture, multiple dilated ducts of Bellini that produce a pitted appearance (arrows), some with protruding mineral deposits (asterisks), and a whitish thickened membrane appearance. Papillary biopsies also reveal a range of histopathology. The Yasue stained section seen in panel C shows minimal IMCD plugging (black material at arrows); micro-CT (insert) examination of the biopsy sample confirms the intra-luminal location and sparseness of crystal deposits. Yasue stained papillary biopsy seen in panel D shows diffuse IMCD plugging (arrows) encased in extensive interstitial fibrosis. The micro-CT micrograph (insert) confirms the location and density of intra-luminal deposits (arrows).

Patients with RTA are at risk of loss of renal function, presumably secondary to severe nephrocalcinosis and recurrent bouts of stone formation.[124]

Bowel Diseases

Small Bowel Resection

Loss of small bowel results in a constellation of abnormal physiologies sometimes referred to as enteric hyperoxaluria: small-bowel malabsorption coupled with the presence of at least some colon that receives small-bowel effluent and through which excess oxalate enters the blood. Typical settings are Crohns disease, or small-bowel resection or bypass, the latter in treatment of obesity or hypercholesterolemia;[125] pancreatic insufficiency or sprue may cause a similar picture. In all cases, treatment is difficult. Oxalate absorption is mediated by many transporter assemblages,[126] and unabsorbed fatty acids in all of these conditions appear to increase colonic oxalate absorption.[127] Reduced colonic reabsorption of water and salts leads to diarrhea with loss of alkali in the stool, and consequent low urine citrate from systemic bicarbonate losses.[125,128] The resulting urine, high in oxalate and low in volume and citrate, is ideal for stone production.

The renal histopathology in small bowel resection from inflammatory bowel disease is like that of PHPT in combining apatite tubule plugging with CaOx stone overgrowth on plaque (Fig. 67.22).[129] Plaque abundance exceeds that seen in PHPT whereas the amount of plugging is less. The plugs contain mainly apatite, with a scattering of CaOx. Mechanisms for plaque include low urine volume and pH. Plugging with apatite would not be expected given the low urine pH and absence of CaP SS. Urine CaOx SS is quite high, however, and possibly crystals of CaOx form as an initial

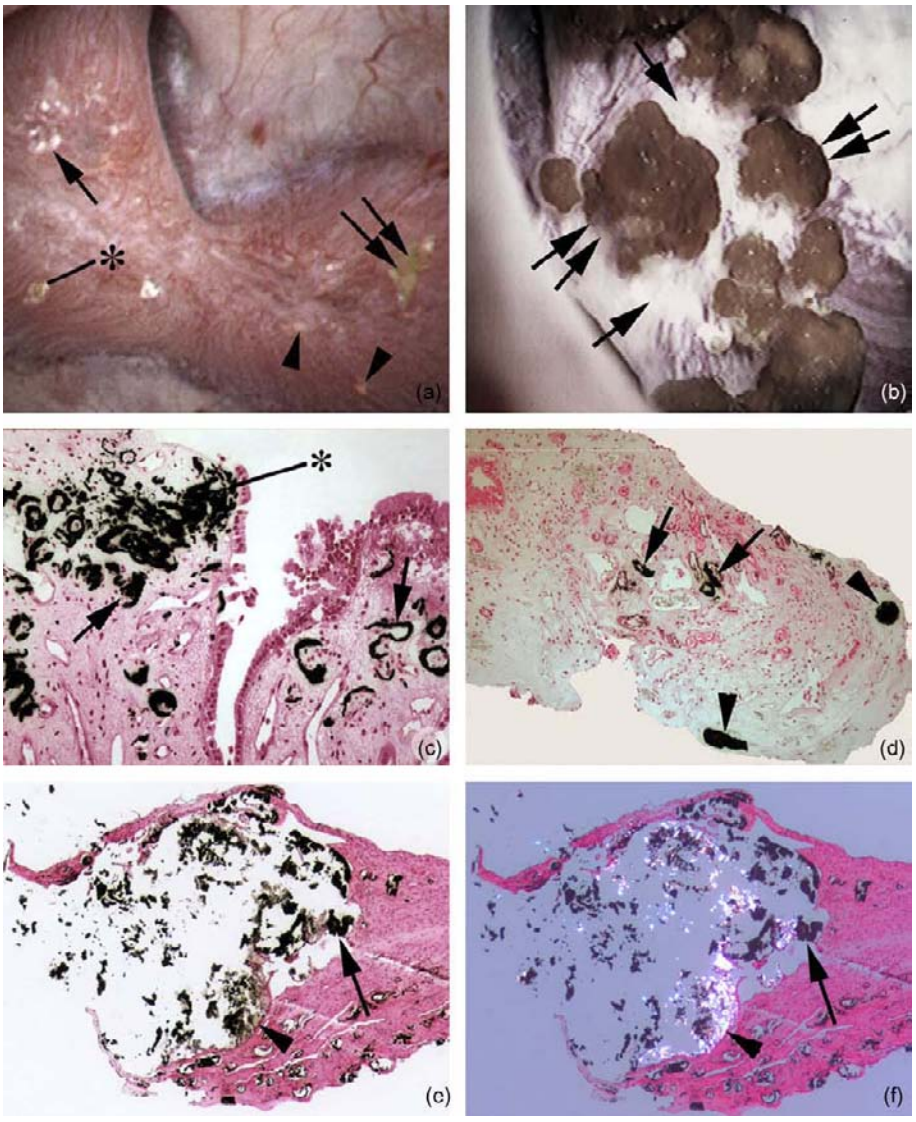

FIGURE 67.22 Endoscopic and histologic images of crystalline deposits in patients with small bowel resection with CaOx stone disease. In panel A papillae from these stone-forming patients are seen to have both attached stones (double arrow) on white plaque (single arrow) and protruding plugs (asterisk) from dilated openings of ducts of Bellini while others have large amount of white plaque (single arrow, panel B) with numerous attached stones (double arrow, panel B). Sites of yellow plaque (arrowheads) are seen in panel A. Yasue stained sections from papillary biopsies show large areas of interstitial plaque (arrows, panel C) surrounding the thin loops of Henle and extending to the base of the urothelial cells (asterisk, panel C). Areas of interstitial plaque (arrows, panel D) and plugged IMCD (arrowheads, panel D) are found in the same biopsy sample at varying amounts. The mineral type was apatite in these tubules. Other biopsy samples showed large deposits in IMCD to be a mixture of apatite (non-birefringent material at arrow, panels E and F) and CaOx crystals (birefringent material at arrowhead, panels E and F). See color plate section at the back of the book.

nucleation and injure cells. Injury could impair acidification, so tubule fluid pH rises and apatite forms in individual tubules. This conjecture requires experimental testing. Stones are generally CaOx and uric acid. The former grow on plaque; the latter presumably form in free solution, but this has not as yet been proven experimentally. Despite low pH, uric acid has not to date been found in tubule plugs.

The usual treatment measures are reasonable, but mediocre in use. Low-fat diet reduces delivery of fatty acids to the colon, but may impair nutrition in someone with small-bowel disease, so its use is marginal in many situations. Low oxalate diet is not difficult to prescribe, especially because vegetables and citrus fruits may already have been reduced because of intolerance. Cholestyramine, 2 to 4 g with each meal, is the measure we have found most effective, but the agent is unpleasant and cumbersome. Being a resin that can adsorb both oxalate and the offending bile and fatty acids,[18] it needs to be swallowed toward the end of a meal so it will migrate along with the food and take up the anions from it. Patients do not like to do this, and often miss doses. The resin has a taste many find objectionable. Even so, we have used it with some success, as have others.[130,131] Finally there is oral calcium, also taken toward the end of each meal. The calcium is intended to precipitate oxalate in the bowel lumen, and may do so if taken with good timing. Reasonable outcomes for stone prevention were published long ago;[132] there are no trials.

Obesity Bypass Procedures and Bariatric Surgery

Both jejuno-ileal bypass and modern bariatric surgery, particularly the Roux-en-Y or duodenal switch type of procedures, lead to hyperoxaluria in significant numbers of patients;[133] gastric banding does not appear to carry this risk.[134] Among bypass patients, papillary plaque abundance is normal (Fig. 67.23).[107] Stones are never attached to the papillary surfaces, but are found free in the renal pelvis. Scattered tubule plugs are apatite admixed with traces of CaOx.[110]

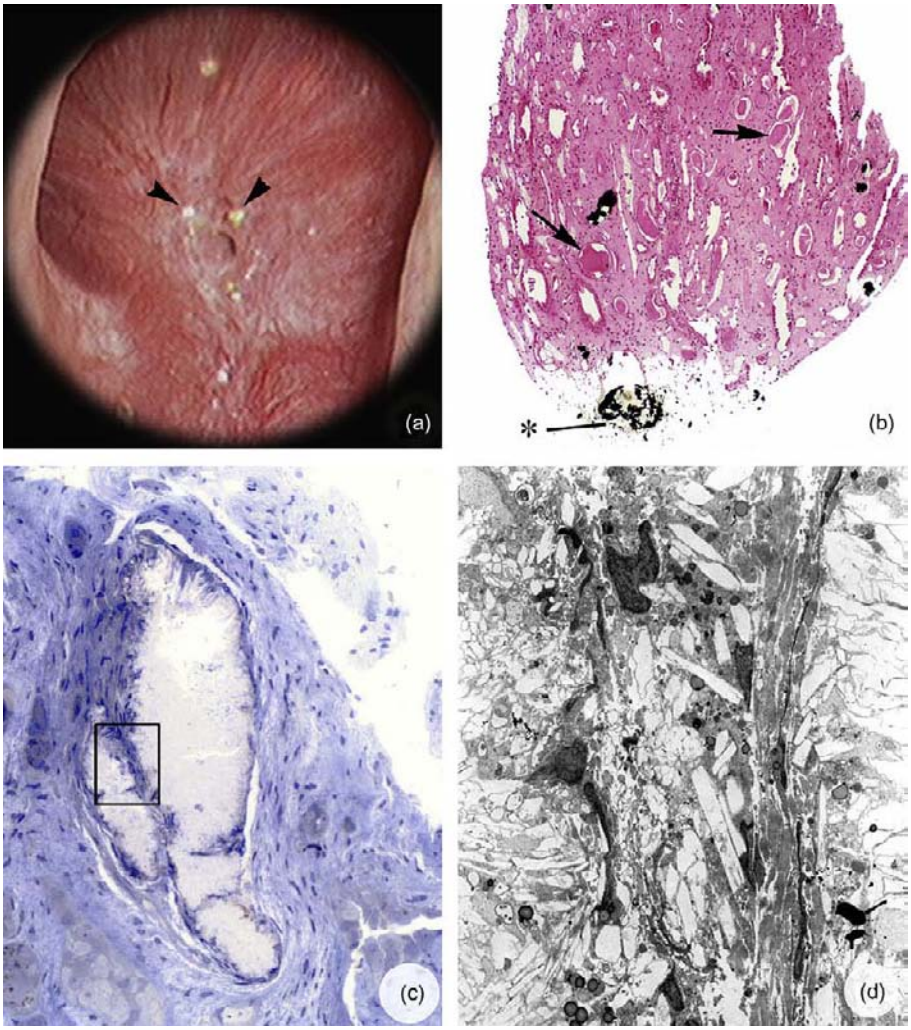

FIGURE 67.23 Endoscopic and histologic images from a stone forming patient who underwent intestinal bypass surgery for obesity. Panel A is an example of a papilla from an intestinal bypass stone former that was video recorded at the time of stone removal. Distinct sites of Randall's plaque were not found, instead, several nodular-appearing structures (arrowheads) were noted near the openings of the ducts of Bellini. Panel B is a low magnification light microscopic image of a papillary biopsy specimen from an intestinal bypass stone former showing crystalline deposits (asterisk) only in the lumens of a few IMCD or ducts of Bellini. No sites of interstitial crystalline deposit were seen. Note dilated collecting ducts (arrows) with cast material and regions of fibrosis around crystal-deposits-filled collecting ducts. Panel C is a light microscopic image showing a collecting duct completely filled with crystalline material. Panel D is an electron microscopic image of a region of the collecting duct seen in panel C (see rectangle). No cellular detail remains; only crystalline material is found. See color plate section at the back of the book.

