Notice

No responsibility is assumed by the publisher for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions or ideas contained in the material herein. Because of rapid advances in the medical sciences, in particular, independent verification of diagnoses and drug dosages should be made

Medicine is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administrations, and contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the authors assume any liability for any injury and/or damage to persons or property arising from this publication

Dedication

This book is dedicated to Steven C. Hebert. Steve was at his heart a kidney physiologist, applying cutting edge technologies to address the most fundamental concepts of kidney function and disease. He was an extraordinary scientist, clinician, mentor, leader and friend.

Foreword

The focus of these volumes ever since the publication of the first edition in 1985 has been on renal physiology, conceived broadly as the analysis of those processes by which the kidney maintains the volume and composition of the body in the face of varied intake, physiologic alterations and pathologic disturbances. The text began with a detailed exploration of the basic mechanisms and their regulation that underlie the exchanges of water and electrolytes across cell membranes of the body. The mechanisms used by the kidney to make appropriate renal homeostatic adjustments were next presented.

In the early texts the renal response was attributed to the whole organ rather than to discrete molecular processes. It was the application of the methods and theories of the generalizing sciences, physics and chemistry, to biologic systems that, in subsequent additions, facilitated a reduction of the explanatory system to the more basic level of molecular biology, thereby providing a more comprehensive understanding of the basic processes that permit the physiologic adjustments.

In this 5th edition, such new and powerful disciplines as genetics and cell biology have been deployed to deepen and widen further the explanatory framework. Not only have previous chapters been extensively updated, but new chapters have been added to incorporate additional disciplines. Individual chapters, for example, now provide detailed treatment of the significance of cilia; the role of stem cells is now given special consideration. Finally, there has been a significant expansion of the section of pathophysiology, incorporating the newer findings of cell biology and genetics.

In a sense, this new edition represents a significant advancement in the march of reduction to a more fundamental level of understanding of the normal and deranged function of the kidney.

Preface

As described in its preface, the first edition of *The Kidney*: *Physiology and Pathophysiology*, published in 1985, focused on renal physiology, "conceived broadly as the study of those processes by which the kidney maintains the volume and composition of the body in the face of physiologic demands and pathologic disturbances." As noted in the fourth edition, science has since then become more reductionist, an evolution that has been reflected in the content of subsequent editions. Dissection of physiologic phenomena at the level of organs and cells has been enriched by descriptions of the roles of individual molecules. While this trend in science has continued, it has been complemented by a renewed focus on integrating these molecular functions to define their roles in cellular and organ physiology, as well as their role in body homeostasis and disease. A complete understanding of physiologic and pathophysiologic processes must include knowledge of individual molecules, as well as their integration into homeostatic systems that function to maintain body composition. A thorough understanding of physiologic mechanisms endows us with a greater understanding of pathophysiology and disease. Reciprocally, an understanding of disease states furnishes us with valuable information about normal physiology. The present edition continues to focus on describing the present state of knowledge of the molecules and the systems that contribute to normal physiologic function of the kidney, and the homeostatic mechanisms subserved by the kidney.

The present edition also concentrates on how these mechanisms malfunction, resulting in the diseased state. Again we will address the pathophysiology of disease states from the molecular to the system level. One of the appealing features of nephrology is the ability to utilize our understanding of normal physiology to elucidate principles of pathophysiology, and secondarily develop rational approaches to the diagnosis, treatment, and prevention of disease. Thus, the clinician addressing a patient with a fluid and electrolyte disorder need not memorize a list of possible causes or algorithms, but can logically deduce a solution through a thorough understanding of kidney function. As science continues to evolve, our understanding of the pathophysiologic basis of disease can now be applied to a much broader set of ailments. We continue, therefore, to broaden the scope of this book so as to place greater emphasis on mechanisms of disease.

The first section of the textbook begins with general principles of epithelial and non-epithelial transport and regulation. This extensive section of the book continues a tradition established in the first edition, but extends it to include a more extensive discussion of transport regulation.

The second section of the book describes the organization of the kidney with an increased emphasis on the glomerulus, as this field continues to evolve. There follows an in-depth review of renal growth and development, including a discussion of the role of stem cells in the kidney.

This is then followed by Section Three, describing mechanisms of fluid and electrolyte regulation and dysregulation. In no other book can one find this subject addressed with the depth and thoroughness found in this textbook. The Fifth Edition includes a more in-depth discussion of recently described families of transporters, integrating this information to describe their role in physiologic and pathophysiologic processes.

Section Four, the pathophysiology of renal disease, has been extended as our knowledge of renal dysfunctions and their contribution to renal ailments has expanded. Many chapters deal with common everyday clinical issues, but are presented in the context of pathophysiologic mechanisms. A series of chapters focus on mechanisms of progression of renal disease, as the importance of interrupting or forestalling this progression has assumed great importance in clinical nephrology. A thorough understanding of the roles of glomerular pressure, proteinuria, inflammation, and oxidants will help researchers and clinicians prevent renal failure, decreasing the need for dialysis and transplant.

The evolution of our understanding of kidney function and dysfunction derives from sequential discoveries made by a series of investigators, each benefiting from the accomplishments of their predecessors. The same can be said for this textbook. Originally conceived by two of the greatest renal physiologists of the twentieth century, Donald Seldin and Gerhard

Giebisch, it was passed on to Steve Hebert and one of the present editors. As the present editors, it is our hope to continue the book's commitment to science, and its role in our understanding and practice of nephrology, and in so doing to honor the previous editors for all that they have contributed to the book, to nephrology, to epithelial physiology, and to science in general.

1

Epithelial Cell Structure and Polarity

Karl S. Matlin[1] *and Michael J. Caplan*[2]

[1]Laboratory of Epithelial Pathobiology, Department of Surgery, University of Chicago, IL, USA
[2]Department of Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, CT, USA

INTRODUCTION

Many of the chapters in this volume are devoted to the mechanisms through which the nephron is able to convert the glomerular filtrate into concentrated urine that is responsive to the metabolic status of the organism as a whole. The multifactorial nature of this problem means it needs to be treated at several levels of resolution. A meaningful description of renal tubular functions requires an understanding of the nephron's properties as an integrated tissue, as well as those of its constituent parts, including the cells and molecules that contribute to its transport functions.

As detailed elsewhere in this volume, the nephron is a remarkably heterogeneous structure. Throughout its length, the renal tubule is notable for the marked variations in the morphologic and physiologic properties of its epithelial cells, reflecting the numerous and diverse responsibilities that neighboring segments are called on to fulfill. At the tissue level, the function of the kidney is critically dependent on the geometry and topography of the nephron. The precise juxtaposition of various epithelial cell types, which manifest distinct fluid and electrolyte transport capabilities, in large measure specifies the course of modifications to which the glomerular filtrate is exposed. This dependence on geometry also extends to renal function at the cellular level.

The Nature and Physiologic Implications of Epithelial Polarity

Despite their variations in form and function, all of the epithelial cells that line the nephron share at least one fundamental characteristic. Like their relatives in other tissues, all epithelial cells are polarized. The plasma membranes of polarized epithelial cells are divided into two morphologically and biochemically distinct domains.[1–6] In the case of the nephron, the apical surfaces of the epithelial cells face the tubular lumen. The basolateral surface rests on the epithelial basement membrane, and is in contact with the interstitial fluid compartment. The lipid and protein components of these two contiguous plasmalemmal domains are almost entirely dissimilar.[1–6] It is precisely these differences that account for the epithelial cell's capacity to mediate the vectorial transport of solutes and fluid against steep concentration gradients. Thus, the subcellular geometry of renal epithelial cells is critical to renal function.

The principal cell of the collecting tubule provides a useful illustration of the importance of biochemical polarity for renal function. As described in other contributions to this volume, the principal cell is required to resorb sodium against a very steep concentration gradient. It accomplishes this task through the carefully controlled placement of ion pumps and channels.[7–9] The basolateral plasma membrane of the principal cell, like that of most polarized epithelial cells, possesses a large complement of Na^+/K^+-ATPase. This basolateral sodium pump catalyzes the energetically unfavorable transport of three sodium ions out of the cell in exchange for two potassium ions, through the consumption of the energy embodied in one molecule of ATP.[10] The apical surface of the principal cell lacks sodium pump, but is equipped with a sodium channel, which allows sodium ions to move passively down their concentration gradient.[11] Through the action of the sodium pump the intracellular sodium concentration is kept low and the driving forces across the apical membrane favor the influx of sodium from the tubular fluid through the apical sodium channels. Thus, the combination of a basolateral Na^+/K^+-ATPase and an apical sodium channel lead to the vectorial movement of

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00001-X

sodium from the tubule lumen to the interstitial space against its electrochemical gradient. This elegant mechanism is critically dependent upon the principal cell's biochemical polarity. If the sodium pump and the sodium channel occupied the same plasmalemmal domain, then the gradients generated by the former could not be profitably exploited by the latter. Thus, the vectorial resorption or secretion of solutes or fluid is predicated upon the asymmetric distribution of transport proteins in polarized epithelial cells.

The fact that epithelial cells manifest biochemical polarity implies that they are endowed with the capacity to generate and maintain differentiated subdomains of their cell surface membranes.[1–6] Newly synthesized membrane proteins must be targeted to the appropriate cell surface domain, and retained there following their delivery. During tissue development, cell division, and wound healing, plasmalemmal domains must be delimited and their biochemical character established. Clearly, specialized machinery and pathways must exist through which this energetically unfavorable compositional asymmetry can be supported. The nature of these specializations has been the subject of intense study for decades. While firm answers are not yet available, a number of fascinating model systems have been developed, and valuable insights have emerged. This chapter will focus on what is known of the processes through which tubular epithelial cells create their polarized geometry.

EPITHELIAL CELL STRUCTURE: MORPHOLOGY AND PHYSIOLOGY

The renal tubular epithelium is composed of a remarkably varied collection of cell types, ranging from the highly specialized glomerular epithelial cells with foot processes that faciliate filtration of the blood through the basement membrane, to the simple squamous epithelium of the loop of Henle. A detailed delineation of its morphologic diversity is beyond the scope of this chapter. However, certain essential features are shared among all cell types in the tubular epithelium and, indeed, most other epithelial cell types found in the body. Among these are a differentiated, microvillar apical surface facing the tubular lumen, a lateral surface specialized for cell–cell interactions and regulation of transepithelial permeability, and a basal surface that adheres to the basement membrane. Furthermore, as described previously, the basolateral plasma membrane is particularly important in ion transport, because it is the location of the Na^+/K^+-ATPase and the cell is able to modulate its surface area in response to the transport activity of individual cell types. The cell–cell adhesive relationships are responsible for the integrity of the epithelium, and also dictate the permeability of the epithelium to small molecules that, in part, give each segment of the epithelium its physiological identity. Furthermore, adhesion of epithelial cells to each other and to the basement membrane sends spatial signals to the cells essential for the establishment and maintenance of epithelial cell polarity. In the following sections the morphology and functional composition of the apical and basolateral domains of the plasma membrane will be described, after detailing the nature of the junctional complex that mediates cell–cell adhesion.

The Junctional Complex

All epithelial cells, including those of the kidney tubule, are joined together along the lateral surfaces by a series of intercellular junctions first noted by their characteristic ultrastructural appearance and relative locations on the lateral plasma membrane.[12,13] These include the tight junction or *zonula occludens*, the adherens junction (*zonula adherens* or intermediate junction), desmosomes, and gap junctions. In most mammalian epithelia the tight junction is located at the apical-most edge of the lateral membrane closely followed by the adherens junction. Desmosomes and gap junctions have less specific locations on the lateral membrane. Desomosomes and gap junctions will be described briefly, followed by a more comprehensive description of tight junctions and adherens junctions, because of their essential functions in the organization, physiology, and morphogenesis of epithelia.

Desmosomes are large, multiprotein complexes primarily responsible for the mechanical strength of cell–cell interactions.[14] They are formed after the assembly of adherens and tight junctions. By transmission electron microscopy they appear as discrete, focal concentrations of dense material in the cytoplasm of adjacent cells, as well as in the intercellular space.[13] In contrast to adherens and tight junctions, desmosomes do not form an adhesive belt around the entire epithelial cell, but are a kind of "spot weld" at various points on adjacent lateral membranes. They are composed of both integral membrane proteins of the cadherin family called desmogleins and desmocollins, and peripheral membrane proteins known as desmoplakins, as well as a variety of other protein constituents.[14] Adjacent cells adhere to each other through cadherin-mediated interactions. The peripheral components then provide mechanical stability to this interaction, via keratin intermediate filaments in the cytoplasm of each cell.[15] Ultrastructurally, these appear as a mass of hair-like protrusions interacting in parallel with each plaque and then splaying out into the cytoplasm.[13,14]

In this manner, desmosomes link all cells in the epithelium. While there is evidence that desmosomal components may play an active role in regulating some aspects of cell–cell adhesion and even gene expression,[16] in general their function is considered to be relatively passive.

Gap junctions are so named because of the characteristic 3 nm gap between adjacent cells that is evident using transmission electron microscopy.[17,18] Examination of freeze-fracture specimens, which permits visualization of the internal topography of membranes, reveals the gap junction as a discrete array of intramembranous particles or connexons.[17,18] Each connexon is composed of five identical connexins, a family of transmembrane proteins. Connexons on adjacent cells interact through their extracytoplasmic domains to form a series of low-resistance channels. These permit the passage of small molecules of less than 1 kDa, linking neighboring cells in the epithelium both electrically and metabolically. In the kidney, it is likely that gap junctions play important roles during morphogenesis and repair, although their precise functions have not been investigated in detail.[17,18]

Among the numerous functions subserved by epithelia, perhaps the most important is that of a barrier between the intra- and extracorporeal spaces. In the case of the kidney, the extracorporeal space is defined by the lumen of the renal tubule. That the chemical composition of urine differs substantially from that of the interstitial extracellular fluid bathing the epithelial basement membranes is evidence that the barrier provided by the tubular epithelium is tight to both small and large molecules. There are two components to this barrier, arranged in parallel.[19–21] The first is comprised of the apical and basolateral membranes of the epithelial cells, which together serve as a pair of series resistances to the flow of solutes across the epithelia. The second barrier is provided by the tight junction or *zonula occludens* that controls movement of molecules between the cells along the so-called paracellular pathway.[20–29]

The tight junction defines a border between the apical and basolateral plasma membranes. In columnar and cuboidal cells of the renal epithelium, it is found at the apical extremity of the lateral membrane and in the plane of the apical surface. Analysis by transmission electron microscopy originally suggested that the tight junction is a zone of partial fusion between the plasma membranes of adjacent cells.[13] Although this is no longer believed to be the case (see below), the ultrastructure of the junctions is consistent with this interpretation. When cells that have been treated with osmium are examined at high magnification, their membranes are distinguished by a characteristic pattern. The two leaflets of the lipid bilayer appear as a "unit membrane," defined by a pair of darkly stained parallel lines separated from one another by 5–10 nm.[30] In areas corresponding to the tight junction, the four parallel lines representing the two unit membrane of adjacent cells are replaced by three lines, which led to the suggestion that the two outer leaflets contributed by the neighboring cells have in some way merged to form a new trilaminar membrane structure.[12]

The putative outer leaflet fusion suggested by morphologic studies received some support from examination of lipid mobility in polarized epithelial cells. The mobility of outer leaflet lipids is restricted by the tight junction.[31,32] Labeled lipid probes inserted into the outer leaflets of epithelial apical or basolateral plasma membranes have unimpeded mobility within their respective domains, but cannot cross the tight junction.[31,32] Furthermore, outer leaflet lipids are unable to diffuse between neighboring epithelial cells through the tight junction. In contrast, inner leaflet lipids can apparently move freely between the two plasma membrane domains, suggesting that the tight junction presents no barrier to their diffusion. These observations are consistent with a model of the tight junction, in which the outer leaflets of the lipid bilayer participate in the formation of some junctional structure, while the inner leaflet remains unperturbed. These results also suggest that the lipid composition of the apical inner leaflet is necessarily identical to that of the basolateral one, because any differences would quickly be randomized by diffusion. Thus, the differences in lipid compositions of the apical and basolateral surfaces alluded to in the introduction to this chapter must be entirely contributed by the constituents of the outer leaflet.[32,33]

Electron microscopy has provided further insights into the structure of the tight junction. Examination of freeze-fracture replicas of epithelial cells reveals the tight junction to be composed of continuous branching and interwoven strands that surround the entire perimeter of the cell.[34] These strands appear as elevations in the P or cytoplasmic fracture face, and are matched by grooves in the E or external face. In some cell types the strands have a fibrillar appearance, and no discrete subunit structure can be resolved. In other cell types, and in samples not fixed with glutaraldehyde, the strands can appear more as a series of particles.[34] Although some early models postulated that the strands were composed of unusually structured lipids, it is now certain that they are primarily composed of integral membrane proteins (see below). Observations of a number of cell types with different amounts of transepithelial electrical resistance revealed a rough correlation between the number and complexity of the anastomosing strands and the degree of transepithelial electrical resistance. While this correlation certainly exists in at least some epithelia,[35] the amount of

resistance is now known to be a function of the specific complement of proteins making up tight junctions in different cells.

The first tight junction protein identified was, appropriately, ZO-1 (*zonula occludens*-1).[36] ZO-1, however, turned out to be a cytoplasmic peripheral membrane protein, suggesting that other, integral transmembrane proteins capable of mediating cell−cell contact and the intermembrane permeability barrier must exist. Shortly thereafter, occludin, a multispanning membrane protein, was identified, followed by many other proteins.[21] It is now clear that the tight junction is an extremely complex structure composed of at least three different families of transmembrane proteins including: multiple claudins; occludin and other members of the MARVEL family; and the junctional adhesion molecules or JAMS.[21] Additional peripheral membrane proteins are also part of the tight junction, including ZO-1, -2, and -3, and cingulins. It is also evident that the functions of these protein complexes extend beyond regulating solute permeability to participation in epithelial cell polarization.[37]

Claudins are the most important tight junctional proteins controlling paracellular permeability of small molecules.[38−43] They are the major protein constituent of the tight junctional strands seen in freeze-fracture; expression of claudins in fibroblasts produces characteristic strands and promotes cell−cell adhesion.[21,38,41,43−45] The claudin family consists of at least 24 members in mammals. All are tetraspanning transmembrane proteins of 20−27 kD, with two extracellular loops. With one exception, the cytoplasmic C-terminal sequence of claudins interacts with ZO-1, -2, and -3. Interacting claudins on neighboring epithelial cells create charge selective channels, with the overall permeability of the tight junction to ions dependent on the particular mix of claudins expressed in the cell.[21,44] This was illustrated dramatically in the renal epithelial cell line MDCK (Madin−Darby canine kidney) when expression of claudin 8, in addition to other endogenous claudins, reduced the paracellular movement of mono- and divalent cations without affecting the permeability of anions or uncharged solute molecules.[46] In the kidney tubular epithelium, cells of the proximal tubule, which has a transepithelial electrical resistance of 6−10 Ωcm^2, express claudins 2, 6, 9, 10, and 11, while cells of the collecting duct, with a much higher resistance of 1000 Ωcm^2, express claudins 3, 4, 6, 7, 8, 10, and 14[29,47] (Figure 1.1). Other cell types along the nephron express other combinations, yielding a range of increasing resistances in the proximal-to-distal direction[29,47] (Figure 1.1).

The selective barrier created primarily by claudins is sometimes referred to as the "pore pathway," because it permits movement only of small ions and other uncharged small solute molecules. However, in at least some epithelia, there is also a kind of "leak pathway" that allows passage of larger molecules, including macromolecules.[21] The nature of the leak pathway and its regulation is poorly understood. Occludin, which is also a tetraspanning membrane protein unrelated to claudins, may play a role in the leak pathway, together with ZO-1 and the actin cytoskeleton. Even though it is counterintuitive, an electrically tight pore pathway can co-exist with an active leak pathway, although the molecular and structural basis of this has not been fully clarified.[21]

The tight junction is a structure whose function is highly dependent on interactions between integral and peripheral components and the actin cytoskeleton. ZO-1 and its family members are perhaps the most important class of proteins linking the various tight junctional proteins together.[36,48,49] ZO-1 contains multiple PDZ (PSD95-Dlg-ZO-1) protein interaction domains. These bind to both claudins and JAMs, while other regions of the molecule bind to occludin and actin. ZO-1 is also capable of binding to components usually identified with adherens junctions, and to a wide variety of signaling molecules.[21] While it is still valid to view the regulation of paracellular permeability as the primary function of the tight junction, it is more appropriate to think of the overall structure as a component of a larger apical junctional complex responsible for a multiplicity of adhesive, signaling, and membrane trafficking functions.

Originally, the tight junction was looked at as a stable, static structure in intact epithelia. Recent results using, among other approaches, expression of fluorescent tight junction proteins in cultured and intact epithelia, indicate that, in fact, the tight junction is highly dynamic.[50] In the intestine, the epithelial leak pathway will open to permit uptake of glucose beyond the capacity of the Na^+-glucose transporter in the apical membrane. This process is controlled by the actomyosin cytoskeleton, since drug-induced actin depolymerization, as well as activation of myosin light chain kinase (MLCK), compromises the epithelial barrier.[50−52] Breakdown in the barrier is accompanied by simultaneous endocytosis of occludin, both implicating occludin in the regulation of the leak pathway and further demonstrating the cell's capacity to reshape the junction. Tumor necrosis factor (TNF), which is involved in the pathogenesis of Crohn's disease, will cause barrier breakdown through a mechanism also dependent on MLCK.[50] Although these studies of tight junction plasticity have concentrated on the intestine, it would be surprising if similar mechanisms were not operable in the renal tubular epithelium, especially in the proximal tubule which morphologically resembles intestinal absorptive cells, and where uptake of a variety of filtered materials occurs.

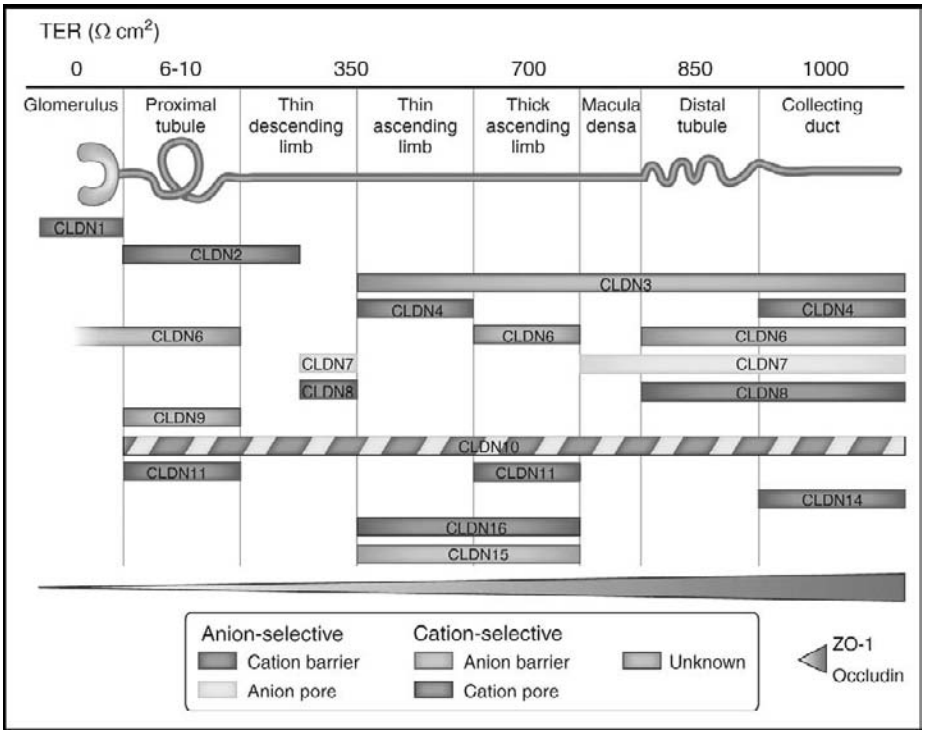

FIGURE 1.1 **The relationship between transepithelial resistance and claudin subtype expression along the nephron.** *(Reprinted from ref. [29].)*

The adherens junction, or *zonula adherens*, forms a belt just below the tight junction in most epithelial cells, connecting them via extracellular interactions and cytoplasmic linkages to the actin cytoskeleton (Figure 1.2). In the electron microscope, adherens junctions appear as a dense, somewhat amorphous concentration of submembranous staining, with a mass of impinging actin filaments.[13] The major adhesive component of the adherens junction is E-cadherin.[25,53,54] E-cadherin is a single-pass transmembrane protein that consists of a series of calcium-binding extracellular or EC repeat domains, and a cytoplasmic tail that interacts with members of the catenin family. In adherent cells E-cadherin is concentrated in the adherens junction, but can also be more diffusely distributed over the lateral plasma membrane. Adhesion between cells occurs through *trans* interactions between the EC1 domains contributed by different cells in the presence of calcium, which maintains the proper conformation of the extracellular part of E-cadherin. Interactions occur initially through individual molecules, but are then consolidated and strengthened through lateral interactions of individual units.

The stability of E-cadherin-mediated adhesion is dependent on the binding of catenins to the cytoplasmic tail of E-cadherin.[25,54] P120-catenin binds to a specific octapeptide located in the cytoplasmic juxtamembranous part of the cytoplasmic tail, and appears to be responsible for maintaining the stability of E-cadherin in the membrane, preventing its endocytosis and degradation. It is also involved in signaling related to cell motility, and is a substrate for the Src-receptor tyrosine kinase. The second catenin that associates with E-cadherin is β-catenin, which binds to the carboxy terminus of the cytoplasmic tail in a phosphorylation-dependent manner.[25,54] Certain serine phosphorylations of E-cadherin increase the affinity of the β-catenin–E-cadherin interaction, while phosphorylation of serines on β-catenin disrupt the interaction with E-cadherin, and with α-catenin. In addition to its role in cell–cell adhesion, β-catenin is itself an important signaling molecule that is capable of entering the nucleus and regulating transcription of genes related to cell proliferation and differentiation.[16,55,56] Its function in transcription is carefully regulated by the Wnt signaling pathway by keeping the cytoplasmic concentration of β-catenin low, either through its interaction with E-cadherin or through its degradation by a mechanism dependent on a cytoplasmic "destruction complex" and ubiquitination.

In the adherens junction, β-catenin serves as a bridge between E-cadherin and α-catenin that, in turn, interacts with the actin cytoskeleton. In this manner, cell–cell adhesion through the adherens junction is given both a degree of mechanical stability and mobility through actomyosin contraction.[54] Originally the β-catenin–α-catenin–actin interaction was believed to be somewhat static, but recent evidence indicates that it is very dynamic. Alpha-catenin can exist as either a monomer or dimer, with the monomer able to bind β-catenin, but not actin, and the dimer able to bind actin, but not β-catenin. Three pools then exist in the cell: a monomer

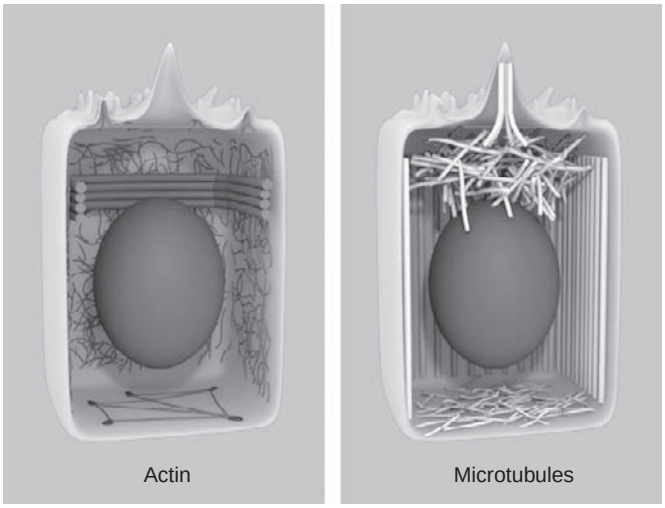

FIGURE 1.2 **The distribution of actin filaments and microtubules in polarized renal epithelial cells, based on the Madin–Darby canine kidney (MDCK) cell line.** *(Images courtesy of Jonathan Bowen and Elias T. Spoliotis, Drexel University, Philadelphia, Pennsylvania.)*

pool bound to β-catenin; a free cytoplasmic monomer pool; and a dimer pool bound to actin. As the adherens junction forms and consolidates, a high concentration of monomers is transported to a localized site on the membrane through β-catenin interactions. This then drives dimer formation and a dynamic linkage to the actin cytoskeleton. Localized concentration of α-catenin dimers can also inhibit Arp2/3, a mediator of actin branching essential for cell migration, and thus facilitate the transformation from a migrating cell to an adherent polarized cell during processes such as injury repair.[54] The recognition that the adherens junction is dynamic and plays a role in cell motility has helped to transform our view of epithelia from that of a static sheet of cells to one of interlocking cells capable of constant motion and remodeling, all the while maintaining a precise permeability barrier between the inside and outside compartments of the body.

The Apical Microvillar Surface

The apical brush border membrane is perhaps best epitomized by the one that graces the epithelial cells of the proximal tubule. Named for its appearance, the proximal tubular brush border is comprised of densely packed parallel microvilli which rise like the bristles of a brush from the level of the tight junctions to a height of 1 to 1.3 μm. The proximal tubular brush border is by far the most luxuriant to be found in the nephron; although the apical membranes of other renal epithelial cell types are endowed with small collections of microvillus-like structures, much less is known about the structural specializations characteristic of the apical membranes of more distal renal epithelial cells.[57]

The functions subserved by apical microvilli are not entirely clear. Certainly their most dramatic and obvious effect upon the properties of the apical membrane is manifest as a tremendous amplification of the apical membrane surface area. For the proximal tubule this amplification is in the order of 20-fold.[58,59] As is the case for the epithelia of the small intestine, it is through this redundancy that the proximal tubular epithelial cells markedly increase the efficiency of both their absorptive and degradative functions.

Physiologically, the proximal tubule is responsible for the resorption of ~60% of the filtered load of fluid and solutes.[60] Furthermore, it mediates the digestion of essentially all of the polysaccharides and peptides present in the glomerular filtrate, and transports the resultant sugars and amino acids from the lumen to the interstitial fluid space.[58] It is apparent, therefore, that the epithelial cells of the proximal tubule must be specially equipped, in order to cope efficiently with the comparatively enormous quantities of fluid and substrates that rapidly transit this nephron segment. The presence of an extravagant brush border greatly increases the fraction of the tubular fluid that comes into close contact with the enzymatic and transport systems arrayed on the microvillar surfaces prior to its passage from this tubule segment into the descending loop of Henle. Concomitantly, it proportionally multiplies the number of enzymatic and transport systems available to modify the substrates dissolved in the tubular fluid. Thus, the brush border membrane provides the scaffolding for the relatively massive arsenal of enzymatic and transport machinery required to accomplish the proximal tubule's function as a high-capacity and high-throughput absorptive system.

Ultrastructurally, a microvillus is composed of a bundle of ~19 parallel thin filaments that are linked to one another and to the overlying surface membrane by protein cross bridges.[61,62] The thin filaments extend well beyond the base of the microvillus, and are anchored in a dense matrix of fibers oriented parallel to the plane of the membrane. This meshwork, referred to as the terminal web, underlies the entire apical surface and anastomses with the filaments that radiate from the lateral desmosomes and zonulae adherens (Figure 1.2). The functional implications of these structural arrangements have become clearer as their components have been biochemically identified.[63,64]

The thin filaments that form the microvillar core are composed of actin[61,65] (Figure 1.2). Ultrastructural studies employing heavy meromyosin reveal that all of the filaments in the bundle share a single polarity, and are oriented with their nucleating end towards the microvillar tip. At their termination in the microvillar tip the filaments are received by an electron-dense cap whose molecular identity has yet to be established.[61]

As they emerge from the base of the microvillus, the actin filaments are caught up in the fibers of the terminal web (Figure 1.2). Fodrin, or non-erythroid spectrin, comprises one of the major components of this network.[61,64,66] It appears to function beneath the brush border as an actin fiber cross-linker. Another of the chief constituents of this fibrillar matrix is a non-muscle form of myosin II that belongs to the same myosin subfamily as its skeletal muscle counterpart. Bipolar myosin thick filaments appear to interact with the actin filaments as they sweep out of the microvillar sheath to join the terminal web.[61,65,67] Paired anti-parallel myosin filaments cross-link the actin filaments of neighboring microvilli to one another, forming a connection which bears close comparison to the actin−myosin arrangement characteristic of the striated muscle sarcomere. The analogy is strengthened by the presence in the microvillar rootlet of tropomyosin, a protein that functions in skeletal muscle to regulate the interaction between actin and myosin.[67,68]

This marked molecular similarity between the terminal web and the skeletal muscle contractile unit prompted speculation that this arrangement might also be functionally homologous. A number of investigators have postulated that activation of myosin-based contraction at the microvillar base might lead to microvillar shortening.[69] Repetitive activation of such a mechanism would lead to a piston-like extension and retraction of these membranous processes, which in turn might stir the surrounding tubular fluid. Such a mixing motion is certainly teleologically appealing, in that it would help to ensure that the tubular fluid is uniformly exposed to the enzymatic and transport systems of the proximal tubular apical membrane surface. No evidence for any such concerted and dynamic properties of microvilli has yet been gathered.

Biochemical studies have shed light on the identities and functional properties of some of the proteins which contribute to the interfibrillar cross bridges observed in transmission electron micrographic profiles of microvilli. Howe and Mooseker identified a protein of molecular weight 110 kDa that participates in cross-linking the filaments of intestinal microvilli to the plasma membrane.[70] This protein exhibits a high affinity for the calcium-binding protein calmodulin, which participates in the transduction of a number of calcium-regulated phenomena.[70] Of further interest was the fact that the 110 kDa protein manifests a myosin-like Mg-ATPase activity.[71] Addition of ATP to intact microvilli results in solubilization of the 110 kDa protein, and disruption of the cross-links between the actin filaments and the microvillar membrane.[72,73] Thus, attachment of the plasma membrane to the thin filaments may be regulated by ATP and calcium. The degree to which this putative capacity for structural modulation plays a role in microvillar function has yet to be clarified. Subsequent molecular analysis revealed that the brush border 110 kDa protein belongs to the myosin I family of unconventional myosin molecules.[74,75] Unlike skeletal muscle myosin (which is assigned to the myosin II classification), brush border myosin I molecules possess a single globular head group, and do not form bipolar filaments.[71,72,76,77] Members of the myosin I family, including brush border myosin (myosin Ia), have been found to associate with the membranes of intracellular vesicles, prompting the hypothesis that these motor proteins serve to propel vesicles through the cytoplasm along actin filament tracks.[78,79] Co-localization studies have demonstrated that brush border myosin I and the microtubule-dependent motor protein dynein can be found together on the membranes of post-Golgi vesicles.[80] This observation has inspired the hypothesis that apically-directed vesicles depart the Golgi along microtubule tracks powered by the action of dynein. Upon their arrival at the actin-rich terminal web, they switch engines and are carried the rest of the way to the brush border by myosin I.[81] While brush border myosin I is abundantly expressed in intestinal epithelial cells, it may be present at lower levels in the renal proximal tubule.[82] Since the myosin I family is large and diverse, however, it is extremely likely that an as-yet-unidentified member of this class subserves similar structural and mechanical functions in the epithelial cells of the kidney.[83,84]

Another protein that apparently participates in the organization of the microvillus has a molecular weight of 95 kDa, and has been dubbed villin.[85] Villin belongs to a large family of actin-binding proteins.[86] Prominent in its structure is a pair of sequence domains that appear to be involved in associations with f-actin. The presence of this tandem repeat justifies the contention that villin mediates the bundling of actin fibers. It is interesting to note that villin is a calcium-binding protein, and that interaction with calcium alters its behavior in the presence of actin filaments.[87] In experiments carried out with purified villin in solution, it has been found that this protein bundles actin filaments when the free calcium concentration is less than 1 μM. When the calcium concentration rises to 10 μM, villin severs actin filaments into short protofilaments. At intermediate calcium concentrations, villin binds to actin filaments at their growing ends, forming a cap that prevents further elongation. Due to the dynamic nature of the microfilament polymer, this capping results in the formation of shortened filaments. It is not known whether these calcium-dependent activities of villin are manifest *in vivo*. If villin does indeed sever or shorten actin filaments within the living cell, it would seem likely that perturbations which produce elevations of intracellular calcium concentrations may lead to structurally significant alterations in the organization of the microvillar scaffolding. During embryonic development, villin is expressed throughout

the cytoplasm of epithelial cells prior to the elevation of a brush border.[88] At later stages, villin becomes localized to the cytosolic surface of the apical membrane, and is subsequently incorporated into forming microvilli. This behavior has led to the suggestion that the localization of villin to the apical surface is a watershed event in the biogenesis of microvilli. Thus, the formation of inter-filamentous bridges, presumably mediated by villin, may be a critical first step in the organization of the microvillar infrastructure. Supporting this model are the results of experiments in which Caco-2 intestinal epithelial cells were stably transfected with a vector encoding antisense villin mRNA.[89] The consequent reduction in villin expression resulted in a loss of the brush border and mis-sorting of a subset of apical microvillar proteins. It must be noted, however, that results from gene knockout experiments argue against an obligate role for villin in microvillus formation.[90] Mice whose villin genes have been disrupted, and which produce no villin protein, are able nonetheless to generate morphologically and apparently physiologically normal brush borders. Presumably, other components of the microvillar infrastructure can shoulder the cross-linking and organizational duties normally performed by villin. Such functional redundancy is typical of biological systems endowed with architecture as esthetically elegant and complex as that which graces the microvillus.

While villin is limited in its distribution to those cell types endowed with brush borders, another actin-bundling component of the microvillus is present in numerous structures. Plastin-1, which is also known as fimbrin, is a 68 kDa polypeptide associated with the interfilamentous cross bridges that can also be detected in hair cell stereocilia and in ruffled borders.[91] Plastin-1 is clearly a multivalent actin-binding protein, and participates in the cross-linking of the microvillar actin filament array. Structural studies suggest that the cross-linking activity of plastin-1 constitutes the principal means through which the parallel actin filaments are interconnected in microvilli,[92] and the length and organization of brush borders are abnormal in plastin-1 knockout mice.[93] A third bundling protein, known as espin, also participates in the organization of the microvillar actin filaments.[94] While microvilli appear to form normally in the absence of espin,[95] espin overexpression leads to microvillar lengthening[96] by exerting subtle effects on the relative rates of actin filament polymerization and depolymerization. Simultaneous knockout of plastin-1, villin, and espin produces animals whose brush borders are short, and characterized by reduced numbers of disorganized actin filaments and mislocalized myosin. Interestingly, localization of enzymes that are normally concentrated in microvilli is markedly compromised in epithelial cells from these animals, suggesting that the organization of the overlying plasma membrane is dependent upon the structural integrity of the microvillar actin bundle.[97]

Several other polypeptides, associated with the microvillus core and the terminal web, have also been identified. Among the most interesting and important of these is ezrin, a member of the ezrin−radixin−moesin family of proteins.[98] The C-terminal tails of these polypeptides bind to actin filaments, while their N-termini interact with proteins in the membrane. A number of proteins involved in the generation or regulation of intracellular second messengers associate in macromolecular complexes with ezrin−radixin−moesin family members, suggesting that in addition to functioning as linkers these proteins may also act as scaffolding for the assembly of components involved in signal transduction. Knockout of ezrin expression results in shortened and poorly formed brush border microvilli, and perturbations in the organization of the terminal web.[99] In addition, ezrin participates in forming complex molecular scaffolds that regulate and stabilize the expression of solute transport proteins in the apical membranes of renal epithelial cells.[100]

The terminal web mentioned above consists of three morphologically distinguishable domains. In addition to the cytoskeletal fibers that receive the rootlets of the microvilli, fibers that arise from desmosomes and the *zonula adherens* contribute to this meshwork. The desmosomal fibers consist primarily of 10 nm intermediate filaments composed of keratins.[15] At the level of the *zonula adherens*, the cell is ringed by a complex of randomly polarized actin filaments which also contains myosin and tropomyosin[67] (Figure 1.2). *In vitro* experiments have demonstrated that this ring has the capacity to contract circumferentially.[101] This capacity has led to the idea that contraction of the *zonula adherens* ring might contribute to the alterations in tight junctional permeability which have been observed in several epithelial systems in response to certain second messengers and osmotic stress, as described earlier.[20] Thus, activation of sodium-coupled glucose uptake in cultured intestinal epithelial cells has been shown to induce a decrease in transepithelial resistance. This effect is dependent upon the activity of myosin light chain kinase.[51,52] It is thought that by shortening in a "purse-string" fashion, these filaments might actually draw neighboring cells away from one another, and thus modify the structure and permeability of the occluding junctions. The relevance of this model to the functioning of renal epithelia has yet to be established.

The anisotropy and structural complexity that characterize the filamentous core of the microvillus apparently also extend to its overlying plasma membrane. The proteins embedded in, and associated with, the plasmalemma of the proximal tubule brush border are not uniformly distributed over its surface, but rather

are restricted to specific subdomains. This lateral segregation is epitomized by the behavior of two transmembrane polypeptides, maltase and gp330. The 300 kDa enzyme maltase is distributed over the entire surface of the microvilli themselves, but is absent from the intermicrovillar membrane regions.[102,103] In contrast, the heavily glycosylated gp330 (also known as megalin) is restricted in its distribution to these intermicrovillar regions. The restriction of megalin to the intermicrovillar regions appears to be mediated by its interactions with protein components of the endocytic machinery. Ultrastructural examination of the intermicrovillar regions reveals the presence of coated pits. The cytosolic surface of the plasma membrane in these domains is coated with an electron dense material that biochemical and immunoelectron microscopic studies have demonstrated to be clathrin.[103] The presence in these intermicrovillar pits of morphologic and compositional features associated with the process of endocytosis has led investigators to believe that this domain mediates the retrieval of large peptides and proteins from the proximal tubular fluid. The proximal tubular epithelial cells are responsible for capturing and degrading any proteins that pass through the glomerular filtration barrier.[58] This function is apparently served by the profusion of coated pits and vesicles that decorate the surfaces of membranes at the microvillar base. Megalin is a member of the LDL receptor family and, together with cubulin, serves as a receptor that binds to and mediates the uptake of filtered proteins and peptides. Megalin knockout mice exhibit low molecular weight proteinuria, establishing the critical role for megalin as the proximal tubule's pre-eminent scavenger.

Finally, it is worth noting that most or all of the epithelial cells of the nephron are endowed with a single primary cilium (Figure 1.2). This non-motile cilium possesses a ring of nine microtubules, but lacks the central pair of microtubules found in motile cilia. This primary cilium appears to serve sensory functions. Bending the primary cilium, in response to flow or mechanical stimuli, induces calcium signaling in renal epithelial cells. Furthermore, the functional integrity of the primary cilium appears to be a prerequisite for the maintenance of normal renal tubular architecture. A number of cystic diseases of the kidney are attributable to mutations in genes encoding proteins found in cilia.[104–108] Similarly, mice in which expression of ciliary proteins has been disrupted develop cysts. The mechanisms through which loss of the cilium's mechanosensory functions leads to cystic transformation remain to be established.

The Basolateral Plasma Membrane

The rigid subservience of structure to function so elegantly exemplified by the apical microvillar membrane also extends to the basolateral surface of the epithelial plasma membrane. As was mentioned above, the basolateral membrane possesses the ion pumps that power the transepithelial resorption of solutes and water. The resorptive capacity of a given cell type is thus largely dependent on the quantity of ion pumps embedded within its basolateral membrane. This parameter appears, in turn, to be roughly proportional to the surface area encompassed by this membrane domain.[8] Consequently, renal epithelial cells that participate in resorption of large quantities of ions and fluid (such as those of the proximal tubule), as well as cells that carry out resorption of ions against steep concentration gradients (such as those of the thick ascending limb of the loop of Henle), are endowed with basolateral plasma membranes whose surface areas are amplified through massively redundant infoldings.

As was detailed in the discussion of the apical membrane, the lateral distribution of proteins within the plane of the basolateral membrane is not uniform. This fact is most dramatically illustrated by epithelial cell types that lack the deeply invaginated basolateral infoldings discussed above. Studies have demonstrated that the Na^+/K^+-ATPase is concentrated in subdomains of the basolateral membranes of small intestinal epithelial cells.[109] The sodium pump is essentially restricted to the lateral membranes of these cells, and is absent from the basal surfaces that rest on the basement membrane. Dislodging these cells from the underlying basement membrane produces a redistribution of the sodium pump throughout the entire basolateral surface. These results suggest that the sodium pump is either actively or passively prevented from entering the basal domain of the plasma membrane, in some manner that is dependent on an intact interaction with the basement membrane. The meshwork of cytoskeletal elements associated with those sites at which the epithelial cell is anchored to the basement membrane may be too dense to allow membrane proteins such as the sodium pump to penetrate. Conversely, cytoskeletal restraints whose integrity requires cell attachment to the basement membrane might retain the sodium pump within the lateral subdomains. In each of these scenarios, the cytoskeleton plays an important role in determining the subcellular distribution of a transmembrane protein. Research over the years has made it quite clear that the cytoskeleton plays a critical role in defining polarized domains, and in determining aspects of their protein compositions.[110–125]

The Basement Membrane

The basement membrane, while not strictly part of the epithelium, is such an essential contributor to epithelial function that it cannot be excluded from any comprehensive description of the renal epithelium. The basement

membrane is a thin layer of secreted and assembled extracellular matrix that underlies all epithelia and endothelia in the body, and also surrounds skeletal muscle fibers and peripheral nerves.[126] In the past, the terms basement membrane and basal lamina were used inconsistently to describe morphological features of this layer, but there is no longer sufficient reason to distinguish these terms from each other, and they may be used interchangeably.[12] In the kidney, the tubular basement membrane is comparable to that found under other epithelia in the body, while that of the glomerulus is more complex and unusual.[127–129] In the glomerulus, the basement membrane is synthesized from proteins secreted by both podocytes and the closely apposed endothelium, resulting in a double-thick layer of matrix proteins that is an essential part of the glomerular blood filter. Diseases affecting the glomerular basement membrane often lead to compromise of the filter and proteinuria. Detailed discussion of this barrier and its specialized and distinctive composition is beyond the scope of our overall discussion of the biology of the renal epithelium, and will not be pursued in this chapter.