Although hyperoxaluric, bypass patients maintain high urine volumes and have rather modest CaOx SS;[125] perhaps for this reason deposits are modest. Likewise high urine volumes with low normal pH would predict little plaque. Stones themselves can be abundant and their origin is uncertain; free solution crystallization is a real possibility. We do not have tissue from bariatric patients as yet. Presumably they will be like the bypass patients. Both categories of obesity surgery have the same underlying physiology and treatments are the same as for enteric hyperoxaluria from bowel resection. In some cases, severe hyperoxaluria may lead to tissue deposition of oxalate with acute or chronic renal failure.[135]

Ileostomy

Unlike small bowel resection and bypass procedures, there is no colon and therefore no hyperoxaluria. Instead volume depletion and bicarbonate wasting predominate, causing very scanty and acidic urine. From this one would predict considerable interstitial plaque, and that is indeed found (Fig. 67.24).[136] CaOx stones grow on the plaque as expected. Because of very low urine pH, uric acid SS is marked, but CaP SS is absent, so one might expect stones to contain uric acid and no CaP; this is true. However, tubule plugging is marked (Fig. 67.24) and the crystals in plugs are a mixture of apatite and the sodium and ammonium salts of uric acid; all three crystals are stable at high, not low pH. This discordance between crystal type and urine SS must arise from local acidification defects in the individual tubules as crystals are a form of pH indicator. Mechanisms are as yet unknown. Treatment is well established: maintain fluid intake as possible, use supplemental alkali as tolerated. Management is very complex as these can be sick and fragile patients. Of note, acute dehydration episodes can produce acute kidney injury from many causes: falling blood pressure, uric acid plugging of ureters, and acute uric acid nephropathy.[137]

Primary Hyperoxaluria

These rare autosomal recessive enzyme defects cause very high oxalate excretion rates, above 80 mg daily and typically in the range of 150 to 300 mg daily, due to overproduction of oxalate in the liver. Stones often begin in childhood, and renal failure is common as well. The high production of oxalate after kidneys fail can promote systemic oxalate deposition in heart and skin and blood vessels, and sudden bursts of oxalate into the tubule fluid of a renal transplant can destroy the organ.[138] Stone disease is CaOx, and may be very severe.

The usual type (type I: MIM 604285) is absence or ineffectiveness of the enzyme alanine/glyoxalate aminotransferase (AGT), that converts glyoxalate to glycine.[95] Without it, glyoxalate amounts increase, which is converted to oxalate by lactate dehydrogenase. In 40% of cases, the enzyme is not absent but is misdirected from its proper peroxisomal location to mitochondria, within which it cannot function except at a minimal level. Liver tissue has 3% to 40% of normal enzyme activity but full immunoreactivity, and the latter shows the improper location. The remainder lacks the enzyme because of one or more mutations in its structure. While the kidneys are functioning, one can diagnose this condition by high urine glyoxylate and glycolate levels as well as high oxalate levels. When renal failure has occurred, study of liver tissue remains definitive, however genetic diagnosis is becoming available, and may obviate the need for biopsy in many cases.[139]

In kidneys, plaque is absent (Fig. 67.25). Tubules are plugged with CaOx admixed with apatite. The numbers of plugged tubules approximate those seen in RTA, but deposits extend higher up in the nephron than usual in stone diseases, involving the thin loops and PT. Interstitial fibrosis also far exceeds that seen in any other stone disease.

Treatment can begin with large fluid intake and pyridoxine, 25 to 100 mg daily, the dosing raised by doubling depending on response. Pyridoxine is a cofactor for AGT, and patients with mutations associated with mitochondrial translocation seem to be the ones that respond.[138] Orthophosphate supplements and potassium citrate have also been reported as effective[140] but without controlled trials. Renal failure is common and is treated by combined liver–kidney transplantation.[141] Transplant nephrologists should beware of this condition, which can sneak by if stone history is slighted, especially if native biopsy was not performed. Management of transplantation is discussed in Chapter 94.

Type II hyperoxaluria (MIM 260000, 604296) is rare. The defect is loss of glyoxylate reductase/hydroxypyruvate reductase (GRHPR), leading to oxalate and L-glyceric acid overproduction. Treatment is the same as that for type I except that pyridoxine is not likely to be useful and renal failure is not as common.[142]

Recently, mutations in an uncharacterized gene, DHDPSL, on chromosome 10, have been associated with a third type of PH, now termed PH III. This autosomal recessive disorder is associated with presentation of stones in childhood, and preservation of renal function with conservative treatment appears to be the norm in the 9 families described thus far.[143]

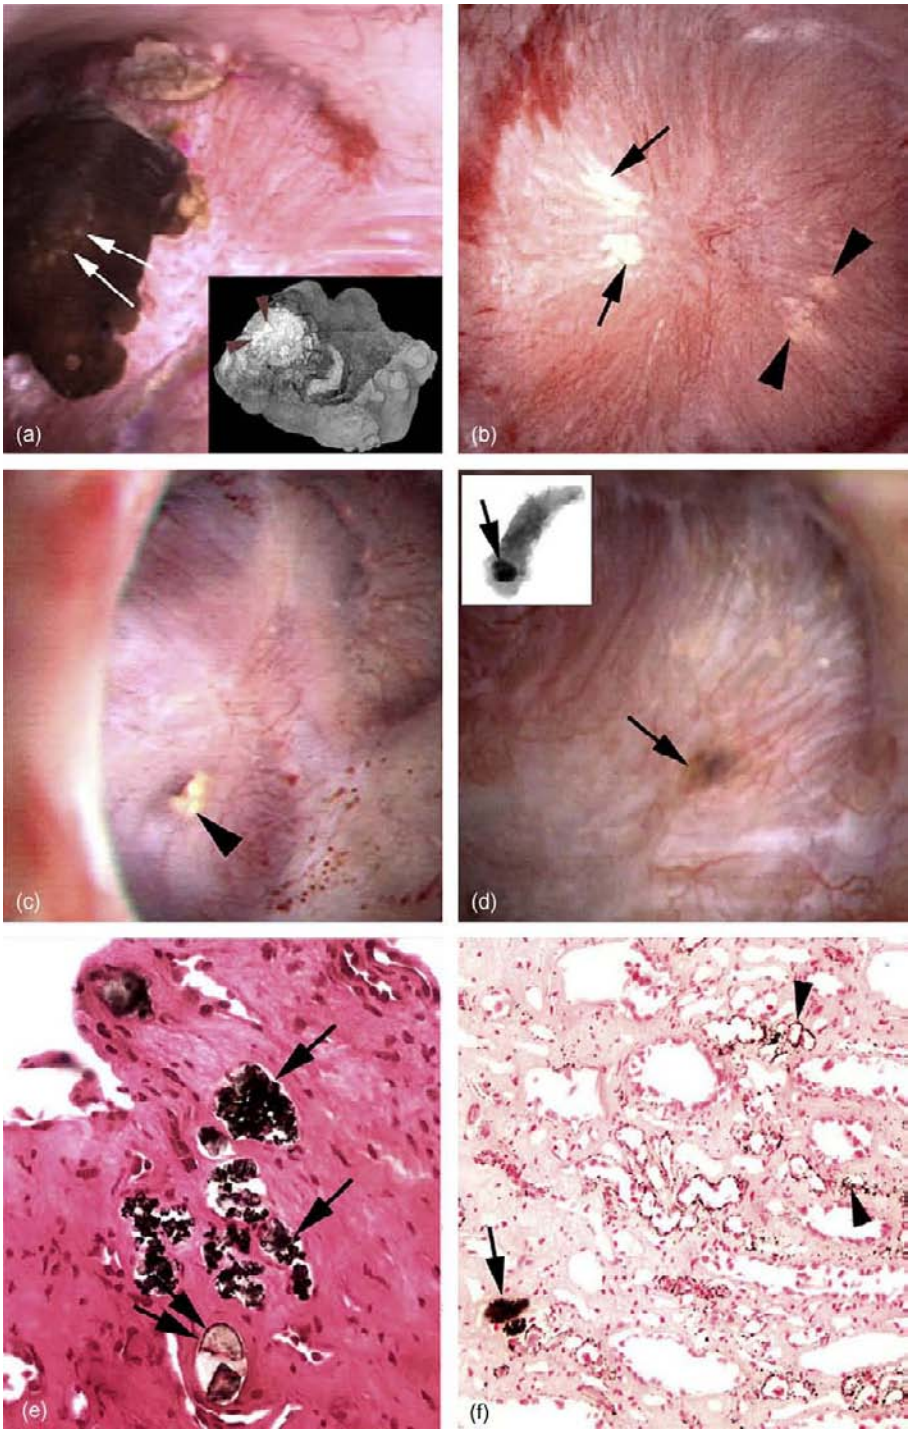

FIGURE 67.24 Endoscopic and histologic views of papillae from ileostomy stone patients. Papillary morphology as viewed by digital endoscope varied from normal (panels A and B) to retracted (panel C) and with attached stones (double white arrow, panel A) near white plaque (arrows, panel B) and/or protruding plugs from ducts of Bellini (arrowhead, panel C) with yellow plaque (arrowheads, panel B). Attached stones when removed and examined by micro-CT showed regions of apatite on their tissue surface (arrowheads, insert in panel A). By endoscopy, large intraluminal deposits were noted as dark spots on the papillary surface (arrow, panel D) which were confirmed by micro-CT (arrow in insert of panel D). Intraluminal plugging of IMCD and ducts of Bellini was more prominent than attached stones. Yasue stained papillary biopsy samples revealed numerous dilated IMCD and ducts of Bellini filled with Yasue-positive deposits (arrows panels E & F) and Yasue-negative deposits (double arrow, panel E). The Yasue-positive material was apatite while the Yasue-negative material was sodium and ammonium salts of uric acid. Sites of interstitial plaque were noted in the basement membrane of thin loops of Henle (arrowheads, panel F). See color plate section at the back of the book.

URIC ACID (AND OTHER PURINES) IN STONES

We have already pointed out that urine pH controls uric acid SS (Fig. 67.5), and at a pH of above 6.2 SS does not occur. For this reason, alkali sufficient to raise urine pH will abolish uric acid crystallization. That patients with uric acid stones have low urine pH is evident from Fig. 67.6. Mechanisms creating the low pH have been advanced in the past few years. A crucial factor appears to be insulin resistance[144,145] which reduces renal ammonia production.[144] This accounts for the well-known links between uric acid stones and diabetes.[146] Mere obesity seems important in that urine pH falls as body weight, adjusted for urine creatinine (an index of obesity) rises.[147] Metabolic syndrome,

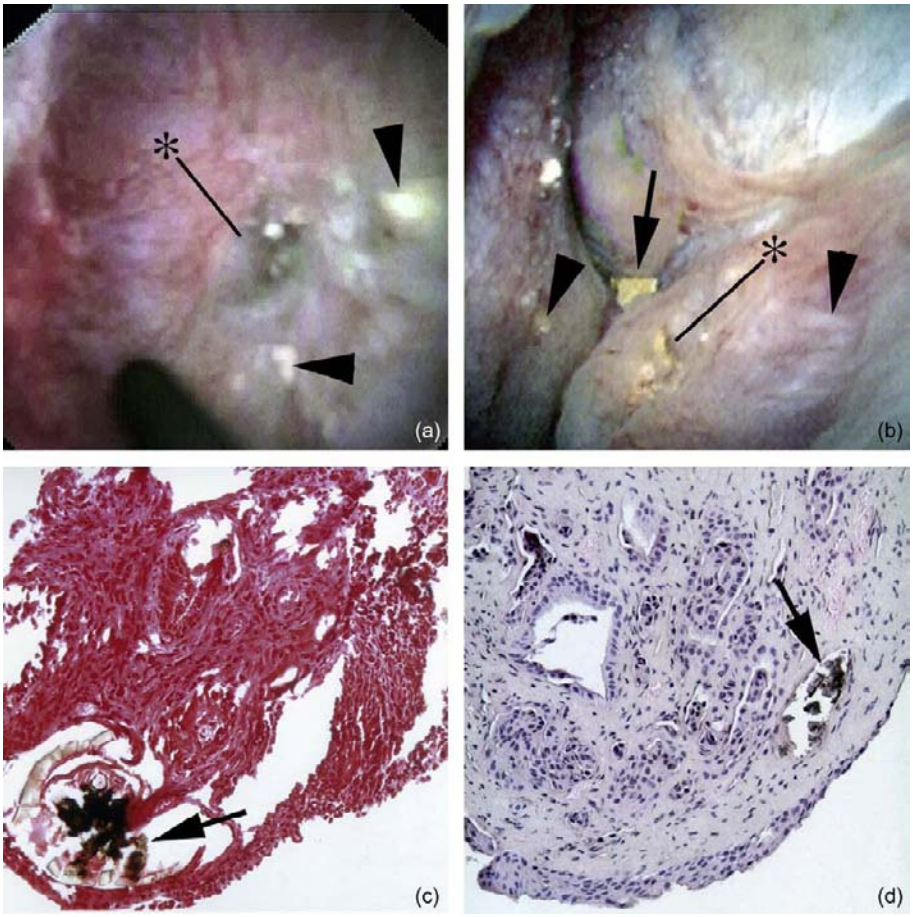

FIGURE 67.25 Endoscopic and histologic images of stone-forming patients with primary hyperoxaluria. Endoscopic examination at time of stone removal reveals normal appearing papilla with dilated openings of ducts of Bellini (asterisks, panels A and B) containing mineral as well as protruding plugs with attached stone (large arrow, panel B). Regions of yellow plaque were numerous (arrowheads, panels A and B) but no white plaque was noted. Histopathology showed intraluminal plugging in IMCD (arrow, panel D) and ducts of Bellini (arrow, panel C). All mineral deposits were found to be CaOx with only a small amount of apatite. See color plate section at the back of the book.

characterized by insulin resistance, is also associated with decreased 24-hour urine pH. Chronic diarrhea causes uric acid stones, as already pointed out in our discussion of ileostomy.

Potassium alkali salts are best because they avoid sodium loads, with their attendant disadvantages of volume expansion and high blood pressure. But diabetes or age occasionally impairs potassium excretion in this group of patients. In some instances, potassium retention reduces ammonia excretion producing the low pH (Type 4) RTA. For such patients a sodium alkali salt is needed. We find that 25 mEq twice daily of citrate or bicarbonate is sufficient for most people, a few requiring a third dose. Unlike CaOx, uric acid can dissolve at pH values attainable in human urine, and stones may well shrink. More often, large ones lose outer mass, and their constituent fragments become unglued and begin to pass.

The syndromes of uric acid crystallization merit comment as they differ from those of calcium stones. Given a sudden delivery of uric acid into the renal tubules, from lysis of tumors, a uricosuric drug, or a sudden fall in urine volume in someone with a low urine pH, crystals of uric acid may form in renal tubules, and cause acute renal failure—so-called acute uric acid nephropathy. Hydration and alkali may reverse this condition; in the case of uric acid overproduction, such as tumor lysis syndrome, rasburicase, recombinant urate oxidase, is the most effective treatment.[148] Another outcome of sudden uricosuria or fall in pH or volume is formation of sludge made from a mass of uric acid crystals that obstructs both ureters and leads to obstructive renal failure. Less dramatic, uric acid crystals may pass with pain and bleeding, yet being radiolucent and prone to disperse in the bladder the crystals may never be seen. The easiest syndrome to diagnose is uric acid gravel, which passes as a gritty material and is orange-red from adsorbed pigment. Management of obstructive uropathy and prevention of tumor lysis syndrome are discussed elsewhere in this volume. Finally, uric acid stones were described as radiolucent in years past, being so on routine abdominal flat-plate radiographs and intravenous pyelography. With CT scanning uric acid stones look identical to calcium stones; however, they may be distinguished by their lower density by Hounsfield units.[149]

The rare hereditary uric acid overproduction states, such as Lesch-Nyhan syndrome, should be considered when uric acid stones present in childhood. 2,8-dihydroxyadenine urolithiasis occurs in patients

with a deficiency of adenine phosphoribosyltransferase (APRT, MIM 102600) and may cause renal failure as well as stones. Other rare purine stones include ammonium acid urate stones, which are associated with diarrheal syndromes and laxative abuse, and with hypokalemia. Correction of the potassium depletion and control of diarrhea are therapeutic.

CYSTINURIA AND CYSTINE STONES

The two genes responsible for cystinuria (Table 67.2) encode the light and heavy subunits of the dibasic amino acid transporter that normally reabsorbs the majority of filtered cystine in PT.[150] Modern classification of cystinuria is type I or non-I (Table 67.2) depending on the gene defect, if known, or the urine cystine of heterozygotes in the family. Cystinuria causes stones via simple supersaturation because of the poor solubility of cystine in urine, and clinical presentation does not differ between the two types, nor does the treatment. Presentation is often in childhood, and the disease is associated with very frequent stone formation and need for procedures. Cystine stones do not fragment will with extracorporeal shock wave lithotripsy, and this, combined with the large size to which cystine stones often grow, means that these patients often need percutaneous approaches for stone removal.

Among seven patients with typical cystinuria and passage of cystine stones, papillary morphology varies from nearly normal to massively scarred (Fig. 67.26).[151] Bellini ducts are plugged with cystine, as one would expect, but IMCD are plugged with massive deposits of apatite, which one might not expect, and apatite deposits can be found even in the thin limbs of Henle (Fig. 67.26, panels C and D**)**. We suspect the process here resembles that in IPSF in that lumen pH rises and initiates a vicious cycle of apatite crystallization and cell injury. The initiating event may be obstruction by cystine deposits in the BD. The well-known reduction of renal function in cystinuria patients[152] could well reflect the plugging and cell destruction illustrated here. Alternatively, these patients might lose function simply because they have an inherited PT transport disorder; this matter has not been studied to date.

Cystine solubility is about 1 mM/l of urine (243 mg/l) and rises with pH.[153] Supersaturation is best measured directly, if possible, because simple calculations from molarity and urine pH are not accurate.[154] However, direct measurements are complex and may not be available.[155] In general, a urine volume between 3.5 and 5 liters daily will dissolve the urine cystine of many patients. In others, one must raise pH using potassium citrate, 25 mEq two to three times daily, to about 7. Reduction of diet sodium and protein can reduce urine cystine excretion modestly.

When volume, citrate, and diet measures are in place, how can one tell if treatment is adequate apart from waiting for more stones? We usually re-measure total urine cystine and calculate if the urine volume will dissolve it at the pH of the 24-hour sample or, if possible, measure supersaturation directly. If stones continue, or when patients do not maintain volume or pH high enough, we use drugs, which are limited in value by side effects. D-penicillamine and alpha-mercaptopropionylglycine (tiopronin) form mixed disulfides with cysteine, thereby reducing cystine, the cysteine homodimer.[156] Dosing of either is reasonably simple. D-penicillamine comes in 125- and 250-mg tablets, providing 0.83 and 1.6 mM of drug, respectively. Given 4 to 8 mM of cystine excretion daily, 125 or 250 mg four times a day is reasonable depending on the divergence between total cystine excretion and total urine volume. For example, given 4 mM cystine excretion per day in someone who will not raise urine volume above 2 liters per day, the former dose of 125 mg four times daily should complex about 2.4 mM, or close to the extra cystine. For alpha-mercaptopropionylglycine the dose size is 100 mg giving 0.61 mM of the drug. Both drugs have similar side effects but the incidence is lower with

TABLE 67.2 Cystinuria

Disease	MIM	Inheritance	Locus/ Gene	Gene Product	Functions	Location	Phenotype
Cystinuria type A (type I)	104614	Autosomal recessive	2p16.3/ SLC3A1	rBAT	Heavy unit of heteromeric aa transporter	Proximal tubule, S3	Heterozygotes: Normal urine cystine excretion
Cystinuria type B (usually type non-I)	604144	Incompletely autosomal recessive	19q13.1/ SLC7A9	b0, + AT	Light subunit of heteromeric aa transporter	Proximal tubule, S1 and S2	Heterozygotes: Elevated urine cystine excretion

(From *Coe FL, Evan A, Worcester E. Kidney stone disease. J Clin Invest. 2005;115:2598–2608, with permission.)*
aa, amino acids; MIM, Mendelian Inheritance in Man; S1, S2, S3, segments 1–3 of the proximal tubule.

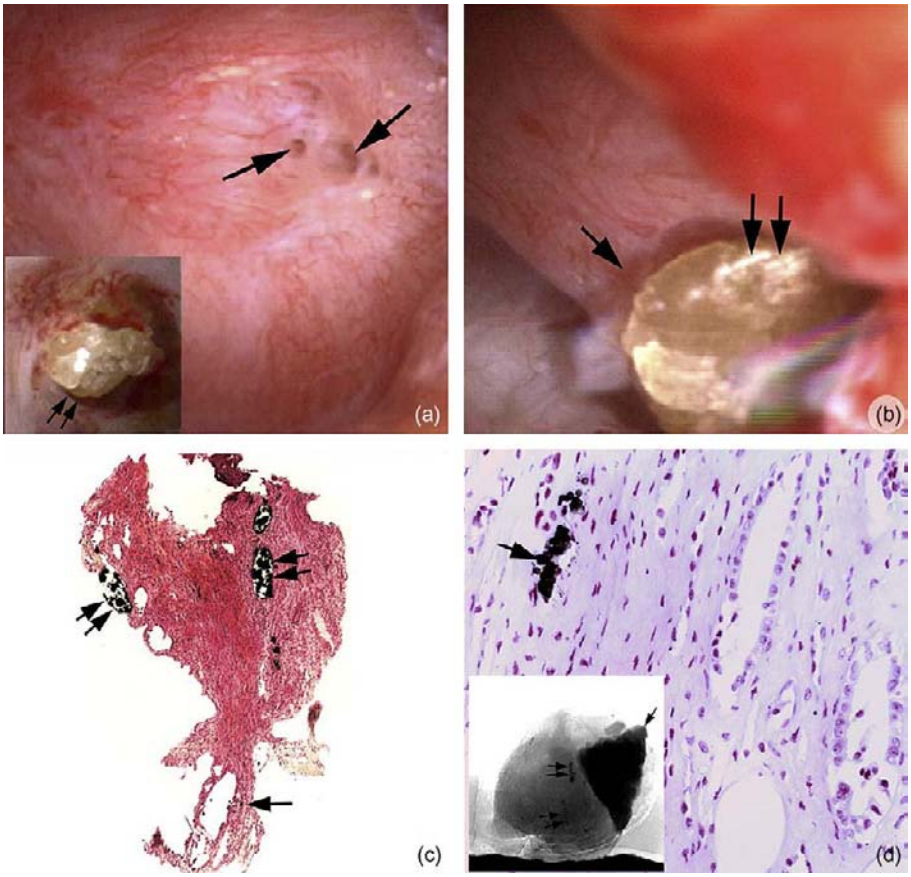

FIGURE 67.26 Endoscopic and histologic views of papillae from cystine stone patients. Papillary morphology as seen through the endoscope varies from normal to flattened with greatly enlarged openings (arrows, panel A) of the ducts of Bellini. Some dilated ducts of Bellini contained protruding plugs (insert panel A) of crystalline material (double arrow). In addition, small sites of suburothelial Randall's plaque were noted. Occasionally, large masses of crystalline material were seen at the time of PNL to lie under the urothelium at a site marked by dilated ducts of Bellini and upon unroofing the urothelium during the biopsy procedure (single arrow in panel B), deposits were exposed that were located within a tubular lumen (double arrow in panel B). The deposits were determined to be cystine. The papillary histopathology of the cystine patients also showed variation from normal to regions of plugging, dilation and injury of IMCD (double arrows in panel C). Intraluminal plugging with crystals was noted in thin loops of Henle (single arrow in panels C and D), and IMCD (double arrows in panel C). The insert in panel D shows a 3-D reconstructed micro-CT image of a papillary biopsy and the arrow indicates the site of the protruding plug like that seen in the insert in panel A. The large, dense triangular deposit was determined to be cystine. Surrounding this large deposit are several smaller regions of mineral (double arrow) that are consistent with apatite. Panel D is a paraffin section from the lower half of the biopsy seen by micro-CT and shows Yasue positive material in a thin loop of Henle (arrow). See color plate section at the back of the book.

tiopronin, which is our drug of choice. Adequate therapy can prevent new stone formation and may be able to decrease the size of existing stones if supersaturation is lowered adequately.

Cystine stones are hard to see with routine radiographs, having only sulfur as a heavy atom, sparsely distributed in the molecule and crystals. CT scanning resolves the stones perfectly. Some cystine stones become coated with calcium salts, particularly if pH of the urine has been raised in someone who is also hypercalciuric; such "eggshell" stones will not dissolve and can be hard to fracture. Some writers recommend screening all cystinurics for routine metabolic stones because they harbor such disorders no less frequently than other people. All stones should be analyzed to be sure they do not contain additional phases that might need individual treatment. The lemon-yellow color of cystine is no guarantee that no more lies inside.