Basement membranes are visible by transmission electron microscopy of glutaraldehyde-fixed and heavy metal stained thin sections of epithelia, and classically appear as an electron dense layer (*lamina densa*) separated from an electron lucid (*lamina lucida*) layer adjacent to the basal epithelial surface.[12] While these morphological features were originally believed to have a structural basis, there is now evidence that they may be fixation artifacts. All basement membranes are composed of a common set of protein components which include laminins, type IV collagen, heparan sulfate proteoglycans, and nidogen, although the specific types of these can vary depending on both developmental stage and tissue, as well as accompanying pathology.[126] The most important component is probably laminin, because of its role in both assembly of the basement membrane and signaling.[130] Laminins consist of large (~400–800 kDa) heterotrimeric secreted glycoproteins. In mammals, five α-, three β-, and three γ-subunits have been identified in at least 15 different heterotrimeric complexes. Prototypical laminins are cross-shaped molecules in which the short arms of the cross are contributed by the amino-termini of each subunit, and the stem by a coiled-coil made up of the carboxy-terminal halves of each subunit.[130] Typically, the amino-termini of each subunit consist of a globular LN or polymer domain that is involved in basement membrane assembly. The carboxy-terminus of the α-subunit is folded into a series of five globular domains (G1–5) that are essential for binding to the cell surface. Laminins are named according to their subunit composition, such that LM-511, the most common laminin in the kidney, is composed of the α5-, β1-, and γ1-subunits.[131] Like all collagens, collagen IV is a trimeric molecule composed of combinations of various type IV α-subunits that fold into an elongated triple helix.[126] In contrast with fibrillar collagens such as collagen I, type IV collagen does not form bundles, because of the persistence of carboxy-terminal noncollagenous domains (NC1) and interruptions in the collagen repeats within the triple-helix forming regions that render the molecule more flexible. The most common types of proteoglycans found in the basement membrane are perlecan and agrin.[126] Each is a complex molecule that contains a variety of structural motifs resembling those found in laminins, in addition to substantial negatively-charged heparan sulfate polysaccharides. Nidogen (also called entactin) is a relatively small basement membrane protein that acts primarily to link laminin and collagen IV in the assembled structure. In addition to the core components of laminin, collagen IV, and proteoglycans, a variety of other minor components may also be present under particular, poorly-defined conditions, including extracellular matrix proteins normally considered to be primarily components of the interstitial matrix, such as fibronectin.

Basement membranes initially form during embryogenesis, and are then remodeled during development.[132,133] In addition, *de novo* basement membrane assembly may occur in adults following injuries that interrupt basement membrane continuity. Assembly is believed to occur through a mass-action process driven primarily by laminin polymerization.[126,130,134] Laminin molecules secreted by epithelial cells bind to receptors on the basal cell surface until the density of bound molecules permits formation of heterotrimeric complexes of α, β, and γ amino-terminal LN domains contributed by three different laminin molecules. The resulting structure is a polymerized network of molecules closely associated with the basal surface. Subsequently, collagen IV intercalates into this primary network to form a secondary network created by head-to-tail interactions between collagen IV molecules. The two networks are then linked through nidogen interactions between laminin and collagen, and other molecules, including notably proteoglycans, fill the spaces within the interlocked laminin and collagen networks.[126,130,134]

During pathological processes such as renal cyst formation and recovery from ischemic injury to the tubular epithelium, there is evidence that the atypical laminin isoform LM-332 is expressed.[135–138] This laminin consists of the α3-, β3-, and γ2-subunits, with both the α3- and γ2-subunits lacking amino-terminal LN domains, precluding the molecule from participating in typical network formation. The specific function of LM-332 in these pathological situations is unknown, but one hypothesis is that it interacts with prototypical laminins, such as LM-511, to terminate or even disrupt normal basement membrane assembly, facilitating remodeling of the basement membrane, and possibly

signaling the epithelium to differentiate into a more plastic state suitable for injury repair.[139]

The basement membrane interacts with epithelial cells primarily by binding to the integrin family of extracellular matrix receptors. Integrins are a superfamily of cell adhesion receptors found in nearly all cells.[140] Each integrin consists of a heterodimer of α- and β-subunits, both of which are transmembrane glycoproteins. A total of 18 α- and 8 β-subunits are known in mammals, resulting in at least 24 heterodimers.[140] Although integrins are known primarily as receptors for extracellular matrix proteins, they may also participate in cell−cell adhesion.[141] Epithelial cells of the kidney and other organs typically express an array of integrins, including multiple forms with the β1-subunit, such as α2β1 and α3β1, as well as integrins with the β3-, β5-, and β6-subunits in combination with αV[142] (A. Manninen, personal communication). Many, if not all, epithelial cells also express integrin α6β4.[140,142] The β4-subunit is uniquely found in epithelial cells and, unlike most other epithelial integrins, interacts on the cytoplasmic side with cytokeratins, rather than the actin cytoskeleton. Integrin α2β1 is a collagen receptor, while α3β1 and α6β4 are receptors for multiple isoforms of laminin.[140] The various αV-containing integrins are receptors for ligands containing the binding sequence arginine−glycine−aspartate (RGD), such as fibronectin and vitronectin.[140] They may also play a role in activation of transforming growth factor β (TGFβ), which is important in epithelial repair and other processes.[143] The MDCK cell line, for example, expresses α2β1, α3β1, α6β4, and several αV-containing integrins, with α3β1 and α6β4 mediating adhesion to different laminins, and with αVβ3 (and possibly other αV integrins) activating TGFβ to turn on specific laminin expression during wound-healing.[143,144] In the kidney tubule, the complement of integrins expressed varies along the nephron, as does the expression of their extracellular matrix ligands, underlining their involvement not only in cell adhesion, but also in differentiation.[142]

In adherent cells, most integrins facilitate adhesion through dynamic interactions with the actin cytoskeleton.[145−148] Linkage to actin is mediated by adapter protein complexes that bind to integrin cytoplasmic tails and then to actin. Proteins found in these complexes include talin, which binds directly to integrins and activates their adhesive properties, paxillin, α-actinin, and vinculin.[145−148] Studies of migrating cells suggest that initial adhesive interactions occur through small "focal complexes" that form on leading lamellipodia and are linked to branched actin through the action of the Rac1, a small GTPase of the rho family. As the cell moves over these contacts, they mature into larger "focal adhesions" that associate with robust actin stress fibers (at least in culture) controlled by another GTPase RhoA and its effectors.[145−149] While the general elements of this model have been somewhat validated in epithelial cells during wound healing, the status of focal complexes and focal adhesions in mature polarized epithelia of the kidney and elsewhere remain, for the most part, unexplored. As mentioned previously, α6β4 is a novel integrin, in that it is epithelial-specific and is capable of assembling adhesion complexes that interact with the cytokeratin cytoskeleton.[140] In normal skin, α6β4 is an essential part of hemidesmosomes.[150] These are large protein complexes containing a second transmembrane protein BP180 in addition to α6β4, as well as the cytoplasmic proteins BP230 and plectin that interact with cytokeratin filaments. The type of hemidesmosome found in the skin (type I) is visible as a dense plaque on the cytoplasmic surface of the basal plasma membrane under the electron microscope.[151] In the kidney such structures have not been reported. However, it is possible that a less developed type of hemidesmosome that is not apparent ultrastructurally (type II) is present in the kidney, although this has not been examined.[151]

In addition to their role in mechanical adhesion, focal complexes and focal adhesions are also platforms for signaling.[145−149] A variety of kinases including, notably, focal adhesion kinase (FAK) and members of the src family of tyrosine kinases, associate with integrin adhesion complexes and are activated by binding to the extracellular matrix. Subsequent signals then activate downstream serine/threonine kinases, such as integrin-linked kinase (ILK), and MAP kinases, such as ERK, to regulate a diverse range of processes including proliferation, migration, and apoptosis. Indeed, at least 180 different cytoskeletal, adapter, and signaling proteins are known to be associated with integrin adhesion complexes, depending on the cell type and circumstances.[149]

In addition to integrins, other membrane proteins are involved in epithelial cell adhesion to the extracellular matrix, including dystroglycan, a laminin receptor, and possibly a membrane-bound form of the Lutheran antigen.[129,130] There is evidence that glycolipids may also serve as transient laminin receptors.[152,153] While it is not proven that any of these receptors play a direct role in epithelial polarization, they may act indirectly by affecting assembly of the basal lamina.[152,153]

BIOGENESIS OF EPITHELIAL POLARITY

In the kidney, polarization of epithelial cells occur under two different circumstances: early development of the tubular epithelium; and repair of an existing epithelium following injury. In mammals, formation of the renal tubular epithelium is initiated by induction of the metanephric mesenchyme by the invading ureteric bud.[154] Following induction, cells of the mesenchyme

form aggregates known as condensates, and these subsequently differentiate into polarized epithelial cells facing a central lumen. Extension of this lumen and further, more specialized, differentiation of epithelial cells eventually forms the nephron. In the case of injury by, for example, nephrotoxic substances or ischemia, the existing polarized tubular epithelium is disrupted in spots.[155,156] Cells at the periphery of these damaged areas then convert from relatively sessile cells polarized along an apical-to-basal axis to flatter, more migratory cells that now have front–rear rather than apical–basal polarity and the capacity to proliferate, enabling them to fill gaps in the epithelium. Once continuity has been achieved, apical–basal polarity is restored.[155,156] While front–rear and apical–basal polarization would seem to be quite distinctive, there is evidence that many of the important molecules and signals are shared. Indeed, as we are now beginning to understand, even front–rear polarization during injury repair is a close mechanistic cousin of apical–basal polarization.[157]

In the following sections, our current understanding of the mechanism of epithelial polarization will be described, after a brief introduction to the predominant experimental system used to study these processes.

In Vitro Systems

The kidney's complicated architecture and cellular heterogeneity renders it a poor substrate for studies designed to examine dynamic cell biological processes. Over the past four decades, the vast majority of research into the mechanisms through which epithelia generate and maintain their polarized phenotype has made use of several continuous lines of cultured epithelial cells. These cell lines retain many of the differentiated properties of their respective parent tissues *in vitro*. Thus, LLC-PK1 cells resemble the proximal tubule (although their precise origin is uncertain).[158] Similarly, Caco-2, HT-29, and T84 cells behave like their progenitors, the colonocytes of the large intestine.[158] Most importantly for this discussion, they manifest in culture the biochemical and morphologic features of the polarized state. Perhaps the best characterized and most heavily used of these culture models is the Madin–Darby canine kidney (MDCK) cell line (Figure 1.3). MDCK cells were originally derived from normal dog kidney in 1959, and grown in culture as a partially transformed line; that is, MDCK cells grow immortally as a monolayer and will not form tumors in nude mice.[159,160] Although their precise point of origin along the nephron is not entirely clear, their physiological and morphological properties suggest that they derive from cells of the thick ascending limb, distal tubule or collecting tubule.[161]

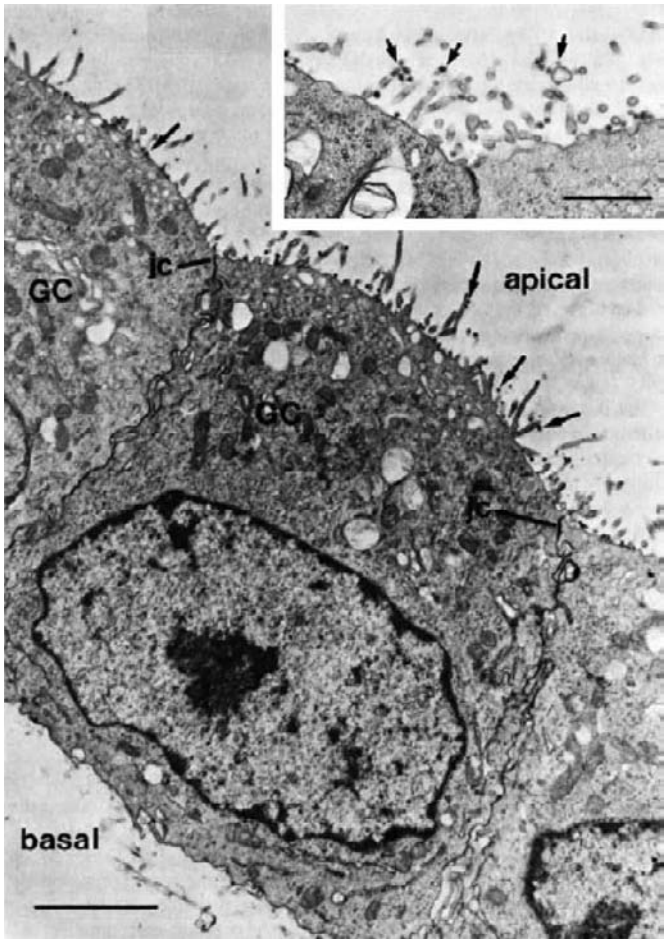

FIGURE 1.3 **Influenza virus buds from the apical surface of polarized MDCK cells.** MDCK cells were grown on a hydrated collagen gel, infected with influenza virus for 6 hours, and prepared for electron microscopy. The arrows denote mature virions which assemble at, and bud from, the apical surface. No virus particles are detected at the basal or lateral surfaces. Bar represents 3.0 μm (inset bar represents 1.0 μm) (GC: Golgi complex; jc: junctional complex). *(Reprinted with permission ref. [1].)*

The first clues to the polarized nature of the MDCK cell line came from the direct observation of these cells' capacity for vectorial transport. When grown on impermeable substrata, MDCK cells form domes (also called blisters or hemicysts).[162] Physiological studies have demonstrated that domes develop as a result of the transepithelial transport of solutes from the apical media to the basolateral surface.[163] Water that passively follows these solutes results in the generation of the fluid-filled blisters. It is fair to say that domes arise in regions where the cells have literally pumped themselves up off the dish. In keeping with this dramatic propensity for unidirectional solute movement, each MDCK cell manifests a polarized distribution of ion transport proteins, including several routes for sodium entry into its apical membrane, and approximately one million molecules of the

Na^+/K^+-ATPase in its basolateral plasmalemma.[164] The popularity of MDCK cells for polarity research developed out of the seminal observations of Rodriguez-Boulan and Sabatini in 1978.[165] In studies of enveloped virus budding from infected MDCK cells, these investigators found that influenza virus assembles at, and buds from, the apical cell surface (Figure 1.3). Of even greater significance was the demonstration that the spike glycoproteins which populate the membranes of these viruses accumulate preferentially at the cell surface from which budding is to occur.[166] Thus, the influenza hemagglutinin (HA) protein is predominantly on the apical surface early in infection. Similarly, the G protein of vesicular stomatitis virus (VSV) is almost exclusively basolateral in infected cells. The viral proteins provided investigators with the first experimentally manipulatable system for the study of membrane protein sorting. A large number of studies have subsequently elucidated the sorting of many endogenous MDCK cell proteins, as well as exogenous proteins expressed from vectors. This system remains the most thoroughly investigated paradigm and, as will be detailed below, has yielded important insights into the nature of pathways and signals that participate in membrane protein targeting and the overall biogenesis of epithelial polarity.

More recently, investigators have endeavored to develop new cell lines to study particular aspects of renal cell biology.[167–170] For example, immortalization genes from human papillomavirus or a hybrid between adenovirus and SV40 have been used to create permanent cell lines from human proximal tubule cells. These lines are of particular interest because of the proclivity of the proximal tubule to suffer injury following ischemic insult. The cell lines retain some differentiated characteristics of the proximal tubule, including expression of brush border markers and sodium dependent/phlorizin-sensitive sugar transport.[169,170] Cultures of cell lines derived in this fashion are not, however, always able to stably maintain the uniform morphology of a simple epithelium, limiting their usefulness for studies of epithelial polarity. More promising results have been obtained using cell lines derived from mice constitutively expressing immortalization factors as transgenes. Among these is the BUMPT-306 line derived from the mouse proximal tubule.[167,168] While certainly not perfect, this line does grow as a simple epithelium, and has the added advantage of providing an *in vitro* correlate to *in vivo* mouse experiments.

The study of epithelial polarization using cell lines has been facilitated by culturing cells in configurations that more closely resemble *in vivo* conditions (Figure 1.4 and 1.5). For example, many varieties of epithelial cells can be grown on permeable filter supports.[171,172] Originally, these were designed to mimic the Ussing chamber used for physiological studies, but later turned out to also be very useful for biochemical and morphological experiments. In their most common commercially-available configuration, these supports are composed of polycarbonate filters with pore sizes typically in the range of 0.4 μm that form the bottom cup. The cup is then suspended in a plastic well containing culture medium, and medium is also added to the inner compartment of the cup (Figure 1.4). Cells are plated on the upper surface of the filter. When a confluent monolayer is formed, it effectively creates a barrier between media compartments. The medium in the interior of the cup bathes the epithelial apical surface, whereas the basolateral surface communicates with the exterior media compartment through the pores of the filter (Figure 1.4). As epithelial cells in the kidney and other organs would normally receive most of their nutrition from the basolateral (serosal) surface, permeable supports are, in a sense, a more natural growth environment than impermeable tissue culture plastic or glass. Indeed, there is some evidence that epithelial cells are more polarized in filter cultures than on solid substrata.[173] Furthermore, the use of filters for the culture of epithelial cells permits investigators simultaneous and independent access to the apical and basolateral plasmalemma surfaces.[174–176] This useful capacity has been extensively exploited in the experiments described in the protein sorting section of this chapter.

In addition to permeable supports, a number of investigators also culture renal and other epithelial cell lines embedded in a gel of collagen type I or other

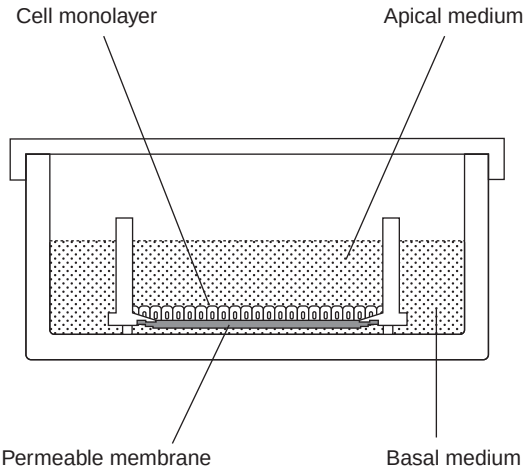

FIGURE 1.4 **Epithelial monolayers can be grown on permeable filter supports.** As depicted in the diagram, a porous filter, composed of cellulose actetate or polycarbonate, forms the bottom of a cylindrical cup. Epithelial cells are plated on top of the filter, and the cup is placed in a well filled with media. When the cells become confluent, the resultant monolayer forms a barrier between the media bathing the apical surface and the media in communication with the basolateral surface. This system thus provides investigators with simultaneous and independent access to both plasmalemmal domains.

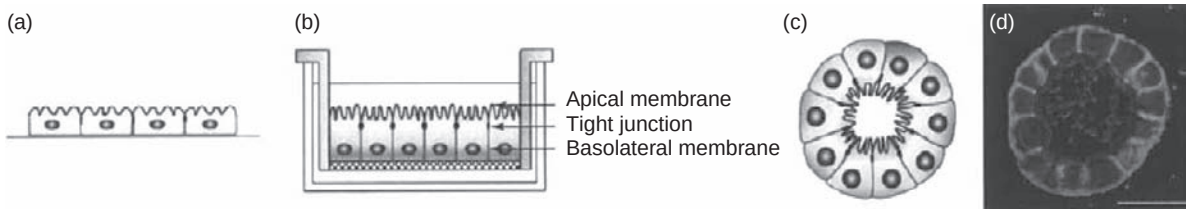

FIGURE 1.5 **Two- and three-dimensional cultures of polarized epithelial cells.** Epithelial cell lines may be grown on conventional impermeable substrata such as plastic or glass (a), or on permeable supports (b). In both cases, the provision of a flat, two-dimensional surface may provide spatial signals that normally would be generated by the cells themselves *in vivo*. In this regard, three-dimensional culture of cells in collagen gels, where a polarized cyst develops over 7 to 10 days (c), may more accurately represent the *in vivo* environment. In (d), an MDCK cell cyst is fluorescently labeled with antibodies to β-catenin to highlight the basolateral surface. *Reprinted with permission from ref. [178].)*

extracellular matrix molecules (Figure 1.5). These are called three-dimensional (3D) cultures, to distinguish them from more common two-dimensional (2D) cultures on either solid or permeable surfaces.[177,178] As with permeable supports, the idea behind 3D cultures is that placing the epithelial cell in an environment in which it is surrounded by extracellular matrix similar to that of the interstitium more closely resembles the *in vivo* environment. While that conclusion is subject to debate, there is no doubt that certain epithelial phenotypes are more readily expressed in 3D than in 2D cultures.[177,178] Nevertheless, these phenotypes are often slow to develop, frequently taking 7–10 days, and may occur asynchronously; this, and the inaccessibility of the cultures, somewhat limits their usefulness for biochemical studies. With the advent of high resolution confocal fluorescence microscopy and the wide array of fluorescent proteins and probes, the impact of this limitation is lessened. In the case of MDCK cells, individual suspended cells develop into polarized cysts or, when stimulated with certain growth factors, tubules. As will be described below, use of 3D cultures has led to important fundamental observations about epithelial cell polarization.[177,178] As a final note on the experimental use of 2D and 3D culture modalities, it is important to point out that formation of polarized cysts in 3D may be most closely analogous to the formation of the primordial kidney epithelium from condensed metanephric mesenchyme during development. In contrast, *in vitro* polarization of kidney epithelial cells in 2D cultures is more akin to the repair of existing kidney tubular epithelia following injury, a scenario that requires the spreading, migration, and proliferation of cells on a pre-existing surface to re-establish a contiguous epithelium.

Polarization Mechanisms: Spatial Cues from Cell Adhesion

It is now understood that not only epithelial cells but, indeed, all cell types are capable of polarizing in response to signals from the environment.[3,4,154,157,179,180] Migrating cells of all types, for example, are polarized in the direction of migration in response to chemotactic or haptotactic gradients and even dividing cells can polarize through unequal division of their cytoplasm upon cytokinesis.[157,181] Epithelial cells are unique, in that their polar organization is stable over time and the apical–basal axis of polarity exhibited by each cell in the epithelium is parallel to the axes of its neighbors. These features permit epithelial cells to form an asymmetrically organized, semipermeable surface that defines the borders of tissues in complex organisms, and separates the inside of the body from the outside environment, while helping to create and maintain distinctly different milieus on each side.[182] The mechanism of epithelial cell polarization depends on specific spatial cues that cause the assembly and asymmetric reorganization of the intrinsic polarization machinery. The spatial cues are adhesive interactions between neighboring cells and the extracellular matrix, while the intrinsic machinery consists of primarily three polarity complexes called Par, Scribble, and Crumbs.[157,182] If the pattern of cell adhesion is asymmetric, then the response of the cell is asymmetric, and a polar phenotype results (Figure 1.6). This section will describe the specific nature of the cell–cell and cell–extracellular matrix adhesive interactions. The mechanisms by which adhesion is translated by the intrinsic polarization machinery into a polarized epithelial cell with distinct apical and basolateral plasma membrane domains will be presented in subsequent sections.

As mentioned previously, polarization of kidney epithelial cells occurs during initial differentiation of the primordial tubular epithelium from condensed mesenchyme, and after disruption of an existing mature epithelium following injury. These two situations are somewhat mimicked *in vitro* by, respectively, 3D culture and 2D culture of renal epithelial cell lines. It is important to recognize that the pattern of spatial cues provided by adhesive interactions is different in these two situations. In the developing kidney epithelium, cell–cell interactions in the condensed

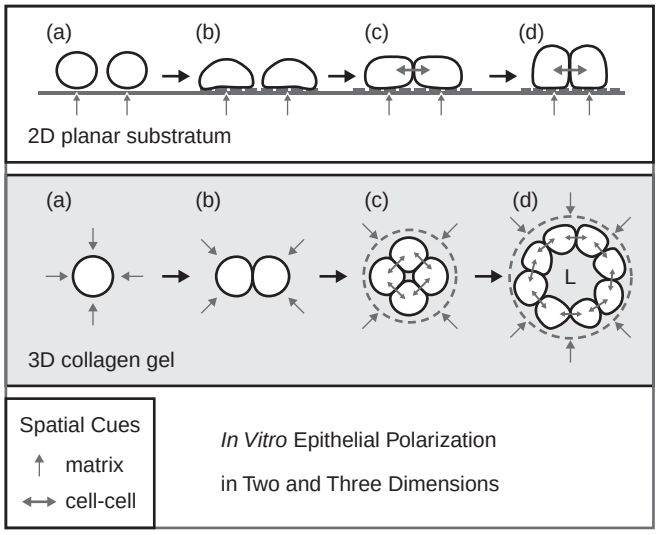

FIGURE 1.6 **Geometry of spatial cues in two-dimensional and three-dimensional culture of epithelial cells.** In two-dimensional culture (top) an asymmetric spatial cue is given by substratum adhesion as soon as contact occurs between the cell and the culture surface. A second spatial cue orthogonal to the first occurs when cell–cell contacts are initiated. In three-dimensional culture (bottom), the initial spatial cue impinging on single cells suspended in the collagen gel is isotropic. As soon as cell division takes place, an asymmetry is set up in which both the spatial cue from the collagen (and other secreted extracellular matrix proteins) and from cell–cell adhesion are asymmetric. The combination of asymmetric cues is required for full apical–basal polarization of epithelial cells.

mesenchyme are believed to precede meaningful cell matrix interactions[154] (Figure 1.7). These condensates are spatially differentiated: cells at the peripheries of the condensates have both a "free" plasma membrane domain facing the outside of the condensates and the undifferentiated mesenchyme, and an "attached" plasma membrane domain in contact with other cells of the condensate. Following this rudimentary polarization, the adherent mesenchymal cells in the condensate become more polarized, eventually forming a lumen and reorganizing into a simple epithelium attached to a basement membrane.[154,183] Similarly, in 3D collagen gel cultures of MDCK cells, individual cells are initially suspended in the gel. Spatial cues from collagen adhesion at this point are isotrophic rather than asymmetric, in that any signals impinging on the cell are unbiased with regard to direction (Figure 1.6). As soon as that cell divides, an asymmetric spatial cue is elicited from the resulting cell–cell adhesion, because the cells remain attached. This situation persists through subsequent divisions until at some point a basement membrane is formed, and the individual cells create a lumen.[178] In contrast, in a wounded epithelium and in 2D culture of epithelial cell lines, the persistent spatial cue from the extracellular matrix substratum is asymmetric, and then an additional although qualitatively different asymmetric spatial cue develops as cell–cell adhesion is restored[139,157] (Figure 1.6). The take-home message from this discussion is that epithelial cells utilize both cell–cell and cell–extracellular matrix interactions as asymmetric spatial cues to polarize. The order in which these cues are provided to the cell may yield qualitatively different results but, in the end, both are required for full apical–basal polarization.

The hierachical relationship between cell–cell and cell–substratum interactions in epithelial cell polarization is illustrated best by a description of early experiments utilizing the MDCK cell line. MDCK cells cultured in suspension as individual cells lack polarized plasma membrane domains.[118,184] Upon attachment to a substratum in 2D culture, apical proteins are restricted to the free or apical surface, while basolateral proteins are distributed over the entire plasma membrane. This situation persists as the cell density increases and initial cell–cell contacts form until, as the cells reach confluency to form a true epithelium, basolateral proteins also become completely polarized.[118,185]

The relative roles of cell–cell and cell–substratum interactions can also be dissected by culturing MDCK cells in medium containing reduced amounts of calcium.[120,186,187] If cells are cultured on collagen-coated surfaces in medium with less than 5 μM calcium, they attach to the substratum but formation of cell–cell contacts mediated by the calcium-dependent adhesion protein E-cadherin is inhibited.[120,186,187] Cells assume a rounded morphology with no appreciable lateral membrane. In this situation, an immature apical surface forms. Microvilli are decreased in number, and expression of apical proteins on the cell surface, although reduced in quantity, remains polarized to the free surface.[186] Basolateral proteins, in contrast, are not polarized in cells cultured in medium containing low calcium concentrations. However, when the calcium concentration is raised to normal values (1.8 mM), then cell–cell contacts rapidly form and basolateral proteins polarize.[186]

The culturing of MDCK cells as multicellular aggregates in suspension also permits the relative effects of cell–cell and cell–substratum interactions to be independently evaluated. Under these conditions, which are different from the 3D culture described previously because the cells are surrounded only by culture medium, aggregated cells gradually form cysts with small central lumina.[184] In the absence of recognizable cell–substratum contact, both apical and basolateral polarization occurs, with the apical surface facing the outside of the cell aggregate. At this time, the tight junctional protein ZO-1 is found distributed over the entire lateral membrane, where cell–cell contacts occur. As the lumen forms, the cells secrete and deposit type IV collagen and laminin into the lumen.[184] Interaction with

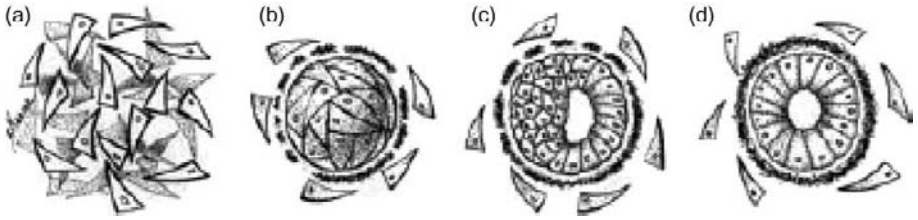

FIGURE 1.7 **Development of the kidney epithelium from induced mesenchyme.** The kidney epithelium develops *in vivo* following induction of the metanephric mesenchyme by the ureteric bud. The initial stages of differentiation from mesenchymal to epithelial cells may also be followed *in vitro* by organ culture. In this schematic view, induced mesenchymal cells are initially randomly oriented and show little cell–cell adhesion (a); Some mesenchymal cells adhere closely to each other and begin to produce a basement membrane at the periphery of the condensate (b); The cells of the condensate begin to reorganize into an epithelium and form a lumen as the basement membrane becomes more extensive (c); Finally, formation of the pretubular renal vesicle consisting of a polarized epithelium is complete, (d). *Redrawn with permission from ref. [154].*

this interior extracellular matrix then triggers redistribution of ZO-1 to the point of intersection between the apical and lateral membrane.[184] Thus, as in the reduced calcium experiments, cell–cell and cell–substratum interactions have somewhat independent but complementary effects on cell polarization.

The adherens junction provides the spatial cue from cell–cell interactions leading to polarization of epithelial cells. One of the most important components of the adherens junction is E-cadherin, the calcium-dependent homophilic cell adhesion molecule discussed previously. Suppression of E-cadherin expression by small-interfering RNAs prevents polarization, clearly implicating it in the polarization process.[188] However, other cell–cell adhesion proteins such as nectins and JAMs may be important as well. Nectins are transmembrane adhesion molecules containing immunoglobulin-like extracellular domains.[189] When epithelial cells transition from a migratory phenotype, as they exhibit during wound healing, nectins may be one of the earliest molecules in nascent cell–cell adhesions. Homophylic interaction of nectins between neighboring cells activates a variety of signaling pathways, among which are those involving the small GTPases Cdc42 and Rac1.[189,190] This, in turn, leads to reorganization of the cortical actin cytoskeleton and, consequently, facilitates the formation and stabilization of E-cadherin-mediated contacts, creating the mature adherens junction.[189] During this process, both nectins and JAMs may initiate the asymmetric activation of the intrinsic polarization machinery. Nectins and JAMs bind Par3, an element of the Par polarization complex (see below).[189,191,192] As the adherens junction matures, other polarization complexes bind and specification of the apical and basolateral plasma membrane domains occurs, with the dividing line located just at the adherens and tight junctions, collectively referred to as the apical junctional complex. At the same time, a complex of proteins known as the exocyst is also assembled at this location.[157,191,192] The exocyst is a kind of tethering complex designed to capture transport vesicles carrying newly synthesized membrane proteins. Delivery of these proteins to this region of the plasma membrane then facilitates the development of the apical and basolateral surfaces.[193,194]

It is likely that the spatial cue emanating from cell–substratum adhesive interactions originates from integrin-mediated cell interactions with the basement membrane protein laminin. In the developing kidney, conversion of condensed mesenchyme into a polarized epithelium is dependent on laminin.[154,195,196] The laminin α1-subunit and integrin $\alpha 6\beta 1$, a laminin receptor, are first detected in the induced mesenchyme following condensation.[129,154,195,196] Laminin localizes to the periphery of the condensate, suggesting that the crude polarization caused by condensation leads to polarized laminin secretion to the periphery. In organ culture antibodies against laminin α1 or the integrin α6-subunit block formation of a polarized epithelium from condensed mesenchyme, suggesting that their involvement in epithelial differentiation is critical.[154,196,197]

Results from a variety of other experimental systems generally support the conclusion that laminins and their integrin receptors play a role in epithelial polarization. Mutations in either integrin or laminin subunits lead to disruption of epithelial differentiation and polarization in the nematode *Caenorhabditis elegans*, and the fruit fly *Drosophila melanogaster*.[132] Expression of laminin in the early mouse embyro generally coincides with development of epithelial tissues. In embryoid bodies derived from cultures of aggregated embryonic stem (ES) cells, an LM-111 containing basement membrane forms between the endoderm and the polarizing inner cell mass cells. When ES cells deleted of both laminin γ1 alleles are aggregated into embryoid bodies, the inner cell mass forms, but does not polarize.[132] Laminin has also been implicated in the polarization of MDCK cells. When MDCK cells are cultured in 3D collagen gels for 7–10 days, they form polarized cysts with the apical surface facing the

lumen, and the basal surface facing the extracellular matrix. Under these conditions, the cells secrete LM-511 and form a discrete layer closely associated with the basal surface, resembling an assembled basement membrane.[198,199] When MDCK cells are treated either with a function-blocking anti-β1 integrin antibody or express dominant-negative Rac1 during cyst formation, the laminin layer does not form properly, although laminin is secreted, and the cells display an inverted and somewhat disorganized polarity with apical antigens expressed on surfaces facing the extracellular matrix.[198,199] Addition of excess exogenous LM-111 to the collagen gel partially rescues both basement membrane assembly and correct polarization in cells expressing dominant-negative Rac1, possibly by driving laminin assembly adjacent to the basal plasma membrane.[198,199] Inverted polarization of the cyst caused by anti-β1 integrin can also be rescued by expression of constitutively-active Rac1.[198,199] These experiments suggest that a "serpentine" signaling pathway exists, leading from ligation of a β1 integrin outside the cell, to Rac1 activation inside the cell, to laminin assembly outside the cell, and finally to polarization. It is important to emphasize that the perturbations that lead to inverted polarity do not seem to affect the segregation of apical and basolateral proteins in individual cells, but instead affect the orientation of apical–basal axes in the cyst. It is unclear how intracellular signaling events can cause laminin assembly. Recent findings have implicated the polarization signaling molecule Par1b and dystroglycan, a non-integrin laminin receptor, in effecting laminin assembly, but the mechanisms are not apparent.[200,201]

Polarization Mechanisms: The Intrinsic Polarization Machinery

In epithelial cells, the intrinsic polarization machinery has traditionally been separated into three so-called polarity protein complexes that function collectively to control the formation of apical and basolateral domains of the plasma membrane.[191,192] Many of the components of the polarity complexes were initially identified in mutant screens in *Caenorhabditis elegans* and *Drosophila melanogaster*, but homologs that function in an essentially identical manner have also been identified in mammals. The first, and perhaps most important, polarity complex generally associated with apical surface determination is the Par complex composed of Par3, Par6, atypical protein kinase C (aPKC), and the small-GTPase Cdc42 (Figure 1.8). A second apical complex is the Crumbs complex, containing in mammals the transmembrane protein Crumbs (Crb3 in the kidney) associated with Lin-7 (PALS1), and PALS1-associated tight junction protein (PATJ). The final complex, which is located on the lateral surface in polarized epithelia, is the Scribble complex composed of Scribble (SCRIB), discs large (Dlg), and lethal giant larvae (Lgl).[191,192] In the case of the Par and Crumbs complex, physical interactions between the components have been demonstrated, while interactions of Scribble complex components have been implied by genetic experiments. In addition to these polarity complexes, other proteins are involved in regulating apical–basal polarization in mammals or lower organisms including, in particular, Par1b and LKB1 (Par4). In the core polarity protein complexes, only aPKC and Cdc42 have enzymatic activities: the former a serine/threonine kinase; and the latter a GTPase-mediated molecular switch, while the others are largely scaffolds with a myriad of binding domains, including on many PDZ domains, that facilitate association with the apical junctional complex of the polarized cell.[191,192]

The mechanisms by which these complexes function to help establish and maintain apical–basal polarity is often described as a process of mutual antagonism or inhibition that creates and maintains a particular balance between the amounts of distinct apical and basolateral plasma membranes, with the "front line" of this battle being the apical junctional complex[191,192] (Figure 1.8). While the concept of mutual antagonism is not inaccurate, how this translates into intuitively comprehensible mechanisms has, until recently, not been obvious. Studies in *Drosophila* have highlighted the critical role of Par3 (Bazooka or Baz in *Drosophila*) and have, to some extent, called into question the idea of distinct, somewhat independently functioning polarization protein complexes.[191] A compelling model proposes that initiation of polarization commences when Par3 (Baz) associates with the region of cell–cell adhesion that will become the adherens junction, prior to the concentration of DE-cadherin (the *Drosophila* version of E-cadherin) in that location. Association is facilitated by phosphoinositides. Once the adherens junction forms, then Par3 binds Par6 and aPKC, and Cdc42 is activated. Activation of aPKC then leads to phosphorylation of Par3, as well as Crb and Lgl, following the delivery of Crb to the plasma membrane through vesicles. The phosphorylation of Par3 on serine 980 by aPKC weakens the interaction between Par3 and aPKC, as well as the interaction between Par3 and the Crb complex protein PALS1 (Lin-7, Stardust or Sdt in *Drosophila*). These changes permit formation of the apical complex Crb–PALS1–PATJ, while interactions between Crb and Par6 prevent association of Par3 with the forming apical surface. At the same time, Par1-mediated phosphorylation of Par3 creates binding sites for the scaffold 14-3-3, and the subsequent Par3-14-3-3 interaction further inhibits the association of Par3 with Par6/aPKC. Since Par1 is localized to the lateral surface, this prevents Par3 from assembling on the lateral surface.

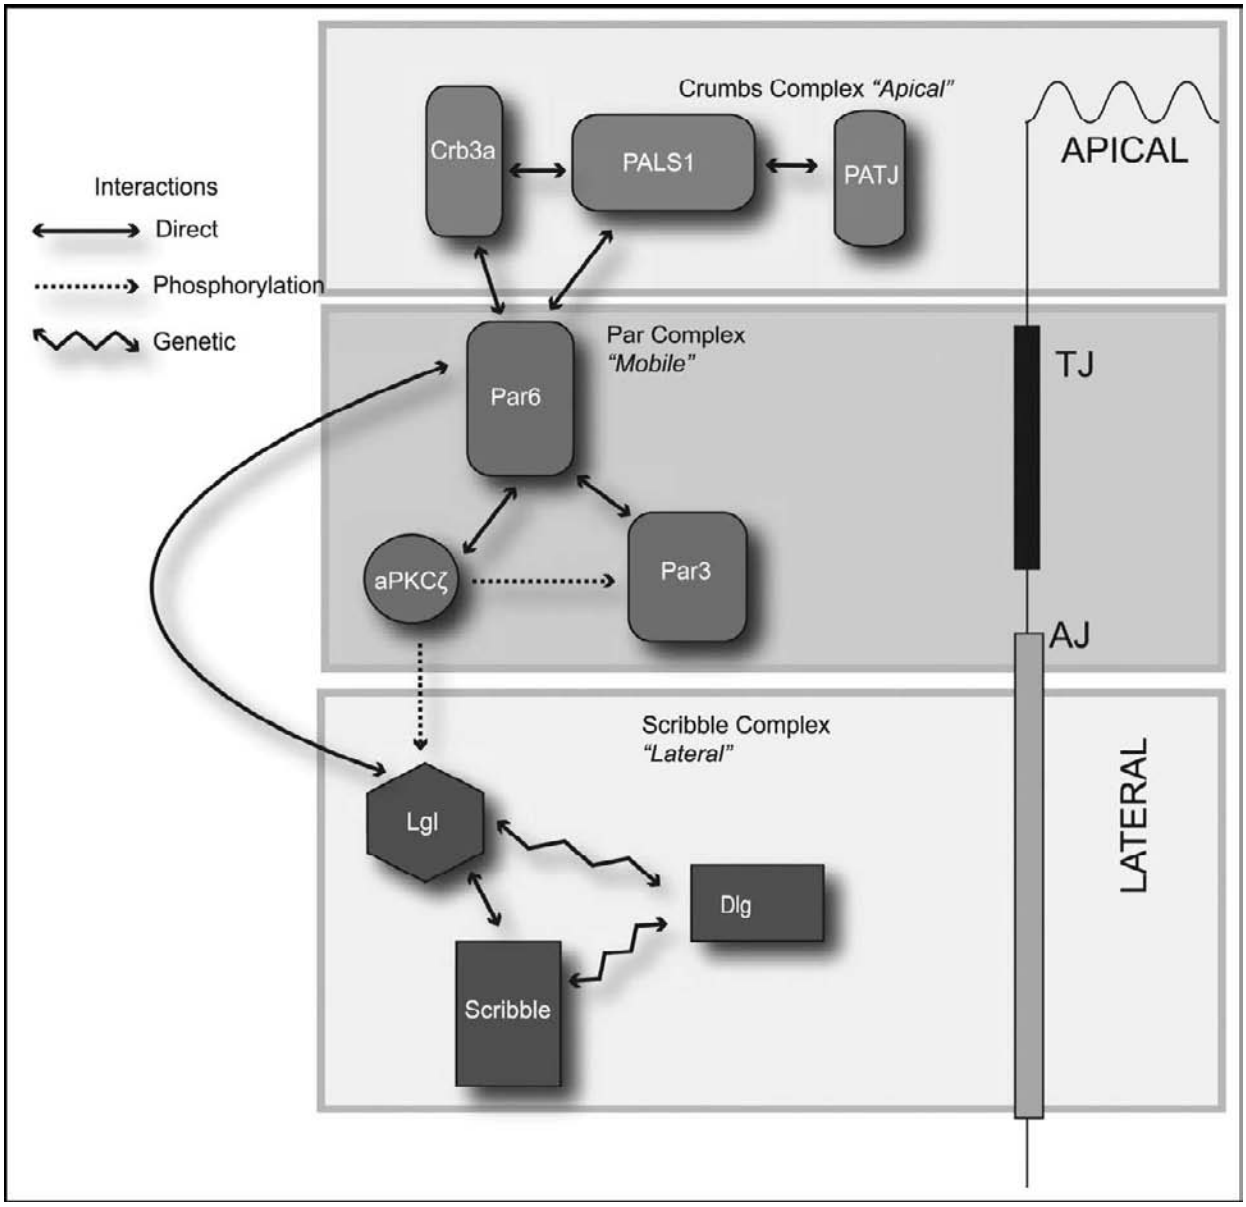

FIGURE 1.8 **Distribution of polarity complexes in polarized epithelial cells.** Solid lines indicate demonstrated physical interactions between components, while jagged lines indicate genetic interactions established from studies of invertebrate epithelial cells. *(Reprinted with permission from Laprise, J. and Margolis, B. (2011). AJP Renal Physiology **300**, F589–F601.)*

Lgl is also phosphorylated by aPKC, which prevents its apical localization.[191] With Dlg and Scrib, it then contributes to maintaining the identity of the lateral membrane in a manner that is poorly understood.

In all likelihood this scenario, derived primarily from experiments on *Drosophila*, is also valid in renal epithelial cells. Studies in MDCK cells, in particular, have illuminated a number of steps and, in some instances, provided additional critical details. As mentioned previously, nascent cell–cell contacts may be initiated by nectins and JAMs prior to the coalescence, stabilization, and assembly of the adherens junction nucleated by E-cadherin and its associated proteins.[189,191,192] Nectins and JAM, which bind Par3, may serve to localize Par3 to the forming junction. In addition to its roles in facilitating the assembly of the other polarization complexes as described earlier, Par3 binds phosphoinositides in the membrane, as well as the phosphoinositide phosphatase PTEN (phosphatase and tensin homolog).[191,192] This phosphatase converts phosphatidylinositol (3,4,5)P_3 (PIP3) on the inner leaflet of the membrane to phosphatidylinositol (4,5)P_2 (PIP2). The latter lipid then facilitates the development of the apical surface by binding annexin2, which then

recruits Cdc42, leading to the cascade of events involving aPKC described earlier.[202] The importance of the conversion of PIP3 to PIP2 in the formation of the apical surface was highlighted dramatically when exogenous PIP2 was added to the basolateral pole of mature MDCK cell cysts in 3D culture.[202] Incorporation of PIP2 into the basolateral plasma membrane led to gradual extension of the apical surface to the basal pole with collapse of the lumen.