PLAQUE AND DEPOSITS IN ALL FORMS OF STONE DISEASE: AN INTEGRATION

Quantities of Plaque and Deposits

In biopsy samples, using high resolution micro-CT analysis, deposits can be quantified as number/cubic mm of tissue and mean size of deposit. Plaque abundance can be quantified as the fraction of papillum covered using intra-operative digital imaging. For the

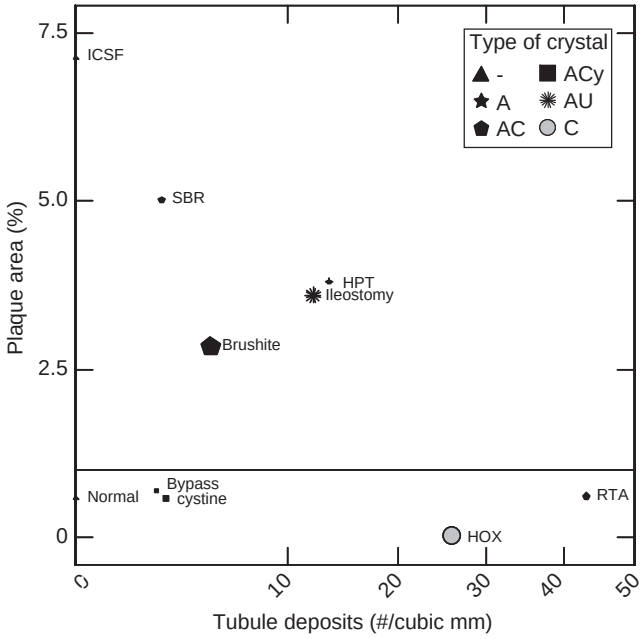

FIGURE 67.27 Papillary plaque surface area (*y*-axis) versus tubule deposit density (*x*-axis) in nine stone forming conditions (ICSF, brushite, small bowel resection (SBR), hyperparathyroidism (HPT), ileostomy, obesity bypass, cystine, primary hyperoxaluria (HOX), renal tubular acidosis (RTA)) and normal subjects. Size of symbol gauges mean size of individual deposits. Deposit density and size are from micro-CT analysis. The *horizontal line* represents the upper boundary of plaque abundance in normal renal tissue. Type of crystal in deposits: *A* apatite, *C* CaOx, *Cy* cystine, *U* sodium and ammonium urate crystals, *dash* no deposits, shown as *triangles* for normal and ICSF. *(Reprinted with permission from: Coe FL, Evan AP, Lingeman JE, Worcester EM. Plaque and deposits in nine human stone diseases. Urol Res 38:239-247, 2010).*

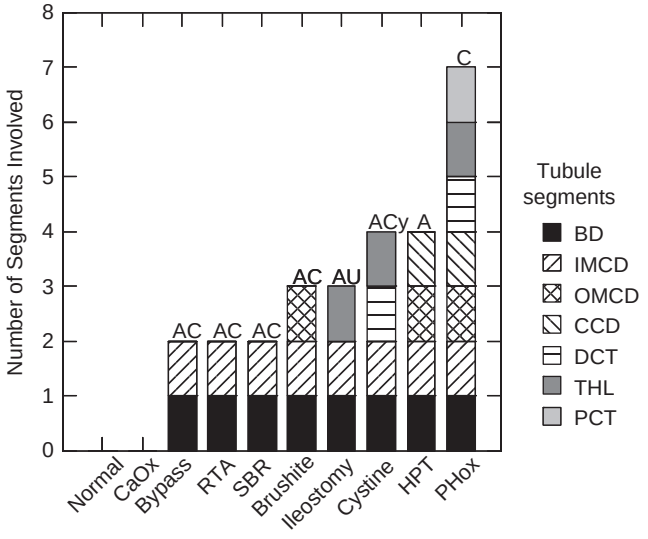

FIGURE 67.28 Renal tubule segments containing crystal deposits in 9 stone forming conditions and normal subjects. Abbreviations as in Fig. 27. *BD*, Bellini ducts; *IMCD, OMCD and CCD*, inner and outer medullary and cortical collecting ducts; *DCT*, distal convoluted tubule; *tHL*, thin limbs of Henle's loop; *PCT*, proximal tubule. *(Reprinted with permission from: Coe FL, Evan AP, Lingeman JE, Worcester EM. Plaque and deposits in nine human stone diseases. Urol Res 38:239-247, 2010).*

nine diseases with tissue analysis, 4 have no more than normal amounts of plaque (Fig. 67.27): obesity bypass, cystinuria, primary hyperoxaluria and RTA. ICSF are unique in having abundant plaque without any deposits, and normal subjects, of course, have trivial plaque and no deposits. Primary hyperoxaluria and RTA have the most deposits, and primary hyperparathyroidism, IPSF (brushite), ileostomy and small bowel resection have high amounts of both deposits and plaque. As noted in the symbols and legend, apatite is the most common crystal in deposits, accompanied by CaOx; cystine and urate species are unique to cystinuria and ileostomy, respectively.

Abundance and deposit size tell, however, only part of the story. In obesity bypass, RTA and small bowel resection, deposits are limited to the BD and IMCD (Fig. 67.28), in other words to the most terminal nephron segments. They extend into the outer medullary collecting ducts in IPSF (brushite), primary hyperparathyroidism and primary hyperoxaluria, essentially by contiguity. In primary hyperparathyroidism they extend even further, into the cortical collecting ducts, and in ileostomy and cystinuria they involve the thin limbs and distal tubule (DCT). Primary hyperoxaluria is unique in that deposits invade the entire nephron. The stone diseases therefore form a spectrum along three axes: deposit density, deposit size, and deposit extent, which are often discordant from one another. Exactly why this happens is not clear except perhaps for the extreme invasiveness of primary hyperoxaluria, which floods the nephron with oxalate, lifelong.

Physiological Correlates of Plaque

The effects of urine calcium excretion, volume, and pH on plaque abundance found among ICSF, obesity bypass, and normal subjects (Fig. 67.16) can be reproduced in the nine separate conditions we have data for. A multivariable score derived from these three measurements separates the conditions into two groups (Fig. 67.29, left panel): low plaque states (lower left) and high plaque states (upper right). The five high plaque states are to the lower right on the middle panel of the figure, because of having higher urine calcium molarities (x axis) and lower pH values vs. the 4 low plaque states: plaque increases with the ratio of calcium to water excretion and falls with pH. When urine volume is plotted against urine calcium excretion (right panel) the high plaque states are at higher urine calcium excretions for a given urine volume (downward and to the right of the low plaque states). So the effects

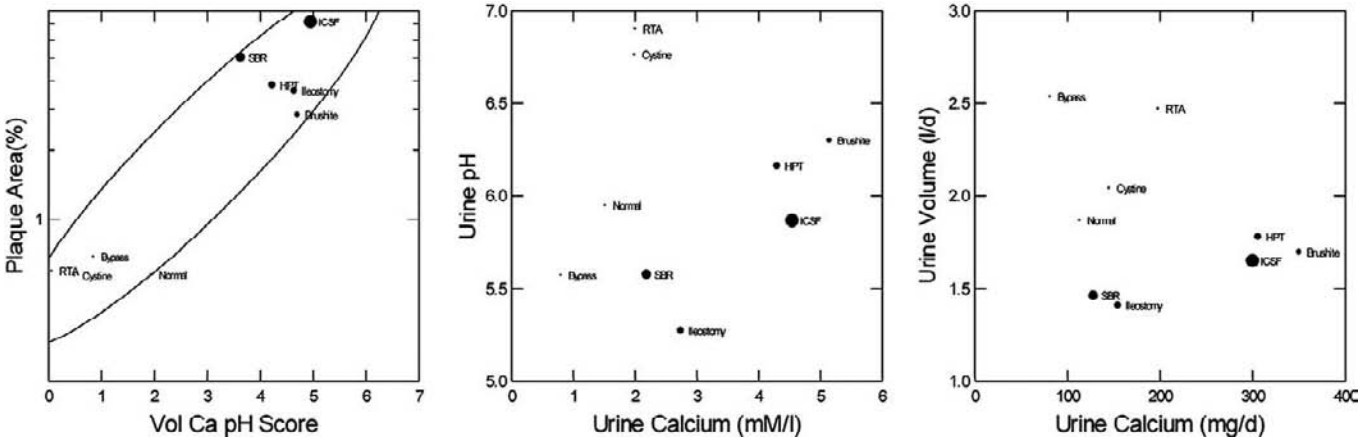

FIGURE 67.29 Determinants of plaque surface area in 8 stone forming conditions and normal subjects. Relationship between urine volume and calcium excretion (*right panel*) and urine pH and urine calcium molarity (*middle panel*); abbreviations as in Fig. 68.27. *Size of symbol* denotes plaque surface area. Note clustering of high (*large symbols*) plaque states to the lower right of both panels and marked separation from low plaque states. A score incorporating volume, urine calcium and urine pH predicts plaque coverage well across all stone forming conditions studied so far. *(Reprinted with permission from: Coe FL, Evan AP, Lingeman JE, Worcester EM. Plaque and deposits in nine human stone diseases. Urol Res 38:239-247, 2010).*

of high calcium and low water excretion and pH to promote plaque can be duplicated among normals and eight separate stone forming diseases, meaning the relationships are robust.

INFECTION (STRUVITE) STONES

Magnesium ammonium phosphate crystals, literally the solid phase of a triple salt, were described by Struve, who found them in caves, and gave his name to them: struvite.[157] These stones form only when the kidneys are colonized by bacteria that possess the enzyme urease, which hydrolyzes urea to ammonia and CO_2. The ammonia raises pH by accepting protons; HCO_3 is produced as the CO_2 dissolves in the alkaline urine, raising local levels of bicarbonate and eventually of carbonate ions. Protons are removed from phosphate as well, raising local concentrations of PO_4^{-3} as ammonia converts to ammonium ion. In the micro-environment of bacterial colonies, struvite crystallizes out of solution along with calcium carbonate to make large branched stones that often fill multiple calyces in a staghorn conformation.

The bacteria involved are usually *Proteus*, *Klebsiella*, *Pseudomonas*, and *Enterobacter* species, never *Escherichia coli*, and appear to colonize the urine mainly after multiple episodes of antibiotic treatment for routine infections. Once in place, the stones and their bacteria cannot be treated with antibiotics, as they act like all infected foreign bodies. The bacteria lodge in and stick to the stone, and antibiotics cannot penetrate into the depths of the crystal masses to kill all of the organisms. Resistance evolves easily under such circumstances. The only treatment option is surgical.

We have found two clinical divisions of struvite stone patients.[158] One forms struvite stones with at least some CaOx in them. These patients are men and women and harbor the conventional set of metabolic causes of stones. They usually report having passed stones, and their renal function is only slightly below normal, as is the case with most stone formers.[124] The second type is mainly women, in whom a large stone is found on radiograph, the latter often obtained in evaluation of infection or bleeding or pain. The stones contain no CaOx, and the patients have no usual metabolic cause of stones. Renal function is frequently reduced by a small amount. In either case, the stone must be removed and the infection treated.

A third kind of patient presents with acquired or hereditary deformity of the urinary system or a spinal cord injury with subsequent bladder dysfunction and need for chronic catheterization. Abnormal drainage, catheter infections, and dead space in distorted anatomy promote bacterial lodgment and colonization and eventuate in struvite stones. This last category of patient is in the purview of surgical urology and rehabilitation medicine and requires unusually complex management. In cases where complete removal of stone material is not possible, aceto-hydroxamic acid may be used to inhibit urease and prevent stone growth.[159,160] However, many patients exhibit serious side effects, including deep vein thrombosis and headache, limiting the use of this agent.

When surgery is undertaken for infection stones, the goal must be removal of all fragments, for all parts of the stone are infected and can grow back. We cannot

dwell, here, on details of surgery, but this kind of work is best left to centers with high levels of experience and instrumentation. Antibiotic treatment after complete removal of the stones should be with bactericidal agents with the intent to sterilize the urinary tract and prevent re-growth. Given a successful removal of the foreign bodies, this is a reasonable goal. Prevention of struvite stones depends on proper and judicious treatment of the many urinary tract infections that stone passage and removal engender, a matter covered elsewhere in this volume.

FINAL THOUGHTS

Stone patients are sometimes approached with therapeutic nihilism, as though further stone formation was inevitable. However, experience has shown that stone recurrence is highly preventable. Treatment aimed at lowering urinary SS with respect to the stone matrix by correcting metabolic abnormalities uncovered using 24 hour urines for evaluation has been shown to decrease stone recurrence over decades.[161] Such treatment can markedly lower the need for procedures for stone removal as well. Careful follow-up is required, to confirm that urine SS remains low and to modify the treatment regime—fluids, diet and medications—as needed to maintain the lowest possible SS. With such attention, prevention of stones is attainable over long time periods.

CHAPTER

68

Proximal Tubular Handling of Phosphate

Heini Murer, Ian C. Forster, Nati Hernando, Jürg Biber

Institute of Physiology, University of Zürich-Irchel, Zürich, Switzerland

INTRODUCTION

The renal capacity to reabsorb inorganic phosphate ions ($H_2PO_4^-/HPO_4^{2-}$; abbreviated as Pi) is a major determinant of whole-body Pi homeostasis, which is required for normal cellular functions (e.g., energy metabolism and signaling mechanisms) and bone growth and remodeling. Consequently, urinary excretion of Pi is tightly controlled according to the body needs by a variety of hormones, diets, and metabolic factors.[1–4] Diverse pathophysiological conditions and genetic diseases that are manifested by an altered renal reabsorption of Pi have been described[6,7,40,50,185] (see also Chapter 69).

The basic concepts of the renal handling of Pi and the regulation of renal Pi excretion have been reviewed in a number of articles[1–5,12,177] to which the reader is referred for original publications not cited in this chapter. Here we will focus on sodium-dependent Pi cotransporters that are responsible for renal reabsorption of Pi and we will address the cellular mechanisms involved in the regulation of these cotransporter proteins.

PROXIMAL TUBULAR REABSORPTION OF PHOSPHATE

Under normal physiological and dietary conditions, approximately 80% of the filtered Pi is reabsorbed in the proximal tubules. Studies on isolated perfused proximal tubules and brush border membrane vesicles (BBMVs) isolated from the superficial or the deep kidney cortex indicated that the rates of Na-dependent Pi transport in convoluted tubules are approximately threefold higher than rates observed in straight tubules, which suggests intranephronal heterogeneity along the proximal segments S1, S2, and S3. In addition, there is evidence of an internephronal heterogeneity as the fractional delivery of Pi to the early distal tubules of juxtamedullary nephrons is smaller compared with that of superficial nephrons.[1]

There is no Pi reabsorption in the segments of the loop of Henle and Pi reabsorption along the distal part of the nephron remains controversial. Taking different methodological approaches and species differences into account, it appears that up to 10% of the filtered load may be handled by distal tubular segments, yet the molecular mechanisms are still unknown.

Apical Entry Step

Studies performed with isolated proximal tubules and BBMVs showed that the apical uptake of Pi is strictly dependent on the presence of sodium ions (i.e., occurs via secondary active, sodium-dependent transport mechanism(s): Na/Pi-cotransport). Furthermore, in all experimental systems, Na/Pi-cotransport activity is modulated by the extracellular pH, with higher uptake rates observed at more alkaline pH.[12]

Assuming a membrane potential of ≈ -65 mV, a stochiometry of overall Na/Pi cotransport of at least two sodium ions per one Pi ion and a concentration gradient for sodium of 10:1, the intracellular accumulation of Pi is found to be >100:1 (intra- versus extracellular). However, as indicated by nuclear magnetic resonance (NMR) studies, the intracellular Pi concentration may be assumed to be in the range of 0.7 to 1.8 mM.[55] As this concentration of Pi is far below the thermodynamic equilibrium, it follows that the driving

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00068-9

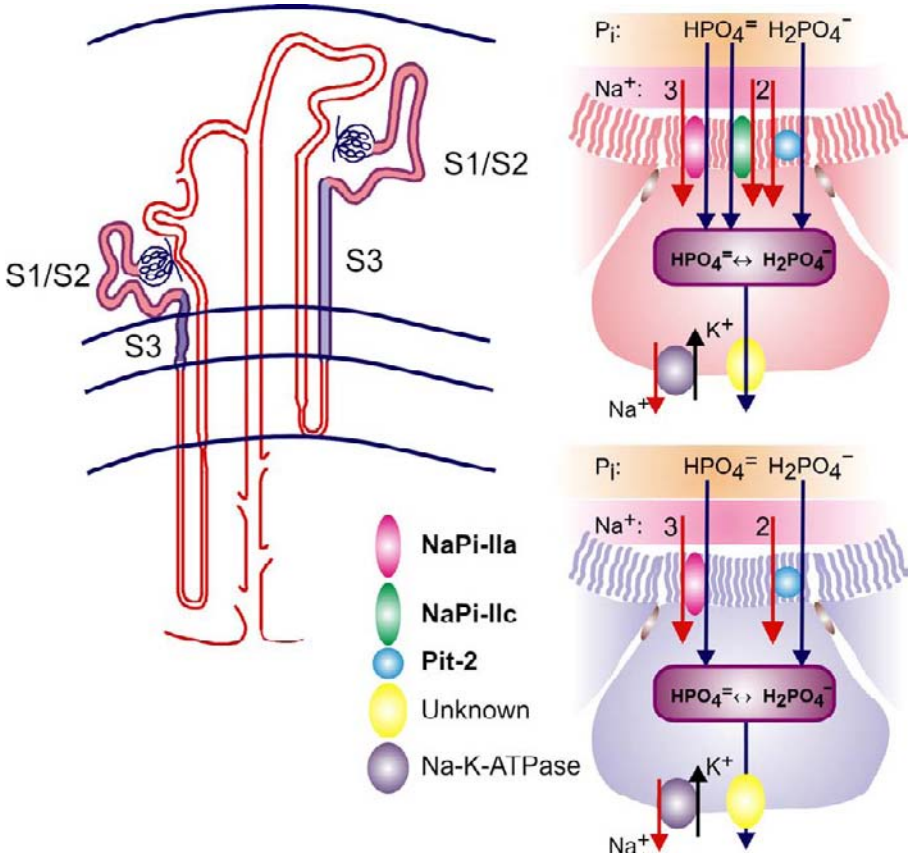

FIGURE 68.1 Na/Pi-cotransporters localized in the proximal tubular cells. In adults, uptake of filtered phosphate in the apical brush border membrane has been shown to be mediated mainly by NaPi-IIa and NaPi-IIc in the S1/S2 segments (pale pink) and NaPi-IIa in the S3 segments (pale blue). They transport preferably divalent Pi with different Na:Pi stoichiometries, as indicated. In addition PiT-2 is found in S1, S2 and S3 and transports preferably monovalent Pi. Its contribution to overall Pi transport is unclear, but has been shown to show a different regulatory time course from the SLC34 proteins in rodents. Furthermore, NaPi-IIa and NaPi-IIc represents the major target for the regulation of proximal tubular Pi reabsorption (see text). Compensation for Na^+ loading and altered membrane potential due to electrogenic transport by NaPi-IIa and PiT-2 is mediated by the Na-K-ATPase in the basolateral membrane. The basolateral Pi exit pathway has still not been identified.

forces for the apical entry step(s) of Pi are always in excess. Therefore, changes of the transport rates (due to changes on either the number of transport units or their kinetic properties. e.g., K_m) offer possibilities for an efficient regulation of the apical uptake of Pi. In fact, there is ample evidence showing that most regulatory factors that influence the overall proximal tubular Pi transport capacity (TmPi/GFR-tubular maximum for Pi reabsorption per unit of glomerular filtration rate) alter the abundance of apical Na/Pi-cotransporters.

Basolateral Exit of Phosphate

Exit of Pi at the basolateral side of the proximal tubular cell occurs down the electrochemical gradient of Pi. Transport of Pi through the basolateral membrane is not well understood and the corresponding Pi transporter proteins have not been identified. To maintain the intracellular Pi concentration high enough to sustain the intracellular metabolism, basolateral exit mechanisms are regarded as "controlled leak" pathways. Different mechanisms for the basolateral exit of Pi have been proposed, such as a phosphate/anion (bicarbonate) exchange or a sodium-independent, pathway.[12]

GENE PRODUCTS INVOLVED IN PROXIMAL TUBULAR PHOSPHATE REABSORPTION

Several mammalian membrane proteins have been cloned, which, after expression in oocytes of *Xenopus laevis*, mediate Na/Pi cotransport. These Na/Pi-cotransporters have been grouped into type I, type II, and type III Na/Pi-cotransporters and more recently were assigned to the solute carrier (SLC) families 17 (type I), 20 (type III), and 34 (type II).[16–19] Studies with Npt2 knockout mice and analysis of patients with hereditary hypophosphatemic rickets with hypercalciuria (HHRH) indicated that the type II Na/Pi-cotransporters are of major importance for proximal tubular reabsorption of Pi.[20,21,36,87] One member of the SLC20 family, PiT-2, has been localized at the BBM of proximal tubules as well, however its role in renal handling of Pi is however less clear.[23,25,37] Na/Pi-cotransporters localized at the apical membrane of proximal tubular cells are indicated in Figure 68.1.

The type I Na/Pi-cotransporter (NaPi-I, SLC17A1) was originally identified on the basis of its Na/Pi cotransport activity after expression in oocytes. Moreover, a number of findings have questioned its role in the renal handling of Pi-I besides acting as a

Na/Pi-cotransporter: i) NaPi-1 also exhibits anion channel activity; ii) Na/Pi-cotransport mediated by NaPi-I is not dependent on the pH; and iii) alterations of the renal handling of Pi could not be correlated with changes of NaPi-I protein content.[12,24]

The Type ll Na/Pi-Cotransporter Family SLC34

The Na/Pi-cotransporter family SLC34 comprises three members: type IIa/NaPi-IIa (SLC34A1), type IIb/NaPi-IIb (SLC34A2), and type IIc/NaPi-IIc (SLC34A3) NaPi-IIa and NaPi-IIc are expressed in the kidneys. Expression of NaPi-IIb has not been reported in the kidney but in a number of other epithelial and epithelial-like tissues, for example in small intestine, liver, testes and lung.[143] In the small intestine NaPi-IIb protein is localized at the apical membrane of enterocytes and, as demonstrated with a conditional mouse knock-out model, is involved in reabsorption of dietary Pi.[89,116]

NaPi-IIa (SLC34A1) has been cloned from renal tissues of different species. The human (NPT2; chromosome 5q35) and mouse genes (Npt2; chromosome 13) are approximately 16 kb in length and are arranged into 13 exons and 12 introns.[17–19,143] In promoter constructs analyzed so far, elements for transcriptional regulations by bicarbonate/CO_2 tension, vitamin D, and Pi deficiency have been detected. However, the physiological significance of transcriptional regulation of NaPi-IIa gene expression has not been established unequivocally.[12]

By reverse transcriptase-polymerase chain reaction (RT-PCR) and *in situ* hybridizations, expression of NaPi-IIa mRNA has been detected exclusively in the proximal tubules. This was confirmed by immunohistochemical analysis, which demonstrated that NaPi-IIa protein is restricted to the BBM of proximal tubular cells. By immunogold electron microscopy it was shown that NaPi-IIa cotransporters are evenly distributed along the whole length of the microvilli.[12,28] Under Pi balanced dietary conditions the abundance of the NaPi-IIa protein is usually stronger in proximal tubules of juxtamedullary nephrons and decreases gradually along the tubular axes.

NaPi-IIa consists of approximately 635 amino acids. On immunoblots this protein is detected between 80 and 100 kDa. Interestingly, after denaturation in the presence of reducing agents, two bands of approximately 45 and 50 kDa are observed, which is likely due to a proteolytic cleavage between the N-glycosylation sites contained within the extracellular loop between the transmembrane regions TM5 and TM6 (see Figure 68.2).[29] Separate expression of the cleavage products in oocytes of *X. laevis* oocytes did not result in Na/Pi cotransport activity, whereas after coexpression of both parts, Na/Pi cotransport could be restored[30,147] indicating that proteolytically cleaved NaPi-IIa-cotransporters are functional. Whether a fraction of the NaPi-IIa protein content in apical membranes is proteolytically processed *in vivo* or if cleavage occurs during the isolation of proximal tubular BBMV, is currently not known.

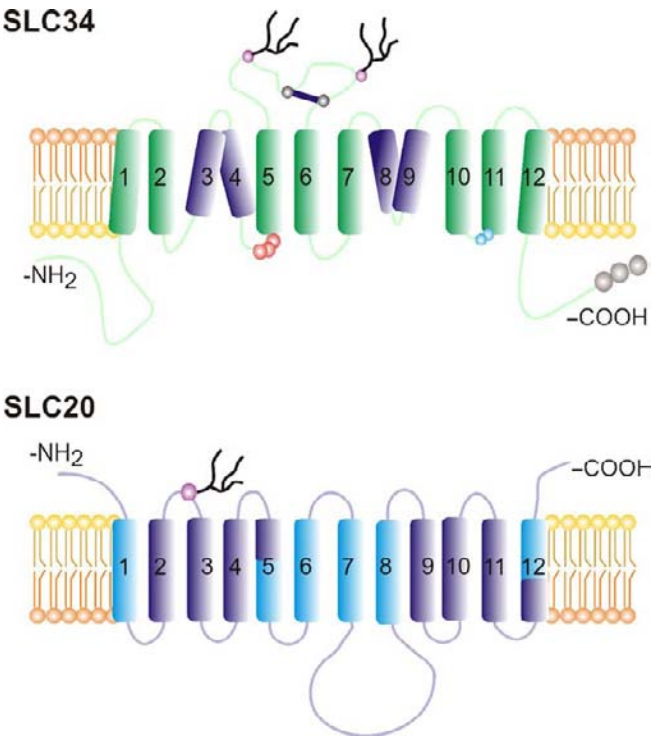

FIGURE 68.2 Topology models Na/Pi-cotransporters. Upper: SLC34 proteins (NaPi-IIa, NaPi-IIc) are predicted to comprise 12 transmembrane helices and intracellular N- and C-termini. A large extracellular loop between helices 5 and 6 contains two N-glycosylation sites (in NaPi-IIa) and a disulfide bridge, essential for correct function. The two halves of the protein, comprising helices 1–5 and 6–12 contain inverted repeat regions that include two putative re-entrant domains (purple: helices 3,4 and 8,9) that are thought to associate and form the transport pathway. In NaP_i-IIa, the dibasic KR motif (brown) was shown to be necessary for the responsiveness to parathyroid hormone. At the C-terminus, interaction with the PDZ proteins NHERF1 and PDZK1 occurs via the TRL C-terminal PDZ-binding motif (red). Three residues (AAD motif) responsible for conferring electrogenicity and a 3:1 Na:Pi stoichiometry for NaPi-IIa are also indicated (red). Lower: SLC20 proteins (PiT-1,2) are predicted to comprise 12 transmembrane helices and extracellular N- and C-termini. Two conserved inverted repeat domains are indicated (purple). There is one confirmed N-glycosylation site in the first extracellular loop of PiT-2.