The description of the polarization process so far has focused only on events initiated by cell–cell adhesion. However, as was described in the previous section, adhesion of epithelial cells to the basement membrane is also a key part of polarization, functioning particularly to orient the apical–basal axis in a coordinated fashion in neighboring cells. How basement membrane adhesion and, particularly, adhesion to laminin does this is not clear, but it likely involves the microtubule cytoskeleton (Figure 1.2). In individual MDCK cells adherent to a substratum in 2D culture, the organization of microtubules resembles that in other nonepithelial adherent cells, in that microtubule growth is initiated from a juxtanuclear centrosome or microtubular organizing center, and extends radially towards the cell surface.[203–205] Once cell–cell adhesion is initiated, the microtubule organizing activity begins to disperse to the cell periphery and, as the cell polarizes, it relocalizes diffusely to the apical surface.[203–205] In response to this, microtubules reassemble along the apical–basal axis with the plus (growing) ends pointing basally. Networks of microtubules also form roughly parallel to the basal and apical surfaces[203–205] (Figure 1.2). Reorganization of the microtubules depends on a family of GTPases known as septins, which provide directionality to the process,[206,207] while stabilization and anchoring depend on the plekstrin homology-like domain family A protein LL5, microtubule plus-end tracking proteins, and the APC (adenomatous polyposis coli) tumor suppressor.[208–211] LL5 anchors microtubule plus ends to the basal plasma membrane by associating with integrin-mediated cell adhesions to laminin.[208] Furthermore, the polarity protein Par1b, which has been implicated in assembly of the laminin network in the basement membrane, is also important in the formation of the apical surface in 3D cysts, reportedly through a mechanism that depends on signaling from the extracellular matrix.[212] Thus, there appears to be a signaling network linking laminin assembly and microtubule reorganization to formation of the apical surface in the correct location. How these microtubules mechanistically contribute to polarization is not clear, but it is known that they provide tracks for vesicle transport that are necessary for formation of the apical lumen through its population with specific proteins, a process facilitated by septins.[121,122,125]

Ultimately, cooperation of extrinsic spatial cues and the intrinsic polarization machinery creates a polarized cellular infrastructure composed of adhesive interactions, a spatially-differentiated cytoskeleton, and asymmetrically disposed signaling complexes. Completion of polarization, and its maintenance during cell and tissue function, then depends on the targeting of specific membrane proteins to the apical and basolateral plasma membrane domains. How this is accomplished is the subject of the following section.

Sorting Pathways

One of the first, and perhaps most easily addressed, questions presented by the phenomenon of epithelial polarity relates to where, within the cell, sorting occurs. The membrane proteins that populate the apical and basolateral plasmalemmal domains are all synthesized in association with the membranous elements of the rough endoplasmic reticulum (RER).[213] It has further been shown that after their co-translational insertion into the membranes of the RER, apically- and basolaterally-directed proteins share the same cisternae of the Golgi complex as they transit the secretory pathway en route to their respective sites of ultimate functional residence.[214,215] Immunoelectron microscopic studies performed on MDCK cells doubly infected with the VSV and influenza viruses revealed, through double labeling, that the influenza HA protein and the VSV G protein could be co-localized throughout the cisternae of the Golgi complex.[215]

This observation was confirmed and extended through a series of elegant biochemical studies. It had previously been shown that when cells are incubated at 20°C newly synthesized membrane proteins accumulate in the trans-most cisterna of the Golgi complex.[216,217] Elevating the temperature to 37°C relieves this block, and allows the proteins to proceed to the cell surface.[218] By examining the nature of the complex N-linked glycosylation associated with the VSV G protein, it was demonstrated that sialic acid residues are added in the 20°C compartment.[214] These investigators took advantage of the fact that in addition to the HA protein the membrane of the influenza virus contains a neuraminidase in their efforts to determine whether segregation of the apically directed influenza proteins from the basolaterally targeted VSV G protein occurs before or after the 20°C block compartment. They found that in singly infected cells incubated at 20°C, the VSV G protein became heavily sialylated. In contrast to this, when cells which had been doubly infected with both the VSV and influenza viruses were incubated at 20°C, little if any sialic acid could be detected on the newly synthesized VSV G protein.

These results demonstrate that as late as the 20°C block compartment, which corresponds to the trans-most cisterna of the Golgi complex, the newly synthesized apical neuraminidase and basolateral VSV G protein are still intermingled and capable of physical interaction. The segregation of these two classes of proteins from one another must, therefore, occur at or after this subcellular locus. It is interesting to note that immunoelectron microscopic studies of endocrine cells reveal that proteins destined for packaging in secretory granules are separated from those bound for constitutive delivery to the cell surface in the trans-most cisterna of the Golgi complex.[219–221] Observations such as these have prompted investigators to speculate that this compartment, which is referred to as the Trans Golgi Network (TGN), might be the site of several intracellular sorting events.[222] More recently, it has been shown that sorting may occur as well at the level of the recycling endosome. Loading endosomes with HRP-conjugated transferrin, and subsequently disrupting endosome function through the deposition of peroxidase reaction product, prevents the surface delivery of a subset of newly synthesized basolateral membrane proteins.[223] While the delivery of the VSV G protein to basolateral plasma membrane is prevented by this ablation of the recycling endosome, the delivery of the newly synthesized Na^+/K^+-ATPase to the basolateral surface is unaffected by this maneuver.[224] Thus, it would appear that proteins can pursue more than one route from the TGN to the basolateral membrane domain.

Three epithelial sorting pathways can be imagined (Figure 1.9).[1,2,158] In the direct model, sorting would take place prior to cell surface delivery. Segregation of basolateral from apical proteins would be completed intracellularly, and proteins would never appear, even transiently, in the inappropriate membrane domain. The random sorting scheme dictates that no separation of apical from basolateral proteins occurs prior to arrival at the cell surface. Following their insertion into the plasmalemma, proteins that find themselves in the wrong surface domain would be removed by endocytosis, and either transcytosed to the proper surface[225] or degraded. Finally, the indirect paradigm predicts that all newly synthesized plasmalemmal proteins initially appear together, either at the apical or basolateral membrane. The proteins for which this delivery is correct would be retained in that membrane domain, while those which had been mis-delivered would be internalized and transcytosed to their sites of ultimate functional residence.

These three models, although perhaps somewhat simplistic, are valuable for the relative ease with which they can be experimentally distinguished. Over the past two decades a great deal of effort has been invested in identifying which of these routes is, in fact, operational. The rather surprising answer appears to indicate that the sorting pathway pursued varies among different cell types, and even among different proteins within the same cell type.

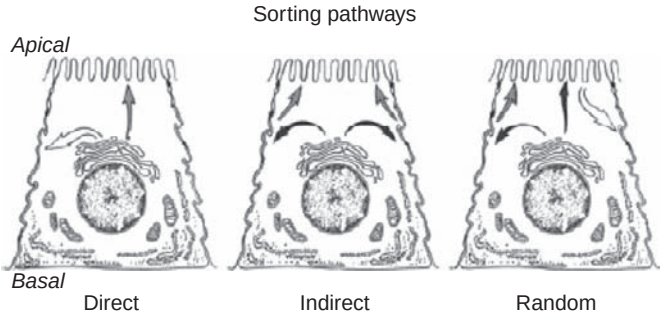

FIGURE 1.9 **Three potential pathways for the sorting of membrane proteins in polarized epithelial cells.** In the vectorial sorting scheme, apical and basolateral membrane proteins are separated from one another intracellularly and prior to plasmalemmal delivery (left). The indirect, or obligate, misdelivery model predicts that all newly synthesized plasma membrane proteins are carried together to a common cell surface domain. Proteins destined for the opposite surface are then internalized and transported to their appropriate destinations (middle). Finally, random sorting is defined by a complete lack of intracellular segregation. Apical and basolateral proteins are delivered without preference to both surfaces, and are subsequently redistributed by endocytosis and transcellular transport (right). Clear arrows represent vesicles carrying only basolateral proteins; hatched arrows denote vesicles carrying only apical proteins; and black arrows indicate vesicles carrying intermixed apical and basolateral membrane proteins. *Reprinted with permission from ref. [1].*

Technical Approaches

Much of the early research into the nature of epithelial sorting pathways was carried out on MDCK cells that had been infected with the VSV or influenza viruses. The infected cells produced massive quantities of viral proteins, and retained their polarized distribution throughout at least the initial stages of the infection. These properties greatly facilitated the detection of cohorts of newly synthesized membrane proteins in the pulse chase protocols generally employed to monitor the polarity of cell surface delivery. Pulse labeling experiments demonstrated that the VSV G protein was not accessible to apically added antibodies at any point during its post-synthetic processing.[226] In the case of the influenza HA protein, the converse was true. Proteases[174] or antibody probes[227] added to the media compartment bathing the basolateral surfaces of MDCK cells grown on filters could not cleave or interact with this polypeptide during its journey to the apical cell surface. From these results, it was concluded that the direct model of sorting applied for at least these two proteins in MDCK cells.

Other labeling tools have also been brought to bear on the study of sorting pathways. The N-hydroxysuccinimidyl (NHS) derivative of biotin is a membrane impermeant molecule that will covalently combine with the ε-amino groups of exposed lysine residues.[228] Proteins thus modified are substrates for precipitation or detection with avidin-conjugated secondary reagents. These tools can be used to follow the fate of large numbers of membrane proteins that have been exposed at one or other cell surface to the NHS biotin compound. Using such a protocol, it has been demonstrated that several MDCK cell apical and basolateral membrane proteins are directly targeted to their appropriate membrane domains.[229,230]

Advances in the development of genetically encodable probes have also permitted sorting pathways to be visualized directly. By creating chimeras that incorporate photoactivatable versions of the green fluorescent protein (GFP), the trafficking of newly synthesized proteins of interest can be observed in intact cells in real-time.[231] Alternatively, the SNAP tag similarly permits newly synthesized cohorts of proteins to be observed in pulse chase protocols. The 20 kDa SNAP-Tag is a modified version of the DNA repair protein 0^6-alkylguanine-DNA alkyltransferase, which cleaves para-substituted benzyl guanines (BGs) by covalently transferring the substituted benzyl group to its active thiol.[232] The resulting thioether bond irreversibly prevents the reacted SNAP-Tag from participating in any further labeling reactions. Fluorescent BG derivatives allow for the labeling and detection of SNAP-Tagged fusion proteins in either live or fixed cells.[232,233] Through the combination of a "pre-pulse" blocking step with non-fluorescent BG, followed by selective labeling of newly synthesized protein with fluorescent BG, it is possible to follow a cohort of protein as it is synthesized and trafficked.[224]

Sodium Pump Targeting

Further support for the direct pathway paradigm in MDCK cells came from studies on the sorting of the endogenous Na^+/K^+-ATPase.[175] Filter grown MDCK cells which had been pulse-labeled with [35S]-methionine were exposed to the N-azidobenzoyl (NAB) derivative of ouabain at either their apical or basolateral surfaces during the course of a 90 minute chase. NAB-ouabain will bind to catalytically active sodium pumps with high affinity and, following UV photolysis, will become covalently incorporated into the protein backbone of the Na^+/K^+-ATPase α-subunit.[234–236] By analyzing immunoprecipitates prepared from these cells using an anti-ouabain antibody, it was possible to demonstrate that no sodium pump in a state competent to bind ouabain ever appears at the apical surface. Subsequent studies using a SNAP-tagged version of the Na^+/K^+-ATPase expressed in the same MDCK cell line recapitulated the finding that the newly synthesized pump trafficks directly to the basolateral surface in these cells.[224]

Another investigation of sodium pump sorting in a different clonal line of MDCK cells made use of the NHS biotin surface-labeling technique, and arrived at a conclusion diametrically opposed to the one described above. The results of this study indicated that the Na^+/K^+-ATPase is randomly delivered to the apical and basolateral plasmalemmal surfaces.[237] The authors further suggested that stabilizing interactions with cytoskeletal elements which underly the basolateral, but not the apical, cell surface[112,114,119] result in a much longer residence time for pump inserted into the basolateral domain. These studies are thus consistent with a model in which sodium pump is not sorted intracellularly, but instead achieves its basolateral distribution through a mechanism based on random delivery followed by differential stabilization.

The apparent discrepancy among these studies appears to be attributable to differences in the pathways and processes through which these closely related cell lines achieve the polarized distribution of the Na^+/K^+-ATPase. While one line targets the pump directly to its basolateral destination, the other delivers it randomly and depends upon cytoskeletal interactions to stabilize only the basolateral pool.[238,239] Clearly, therefore, while cytoskeletal interactions may be sufficient to localize the Na^+/K^+-ATPase to the basolateral surface, they are not the sole mechanism involved in producing the sodium pump's anisotropic distribution. Instead, they may act as a failsafe mechanism to back up and reinforce the initial biosynthetic sorting of the Na^+/K^+-ATPase, to ensure that its polarized distribution is attained and maintained.

The preceding discussion suggests that the direct scheme cannot be applied to all epithelia or even to all MDCK cell clones. An alternative system has been shown to apply to the liver, for example. Cell fractionation studies performed on liver by Bartles et al. reveal that several apical membrane proteins appear in the fraction corresponding to the hepatocyte basolateral plasma membrane prior to being delivered to the apical surface.[240] This route has been especially well-documented for the polymeric immunoglobulin receptor (pIgR) expressed by hepatocytes. This 120 kDa polypeptide serves to carry dimeric IgA from the blood to the lumena of the bile cannaliculi. During its biosynthesis, the pIgR is transported directly from the TGN to the basolateral cell surface where it is available to bind dimeric IgA.[241,242] Independent of any interaction with IgA the receptor becomes phosphorylated in the basolateral plasmalemma, and the phosphorylated form is internalized and carried by a transcytotic vesicle to the apical, or canalicular, surface.[243] Following its insertion

into the apical plasma membrane the ectodomain of the pIgR is cleaved and released into the bile as an 80 kDa protein referred to as secretory component.[241,242] Association with secretory component helps to protect the bound IgA from intestinal proteases. Coupled with other results,[240] the behavior of pIgR in hepatocytes supports the contention that apical membrane proteins arrive at their site of ultimate functional residence via obligate mis-delivery to the basolateral domain. This paradigm may not apply to all apical proteins in hepatocytes. Studies of the trafficking of apical members of the multidrug resistance (MDR) family of transport proteins indicate that these polytopic membrane proteins do not make an appearance at the basolateral surface en route to the apical membrane.[244,245] Thus, within a single polarized cell type multiple trafficking routes can be employed to target different proteins to the same place.

A combination of the direct and indirect paradigms seems to be involved in membrane protein delivery in cultured intestinal cells. The Caco-2 line of human colon carcinoma cells can be grown on filters and subjected to the NHS-biotin labeling protocol described above. Such experiments reveal that the basolateral protein followed is vectorially targeted.[246] Analysis of the apical polypeptides produced a somewhat more complicated picture. A fraction of these proteins appeared to transit through the basolateral plasmalemma prior to their apical delivery. The remainder of the apical proteins studied in this sampling were sorted intracellularly and inserted directly at the apical domain. Related and somewhat more complicated results have been gathered from studies on the biogenesis of brush border hydrolases by colonocytes *in situ*.[110,247,248]

To complete this already confusing picture it is necessary to return to a discussion of targeting studies in MDCK cells. A cDNA encoding the pIgR has been expressed by transfection in this cell line. Remarkably, the sorting pathway pursued by this protein in the cultured renal epithelium is apparently identical to the rather baroque scheme that characterizes its route in hepatocytes.[249] From the TGN, the pIgR travels to the basolateral surface from which it is internalized and subsequently transcytosed to the apical pole or recycled to the basolateral side. These observations demonstrate that an obligate mis-delivery pathway is either created or simply revealed in MDCK cells expressing the pIgR. Results from studies employing real-time imaging to follow the surface delivery of a class of newly synthesized apical proteins support the possibility that this indirect pathway does, in fact, exist constitutively in MDCK cells. As discussed in greater detail in the section on sorting signals, proteins whose attachments to the membrane are mediated by covalent linkage to glycosylphosphotidyl inositol (GPI) lipids tend to accumulate in the apical domains of most varieties of polarized epithelial cells. A study that employed live cell imaging to track the sorting of GPI-linked proteins found that these proteins were delivered to the basolateral surface, after which they were endocytosed and carried to the apical plasmalemma.[250] It is worth noting, however, that subsequent studies found that several GPI-linked proteins were delivered directly to the apical membrane in MDCK cells, without making any detectable transient appearance at the basolateral surface.[251]

This apparent diversity of sorting pathways is perhaps not as surprising as it first appears. The relative flow of membranous vesicles from the Golgi complex to the two plasmalemmal surfaces in different epithelial cell types is likely to reflect a cell's biologic mission, as well as the nature of the environment in which it functions. It appears, for example, that although hepatocytes produce copious quantities of secretory proteins, none are released directly into the bile.[252] It has been proposed that newly synthesized membrane proteins depart the Golgi in the same transport vesicles that carry proteins destined for constitutive secretion.[158,252] Were this the case, then cells which do not produce a secretory content targeted for one or another membrane domain may also lack a direct traffic of membrane vesicles directed from the Golgi to that domain. The full complement of plasmalemmal proteins might thus be forced by default to share the same carrier out of the Golgi, and to be sorted by transcytosis subsequent to cell surface delivery. Some hepatic apical membrane proteins may transit through the basolateral surface, because there is very little non-stop cargo traveling from the TGN to the apical domain in this particular cell type. The apparent multiplicity of sorting pathways available to different proteins within the same cell type may reflect specializations relevant to these proteins' functions. Diversity may also arise from the nature of the signals and mechanisms that mediate these proteins' polarized distribution. The potential contribution of this latter influence will be referred to again in sections to follow. The lack of a single answer or unifying solution to the problem of sorting pathways is a theme that carries through the entire study of epithelial polarity. A number of equally effective mechanisms appear to have evolved for segregating membrane proteins into distinct domains. It remains to be determined how these differing approaches benefit their respective tissues and contribute to the maintenance of their unique functions.

Regulation of Renal Transport Protein Function by Endocytosis and Recycling

The delivery of a protein to its site of functional residence in a domain of the plasma membrane does not

end that protein's involvement with the cellular sorting machinery. Cell surface proteins are subject to endocytic internalization, after which their fate is determined through processes that are mechanistically closely related to those that mediate biosynthetic sorting. Following their delivery to endosomes, endocytically internalized proteins can be recycled, meaning that they are returned to the same domain of the plasma membrane. Alternatively, they can be carried by transcytosis to the opposite plasma membrane domain. Finally, they can be targeted for degradation in the lysosome. The cellular machinery and molecular signals that govern these post-endocytic sorting processes appear to closely resemble those that mediate biosynthetic sorting.

From the perspective of the renal tubular epithelial cell, perhaps the most important implication of post-endocytic sorting relates to its role in the regulation of ion transport protein activity. The activities of a number of critically important transport proteins are controlled by regulated membrane insertion and endocytotic events.[253] Included on this list are the aquaporin 2 water channel (AQP2),[254] the ROMK potassium channel,[255] and the ENaC sodium channel of collecting duct principal cells[256]; the V-type proton ATPase of collecting duct intercalated cells[257]; the Na,Cl co-transporter (NCC) of the distal convoluted tubule[258]; the Na phosphate co-transporter (NaPi),[100] the Na proton exchanger (NHE3),[259] and the Na^+/K^+-ATPase of the proximal convoluted tubule.[260] These regulated trafficking events are precipitated by a variety of hormonal and physical stimuli, and involve the participation of a diverse collection of signaling cascades and trafficking proteins. While their details will be explored in far greater individual detail in the chapters that relate to each of the specific tubule segments and relevant transport systems, it is worth noting that these regulated trafficking processes exploit many of the biosynthetic sorting signals and components of the cellular trafficking machinery that are discussed in the following sections.

Sorting Signals

Rodriguez-Boulan and Sabatini's 1978 observation that viral spike glycoproteins are targeted to opposite domains of polarized epithelial cells[165,166] gave rise to the hypothesis that sorting signals – that is, the information required to direct a protein or proteins to a given subcellular location – might be wholly contained within the structure of the sorted proteins themselves. Evidence in favor of this contention has come from studies examining the distribution of viral membrane proteins expressed by transfection (rather than infection) in polarized cultured cells. A number of investigators have shown that the influenza HA protein, the VSV G protein, and related viral spike glycoproteins are sorted correctly in the absence of any other proteins encoded by viral genomes.[261–264] It is apparent, therefore, that all of the addressing information necessary to produce the polarized distributions of these polypeptides must be embodied within the proteins themselves. It has further been shown that this information is almost certainly associated with the protein backbone, rather than with any post-translational modification. Cells whose capacity to add asparagine-linked sugar residues has been impaired, either through mutation or via treatment with tunicamycin,[265,266] are nonetheless able to correctly target the viral spike proteins. Observations such as these have sparked an intensive search for the actual molecular information that specifies localization, and for the machinery that acts upon this information. It must be stated at the outset, however, that despite the rather confident and declarative tone of this section's heading the identification and characterization of epithelial sorting signals and mechanisms is far from complete.

Several distinct classes of signals have been found to specify basolateral sorting.[267] Perhaps the best characterized of these are short motifs that contain tyrosine residues and resemble or overlap with sequences involved in endocytosis. Work from a number of groups has suggested that sequences in the cytosolic tail of membrane proteins determine the rates at which these proteins are internalized. The presence of a tyrosine residue appears to be a critical determinant of the efficacy of an endocytosis signal.[268] The rapid endocytosis of both the LDL receptor and the transferrin receptor, for example, is dependent upon the presence of short, tyrosine-containing sequences in these proteins' cytoplasmic tails. Mutation of this tyrosine residue to any other amino acid vastly reduces the rates at which both of these proteins are internalized. The apically sorted influenza HA protein is normally endocytosed extremely slowly. Addition of a tyrosine residue to the cytosolic tail of the influenza HA protein causes it to behave like the LDL receptor or transferin receptor with respect to endocytosis – that is, it is rapidly internalized and recycled.[269] When this altered form of the HA protein is expressed in MDCK cells it is detected predominantly at the basolateral plasma membrane.[270] It would appear, therefore, that a signal that is permissive for endocytosis is also competent to mediate basolateral accumulation.

Studies of the VSV G protein reveal that its basolateral sorting is also driven by a tyrosine-containing motif.[271,272] Uptake measurements suggest, however, that the VSV G protein is internalized relatively slowly, suggesting that its tyrosine-based motif confers basolateral targeting, but not rapid endocytosis. Mutagenesis studies of the tyrosine-modified influenza HA protein, as well as several other basolateral

membrane proteins, indicate that while internalization signals and basolateral sorting signals can share the same critical tyrosine residues, they are not identical.[273] Altering residues near the tyrosine can produce apically sorted influenza HA protein that is rapidly endocytosed, and basolateral HA protein that is internalized only slowly. Thus, basolateral and endocytosis signals can overlap, sharing one or more residues, but are clearly distinguishable from one another. Presumably, therefore, they must be interpreted by non-identical cellular machinery.

Data pointing to a similar conclusion have been gathered for Fc receptors.[274] One of the Fc receptor isoforms includes a di-leucine sequence in its cytoplasmic tail. This sequence has been shown to function as an endocytosis signal, and it also appears to confer basolateral targeting when the protein is expressed in polarized cells. Once again, alteration of residues flanking the di-leucine motif demonstrates that the sequence requirements for basolateral sorting are distinct from those that specify internalization.[275,276]

Tyrosine-containing basolateral sorting signals that are entirely distinct from recognizable endocytosis motifs have also been detected. The LDL receptor depends upon a basolateral sorting signal that bears no sequence resemblance to any known internalization motif.[276,277] Although this motif includes a tyrosine residue, mutation of that tyrosine to phenylalanine still permits basolateral localization. A distinct tyrosine-containing motif appears to mediate the internalization of the LDL receptor.[278] In the absence of the primary basolateral signal, this endocytosis motif can mediate a basolateral sorting function. Once again, however, with the exception of the tyrosine residue, the amino acids that contribute to the basolateral and endocytic aspects of this signal are distinct from one another.

Several basolateral sorting signals unrelated to tyrosine residues have also been reported. The well-characterized tyrosine-based endocytosis motif of the transferrin receptor is completely distinct from this protein's basolateral targeting signal, which resides in a different portion of the cytoplasmic tail. The peptide processing enzyme furin cycles between the trans-Golgi network and the basolateral plasmalemma. Its trafficking to the basolateral surface appears to be driven by residues that are associated with a casein kinase II phosphorylation site.[279,280] The invariant chain of the major histocompatibility class II complex is sorted to the basolateral membrane by virtue of the dihydrophobic sequence Met−Leu.[281] Once again, endocytic internalization of this molecule is conferred by a similar dihydrophobic sequence, Leu−Ile, which is present at another position on the cytoplasmic tail. All of the basolateral sorting motifs discussed thus far function in the context of membrane proteins that span the bilayer once. As will be discussed below, a distinct cadre of molecular sequences appears to mediate the targeting of many ion transporters and other multispanning membrane proteins.

The list of identified basolateral sorting signals is considerably more extensive than the inventory of characterized apical membrane protein sorting signals. Perhaps the best studied member of this latter roster is not, in fact, a protein-based signal at all, but is instead constituted entirely of phospholipid. Glycophospholipid (or GPI)-linked proteins are synthesized as transmembrane polypeptides that are co-translationally inserted into the membrane of the RER.[282] While still associated with the ER, the GPI-linked protein's ectodomain is proteolytically removed and transferred to a preassembled structure composed of a complex glycan tethered to the membrane through its attachment to a molecule of phospholipid (frequently phosphotidylinositol). Previous work has shown that in polarized epithelial cells, most of the GPI-linked proteins reside in the apical plasmalemma.[230,283] Interestingly, the apical surface also plays host to most of the cell's complement of glycolipid.[284] Investigators prepared a construct in which the VSV G ectodomain was wedded to the transmembrane tail of Thy-1, which carries a signal for glycophospholipidation.[285] The resultant GPI-linked G protein is sorted to the apical membrane. The results of these and related experiments have generally been interpreted to indicate that a strong apical sorting signal is embodied in some component of the GPI linkage itself. The transmembrane domains of several single-spanning apical membrane proteins appear to carry information important for apical targeting. The transmembrane domains of the influenza virus neuraminidase and HA proteins, for example, are sufficient to mediate sorting to the apical surface when they are included in constructs expressed by transfection in MDCK cells.[286] As will be discussed below, the same mechanisms that are thought to be involved in recognizing the GPI tail as an apical sorting motif may also interpret signals embedded in transmembrane domains. Furthermore, transmembrane domain sorting signals may be important not only in the localization of single spanning membrane proteins, but may also determine the distributions of polytopic ion pumps such as the Na^+/K^+- and H^+/K^+-ATPases (see below). It should also be noted that the extracytoplasmic or ecto domains of several apical proteins appear to incorporate directional signals. Roth et al. have shown that the ectodomain of the influenza HA protein is sufficient to specify apical targeting.[287] When a cDNA construct encoding an anchor-minus form of the HA protein, which lacks both the cytosolic and transmembrane segments, is expressed in polarized cells it is secreted exclusively into the apical medium compartment. This is also true well for the polymeric immunoglobulin receptor.[288] These results suggest

that a signal involved in apical sorting resides in the lumenal portion of the HA molecule, and that this signal remains interpretable when it is presented as a soluble protein or in association with portions of a basolateral membrane polypeptide. Finally, N-linked sugar groups, which are also present on the extracytoplasmic domains of membrane proteins, can in some circumstances contribute apical sorting information.[289] It is logical to conclude from this discussion that machinery necessary to read and interpret this putative ectodomain apical sorting information must be exposed at the lumenal surface of the organellar compartments involved in the segregation and targeting of newly synthesized membrane proteins.

As discussed above in the section on sorting pathways, not all of the plasma membrane proteins expressed by polarized epithelial cells pursue a direct course to their sites of ultimate functional residence. The polymeric immunoglobulin receptor (pIgR) for example, when examined in its native liver[241,242,290] or in transfected MDCK cells,[249] travels first to the basolateral surface and subsequently to the apical pole. A number of studies have examined the contributions that various portions of the pIgR molecule may make to this complicated sorting behavior. Anchor-minus ectodomain constructs of the pIgR are secreted apically from transfected MDCK cells.[288] Furthermore, deletion of the pIgR cytosolic tail results in a membrane protein that travels directly to the apical surface without ever appearing at the basolateral side.[291] These observations have led to the suggestion that the ectodomain of the pIgR receptor contains an apical sorting signal, and that this protein's cytosolic tail embodies information that is required for its initial appearance at the basolateral plasma membrane. Extensive mutational analysis reveals that a trio of amino acids in the sequence His, Arg, Val is primarily responsible for the vectorial targeting of the newly synthesized pIgR protein to the basolateral plasmalemma. This motif constitutes yet another addition to the growing collection of distinct amino acid sequences that can encode basolateral sorting.[292,293]

During its tenure at the basolateral membrane, the pIgR's cytosolic tail becomes phosphorylated on a serine residue. The phosphorylation event occurs both in liver[243] and in transfected MDCK cells.[294] Intriguing experiments demonstrated that the addition of this phosphate group acts as a switch that allows the apical sorting signal to predominate, and results in the protein's transcytosis to the apical side. Site directed mutagenesis has been performed on the cDNA encoding the pIgR in order to convert the serine of interest into either an alanine or an aspartate residue.[294] When expressed in MDCK cells, the wild-type, as well as the two mutant forms, are all initially targeted to the basolateral surface, and all three undergo endocytosis and recycling at similar rates. Interestingly, however, while the wild-type receptor undergoes fairly rapid transcytosis, the alanine form remains largely associated with the basolateral plasma membrane. In contrast, the aspartate form is transcytosed at a rate that exceeds that characteristic of the non-mutant form. These observations suggest that the negative charge associated with the phosphate and aspartate residues permits or activates the incorporation of the pIgR into transcytotic vesicles, and thus initiates the protein's delivery to the apical surface. The mechanism through which this signal is detected and interpreted remains unclear.

The recognition and segregation of pIgR destined for transcytosis probably occurs in an endosome following internalization from the basolateral surface. The second sorting event involved in the targeting of the pIgR is thus almost certainly completed at a subcellular location distinct from the TGN. This behavior suggests that, once again, the sorting of apical from basolateral proteins need not occur exclusively on the exocytic pathway. The endosome or an endosome-related compartment appears competent to sense and act upon the sorting signals that are necessary for the pIgR's apical localization. It remains to be determined whether signals detected in the endosome correspond to the same ectodomain-associated information that mediates the apical secretion of an anchor-minus form of the pIgR. The segregation of this secretory form to the apical pathway almost certainly occurs during its passage through the Golgi, and is not likely to involve elements of the endocytic apparatus.

Most ion transport proteins and receptors span the membrane several times, and many are composed of multiple subunits. Their intricate structures complicate the search for sorting signals and increase the likelihood that multiple independent or hierarchical signals might be present. This is clearly the case for the gastric H,K-ATPase. Acid secretion in the stomach is mediated by the gastric H^+/K^+-ATPase. This dimeric ion pump is stored within an intracellular population of membranous vesicles, known as tubulovesicular elements (TVEs), in gastric parietal cells. Stimulation of acid secretion by secretagogues induces the TVEs to fuse with the parietal cell apical plasma membrane, resulting in the formation of deeply invaginated secretory canaliculi rich in H^+/K^+-ATPase. The cessation of acid secretion involves the retrieval of the H^+/K^+-ATPase from the cell surface, and the regeneration of the TVE storage compartment.[295] Both the α- and β-subunits of the H^+/K^+-ATPase belong to the large P-type ATPase gene family.[296] Their closest cousins in this collection are the corresponding α- and β-subunits of the Na^+/K^+-ATPase. Interestingly, while the H^+/K^+-ATPase functions at the apical surface of gastric parietal

epithelial cells, the Na^+/K^+-ATPase is restricted in its distribution to the basolateral plasmalemma, in this and most other epithelial cell types.[297] The homology relating these ATPases has permitted the creation of chimeric ion pumps, whose subunits are composed of complementary portions of the H^+/K^+- and Na^+/K^+-ATPase α- and β-polypeptides. By expressing these constructs in cultured polarized epithelial cells it has been possible to determine the molecular domains of the ion pump subunit proteins that are responsible for their sorting. Through this analysis it has become clear that both the α- and β-subunit polypeptides of the H^+/K^+-ATPase contain molecular signals which can contribute to the targeting of the holo-enzyme.[298–300] Expression of a large number of progressively more refined α-subunit chimeras reveals that an eight amino acid sequence within the α-subunit of the H^+/K^+-ATPase is sufficient to specify apical sorting.[300] This domain is predicted to reside within a transmembrane helix, thus suggesting that protein–lipid or protein–protein interactions within the plane of the membrane are responsible for pump sorting.

The β-subunit of the H^+/K^+-ATPase contains a tyrosine-based sorting signal that functions to internalize the pump complex from the surface of the gastric parietal cell, and return it to an intracellular regulated storage compartment.[301] This internalization is responsible for the cessation of gastric acid secretion following the removal of secretagogue stimulation. This was demonstrated by generating a transgenic mouse which expresses an H^+/K^+-ATPase β-subunit lacking this endocytosis signal.[301] These animals are unable to reinternalize H^+/K^+-ATPase from the apical surfaces of their gastric parietal cells. Consequently, they produce elevated gastric acid secretion during the interdigestive period. Mice carrying the mutant β-subunit develop gastritis and gastric ulcerations, with histologic features that are essentially identical to those found in human disease. Examination of renal potassium clearance in these animals reveals that the same β-subunit sorting signal regulates active potassium resorption in the collecting tubule.[302]

Several studies have begun to define other signals employed in the polarized sorting of polytopic membrane proteins. Recently, for example, a novel motif has been identified in the cytoplasmic tail of the seven-membrane-span receptor rhodopsin that mediates this protein's apical sorting when it is expressed in MDCK cells.[303] Another member of the seven transmembrane G protein-coupled receptor family, the P2Y2 receptor, manifests an apical sorting signal in one of its extracellular loops.[304] Furthermore, studies of neurotransmitter re-uptake systems have demonstrated that the four members of the highly homologous GABA transporter gene family are differentially sorted in epithelial cells and in neurons.[305,306] The GAT-1 and GAT-3 isoforms, which are restricted to axons when expressed endogenously or by transfection in neurons, are sorted to the apical membranes of epithelial cells. The GAT-2 and betaine transporters, which are 50–67% identical to GAT-1 and GAT-3, behave as basolateral proteins in epithelia, and are restricted to dendrites when expressed in neurons. Production of chimeric and deletion constructs have permitted the identification of very short amino acid sequences at the extreme C-terminal tails of these transporters which manifest targeting information. The nature of these sequences suggests that they may interact with polypeptides containing PDZ-type protein–protein interaction domains, raising the possibility that this association may play a direct role in the sorting of ion transport proteins.[307] A similar PDZ-dependent mechanism also appears to mediate the apical trafficking of CFTR.[308–311] The basolateral isoform of the Na,K,2Cl co-transporter, NKCC1, has recently been shown to be targeted to the basolateral surface by virtue of a di-leucine motif in its cytoplasmic C-terminal tail. The renal isoform of this protein, NKCC2, depends for its apical localization on a two non-contiguous stretch of amino acids that appear to collaborate to form a conformation-dependent signal in the context of the fully folded transporter's C-terminal domain. The mechanism through which this non-contiguous conformational determinant is recognized by the cellular sorting machinery has yet to be determined.[312]

Cell Type-Specific Sorting: Patterns

The message encoded within a membrane protein's sorting signal is dependent not only upon its own specific biochemical composition, but also upon the cellular context in which it is expressed. Several examples of membrane proteins that are differentially targeted in distinct epithelial cell types have been documented. The vacuolar H^+-ATPase, for example, accumulates at the apical surfaces of α-type intercalated cells, but at the basolateral plasmalemmas of β-type intercalated cells in the renal collecting duct.[313] Similarly, the Na^+/K^+-ATPase is basolateral in most epithelia, but behaves as an apical protein in cells derived from the neural crest, such as choroid plexus and retinal pigment epithelium.[314,315] Targeting of particular proteins or classes of proteins can also vary as a function of the differentiation states of epithelial cells. For example, the sorting of well-characterized polarity markers expressed in *Drosophila* via germ line transformation was followed in the developing *Drosophila* embryo. Human placental alkaline phosphatase (PLAP) is a glycosylphosphatidyl inositol (GPI)-linked protein that accumulates at the apical membranes of mammalian epithelial cells. A chimeric construct composed of the

transmembrane and cytosolic portions of the vesicular stomatitis virus (VSV) G protein coupled to the ectodomain of PLAP has been found to behave as a basolateral protein when expressed in the MDCK cell system.[285] The subcellular distributions of these proteins were examined in the epithelial tissues of transgenic *Drosophila* embryos which expressed these proteins under the control of a heat shock promoter.[316] In the surface ectoderm both PLAP and PLAPG were restricted to the basolateral membranes throughout development. Internal epithelia derived from the surface ectoderm accumulated PLAP at their apical surfaces, while PLAPG retained its basolateral distribution. The redistribution of PLAP from the basolateral to the apical plasma membrane was found to be coincident with the invagination of the surface epithelium to form internal structures, suggesting that the sorting pathways which function in the epithelium of the *Drosophila* embryo are developmentally regulated.

In light of both the multiplicity of sorting signals presented in the preceding section, and the apparent potential for heterogeneity in their interpretation discussed above, it is natural to wonder whether any logic or consistency governs nature's solution to the deceptively simple problem of apportioning proteins among two separate membrane domains. Upon further reflection, however, the complexity and degeneracy of the "sorting code" can be seen as a tremendous virtue. Two different epithelial cell types may need to target a given membrane protein to opposite surfaces of their respective plasma membranes in order to fulfill their unique physiologic functions. These same functions may also require, however, that other membrane proteins occupy the same surface distributions in both cellular contexts. Thus, while the sodium pump occupies the apical membranes of the cells of the choroid plexus and the basolateral membranes of renal epithelial cells, receptors for basement membrane components are present at the basolateral surfaces of both cell types. If only a single class of basolateral sorting signal and a single class of apical sorting signal existed, then it would not be possible for a cell to selectively alter the distribution of one set of plasmalemmal proteins, without simultaneously altering the distributions of the entire population of the plasma membrane. In order to target the sodium pump to the apical surface, choroid plexus epithelial cells would be forced to target basement membrane receptors there as well. This would obviously constitute a wasteful compromise. In order to endow each epithelial cell type with the capacity to select individualized complements of proteins for its apical and basolateral domains, a dizzying multitude of sorting signals has evolved. Cells can thus customize the distributions of proteins among their plasmalemmal domains, without the constraints that would be imposed by a limited number of sorting signals. According to this interpretation, sorting signals do not specify a specific destination such as apical or basolateral. Instead, they specify classes of proteins whose members are always sorted together. The membrane domain to which any one of these classes is sorted will depend upon the cellular context in which it is expressed, and will be determined by the idiosyncratic array of sorting machinery and pathways present in each individual epithelial cell type.

Sorting: Mechanisms

Extensive progress has been made in illuminating the mechanisms through which the sorting signals discussed above exert their effects and ensure the polarized delivery of newly synthesized plasma membrane proteins. The strong evidence for the existence of sorting signals leads quite naturally to the postulate that sorting receptors must exist that are capable both of recognizing these signals, and of transducing their messages to the relevant cellular machinery. Such receptors have, in fact, been demonstrated in the case of lysosomal enzyme sorting. Targeting of a newly synthesized hydrolase to the lysosome is mediated by the interaction between the enzyme's mannose-6-phosphate (man-6-p) recognition marker, and one of two receptors which bind man-6-p bearing ligands in the Golgi and mediate their segregation to pre-lysosomal endosomes.[317] Binding of newly synthesized lysosomal enzymes to the man-6-p receptors is pH-dependent. At the relatively neutral pH of the Golgi ligands are tightly bound, whereas in the acid environment of the pre-lysosomal endosome they are rapidly released. No such well-characterized receptor systems have yet emerged to explain the sorting behavior of secretory and membrane proteins in polarized cells. While sorting receptors for secretory proteins remain to be identified definitively, some progress has been made in understanding how such receptors might function. Lysosomotropic amines, such as NH_4Cl and chloroquine, elevate the lumenal pH of acidic organelles.[318] The resulting neutralization of acidic compartments can have profound effects on sorting. In the case of lysosomal enzyme targeting, addition of NH_4Cl raises the pH of the pre-lysosomal endosome, and thus prevents the acid-dependent unbinding of newly synthesized hydrolases from the man-6-p receptor.[317] In the continued presence of the drug, the Golgi becomes depleted of receptors available to complex with free ligand. Newly synthesized enzymes bearing the man-6-p recognition marker are thus secreted constitutively and by default. Experiments on cultured polarized epithelial cells suggest that a similar pH-dependent mechanism may function in the sorting of basolateral secretory proteins.[176]

Laminin and heparan sulfate proteoglycan are constituents of epithelial basement membranes.[130,319] Studies of MDCK cells grown on permeable filter supports revealed that both of these proteins are normally secreted predominantly into the basolateral medium compartment.[176] When secretion from cells treated with NH_4Cl was monitored, it was found that both proteins were released into both media compartments in roughly equal proportions. Removal of the drug reversed this effect and restored normal basolateral secretion. As mentioned above, studies have demonstrated that the secretory default pathway for MDCK cells – that is the route pursued by soluble proteins which lack any means of interacting with the cellular sorting machinery – is apical and basolateral.[176,261,320] It appears, therefore, that targeting of these two basolateral secretory proteins requires the participation of an intracellular acidic compartment. Elevation of the lumenal pH of this compartment reversibly blocks laminin and HSPG sorting, and results in their apical and basolateral default secretion.

Although the nature of the dependence of this sorting event on acidic compartments remains unknown, it is interesting to speculate that a mechanism similar to that which functions in lysosomal enzyme sorting may also be involved in routing basolateral secretory proteins. In such a model, binding or unbinding of laminin and HSPG from a sorting receptor would require the participation of an acidic organellar pH. Confirmation of this hypothesis will await the identification of such a pH-dependent binding protein with affinity for these and other basolaterally targeted proteins.[321] Finally, it is worth noting that the basolateral sorting of the Na^+/K^+-ATPase, and the apical sorting of the influenza HA protein and a complex of secretory polypeptides, occurs normally in the presence and absence of NH_4C1.[175,176,322] It would appear, therefore, that different mechanisms are brought to bear in ushering different classes of proteins to their sites of ultimate functional residence.

Tyrosine-Based Motifs and Adaptors

Recent studies suggest that several different classes of soluble proteins may regulate the subcellular distributions of proteins bearing tyrosine-based signals. Perhaps the best understood of these are the adaptins.[323] The adaptins comprise a group of peripheral membrane proteins that mediate the interaction between transmembrane proteins and the clathrin skeletons of coated pits and vesicles. Adaptins recognize and bind to tyrosine-containing coated pit localization sequences and link the proteins bearing these motifs to the clathrin coat.[323–327] Adaptins can thus be considered to be among the most proximal elements of the endocytic sorting machinery – they recognize polypeptides endowed with endocytosis signals and ensure that they are incorporated into the specified internalization pathway. Distinct classes of adaptins function in the segregation of proteins into the coated structures associated with the trans-Golgi network, and into cell surface coated pits.[230] While AP2 adaptors mediate internalization of proteins from the cell surface, AP1 adaptor complexes participate in trafficking proteins out of the TGN. The μ-subunits of adaptor complexes appear to be responsible for interacting with tyrosine-based motifs.[325] Two isoforms of μ-subunits are found in AP1 complexes. The μ1a protein is ubiquitously expressed, and is found in both polarized and nonpolar cell types. The μ1b protein is instead found in only a subset of polarized cell types.[328] Proteins bearing tyrosine-based motifs are basolaterally sorted in MDCK cells, but accumulate apically in LLC-PK cells.[329] It was noted that MDCK cells express μ1b, whereas this protein is absent from LLC-PK cells. Remarkably, expression of μ1b in LLC-PK cells at least partially "normalizes" their sorting properties, so that many (but not all) membrane proteins containing tyrosine-based signals are directed to the basolateral surface.[330] Thus, μ1b constitutes perhaps the best characterized component of the sorting machinery. It is clearly capable of recognizing a class of sorting signals and acting upon the instructions that they convey. Consistent with the idea that clathrin adaptors play an important role in the sorting of at least some basolateral proteins, it has been demonstrated that knockdown of clathrin expression in cultured renal epithelial cells perturbs basolateral, but not apical, protein delivery.[331]

It is interesting to note that recent studies demonstrate that different proteins bind to and interpret the messages encoded by tyrosine-based and di-leucine endocytosis motifs. Overexpression of tyrosine-motif containing proteins can inhibit the endocytosis of other proteins carrying a similar endocytosis signal, presumably by competing for limited quantities of the adaptor proteins that cluster proteins bearing these signals into clathrin-coated pits. This intervention does not affect, however, the internalization of proteins endowed with di-leucine motifs, indicating that they must be recognized and interpreted by a different class of polypeptides.[332] It appears that the β-subunits of adaptor complexes interact with di-leucine motifs.[333] Finally, a very different type of protein has been shown to interact with a tyrosine-based proline-rich sequence in the C-terminal tails of epithelial sodium channel (ENaC) subunits. The Nedd-4 protein possesses a ubiquitin ligase domain, and through its interaction with the ENaC tails may lead to these channels' downregulation through degradation.[334]

The association of basolateral membrane proteins, such as the Na^+/K^+-ATPase with elements of the subcortical cytoskeleton,[112,119] has led to the speculation

that this interaction may play a role in targeting. Evidence in support of this proposition was found in the studies, described above, which suggested that, at least in one MDCK cell clone, the Na^+/K^+-ATPase may be delivered in equal proportions to the apical and basolateral surface.[237] Apically delivered material may be rapidly degraded, whereas basolateral sodium pump would be stabilized through interaction with the cytoskeleton and consequently would turn over very slowly. The pump's polarized distribution would thus be the product of differential susceptibility to degradation, rather than sorting at the level of the Golgi. The degree to which stabilization through interaction with the cytoskeleton contributes to the polarized distribution of the sodium pump or any other proteins remains to be established.