Expression of NaPi-IIc (SLC34A3) has been detected in kidney, heart, spleen, and placenta. In kidneys, the largest amount of NaPi-IIc protein was detected in weaning animals; in adult mice, the abundance of this cotransporter is markedly decreased. On the basis of

these observations, NaPi-IIc has been referred as a "growth related Na/Pi-cotransporter".[167,174] In mouse and rat kidneys, NaPi-IIc was localized at the BBM of S1 and S2 segments but was not observed at the luminal membrane of S3 segments.[127]

Type III Na/Pi-Cotransporters Family SLC20

The retroviral receptors Glvr-1 (PiT-1) and Ram-1 (PiT-2) have been shown to induce Na/Pi-cotransport in oocytes of *X. laevis* and were assigned to the SLC20 Na/Pi-cotransporter protein family.[16,103]

Transcripts of PiT-1 and PiT-2 have been detected in many tissues, including kidney, small intestine, liver, lung, striated muscle, heart, and brain. In kidneys, expression of PiT-1/2 mRNA was observed in the cortex and medulla. It has been estimated that SLC20 mRNA accounts for only approximately 0.5% of total renal Na/Pi-cotransporter mRNA.[10]

In addition to NaPi-IIa and NaPi-IIc, PiT-2 (SLC20A2) has also been localized at the proximal tubular apical membrane as well[23,37] (Figure 68.1). No other nephron localization for PiT-2 is known so far. Although, by *in-situ* hybridization, PiT-1 mRNA has been detected throughout the entire renal tissue,[10] the localization of the PiT-1 protein remains to be determined.

Relative Roles of Na/Pi-Cotransporters in Renal Handling of Pi

Studies performed with knock-out mouse models and analysis of hereditary human diseases with hypophosphatemia suggested that the relative roles of NaPi-IIa and NaPi-IIc in renal reabsorption of Pi in rodents and humans might differ. In mice (and possibly all rodents) NaPi-lla appears to be of major importance whereas in humans the relative roles of NaPi-IIa and NaPi-IIc are less clear.

Mouse Studies

A central role of NaPi-IIa in the renal handling of Pi was demonstrated with mice in which the Npt2 (NaPi-IIa) gene was ablated.[20,22,36] Npt2 deficient mice show massive renal loss of Pi and consequently hypophosphatemia, as well as hypercalciuria due to elevated levels of 1,25-$(OH)_2$VitD3. Flux measurements performed with isolated BBMVs demonstrated that, compared with BBMV's of control mice, Na/Pi uptake was reduced by 70 to 80%. The remaining 20 to 30% of Na/Pi-cotransport activity was attributed to an up-regulation of NaPi-IIc.[163] In contrast, NaPi-IIc deficient mice did not develop hypophosphatemia or phosphaturia, and Na/Pi-cotransport in isolated BBMVs was unchanged.[176] NaPi-IIc$^{-/-}$ mice showed hypercalcemia and hypercalciuria due to elevated levels of 1,25-$(OH)_2$VitD3 suggesting a role of NaPi-IIc in calcium metabolism. In BBMVs isolated from kidneys of NaPi-IIa/NaPi-IIc double knock out mice still residual Na/Pi-cotransport was observed that is likely due to PiT-2. However, the overall role of PiT-2 in renal handling of Pi remains to be determined.

Human Studies

In a genome-wide study of a large prospective cohort NaPi-IIa has been found to be associated with serum concentration of Pi.[35] In fact, several mutations in the NaPi-IIa gene have been described in patients with hypercalciuria and elevated urinary Pi excretion. However, in all carriers, NaPi-IIa mutations were heterozygous and could not be correlated with hyperphosphaturia.[68,157] On the other hand, a homozygous duplication in the NaPi-IIa gene (I154_V160 dup) causes autosomal recessive Fanconi's syndrome and hypophosphytemic rickets.[148] Complete loss of function of this mutant due to the missorting of the mutated NaPi-IIa was observed in *in-vitro* studies. Compared to NaPi-IIa, a more critical role of NaPi-IIc in Pi homeostasis in humans has been become evident. In patients with HHRH several mutations have been mapped in the SLC34A3 gene.[21,104] Thus, these findings indicate that the function of NaPi-IIc in humans likely remains more important during adulthood compared to mice and may not be strongly dependent on growth.

Transport Mechanisms

SLC 34

Once correctly targeted to the membrane, NaPi-IIa/c transport characteristics are influenced only by changes in membrane potential (for NaPi-IIa) and external pH (for both NaPi-IIa and NaPi-IIc). So far, no evidence exists of post-translational modification of their kinetic properties. With constant pH and membrane potential, the transport capacity is therefore a direct function of the number of proteins present in the membrane. SLC34 protein membrane abundance is influenced by a variety of physiologically important regulatory factors (see below). NaPi-IIa and NaPi-IIc Na/Pi cotransport kinetics have been characterized in Sf9 cells and in *Xenopus* oocytes (by tracer uptake and electrophysiology).[14,46–48,53,54,67,69] Transport is Na^+-dependent and displays an apparent affinity constant for Pi typically <0.1 mM and an apparent affinity constant for Na^+ in the range 40–60 mM. Arsenate is the only other substrate known to be transported by the type IIa Na^+/Pi-cotransporters.[51]

It was established by means of heterologous expression in *Xenopus* oocytes that NaPi-IIa and NaPi-IIc preferentially transport divalent Pi (HPO_4^{2-}).[52,53,67] An important mechanistic difference between NaPi-IIa and NaPi-IIc is that transport activity for NaPi-IIa is electrogenic, whereas for NaPi-IIc it is electroneutral. Electrogenic NaPi-IIa translocates one net positive charge per transport cycle and the transport rate increases with membrane hyperpolarization, whereas electroneutral NaPi-IIc is insensitive to membrane potential and no net charge is translocated. This functional distinction is reflected in their respective Na^+:Pi stoichiometries- 3:1 for NaPi-IIa and 2:1 for NaPi-IIc.[52–54,67] It also follows that the theoretical Pi concentrating capacity is approximately 100-fold higher for NaPi-IIa, which, however implies a greater energetic cost to the cell resulting from Na^+ and charge accumulation. The preference for divalent Pi explains, in part, the strong dependence on external pH that would result from the titration of Pi species. In addition, protons can act directly on the transporter protein by competing with Na^+ binding and modulating conformational changes associated with the empty carrier states.[47,48]

The loading of NaPi-IIa and NaPi-IIc proteins with substrates is proposed to be ordered. Biophysical studies (presteady-state analysis and voltage clamp fluorometry) have established that two Na^+ ions bind sequentially and cooperatively before phosphate.[14,56] A third Na^+ binding transition precedes a rate-limiting reorientation of the fully loaded carrier. The order of substrate release at the cytosol is unknown. For NaPi-IIc, one of the two Na^+ ions, which confers electrogenicity to NaPi-IIa, can still interact with the protein but is not cotransported.[67]

Transport by NaPi-IIa and NaPi-IIc is blocked by the competitive inhibitor phosphonoformic acid or foscarnet (PFA) with a reported inhibition constant $\approx 0.4–0.6$ mM.[46,182] PFA itself is not transported. Several other inhibitors of type IIb Na/Pi-cotransporters with significantly lower inhibitory constants than PFA have been reported.[59] These possibly act in a noncompetitive manner on NaPi-II proteins and a phosphophloretin compound was reported to exhibit inhibition at micromolar concentrations[32] although its efficacy on heterologously expressed NaPi-II-cotransporters is unknown.

In addition to the cotransport-related current, two other currents related to the expressed protein can be observed for the electrogenic NaPi-IIa under voltage clamp: a cation leak that is active in the absence of Pi, and presteady-state currents. The leak is proposed to be mediated by the translocation of a single Na^+ ion per cycle at a rate $<10\%$ of the cotransport mode.[61] It is unlikely to have physiological consequences, because Pi is normally present at sufficiently high concentrations to ensure that cotransport mode dominates and it is not observed in the electro-neutral NaPi-IIc.[52] However, naturally occurring mutations in NaPi-IIc are reported to result in a significant Na^+-leak, which illustrates how minor changes in the amino acid composition can have profound effects on function and important clinical consequences for phosphate homeostasis.[104] Presteady-state current relaxations, induced by rapid changes in membrane voltage reflect nonlinear charge movements associated with the electrogenic NaPi-IIa.[47,48] Detailed study of their properties led to the identification and quantification of voltage-dependent steps in the transport cycle (namely the voltage-dependent reorientation of the empty carrier and the first Na^+ binding step) and estimations of the transport or turnover rate (number of Pi molecules translocated per second per protein), to be $\approx 10\,s^{-1}$ (e.g., see Table 2 in Ref 67).

SLC20

The two known mammalian isoforms of SLC20 proteins (PiT-1, SLC20A1 and PiT-2, SLC20A2) were originally identified as retroviral receptors Glvr-1 and Ram-1, respectively. They were later shown to be Na^+-coupled Pi transporters and the electrogenicity and basic kinetics of transport characterized.[103] It became apparent from these and other studies, e.g.,[63,64] that SLC20 proteins were functionally distinct from SLC34 transporters and the differences were underscored in an electrophysiological characterization of PiT-1 transport kinetics.[9] The most important kinetic parameter that distinguishes SLC20 from SLC34 proteins is that the former preferentially transport monovalent Pi ($H_2PO_4^-$) with a 2:1 Na^+:Pi stoichiometry.[9] Like SLC34 proteins, the apparent affinities for Pi and Na^+ are also typically $\leq 100\,\mu M$ and ≈ 50 mM, respectively. Another kinetic property that distinguishes SLC34 and SLC20 proteins is the weaker sensitivity to pH in the latter case: for PiT-1 the maximum transport rate is relatively constant over a 3 pH units and the apparent Pi affinity decreases only at pH <6. The preference for monovalent Pi and insensitivity of transport kinetics to reduced pH would allow SLC20 proteins to transport Pi under conditions where SLC34 proteins are functionally compromised. Unlike SLC34 proteins that are considered exclusively Na^+ driven, it was shown that Li^+ can replace Na^+ as the driving cation for PiT-1, albeit with a reduced transport rate.[9] Furthermore, in the absence of Na^+, lowering pH from 7.5 to 6.0 induces significant Pi uptake in *Xenopus* oocytes that expressed PiT-2. It has been proposed that H^+ may also substitute for Na^+ for this isoform.[64,66] PFA is a weak inhibitor of PiT-1,2 mediated transport activity[66] and to date no specific inhibitors for SLC20 have been

reported. Kinetic studies suggest that Na^+ is the first ion to interact followed by a random binding of Na^+ and Pi.[9] Finally, in contrast to SLC34 proteins in which the final translocation of substrates is assumed electroneutral, this partial reaction of the transport cycle may confer electrogenicity to PiT-1,2.[67]

Structure-Function Relationships

SLC 34

The current model of the secondary structure of the type II Na/Pi-cotransporter is depicted in Figure 68.2 and predicts 12 transmembrane domains (TMDs) and cytoplasmically oriented N- and C-termini, the intracellular localization of which has been verified by epitope tagging and *in vitro* glycosylation assays.[8] In this model, TMDs 1 to 5 are separated, from TMDs 6 to 12 by a large extracellular loop that contains two N-glycosylation sites. This loop also contains one essential disulfide bridge; a second bridge has also been proposed that possible links TMD 5 to TMD 11.[70] Both bridges are thought to be important for defining final folding of the membrane-bound protein. The large extracellular loop and the N- and C-termini represent the greatest source of variation between species.[18] The C-termini is important for targeting and protein-protein interactions. For example, the TRL motif in the C-terminus plays a role as a PDZ binding motif and a KR motif located in an intracellular linker region (Figures 68.2 and 68.3) is critical for PTH sensitivity (see below). In contrast, the central "core" of TMDs shows a high degree of residue similarity or identity, and is largely conserved even in bacterial homologs, which suggests its importance in defining the transport characteristics.[18,19] Given that the electrogenic (NaPi-IIa) and electroneutral (NaPi-IIc) isoforms share the same substrate specificities and preference for divalent Pi,[67] this suggests that structural features that determine substrate recognition and translocation are similar. Substituted cysteine accessibility mutagenesis assays have provided additional insight into the membrane topology and strongly suggest that the transport pathway is likely formed by two inverted repeat segments comprising TMDs 3 and 4 and TMDs 7 and 8.[71–73] It was also established that the NaPi-IIa functional unit is a monomer[31] although evidence from biochemical studies[75] and using the split ubiquitin approach[101] and freeze fracture of *Xenopus* oocyte membranes containing the expressed transporter[77] suggest that dimerization is likely. Close comparison of the NaPi-IIa and NaPi-IIc sequences has revealed one region between the predicted TMD3 and TMD4 that contains specific residues important for conferring electrogenicity and defining the transport stoichiometry.[52]

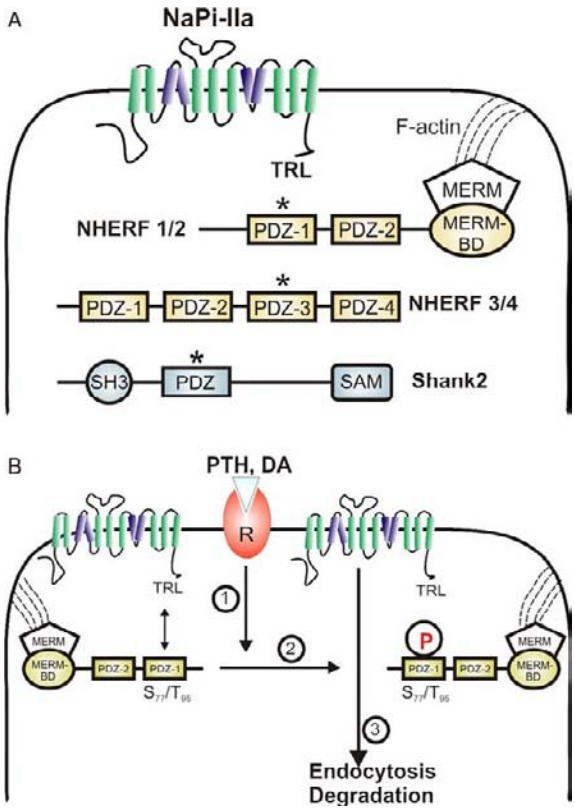

FIGURE 68.3 A: Interaction of NaPi-IIa with PDZ-proteins. NaPi-IIa interacts with the 4 members of the NHERF family (NHERF1–4) as well as with Shank2E. All these proteins are located at the brush border membrane (BBM) or in close proximity. The asterisks indicate which PDZ domains are engaged in association with NaPi-IIa. Other domains are: The Src Homology 3 (SH3), Merlin-Ezrin-Radixin-Moesin (MERM), MERM-binding domain (MERM-BD) and sterile alpha motif (SAM). B: The association of NaPi-IIa with NHERF1 is regulated by several hormones through a mechanism that involves phosphorylation of NHERF1. Parathyroidhormne (PTH) as well as dopamine (DA) treatment induces endocytosis of NaPi-IIa without altering the expression of NHERF1. Binding of these hormones to their receptors (R) triggers an intracellular signal (step 1) that leads to phosphorylation of two residues located within the first PDZ-domain of NHERF1: serine-77 and threonine-95 (step 2). This phosphorylation destabilizes the association of NaPi-IIa with NHERF1, thus allowing the removal of NaPi-IIa from the brush border membrane (step 3); in contrast, NHERF1 remains anchored to the apical cytoskeleton via its MERM-binding domain. Internalized NaPi-IIa is finally degraded in lysosomes.

The functional importance of these residues was confirmed experimentally.[52,78]

SLC20

Like SLC34 proteins, their current topology is predicted to comprise 12 TMDs but with extracellular N- and C-terminal tails (Figure 68.2). Also like SLC34 cotransporters, the structure of SLC20 proteins contains an inverted repeat architecture. This topology is

suggested by bioinformatic predictions, epitope tagging, cysteine scanning and *in vitro* glycosylation studies, e.g.,[67,79,132] Several studies have focussed on identifying the viral receptor domains, which has led to further insight into the secondary structure of PiT's.[81,82] For example, the large intracellular domain and associated TMDs have been removed and shown not to be required for retroviral recognition,[81] although it is unknown if the transport function was compromised. PiT-1 and PiT-2 differ in the location of their virus binding sites: for PiT-2 this has been identified in the first extracellular loop, whereas that for PiT-1, has been suggested to be in the fourth extracellular loop[81,82,88] (Figure 68.2).

PROTEIN-PROTEIN INTERACTIONS OF TYPE II NA/PI-CO-TRANSPORTERS

Intracellular sorting, hormonal regulation and stability at the plasma membrane of a given protein may be controlled via its association with interacting partners. By Yeast-two hybrid screens several proteins have been identified that interact with NaPi-IIa and NaPi-IIc. No proteins that may interact with the PiT-2 transporter have been identified so far.

NaPi-IIa Associated Proteins

NaPi-IIa interacts, among others, with several PDZ domain-containing proteins, namely the four members of the NHERF family[76,84,91,101] and Shank2E[26] (Figure 68.3). Importantly, these five proteins are located either at the renal proximal BBM (NHERF1, NHERF3 and Shank2E) or in its close proximity (NHERF2, NHERF4).[84,159]

PDZ domains are modules involved in protein-protein interactions, and are widely expressed across philia (for review see [62]). They consist of 80 to 100 amino acids distributed in six β strands (βA−βF) and two α helices (αA−αB). PDZ domains typically bind to the C-terminus (PDZ-binding motif) of their interacting partners, via a conserved motif (R/K-XXX-G-ϕ-G-ϕ, where X is any amino acid and ϕ is a hydrophobic residue) located between helix αB and strand βB. NHERF1 and NHERF2 consist of two PDZ domains and a C-terminal sequence that interacts with actin-binding proteins from the Ezrin-Radisin-Moesin (ERM) family[65,159] (Figure 68.3). NHERF3 and NHERF4 contain 4 PDZ domains but lack the ERM-binding domain, whereas Shank2E contains six ankyrin repeats, one SH3 domain and a single PDZ domain (Figure 68.3). The presence of multiple interacting domains within each of these proteins, together with their ability to form homo or heterodimers, opens the possibility for the formation of multiprotein complexes that can bring together regulatory and target proteins. Indeed, in addition to NaPi-IIa and several other renal transporters, NHERF1 and NHERF2 also interact with other proteins involved in Pi homeostasis, such as the parathyroid hormone receptor (PTHR), phospholipase Cβ and small G-proteins.[90] Similarly, NHERF3 interacts with several renal transporters as well as with the Ste20-related serine/threonine protein kinase (SLK) and the Dual-specific A-kinase anchoring protein 2 (D-AKAP2).[76] Shank2 associates with several renal transporters and with the F-binding proteins cortactin, α-fodrin, and Abp1.[92]

Biochemical studies indicated that the interaction of NaPi-IIa with PDZ-proteins requires the presence of the last three amino acid residues (TRL) and involves particular PDZ domains within the NHERFs.[91] NaPi-IIa interacts with the first PDZ domain of NHERF1, and this interaction is hormonally regulated by a mechanism that involves phosphorylation of NHERF1 (see below).[94,95,113,114] The absence of NHERF1, or preventing its association with NaPi-IIa, leads to mislocalization of the cotransporter.[86,93,171] Thus, NHERF1 deficient mice are characterized by hyperphosphaturia due to reduced expression of NaPi-IIa in the BBM.[86] As the proximal BBM is heavily enriched in actin, the molecular mechanism by which NHERF1 controls the apical expression of NaPi-IIa may rely on the ability of NHERF1 to bind to the actin cytoskeleton via its ERM-binding domain.[159] Despite being phosphaturic, NHERF1 deficient mice are normophosphatemic,[86] suggesting a compensatory extra-renal mechanism. Normal phosphaturia and normal apical expression of NaPi-IIa has been observed in NHERF2$^{-/-}$ mice.[98,159]

NHERF3, previously known as PDZK1, also colocalizes with NaPi-IIa at the BBM of proximal tubules.[76] Unlike NHERF1, NHERF3 does not have a domain able to bind to the actin cytoskeleton. However, its presence at the proximal BBM may be explained by its ability to heterodimerize with NHERF1.[76,91] Nevertheless, the physiological role of the interaction of NHERF3 with NaPi-IIa remains unknown, since the absence of NHERF3 does not affect neither the expression nor the regulation of NaPi-IIa.[11,99]

NaPi-IIc Associated Proteins

NaPi-IIc interacts with NHERF1 and NHERF3, but not with the other PDZ-proteins that associate with NaPi-IIa.[135] However, NaPi-IIc does not contain a typical C-terminal PDZ-binding motif, and the molecular domains involved in the interactions are different from those of NaPi-IIa. In contrast to NaPi-lla,[99] chronic

adaptation of NaPi-IIc to a low Pi-diet is impaired in PDZK1 deficient mice.[49]

REGULATION OF PROXIMAL TUBULAR REABSORPTION OF PI

The extent of the renal proximal tubular reabsorption of Pi is regulated by a variety of hormones, diets, and metabolic factors and several hereditary and acquired disorders have been shown to result in disturbances of renal clearance of Pi.[1,2,4,6,12,177] Most physiological and pathophysiological alterations of proximal Pi reabsorption can be explained by changes of apical Na/Pi-cotransport activity that is due to an alteration of abundances of Na/Pi-cotransporters NaPi-IIa, NaPi-IIc and PiT-2. Alternative modes for the regulation of Na/Pi-cotransporters, such as by changes of the membrane lipid composition (see below), have been proposed as well.

A reduction of the number of type II Na/Pi-cotransporters is achieved by endocytic retrieval at the intermicrovillar clefts (Figure 68.3). Endocytosis of NaPi-IIa occurs by receptor-mediated endocytosis involving clathrin-coated vesicles.[28] Results obtained with kidney-specific megalin knockout mice are also in accord with this notion. In proximal tubules of these mice, the endocytotic machinery was severely impaired and the apical abundance and rate of endocytosis of NaPi-IIa were reduced.[102] In contrast to NaPi-IIa, NaPi-IIb (transfected into OK cells) is not regulated by PTH. On the basis of chimera constructs made between the NaPi-IIa and the NaPi-IIb proteins, a dibasic amino-acid motif (RK or RR) contained in an intracellular loop (Figure 68.2) was identified and demonstrated to be required for the PTH responsiveness of NaPi-IIa.[184] A yeast two-hybrid screen performed against this intracellular loop identified PEX19, a peroxisomal farnesylated protein, as an additional NaPi-IIa associated protein.[151] Although PEX19 interacts with AP2, it remains to be shown if PEX19 provides a link between NaPi-IIa and the endocytotic machinery.

After its internalization, NaPi-IIa is associated with early endosomes and subsequently routed to lysosomes and degraded.[12,28] In contrast, although initially associated with clathrin-coated vesicles, internalized NaPi-IIc has not been detected in the early endosomes and was not degraded in the lysosomes.[105] Therefore, it was proposed that, under acute regulatory conditions, internalized NaPi-IIc, in contrast to the NaPi-IIa isoform, may be able to recycle back to the membrane.

Little is known about the recovery of NaPi-IIa proteins after PTH-induced internalization and lysosomal degradation. In a study performed with rats, it was shown that after PTH stimulation, the recovery of urinary excretion of Pi and the apical abundance of the NaPi-IIa did not parallel in time. Three hours after PTH injection, renal Pi excretion was normalized, whereas the abundance of the NaPi-IIa protein was still reduced.[139] Based on in vitro experiments, *de novo* protein synthesis is required for the recovery of NaPi-IIa.[12]

Parathyroid Hormone

Although the main signal activating parathyroid hormone (PTH) secretion is a reduction in the circulating levels of calcium, there is also evidence suggesting that the parathyroid gland responds to changes in circulating Pi.[5] PTH reduces renal reabsorption of Pi by inhibiting proximal Na/Pi-cotransport. PTH receptors (PTHR) belong to the family of G-protein coupled receptors, and within the renal proximal tubule are localized at the apical and basolateral membranes.[109,164] Binding of PTH to the apical PTHR results predominantly in an activation of PLC and subsequent stimulation of protein kinase C (PKC) pathways. In contrast, binding of PTH to basolateral receptors leads preferentially to activation of adenyl cyclase, and via cyclic AMP (cAMP), to stimulation of protein kinase A (PKA). The effect of basolateral PTHR on Pi transport may be modulated by the calcium sensing receptor.[110]

The phosphaturic effect of PTH is achieved by promoting endocytosis of NaPi-IIa followed by its lysosomal degradation, thus resulting in a reduced amount of cotransporters at the BBM.[12,28,77] This effect is detected within minutes upon PTH administration, and was reproducible in different animal and cellular models. In isolated proximal tubules, agonist binding to apical and basolateral PTHR results in internalization and degradation of NaPi-IIa, which suggests that activation of both PKC and PKA pathways trigger endocytosis of NaPi-IIa.[28,164] However, recent studies using modified PTH analogs indicate that PKA signaling represents the predominant pathway.[13] Both signaling cascades seem to involve MAP kinases ERK1/2.[28] PTH also seems to reduce the apical abundance of NaPi-IIc and PiT-2.[105,127] However, both effects are considerably slower than the regulation of NaPi-IIa. Although endocytosed NaPi-IIc undergoes degradation, this process does not take place in lysosomes.[105] Thus, it appears that upon removal from the BBM NaPi-IIa and NaPi-IIc are not targeted to the same intracellular compartment.