Glycosphingolipid-Rich Membrane Domains

The observation that all of the glycolipids and GPI-linked proteins associated with epithelial cells tend to be found in the apical plasmalemmal domain led to the proposal that lipids may play a role in membrane protein sorting.[335] Since glycolipids and GPI-linked proteins are only associated with the outer leaflet of the plasma membrane, these molecules will be exposed at the lumenal face of the organelles of the biosynthetic pathway. Any sorting machinery that interacts with glycolipids, therefore, must do so either at the lumenal surface or within the plane of the membrane itself. These constraints have suggested to some investigators the possibility that lipid–lipid interactions are sufficient to segregate apically directed glycolipids and GPI-linked proteins into distinct patches during their residence in the Golgi. These self-assembled patches could then serve as the nuclei from which apically directed vesicles would bud. The biophysical properties of these patches might be involved in ensnaring other apically directed proteins, as well as the components necessary to appropriately target the resultant transit vesicle.[336] While evidence of lipid patches exists in both *in vitro* and *in vivo* systems,[284,337] their precise role in the sorting process remains to be elucidated. Independent of its applicability, however, this model is extremely interesting. It is a useful reminder that forces other than simple receptor–ligand interactions are likely to be involved in generating and maintaining the anisotropic protein distributions that define the polarized state.

As noted above, several proteins are targeted to the apical membrane by virtue of signals embedded within their transmembrane domains. The fact that the amino acid residues of a transmembrane domain may be in direct contact with lipid molecules suggests the possibility that they may mediate apical sorting through interactions with glycosphingolipid-rich membrane domains. According to this hypothesis, the composition of its transmembrane domain may permit a protein to partition into glycosphingolipid rich patches, and thus to become concentrated in a region of the membrane that will give rise to an apically directed transport vesicle. GPI-linked proteins which have become associated with glycosphingolipid-rich membrane domains are insoluble in 1% TritonX-100 at 4°C. When a cell lysate prepared in this fashion is fractionated on a sucrose gradient, insoluble proteins are found near the top of the gradient, whereas soluble proteins remain in the heavier fractions.[337] Interestingly, the transmembrane domain of the apical protein influenza neuraminidase carries apical sorting information, and also enables the protein to incorporate into insoluble material.

PDZ Domain-containing Proteins

As discussed above, the C-terminus of GABA transporter GAT-3 appears to be important for its apical localization in MDCK cells.[307] The final residues of this C-terminal tail, threonine, histidine, and phenylalanine (THF), are reminiscent of the sequences present at the extreme C-terminal tails of proteins known to associate with members of the membrane-associated guanylate kinase (MAGUK) family. The MAGUK proteins incorporate one or more copies of the PDZ domain, which is named for three of the proteins in which the sequence homology defining this protein–protein interaction motif were first identified; PSD-95/SAP90, Dlg, and ZO-1. Interactions between the PDZ domain of a MAGUK protein and the extreme cytoplasmic tail of an integral membrane polypeptide appear to be important in organizing the surface distributions of intrinsic membrane proteins.[338,339]

Observations obtained from a number of experimental systems provide further evidence for the involvement of PDZ domain-containing polypeptides in epithelial membrane protein sorting.[340] The LET-23 receptor tyrosine kinase is localized to the basolateral cell surfaces of vulvar epithelial cells in *C. elegans*. Genetic studies reveal that at least three proteins contribute to the generation or maintenance of this distribution. Mutation of the lin2, lin7 or lin10 genes leads to loss of LET-23 basolateral polarity. Each of the proteins encoded by these genes includes one or more PDZ domains. A mutation in the *Drosophila* discs lost protein, which contains multiple PDZ domains, also leads to the mis-localization of several apical and basolateral proteins in the epithelial structures of affected embryos.[341] It would appear, therefore, that PDZ domain-containing proteins may play a direct role in the polarized sorting of at least some membrane proteins or may be required for the generation or definition of polarized domains. These observations may be especially relevant to physiologic function of polarized renal epithelial cells, since a number of important ion

transport proteins, including CFTR and NHE3, appear to interact with cytoplasmic proteins containing PDZ domains.[342–344] It seems likely that these interactions may play a role in establishing these proteins distributions, and hence in determining their capacity to participate in vectorial ion transport.

Finally, it is important to note that once proteins have been sorted into the vesicles that will carry them to the appropriate cell surface domain, these vesicles themselves need to be targeted appropriately. Presumably, the vesicular membranes include proteins that ensure that the vesicles will interact and fuse with only the proper domain of the epithelial plasmalemma. This recognition machinery is likely to include components of the membrane fusion machinery, such as vesicular SNARE (soluble NSF attachment receptor) proteins.[345] SNARE proteins present in both vesicular and target membranes form complexes that appear to be necessary for most normal cellular fusion processes. The extent to which different members of the SNARE family impart specificity to intracellular vesicular fusion events remains to be established.[346–348] Interestingly, however, a component of the machinery involved in vesicular targeting in yeast was identified in mammalian cells.[349] This Sec 6/8 "exocyst" complex appears to play a role specifically in the fusion of basolaterally-directed, but not apically-directed, post-Golgi carrier vesicles in epithelial cells.[350] It is likely that the number of "destination-specific" vesicular and plasma membrane proteins important for directing vesicular traffic in polarized cells will continue to grow.

Epithelial Cell Polarity and Renal Disease

Because kidney function is dependent on the polarity of tubular epithelial cells, any condition that compromises this polarity will lead to renal failure.[351,352] In general, this may occur through neoplastic processes, cell injury due to ischemia or nephrotoxicity, or through inherited genetic effects.[179,351] Each of these may affect the tubular epithelial cells, their surrounding environment including the basal lamina and interstitial compartment, or both.

Carcinogenesis

During neoplastic growth it can be appreciated on the basis of morphology alone that the changes in cell and tissue organization wrought by tumorigenesis are likely to affect cell polarity.[179] Model studies confirm this suspicion. When MDCK cells, which are not normally tumorigenic, are oncogenically transformed by introduction of the v-Ki-*ras* oncogene, they are converted from a simple epithelium to a multilayer, with great heterogeneity in overall cell morphology.[179] Ultrastructural examination of these cells suggests that apical–basal polarity is severely compromised. Microvilli are diminished from the cells at the top layer, and organization of the cytoplasm is scrambled. Golgi complexes and centrosomes, which normally reside in an apical supranuclear location, are now randomly positioned.[179] Despite this apparent high degree of disorganization, immunocytochemical localization of specific antigens and physiological measurements suggests that polarity is not totally disrupted. Basolateral proteins, including Na^+/K^+-ATPase and the cell-adhesion molecule E-cadherin, are restricted to regions of cell–cell contact, as in normal polarized MDCK cells. Apical proteins, on the other hand, are randomly localized to the free surface of the multilayered epithelia, as well as to areas of cell–cell contact in cells throughout the multilayer. The tight junctional antigen ZO-1 is found typically at the point where the free and adherent surfaces of the uppermost cell layer meet, as well as at a number of sites within the multilayer.[179] The latter may be intercellular lumina or canaliculi connected to the upper surface. This localization probably reflects the presence of functional tight junctions, because the multilayer is both electrically tight and impermeant to inulin.

It is interesting to note that recent studies demonstrate that proteins encoded by tumor suppressor genes may function as key regulators of polarity. Mutations in the von Hippel–Lindau tumor suppressor gene can lead to renal cell carcinoma. While the primary function of the von Hippel–Lindau gene product (VHL) relates to the negative regulation of the activity of the hypoxia inducible factor (HIF) transcription factor, the VHL protein also appears to participate in the formation or stabilization of intercellular adhesive junctions.[353] Mutations in the gene encoding the LKB1 protein kinase are responsible for Peutz–Jaeger syndrome, an inherited form of tumor susceptibility associated with the development of numerous hamartomas. Epithelial cells expressing LKB1 that is constitutively activated are able to form polarized domains in the absence of cell–cell and cell–substratum contact.[354] Thus, proteins that participate in epithelial polarization may function as tumor suppressors by virtue of their capacity to control the growth and morphogenesis of the cells in which they are expressed.

Ischemic Injury

Other alterations in cell polarity may come about through the effect of renal ischemia on the tubular epithelium.[355–358] Ischemic episodes of less than 1 hour often do not lead to tubular necrosis but may, nevertheless, cause diminished sodium and water uptake by the proximal tubule.[359] Such brief ischemia compromises the polarity of tubular cells, resulting in

the redistribution of a fraction of the Na^+/K^+-ATPase from the basolateral domain to the apical domain, preventing net sodium uptake by the tubule.[359,360] At the same time, leucine aminopeptidase moves from the apical to the basolateral domain, and also becomes intracellular, presumably through endocytosis. At later times, Na^+/K^+-ATPase and leucine aminopeptidase are randomly distributed on the plasma membrane of tubular epithelial cells, remaining attached to the basement membrane or exfoliated into the lumenal space. The mechanism leading to this loss of polarity is not known. It is possible that ischemia, which is known to affect mitochondria and other organelles and to possibly alter the permeability of the plasma membrane, may result in increased cytoplasmic calcium concentrations.[355,358] This, in turn, could disrupt elements of the cytoskeleton, perhaps affecting the maintenance of polarity. These may represent disruption or perturbation of the cortical actin cytoskeleton. In fact, *in vitro* studies with renal epithelial cell lines demonstrate that ATP depletion causes disassembly of the cytoskeleton and redistribution of actin from its normal locations in the cell cortex, terminal web, and microvilli to perinuclear cytoplasmic aggregates.[361,362] In addition, energy depletion can lead to the endocytic internalization and proteolytic cleavage of cell adhesion molecules such as E-cadherin.[363,364] Such alterations might affect transduction of spatial signals from the extracellular matrix to the polarization machinery along the lines previously discussed.

During reperfusion following renal ischemia, tubular epithelial cells detach from the basement membrane and accumulate in the lumen. It has been postulated that ischemia-induced depolarization of integrins from basal to apical domains of the plasma membrane contributes not only to cell detachment, but also to cell aggregation and tubular obstruction. According to this hypothesis, at early times post-ischemia, redistribution of integrins would loosen attachment of cells from the basal lamina, allowing some of them to detach.[365–367] Released cells would then aggregate and adhere to remaining tubular epithelial cells via their integrins. These would either bind directly to each other by homotypic interactions or associate through bridging matrix molecules. Collections of such aggregates would obstruct the tubules, causing oliguria and destruction of renal tissue.[365–367] In support of this hypothesis, integrins were observed to redistribute apically in oxidatively injured epithelial cell lines.[365] Even more compelling was the observation that infusion of RGD peptides, which block some integrin–matrix interactions, appeared to ameliorate the effects of ischemia-induced by clamping of the renal artery.[367,368] More recent *in vivo* findings utilizing a rat model of renal ischemia do not, however, support this hypothesis, at least with regard to β1 integrins.[156] Soon after reperfusion, β1 integrins redistributed from a strictly basal to basolateral location in cells of the S3 segment of the proximal tubule, but did not appear on the apical plasma membrane at this time.[156] Surprisingly, β1 integrins could not be detected by immunofluorescence in cells released from the basal lamina into the tubular lumen, precluding the possibility that they were mediating either cell aggregation or attachment of exfoliated cells to the residual tubular epithelium. Apical β1 integrins only appeared at later times post-ischemia, as cells lost polarity in the process of regeneration.[156]

Genetic Diseases of Proximal Tubule Apical Endocytosis: Dent's Disease and the Oculo Cerebral Renal Syndrome of Lowe

It is interesting to note that at least two genetic diseases with overlapping constellations of symptoms lead to perturbations of the proximal tubule's megalin-mediated scavenging activity that normally prevents the urinary loss of low molecular weight filtered proteins. Dent's disease is caused by inactivating mutations in the gene encoding the ClC5 protein, which functions as a chloride:proton exchanger in the membranes of proximal tubule epithelial cell endosomes.[369,370] ClC5 activity leads to the accumulation of chloride ions in these endosomes, which appears to be required for steps in the internalization or recycling of the proximal tubule endocytic machinery. The Oculo Cerebral Renal Syndrome of Lowe is caused by mutations in an inositol lipid phosphatase that participates in controlling the inventory of inositol phospholipids in subcellular membranes.[371] These inositol phospholipids help to establish the compartmental identity of subcellular membranes, and to facilitate the assembly of trafficking machinery on their cytosolic surfaces. While the precise mechanisms through which intra-endosomal chloride concentrations and intramembranous inositol phospholipid levels participate in the process of megalin endocytosis remain to be elucidated, it is clear that both of these parameters collaborate in generating or maintaining the proximal tubule epithelial cell's unusual active apical endocytic machinery.

Polycystic Kidney Disease

The progressive formation of renal cysts, which characterizes autosomal dominant polycystic kidney disease (ADPKD), has also been suggested to occur as a result of polarity defects. ADPKD is the most common potentially lethal dominant genetic human disease. Approximately 85% of all cases are linked to mutations in the PKDl gene, with another 10% linked to PKD2.[108,372] While the specific functions of the proteins encoded by these genes are the focus of intense study, the behavior of cyst

epithelial cells *in situ* and in culture is consistent with a role for the PKD proteins in directing epithelial differentiation. Whereas renal tubular epithelial cells normally mediate fluid and electrolyte absorption, cyst epithelial cells carry out net secretion.[373,374] It has been suggested that the proximal cause of renal cyst formation in polycystic kidney disease may be the mis-targeting of Na^+/K^+-ATPase to the apical plasmalemma.

According to this model, the presence of sodium pump at the apical surface leads to active apical ion secretion and the accumulation of lumenal cyst fluid.[375,376] Other studies suggest that mis-localization of Na^+/K^+-ATPase cannot be the primary driving force for cyst fluid accumulation. When examined in cyst cells in culture or *in situ*, the Na^+/K^+-ATPase was found to be exclusively basolateral.[377] Instead, the secretion appears to be driven by intracellular chloride accumulation via a basolateral $Na^+/K/^+2Cl^-$ co-transporter and apical chloride exit through the CFTR protein.[377] A similar mechanism is responsible for fluid secretion by the poorly differentiated epithelial cells lining the crypts of the small intestine. As these crypt cells migrate up the intestinal villus they mature functionally, metamorphosing from secretory into resorptive epithelial cells.[378] It has been suggested that the secretory phenotype is characteristic of immature epithelial cells, while more highly developed epithelial cells acquire the capacity to absorb fluid and electrolytes.[379] The physiologic similarities relating cyst and crypt epithelial cells has prompted the hypothesis that loss of appropriate PKD function results in the dedifferentiation of mature resorptive renal tubular epithelial cells into more primitive secretory cells. The precise mechanisms through the PKDl and PKD2 mutations produce the dramatic pathology associated with ADPKD, and the potential role of epithelial differentiation and sorting pathways, remain to be determined.

Acknowledgments

K. S. Matlin and M. J. Caplan acknowledge support for the research in their laboratories through grants from the National Institutes of Health. They would also like to thank Aki Manninen for permitting the use of unpublished material, Jonathan Bowen and Elias T. Spoliotis for the images in Figure 1.2, and Ms. Ruth Crawford for assistance with the references.

CHAPTER

2

Mechanisms of Ion Transport across Cell Membranes

Luis Reuss and Guillermo A. Altenberg

Department of Cell Physiology and Molecular Biophysics, and Center for Membrane Protein Research, Texas Tech University Health Sciences Center, Lubbock, Texas, TX, USA

INTRODUCTION

Ion transport by cell membranes serves two important purposes in pluricellular organisms, the maintenance of the volume and composition of the intracellular fluid, and the preservation and regulation of the volume and composition of the extracellular fluid. The first process involves fluxes between the cell interior and its surrounding medium ("homocellular" transport[91]), whereas the second one occurs because of transport across epithelial and endothelial cell layers (transcellular or "heterocellular" transport[91]). In addition, ion transport across intracellular membranes, which surround the nucleus and cytoplasmic organelles, is essential to generate and maintain ion concentration gradients between those organelles and the cytosol.

Needless to say, the narrowly regulated volume and ionic composition – inorganic cations (Na^+, K^+, H^+, Ca^{2+}, Mg^{2+}) and anions (Cl^-, phosphate, bicarbonate) – of the intracellular fluid is essential for cell survival, and for the cell's normal functions. A similar argument can be made for the extracellular fluid compartments, that is, whole body balances of water and the ions listed above are essential for the survival, growth, and development of the organism.

Our main focus in this chapter will be on the molecular mechanisms of ion transport by the plasma membranes of cells. The cell membrane is a phospholipid bilayer doped with abundant proteins. This structure is both a barrier between the cytoplasm and the extracellular fluid, and the pathway for ion and water transport between the two compartments. For most ions, the lipid bilayer is the barrier and membrane transport proteins are the pathway for these fluxes.

The Cell Interior and Extracellular Fluid Have Different Ionic Compositions

A crucial property of living cells is their capacity to maintain an internal (intracellular or cytosolic) composition different from that of the surrounding (extracellular) medium. As with all other ionic solutions, the cytosol and the extracellular fluid obey the principle of macroscopic (or bulk) electroneutrality, that is, the sum of cationic and anionic charges are the same in each compartment. As discussed below, there is a microscopic deviation from this principle at the membrane surfaces when there is a difference in electrical potential across the membrane, but the actual differences between anion and cation concentrations are extremely small.

The maintenance of ionic asymmetry between intracellular and extracellular compartments is based on the existence of the cell membrane (or plasma membrane), which separates the cell interior from its surroundings. As shown schematically in Figure 2.1, the membrane is a phospholipid bilayer, with high protein content. Membrane proteins can span the phospholipid bilayer (integral proteins, some of which span the membrane and are known as transmembrane proteins) or can be associated with the membrane surface (peripheral proteins). Transmembrane proteins perform many functions, including translocation of ions, nonelectrolytes, and water across the membrane (transport function, the main theme of this chapter); sensing and early transduction of extracellular events (signaling function); attachment to components of the cytoskeleton, the extracellular matrix or adjacent cells (adhesion function).

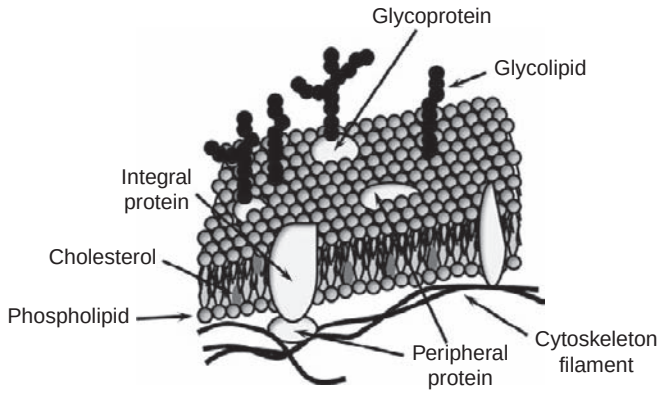

FIGURE 2.1 **Structure of the plasma membrane.** This two-dimensional representation of the plasma membrane is based on the fluid-mosaic model[95,96] modified according to recent observations.[30,59,71,94,112] The membrane is a lipid bilayer that contains integral and peripheral membrane proteins. The bilayer is largely made of phospholipids that have polar heads and hydrophobic tails. The hydrophobic tails face each other, while the polar head groups face the adjacent aqueous solutions (extracellular fluid and cytosol). In addition, the membrane contains glycolipids and cholesterol. The phospholipid compositions of the two leaflets differ; e.g., phosphatidyl inositol is more abundant in the inner leaflet. Additionally, certain areas of the membrane form *lipid rafts* (see text). A small fraction of the membrane surface area is occupied by either strongly-bound proteins (integral membrane proteins), some crossing the membrane one or more times (transmembrane proteins) or loosely attached (peripheral) membrane proteins. Membrane proteins can be glycosylated or have other post-translational modifications (not shown). Some membrane proteins are attached to components of the cytoskeleton or the exoskeleton, directly or via other proteins. Integral membrane proteins can associate forming oligomers, as well as macromolecular complexes.

Two properties of the cell membrane are needed to generate and maintain the intracellular ion composition essential for life: the barrier function and the transport function. This distinction is didactically convenient, although both functions are clearly linked. By the barrier function, the cell membrane prevents the flux of certain molecules; by the transport function, it translocates certain molecules. These two functions bring about a steady-state in which cell volume and composition are kept constant and appropriate for cell survival. Relative to the extracellular fluid, some substances are maintained at high concentrations (e.g., K^+ and ATP), whereas others are maintained at low concentrations (e.g., Ca^{2+} and Cl^-) inside the cell.

The cell interior is not homogeneous, but is rather a complex medium including a highly structured cytoplasm (cytosol and cytoskeleton) and numerous organelles. The latter are separated from the cytosol by their membranes. Exchanges between each organelle and the cytosol occur by mechanisms similar to those present in the plasma membrane. In this chapter, we will not address organelle membrane function.

The Plasma Membrane: Structure Related to Function

The plasma membrane, which is 3–8 nm thick, is largely formed by phospholipids, organized in a bilayer, and proteins. The main phospholipids are phosphatidylcholine and phosphatidylethanolamine, with lower levels of phosphatidylinositol, phosphatidylserine, and phosphatidylglycerol, and sterols (cholesterol, ergosterol, zymosterol).[6,63] The precise proportions vary among cells. Hydrophobic or amphipathic proteins are essential components of biological membranes. In most membranes, the w/w protein: lipid ratio is *ca.* 1, and therefore a membrane protein of *ca.* 40 kDa is surrounded by 50–55 lipid molecules.

Experimental work during the last two or three decades has ruled out the "fluid-mosaic" (Singer and Nicolson) model of membrane structure.[95,96] In this model, biological membranes are considered two-dimensional viscous phospholipid bilayers in which integral membrane proteins are randomly distributed and free to rotate and diffuse laterally. A main objection is the demonstration of asymmetry in the lipid composition of the membrane.[71] The current view is that the plasma membrane is a highly-organized and asymmetric structure composed of lipids and proteins.[30] There are lateral differences in lipid composition within a monolayer; sphingolipids, sterols, and phosphatidylcholine predominate on the extracellular leaflet, whereas the cytoplasmic leaflet is enriched in phosphatidylinositol, phosphatidylethanolamine, phosphatidylserine, and phosphatidic acid, which results in a negative charge that facilitates binding of peripheral and transmembrane proteins.[71] In addition, many membrane proteins cluster with others in microdomains, in which the lipid composition may differ from that of the bulk bilayer. These clusters are maintained by intramembrane lipid–lipid, protein–protein, and protein–lipid interactions, as well as interactions with intracellular molecules (cytoskeletal proteins) and extracellular components (extracellular matrix proteins and membrane proteins of adjacent cells). It is clear that the two monolayers also differ in composition. Lipid rafts are microdomains in the submicron range in which cholesterol and sphingolipids are enriched in the external leaflet, and cholesterol and phospholipids with saturated fatty acids in the internal leaflet of the plasma membrane. The surrounding bilayer is abundant in unsaturated fatty acids and contains more fluid than that in the raft.[59] Lipid rafts exclude certain proteins and organize others in specific oligomeric structures.[94] Rapid changes in composition and location in the membrane are essential for the role that lipid rafts play in signaling processes (e.g., receptor tyrosine kinases).

Phospholipids in the plasma membrane are not just a barrier and a "solvent" for membrane proteins, but play important roles in signaling processes. Inositol-1,4,5-triphosphate, diacylglycerol, and phosphatidylinositol-3,4,5-triphosphate (derived from phosphatidylinositol) are good examples.[9,72,73] Phosphatidylinositol 4,5-bisphosphate (PIP_2) exerts regulatory effects on a number of ion channels and other transport proteins. Its effects can be stimulatory or inhibitory and appear to require PIP_2 binding.[49,102] Other signaling molecules originating from plasma membrane phospholipids are arachidonic and docosahexaenoic acids, which are generated from phosphatidylethanolamine, phosphatidylcholine, and phosphatidylinositol by the action of phospholipase A_2. Certainly, being a dielectric is not the only function of the phospholipid moiety of the cell membrane.

This new notion of the structure of the plasma membrane[112] is based on results of biophysical studies, including fluorescence recovery after photo-bleaching, single-particle tracking techniques, optical trapping by laser tweezers, and fluorescence correlation spectroscopy. These methods, applied to cell membranes, have yielded quantitative dynamic information on the distribution, mobility, and compartmentalization of membrane proteins.[112] Biochemical, molecular, and physiological studies indicate that membrane transport proteins are not randomly distributed, but that they undergo homo- and hetero-associations,[59] and that these associations may have functional significance. A case in point is the proposed proximity between plasma membrane Ca^{2+} channels and Ca^{2+}-sensitive proteins, including Ca^{2+}-activated channels: Ca^{2+} entry results in a large, but highly localized, increase in intracellular [Ca^{2+}], because of effective cytosolic buffering, and thus its signaling effects may be quite local.[70]

In summary, the current view of the structure of the plasma membrane is that of a compartmentalized two-dimensional structure, mosaic-like, with less fluidity than proposed by the Singer–Nicolson model. The phospholipids have signaling functions in addition to previously recognized ones. The mobility of membrane proteins may be restricted by the structure of the lipid domain, interactions with cytoskeletal proteins or other cytoplasmic components, and/or homo- and hetero-associations with other integral membrane proteins. Future studies of membrane transport proteins along these lines are likely to reveal important aspects of their function and regulation in health and disease (see Chapter 14).

The Plasma Membrane is Selectively Permeable

The barrier and transport functions of the plasma membrane are determined by its composition, mostly regarding lipids and integral transmembrane proteins (for membrane structure, see references [59,95,96] and [112]; for a review of membrane proteins, see [103]). When the membrane is *permeable* to a specific molecule, then that molecule can cross the membrane. *Permeability* (cm s^{-1}) is a property of a specific membrane for a specific molecule. The amount of substance that crosses the membrane per unit of time and membrane area is the *flux*. Using radioactive techniques, unidirectional fluxes can be measured (e.g., in case of a cell, influx and efflux); the *net flux* is the difference between the two unidirectional fluxes. A finite net flux denotes the presence of either a net driving force across the membrane or an active process.

Permeation of a specific molecule can take place through the lipid phase (i.e., *solubility diffusion*) and/or through membrane proteins (i.e., *mediated transport*). Solubility diffusion always results in equilibrating transport, dissipating differences in concentration or electrochemical potential (see the section "Diffusion and Electrodiffusion," below). In contrast, mediated transport can either dissipate or generate differences in chemical or electrochemical potentials across the membrane. An example of mediated transport is the operation of the sodium pump, the Na^+,K^+-ATPase.

The lipid phase of the plasma membrane is hydrophobic, and therefore has high permeability for lipophilic molecules and low permeability for hydrophilic molecules. Thus, a protein-free phospholipid membrane has a high permeability for nonpolar small molecules such as O_2 and CO_2, a much lower permeability for uncharged small polar substances such as water, urea, and glycerol, and an extremely low permeability for ions and larger uncharged polar molecules, such as glucose. Most molecules are measurably permeable across plasma membranes. However, the diffusive permeability coefficients range over several orders of magnitude. It is thought that hydrophilic molecules permeate the membrane bilayer to some extent, because the thermal motion of the phospholipid molecules causes transient kinks in the bilayer structure.

Transport proteins can be classified in four groups, namely pores, channels, carriers (also referred to as transporters), and pumps (see next section). The expression of some transport proteins can be specific to tissue, cell, and sometimes membrane domain. Others are expressed in most, if not all, cell membranes. The functional significance of transport proteins is apparent in two realms. Some are primarily related to the establishment and maintenance of cellular composition (intracellular "homeostasis"), such as the Na^+,K^+-ATPase and K^+ channels in most animal cells. Others are primarily related to specific cell functions, such as excitability (e.g., the tetrodotoxin-sensitive, voltage-activated Na^+ channel in nerve and muscle), and transepithelial Na^+ transport (e.g., the

amiloride-sensitive, voltage-insensitive Na^+ channel in the apical membrane of certain epithelial cells).

A *pore* is an aqueous communication between both sides of the membrane, accessible to both sides at all times – that is, it is always "open" (permeable). A *channel* is also an aqueous communication between the two sides of the membrane, but it opens and closes stochastically by changes in conformation called *gating*; when open, a channel is accessible from both sides of the membrane, when closed, it is impermeable. A *carrier* is a membrane transport protein whose permeation pathway is not simultaneously accessible to both sides of the membrane, but to one side at a time; changes in conformation change the orientation of the carrier, moving the transported ion to the other side; an appropriate simplified description is that a carrier has two gates and they are never open at the same time. Finally, a *pump* has the properties of a carrier, but in addition it is coupled to a metabolic energy source, in most cases hydrolysis of ATP.

MECHANISMS OF ION TRANSPORT

Ion Transport can be Active or Passive

The definitions of active and passive transport are thermodynamic. Passive transport occurs in the direction expected for the existing driving force, which in the case of ions involves the chemical gradient (given by the difference in concentration between the two sides of the membrane) and the electrical gradient (given by the transmembrane electrical potential difference or membrane voltage). In other words, passive transport is energetically downhill. In contrast, active transport takes place in the absence of or against the prevailing electrochemical gradient. In other words, active transport is energetically uphill, and therefore requires an energy input. Depending on the origin of this energy, one can distinguish two types of active transport.

Primary active transport is characterized by the direct use of metabolic energy, supplied by light, redox potential or ATP hydrolysis. In most cases of plasma membrane primary active transport in eukaryotic organisms, the energy is provided by the hydrolysis of ATP, a process catalyzed by the same molecule that performs the transport. Hence, in this case the transporter is also an ATP hydrolase (ATPase). Transporters responsible for primary active transport are referred to as pumps. In plasma membranes of most animal cells there can be expression of one or more of four ion-transporting ATPases. These are the Na^+,K^+-ATPase, H^+-ATPase, H^+,K^+-ATPase, and Ca^{2+}-ATPase.

Secondary active transport is characterized by the indirect use of metabolic energy. The energy stored in the electrochemical gradient of one substrate is utilized to transport actively another species (ion or molecule). In animal cells, including those from epithelia, secondary active transport is most frequently linked to Na^+ transport. The Na^+,K^+-ATPase establishes an electrochemical potential gradient for Na^+ across the plasma membrane, which includes chemical (high extracellular and low intracellular [Na^+]) and electrical components (cell electrically negative to the extracellular compartment), both contributing to a net driving force favoring Na^+ entry into the cell. This gradient is then utilized by carriers to actively transport other substrates, by coupling their translocation to that of Na^+ at the molecular level.

Depending on the directions of the fluxes, there are two kinds of secondary active transport: One is *co-transport* (or *symport*) in which the substrates move in the same direction, such as downhill for Na^+ and uphill for the co-transported substrate (e.g., Na^+-glucose co-transport). The other one is *countertransport* (also *antiport* or *exchange*), in which the fluxes are in opposite directions (e.g., $Na^+ - H^+$ exchange). In most instances, secondary active transport involves only two species (Na^+ and another substrate), but in some cases there are three: an example is the Na^+-K^+-$2Cl^-$ co-transporter, an electroneutral symporter that is expressed principally in epithelial cells. This transporter accounts for uphill Cl^- uptake, a step necessary for Cl^- absorption (e.g., in the apical membrane of cells of the thick ascending limb of the loop of Henle) or Cl^- secretion (e.g., in the basolateral membrane of crypt cells in the intestine and epithelial cells in the airway). For quantitative analyses of membrane transport processes, see Läuger,[64] Macey and Moura,[67] and Stein.[99]

Active and Passive Transport Processes can be Evaluated by Considering Direction of Electrochemical Potential Difference (Driving Force)

As stated above, passive transport is energetically downhill, driven by the pre-existing driving force; this force depends on the chemical or electrochemical gradient, for uncharged and charged solutes, respectively. Under isothermal conditions the driving force encompasses differences in concentration, electrical potential, and/or pressure across the membrane. Under these conditions, the electrochemical potential difference ($\Delta\overline{\mu}_j$) for the jth ion is given by Eq. (2.1):

$$\Delta\overline{\mu}_j = z_j V_m F + RTln\left(\frac{C_j^i}{C_j^o}\right) + \Delta P\overline{V}_j \qquad (2.1)$$

where z is the valence, V_m is the membrane voltage, F is the Faraday constant, R is the gas constant, T is the absolute temperature, C is the concentration, i and o refer to

the two sides of the membrane (inside and outside, respectively), ΔP is the transmembrane hydrostatic pressure difference, and $\overline{V}_j$ is the ion's partial molar volume. The electrochemical potential has the three components defined above, given by the three terms on the right side of the equation. Across animal cell membranes, steady-state hydrostatic or osmotic pressure differences are small or nil (see Chapter 4), and therefore the third term of Eq. (2.1) is eliminated, yielding:

$$\Delta\overline{\mu}_j = z_j V_m F + RTln\left(\frac{C_j^i}{C_j^o}\right) \tag{2.2}$$

This equation is used to evaluate the driving force for ion transport under isobaric conditions. In the case of nonelectrolytes, $z = 0$ and the first term of Eq. (2.2) can also be eliminated, yielding:

$$\Delta\mu_j = RTln\left(\frac{C_j^i}{C_j^o}\right) \tag{2.3}$$

where $\Delta\mu_j$ denotes the chemical potential difference. This equation describes the driving force for nonelectrolyte transport.

From Eq. (2.2) (under isobaric and isothermal conditions), Ussing[111] derived the flux-ratio equation, a fundamental expression which provides a thermodynamic test for active or passive transport:

$$J_{in}/J_{out} = (C_i/C_o)\exp(zV_mF/RT) \tag{2.4}$$

where J is flux (the subscripts denote influx and efflux, respectively). The test proceeds as follows: the ratio of unidirectional fluxes (J_{in}/J_{out}) is determined experimentally, and the driving forces are measured; if the ratio deviates from the prediction given by Eq. (2.4), which evaluates the passive driving forces, then active transport is suspected. Deviations from the flux-ratio equation can also result from the presence of exchange diffusion and single-file diffusion, as discussed by Schultz.[90]

Pathways and Mechanisms of Passive Transport

Passive transport can be *via* the lipid bilayer (solubility diffusion) or *via* transmembrane proteins (mediated). Solubility diffusion is a permeation process that involves the movement of a molecule dissolved in the aqueous solution bathing one side of the membrane into the lipid phase of the membrane, then across the membrane, and then from the membrane lipid into the solution bathing the opposite side. Clearly, two processes are involved. The first one ("solubility") governs the fluxes at the solution–membrane interface, and depends on the relative solubility of the molecule in lipid and water, which can be quantified by the oil–water partition coefficient, β, a coefficient equal to the ratio of the molecule's steady-state concentrations in lipid and water. The second process ("diffusion") governs the solute translocation within the membrane lipid, which depends largely on the mass and shape of solute molecules. The lipid solubility of the molecule is the main factor determining its permeability via the lipid moiety of the membrane.

Mediated transport is the mode of transmembrane transport of substances with very low solubility in phospholipids, that is, charged and polar substances. The transport proteins provide a hydrophilic path across the membrane, through which the solute permeates or a narrow pore in which amino acid charges replace the water molecules surrounding the ion or polar molecule in free solution.

Diffusion and Electrodiffusion

Diffusion and electrodiffusion are the main processes of passive solute transport across homogeneous phases (e.g., lipid membranes or aqueous pores) by independent motion of the solute molecules. Diffusion applies to uncharged particles and electrodiffusion to ions. Although diffusion does not strictly apply to ion transport, its analysis is simpler and helps in understanding electrodiffusion.

Diffusion of a solute in aqueous solution is the result of the random thermal motion of solute molecules. In the absence of convection, if there are differences in concentration between different sectors of the solution, then random solute motion will tend to make its distribution homogeneous (equilibrating transport). All solute particles move randomly at uniform average velocities, dependent on the solution temperature. Hence, more particles will tend to move from regions of high concentration to sectors of low concentration than in the opposite direction, simply because there are more particles per unit volume in the high concentration regions. In other words, differences in concentration cause unequal unidirectional fluxes in a regime of diffusion because of differences in the number of particles flowing in each direction per unit of time, not because of different velocities of individual particles flowing in one direction or the other. In diffusion, the molecules move independently of each other and of other particles present in the solution, that is, there is no flux coupling. This is the *independence principle*.

Diffusion of a nonelectrolyte in solution is described by Fick's first law[34]:

$$J_s = -D_s\frac{dC_s}{dx} \tag{2.5}$$

where J_s is the solute flux (moles $cm^2\,sec^{-1}$), D_s is the solute diffusion coefficient ($cm^2\,sec^{-1}$) and dC_s/d_x is the concentration gradient. The negative sign denotes the direction of the flux.

Fick's second law of diffusion[34] considers the time course of the process:

$$\frac{dC}{dt} = D_s \frac{d^2C_s}{dx^2} \tag{2.6}$$

where dC/dt is the rate of change in solute concentration, and x denotes distance.

The average time required by diffusing particles to cover a given distance is inversely proportional to the diffusion coefficient, and directly proportional to the square of the traveled distance. Einstein approximated the second law of diffusion with $\lambda = (D_s t)^{1/2}$, where λ is the traveled distance in the x-axis. The dependence of t on the square of the distance makes diffusion a very slow transport process for long distances. For a typical $D_s = 10^{-5}$ cm^2 sec^{-1}, it takes 1 millisecond for the solute to diffuse 1 μm, but it takes 1000 seconds (*ca.* 16.7 minutes) to diffuse 1 mm. Convective flow (see Chapter 9) is a much more effective mass transport mechanism for long distances.

Now we consider a thin lipid membrane of thickness δ_m separating two aqueous compartments (Figure 2.2). The solutions on both sides are well stirred, so that the solute concentrations are homogeneous in both. Inserting the solute partition coefficient (β_s) in Eq. (2.5) (β_s denotes lipid solubility relative to water solubility), we obtain the following expression for the solute flux:

$$J_s = -\frac{D_s \beta_s}{\delta_m} \Delta C_s \tag{2.7}$$

where ΔC_s is the solute concentration difference between the two solutions. Defining the solute permeability (P_s) as $P_s = D_s\, \beta_s\, / \Delta_m$, Eq. (2.7) reduces to:

$$J_s = -P_s \Delta C_s \tag{2.8}$$

The diffusive permeability coefficient of the membrane relates the flux to the driving force and denotes the ease with which the membrane permits mass transfer of a particular species. Its units are cm s^{-1}, those of velocity. In the simple case of a nonelectrolyte, under isothermal and isobaric conditions, the permeability (P) of solute s is given by a rearrangement of Eq. (2.8): $P_s = J_s/\Delta C_s$. This is the phenomenological, experimentally determined permeability, calculated by dividing the steady-state solute flux by the difference between the solute concentrations of well-stirred bathing solutions. The other definition of diffusive permeability is mechanistic, and considers the factors involved in solubility diffusion, D_s, β_s, and δ_m, as described above.

The preceding discussion considers the specific case of solubility diffusion, but the phenomenological definition of permeability can be applied in principle to any transport mechanism. Of course, its interpretation varies. An important case is that of the permeation of certain hydrophilic nonelectrolytes through aqueous pores in the membrane. If the lipid bilayer is impermeable to the solute, then diffusive transport is entirely via the pores. The permeable area of this membrane (S_p) is only a fraction of the total membrane area, given (for 1 cm^2 of membrane) by $S_p = n\pi r^2$, where n is the density of homogeneous pores of radius r. The partition coefficient is unity (the solute is dissolved in water both inside and outside of the pore), and is hence eliminated from the equation:

$$P_s = n\pi r^2 D_s / L \tag{2.9}$$

where L is the pore length (nearly equivalent to membrane thickness).

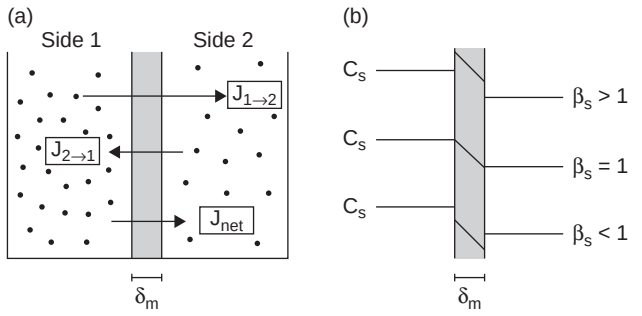

FIGURE 2.2 **Diffusion across a membrane.** (a) A membrane separates two aqueous solutions (1 and 2). The dots represent molecules of a solute to which the membrane is permeable; the solute concentration (C_s) is greater in solution 1. Solute molecules move randomly in each solution and collide with the membrane with a probability proportional to the concentration. Solutes collide, dissolve in, and diffuse across the membrane. The unidirectional fluxes ($J_{1\rightarrow2}$ and $J_{2\rightarrow1}$) are proportional to the solute concentrations in sides 1 and 2, respectively; the net flux (J_{net}) is proportional to the concentration difference. The concentration difference does not accelerate the molecules, and hence it is not a force, although it is usually referred to as the *chemical driving force*. Diffusion is a passive, equilibrating transport, i.e., net transport ceases when the concentrations on both sides of the membrane are equal. (b) Lines denote solute concentration profiles in the solutions and the membrane depending on the partition coefficient (β_s). When $\beta_s = 1$, solute concentration in the membrane boundaries are identical to those in the adjacent solutions; concentrations in the membrane are greater or smaller than those in the adjacent solution if β_s is greater or smaller than unity, respectively. The membrane thickness is denoted by δ_m.

Electrodiffusion

Electrodiffusion is the main mechanism of passive transport of ions in homogeneous media, that is, bulk aqueous solution or relatively large water-filled pores. Electrodiffusive transmembrane ion transport is a mediated transport process, but it is better discussed with diffusion for continuity. In large-diameter pores, electrodiffusion theory explains ion permeation very well. In ion channels, which have smaller diameter and are highly selective, there are significant interactions between the

ions and the permeation pathway. For this reason, simple electrodiffusion theory is not entirely applicable to ion channels, but is nevertheless a useful approximation. For ion transport across a membrane, two factors determine the flux: the chemical potential difference (difference in concentration across the membrane) and the electrical potential difference (membrane voltage). The net ion flux (J_i) is given by the Nernst–Planck equation (see [50]). If a constant electrical field is assumed in the membrane and other assumptions are made, the Nernst–Planck equation can be solved, yielding the Goldman–Hodgkin–Katz (GHK) equation[41,51]:

$$J_i = -P_i \frac{z_i V_m F}{RT}\left[\frac{C_i^o - C_i^i \exp(V_m F/RT)}{1-\exp(V_m F/RT)}\right] \qquad (2.10)$$

where R, T, z, and F have their usual meanings, P is permeability, V_m is membrane voltage, C is concentration, the subscript i denotes the ith ion, and the superscripts i and o denote the two sides of the membrane.

Under zero current conditions, the GHK flux equation yields the membrane voltage as a function of the permeabilities and concentrations of all permeant ions. For the case of three monovalent permeant ions (Na^+, K^+, and Cl^-), the equation (GHK voltage equation) is:

$$V_m = -\frac{RT}{F}\ln\frac{P_{Na}[Na^+]_i + P_K[K^+]_i + P_{Cl}[Cl^-]_o}{P_{Na}[Na^+]_o + P_K[K^+]_o + P_{Cl}[Cl^-]_i} \qquad (2.11)$$

where the brackets denote concentrations. Note that if the fraction including permeability coefficients and ion concentrations is inverted, then the sign of the right side of the equation is also inverted. We prefer the notation given here, because it gives the intracellular potential minus the extracellular potential, the convention used in electrophysiology. This also applies to the Nernst equation below.

Note that if only one ion is permeable, e.g., if P_{Na} and P_{Cl} are 0 in Eq. (2.11), then the membrane voltage becomes equal to the equilibrium potential for that ion, in this example K^+. The equilibrium potential is given by the Nernst equation[81]:

$$V_m = -\frac{RT}{F}\ln\frac{[K^+]_i}{[K^+]_o} \qquad (2.12)$$

Under these conditions, the two compartments separated by the membrane are at a *steady-state* (the amounts of K^+ on each side remain constant with time), but also at *equilibrium*, which means that the net driving force for K^+ is zero, and hence the unidirectional fluxes are equal (Figure 2.3). In the case of cells, one frequently observes a steady-state K^+ distribution without equilibrium; the net efflux through channels is exactly balanced by influx via the Na^+,K^+-ATPase.

Another interesting point is that the Nernst equation indicates that if only one ion is permeable, then the membrane voltage is determined by the concentration ratio for that ion, not its absolute concentrations. In addition, the membrane voltage is independent of the absolute value of the ion permeability. As shown by the GHK voltage equation, in the case of a membrane permeable to more than one ion, the membrane voltage depends on the absolute concentrations and permeability coefficients of all permeant ions. The Nernst equation can be derived more directly from the definitions of electrochemical potential (Eq. (2.1)) and equilibrium ($\Delta\overline{\mu}_i = 0$).

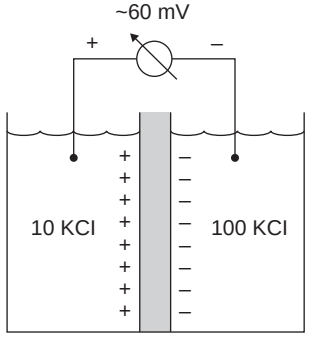

FIGURE 2.3 **Electrochemical equilibrium.** A membrane permeable to K^+ and impermeable to Cl^- separates two KCl solutions of 10 mM and 100 mM concentrations, respectively. Because of the difference in concentrations, there is a chemical driving force for K^+ and Cl^- fluxes from right to left. While the impermeant Cl^- cannot move, the permeant K^+ moves across the membrane, and in doing so creates a difference in electrical potential across the membrane. The membrane becomes electrically charged by a tiny excess of K^+ on the left, and a tiny excess of Cl^- on the right. This difference in electrical potential (the *transmembrane voltage*) opposes further K^+ flux, and a state is reached at which the chemical driving force and the electrical driving force for K^+ movement are equal and opposite. This condition, described by the Nernst equation (Eq. (2.12)), denotes electrochemical equilibrium.

The essential points concerning electrodiffusion are that ion fluxes across membranes are determined by both permeability and driving force, and that the driving force has chemical and electrical components. Hence, these three elements must be known to predict the direction and magnitude of the flux. For example, knowledge of the K^+ concentrations inside and outside a cell is insufficient to decide whether the ion is at equilibrium across the membrane or whether there is a passive driving force inwardly or outwardly directed. To establish this simple point, it is necessary to know the membrane voltage. However, knowledge of the electrochemical gradient is insufficient to predict the magnitude of the K^+ flux expected for this gradient; the K^+ permeability of the membrane must also be known.

Mediated Transport

This expression means that translocation across the membrane is not via the lipid bilayer, but via membrane

transport proteins: pores, channels, carriers or pumps. Mediated transport is the process by which ions and polar nonelectrolytes undergo passive transport across the cell membrane. Hence, this mechanism is complementary to that provided by solubility diffusion, in that it is specialized for hydrophilic solutes, whereas solubility diffusion is more effective for lipophilic solutes. For certain solutes, both mechanisms may operate. Even for solutes with very low permeability across the phospholipid moiety of the membrane, a significant contribution of the diffusive flux may exist because of the large fractional area covered by phospholipids, in particular if there is also a low level of expression of the relevant transporters.

In mediated transport, specialized proteins spanning the membrane provide an aqueous environment that allows for the transmembrane flux of particles that are virtually insoluble in phospholipids. Recent advances have permitted the molecular identification of many of these proteins, as well as the genes that encode them. In addition to providing an aqueous environment for solute translocation, these molecules may undergo conformational changes during or related to the substrate translocation. The transport proteins underlying mediated transport can be classified in four groups: pores; channels; carriers; and pumps.

Thermodynamics of Mediated Passive Transport

Pores, channels, and carriers are membrane transport proteins that can only perform *overall* passive transport, meaning that the total energy employed in the transport is equal to or less than the energy available in the electrochemical gradients (see "Secondary Active Transport" section below). Carriers and channels do not use a metabolic energy supply for solute translocation. Some channels are activated by ATP binding and hydrolysis, but once they become permeable, ion translocation is passive and does not use metabolic energy. Some carriers are able to transport more than one solute in the same cycle. In this case, the energy stored in the electrochemical gradient for one of these solutes (accessory) can be employed for uphill transport of another (principal) solute, a process known as secondary active transport. Nevertheless, the total energy change is dissipative, that is, the energy stored in the accessory solute's electrochemical gradient is always greater than that used to actively transport the principal solute.

Kinetics of Mediated Passive Transport

The dependence of the transport rates on solute concentration are different in solubility diffusion and carrier-mediated transport. As shown in Figure 2.4, in diffusion the flux increases linearly with the concentration, whereas in carrier-mediated transport it saturates. This is explained because transport occurs via a finite number of carrier molecules that can also operate at a finite rate. The simplest case of carrier-mediated transport can be described by the Michaelis–Menten equation; the two kinetic parameters are the maximum flux (J_{max}) and K_m, the concentration at which the flux is half-maximal (see Figure 2.4):

$$J_s = -\frac{C_s J_{\max}}{C_s + K_m} \tag{2.13}$$

where J_s is the solute flux, and C_s is its concentration. For a detailed description of this, and more complex kinetic processes, see Segel.[92]

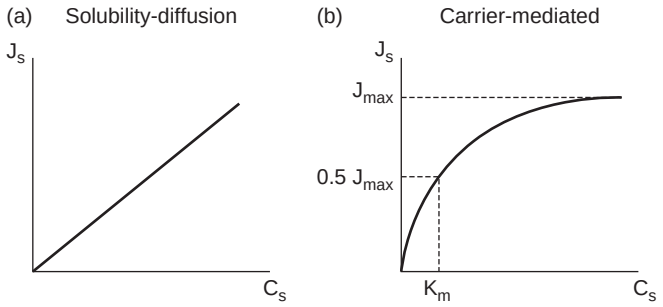

FIGURE 2.4 **Kinetics of diffusion and carrier-mediated transport.** Both graphs depict solute flux (J_s) as a function of solute concentration (C_s). In (a), the mechanism of translocation across the membrane is diffusion, which does not involve chemical reactions between solute and membrane. In (b), the mechanism of translocation is mediated (i.e., it involves a transport protein in the membrane). In (a), the flux is linear with the concentration, whereas in (b) it saturates, because of occupation of a finite number of sites by a solute that moves at a finite velocity. In the simplest case, the relationship in (b) is described by the Michaelis–Menten equation (Eq. (2.13)).

Modes of Coupled Transport

Coupled transport denotes the linked translocation of two or more species (ions and/or molecules) through a barrier. One can distinguish two coupling modes. *Molecular* coupling denotes carrier- or pump-mediated transport of more than one species by the same molecule. Examples shown in Figure 2.5a are the Na^+ and glucose fluxes via the Na^+-glucose co-transporter, and the Na^+ and K^+ fluxes via the Na^+K^+-ATPase. In addition, there is *thermodynamic* coupling. In this case, the fluxes of two or more species occur through different molecules, but are related to each other by electrochemical driving forces. For example, transepithelial Na^+ transport via cell membranes (apical membrane Na^+ channel in series with basolateral membrane Na^+ pump) can produce a transepithelial electrical potential difference responsible for a passive Cl^- flux via the intercellular (junctional) pathway. In this instance, the

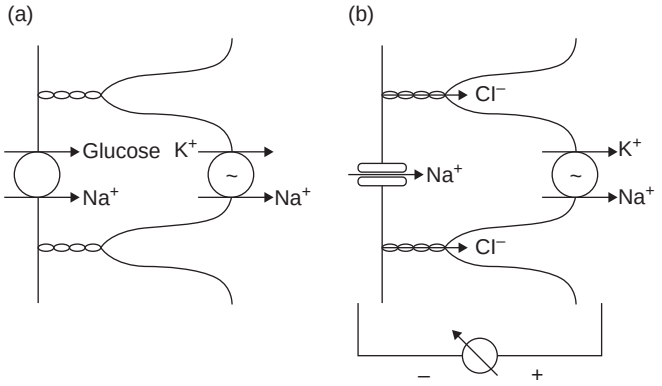

FIGURE 2.5 **Modes of coupled transport.** (a) Molecular coupling: glucose-absorbing epithelial cell (e.g., renal proximal tubule). Two cases of molecular coupling are depicted: the Na^+-glucose symporter (SGLT) at the apical membrane, and the Na^+,K^+-ATPase at the basolateral membrane. In both instances, the transport of two substrates occurs obligatorily in the same transport molecule. (b) Thermodynamic coupling: the epithelial cell depicted absorbs Na^+ by an electrogenic process that generates a lumen-negative transepithelial voltage. This voltage drives a paracellular, electrodiffusive Cl^- flux. The Na^+ and Cl^- fluxes occur via different pathways, and are linked by the driving force, not by binding to the same molecule.

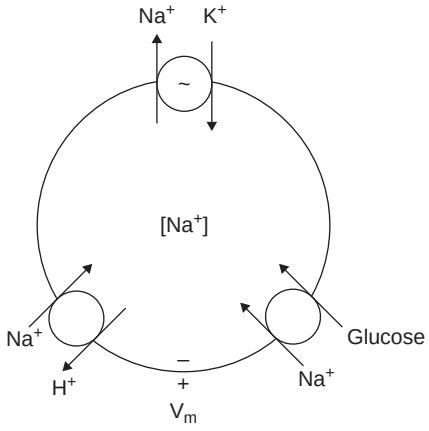

FIGURE 2.6 **Active transport.** The diagram represents a cell expressing three membrane transporters. Top: Primary-active transport of Na^+ and K^+ via the Na^+,K^+-ATPase. The energy for active transport is provided by the hydrolysis of ATP. The flux coupling is $3Na^+$:$2\,K^+$ per ATP molecule hydrolyzed. Bottom: Two mechanisms of secondary active transport. In both cases, the Na^+ electrochemical gradient (oriented inwards) is the driving force for the uphill movement of the other solute (glucose or H^+). On the right, Na^+-glucose co-transport via SGLT, the stoichiometry (Na^+:glucose) is 1:1 (SGLT2) or 2:1 (SGLT1). On the left, Na^+–H^+ exchange via NHE; the stoichiometry is 1:1. Note that the Na^+ driving forces operative in the two cases are different. Since Na^+–H^+ exchange is electroneutral, the driving force depends only on the difference in Na^+ concentrations. Since Na^+-glucose co-transport is electrogenic the driving force involves both the Na^+ chemical gradient and the membrane voltage. For a quantitative analysis, see text.

coupling is not obligatory (if the potential difference is abolished, Cl^- transport ceases while Na^+ transport continues), and does not involve the Na^+ transport molecules. Instead, it corresponds to the parallel operation of two transporters linked by a driving force (Figure 2.5b). This apparently simple point has been a source of confusion in the transport literature (in particular of epithelial cells), where on occasion it has been incorrectly implied that all coupling is molecular.

Pathways and Mechanisms of Active Transport

Primary Active Transport

Primary active transport occurs in the absence of or against the existing electrochemical gradient, and is powered by metabolic energy, such as that originated by the exergonic hydrolysis of ATP (Figure 2.6). Ion pumps are the only molecules capable of performing primary active transport. Most ion pumps of interest to us are transport ATPases, bifunctional molecules that hydrolyze ATP and perform the translocation of the substrate against the prevailing electrochemical gradient. The Na^+,K^+-ATPase[85], Na^+-K^+ pump or Na^+ pump, was the first enzyme demonstrated to be an active ion transporter (reviewed in[97,98]). It is likely that the energy-consuming steps are the conformational changes of the pump protein required for the substrate translocation, that is, for making the substrate first inaccessible to the *cis* side, and then accessible to the *trans* side of the membrane.

Secondary Active Transport

Secondary active transport is characterized by the indirect use of metabolic energy. The electrochemical gradient drives a downhill substrate flux, and part of this energy is utilized for the uphill flux of another substrate (Figure 2.6). The coupling between the two fluxes occurs in the same transport protein, and therefore there is molecular coupling.

In animal cells, secondary active transport is most frequently linked to Na^+ transport. The Na^+,K^+-ATPase establishes an electrochemical potential gradient for Na^+ across the plasma membrane, which includes a chemical (higher extracellular [Na^+]) and an electrical component (cell electrically negative to the extracellular compartment), both contributing to a net driving force (electrochemical gradient) favoring Na^+ entry into the cell. This energy is utilized to transport other substrates by coupling translocation to that of Na^+ at the molecular level.

Depending on the directions of the fluxes, there are two kinds of secondary active transport: *co-transport* (or *symport*), in which the substrates move in the same direction, such as downhill for Na^+ and uphill for the co-transported substrate (e.g., glucose); and *counter-transport* (also *antiport* or *exchange*) in which the fluxes are in opposite directions. Secondary active transport

may involve two substrates (Na^+ and another substrate) or more (e.g., the Na^+-K^+-$2Cl^-$ co-transporter). Sodium-glucose co-transport was the first secondary active transport mechanism studied experimentally, giving rise to the *Na^+ gradient hypothesis*.[16]

Transport by Na^+-glucose co-transporters and Na^+-Ca^{2+} exchangers is electrogenic, that is, there is net translocation of charge across the membrane in each cycle. The concentration ratios (intracellular/extracellular) for glucose and Ca^{2+}, respectively, depend on both the Na^+ concentration ratio and the membrane voltage (V_m). The equation describing the maximum substrate concentration ratio that can be obtained by co-transport is:

$$\frac{S_i}{S_o} = \left[\frac{A_o}{A_i}\right]^n \exp\left(\frac{-nzFV_m}{RT}\right) \tag{2.14}$$

where S is the main substrate (glucose), A is the accessory substrate (Na^+), the subscripts i and o denote intra- and extracellular concentrations, respectively, n is the transport stoichiometry (number of A molecules/number of S molecules), z is the valence of the translocated species per cycle ($z = zA + zS$), V_m is the membrane voltage, and R, T, and F have their usual meanings. Changing to decimal power notation and inserting appropriate values for the constants, the exponent becomes $\sim nzV_m/60$. Hence, in the case of glucose transport via SGLT1 ($n = 2$), for $V_m = -60$ mV and Na^+ concentration ratio is 10, the maximum glucose concentration ratio (cell/lumen) is 10^4.

A similar equation describes the minimum concentration ratio of main substrate that can be achieved by an antiport:

$$\frac{S_i}{S_o} = \left[\frac{A_o}{A_i}\right]^n \exp\left(\frac{-nzFV_m}{RT}\right) \tag{2.15}$$

where the symbols are the same as for Eq. (2.14). The difference is that the concentration ratios for A are inverted in these equations, denoting that in one case S and A are transported in the same direction, and in the other case they are transported in opposite directions. For the example of Na^+–Ca^{2+} exchange with $V_m = -60$ mV and Na^+ concentration ratio is 10, the minimum Ca^{2+} concentration ratio (cell/extracellular) is 10^{-6} for $n = 4$, the most likely stoichiometry.

ION TRANSPORT PROTEINS

Ion transport proteins are best classified in four groups: pores; channels; carriers (also called *transporters*); and pumps. Ion pores and channels are integral membrane proteins that when "open" communicate the aqueous solutions adjacent to the membrane, and permit ion flux in a direction determined by the electrochemical gradient. The permeant ion interacts little with the pore or channel, and thus the number of ions translocated per unit time (turnover number) is very high, typically 10^6–10^8 s^{-1}. Whereas pores are always open (ion conductive), ion channels undergo "gating," transitions between open (conductive) and closed (nonconductive) states. The part of the protein thought to move or change conformation during the gating is called the *gate*. Gating can be elicited by physical factors (changes in membrane voltage or mechanical stretch) or chemical factors (such as neurotransmitters or second messengers).

Carriers are also integral membrane proteins. In contrast with channels, the function of carrier proteins involves a chemical interaction with the transported ion, namely ion binding, which elicits conformational changes in the carrier, eventually resulting in the translocation of the ion across the membrane. Because of these interactions between the carrier and the transported ion, the transport rate is much slower than that of channels, typically 10^2–10^4 s^{-1}. The net ion flux through carriers is also determined by the electrochemical gradient, as in channels, but in a more complex fashion, because certain carriers can transport several ions in the same cycle.

Pumps are similar to carriers in that there are ion binding and conformational changes that cause ion translocation, but differ in that their function is coupled to a metabolic energy source, such as ATP hydrolysis. Pumps have low turnover numbers, similar to those of carriers.

Many ion transport proteins associate with so-called adapter proteins that appear to have two roles: to determine the subcellular location of the transport protein; and to facilitate its interaction with signal transduction components, including receptors, second messenger producing enzymes, and protein kinases. These adapter proteins often contain a specific protein–protein interaction domain called the *PDZ domain*.[82] Adapter proteins therefore contribute to the formation of macromolecular complexes of which ion transport proteins are important components.

During the last decade, atomic-resolution structures have been obtained by X-ray crystallography for a number of prototypical transport proteins, including bacterial pores,[21,89] prokaryotic ion channels,[26,28] the lac-permease of *Escherichia coli* carrier,[1,2] the mammalian sarcoplasmic-reticulum Ca^{2+} pump,[107,108] and several ATP-binding cassette (ABC) proteins.[4,19,53,113] These studies have provided detailed insight into the mechanism of the function of these specific transport proteins, as well as a framework in which to analyze other proteins. An example is the modeling of the cystic fibrosis transmembrane conductance regulator (CFTR) channel, based on the structure of other ABC proteins.[78]

As summarized in an excellent recent review,[74] the first atomic-resolution structure of an integral membrane protein, the reaction center from photosynthetic bacteria, was reported in 1985.[20] At that time there were 268 entries in the Protein Data Bank (PDB). In 2010, the PDB contained almost 60,000 entries, with about 700 of these being membrane proteins, and 80% of these belonging to the all-alpha type (i.e., the transmembrane regions are α helices, instead of the β sheets found in prokaryotic membrane proteins). Only *ca.* 250 of these structures are considered unique.[114]

An essential property of membrane proteins involved in ion transport is their selectivity, i.e., their capacity to "distinguish" between similar ions. This requires the ion pathway to have specific binding sites. In ion selective channels, the ion is at least partially dehydrated, with the binding sites providing favorable interactions, i.e., "replacing" the water molecules surrounding the ion in free solution. Selectivity results from a more favorable interaction of the site with one type of ion than another.[42] Ion-binding sites in transport proteins are formed by amino acid residues that provide charges of the opposite sign, with a size that specifically accommodates the ion. These sites have been identified in several crystal structures of transport proteins.[42] Small molecules selective for monovalent cations have been synthesized by changing the size of the cavity.[23,42]

Pores

Pores are wide conduits across biological membranes that are permanently open; they do not gate (Figure 2.7a). The best studied examples are those formed by bacterial porins, but they are also present in mitochondria (porins) and lymphocytes (perforin, a secretory product). It is also possible that most aquaporins are pores (see Chapters 4 and 41).

Bacterial pores formed by the transmembrane proteins called *porins* are radically different from animal membrane proteins, in that the transmembrane domains, instead of being α helices, are β sheets. For discussions of porin structures, see Delcour[21] and Schulz.[89]

Channels

Like pores, channels have the property of being accessible to both sides of the membrane at the same time, but this occurs only part of the time. Channels open and close stochastically. Gating may be determined by physical or chemical processes (see below), both requiring a sensing mechanism. In the open channel there is ion permeation with a characteristic selectivity for one or more ion species. Channels also have typical conductance (related to ion permeability),

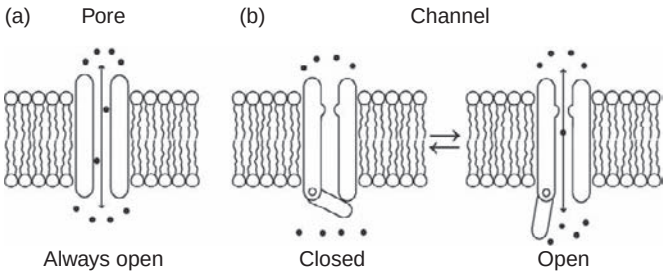

FIGURE 2.7 **Pores and channels.** (a) A pore is a transmembrane protein that forms an aqueous conduit across the membrane that is always accessible from both sides and never closed. Pores are generally of large diameter, and thus permit passive transport of small ions as well as larger hydrophilic solutes, driven by the electrochemical gradient across the membrane. (b) A channel is also a transmembrane protein that forms an aqueous conduit across the membrane. However, in contrast with a pore, it can have at least two conformations, closed and open. The change in conformation is depicted in the figure by a swiveling portion of the molecule, the gate. Gating is the process by which the channels open and close. When the channel is open, it is permeable (conductive), and its interior is accessible to both sides. When the channel is closed, it is impermeable. Channels are generally of smaller radius than pores, and exhibit varying degrees of ion selectivity. As in the case of pores, ion fluxes through channels are driven by the electrochemical gradient across the membrane.

physiological regulation, and inhibitor pattern. Hence, the functional "fingerprint" of a channel includes gating, sensing mechanism, conductance, selectivity, regulation, and pharmacological inhibition.

In channels, the main transport-related conformational change is the gating between open and closed states (Figure 2.7b). The gate is the portion of the channel protein that "moves" to cause channel opening and closure. When the channel is closed, it is impermeable, that is, nonconductive. When it is open, it is permeable or conductive, and allows ion fluxes, with a net flux that can also be expressed as the current carried by the ions. The flux, and hence the current, are determined by the permeability of the channel and the driving force, that is, the electrochemical gradient for the permeant ion. The channel persists in the open state for a given time and allows ion permeation without additional conformational changes during the opening. Hence, one conformational change (gating) allows for transport of a large number of ions, with no additional chemical modification of the protein. The open channel constitutes a water-filled conduit that spans the lipid bilayer communicating the two solutions separated by the membrane. The interior of the open channel is accessible from both solutions at the same time. The large number of ions that cross a channel per unit of time causes a measurable electrical current, allowing investigators to measure single channel events, net ion movements across individual molecules, either *in situ*, using the patch-clamp technique[88] or reconstituting purified channels and incorporating them

in artificial planar bilayers.[75] The two channel conformations, open and closed, underlie the discrete levels observed in current records.

The total current (which denotes ion flux) via a population of channels of one kind in a membrane is given by:

$$I = N \cdot P_o \cdot g \cdot (V_m - E_i) \tag{2.16}$$

where I is the current, N is the number of functional channels in the membrane, P_o is the channel open probability (time open/total time), g is the single channel conductance (the reciprocal of resistance), V_m is the membrane voltage, and E_i is the permeant ion's equilibrium potential. Note that the term $g\ (V_m - E_i)$ denotes i, the single channel current. Equation (2.16) encompasses all mechanisms of channel function regulation: number of copies in the membrane; open probability (gating); conductance; and electrochemical driving force. The ion flux and the ion current through are related by the Faraday constant and the ion valence.

Whereas carriers can be uniporters, symporters or antiporters, channels can only be uniporters. There can be ion–ion interactions in channels, such as single file diffusion,[36,50] but molecular flux coupling, such as observed in carriers, does not occur. As is the case of carriers, channels exhibit substrate selectivity, typical pharmacological inhibition, and transport saturation, although the latter is more evident in carriers.

Plasma membrane ion channels are classified based on their selectivity. The most studied can be selective for K^+, Na^+, Ca^{2+}, H^+, Cl^-, cation or anions, or may be nonselective. Certain channels are highly selective for specific ions, whereas others discriminate less among different ions. The bases of selectivity are ion size and charge. It has been well-established that the Na^+, K^+, and Ca^{2+} channels of excitable membranes, as well as the epithelial Na^+ channel, K^+ channels, and Cl^- channels, are highly selective, where permeability ratios between two ions of the same charge and similar size can be 100 or more. As explained in more detail below, the structural basis of high selectivity channels is a very narrow region in the pore, called the *selectivity filter*, in which the dehydrated permeant ion is coordinated by dipoles in the protein.[69] Other ion channels are less selective. For example, gap junction channels, which communicate between adjacent cells, have cation–anion permeability ratios ranging from about 1 to 10, values similar to those of tight junctions of leaky (high permeability) epithelia. These channels are wider, the ions permeate in the hydrated state, and the cation–anion selectivity is probably governed by fixed charges facing the pore.

K^+-Selective Channels

All known K^+ channels belong to a single protein family, characterized by the highly conserved K^+ channel signature sequence,[48] which forms the selectivity filter. K^+ channels display high selectivity and high conduction rates. X-ray crystallographic studies performed in recent years have revealed the atomic structures of several K^+ channels. Roderick MacKinnon was awarded the 2003 Nobel Prize for Chemistry for this work. In this section, we summarize the current understanding of K^+ channel selectivity and conduction derived from structural studies. For a discussion of the gating process, see MacKinnon.[69]

The K^+ channel is formed by four subunits arranged around a central pore.[24,120] Each subunit consists of two transmembrane α helices (inner and outer, relative to the pore), and the pore helix, which is tilted and penetrates only half of the membrane thickness. Near the center of the membrane the pore forms a water-filled cavity that contains a hydrated K^+.[120] As shown in Figure 2.8, the selectivity filter, formed by the signature-sequence amino acids, is located between the central cavity and the extracellular solution. The filter consists of four layers of carbonyl oxygen atoms and a layer of threonine hydroxyl oxygen atoms, creating four K^+-binding sites (numbered one to four starting from the extracellular side). Thus, each dehydrated K^+ is surrounded by eight oxygen atoms, four "above" and four "below." The selectivity filter thus mimics the arrangement of the K^+ hydration shell, in which a single K^+ is surrounded on average by eight water molecules. The K^+ ions are "transferred" by diffusion from water to the selectivity filter, the hydration energy being compensated for by the binding energy in the filter. Sodium ions do not enter the selectivity filter,[119,120] because the selectivity filter binding energy cannot compensate for the Na^+ higher hydration energy. The small distances between the four K^+-binding sites cause electrostatic repulsion, so only two sites (one and three or two and four) are thought to be occupied at a time.[77] The electrostatic repulsion tends to balance the binding forces, thus ensuring a high turnover number.[69]

K^+ channels are present in the plasma membranes of virtually all cells. Their principal functions are generation of the resting membrane potential of the cell (inside negative), and performance of transepithelial K^+ transport, principally in renal and intestine epithelia. In addition, K^+ channels are involved in cell volume regulation, in the regulation of insulin secretion by pancreatic β-cells, and probably in cell growth and differentiation, although the latter functions remain controversial.

Na^+-Selective Channels

There are two broad classes of Na^+ channels: depolarization-activated Na^+ channels expressed in neurons and other excitable cells and the ENaC/degenerin ion family, which includes the epithelial Na^+ channel

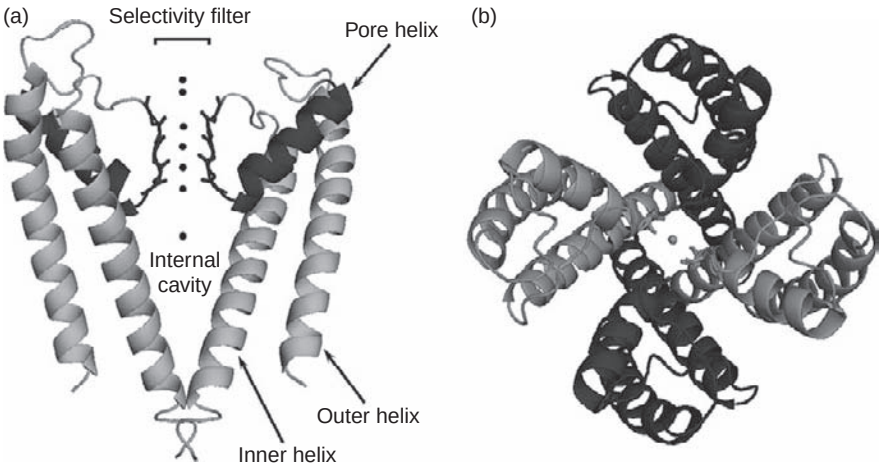

FIGURE 2.8 **Structure of a potassium channel.** (a) Side view of the KcsA channel showing only two subunits for simplicity. Two TM2 helices (pore helices) are shown in darker gray. The oxygens from backbone carbonyl groups at the selectivity filter coordinate K^+ (black circles) at four sites. There are two additional binding sites on the extracellular side (ions in transition), and one ion trapped in the internal cavity, presumably stabilized by the electrical dipole of the pore helices. (b) Tetrameric structure of the channel viewed from the extracellular side. The inner helices form the pore, with the narrowest part corresponding to the activation gate. Each subunit is shown in a tone different from that of the neighboring subunits (built with PyMol).

(ENaC). Other family members are proteins involved in mechanoreception and neuronal degeneration. ENaC is expressed in the apical (luminal) membrane of principal cells of the collecting duct, and in epithelial cells of colon and airway epithelium. ENaC has slow kinetics, low conductance, and a high open probability. Its function is to absorb Na^+ across the apical membrane of the epithelial cells; the Na^+ is then pumped out of the cell by the Na^+,K^+-ATPase expressed in the basolateral membrane. Mammalian ENaC is a heterotrimer (α-, β-, and γ-subunits with high structural homology[12]). All three subunits are thought to contribute to the formation of the pore, but no crystal structure is available.[100]

Cl^- Selective Channels

The largest family of Cl^- channels is the ClC family, with nine members in mammals. ClC channels participate in cell excitability, maintenance of the resting potential, Cl^- transport in certain epithelial cells, Cl^- and H^+ transport in intracellular vesicles, and cell volume regulation. ClC genes, expressed in both prokaryotes and eukaryotes, encode both Cl^- channels and Cl^-/H^+ antiporters.[27,60] In mammals, the channels (ClC-1, ClC-2, ClC-Ka, and ClC-Kb) are expressed in the plasma membrane, whereas the antiporters (ClC-3, 4, -5, -6, and -7) are expressed in endosomal/lysosomal membranes. This is an interesting case in which members of a family of ion transport proteins include channels and carriers.[60,76]

The structure of a bacterial ClC protein[28,29] shows a double-barrel channel: homodimer with each monomer containing a pore. Each subunit has 17 transmembrane helices and Cl^- in the channel is coordinated by residues from several helices, including a highly-conserved Lys. In the membrane, ClC proteins form two hourglass-like funnels that meet in a narrow constriction near the middle of the bilayer, the anion selectivity filter.[29] Some mammalian isoforms of ClC proteins require α- and β-subunits for function.[60] The cystic fibrosis transmembrane conductance regulator (CFTR) is a Cl^- channel expressed in Cl^--secreting epithelial cells; it does not belong to the ClC family, but is a member of the ABC superfamily. ABC proteins can be either channels or pumps. CFTR is expressed in the apical membranes of airway, small intestine, pancreatic duct, biliary tree, and vas deferens epithelia. It consists of two homologous halves, each formed by six transmembrane helices followed by a nucleotide-binding domain (NBD). The two halves are joined by the regulatory or R domain, a large hydrophilic sequence located in the cytoplasm. The function of CFTR is Cl^- secretion across the apical membrane, which is the primary event for salt and water secretion by the epithelia listed above. CFTR gating is a complex process involving phosphorylation of the R domain by protein kinase A, ATP binding to the NBDs, their dimerization, and ATP hydrolysis.[15] CFTR also appears to regulate other Cl^- channels, as well as Na^+ and K^+ channels, by unclear mechanisms. CFTR is expressed in all segments of the renal tubule, but its functional role in the normal kidney is not clear; also, cystic fibrosis patients have no discernible renal phenotype.[22] In polycystic kidney disease, CFTR is abundantly expressed in the apical membranes of the cysts cells, and plays an essential role in Cl^- secretion, which drives fluid secretion and cyst growth[11] (Chapter 81).

A third group of Cl^- channels are Ca^{2+}-activated (Ca^{2+}-activated Cl^- channels or CaCCs). They are involved in epithelial absorption and secretion, muscle contraction, neuronal excitability, sensory transduction, cell volume regulation, and other cell functions. Several protein types have been proposed to account for CaCC currents, but very recent studies by three groups have provided solid evidence that TMEM16A (also named anoctamin-1 or ANO1) has functional characteristics consistent with CaCCs. Site-specific mutations alter channel properties, suggesting that TMEM16A is at least part of the channel. Expression of TMEM16B also results in CaCC functions, but with different biophysical properties than those associated with TMEM16A. The function(s) of other TMEM16 proteins remain unknown. TMEM16A and the nine other members of the family have a similar topology and secondary structure, with eight transmembrane helices and intracellular N- and C-termini. This protein family has been long-studied by developmental and cancer biologists. Some family members are upregulated in tumors and loss-of-function of others is conducive to defects in development (see [39] and [45] for reviews).

For a detailed discussion of ion channels, see Chapter 8. In addition, excellent treatments of ion channels in general can be found in the book by Hille,[50] and the review articles by Catterall[13] and Dawson.[18] There are also several excellent recent reviews on ion channel structure–function relationships,[24,25,42,68,69] and on ion channels in renal epithelial cells.[14,46,52,56,60] Chapters 8, 30, 31, 47, and 63 cover renal ion channels.

Carriers

Carriers are transporters that perform transmembrane translocation of solute (and perhaps water; see Chapter 4) by a sequential process thought to involve three basic steps. First, binding of the transported substrate to the carrier facing one side of the membrane; second, change in conformation of the carrier, with translocation of the substrate (and the binding site) to the opposite side of the membrane; and third, release of the substrate. It is thought that access to the binding site from either bathing solution is by diffusion (or electrodiffusion) in pore-like regions of the carrier molecule.[61] Hence, two such steps could be added to the simplified scheme above.

In carriers, there is a state in which the binding site and the substrate are inaccessible from either side of the membrane.[62] The existence of this state, called *occlusion*, is one of many arguments supporting the idea of conformational change in carrier function. Carriers behave like enzymes, in that the substrate binds to the protein; however, instead of chemical transformation of the substrate, the carrier performs its translocation. Carriers contain substrate-binding domains accessible from one side of the membrane at a time. In contrast with channels, they never form a conduit that communicates the two bathing solutions, i.e., the binding site is never accessible from both sides of the membrane. Instead, carriers undergo conformational changes that alter the "sidedness" of the substrate-binding site; the substrate binds on one side, the conformation of the carrier protein changes, the substrate is occluded, the binding site is translocated (with substrate) to the other side of the membrane, and the substrate is then released. In comparison with a channel, which has one gate, a carrier may be considered to have two gates, as illustrated in Figure 2.9.

The notion of a carrier protein as a "ferryboat" binding the substrate at a membrane–solution interface and carrying it to the other side, where the solute is released to the other solution, is inconsistent with current knowledge of the biochemistry and molecular biology of carriers. Nevertheless, kinetic schemes based on the ferryboat model remain very useful to explain carrier function at a phenomenological level.

Substrate transport by carriers is inherently slow, because each substrate molecule (or group of molecules in cases of coupled transport; see below) must undergo an independent binding reaction, followed by the conformational change of the carrier molecule. This explains the low turnover number of carriers, similar to typical rates of enzyme catalysis of 10^2–10^3 per second.[99]

Most carriers have exquisite substrate selectivity (e.g., the glucose carrier GLUT1 transports D-glucose, but not L-glucose) and can also exhibit quite specific pharmacological inhibition. At low substrate concentration, the substrate flux increases linearly with the concentration, and can be confused with simple diffusion, but at high substrate concentration it saturates, as expected from occupancy of a limited number of slowly turning binding sites. The low turnover number, high substrate selectivity and saturation of carriers, and to some extent the mechanisms of pharmacological inhibition, also support the notions of substrate binding and conformational change during the transport cycle.

Carrier-mediated transport can be classified in three types depending on the number of substrates and the transport directions (Figure 2.10). When the carrier transports only one substrate, the process is called *facilitated diffusion* or *uniport*; the carrier is a uniporter. Other carriers transport two or more substrates. When all substrates are transported in the same direction, the process is called *co-transport* or *symport*; the carrier is a *co-transporter* or *symporter*. When there is substrate transport in opposite directions, the process is called

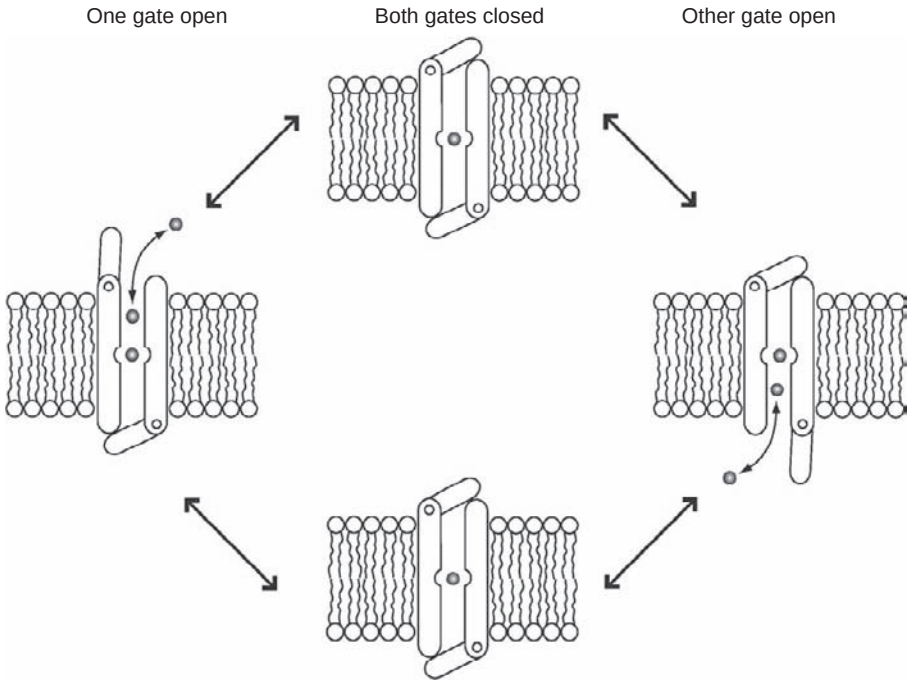

FIGURE 2.9 **Carriers.** A carrier can be understood as a membrane transport protein with two gates and one or more binding sites for the substrate. The figure depicts the transport stages for a uniporter, the simplest kind of carrier molecule. From left to right: the substrate binds to the carrier at a site available to only one side of the membrane (first gate open, second gate closed); this closes the second gate and the substrate is occluded (both gates closed); the second gate opens and the binding site and the substrate become accessible to the other side of the membrane, and the substrate is then released. The transport process is passive. The unidirectional and net fluxes are determined by the chemical or electrochemical potential difference, for uncharged and charged substrates, respectively (*modified with permission from ref. [37]).*

exchange or *antiport*; the carrier is an *exchanger* or *antiporter*. Uniporters, like channels, can only perform passive transport. The overall transport via a symporter or an antiporter is downhill. There is always passive translocation of at least one substrate, and there can be secondary active translocation of one or more additional substrates, using the energy stored in another substrate's chemical or electrochemical gradient. For example, in the case of two substrates, all the energy employed in uphill translocation of one species derives from the passive transport of the other one, so that no metabolic energy is directly used.

The largest family of secondary active transporters is the major facilitator superfamily (MFS).[87] MFS proteins are expressed from bacteria to vertebrates. They range from 400 to 600 amino acids in size, have 12 transmembrane helices, and N- and C-termini are located on the cytoplasmic side. These proteins transport numerous substrates, and may be uniporters, symporters or antiporters. The atomic structures of four bacterial members of the MFS have been solved: the H^+-lactose co-transporter (LacY) or lac-permease,[2] the P_I/glycerol-3-phosphate antiporter (GlpT),[58] the multidrug-resistance antiporter EmrD,[117] and the fucose permease FucP.[17] In all structures the transmembrane helices form two domains, N- and C-termini (each consisting of a six-helix bundle) with a pseudo two-fold symmetry. A large cavity open to the cytoplasm and closed to the periplasm is present in the LacY and GlpT structures, suggesting that the crystals correspond to the inward facing conformation.[2,58] The structure of the FucP shows an outward open amphipathic cavity.[17]

Of great importance for mammalian physiology in general and renal physiology in particular are the solute sodium symporters (SSS), a subset of the MFS. These constitute a large family of proteins that co-transport Na^+ with a variety of solutes, including sugars, amino acids, inorganic acids, and vitamins.[115] They are expressed in the kidney and other transport organs. The crystal structure of a bacterial Na^+-galactose symporter was solved in 2008.[32] As predicted from earlier studies, it has 14 transmembrane helices, extracellular N- and C-termini, and a structural core formed by two clusters of five helices each, with opposite orientations. This structure is similar to that of lac-permease,[2] suggesting a common structure for sugar co-transporters. The galactose-binding site is central, and is separated from the adjacent solutions by hydrophobic amino acid residues; the Na^+-binding site could not be identified in the crystal structure.[32] Another

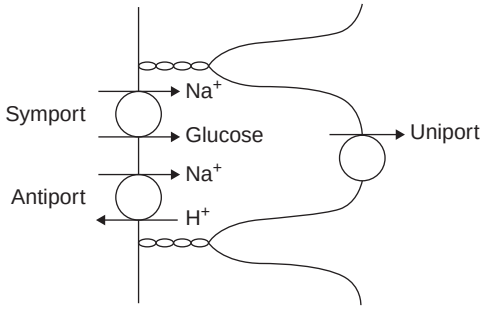

FIGURE 2.10 **Types of carrier-mediated transport.** The figure depicts an epithelial cell (e.g., renal proximal tubule) expressing different kinds of carriers, classified according to the number of substrates and the directions of the net fluxes. *Uniporter* is a carrier that transports only one substrate in a complete cycle; the process is known as facilitated diffusion or uniport, and is always passive. Shown in the figure is a glucose uniporter at the basolateral membrane. *Symporter* is a carrier that transports at least two substrates in the same direction in each cycle. The process is known as co-transport or symport; the overall transport process is downhill, but the electrochemical gradient of one substrate can be used to transport the other one actively (a form of secondary active transport). Shown in the figure is a Na^+-glucose symporter at the apical membrane. *Antiporter* is a carrier that transports at least two substrates in opposite directions in each cycle. The process is known as countertransport, exchange or antiport; the overall transport process is downhill, but again the electrochemical gradient of one substrate can be used to translocate the other one actively (secondary active transport). Shown in the figure is a Na^{++}/H^+ antiporter at the apical membrane. See also Figure 2.6.

symporter, LeuT (leucine and Na^+)[116] clearly shows leucine and Na^+ bound to a deep region of the protein (Figure 2.11). The Na^+ ions are fully dehydrated and surrounded by six oxygen atoms in one site and by five in the other. These studies represent impressive progress in a few years, but considerably more work will be needed to fully understand the function of these proteins at the atomic level.

Specific aspects of carrier-mediated transport are covered in Chapters 32, 53, 54, 55, and 73. The reader is also referred to LeFevre,[66] Schultz,[90] and Stein[99] for quantitative treatments of carrier-mediated transport. Some specific carriers are well covered in recent reviews by Abramson et al.,[1] Hediger et al.,[47] Tanner,[104] and Zachos et al.[118]

Pumps

Ion pumps are discussed in Chapter 3. Other reviews of ion pumps are Apell,[5] Brini and Carafoli,[10] Facciotti et al.,[31] Fambrough and Inesi,[33] Finbow and Harrison,[35] Horisberger,[54,55] Läuger,[65] Pedersen,[83] Sachs and Munson[85] and Toyoshima.[106]

Ion pumps can be classified according to the source of metabolic energy. Pumps in general can be driven by light, redox potential or ATP hydrolysis. Animal cell plasma membrane ATPases belong to the P type, which is characterized by the formation of a phosphorylated intermediary (Na^+,K^+-, H^+,K^+-, and Ca^{2+}-ATPase) (Figure 2.12) or to the V type (vacuolar H^+-ATPase). In intracellular membranes, there is expression of the vacuolar-type H^+ pump, as well as F-type (or F_{1-} or F_{0-} type) ATPases, the ATP synthase expressed in the inner mitochondrial membrane. ATP synthases are also expressed in purple bacteria and in green plants. Their function can be outlined as follows. Multimeric protein complexes (respiratory chain complex in mitochondria, bacteriorhodopsin in purple bacteria, photosynthetic reaction center in chloroplasts) generate an H^+ electrochemical gradient from the redox potential of NADPH (mitochondria) or light energy (others). The transmembrane H^+ electrochemical gradient is then used by ATP synthases to synthesize ATP from ADP and P_i. Hence, the function of these proteins is to synthesize ATP, dissipating the ion gradient in the process. However, they are reversible, and under appropriate conditions they will hydrolyze ATP and generate an electrochemical ion gradient. Similarly, the Na^+,K^+-ATPase normally hydrolyzes ATP to transport actively Na^+ out of the cell and K^+ into the cell, but under certain experimental conditions it can operate in a reverse mode, that is, downhill ion fluxes (Na^+ into the cell and K^+ out of the cell) coupled to the synthesis of ATP.

The ion pumps present in plasma membranes of epithelial cells are the Na^+,K^+-ATPase, Ca^{2+}-ATPase, H^+-ATPase, and H^+,K^+-ATPase. Other pumps have been suggested to exist in these tissues, but they are either unique to certain epithelia or controversial. The molecular structures of these pumps have been identified, and significant progress has been made in understanding their function, but much work remains to be done in this area. Ion occlusion is a well-known stage during the pump cycle.[40] As is the case with carrier function, occlusion denotes that the conformational change necessary for transport does change the accessibility of the substrate-binding sites to the solutions bathing the membrane.

The Na^+,K^+-, H^+,K^+-, and Ca^{2+}-ATPase are all of the P type, which is characterized by the phosphorylation of an aspartic acid residue (in the sequence DKTG) during the pump catalytic cycle. The Na^+,K^+-ATPase is a ubiquitous pump in epithelial cells. In each cycle, one ATP molecule is hydrolyzed, three Na^+ are transported from the cytoplasm to the interstitial fluid, and two K^+ are transported in the opposite direction. In each cycle there is thus a net transfer of charge across the membrane (one net positive charge is extruded), and hence the pump is electrogenic, tending to hyperpolarize the cell. Its turnover number is in the range of values for carriers less than $10^2\ s^{-1}$. The catalytic cycle of P-type ATPases is shown in Figure 2.12.

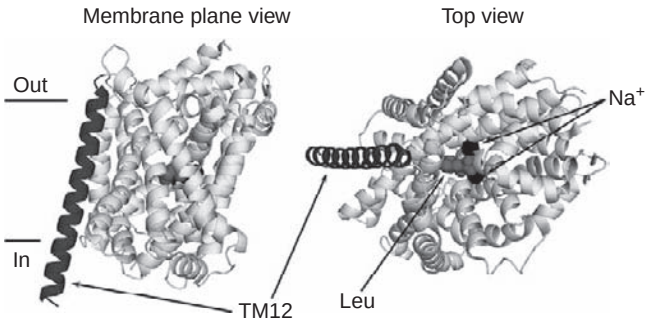

FIGURE 2.11 **Structure of a symporter.** Side (left) and extracellular (right) views of the LeuT, a prokaryotic Leu-Na^+ symporter that belongs to the neurotransmitter sodium symporter family. One protomer of the dimer in the crystal structure is shown. Transmembrane helix 12 is shown in darker gray. Leu and Na^+ bound deep into the structure core are shown in darker gray and black, respectively (built with PyMol from PDB 2A65).