PTH does not induce internalization of the NaPi-IIa interacting proteins NHERF1 and NHERF3.[93] This suggests that the association of NaPi-IIa with these partners may be hormonally regulated by an on/off mechanism. NHERF1 and NHERF3 are

phosphorylated in basal conditions.[93,159] Several kinases, including GRK6A, PKC, PKA and Cdc2, are known to phosphorylate NHERF1. Moreover, incubation with PTH or pharmacological stimulation of PKA and PKC results in NHERF1 hyperphosphorylation. Serine-77 and threonine-95 were identified as the residues phosphorylated in response to PTH.[94,95,113] Both amino acids are located within the first PDZ domain of NHERF1, i.e., the domain engaged in interaction with NaPi-IIa. This modification destabilizes the association of NaPi-IIa with NHERF1, allowing the retrieval of the cotransporter from the BBM.[114] Current data suggest that NaPi-IIa is not a phosphoprotein, either in basal conditions or upon PTH administration.[93]

NHERF1 interacts with apical PTHR as well as with PLCβ.[43,115] The presence of an apical complex consisting of NHERF1, PTHR and PLCβ plays a critical role on the regulation of NaPi-IIa. Thus, endocytosis of NaPi-IIa after stimulation of apical PTHR is impaired in proximal tubules of NHERF1-deficient mice.[117] This effect could not be explained by a general impairment of the endocytic machinery, since the internalization of the NaPi-IIa in response to pharmacological activation of PKC or PKA was normal. Instead, it seems to be due to the inability of the NHERF1-deficient tubules to properly activate PLC in response to PTH administration.

NHERF1 and NHERF3 also interact with the PKA anchoring proteins ezrin and D-AKAP2, respectively.[76,91] However, such a close spatial arrangement of PKA with NaPi-IIa appears not to be required for the regulation of the cotransporter, since the endocytosis of NaPi-IIa induced via the PKA signaling pathway is normal in NHERF1 as well as PDZK1-deficient mice.[99,117]

Dopamine

The cells of the proximal tubule have the ability to produce dopamine (DA), and this intrarenal production is stimulated in response to high dietary Pi.[15,118,119] The DA receptors are G-protein coupled receptors that act by stimulating (D1-like) or inhibiting (D2-like) adenylyl cyclase.[120] DA exerts a phosphaturic effect which, as in the case of PTH, is achieved by reducing the expression of NaPi-IIa at the BBM.[121] Pharmacological experiments in isolated proximal tubules indicated that agonist binding to apical (but not to basolateral) D1-like receptors results in internalization of NaPi-IIa.[121] Furthermore, this effect was blunted by PKA inhibitors but not by inhibitors of PKC or ERK1/2. This suggests that PTH and dopamine down-regulate NaPi-IIa via independent pathways.

Similar to the PTHR, D1-like receptors interact with NHERF1 and this interaction seems to be crucial for the DA-induced downregulation of NaPi-IIa.[94] Indeed DA failed to downregulate NaPi-IIa in NHERF1-deficient mice, an observation that associates with the inability of DA to stimulate either cAMP accumulation or PKC activity.[94] Furthermore, DA administration results in phosphorylation of NHERF1 at the same sites than PTH does (serine-77 and threonine-95).[113] Thus, endocytosis of NaPi-IIa in response to either PTH or DA requires previous destabilization of the association between the cotransporter and NHERF1.

Phosphatonins

Hereditary and acquired disorders such as X-linked hypophosphatemia (XHL), autosomal hypophosphatemic rickets [ADHR), and oncogenic hypophosphatemic osteomalacia (OHO) show hypophosphatemia due to increased renal wasting of Pi.[6,7] These disorders led to the identification of several factors (phosphatonins) such as fibroblast growth factor-23 (FGF23), secreted frizzled related protein-4 (sFRP4), and matrix extracellular phosphoglycoprotein (MEPE).[42,80,122,129,168]

FGF23 is produced and secreted in bones by osteoblasts/osteocytes.[124] Both serum concentrations of Pi and 1.25-$[OH]_2$VitD3 stimulate secretion of FGF23.[27,60,97,125,126,128] The phosphaturic effect of FGF23 is explained by reduction of the apical abundances of NaPi-IIa and NaPi-IIc. Accordingly, FGF23 deficient mice are hyperphosphatemic and show elevated serum levels of 1,25-$[OH]_2$VitD3.[108,128] As expected, FGF23 transgenic mice show phosphaturia that correlates with reduced amounts of both NaPi-IIa and NaPi-IIc proteins.[134] Similarly, overexpression of FGF23 and *in vitro* treatment of isolated proximal tubules reduce the abundances of NaPi-IIa, NaPi-IIc and PiT2.[22,131,178] Cellular mechanisms leading to altered abundances of apical Na/Pi-cotransporters by FGF23 are not known. Klotho is required as a cofactor for the cellular effect of FGF23 via its receptor FGFR1c.[111,131,134,192] Additionally to its function as a cofactor, Klotho may act directly on Na/Pi-cotransporters by modifying sugar residues and thereby altering transport rates.[96]

Injection of sFRP-4 elicits a decrease of NaPi-IIa abundance and an increase of Pi excretion.[137] Observed altered phosphorylation of beta-catenin indicates a mechanism involving Wnt-signaling pathway upstream to down-regulation of NaPi-IIa by sFRP-4.[137]

MEPE, a member of the SIBLING (short integrin-binding ligand interacting glycoprotein) protein family, is primarily expressed in bone cells. The phosphaturic action of MEPE is paralleled by a decrease of NaPi-IIa protein abundance.[138]

Atrial Natriuretic Factor/Nitric Oxide

The atrial natriuretic factor (ANF) and nitric oxide (NO) have been described to regulate proximal

tubular Na/Pi-cotransport.[1,4,12,177] Studies on isolated tubules demonstrated that these factors lead to a reduction (via endocytosis) of the content of NaPi-IIa in the apical membrane, via an activation of protein kinase G.[140]

Dietary Phosphate Content

The dietary content of Pi is a potent regulator of proximal tubular Pi reabsorption and its effect has been extensively studied by micropuncture/microperfusion experiments and using isolated BBMVs.[38,153] The content of Pi in the diet provokes altered rates of apical Na/Pi-cotransport; no changes of the apparent K_m value for Pi have been described. To a large extent, this adaptive phenomenon is independent of PTH, 1.25-$[OH]_2$VitD3, growth hormone, or plasma calcium.[4,12] The effects of changes in the dietary content of Pi on the rate of apical Na/Pi-cotransport and the abundances of Na/Pi-cotransporters are observed within two to four hours (acute adaptation).[141,142,153] The physiological signaling mechanisms involved in this adaptive phenomenon are poorly understood. It remains to be shown if hypophosphatemia is sensed directly by the proximal tubules or eventually at other sites such as in the central nervous system[149] or in the small intestine.[116,144] Of interest, after gavage of Pi to the upper small intestine of rats, urinary excretion of Pi increased within 15 minutes and was independent of PTH, FGF23 and altered serum Pi concentration. Based on these observations it has been postulated that a (yet unknown) phosphaturic factor is released from small intestinal mucosa due to an activation of one or more phosphate sensing mechanisms.[100,144]

Intake of diets of different contents of Pi alters the abundances of NaPi-IIa, NaPi-IIc and PiT-2, yet with different half-times of responses.[23,25] The fastest response is observed for NaPi-IIa ($t_{1/2} \approx 1$ hr), followed by PiT-2 ($t_{1/2} \approx 8$ hrs) and NaPi-IIc ($t_{1/2}2 \approx 24$ hrs). The acute (within two hours) upregulation of NaPi-IIa was shown to be independent of protein synthesis,[12] and an important role of the microtubules has been suggested on the basis of the blockage of the adaptive response by colchicine.[12] High-Pi diet leads to an internalization of NaPi-IIa, which is followed by degradation in the lysosomes.[12] High-Pi diet also promotes an internalization of the NaPi-IIc, however no lysosomal degradation of the NaPi-IIc protein was observed.[39]

In agreement with the role of NHERF1 in the apical positioning of NaPi-IIa, upregulation of this cotransporter by low-Pi diet was slightly impaired in NHERF1-deficient mice.[146] Although NaPi-IIa strongly interacts with NHERF3 (PDZK1), its adaptation to dietary Pi is not impaired in NHERF3 $^{-/-}$ mice.[99] In contrast, dietary regulation of NaPi-IIc is blunted in the absence of NHERF3.[49]

In adult mice, adaptation of the NaPi-IIa protein to a low-Pi diet was not paralleled by a change of the NaPi-IIa mRNA, whereas in weaning animals, an increase of NaPi-IIa mRNA has been reported. In contrast, NaPi-IIc mRNA has been shown to be upregulated by a low-Pi diet in all development stages.[45] Enhanced transcription of type II Na/Pi-cotransporter mRNA induced by a low-Pi diet may be explained by an enhanced binding of the transcription factor TFE3 to a phosphate response element contained within the promoter regions of the NaPi-IIa and NaPi-IIc gene.[150] In a mouse model deficient in the phosphatase calcineurin Aα, the level of NaPi-IIa mRNA was reduced and the adaptive effect of a low-Pi diet was blunted.[155]

Regulation by Lipids/Potassium Depletion

In addition to changes in the number of NaPi-IIa proteins, alterations in the proximal tubular Pi reabsorption, such as those observed after adaptation by a low-Pi diet or potassium depletion, have been proposed to correlate with changes in the membrane lipid composition including cholesterol, shingomyelin, and glycoshingolipids.[44,130,142,145,156] Furthermore, thyroid hormone status was shown to modulate Na/Pi-cotransport and the cholesterol/phospholipids ratio in proximal tubular apical membranes.[165]

Potassium depletion provokes increased urinary excretion of Pi, and BBMVs isolated from potassium-depleted rats exhibited decreased Na/Pi-cotransport. Decreased Na/Pi-cotransport in BBMV's was explained by a reduction of the abundance of NaPi-IIc and PiT-2, but not of NaPi-IIa protiens. Paradoxically, the abundance of NaPi-IIa is upregulated by potassium depletion.[37]

Fasting/Diabetes

Fasting increases urinary Pi excretion, which is due to a decrease of tubular reabsorption of Pi. Northern blot analysis indicated that fasting for 48 hours did not result in a decrease of renal expression of NaPi-IIa or NaPi III mRNA.[154]

Insulin stimulates BBM Na/Pi-cotransport.[5,12,106,177] In agreement, proximal Pi reabsorption was reduced in streptotocin-induced diabetes, though without changes of NaPi-IIa or type III Na/Pi-cotransporters mRNAs.[160] Moreover, no change of the NaPi-IIa protein abundance in BBMV was detected. In rats treated with streptotocin, the adaptive response to a low-Pi diet on the amount of NaPi-IIa was blunted indicating that

insulin may have a permissive effect on the response of NaPi-IIa to changes of the dietary content.[160]

Ontogeny/Aging

During ontogenesis and aging, transport rates in renal BBMv and the relative abundances of NaPi-IIa and NaPi-IIc are altered.[161,179] In kidneys of newborn rats, expression of the NaPi-IIa was only observed in functional, juxtamedullary nephrons and was absent in the undifferentiated structures (S-shaped bodies) of the outer cortex. During suckling, the distribution of NaPi-IIa is uniform throughout the cortex and correlates with the formation of differentiated brush borders. In kidneys of weaning rats, the expression pattern changed to a pattern similar to that observed in adults. Since during these transitions no changes of NaPi-IIa mRNA have been detected, it was suggested that the ontogenic changes on the expression of NaPi-IIa are due to posttranscriptional mechanisms.[57,133] Expression of NaPi-IIc is not observed in suckling animals; instead it is expressed predominantly in weaning animals and is markedly reduced in adults.[174]

Acidosis

Metabolic acidosis leads to an increased urinary Pi excretion, which is related to a reduction of proximal tubular apical Na/Pi-cotransport. As this effect was dependent on intact adrenal glands, an involvement of corticosteroids has been suggested.[1,2,34]

In rats fed a normal-Pi diet, metabolic acidosis provoked a decrease of the content of the NaPi-IIa protein as well as of mRNA.[166] In mice, fed a normal-Pi diet, metabolic acidosis results in a decrease of the content of NaPi-IIa and NaPi-IIc mRNA. However, both transporters were upregulated at the protein level.[112,162] Increased urinary excretion under metabolic acidotic conditions may be explained, at least in part, by the sensitivity of type II Na/Pi-cotransporters to luminal pH -values.[47,169]

Intoxication by Heavy Metals

In kidneys of rats injected with cadmium for two or more weeks, reduced Na/Pi cotransport correlated with a decrease of NaPi-IIa. Despite morphological changes of the microvillar structures, the abundance of aquaporin-1 and the Na/sulfate cotransporter NaSi-1 were not affected, indicating that exposure to cadmium results in a selective loss of NaPi-IIa.[85,170] On the other hand, a direct effect of heavy metals, including cisplatin,[172] on NaPi-IIa cannot be excluded as SH groups may play an important role in the Na/Pi-cotransport.[74]

Mice that were injected with cadmium, showed increased levels of FGF23 and increased urinary excretion of Pi that correlated with a decreased abundance of NaPi-IIc, but, interestingly, not of NaPi-IIa proteins.[173]