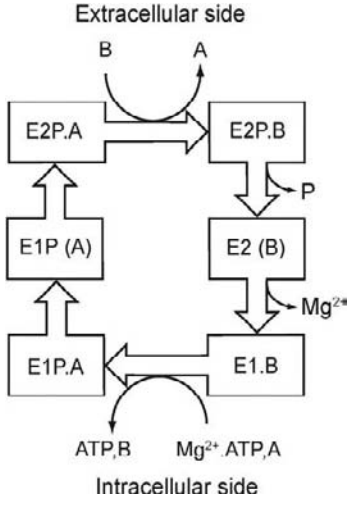

FIGURE 2.12 Catalytic cycle for P-type ATPases modeled as countertransport pumps exchanging Na^+ (*A*) for K^+ (*B*), Ca^{2+} (*A*) for H^+ (*B*) or H^+ (*A*) for K^+ (*B*) (Na^+,K^+-, Ca^{2+}-, and H^+,K^+-ATPase, respectively) (E1: conformation with ion-binding sites accessible from cytoplasm; E2: conformation with ion-binding sites accessible from the extracellular face; E(A) or E(B): ion "occluded" in the protein) (*modified with permission from ref. [85]).*

The Na^+,K^+-ATPase is expressed in virtually all vertebrate epithelial cells, where it is usually targeted to the basolateral membrane. In two cases, the choroid plexus and the retinal pigment epithelium, the pump is targeted to the apical membrane and epithelial cell polarity is inverted *vis-à-vis* other tissues. The pump consists of α- and β-subunits in a 1:1 stoichiometry (likely α2:β2). The α-subunit is responsible for both ion transport and ATPase activity, and contains the binding sites for Na^+, K^+, and ouabain, a specific inhibitor, as well as the phosphorylation site. The β-subunit, previously thought to be just involved in assembly and delivery of the pump, has in addition an important role in K^+ binding.[93] The α-subunit has three isoforms (apparent molecular mass 120 kDa) and the β-subunit has two isoforms, with apparent molecular mass of 50 kDa. Pump isoforms are tissue-specific, change during organ development, and exhibit different pharmacological properties. The Na^+,K^+ pump was first crystallized in 2007,[79] and a higher resolution structure was obtained in 2009.[93] At this time, our understanding of the structure−function relationships is less than that for the sarcoplasmic reticulum Ca^{2+} pump (see below). The regulation of the activity of the Na^+,K^+ pump is complex, and an important regulatory mechanism in the kidney is the increase in Na^+ pump expression in principal cells of the collecting duct under the action of mineralocorticoids. These hormones stimulate of Na^+ entry via ENaC, which results in an increase in intracellular Na^+ concentration that appears to mediate the stimulation of pump expression.

The plasma membrane Ca^{2+} pump (PMCA pump) actively exports Ca^{2+} from the cell, exchanging it for H^+ (the stoichiometry appears to be 1 Ca^{2+} out:2 H^+ in:1 ATP molecule hydrolyzed). The pump is 120−140 kDa, with ten transmembrane helices and three substantial intracellular domains. The crystal structure of the Ca^{2+} pump from sarcoplasmic/endoplasmic reticulum (SERCA pump) was solved a decade ago.[107] It has two Ca^{2+}-binding sites from which the ions are extruded, with a stoichiometry of 2 Ca^{2+} per ATP hydrolyzed, different from that of the PMCA pump. The PMCA pump has high affinity for intracellular Ca^{2+}, in the submicromolar range. The conformational change elicited by ATP hydrolysis is thought to make the Ca^{2+} sites face the extracellular space and the affinity decrease, causing Ca^{2+} release. The function of the PMCA pump is to help maintain a low intracellular Ca^{2+} concentration. It is a high affinity, low capacity system. The PMCA pump is stimulated by calmodulin and 1,25-dihydroxyvitamin D (for a review, see [10]).

The H^+/K^+-ATPase is expressed in gastric epithelial cells (gastric isoform), colonocytes (colonic isoform), and renal collecting ducts (both isoforms). As with the Na^+,K^+-ATPase and the Ca^{2+}-ATPases, the H^+/K^+-ATPase consists of α- and β-subunits. The α-subunits of the two isoforms, are very similar in amino acid sequence to the α-subunit of the Na^+,K^+-ATPase. The function of the renal H^+/K^+-ATPase is acid secretion and K^+ reabsorption

In the last decade, crystal structures have been obtained for the Ca^{2+} pump from sarcoplasmic reticulum,[107,109,110] the plasma membrane Na^+,K^+-ATPase[79,80,93] and the plant plasma membrane H^+-ATPase.[83] Although the Ca^{2+}-ATPase from rabbit

skeletal muscle sarcoplasmic reticulum (SERCA1a) is not a plasma membrane protein, it is currently the better known P-type ion transporting ATPase. The mass of SERCA1a is 110 kDa, it has 10 transmembrane helices (M1−M10), three cytoplasmic domains (A [actuator or anchor]; N [nucleotide-binding]; and P [phosphorylation]), and small SR-lumen loops. SERCA1a transports, against the electrochemical gradient across the SR membrane, two Ca^{2+} per ATP hydrolyzed, reducing [Ca^{2+}] in the cytosol, and accumulating it in the SR lumen. Two or three H^+ are exchanged for the Ca^{2+} in each cycle. As is the case with other P-ATPases, primary active ion transport results from a conformational change of the pump (from E1 to E2). In E1, the Ca^{2+} ions bind with high affinity and face the cytoplasm; in E2, the affinity is low and Ca^{2+} ions face the SR lumen. The Ca^{2+} translocation would take place between E1P and E2P, two states of the phosphorylated pump. Similar states exist in the operation of the Na^+,K^+-ATPase (see Chapter 3).

The first determination of the structure of SERCA1 by X-ray crystallography in 2000[107] was followed by over 20 structures in different states that essentially cover the reaction cycle, making it the best characterized P-type ion-translocating ATPase.[106] The atomic structure, represented in Figure 2.13,[107,108] revealed that transmembrane helices 4, 5, and 6 contain the amino acid residues that bind the two Ca^{2+} ions transported per cycle. These results, combined with molecular dynamics simulations[101] have provided detailed information about the binding sites and the conformational changes underlying ion pumping.[105,106] Differences between several structures revealed that SERCA1 Ca^{2+} binding and dissociation elicit large conformational changes in the transmembrane domains, mechanically linked to similar changes in the cytoplasmic domains. Homology modeling suggests that the cation-binding sites of the Ca^{2+}- and Na^+,K^+-ATPases are virtually the same.[84] A critical movement of transmembrane helix 4 causes the release of a cation (Ca^{2+} or Na^+) and the binding of the other cation (H^+ or K^+) at a displaced position with respect to the membrane, thus preventing competition between the cations.

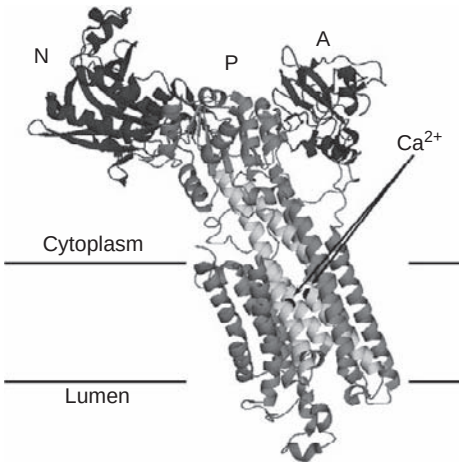

FIGURE 2.13 **Structure of a pump.** Side view of the Ca^{2+}-ATPase in the E1•2Ca^{2+} state. The cytoplasmic nucleotide binding (N) and actuator (A) domains are shown in darker gray. The A domain is part of the mechanism that controls Ca^{2+} binding and release. The cytoplasmic P domain is also labeled. This domain contains the phosphorylation residue Asn^{351} and several P-type ATPase critical residues, including the Mg^{2+} coordination residue Asp^{703}. Transmembrane helices 4−6, which contribute residues to the binding of Ca^{2+}, are shown in lighter gray. The two Ca^{2+} are shown as black balls (built with PyMol from PDB 1SU4).

Similarities and Differences between Ion Transport Proteins

The recent progress in genomics and structural biology of membrane proteins (*ca.* 700 crystal structures, of which 250 are unique[114]), combined with increasing sophistication of biochemical and biophysical studies has began to clarify the essential similarities and differences between these proteins. We wish to make several important points in this closing section. First, there are big differences between ion channels, on the one hand, and carriers and pumps, on the other, and the differences in function are explained by the differences in structure. Second, there are families in which individuals can be either channels or carriers, or either channels or pumps, suggesting something akin to a "common ancestor." Third, there is at least one instance in which pharmacological intervention can transform a pump into a channel. We discuss briefly these three points.

1. *Channels versus carriers and pumps.* The crucial functional difference between channels, on the one hand, and carriers or pumps, on the other, is in the turnover numbers: channels conduct ions rapidly (10^6−10^8 s^{-1}), whereas carriers and pumps are much slower (10^2−10^4 s^{-1}). This difference is related to the relatively slow conformational changes that accompany solute flux in carriers and pumps, while in open channels no conformational changes occur during transport. In addition, there is a difference in access of the transported ion(s) to the critical site. As we saw in the structures of K^+ and Cl^- channels, the narrow region of the permeation pathway (selectivity filter) is short relative to the thickness of the membrane, facilitating rapid conduction. In K^+ channels, in addition, the four binding sites in single file cause repulsion between adjacent ions, also facilitating rapid conduction. In contrast, in carriers (such as LeuT) and pumps (such as the Ca^{2+}-ATPase) the ion-binding sites are located deep inside the protein, with no

unobstructed pathway to the adjacent aqueous solutions. This feature limits the speed of ion transport, but permits occlusion, i.e., the ion pathway is never simultaneously open to both sides of the membrane. These arguments are lucidly presented by Gouaux and MacKinnon.[42]

2. *Functionally different transport proteins present in the same family.* The ClC proteins appear to be an intermediate class of ion transport proteins in between channels and carriers. Their structure is channel-like, with vestibules in series with a short selectivity filter with capacity to contain several ions. Functionally, some ClC proteins are indeed channels, whereas others are antiporters in which the Cl^- flux is coupled to flux of H^+ in the opposite direction.[3,76] A somewhat similar situation holds for the case of ABC proteins, which in most instances are pumps (ATPases), but at least one member (CFTR) is an ion channel. There is no crystal structure of CFTR yet, but from the primary and secondary structures one would not predict that the protein is a channel. It has been recently proposed that both CFTR and ClC-O are Cl^- channels evolved from transporters.[15]
3. *A pump can be transformed into a channel.* The marine toxin palitoxin (PTX) is a ~3000 Da molecule that consists of a chain of over 100 carbons with a complex variety of organic side groups. The mechanism of the toxic effect of PTX is to convert the Na^+,K^+-ATPase from a cation pump into a nonselective cation channel that dissipates the Na^+ and K^+ gradients between the cell and the extracellular fluid. This could be explained if the effect of PTX were to open the two gates necessary for the normal operation of the pump, thus revealing the ion translocation pathway. PTX was shown to interact with the pump in excised membrane patches, this interaction was dependent of the presence of ATP on the inside of the membrane, and was modulated by extracellular K^+, indicating that the PTX-dependent channel function shares properties of the native pump.[7,8] In other studies, the permeation pathway was mapped using the technique known as cysteine-scanning mutagenesis, in which the accessibility of amino acid sites to small hydrophilic thiol reagents is assessed after mutating those sites to Cys. Residues in transmembrane helices 4, 5, and 6 became accessible by exposure to PTX,[43,44,57] consistent with the structural studies described above.

We have presented three arguments that support the notion that ion channels, carriers, and pumps share a basic molecular architecture (see [37] and [38]). In sum, and as illustrated in Figure 2.14, the simplest ion transport protein would be a pore (no gate), followed by a pore with one gate (channel), a pore with two gates (carrier), and finally a pore with two gates coupled to a metabolic-energy source (pump). As more structures of membrane transport proteins become available the "missing links" might be identified.

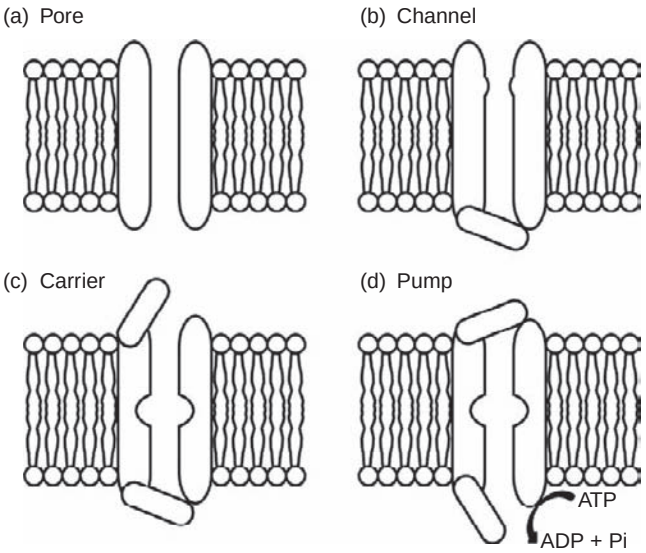

FIGURE 2.14 **A simplified view of structure–function correlations in ion transport proteins.** (a) Pore, the simplest ion transport protein, is a transmembrane aqueous conduit with no gates, accessible to both sides of the membrane at all times (always open). (b) Channel, a pore with a gate whose position determines whether the channel is open or closed. The open channel is accessible to both sides of the membrane. (c) Carrier, a transmembrane protein with two gates that are never open at the same time. Thus, the carrier interior may be accessible to only one side of the membrane; when both gates are closed the substrate is occluded (inaccessible to either side). (d) Pump, a carrier that is directly coupled to a metabolic energy source, e.g., hydrolysis of ATP.

Active transport of solutes across membranes against their concentration or electrochemical gradients requires energy. For ion-motive ATPases (F-type, V-type, and P-type), this process is an exchange between energy contained in the electrochemical gradient and chemical energy provided by ATP hydrolysis. F-type ATPases or ATP synthases are responsible for the generation of ATP using energy of the proton gradient created by the respiratory chain in mitochondria or photosynthetic complexes in chloroplasts. V-type ATPases acidify vesicles by transporting protons from the cytoplasm to the lumen of intracellular organelles (endosomes, lysosomes, vacuoles, . . .). V-ATPases are also present in the plasma membrane of some epithelial cells. Despite sharing a common general architecture and a large number of subunits, F- and V-ATPases usually work in opposite directions. P-type ATPases (also called E1-, E2-ATPases) form a third group of ion-motive ATPases that perform unidirectional or exchange transport of monovalent (H^+, Na^+, K^+) or divalent (Ca^{2+}, Cu^{2+}, Mg^{2+}, . . .) cations.

P-ATPASES

While some members of the P-ATPase family are probably active as a single polypeptide, the functional unit of others consists of several subunits. The major subunit (α- or catalytic subunit for multimeric P-ATPases) consists of a series of hairpins formed by pairs of transmembrane segments linked by short extracellular loops. Two large intracellular loops make the connection between the first, second, and third hairpins. The largest cytoplasmic loop contains the ATP-binding domain and the phosphorylation site. Transient phosphorylation of this aspartate residue occurring during the transport cycle is a hallmark of P-ATPases (Figure 3.1).

STRUCTURE AND FUNCTION OF Ca^{2+}-ATPASES (SERCA AND PMCA)

SERCA is found in intracellular organelles related to the endoplasmic reticulum, such as the sarcoplasmic reticulum of cardiac and skeletal muscle cells. Three differently expressed genes have been identified: SERCA1 in fast-twitch skeletal muscle; SERCA2 in slow-twitch skeletal muscle, heart, and smooth muscle; and SERCA3 in blood, endothelial, and epithelial tissue. SERCA mediates uptake of Ca^{2+} from the cytoplasm into the sarcoplasmic reticulum following calcium release from intracellular stores. It therefore acts as a terminator signal in excitation–contraction coupling processes in muscle, and plays a key role in excitation–secretion coupling in neurons and other secretory cells. Extensive structure–function studies have been performed with SERCA and a high resolution (2.6 Å) structure of this protein was obtained.[1]

PMCA is expressed at the plasma membrane, where it extrudes Ca^{2+} out of the cell. Four PMCA genes are known, with multiple splicing variants for each gene, resulting in the existence of about 20 isoforms. PMCA1 and PMCA4 are ubiquitous, while PMCA2 and PMCA3 are restricted to neurons, brain, muscle, and kidney. PMCA plays an important role in tubular reabsorption of calcium.[1] The long C-terminal intracellular domain maintains PMCA in an inactive state by interacting with the catalytic site. A rise of cytosolic Ca^{2+} concentration increases Ca^{2+}–calmodulin-binding, allowing calmodulin to interact with the PMCA C-terminal domain. This releases PMCA autoinhibition, activating the pump.

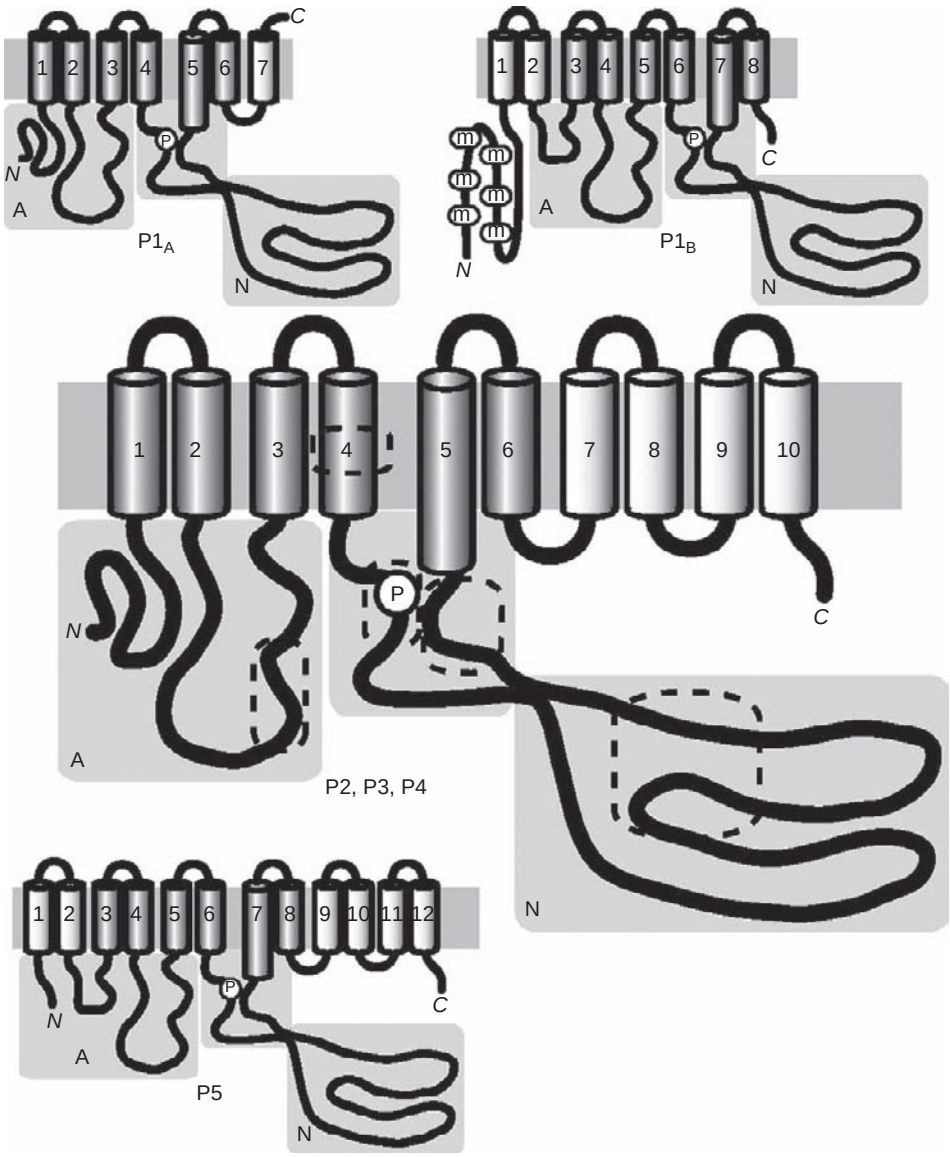

FIGURE 3.1 **General structure and conserved motifs of P-ATPases.** The four schemes show the general architecture of the main catalytic subunit of the large group of P-ATPases. The large scheme in the center corresponds to the common general structure of P2, P3, and P4 subfamilies. The two smaller schemes at the top illustrate the structure of bacterial KDP-B potassium transport ATPase ($P1_A$ subfamily, left) and the universal metal ion transport ATPases ($P1_B$ subfamily, right) in which the large N-terminal domain contains a number (usually 6) of cysteine-rich metal-binding domains (m). The small scheme at the bottom left illustrates the putative structure of P5-ATPase. The six transmembrane segments that are common to all P-ATPase together with the two major intracellular domains form the core of the ion translocation engine, and are shaded in a darker gray. The positions of highly conserved motives common to all P-ATPases are encircled by a dashed line. The cytoplasmic part of the protein is divided into three A, P, and N main functional domains according to Toyoshima et al.[396]. The circled P indicates the location of the phosphorylation site. The N- and C-termini are indicated by italicized *N* and *C*.

Conversely, calcium extrusion decreases cytosolic Ca^{2+} concentration, and consequently its association with calmodulin. Calmodulin release from PMCA increases PMCA auto-inhibition. Regulatory inhibition of SERCA is mediated by the small associated protein phospholamban, which plays a role equivalent to that of the PMCA C-terminal domain. Phosphorylation of phospholamban by protein kinase C releases SERCA inhibition.[1]

STRUCTURE OF Na,K-ATPASE AND H,K-ATPASE

Na,K- and H,K-ATPases are heteromeric proteins consisting of an α-subunit and a smaller glycosylated β-subunit. Na,K-ATPase hydrolytic activity, cation transport activity, and ouabain-binding properties were demonstrated by co-expression of α- and β-subunits in

several expression systems (mammalian cells, *Xenopus* oocytes, baculovirus-infected insect cells, and yeast). Na- (or H-) and K-activated ATPase and cation transport activities (i.e., uphill cation transport driven by ATP hydrolysis) characteristic of Na,K- or H,K-ATPases have been demonstrated only in the presence of both α- and β-subunits. Expression of the α-subunit alone in insect cells[2] resulted in Mg^2-dependent ATPase activity that was not specifically activated by Na^+ and K^+. The exact stoichiometry of the minimal functional unit is still a matter of debate. However, Na,K-ATPase activity is associated with solublized α−β protomers,[3] and cross-linking experiments did not show evidence for a close interaction between α-subunits.[4] A third subunit, the γ-subunit, can be associated with the α−β complex (see below).

Catalytic α-Subunit

Structure

Na,K- and H,K-ATPase α-subunit peptides range in length from about 1000 to 1040 amino acids. Their primary structure is characterized by a first group of four transmembrane segments, followed by a large cytoplasmic loop, and a second group of six transmembrane segments (Figure 3.1). Crystal structures of pig[5] and shark[6] Na,K-ATPase at 3.5 and 2.4 Å resolutions, respectively, confirmed that the α-subunit has three cytoplasmic domains and 10 transmembrane helices, designated *M1* to *M10*. Two-thirds of its mass is contained in the large cytoplasmic domain, while one-third spans the lipid bilayer. Of the total mass, only a small part is extracellular.[6] Sequence homology between Na,K- and H,K-ATPases is high enough to safely predict H,K-ATPase structure, at least for the general architecture of this molecule, and for large domains where homology is highest.

Isoforms

Six different α-subunit genes have been identified in mammals: α1-4 isoforms of the Na,K-ATPase α-subunit; gastric H,K-ATPase α-subunit (αHKg); and colonic H,K-ATPase α-subunit (αHKc). Related isoforms have been identified in birds and amphibians. Na,K-ATPase sequences from *Caenorhabditis elegans* or *Drosophila melanogaster* do not show close similarity with any mammalian isoform. This suggests that the divergence between Na,K- and H,K-ATPase α-subunits precedes the divergence between mammals, amphibians and birds, and has occurred early in vertebrate evolution.

All Na,K-ATPase isoforms primarily maintain Na^+ and K^+ gradients across the cell membrane. The large inward electrochemical gradient for Na^+ is in turn used by numerous secondary active transport systems for various "housekeeping" functions: maintenance of intracellular pH via Na−H exchangers; extrusion of calcium via Na−Ca exchanger; control of cell volume via Na−K−2Cl symport and other coupled transport systems; and import of amino acids, nucleotides, and other nutrients or osmolytes through various Na^+-coupled co-transport systems. The outward electrochemical gradient for K^+ is responsible for the intracellular negative membrane potential, because K^+ flows out of the cell through K^+ selective channels that are active in most cells. In addition to these general functions, Na^+ and K^+ gradients across cell membranes are essential for specialized functions, such as the generation and propagation of action potentials in excitable cells, neurotransmitter uptake, and transcellular transport of solutes and water by epithelial cells.

The α1 isoform is the most ubiquitous and abundant α isoform, and is responsible for the maintenance of whole-cell Na^+ and K^+ gradients necessary for housekeeping functions. Because of its abundance (it is the only α isoform present in many epithelial cells, including renal cells) it provides the driving force for solute and water transepithelial transport. The α2 isoform is found in skeletal and heart muscle, and in the nervous system (neurons and glial cells). The α3 isoform is essentially neuronal, but is also found in blood cells and macrophages. The α4 isoform is mostly expressed in testes, and plays a critical role in sperm motility.[7]

αHKg is abundantly expressed in parietal cells of the gastric gland, where it plays a central role in proton secretion. Under resting conditions, it is mainly located in an intracellular tubulo−vesicular network that fuses with the apical membrane of parietal cells in response to stimuli, allowing the H,K-pump to secrete protons into the gastric gland lumen in exchange for potassium. αHKc is mainly expressed in the (rat) distal colon, but also in the kidney, uterus, and, to a lesser extent, in the heart.[8]

β-Subunit

Isoforms

As stated above, the β-subunit is an essential constituent of functional Na,K-ATPase and H,K-ATPase. Five different genes encoding similar proteins are known in mammalian genomes: β1; β2; β3; βHK; and βm ("m" emphasizes its predominant expression in skeletal muscle). β1, β2, and β3 are clearly Na,K-ATPase β-subunit isoforms, while βHK is co-expressed with gastric H,K-ATPase. Although usually described as ubiquitous, β1 appears to be absent, or at best is only a minor component, in several tissues such as liver and red blood cells. The β2 isoform was initially identified in glial cells, but is also present in other cell types, including neurons, blood cells, and epithelial cells. The β3 isoform, initially identified in nervous systems, is also widely distributed, being most abundant in testes, liver, and lungs and less so in skeletal

muscle and kidney. Despite sharing sufficient sequence similarity to be classified in the same family, βm does not associate with any known mammalian α-subunit.[9]

Structure and α−β Interaction

β-subunit peptides range in length from 288 to 315 amino acids, and show a lower degree of homology (about 30%−40% identity between isoforms) than α isoforms. Crystal structures of Na,K-ATPase obtained at resolutions of 3.5 Å[5] and 2.4 Å[6] have lent detailed insight into β-subunit structure. These studies, together with experimental evidence, show that the β-subunit is a type II membrane protein consisting of a single transmembrane segment, a ∼35-amino acid N-terminal domain, and a large extracellular domain containing two to seven glycosylation sites, depending on the isoform, and six cysteine residues that form three disulfide bridges (Figure 3.1).

Experimental modeling and analysis of Na,K-ATPase crystal structures has revealed complex interactions between α- and β-subunits. The transmembrane helix of the β-subunit forms several hydrogen bonds and numerous contacts with *M7* and *M10* transmembrane helices of the α-subunit, primarily via clusters of aromatic residues. At the extracellular side of the β-subunit, a stretch of amino acids adjacent to its transmembrane domain interacts with the α*M7/M8* extracellular loop that contains a consensus sequence SYGQ.[6] Further downstream, Lys250 of the β-subunit forms a salt bridge with Glu899, located in the α*M7/M8* extracellular loop.[6]

Except for gastric αHK and βHK, which are most abundantly expressed in a single cell type (parietal cells of gastric glands), there is no obvious common pattern of distribution between α isoforms and β isoforms that would define preferential physiological associations. Indeed, some cells even express as many as three α isoforms and at least two β isoforms. Unless formation of specific complexes is favored or repressed by unknown mechanisms, numerous combinations are possible, as suggested by studies using artificial expression systems. β1 is abundantly expressed in tissues in which α1 predominates, such as the kidney, strongly suggesting that α1β1 represents the predominant isozyme in these tissues. The nature of the β-subunit associated with αHKc is also a matter of debate, since all β isoforms are able to associate with αHKc, depending on the expression system used.

Functional Role

The functional interaction between α- and β-subunits has been studied and reviewed in detail.[9] By acting as a molecular chaperone, the β-subunit plays a critical role in the maturation of the α-subunit. Indeed, the α-subunit reaches a mature and functional conformation, ready to be translocated from the endoplasmic reticulum to the plasma membrane, only when associated with a β-subunit.

The β-subunit contributes to intrinsic transport properties of the whole enzyme in several expression systems by influencing its apparent K^+ and Na^+ affinities. Biochemical analysis and crystallization of Na,K-ATPase has lent some mechanistic insight as to how this is achieved. By interacting with the *M7* transmembrane domain of the α-subunit, Tyr40 and Tyr44 of the β-subunit transmembrane helix help confer intrinsic transport properties of the Na,K-ATPase enzyme, as suggested by a mutagenic study.[10] Unwinding of *M7* via hydrogen bonding of Tyr44 with Gly855 appears to be of central importance to K^+ binding. The role of the β-subunit ectodomain in modulating cation transport is further illustrated by the complex interactions between this domain and the α*M7/M8* extracellular loop.

The role of the β-subunit in cell−cell adhesion will be discussed in the section "New Physiological Functions of Na,K-ATPase."

FXYD Proteins

Isoforms

FXYD proteins are a third component of Na,K-ATPase. There are seven isoforms in mammals, ranging from 61 to 95 amino acids in length, except for FXYD5, which consists of 178 amino acids due to an N-terminal extension. Most FXYD proteins are small type 1 membrane proteins containing an extracellular N-terminus. This family of proteins is so named since all members contain a FXYD (Phe-X-Tyr-Asp) sequence located immediately downstream of the transmembrane segment. All members also contain two conserved glycine residues in the transmembrane domain, as well as a serine residue located further downstream. As with α and β isoforms, the tissue distribution of FXYD proteins is isoform-specific.[11] FXYD1 (phospholemman) is predominately expressed in heart and skeletal muscle and, to a lesser extent, in brain, FXYD2 (γ-subunit) in kidney, FXYD3 (MAT-8) in stomach and colon, FXYD4 (CHIF) in kidney and distal colon, FXYD5 (RIC) in kidney, intestine and lung, and FXYD6 and FXYD7 in brain. In the kidney FXYD2 is mostly expressed in proximal tubule and thick ascending limb of Henle, while FXYD4 is exclusively found in the collecting duct where its expression increases from cortical to medullary portions.[12]

Function and Interaction with α- and β-Subunits

FXYD proteins were first thought to be regulators of ion channels or even to act as ion channels themselves. It has now been demonstrated that FXYD proteins interact

with Na,K-ATPase. Contrary to the β-subunit, most FXYD proteins do not associate with H,K-ATPase and do not appear to act as a molecular chaperone. Rather, they regulate Na,K-ATPase functional properties. As recently reviewed,[9] analysis of FXYD-deficient mice and *in vitro* modulation of Na,K-ATPase activity by different FXYD proteins has shown that FXYD1−4, 6, and 7 all decrease Na,K-ATPase apparent affinity for Na^+ and/or K^+, with the exception of FXYD4 which has been shown to decrease apparent affinity for K^+ but increase that for Na^+. FXYD5 does not appear to influence Na,K-ATPase affinity for either Na^+ or K^+, but enhances maximal transport activity. By modulating Na,K-ATPase activity, FXYD proteins play important physiological roles, each isoform playing a different role depending on its tissue-specific distribution. For instance, FXYD1 influences myocardial contractility by modulating Na,K-ATPase activity and calcium handling, as demonstrated in FXYD1-deficient mice that display depressed cardiac contractile function and increased cardiac mass.[13] FXYD6, the only FXYD isoform expressed in the inner ear, may play an auditory and vestibular role by contributing to endolymph ionic compostion, whose production depends on Na,K-ATPase activity.[14] Reflecting altered expression levels in various types of cancer, FXYD3 may be implicated in the control of cell differentiation, proliferation, and/or apoptosis through regulation of Na,K-ATPase activity.[15] Finally, the renal tubule segment-specific distribution of FXYD2 and FXYD4 may explain, at least in part, the higher apparent Na^+ affinity of collecting duct Na,K-ATPase as compared to that of more proximal nephron segments.[16,17]

Crystallization of the Na,K-ATPase holoenzyme[5,6] has deciphered FXYD structure, and revealed how it interacts with α- and β-subunits, providing some insight into how it modulates Na,K-ATPase activity. This notably involves interaction between the transmembrane domain of FXYD proteins, particularly Gly34, with the α*M9* transmembrane domain. Hydrogen bonds between Cys31 and αGlu960 may additionally play a structural role important for FXYD functional regulation. The FXYD motif helps confer β conformational structure. This is partly achieved via Phe12, which anchors this segment to the β-subunit, and Tyr14, which forms a cluster of aromatic residues with Tyr69 of the β-subunit and Trp987 of the α*M9/M10* extracellular loop.

PROPERTIES OF Na,K-ATPase AND H,K-ATPASE

Ion Transport

Under physiological conditions, Na,K-ATPase exchanges three intracellular Na^+ for two extracellular K^+ at the expense of one ATP during each cycle, generating an outward current of one net charge per cycle. The outward current generated by the Na,K-pump tends to hyperpolarize the cell membrane to a few millivolts under steady-state conditions. The majority of the 50 to 80 mV resting-membrane potential is due to flow of K through K channels, which relies on Na,K-pump activity, since high intracellular K^+ concentration is maintained by the Na,K-pump. The apparent affinities for Na^+ and K^+ are dependent on experimental conditions, but under physiological conditions intracellular Na^+ activates the Na,K-pump with a $K^1/_2$ of 10 to 20 mM and a Hill coefficient between 2 and 3. Extracellular K^+ has a $K^1/_2$ of about 1 mM, with a Hill coefficient between 1 and 2.

Despite extensive studies, the difference in transport properties between Na,K-ATPase α isoforms has not been entirely resolved. Initial studies performed in native tissues indicated that α2/α3 isoforms have a higher affinity for Na^+. More recent studies comparing isoforms in the same artificial expression system revealed that α2 has a slightly lower (about 20 mM), and α3 a much lower (30−70 mM), affinity for Na.[18] However, other factors, such as the type of associated β-subunit and FXYD protein, also modulate Na,K-ATPase transport properties (see above).

The mechanism of cation translocation by Na,K-ATPase can be summarized as follows (Figure 3.2). Na,K-ATPase exists under two main conformations, E1 and E2, and transport activity is performed via a cycle in which the protein is transiently phosphorylated, and alternately adopts E1 or E2 conformations. These two conformations differ in their apparent affinities for Na^+ and K^+. The E1 conformation has high affinity sites for Na^+ exposed at the intracellular side of the membrane, while the E2 conformation has high affinity sites for K^+ exposed at the extracellular side of the membrane. Three Na^+ and two K^+ ions are alternately bound to the enzyme and then "occluded," that is, tightly bound inside the protein. This model is compatible with the reported structure of the major conformations of SERCA, and the E2-P conformation of Na,K-ATPase.[6,19]

Non-electrogenic transport is achieved by gastric H,K-ATPase, indicating that a symmetrical number of H^+ and K^+ ions are translocated across the membrane during each cycle. Transport stoichiometry depends on pH. Under conditions of high or near neutral pH, the stoichiometry is 2H,2K^+-1ATP, and shifts to 1H,1K^+-1ATP under physiological conditions, i.e., conditions of very low extracellular pH.[20] The transport properties of colonic H,K-ATPase and its close relatives (human ATP1AL1 and toad *Bufo marinus* bladder H,K-pump) are not yet completely defined. Artificial systems have demonstrated an inward transport of K^+, and an

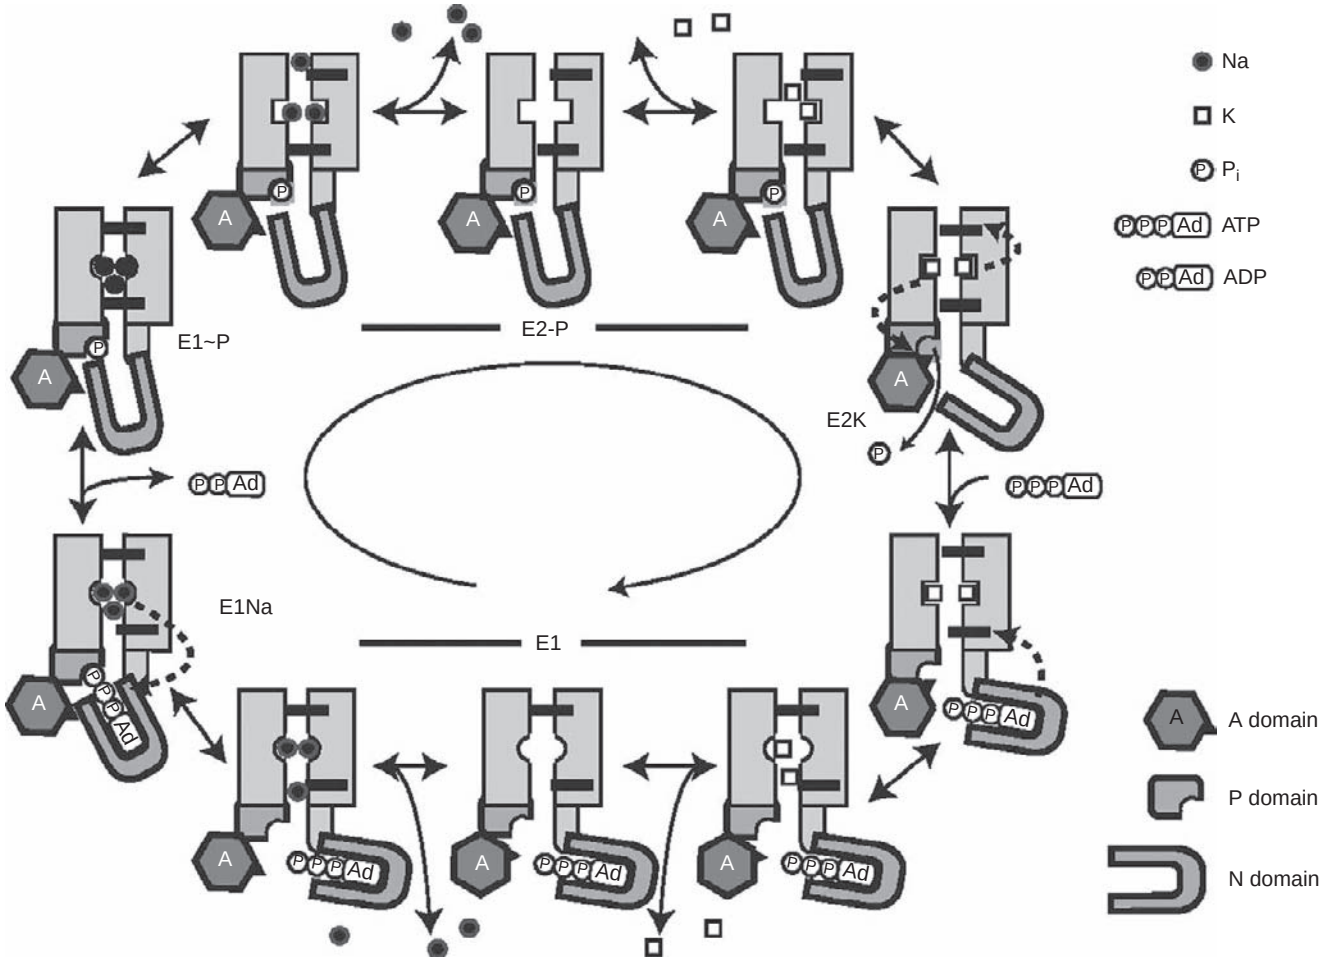

FIGURE 3.2 The Na,K-ATPase transport cycle. This cartoon illustrates the principle of the "alternating access" transport model of Na,K-ATPase. Na^+ ions are indicated by small, filled circles, and K^+ ions by small, open squares. Starting from the E^+ conformation where ATP is present at its binding site, three Na^+ ions enter from the intracellular site through an open, internal gate and reach their occlusion site (E1Na state). Na^+ binding induces (dotted arrow) movement of the N domain, resulting in positioning of the γ phosphate close to the phosphorylation site, phosphorylation of the α-subunit via transfer of the γ phosphate to Asp351, release of ADP and closure of the internal gate which results in the occlusion of the three Na^+ in the E1P state. The conformational change to the E2-P state that follows results in the opening of the extracellular gate, and a structural change of the cation-binding site, resulting in a large decrease of their affinity for Na^+ and an increase of their affinity for K^+. This leads to release of Na^+ to the extracellular side and loading of two K^+. K^+ binding has two major consequences (dotted arrows): first, the external gate closes, resulting in K^+ occlusion; and second, D_{351} (E2K state) is dephosphorylated. This latter event is catalyzed by a conserved motif (TGES, small black triangle) of the A domain that is brought in contact with the phosphorylation site via rotation of this domain. The N domain also moves, allowing it to be accessible (with a low affinity) to ATP. Binding of ATP then results in opening of the intracellular gate (back to the E1 conformation), and allows release of K^+ ions to the intracellular side. This last step can also occur in the absence of ATP, but at a much reduced rate.

outward transport of H^+.[21] However, data obtained in heterologous expression systems have suggested that these enzymes may exchange Na^+ for K^+.[22]

Pharmacology

A group of natural compounds known as "cardiac steroids," so named because they contain a steroid nucleus attached to a lactone ring and are used for treatment of congestive heart failure, are potent Na,K-ATPase inhibitors. In addition, one or several endogenously related compounds may also act as hormonal agents that participate in regulating Na,K-ATPase activity.

Cardiac steroid interaction with Na,K-ATPase, particularly ouabain, has been extensively studied. Differences of ouabain affinity between Na,K-ATPase isoforms, together with mutagenesis studies[23] and recently obtained crystal structures of ouabain bound to Na,K-ATPase,[5] all show that ouabain binds to a deep cavity formed by the transmembrane helices *M1*, *M2*, *M4*, *M5*, and *M6* at the proximity of the K^+-binding site. The slow kinetics of ouabain binding may be associated with partial unwinding of the *M4* helix.

Large differences in ouabain sensitivity occur among animal species. The α1 isoform is ouabain-resistant in rat, mouse, and toad *Bufo marinus*, but is sensitive in human, rabbit, sheep, and *Xenopus*.[23] The α2 and α3 isoforms are more sensitive than the α1 isoform in "resistant" species.[7] However, in humans, little difference of equilibrium binding is found among α1, α2, and α3 isoforms, except for a slightly higher K_I for α2. However, the α2 isoform also exhibits a faster ouabain association and dissociation rate constant than α1 and α3.[24] The "resistant" phenotype of some species is linked to charged amino acids in the first extracellular loop between *M1* and *M2*.[23] The presence of endogenous circulating inhibitors of Na,K-ATPase ("endo-ouabain") is well-demonstrated. However, their precise chemical nature needs to be clarified, their controlled synthesis and release better understood, and their specific effects more precisely described, before the hypothesis of controlled Na,K-ATPase activity by such circulating hormones can be considered as fully established.[25]

Gastric H,K-ATPase is insensitive to ouabain,[20] as demonstrated by an absence of detectable effects at millimolar concentrations of ouabain. On the other hand, non-gastric H,K-ATPases, expressed in *Xenopus* oocytes, show some sensitivity to ouabain and exhibit inhibitory constants (K_I) between 10 and 100 mM.[8] Two types of gastric H,K-pump inhibitors are known. SCH-28080 is a reversible inhibitor that competes with extracellular K^+, while substituted benzimidazole compounds irreversibly inhibit gastric H,K-ATPase by forming a covalent (disulfide) bond between the sulfonamide form of the compound (produced in very acid pH) and the thiol group of a cysteine residue exposed at the cell surface.[20]

Genetics

Gene inactivation studies have shown that Na,K-ATPase is essential for life. Absence of Na,K-ATPase α1 expression is embryonically lethal, even though $\alpha1^{-/-}$ embryos develop beyond the blastocyst stage.[26] In contrast, $\alpha2^{-/-}$ animals are born alive but die soon after birth, most likely as the result of dysfunctional neuronal circuits involved in controlled respiration.[27] α1 or α2 gene inactivation in heterozygous animal tissues leads mostly to disturbances of cardiac phenotype, supporting an important role for the α2 isoform in intracellular calcium homeostasis.[28,29] Only two human genetic diseases are known to be related to mutations of Na,K-ATPase α isoforms. A familial form of hemiplegic migraine has been associated with mutations in the α2 gene that abolish or greatly reduce enzyme activity[30,31] (OMIM #602481). Rapid onset dystonia parkinsonism has been associated with an inactivating mutation of the α3 gene[32] (OMIM #128235). In both cases, the mode of inheritance is dominant, suggesting that the disease is due to a haploinsufficiency of α2 and α3 isoforms, respectively. A dominant form of familial hypomagnesemia has been associated with a mutation in the FXYD2 gene.[33]

REGULATION OF Na,K-ATPASE

Obviously, the activity of an enzyme of such paramount importance for so many cellular and organ functions must be tightly regulated. Physiological regulation of Na,K-ATPase activity is complex and occurs at several levels. First, the activity of Na,K-ATPase depends on its three substrates, Na^+, K^+, and ATP. Second, for short-term regulation, the activity of Na,K-ATPase present at the cell surface can be regulated by post-translational modifications, such as phosphorylation. Third, Na,K-ATPase density at the cell surface is controlled by its rate of synthesis, at both transcriptional and post-transcriptional levels, by its degradation, and by its distribution between the cell surface and intracellular pools. Finally, there is some evidence that protein−protein interactions further regulate Na,K-ATPase activity and abundance.

Substrates

Interaction of intracellular Mg-ATP with Na,K-ATPase is complex and involves high- and low-affinity sites. Since intracellular ATP concentration is usually largely above $K_{1/2}$ values, ATP is not considered a physiological limiting factor for Na,K-ATPase activity. However, under pathological conditions, such as ischemia/hypoxia, ATP may become rate limiting. Similarly, since normal concentrations of extracellular K^+ (3.5−4.5 mM) are above $K_{1/2}$ values, physiological variations are not expected to influence Na,K-ATPase activity, although decreased activity could occur under conditions of severe hypokalemia. In contrast, intracellular Na^+ concentration is below, or close to, $K_{1/2}$ values. Considering the steep concentration−activity relationship, with a Hill coefficient between 2 and 3, a low concentration of intracellular Na^+ implies that Na,K-ATPase operates far from its maximal rate under physiological conditions. It follows that small variations in intracellular Na^+ are immediately followed by parallel variations in Na,K-ATPase activity, in order to maintain a constant intracellular Na^+ concentration.

Intracellular Na^+ and extracellular K^+ concentrations can also have a long-term effect on Na,K-pump density. The influence of extracellular K^+ on α2

expression was demonstrated in skeletal muscle.[34] Under conditions of hypokalemia, α2 is downregulated, allowing release of K^+ from large intracellular pools in muscle and fine regulation of K^+ homeostasis in small extracellular pools. Similarly, intracellular Na^+ modulates Na,K-ATPase expression (see "Na,K-ATPase and the Kidney").

Post-Translational Modifications

Na,K-ATPase α-subunits can be phosphorylated by several protein kinases. PKA phosphorylates a serine residue (S_{943})[35,36] located in a short intracellular loop that links the *M8* and *M9* segments, conserved in all Na,K-ATPase and H,K-ATPase isoforms. However, the functional relevance of this PKA site has been questioned, because it should be poorly accessible under native conformational states,[37] and because its mutation did not alter the effect of PKA on Na,K-ATPase activity in renal epithelial cells.[38] Activation of PKC also results in Na,K-ATPase α-subunit phosphorylation. A conserved, non-conventional PKC phosphorylation site, S_{16}, located in the intracellular N-terminal domain of the α1-subunit,[36,39] as well as two species-specific PKC sites (S_{23} in rat α1, and T_{15} in *Bufo marinus* α1) have been identified. α2- and α3-subunits are poor substrates for PKC or are not phosphorylated at all.[40] PKC phosphorylation of the α-subunit may regulate both apparent Na^+ affinity and cell surface expression of the enzyme.[41–43] More recently, tyrosine phosphorylation of α1 at Y_{10} in response to insulin,[44,45] and also at Y_{260} in response to ouabain,[46] has been described. Similarly, tyrosine phosphorylation of α2 was reported, although the phosphorylation site has not been mapped.[45] Tyrosine phosphorylation of Na,K-ATPase is functionally associated with both an increase of apparent Na^+ affinity and an increase of the enzyme's cell surface expression.[44,45] Finally, phosphorylation of α1 by ERK has been shown *in vitro* and in response to insulin in skeletal muscle. This ERK-dependent phosphorylation is associated with stimulation of Na,K-ATPase activity via increased cell surface expression.[43]

Synthesis and Degradation

Since αβ-subunit stoichiometry is inflexible, controlled synthesis of both subunits is expected to participate in regulating Na,K-ATPase activity. Hormonal control by glucocorticoids, mineralocorticoids, and thyroid hormones has been demonstrated. Thyroid hormones have been shown to regulate the synthesis of both subunits, but the mechanism of this regulation is complex and differs between organs.[47] For instance, glucocorticoids stimulate the transcription of mostly β-subunit mRNA in lungs, even though expression of both α and β protein is increased, indicative of complex transcriptional and post-transcriptional control.[48,49] Regulation of Na,K-ATPase by mineralocorticoids will be discussed later in the section "Na,K-ATPase in the Kidney."

In addition to the rate of synthesis of its subunits, Na,K-ATPase abundance is dependent on its degradation rate. Recent experimental evidence obtained by pulse-chase experiments in lung alveolar[50] and renal (E. Feraille, unpublished results) epithelial cells indicates that the half-life of plasma membrane Na,K-ATPase is approximately 4 hours, while that of newly synthesized α-subunits is approximately 6 hours. Therefore, in contrast to current belief, Na,K-ATPase half-life is relatively short in epithelial cells. The majority of Na,K-ATPase is degraded by lysosomes, and ubiquitination of its α-subunit may participate in this process.[50] Regulation of Na,K-ATPase degradation in response to variations of transepithelial sodium transport will be discussed later in the section "Na,K-ATPase in the Kidney."

Membrane Trafficking

An increasing amount of experimental evidence indicates that plasma membrane Na,K-ATPase expression is controlled via regulated membrane trafficking. Regulated Na,K-ATPase endocytosis was first demonstrated in response to dopamine by atypical PKC-ζ in rat proximal tubule cells.[51] This will be discussed later in the section "Na,K-ATPase in the Kidney." The role of PKC-ζ in Na,K-ATPase endocytosis has been confirmed in alveolar lung cells in response to hypoxia.[52] Downregulation of plasma membrane Na,K-ATPase has also been demonstrated in response to ouabain in renal epithelial cells (LLCPK1 cells),[52] and to AMPK activation in response to CO_2 in lung alveolar cells.[53] Moreover, direct interaction of the Na-K-ATPase α-subunit with arrestins and spinophilin modulates its endocytotic rate in COS-7 cells.[54] It remains to be determined whether internalized Na,K-ATPase units are degraded or recycled back to the plasma membrane.

Rapid recruitment of Na,K-ATPase to the plasma membrane has first been demonstrated in response to insulin in skeletal muscle[55] and following an increase of intracellular sodium concentration in renal collecting ducts.[56] This latter event will be discussed in the section "Na,K-ATPase in the Kidney." Increased cell surface expression of Na,K-ATPase was subsequently demonstrated in response to aldosterone in renal collecting duct cells,[57] and to increased cAMP levels in both renal[58] and lung epithelial cells.[59] This process is sensitive to brefeldin A,[58] suggesting that a latent pool of Na,K-ATPase units is recruited from the trans-Golgi network. In addition, activation of PKC-β in proximal tubule cells[51] and PKC-δ–εδ in lung alveolar cells[60] increases Na,K-ATPase plasma membrane expression. Exocytosis of Na,K-ATPase is dependent on RhoA,[61]

kinesin,[62] and myosin-Va[63] in lung alveolar cells. The amount of active Na,K-ATPase units at the cell surface is therefore highly regulated via both endocytotic and exocytotic processes.

Interaction with the Cytoskeleton

Na-K-ATPase interacts both directly and indirectly with the membrane cytoskeleton in several ways. Na,K-ATPase binds directly to ankyrin, which itself links Na,K-ATPase to spectrin (fodrin) and consequently to the basolateral cytoskeleton.[64,65] Ankyrin-spectrin interaction is thought to participate in specific targeting of Na-K-ATPase to the basolateral membrane of epithelial cells. Na-K-ATPase activity may also be modulated via its association with ankyrin.[66]

Na,K-ATPase and actin filaments display a complex relationship that is not fully understood. Actin filaments may directly modulate Na,K-ATPase activity[67] or indirectly control Na,K-ATPase plasma membrane expression via adducins which control actin polymerization.[68] Mutant α-adducin associated with hypertension in rats and humans was shown to decrease constitutive Na,K-ATPase endocytosis, and thereby increase the number of active Na,K-ATPase units at the cell surface.[68] Direct activation of Na,K-ATPase activity by adducin was also demonstrated.[66] In addition, Na,K-ATPase directly binds to cofilin, which modulates actin filament polymerization.[69] Na,K-ATPase basolateral targeting and modulation of its activity appears additionally to depend on its interaction with multiple cytoskeletal elements.

NEW PHYSIOLOGICAL FUNCTIONS OF Na,K-ATPASE

In addition to its well-known function, i.e., Na^+ and K^+ membrane translocation, Na,K-ATPase modulates a variety of cellular processes involved in cell growth, differentiation, and intercellular adhesion.

Cell Signaling by Na,K-ATPase

Since the pioneering work of Askari et al. which demonstrated that ouabain induces early response genes involved in cardiac hypertrophy in a Ca^{2+}-dependent manner,[70] a large body of experimental evidence collectively indicates that Na,K-ATPase behaves as a signaling platform in both mesenchymal and epithelial cells. Activation of Src and Epidermal Growth Factor (EGF) receptor tyrosine kinases, and downstream activation of MAP kinases (ERK) by ouabain at concentrations that do not alter intracellular Na^+ concentration was demonstrated in cardiac myocytes and in LLC-PK1 renal epithelial cells.[71] Ouabain induces dissociation and activation of Src from Na,K-ATPase,[72] and subsequent transactivation of EGF receptor. This ouabain-induced signaling depends on a pool of non-functional Na,K-ATPase specifically located in caveola.[73–75] In addition to ERK activation, ouabain induces calcium oscillations via close association of phospholipase C and IP3 receptors in cell signaling microdomains.[76,77] However, these ouabain-dependent signaling events remain to be demonstrated in native tissues, and their physiological relevance is not yet established.

Role of Na,K-ATPase in Cell Adhesion

An increasing amount of experimental evidence indicates that the Na,K-ATPase β1-subunit plays a direct role in homotypic cell−cell adhesion.[78] This cell−cell adhesion function is negatively correlated with the level of complexity of β glycosylation.[79] Moreover, the transcription factor Snail, which plays a key role in epithelial-to-mesenchymal transition processes observed in poorly differentiated carcinoma cells, represses Na,K-ATPase β1-subunit transcription.[80] In addition to a direct inhibition of cell motility via increased cell−cell adhesion, Na,K-ATPase may also modulate cell migration via its interaction with the PI3-kinase p85 regulatory subunit.[81] This adhesive function of Na,K-ATPase may play important roles in organogenesis and carcinoma invasiveness.

Na,K-ATPase also modulates tight junction dynamics and permeability in cultured renal epithelial cells.[82] Indeed, both ouabain and low extracellular K^+, which inhibit Na,K-ATPase and increase intracellular Na^+, prevent tight junction recovery in calcium switch experiments performed on MDCK cells.[83] This effect is dependent on inhibition of RhoA GTPase activity by high intracellular Na^+. In addition, ouabain at concentrations that do not alter transcellular K^+ transport increases tight junction permeability via activation of Src and ERK.[84] The physiological relevance of these findings remains to be demonstrated.

Na,K-ATPASE IN THE KIDNEY

Tubular epithelial cells are characterized by their functional polarity. Na,K-ATPase is exclusively located in the basolateral membrane, the infoldings of which are closely surrounded by mitochondria which provide a constant supply of ATP. The Na^+ gradient generated by Na,K-ATPase between intra- and extracellular compartments is mainly dissipated across the apical membrane. A net reabsorption of Na^+ results from this architectural organization, and the main role of Na,K-ATPase in the kidney is to energize Na^+ reabsorption. In humans, kidneys reabsorb over 500 g of

sodium per day, and utilize over 2 kg of ATP to fuel Na,K-ATPase. Although renal Na,K-ATPase also energizes secondary active transport of other solutes, its main function is related to Na^+ transport.

Measurements in microdissected segments of the mammalian renal tubule indicate that Na,K-ATPase activity is high in the thick ascending limb of Henle's loop (TAL) and the distal convoluted tubule (DCT), intermediate in the proximal tubule (PT) and the collecting duct (CD), and very low in the thin segments of Henle's loop. This distribution profile of Na,K-ATPase activity is correlated with transtubular Na^+ reabsorption capacity in various nephron segments.[85] In PT and CD, Na,K-ATPase activity declines from the kidney cortex toward the outer and inner medulla.[48] This distribution profile is confirmed by immunocytochemistry on kidney sections and by quantification of the number of pumps by ^{3}H-ouabain binding or by Western blotting of α1- and β1-subunits. Immunohistochemistry on kidney sections indicate that Na,K-ATPase expression in the collecting duct is much higher in principal than in intercalated cells. In contrast, quantification of Na,K-ATPase mRNA along the rat nephron does not confirm this axial heterogenic distribution, at least for α- and β-subunits (A. Doucet, personnal communication). This suggests the presence of segment-specific control mechanisms for Na,K-ATPase translation and/or degradation.

Regulation of Na,K-ATPase in Proximal Tubule

Na,K-ATPase activity must be tightly controlled, since the PT reabsorbs the bulk of filtrated sodium (more than 60%). Na,K-ATPase is regulated by hormones, neurotransmitters, and para/autocrine factors acting via synergistic or antagonistic signaling pathways, and one should keep in mind that the final effect, i.e., stimulation of inhibition of Na,K-ATPase activity, is not the result of activation of a single signaling pathway, but rather of a highly complex integrated response. Modulation of Na,K-ATPase cell surface expression and its affinity for Na^+ are the most important mechanisms of regulation identified in PT.

Control of Na,K-ATPase by Insulin

Stimulation of Na,K-ATPase by insulin in the PT most likely participates in stimulation of Na^+ reabsorption in this nephron segment.[86] Indeed, in isolated rat PT, insulin stimulates Na,K-ATPase transport activity in the presence of physiological concentrations of intracellular Na^+, not by changing V_{max} values, but by increasing apparent Na^+ affinity.[87] Experiments performed in isolated rat PT and in cultured OK cells (a cellular model of PT) strongly suggest that stimulation of Na,K-ATPase activity relies on phosphorylation of the α-subunit at Y_{10}.[44] However, the causal relationship between tyrosine phosphorylation of Na,K-ATPase and increased Na^+ affinity remains to be directly demonstrated. Insulin also reduces the inhibitory effect of dopamine on Na,K-ATPase (see next section),[88] and this may also participate in its overall stimulatory effect.

Control of Na,K-ATPase by Dopamine and Parathormone

Dopamine is produced from L-dopa by PT, and its synthesis is increased by high sodium intake, making it a putative local modulator of sodium and fluid handling. Dopamine decreases fluid and sodium reabsorption *in vitro* in microperfused rabbit PT.[89] Accordingly, dopamine decreases Na,K-ATPase V_{max} values in rat PT,[90] as well as in OK cells.[42] Although dopamine also increases Na,K-ATPase apparent affinity for Na^+ in the PT,[90] the overall resulting effect in intact cells is Na,K-ATPase inhibition.[42] This inhibition results from activation of both dopamine DA_1- and DA_2-like receptors,[91] and is mediated by PKCζ.[51]

Within minutes, dopamine induces Na,K-ATPase endocytosis from the plasma membrane to intracellular compartments. Decreased Na,K-ATPase expression at the basolateral membrane of rat PT is associated with a sequential increase of Na,K-ATPase abundance in clathrin-coated pits (1 minute), early endosomes (2.5 minutes), and late endosomes (5 minutes).[92] Results obtained in OK cells strongly suggest that the inhibitory effect of dopamine is dependent on PKC-mediated phosphorylation of the Na,K-ATPase α-subunit on S_{23}.[42,93] Following endocytosis, the α-subunit is dephosphorylated in late endosome compartments[42] (Figure 3.3).

Dopamine-induced endocytosis of Na,K-ATPase is also associated with activation of phosphatidylinositol 3-kinase (PI3K), an enzyme critical for membrane trafficking.[94] However, dopamine-induced activation of PI3K is not secondary to its phosphorylation. Rather, S_{23} phosphorylation of the Na,K-ATPase α-subunit serves as an anchor signal for the sequential recruitment of 14-3-3 protein[95] and PI3K[96] to the membrane. Activation of PI3K in turn generates local production of phosphatidylinositol 3-phosphate, which allows binding of Na,K-ATPase with adaptor protein-2 (AP2), recruitment of clathrin, and endocytosis of Na,K-ATPase.[97] Concomitantly, dopamine activates protein phosphatase 2A which in turn dephosphorylates dynamin 2, thus allowing Na,K-ATPase recruitment at the plasma membrane.[98]

Parathormone (PTH) inhibits fluid and solute transport by PT,[99] at least in part via inhibition of Na,K-ATPase activity, as first demonstrated in PT suspensions.[100] This inhibitory effect relies partly on generation of arachidic acid metabolites via the cytochrome P450 pathway.[101] Na,K-ATPase endocytosis in response to PTH has been observed both *in vitro*, in OK

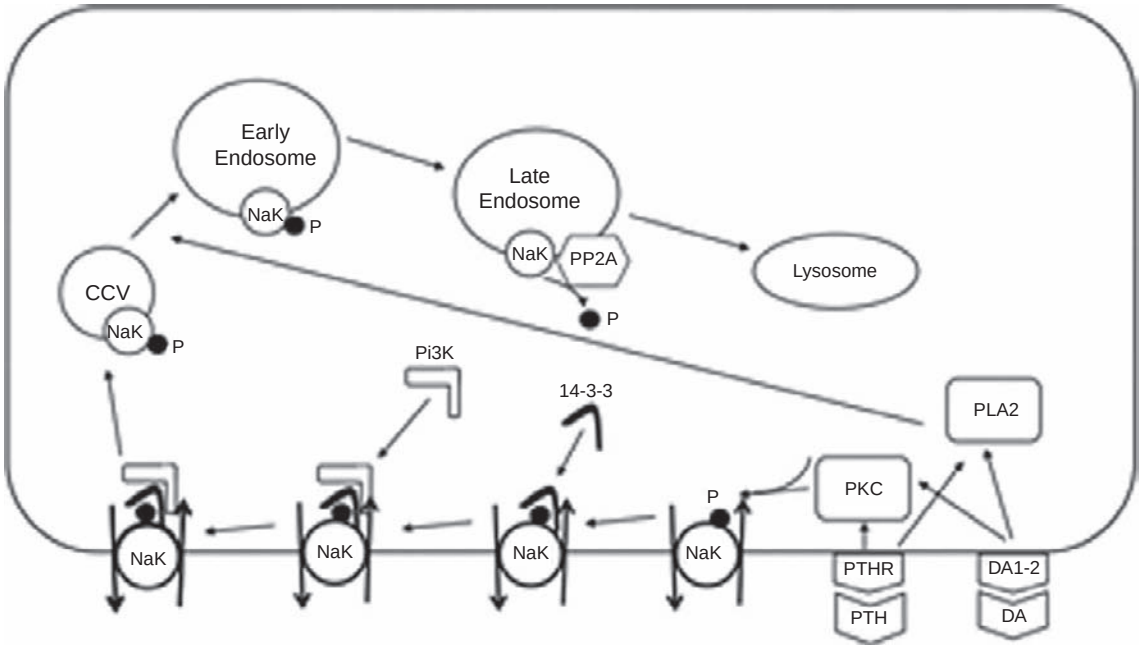

FIGURE 3.3 **Regulation of Na,K-ATPase by dopamine and parathormone (PTH) in proximal tubule.** After dopamine or PTH bind to their cognate receptor, PKC is activated leading to phosphorylation of the Na,K-ATPase α-subunit on S23, followed by binding of 14-3-3 protein and p85 subunit of the Pi3-kinase. This cascade of events leads to Na,K-ATPase endocytosis via clathrin coated vesicles (CVV). Na,K-ATPase is then dephosphorylated in endosomes by PP2A and degraded in lysosomes. Phospholipase A2 (PLA2) activation modulates Na,K-ATPase internalization.

cells,[102] and *in vivo* after infusion of PTH in normal rats,[103] and may account for the inhibitory effect of this hormone. Studies performed in the OK cell model have shown that PTH-induced endocytosis of Na,K-ATPase is ERK-dependent, requires S_{16} phosphorylation of the α-subunit and the scaffolding protein NHERF1.[102,104]

Endocytotic removal of active Na,K-ATPase from the plasma membrane therefore constitutes a major regulatory mechanism of fluid and sodium reabsorption by the PT.

Angiotensin II Exerts a Biphasic Effect on Na,K-ATPase

Angiotensin II (ANG II) controls PT Na^+ reabsorption from both luminal and basolateral sides. High concentrations of ANG II can be found in the PT lumen with respect to plasma circulating concentrations,[105] suggesting that the majority of luminal ANG II originates from local synthesis. Indeed, PT cells express angiotensinogen,[106] renin,[107] and angiotensin converting enzyme.[108] Only a very small fraction of ANG II is excreted in the urine, since it is almost entirely reabsorbed and degraded by PT.[109] ANG II exerts a biphasic effect. Low levels of ANG II (12^{-12} to 10^{-10} M) stimulate, while high levels of ANG II (10^{-9} to 10^{-7} M) inhibit, fluid and solute reabsorption *in vivo* in microperfused rat PT.[110] ANG II also modulates Na,K-ATPase activity in a biphasic manner in isolated PT.[111] At low concentrations, ANG II enhances Na,K-ATPase activity via an increase in its apparent Na^+ affinity.[112] The mechanism by which high levels of ANG II inhibit Na,K-ATPase activity remains to be determined.

Regulation of Na,K-ATPase in Thick Ascending Limb of Henle's Loop

The TAL reabsorbs close to 15% of the filtered Na^+ load and is impermeable to water. As a result, fluid delivered to the distal convoluted tubule is hypotonic, NaCl concentration levels being close to 50 mM. Na^+ enters the luminal side of the cell via a furosemide-sensitive Na-K-2Cl-co-transporter (BSC1 or NKCC2), and Cl^- leaves the cell via Cl^--channels and K-Cl co-transporters. K^+ is recycled back to the lumen via inwardly rectifying and voltage-insensitive K^+-channels expressed at the apical membrane. Conductive diffusion of Cl^- and K^+ depolarizes the basolateral membrane and hyperpolarizes the apical membrane, respectively. The combination of both diffusion potentials generates positive transepithelial voltage which provides the driving force for paracellular cation reabsorption.

Micropuncture and *in vitro* microperfusion experiments show that cAMP analogs and hormones coupled to adenylyl cyclase activation enhance NaCl reabsorption in the TAL.[48] Stimulation of Na^+ reabsorption by the cAMP signaling pathway is at least in

part mediated by stimulation of Na,K-ATPase activity. This stimulatory effect is observed at V_{max} values, and requires sufficient amounts of oxygen and metabolic substrates. Indeed, when metabolic supply is limiting, an increase of cellular cAMP content actually inhibits Na,K-ATPase activity via generation of arachidonic acid metabolites that in turn is dependent on the cytochrome P450 pathway. Na,K-ATPase stimulation by cAMP is correlated with increased phosphorylation levels of the Na,K-ATPase α-subunit.[113] It remains to be determined whether this effect results from phosphorylation of the α-subunit by PKA or by another kinase.

The stimulatory effect of the cAMP/PKA signaling pathway is subject to negative modulation by numerous signaling pathways, including protein Gαi activation by prostaglandins,[114] cGMP generation in response to nitric oxide[115] and natriuretic peptides,[116] and PKC stimulation in response to angiotensin II,[117] bradykinin,[118] and extracellular Ca^{2+} via activation of the extracellular Ca^{2+} receptor.[119]

Control of Na,K-ATPase in Collecting Duct

Mammalian connecting tubules (CNT) and CD (cortical collecting duct: CCD, outer medullary collecting duct: OMCD, inner medullary collecting duct: IMCD) are the main sites for the fine-tuning of sodium reabsorption, crucial for the adjustment of daily urinary sodium excretion to dietary intake. In these renal tubule segments, apical sodium entry is primarily mediated by amiloride-sensitive sodium channels (ENaC),[48] and accessorily mediated by a recently identified sodium-dependent chloride/bicarbonate exchanger, SLC4A8.[120] ENaC was long thought to be the principal player for sodium transport, Na,K-ATPase activity being adapted secondarily to changes of intracellular Na^+ concentration, itself brought about by changes in ENaC activity. However, it is now clearly established that regulation of sodium transport results from the coordinated regulation of both ENaC and Na,K-ATPase.

Aldosterone Induces a Biphasic Stimulation of Na,K-ATPase

Na,K-ATPase activity (V_{max} values) is decreased by ~70% in collecting ducts[121] within 4–5 days of adrenalectomy, but is increased following administration of supraphysiological doses of mineralocorticoid. This latter effect appears after a 24-hour latency, and culminates after approximately 6 days.[85] Administration of aldosterone to adrenalectomized animals[122] or *in vitro* addition of aldosterone to renal tubules isolated from adrenalectomized animals[123] also increases Na,K-ATPase activity (V_{max} values) in the CD, but this effect is much more rapid than in adrenal-intact animals since it is observed after only an hour, and is maximal after only 2–3 hours. These data indicate that low levels of CCD Na,K-ATPase activity and plasma aldosterone concentration is associated with a fast stimulatory response.[124]

Short-term (2–6 hour) aldosterone challenge increases both the activity and cell surface expression of Na,K-ATPase via recruitment of a latent pool of pumps, as shown both in CD isolated from adrenalectomized rats, and in cultured $mpkCCD_{C14}$ cells, a model of CCD principal cells[57] (Figure 3.4). Although cell fractionation and cell-surface labeling studies suggest that a latent pool of Na,K-ATPase is intracellular,[58,92] its exact localization has not yet been established. Short-term stimulation of Na,K-ATPase activity occurs independently of ENaC and apical sodium entry, but does depends on *de novo* transcription and translation.[57] Experiments performed on *Xenopus* oocytes demonstrated that serum and glucocorticoid-regulated kinase-1 (SGK1), an early aldosterone-inducible gene, increased Na,K-ATPase activity and cell surface expression.[125] This suggests that aldosterone-induced recruitment of latent Na,K-ATPase units may be mediated by SGK1. Early recruitment of latent Na,K-ATPase is followed by transcriptional stimulation and synthesis of Na,K-ATPase α1- and β1-subunits.[126] In summary, after a latency period of 1 hour, aldosterone stimulates Na,K-ATPase activity in a biphasic manner. First via recruitment of an inactive Na,K-ATPase reservoir to the cell surface, and then by increased synthesis of Na,K-ATPase subunits.

Vasopressin Stimulates Na,K-ATPase

Vasopressin (AVP) is coupled to adenylyl cyclase via V_2 receptors, and stimulates the cAMP/PKA signaling pathway in CD principal cells. The major role of AVP in CD is to stimulate water reabsorption by increasing water permeability of the apical membrane of principal cells. However, *in vitro* microperfusion studies have shown that AVP also stimulates Na^+ reabsorption and K^+ secretion along the CD.[48] This effect of AVP on urinary Na^+ excretion has recently been confirmed in humans.[127]

Na,K-ATPase stimulation is a prerequisite for increased Na^+ reabsorption, but initial studies reported an inhibitory effect of AVP and cAMP analogs on Na,K-ATPase activity in isolated rat CCD.[128] Results from our laboratory indicate that an arachidonic acid-dependent inhibitory pathway is induced by metabolic stress related to *ex vivo* experimental conditions.[113] Indeed, in both well-oxygenated, isolated rat CCDs, and cultured $mpkCCD_{Cl4}$ cells, cAMP analogs induced a two-fold stimulation of Na,K-ATPase activity.[58,129] This stimulatory effect is rapid (5 min), and is associated with a proportional increase of Na,K-ATPase cell surface

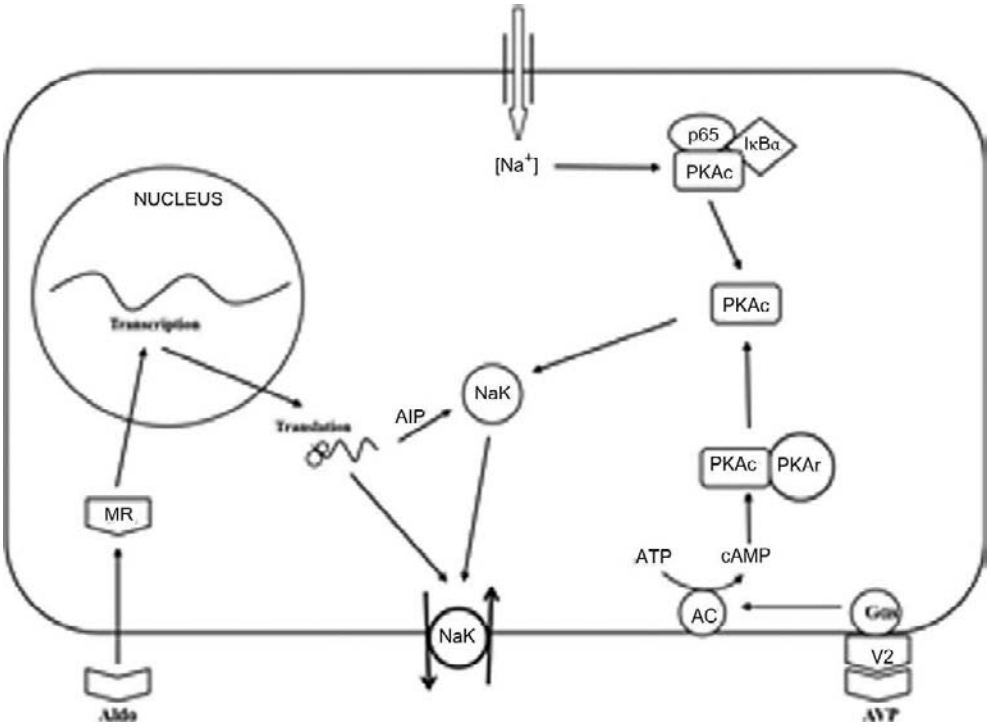

FIGURE 3.4 **Regulation of Na,K-ATPase by aldosterone, vasopressin, and Na^+ in the collecting duct.** Binding of aldosterone to the mineralocorticoid receptor leads to its translocation to the nucleus. This first increases the expression of early aldosterone-induced proteins (AIP), and then induces late expression of Na,K-ATPase. AIP leads to the recruitment of inactive intracellular Na,K pumps to the plasma membrane. Binding of vasopressin to its V_2 receptor induces cAMP synthesis, leading to dissociation of the PKA catalytic subunit (PKAc) from its regulatory subunit (PKAr). An increase of intracellular Na^+ leads to the dissociation of a protein complex containing p65 NF-κB, IκBα and PKAc. Free PKAc participates in the recruitment of inactive intracellular Na,K pumps to the plasma membrane.

expression in the absence of a change in whole-cell Na,K-ATPase abundance in a PKA-dependent manner[38,129] (Figure 3.4). Identification of a cAMP-responsive Na,K-ATPase pool and its relation to an aldosterone controlled reservoir remains to be determined.

Na,K-ATPase Expression is Regulated by Sodium Availability

Acute (hour) increases of intracellular Na^+ in CD not only activate Na,K-ATPase activity via a substrate effect, but also rapidly increase V_{max} values and the number of active Na,K-ATPase units present at the cell surface.[56] This rapid stimulation occurs independently of protein synthesis, suggesting that pre-existing Na,K-ATPase units present in a latent pool are recruited to the cell surface (see above). The effect of intracellular Na^+ is mediated by cAMP-independent PKA activation[130] that itself results from dissociation of a complex consisting of NF-κB, IκBα and the catalytic PKA subunit.[131] This indicates that the pro-inflammatory NF-κB pathway may be part of a Na^+ sensing mechanism that mediates cross-talk between apical Na^+ entry and basolateral Na^+ exit (Figure 3.4). Recent experimental evidence indicates that a sustained increase of apical Na^+ entry also increases Na,K-ATPase expression via inhibition of Na,K-ATPase endocytosis and degradation (E. Feraille, personal communication). Such modulation of Na,K-ATPase activity by Na^+ load may be involved, to some extent at least, in diuretic resistance. Accordingly, chronic administration of the loop diuretic furosemide stimulates CD Na,K-ATPase activity independently of variations of circulating aldosterone.[132]

Induction of Na,K-ATPase is Associated with Sodium Retention in Nephrotic Syndrome and Liver Cirrhosis

Interstitial edema is a cardinal clinical manifestation in nephrotic syndrome. It is secondary to the accumulation of sodium in the extracellular compartment following imbalanced dietary sodium intake and urinary sodium output, and also results from alterations of fluid transfer across the capillary endothelial barrier. Mechanisms behind sodium retention have been extensively investigated using a rat model of puromycin aminonucleoside (PAN)-induced nephrotic syndrome. Both *in vivo* and *in vitro* studies demonstrated that the CCD is the main site of increased Na^+ reabsorption in

PAN nephrotic rats.[133,134] Na,K-ATPase hydrolytic and transport activities are increased two-fold in CCD of PAN nephrotic rats.[135] Increased Na,K-ATPase stimulation, which culminates at day 6 following PAN administration, parallels decreased urinary sodium excretion and development of a positive sodium balance.[136] Moreover, a linear inverse correlation between urinary sodium excretion and CD Na,K-ATPase activity is observed in three different experimental models of nephrotic syndrome.[136] Stimulation of Na,K-ATPase activity is paralleled by increased abundance of α and β Na,K-ATPase mRNA and basolateral protein expression.[129] Sodium retention and induction of Na,K-ATPase activity in CCD are independent of variations of circulating aldosterone.[135,137]

Interstitial edema and ascites are frequently observed in liver cirrhosis. The mechanism governing sodium retention in liver cirrhosis is under debate; however, dysregulation of CD Na,K-ATPase activity may play a key role. Indeed, in the bile duct ligation model Na,K-ATPase activity is specifically increased in mouse CCD independently of variations of circulating glucocorticoids or aldosterone.[138]

In summary, increased Na,K-ATPase activity in the CCD participates in sodium retention in both experimental nephrotic syndrome and liver cirrhosis, and may therefore play a key role in the pathogenesis of edematous diseases.

The previous paragraphs collectively outline the complexity of Na,K-ATPase regulation in the kidney. They demonstrate that: (1) hormonal triggering of intracellular signaling pathways can rapidly alter Na,K-ATPase V_{max} values and/or modulate the pump's affinity for Na^+; (2) these changes are true regulatory mechanisms that occur independently of changes in apical Na^+ entry; and (3) they are generally accompanied by a concomitant regulation of apical Na^+ entry. Thus, despite repetitive and rapid changes of Na^+ reabsorption, whole-body sodium balance and intracellular Na^+ homeostasis are maintained, at least in part, by short-term regulation of Na,K-ATPase activity. Finally, alterations of Na,K-ATPase activity are relevant to the pathophysiology of edematous diseases.

H,K-ATPASES IN KIDNEY

Kidney H,K-ATPase was first described following the discovery that it participates in primary active K^+ reabsorption, a process characterized by H,K-ATPase-like activity in the mammalian distal nephron.[139] Gastric and colonic H,K-ATPase α-subunits were subsequently cloned and mRNAs encoding these two ATPases were shown to be expressed in the kidney. We will discuss the specific inference of gastric and colonic H,K-ATPases in the kidney. Special attention will be paid to studies performed in K^+-replete and K^+-depleted animals in consideration of gastric and colonic H,K-ATPases, respectively. Indeed, kidney expression of αHKc is very low or even absent in K^+-replete animals, whereas it is markedly induced in response to K^+ depletion.

Gastric H,K-ATPase

Gastric H,K-ATPase activity, referred to as type I K-ATPase activity, was first detected as a Na^+-independent, K^+-activated ATPase activity in CD isolated from several mammalian species administered a standard diet.[139] Type I K-ATPase activity is ouabain-insensitive, and is inhibited by omeprazole and Sch 28080. This pharmacological profile fits well with that reported for gastric mucosa K-ATPase and gastric H,K-ATPase expressed in artificial systems. Moreover, Type I K-ATPase is not detected in CD of αHKg knockout mice,[21] thus demonstrating that gastric H,K-ATPase is responsible for type I K-ATPase activity. Most studies have detected moderate levels of αHKg mRNA and protein in rat and mouse CD,[140] while βHKg mRNA has been detected in rat and rabbit CD and CNT.[22] However, HKg-subunit expression remains to be demonstrated in human kidney. *In situ* hybridization, immunochemistry, and functional studies indicate that αHKg is mostly (if not exclusively) expressed in both α- and β-intercalated cells.[140]

In vitro microperfusion studies performed on rats have shown that HCO_3^- reabsorption is inhibited by luminal (but not peritubular) addition of Sch 28080 to OMCD, but not to CCD. However, peritubular addition of Sch 28080 reduces HCO_3^- secretion induced by *in vivo* CCD alkalosis. These results suggest the involvement of apical H,K-ATPase in OMCD α-intercalated cells, and in the basolateral membrane of CCD β-intercalated cells, at least during metabolic alkalosis.[141] The functional role of CD H,K-ATPase has been more extensively studied in normal rabbits. *In vitro* microperfusion studies performed in rabbit OMCD indicate that HCO_3^- reabsorption is markedly reduced by luminal addition of Sch 28080 and by removal of luminal K^+.[140] An Sch 28080-sensitive, K^+-dependent mechanism of H^+ extrusion has been demonstrated in CCD α- and β-intercalated cells by measuring their pH recovery following intracellular acidification.[142] However, the contribution of H,K-ATPase to K^+ reabsorption under normal conditions may be minimal, since most K^+ that enters the cytoplasm via H,K-ATPase is recycled back to the lumen via apical K^+-channels.[143]

Transgenic mice expressing βHKg containing a mutant endocytosis signal display H,K-ATPase that is constitutively expressed at the apical membrane of

stomach parietal cells. This is accompanied by gastric acid hypersecretion.[144] These animals also display constitutively active renal K^+ reabsorption,[145] suggesting that gastric H,K-ATPase participates in K^+ reabsorption in mouse kidney, at least when overexpressed at the apical membrane. In contrast, transgenic mice deficient in αHKg do not display altered H^+ and K^+ renal handling.[146] Indeed, the rate of CCD K^+-dependent proton secretion is similar between wild-type and αHKg-deficient mice.[147] However, K^+-dependent H^+ secretion is sensitive to Sch 28080 in wild-type mice, whereas it is insensitive to Sch 28080 in αHKg-deficient mice.[147] This suggests that αHKg deficiency is functionally compensated by expression of another, yet unidentified, K^+-dependent H transporter.

Altogether, these studies indicate that gastric H,K-ATPase expressed in CD intercalated cells of normal rat, rabbit, and mouse kidney participates mostly in urinary acidification and/or HCO_3^- reabsorption. Its contribution to a K^+-reabsorption process is weak, except when artificially overexpressed.

Only a few studies evaluated how gastric H,K-ATPase adapts to disorders of acid−base balance. On the one hand, type I K-ATPase activity is increased in rat CCD and OMCD during hypercapnia-induced respiratory acidosis, whereas it is reduced by hypocapnia. On the other hand, chronic metabolic acidosis increases H,K-ATPase-mediated H^+ secretion by rabbit CCD that may rely on increased transcription of αHKg during the first hours of acid challenge, and thereafter on post-transcriptional mechanisms.[140,148] In contrast to acidosis, K^+ depletion increases neither type I K-ATPase activity, nor αHKg expression.[140] Post-transcriptional control of gastric H,K-ATPase in rat collecting ducts is demonstrated by the *in vitro* stimulatory effects of calcitonin and isoproterenol on type I K-ATPase,[149] two hormones that stimulate proton secretion and reabsorption in α- and β-intercalated cells, respectively. Stimulation of type I K-ATPase by calcitonin in α-intercalated cells is mediated by activation of ERK, by a cAMP-dependent and protein kinase A-independent mechanism, via the guanine-nucleotide exchange factor Epac 1.[150] Stimulation of type I K-ATPase by isoproterenol in β-intercalated cells is also secondary to ERK activation, occurring rather through PKA-dependent activation of the Ras/Raf1 pathway.[151]

Colonic H,K-ATPase

Type III K-ATPase activity sensitive to both Sch 28080 ($IC_{50} \approx 1\ \mu M$) and ouabain ($IC_{50} \approx 20\ \mu M$) is detected in CD of K^+-depleted, but not normal, rats.[152] Type III K-ATPase activity is absent in CD of K^+-depleted αHKc-deficient mice.[21] In the kidney of normal rats, αHKc mRNA is expressed at low levels along the entire distal nephron, from medullary thick ascending limb of Henle's loop to IMCD.[153] αHKc mRNA and protein expression levels are much higher in K^+-depleted rats than in normal rats.[140,153] Immunohistochemistry studies performed on normal rats revealed that labeling of OMCD principal cells at the apical membrane is markedly increased in K^+-depleted rats,[154] but that curiously K^+ depletion does not induce labeling of CCD principal cells, even though CCD from K^+-depleted rats display increased mRNA expression[153] and increased type III K-ATPase activity.[152] In normal rabbits, αHKc was detected at the apical pole of principal cells and intercalated cells in CNT and CD.[155] In transgenic mice expressing EGFP under the control of the αHKc promoter, EGFP is specifically expressed in CD principal cells.[156] Altogether, these studies demonstrate that αHKc is specifically expressed at the apical pole of CD principal cells, and that this expression is markedly increased in response to K^+ depletion. The site-specific localization of αHKc in principal cells is consistent with the functional localization of type III K-ATPase.[149]

Potassium depletion is a condition in which CD reabsorbs, rather than secretes, K^+. Because of its expression at the apical pole of principal cells, colonic H,K-ATPase was proposed to be the motor for K^+ reabsorption in the collecting duct that occurs during K^+-depletion. *In vitro* microperfusion studies provided the first evidence for H,K-ATPase-dependent reabsorption of K^+ and HCO_3^- in OMCD from K^+-deprived rabbits.[140] Sch 28080-sensitive K^+ reabsorption also occurs in distal tubules, accessible by *in vivo* micropuncture, in K^+-depleted rats, but not in normal rats.[157] In addition, part of HCO_3^- reabsorption is inhibited by both ouabain and Sch 28080 in IMCD of K^+-depleted rats.[158] Surprisingly, αHKc-deficient mice do not display any renal phenotype, even when fed a K^+-depleted diet.[159] This indicates that an alternative transport mechanism functionally compensates for colonic H,K-ATPase deficiency.

Expression of colonic H,K-ATPase in the kidney is markedly increased by dietary K^+ restriction.[140] Because chronic dietary K^+ restriction induces metabolic alkalosis, and reduces plasma aldosterone levels, the role of both of these factors in regulating CD H,K-ATPase expression was investigated. In CD of rats clamped either in the absence of circulating aldosterone or under physiological or high levels of circulating aldosterone, K^+ depletion increased H,K-ATPase activity to similar extents, regardless of aldosterone concentration.[160] In addition, neither adrenalectomy nor a Na^+-depleted diet, which increases endogenous aldosterone levels, altered αHKc mRNA expression in the rat kidney medulla.[154] Thus, aldosterone does not control H,K-ATPase expression in the CD.

Similarly, increased expression of αHKc mRNA in the kidney during K^+ depletion most likely is not related to alkalosis, since it is observed in the absence of a significant change in plasma acid–base parameters.[161]

While changes in plasma acid–base status do not alter αHKc transcription, an increase of pCO_2 results in increased H,K-ATPase-mediated potassium and bicarbonate reabsorption in the CCD of K^+-depleted rabbits,[162] demonstrating post-transcriptional regulation of colonic H,K-ATPase during acidosis. Post-transcriptional regulation of colonic H,K-ATPase also occurs in the CCD of K^+-depleted rats in response to vasopressin, which increases type III ATPase activity in a PKA-dependent manner.[149] In the long-term, cAMP also controls the expression of αHKc by binding to cAMP-responsive elements present in the αHKc promoter.[163]

In conclusion, gastric H,K-ATPase is expressed in intercalated cells of the distal nephron where, along with other systems, it participates in proton transport and helps regulate acid–base balance. Colonic H,K-ATPase is also expressed in the distal nephron, but in principal cells where it energizes potassium reabsorption, especially under conditions of dietary K^+ restriction. Neither ATPase appears to be essential for animal survival or even for the continued maintenance of acid–base and potassium balance, at least under experimental conditions studied so far. Compensatory transport systems are able to palliate the genetic absence of gastric and colonic H,K-ATPase in the kidney. Such compensatory mechanisms need to be characterized, and it remains to be determined whether their activity relies on as yet unidentified ATPases.

V-ATPase

The vacuolar H^+-ATPases (V-ATPases) are among the most broadly expressed enzymes that convert the chemical energy of ATP breakdown into electric and chemical gradients. V-ATPases share a lot of structural similarities with mitochondrial F-ATPases, probably because both complexes have subunits that arise from common ancestors.[164–167] However, F-ATPases differ from V-ATPases, in that their expression is restricted to organelles that arise from bacterial endosymbiosis such as mitochondria (or chloroplast in plants), where they serve to generate ATP at the expense of the proton motive force (pmf), whereas V-ATPases use the energy produced by ATP breakdown to pump protons across membranes. The pmf and membrane potential difference ($\Delta\psi$) that result from the primary active transport of H^+ are then used to energize a large number of secondary active transporters. V-ATPases are found in virtually all eukaryotic cell types in endomembranes of intracellular organelles from the secretory pathway. In addition, in higher organisms V-ATPases can be found at the plasma membrane of highly specialized cells, such as the epithelial cells of the kidney, the male reproductive tract, the inner ear, and in osteoclasts. Because of this broad pattern of expression, V-ATPases play a critical role in a large number of different functions.[168] Plasma membrane V-ATPases are important for biological processes that require acidification of the extracellular space, such as bicarbonate reclamation from the urinary fluid, bone resorption, and sperm maturation, while acidification by intracellular V-ATPases of vesicles or endosomes is critical for normal endocytosis, intracellular trafficking, polypeptide processing, neurotransmitter uptake, accumulation and secretion, and for breakdown of macromolecules.

STRUCTURE AND MECHANISM OF ACTION OF V-ATPASES

Like F-ATPases, V-ATPases are integral macromolecular complexes with up to 14 different subunits. The molecular structure and the function of V-ATPases have received considerable attention, and have been the subject of excellent reviews.[168–171] V-ATPases are divided in two principal functional domains, V0, the transmembrane domain (240 kDa) that mediates the transfer of protons across the membrane and V1, the catalytic domain (900 kDa) that binds and hydrolyzes ATP. The V1 domain is always facing the cytoplasm; hence, when located in the plasma membrane, the pump always mediates extrusion of protons out of the cell, and when present in intracelullar membranes, it mediates acidification of the organelles. The V0 domain represents the proton transporting pore, and is formed by a ring of at least 6 subunits. For example, in mammals, several subunit c assembles with single subunit c″, d, and e in a channel-like structure with the a subunit.[172] The V1 domain comprises at least eight different subunits (A–H), and is divided into the "catalytic unit" which binds and hydrolyzes ATP, and the "stalk" which links the hydrolytic unit to the integral V0 domain.

Studies of the prokaryotic V-Na^+-ATPase of *Enterococcus hirae*[173,174] have reached the conclusion that V-ATPase might function following the model of rotational catalysis initially proposed for F-ATPases[175,176]: the central core of the V1 stalk, consisting of subunits D and F, and the proteolipid ring of c-subunits of the V0 domain rotate, driven by the hydrolysis of ATP, while the remaining subunits of the pump are static. One proton enters the machinery through an inner hemi-channel opened at the cytosolic surface of subunit a, and reaches the binding site of one of the c-subunits in the central ring[174]; the proton is then moved by the complete rotation of the ring

towards the opening of a second hemi-channel, also in the a-subunit, but open on the outer space, where it can unbind. Recently, experiments in which movements of the V1 complex of bacteriae were visualized with fluorescent actin filaments have confirmed that rotational catalysis does exist *in vivo*.[177,178] Bafilomycin and concanamycin A, which are specific inhibitors of the pump, both bind to subunit c.[179,180]

Isoforms

Multiple homologs and splice variants of the different V-ATPase subunits have been identified.[181,182] In mammals particularly, multiple variants exist for the B-, C-, E-, and G-subunits of the V1 catalytic domain, and for the a-, d-, and e-subunits of the V0 integral domain. Some of these homologs or variants, such as B2, C1, E1, G1, a1, d1, e1, have a very broad distribution, while other variants have a very restricted expression pattern. Some subunits also exhibit variable expression during development.[183] Hence, the timing and tissue specificity of V-ATPase expression, as well as the functional diversity of the pump, are thought to stem from combinations of V-ATPase subunit variants, and mutations of genes encoding for different variants of the same V-ATPase subunit can result in very different phenotypes. Furthermore, the existence of highly specific combinations of variants in one cell type or for a particular function raises the exciting possibility of developing targeted pharmacological strategies directed at one specific combination. An extended nomenclature assembly of a unique combination of the different genes and splice variants of V-ATPase subunits has been recently proposed.[182] Importantly, this work included a wide scan of published studies and sequence databases in order to provide the scientific community with the most complete catalog of function, tissue-specificity, and subcellular localization known to date for the different molecular forms of V-ATPase subunits.

Renal Isoforms of the V-ATPase

All the different subunits are necessary for the proper assembly, expression, and function of the pump, and the kidney expresses all the ubiquitous variants of V-ATPase subunits. In addition, among the different subunits with more restricted expression (for review see [184]), some variants such as B1,[185,186] C2,[187] G3,[188,189] a4,[190–192] d2,[193] and e2,[194] although not strictly "specific," are especially enriched in the kidney. In particular, the a4-subunit is expressed all along the nephron, while the B1-subunit is markedly enriched in the intercalated cells of the collecting system. The exact reason for the presence of these tissue-specific isoforms is not yet clear. It is possible that these isoforms have specific targeting or assembly motives required in a given cell type to drive the expression of the pump in a particular subcellular domain. For example, the B1-subunit differs from the B2-subunit by the presence of a COOH-terminal "DTAL" motif typical of a PDZ-interacting domain that is required for molecular interactions with the PDZ protein NHERF-1. Moreover, NHERF-1 is specifically expressed at the basolateral pole of β- but not α-intercalated cells, which raises the possibility that molecular interactions between the B1-subunit and NHERF-1 are required for the characteristic basolateral targeting of the V-ATPase in this particular cell type.[195,196] It is also possible that specific variants of the different subunits allow assembly with regulatory elements. For example, the actin cytoskeleton[197,198] or the glycolytic enzyme aldolase B[199,200] have been demonstrated to interact with the B-subunit of the V1 integral domain, and these interactions are believed to be critical for proper pump trafficking, assembly, and regulation.[201,202] An interaction between the a4-subunit and the enzyme phospho-fructokinase 1 has also been shown to be necessary for coupling the catalytic activity of the pump with its transport activity.[203] Nevertheless, the observation that inactivating mutations or disruption of genes encoding for kidney specific subunits, such as the a4- or B1-subunit, lead to a defect in proton secretion by α-Ics and to distal tubular acidosis[204–207] indicates that these tissue-specific subunits are critical for the proper functioning of the pump in the kidney. Indeed, even though under certain circumstances, such as targeted disruption of the B1-subunit in mouse, the B2-subunit can substitute partly for the B1-subunit, it cannot fully compensate for its loss.[208,209]

Multiple Functions of the V-ATPASE in the Kidney

Expression in the Kidney

The role of V-ATPase in urine acidification was first described in turtle bladder epithelium, whose characteristics are close to those of the mammalian collecting duct. In this system, H^+ secretion was shown to be an active, sodium-independent[210] process coupled to oxidative metabolism.[211,212] Final proof of a role for V-ATPase came from a very elegant study showing that reversal of H^+ fluxes induced ATP synthesis.[213] V-ATPase was subsequently purified and characterized in microsomal fractions isolated from these cells.[214] The bovine renal medulla exhibits the same V-ATPases as turtle bladder epithelium.[215] A number of subsequent studies detected the presence of V-ATPases, in both the apical plasma membrane and membranes of organelles, in almost all mammalian renal epithelial cells,

including the brush border membrane of the proximal tubule,[186,216–222] and the apical membranes of the thick ascending limb[186,216,217] and distal convoluted tubule.[186,216,217] In the collecting duct, V-ATPase is present in the apical membrane and cytoplasm of α-intercalated cells and in the basolateral membrane of β-intercalated cells; low expression levels have also been reported in principal cells.[186,216,223]

Bicarbonate Absorption

Along the nephron, the role of plasma membrane V-ATPases is to excrete protons from cells into the outer space. Hence, except for β-intercalated cells in which the pump is expressed basolaterally, the pump secretes protons into the urinary fluid. Urine acidification is the primary mechanism of renal bicarbonate absorption and acid excretion, and is therefore critical for acid–base regulation. To avoid leaking bicarbonate into urine, the kidney has to reclaim virtually all the bicarbonate filtered at the glomerulus (~4300 mmol/day). Bicarbonate absorption is achieved in the proximal tubule, the ascending limb of the loop of Henle, and to lesser extent in the distal convoluted tubule. In general, protons secreted into the urinary fluid can combine with bicarbonate ions also present therein to yield carbonic acid (H_2CO_3), which is quickly dehydrated into CO_2 and H_2O by a luminal carbonic anhydrase. CO_2 diffuses back from the urinary fluid into epithelial cells down its concentration gradient. Within the cell, it is then rehydrated by a cytosolic carbonic anhydrase, and the resulting bicarbonate ion exits the cell at the basolateral side via an electrogenic Na-HCO_3 co-transporter in the proximal tubule or a Cl^-/HCO_3^- exchanger in the TAL. Functional studies have shown that the main mechanism of proton secretion that drives bicarbonate absorption is Na^+/H^+ exchange,[224–226] a secondary active transport process is energized by the inward Na^+ gradient generated by the basolateral Na^+/K^+-ATPase. Molecular studies have demonstrated that this process depends on NHE3[227–229] and a Na^+-dependent amiloride-insensitive transporter[230] in the proximal tubule, and on NHE2 in the distal convoluted tubule.[228,231,232] However, a number of functional studies have also revealed the presence of bafilomycin A1-sensitive, ATP-dependent H^+ secretion that accounts for at least ~20% of proton secretion in the proximal tubule,[224–227,233,234] and that correlates with V-ATPase immunodetection in this nephron segment (see above). Moreover, pump activity appears to be stimulated by acidosis[235] or by angiotensin II[218,236] suggesting that the pump may participate significantly in bicarbonate reclamation by the proximal tubule.

Approximatively 10% of the bicarbonate filtered at the glomerulus is absorbed by the thick ascending limb of Henle's loop. As in the proximal tubule, the primary mechanism of bicarbonate absorption in the TAL is the Na^+/H^+ exchanger NHE3. Active secretion of protons with pharmacological characteristics of V-ATPases has also been detected in the TAL,[237–239] and immunoreactivity to different subunits of the pump has been shown in the apical membrane of TAL cells.[186,216,217] Even though these observations suggest that the pump might play a significant role in bicarbonate transport in the TAL, direct examination of bicarbonate transport in isolated, microperfused TAL demonstrated that all bicarbonate absorption by the TAL is sodium-dependent and sensitive to amiloride, which indicates that Na^+/H^+ exchange accounts for virtually all bicarbonate transport.[240] Thus, the role of the V-ATPase in the TAL remains unclear.

Role of the V-ATPase in Intercalated Cells

The second process that the kidney uses to keep blood bicarbonate constant is the excretion of the daily acid load generated by protein catabolism (~1 mmol/kg/j). This is achieved in the collecting system, which includes the late distal convoluted tubule, the connecting tubule, the cortical collecting duct and the medullary collecting duct. All these segments are characterized by the presence of intercalated cells (ICs), a subpopulation expressing the proton pump and characterized by the presence of the B1-subunit. At least two different sub-types of intercalated cells have been identified: the "canonical" form of type α IC secretes H^+ through the apical vacuolar H^+-ATPase and reabsorbs HCO_3^- via the basolateral $Cl^-/HCO3^-$ exchanger AE1, whereas the "canonical" form of type β IC has the opposite polarity and function.[223,241,242] There is some evidence for at least one other subtype of intercalated cells, called non-α non-β, which express both the proton pump and a $Cl^-/HCO3^-$ exchanger at the apical membrane.[242] The function of this third type remains unclear. For simplicity, the term β-IC is used in this review to refer to both canonical β and non-α non-β ICs.

Type α-intercalated cells secrete acid into a urinary fluid virtually devoid of bicarbonate, because of bicarbonate absorption in the upstream nephron segments. A fraction of protons remain free in urine and decrease urine pH. However, the amount of protons that can be freely eliminated in solution is very limited, because urine volume has to remain small and because at urine pH values below 4.4, the transepithelial gradient of H^+ overcomes the capabilities of the V-ATPase and proton secretion stops. Thus, a majority of protons secreted in the collecting system are instead titrated by urine buffers that can be weak bases (e.g., in humans, mostly creatinine and HPO_4^-) yielding titrable acids or the strong base NH_3 yielding the ammonium ion (NH_4^+). Since the different products resulting from these reactions cannot diffuse

back across the collecting system epithelium, this titration serves to trap and eliminate protons in urine. In addition, because at an acidic urine pH ammonia (NH_3) is transformed into ammonium NH_4^+, the action of V-ATPase is also crucial to maintain a concentration gradient of NH_3 across the collecting duct epithelium, and V-ATPase can be viewed as the energizer of ammonium secretion.[243] Protons secreted by the V-ATPase into urine are generated, together with bicarbonate ions from CO_2 and H_2O within intercalated cells. Proton secretion is functionally coupled to basolateral bicarbonate extrusion through the Cl^-/HCO_3^- exchanger AE1, because in the absence of bicarbonate exit, accumulation of bicarbonate into the cell would limit proton secretion. Thus, the bicarbonate that has been "generated" from proton secretion by intercalated cells replaces the bicarbonate that has been consumed when buffering the metabolically produced protons.

Type β ICs have the opposite polarity of α ICs.[223,241,242] They mediate bicarbonate secretion and generate protons. They are therefore adapted to excrete bases in response to metabolic alkalosis. In intercalated cells, V-ATPase is expressed both at the plasma membrane and in intracellular vesicles that can be recruited rapidly by exocytosis when increased pump activity is required.[244] Moreover, intercalated cells are also able to reverse the polarity of the pump's expression. Induction of metabolic acidosis or alkalosis produces a profound change in the population distribution of these different cell types, with acidosis shifting the distribution towards type α with apical ATPases, and alkalosis increasing the number of canonical β-cells at the expense of α-cells. The observation that this shift from one cell type to the other occurs while the total number of ICs remains constant was interpreted as evidence that ICs can convert from one phenotype to the other.[245] Since this seminal observation, compelling evidence has shown that this interconversion can occur *in vitro* or in isolated tubules, and that it requires secretion by intercalated cells of the matrix protein hensin, and activation of a complex signaling pathway that involves integrin b1.[246–249]

The contribution of β-intercalated cells to renal NaCl balance and blood pressure regulation is an emerging aspect of intercalated cell function.[250] Studies of a mouse model with disruption of the apical Cl^-/HCO_3^- exchanger pendrin demonstrated that β ICs are the main pathway for chloride absorption across the collecting duct epithelium,[251] and disruption of pendrin impairs renal ability to conserve NaCl.[251] Conversely, disruption of Cl^- absorption by β ICs protects against mineralocorticoid-induced hypertension.[252] It has also been recently demonstrated that coupling of the sodium-independent Cl^-/HCO_3^- exchanger pendrin with the sodium-driven Cl^-/HCO_3^- exchanger NDCBE (SLC4A8) mediates thiazide-sensitive NaCl absorption.[120] Importantly, as indicated above, Cl^-/HCO_3^- exchange in intercalated cells is tightly coupled to proton transport mediated by V-ATPases. Whether the V-ATPase energizes chloride transport and thereby participates in renal NaCl handling has not yet been determined. However, it was recently shown that bafilomycin, a specific V-ATPase blocker, inhibits angiotensin II-stimulated Cl^- absorption,[253] which suggests that V-ATPases may energize part of the NaCl absorption in the distal nephron. It is noteworthy that some patients with dRTA exhibit a salt- and potassium-loosing nephropathy. Even though these features can be explained by the frequent association of dRTA with nephrocalcinosis and interstitial nephritis, the exact involvement of V-ATPase dysfunction in these disorders has not yet been directly evaluated.

Role of the V-ATPase in Endocytosis in Renal Epithelial Cells

As indicated above, V-ATPase is not exclusively present in the plasma membrane of renal cells. As in all other eukaryotic cells, V-ATPase is abundantly expressed in the membrane of intracellular organelles. In intracellular membranes, the V1 catalytic domain is located in the cytosol and therefore the pump drives the transport of protons from the cytosol into the organelles. Many cellular processes, such as endo- or exocytosis, catalytic activity into lysosomes, neurotransmitter uptake into synaptic vesicles or release from secretory granules, receptor recycling, and sorting of proteins from the golgi apparatus, are critically dependent upon proper V-ATPase activity.[168,254]

In the kidney, much attention has been paid to the link between V-ATPase-dependent acidification of endosomes and endo-exocytosis. Receptor-dependent or -independent endocytosis of filtered molecules or of apical membrane proteins is an important function achieved by proximal tubule cells. Impairment of this function leads to low molecular weight proteinuria, which is one of the most prominent features of Dent's disease,[255] a rare condition characterized by a Fanconi-like syndrome associated with nephrolithiasis or nephrocalcinosis, caused by mutations in the chloride transporter CLC5.[256–259] Because proton transport by the V-ATPase is electrogenic, intracellular organelle acidification is accompanied by the development of an inside-positive potential difference. In the absence of an electrical shunt, this membrane voltage would represent a self-limiting factor for proton pump activity. In most cells, this shunt is achieved by a chloride conductance activated by voltage. Since CLC5 co-localizes with the V-ATPase in apical

endosomes,[260] it has been proposed that inactivating mutations of CLC5 inhibit endocytosis, because they prevent endosome acidification.[261–263] This paradigm, however, has been challenged by studies showing that CLC5 is not a Cl^- channel, but is rather an electrogenic Cl^-/H^+ antiporter,[264] and more recently that mutations that switch CLC5 function from Cl^-/H^+ exchange to Cl^- conductive transport are able to restore endosomal acidification, but impair endocytosis.[265] The latter study also suggests that endosomal V-ATPases control endocytosis by energizing chloride accumulation into intracellular organelles, rather than by promoting intravesicular acidification. How intravesicular chloride controls endocytosis, however, remains unsettled.

CHAPTER

4

Mechanisms of Water Transport Across Cell Membranes and Epithelia

Guillermo A. Altenberg and Luis Reuss

Department of Cell Physiology and Molecular Biophysics, and Center for Membrane Protein Research, Texas Tech University Health Sciences Center, Lubbock, Texas, TX, USA

INTRODUCTION

The main purpose of this chapter is to review the basic aspects of water transport mechanisms across cell membranes and epithelia. In the first section we will discuss biophysical principles and definitions, with the aim of providing a theoretical framework useful for the analysis of experimental observations. In the second section, we will address general issues pertaining to water transport across cell membranes, focusing on intracellular water, and the pathways and mechanism for osmotic water flow. In the third section, we will discuss water transport by epithelia, focusing on pathways and mechanisms, in particular the role of solute–solvent coupling. We intend this chapter to serve as both an overview and an introduction to chapters covering specific aspects of water transport (Chapters 5, 9, 41, 42, 43). The three sections of the chapter are to a certain extent independent from each other, and can be studied separately.

The field of water transport across biological membranes has made a recent major transition with the discovery and characterization of the aquaporins. Aquaporins are integral membrane proteins, most of which are highly specific water pores expressed in plants and animals from bacteria to humans. The discovery of the aquaporins confirmed a long-held prediction for the existence of these pores, emanating from biophysical studies in red blood cells[110] and renal proximal tubules.[165]

BASIC PRINCIPLES

This section is largely based on the excellent water transport treaty by Finkelstein.[34] Other sources are House,[62] Reuss and Cotton,[123] Dawson,[26] Hallows and Knauf,[50] and Macey and Moura.[91] Derivations of the equations can be found in Finkelstein's book.[34] Deliberately, this section has been kept simple, and qualitative explanations have been superimposed on a succinct quantitative analysis.

The main mechanism of *net water transport* in animal cells is osmosis, that is, net water flow driven by differences in water chemical potential, in turn dependent on differences in solute concentrations. Concerning water flow across a cell membrane, an important issue is whether water moves through the phospholipid bilayer and/or through specialized water-conducting pores. The mechanisms involved in water permeation via these two pathways constitute the main content of this first section. Hence, we start with osmosis.

Osmotic Equilibrium is a Balance of Osmotic and Hydrostatic Forces

The principle of *osmotic equilibrium* can be illustrated by considering a simple system, that is, a semipermeable membrane separating two aqueous phases: pure water and a solution that contains a nondissociating solute (Figure 4.1). The membrane is permeable to

Seldin and Giebisch's The Kidney, Fifth Edition.

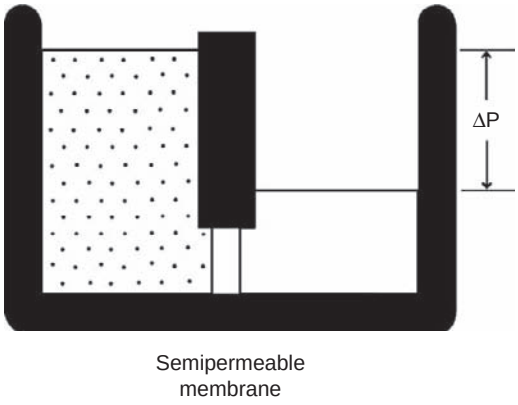

FIGURE 4.1 **Osmotic equilibrium.** A semipermeable membrane (clear section of middle partition) separates two aqueous compartments: a solution containing impermeable solute (left) and pure water (right). If the heights of both compartments are initially equal, then water will flow from right to left until equilibrium is established. At equilibrium, the water flow across the membrane is zero, and is described by Eq. (4.1), that is, ΔP and $\Delta\pi$ cancel each other.

water and impermeable to the solute (hence the term *semipermeable*). At thermodynamic equilibrium, the net water flow across the membrane is zero. (In the case of water, flow can be expressed in molar terms [moles of water per unit area and unit time] or volume terms [volume of water per unit area and unit time]. For conversion to volume flow, the molar flow must be multiplied by $\overline{V}_w$ [partial molar volume, a constant equal to 18 cm^3/mole].) The equilibrium of net flows is the result of the equality of two forces: an osmotic force favoring water flow into the solution; and an opposing hydrostatic force resulting, for instance, from the difference in height of the fluid compartments generated by the osmotic water flow. For dilute solutions, osmotic equilibrium is approximately described by Van't Hoff's law[149]:

$$\Delta P = \pi = RTC_s \tag{4.1}$$

where ΔP (atm) is the hydrostatic pressure difference between the two compartments ($P' - P''$), R (cm^3 atm mol^{-1} K^{-1}) and T [K] are the gas constant and the absolute temperature, respectively, C_s (mol cm^{-3}) is the molar concentration of the solute, and π (atm) is the *osmotic pressure* of the solution. The latter is conveniently defined as the hydrostatic pressure in the solution compartment (relative to the pressure in the water compartment) needed to abolish water flow across the membrane.

When the semipermeable membrane separates two solutions, equilibrium is described by a slightly different equation: $\Delta P = \Delta\pi = RT\Delta C_s$, where $\Delta\pi$ is the difference in osmotic pressure ($\pi'-\pi''$) and ΔC_s is the solute concentration difference ($C_s'-C_s''$).

The osmotic pressure depends on the molar concentration (C_s) and on the degree of dissociation of the solute, that is, the number of particles that each molecule yields in solution (n). Ideally, the osmolality of a solution, in osmol/kg of water, is given by $Osm = nC_s$, where C_s is in mol l^{-1}. However, the effect of solute on the activity of the solvent is generally nonideal, that is, it may depend on the nature of the solute. The correction term for this effect is the osmotic coefficient, φ_s, where the subscript denotes the solute. For physiological concentration ranges, the osmotic coefficient is closer to unity than the activity coefficient, but it can be significantly greater than 1 for macromolecules.[50] For the sake of simplicity, the osmotic coefficient will be neglected in this discussion.

A 1 Osm solution at room temperature exerts an osmotic pressure of about 24.6 atm, which is equivalent to about 18,700 mm Hg. In a mammal, a 1% change in extracellular fluid osmolality (< 3 mosmol/kg) is equivalent, as a driving force for water flow, to a hydrostatic pressure of 56 mm Hg. In animal cells, changes in osmolality cause large water fluxes across the plasma membrane, whereas hydrostatic pressure changes do not. Osmolality is a measure of concentration of particles, not of osmotic pressure, but it is frequently used to denote the latter.

The generation of ΔP in the presence of impermeant solute on one side can be explained[96] on the basis of changes in the water chemical potential (μ_w), which is given by:

$$\mu_w = \mu_w^o + RT \ln X_w + P\overline{V}_w \tag{4.2}$$

where μ_w^o is the standard chemical potential, X_w is the water mole fraction (moles of water/[moles of water + moles of solute]), and $\overline{V}_w$ is the partial molar volume of water. A solute addition to one side (at constant total volume) reduces the water chemical potential in that side (μ_w') because the water is "diluted" by the solute (and X_w falls). The difference in water chemical potential thus generated ($\Delta\mu_w' = \mu_w' - \mu_w''$) is the "driving force" for water flow toward the side of higher osmolality (and lower μ_w). If both compartments are open and of appropriate dimensions, then a ΔP will result from changes in height (Figure 4.1). If a compartment is closed, then its pressure will change in proportion to the water flux, with a proportionality constant dependent on compliance of the compartment.

Osmotic Water Flows Across Lipid and Porous Membranes have Different Properties

Near equilibrium, the volume flow is linearly related to the driving force:

$$J_v = L_p\,(\Delta P - \Delta\pi) \tag{4.3}$$

where J_v is the volume flow (volume area^{-1} time^{-1}), L_p is the *hydraulic permeability coefficient* of the membrane, and ΔP and $\Delta\pi$ are the differences in hydrostatic and osmotic pressure, respectively. The L_p can be expressed in cm sec^{-1} (osmol/kg)$^{-1}$. In most cases, a *filtration* (P_f) or *osmotic permeability coefficient* (P_{os}; $P_f = P_{os}$) is used instead of L_p. The P_{os} (cm sec^{-1}) is related to L_p by $P_{os} = L_p RT/\overline{V}_w$.

The above discussion underscores the fact that ΔP and $\Delta\pi$ are equivalent as "driving forces" in causing osmotic water flow. The mechanism of this equivalence can be understood if one considers the nature of the membrane and the mechanism of osmotic water transport, as explained below.

Osmotic Water Flow Across Lipid Membranes

Osmotic water flow across lipid membranes occurs by *solubility diffusion*. Water molecules move from one aqueous solution into the lipid and then into the other solution by independent, random motion. When $\Delta P = \Delta\pi$ (0 net driving force) there are two diffusive water fluxes of equal magnitude and opposite direction, with no net water flow across the membrane. In the presence of a net driving force ($\Delta P - \Delta\pi \neq 0$), a net flux arises. To examine the mechanism of water flow, let us consider the effects of ΔC_s and ΔP on the water chemical potential in the two compartments.

A net diffusive water flow requires a difference in water chemical potential across the membrane. In a homogeneous membrane, a steady flux denotes a constant chemical potential gradient throughout the membrane thickness. If there is a difference in osmotic pressure between the two solutions, then the water mole fractions (and therefore the water concentrations) at the two sides, *just inside* the membrane must differ. It is commonly assumed that water transport across the membrane–solution interface is faster than water diffusion in the membrane itself. It follows that the water chemical potential just inside the membrane is very close to that in the adjacent layer of solution; therefore, water is near equilibrium across the interfaces. Finally, since μ_w is inversely related to C_s, a gradient of water concentration must exist across the membrane. This intramembrane gradient is the direct consequence of the differences in impermeant solute concentrations in the adjacent aqueous phases.

When $\Delta\pi = 0$, but $\Delta P \neq 0$, the chemical potentials of water in the two solutions differ (see Eq. (4.2)). If $P' > P''$, then the water flux from side $'$ is greater than that from side $''$, creating an intramembrane gradient of water concentration and chemical potential.

The osmotic water permeability coefficient of a lipid membrane is given by:

$$P_{os} = \frac{D_w^m \beta_w \overline{V}_w}{\delta_m \overline{V}_{oil}} \tag{4.4}$$

where D_w^m is the diffusion coefficient of water in the membrane, β_w is the partition coefficient of water in the membrane (oil/water), δ_w is the thickness of the membrane, and $\overline{V}_{oil}$ is the partial molar volume of the membrane lipid.

Osmotic Water Flow Across a Porous Membrane

Let us consider a membrane made of a rigid, water-impermeable material. The pore density (number of pores per unit area) is n. Each pore is a water-filled cylinder of length L and radius r, and cannot be penetrated by the solute. The mechanism of water flow in this situation depends mostly on the pore radius. In large pores there is viscous water flow that can be described by Newtonian mechanics. In pores of molecular dimensions there is no appropriate theoretical treatment, but if the pores are so small that there is single file water transport (i.e., water molecules in the pore cannot slip past each other), then there is a surprisingly simple solution.

LARGE PORES

In large pores water flow driven by a hydrostatic pressure is described by Poiseuille's law, which was derived for water flow in thin capillaries:

$$J_v = n\frac{(\Pi) r^4}{8L\eta}\Delta P \tag{4.5}$$

where η is the water viscosity and π denotes 3.1415 ... (do not confuse with π, the osmotic pressure). This law is valid for steady-state flow and neglects pore access effects. Under these conditions, the pressure gradient along the pore (dP/dL) has a constant value (Figure 4.2a). From Eq. (4.4) and the definition of P_{os}, the P_{os} for a membrane containing large homogeneous cylindrical pores is $n(\pi)r^4 RT/8L\eta\, V_w$.

If the only driving force is osmotic, then the mechanism of water flow involves the development of a hydrostatic pressure gradient within the pore. Initially, the water concentrations in the pore and in the water-filled compartment are the same, but at the other interface the solution has lower water concentration than the pore. If water transport across the membrane interfaces is faster than within the membrane, then the water chemical potentials just inside the pore are equal to those in the adjacent solutions. At the pore end facing the water compartment there is no difference in hydrostatic pressure, but at the end facing the solution

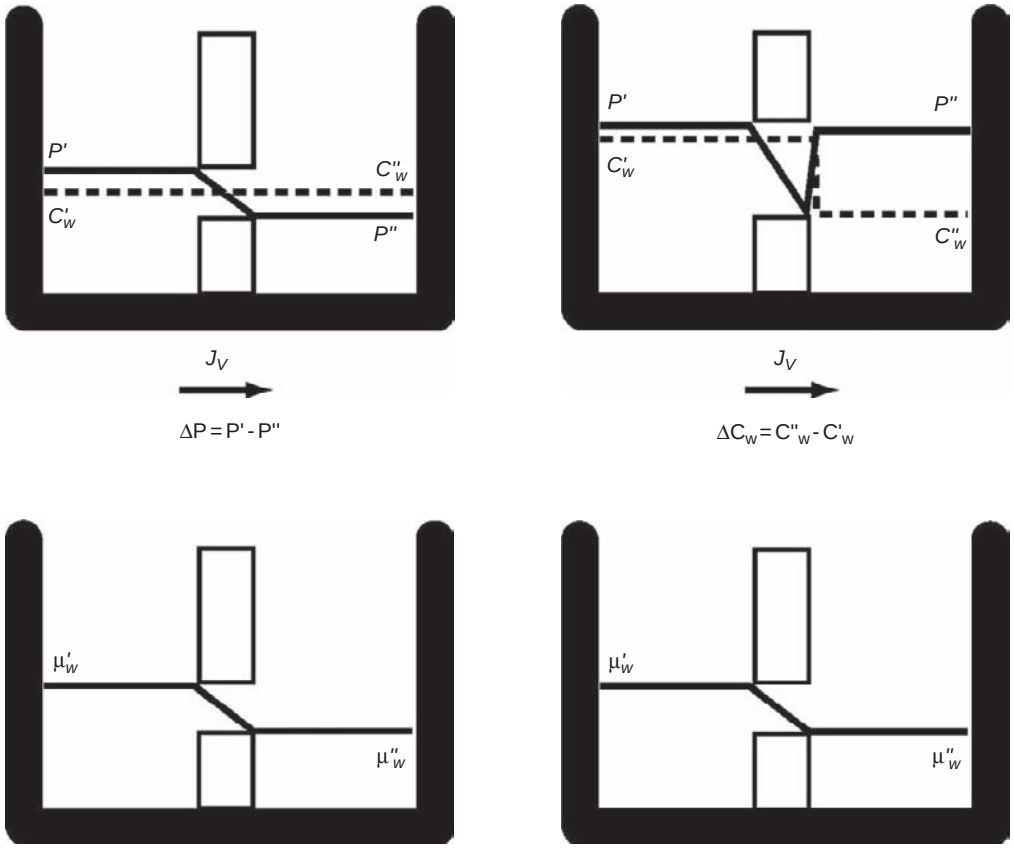

FIGURE 4.2 **Water flow across a porous membrane.** Top left: Driving force is a hydrostatic-pressure difference ($P' - P''$), continuous line. Same water concentrations on both sides ($C'_w - C''_w$), segmented line. Top right: Driving force is a difference in osmotic pressure. Same hydrostatic pressure on both sides, but the water concentrations differ. Bottom: The steady-state water chemical potential gradients (μ_w, proportional to the sum of hydrostatic and osmotic pressure) are the same for both conditions. *(Modified with permission from Reuss, L. (2000). General principles of water transport*. In *"The Kidney: Physiology and Pathophysiology," 321–340, Seldin, D. W. and Giebisch, G. (eds.). Raven Press, New York.)*

compartment the pressure inside the pore falls, because the lower water concentration in the solution elicits a water efflux from the pore. If $\Delta\mu_w$ is zero across the opening, then the difference in water concentration between solution and pore is exactly balanced by a drop in the pore pressure.[96] In the steady-state, the pressure gradient in the pore is constant (Figure 4.2, top right).

The analysis presented above holds for pores of r equal to or greater than 15 nm.[12] For pores smaller than 15 nm, several corrections have been attempted, but the underlying assumptions are questionable.[34] Regardless of the lack of a satisfactory theory, it has been suggested that Poiseuille's law is a reasonable approximation for water diffusion and convection in small pores.[86]

SINGLE-FILE PORE

The P_{os} of a single-file pore is given by[34,35]:

$$P_{os} = n\frac{\overline{v}_w kTN}{\gamma L^2} \tag{4.6}$$

where $\overline{v}_w$ is the volume of a water molecule, k is the Boltzmann constant (gas constant/molecule, equal to R/N_A where N_A is Avogadro's number), N is the number of water molecules inside the pore, and γ is the friction coefficient per water molecule. Assuming that the water densities in the pore and in the bulk solution are equal, and recalling that $kT/\gamma = D_w$:

$$P_{os} = n\frac{(\Pi)r^2 D_w}{L} \tag{4.7}$$

which is the result expected for osmotic water flow through a single-file pore if it can be described as a diffusive flux.

Comparison of Diffusion and Osmotic Permeability Coefficients Reveals Whether Water Permeates Lipid Bilayer or Pores

Now we consider a membrane exposed to solutions of identical composition, except that water is partially replaced with tracer water at a concentration C_w (Figure 4.3). There are no other differences in composition or pressure between the two compartments.

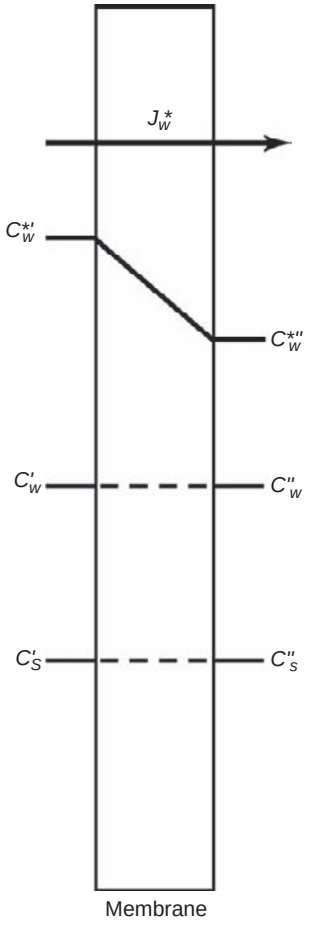

FIGURE 4.3 **Tracer water diffusion across a lipid membrane separating solutions of identical compositions ($C_w' - C_w''$, $= C_s' - C_s''$, $= 0$, as shown by the two lines at the bottom).** At the steady-state (constant flux, J_w^*), the tracer concentration gradient in the membrane (second line from top) is also constant. Arbitrarily, the oil/water partition coefficient (β) of tracer water is 1.0. If β were smaller, the tracer water concentrations inside the membrane would be less than in the respective solutions. *(Modified with permission from Reuss, L. (2000). General principles of water transport.* In *"The Kidney: Physiology and Pathophysiology," 321–340, Seldin, D. W. and Giebisch, G. (eds.). Raven Press, New York.)*

Both contain solutions of infinite volume and ideally mixed (C_w at the membrane surface $= C_w$ in the bulk solution). The tracer water flux is given by:

$$J_w^* = P_{dw}\Delta C_w^* \tag{4.8}$$

where P_{dw} is the diffusive water permeability coefficient and ΔC_w^* is the difference in concentration of tracer water ($C_w^{*\prime} - C_w^{*\prime\prime}$). In the case of a lipid membrane, the tracer–water flux is by solubility diffusion; hence:

$$P_{dw} = \frac{D_w^m \beta_w \overline{V}_w}{\partial_m \overline{V}_{oil}} \tag{4.9}$$

This expression is identical to that for P_f (or P_{os}) for a lipid membrane (Eq. (4.7)). Therefore, for a lipid membrane, $P_{os} = P_{dw}$.

The case of a porous membrane is discussed below.

Porous Membrane

If the pores obey Poiseuille's law, the diffusive water flux *via* the pores is:

$$J_w^* = \frac{n(\Pi)r^2 D_w}{L}\Delta C_w^* \tag{4.10}$$

where the pore cross-sectional area $[n(\Pi)r^2]$ is available for water diffusion and is the water self-diffusion coefficient (tracer water traverses the membrane via the aqueous pores). P_{dw} is $n(\Pi)r^2 D_w/L$. Hence, the ratio between and for a porous membrane is:

$$P_{os}/P_{dw} = \frac{RT}{8\eta D_w \overline{V}_w} r^2 + 1 \tag{4.11}$$

where the second term on the right ($=1$) denotes the diffusive water flow via the pores. The equivalent pore radius can be estimated from experimental values using Eq. (4.11); at 25°C, the value of $[RT/(8\eta D_w \overline{V}_w)]$ is 8.04×10^{-14} cm^{-2}.

For single file pores, the diffusive water flux is $J_w = nP_{dw}\Delta n^*$, where Δn^* is the tracer-water concentration difference (molecules per unit volume). P_{dw} is given by:

$$P_{dw} = \frac{n\overline{v}_w kT}{dL^2} \tag{4.12}$$

and the ratio P_{os}/P_{dw}, from Eqs. (4.6) and (4.12), equals the number of water molecules in the pore: $P_{os}/P_{dw} = N$.

Water movement in single file pores is not independent of the movement of neighboring water molecules: for a tracer molecule to cross the pore, other water molecules must also cross.

Unstirred Layers are a Major Source of Artifacts in Water Permeability Measurements

Unstirred layers are static layers of fluid at membrane–solution interfaces, that is, they are not mixed by convection. Unstirred-layer solute concentrations are entirely determined by diffusion, can differ from that of the bulk solutions, and are position dependent. Unstirred layers introduce errors in the experimental determination of P_{dw} and P_{os}. These errors can lead to incorrect conclusions about the existence of aqueous pores. For an excellent treatment of unstirred layers, see Barry and Diamond.[11]

Unstirred-Layer Effects on Measurement of P_{dw}

In the system illustrated in Figure 4.4, tracer water encounters three barriers to diffusion between the two

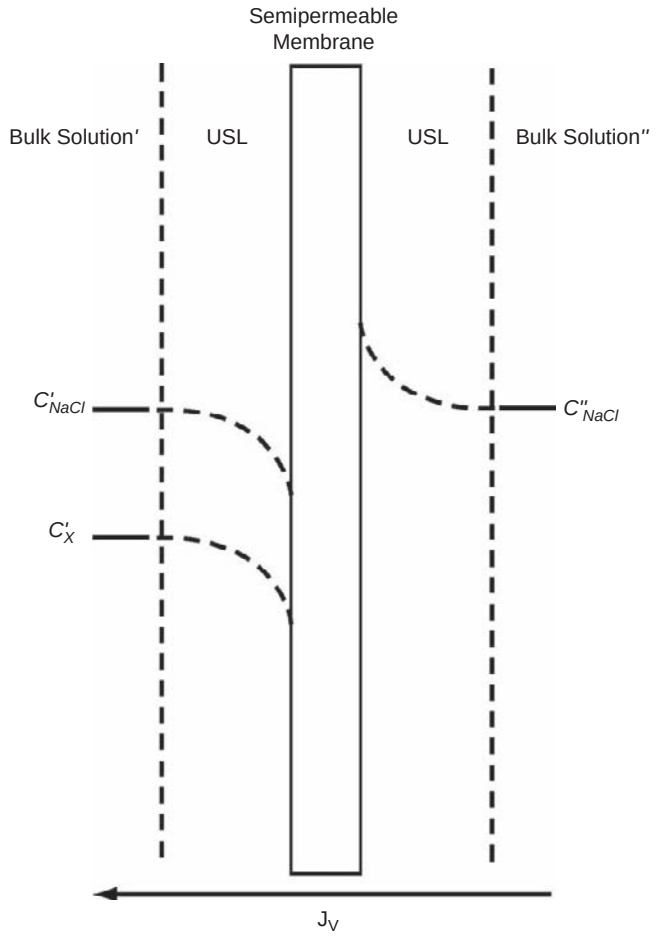

FIGURE 4.4 Unstirred-layer effects on the measurement of P_{os}, C_{NaCl} and C_x, concentrations of NaCl and the osmotic solute, respectively. Both are assumed impermeant for simplicity. The osmotic water flow ($J_w = J_v$) "dilutes" both solutes on the hyperosmotic side (solution′) and "concentrates" the NaCl on the hyposmotic side (solution″). The net result is a reduction in the concentration gradient of the osmotic solute (reduced ΔC_x), and the creation of an opposing ΔC_{NaCl} at the membrane boundaries. Hence, the driving force for J_v is diminished. *(Modified with permission from Reuss, L. (2000). General principles of water transport.* In *"The Kidney: Physiology and Pathophysiology," 321–340, Seldin, D. W. and Giebisch, G. (eds.). Raven Press, New York.)*

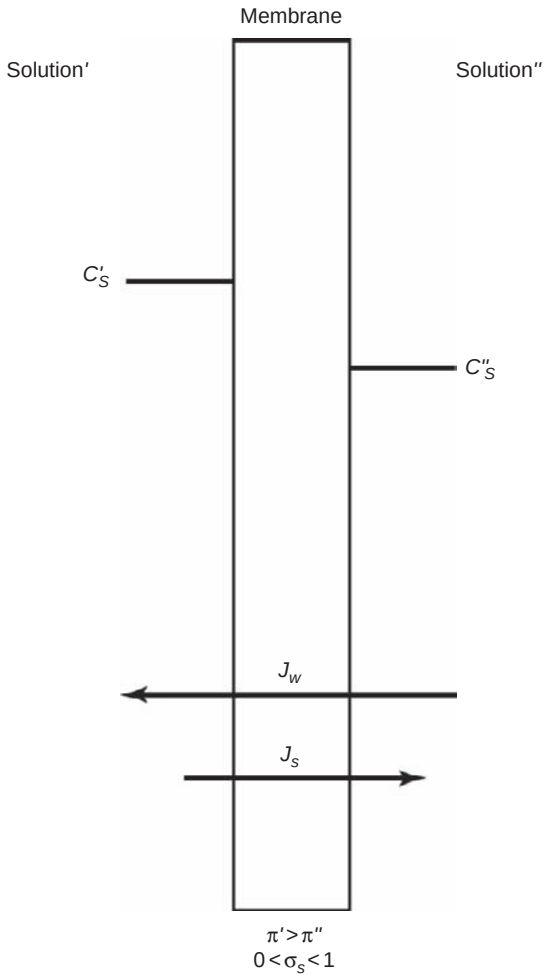

FIGURE 4.5 Volume flow (J_v) between solutions containing different concentrations of a permeant solute ($0 < \sigma_s < 1$). C_s is the solute concentration. J_v is the difference between the net water flow (J_w) to the left, and the net solute flow (J_s) to the right (i.e., $J_v = J_w - J_s$). *(Modified with permission from Reuss, L. (2000). General principles of water transport.* In *"The Kidney: Physiology and Pathophysiology," 321–340, Seldin, D. W. and Giebisch, G. (eds.). Raven Press, New York.)*

solutions, namely the membrane and the two unstirred layers (of width Δ_1 and Δ_2, respectively). These three barriers are in series. The *observed* (experimentally determined) diffusive water permeability of the system differs from the true diffusive water permeability of the membrane (P_{dw}) according to:

$$\frac{1}{P^o_{dw}} = \frac{1}{P_{dw}} + \frac{1}{D_w/\delta_1} + \frac{1}{D_w/\delta_2} \tag{4.13}$$

where P^o_{dw} is the observed value. Inasmuch as D_w has a finite value, P_{dw} and P^o_{dw} are equal only when $\delta_1 = \delta_2 = 0$. For typical permeability and unstirred-layer thickness values, P_{dw} can be easily underestimated by 50% or more.

Unstirred-Layer Effects on the Measurement of P_{os}

In the experiment depicted in Figure 4.5, a semipermeable membrane separates equal NaCl solutions; then, a second solute is added to one side ($C'_s > C''_s$, eliciting osmotic water flow. The NaCl concentration in the unstirred layers changes because of the water flow, rising in the right side and falling in the left side, relative to the bulk solution concentrations. The added solute qualitatively behaves like the NaCl present on the same side. Water flow tends to accentuate the changes described, whereas solute diffusion in the solution has the opposite effect. At the steady-state, the effects of osmotic water flow and solute diffusion balance each other and the unstirred-layer

concentration profiles remain constant. At the surface of the membrane:

$$C_m = C_b \exp(\pm v\delta/D_s) \quad (4.14)$$

where the sign of the exponent is (−) for the left ("diluted") side and (+) for the right ("concentrated") side, and denote solute concentrations (membrane surface and bulk solution, respectively), v is the water flow velocity (normal to the membrane), and D_s is the solute diffusion coefficient in water.

The ratio between P^o_{os} (observed value) and P_{os} (true value) is $-v\Delta/D_s$, that is, the magnitude of the error in estimating P_{os} is directly proportional to v and inversely proportional to D_s. In planar membranes, for small v (low water flux and flow velocity) the exponential term approaches 1. In folded membranes, where there can be water "funneling" (microvilli, lateral intercellular spaces), v can be much larger than in a planar membrane and can be seriously underestimated.[11]

The above analysis is limited to the effect of J_v on impermeant solute concentration. If permeant solutes are present as well, they must be considered, making the analysis more complex.[11]

Solute Reflection Coefficients Denote Effective Osmolality of a Solution vis-à-vis a Membrane

The situation is more complicated than the preceding analysis if the solute is permeant (Figure 4.6). In this case, J_v will be described by:

$$J_v = L_p(\Delta P - \sigma_s \Delta\pi) \quad (4.15)$$

where σ_s is the reflection coefficient of the solute. If $\sigma_s < 1$, then J_v will be less than if the same osmotic gradient is elicited with an impermeable solute. The value of σ_s is specific for each combination of membrane and solute, and depends on both permeabilities and partial molar volumes of water and solute (see below). In general, the value of σ_s varies between 0 (solute as permeable as water) and 1 (solute impermeable).

Lipid Membrane

It can be shown that the solute reflection coefficient of a lipid membrane is[34]:

$$\sigma_s = 1 - \frac{P_{ds}\overline{V}_s}{P_{dw}\overline{V}_w} \quad (4.16)$$

As expected, $\sigma_s = 1$ when $P_{ds} = 0$, $\sigma_s = 0$ when $P_{ds}\overline{V}_s = P_{dw}\overline{V}_w$, and $\sigma_s < 0$ when $P_{ds}\overline{V}_s > P_{dw}\overline{V}_w$. In other words, σ_s depends on the solute permeability and partial molar volume compared with those of water. If the products are the same for solute and water, then the reflection coefficient is zero: solute addition to one side causes no transmembrane volume flow because the water flux toward the solute is of the same magnitude as the solute flux in the opposite direction. A solute with a negative σ_s will elicit a net volume flow in the opposite direction to the water flow ("negative osmosis").[34]

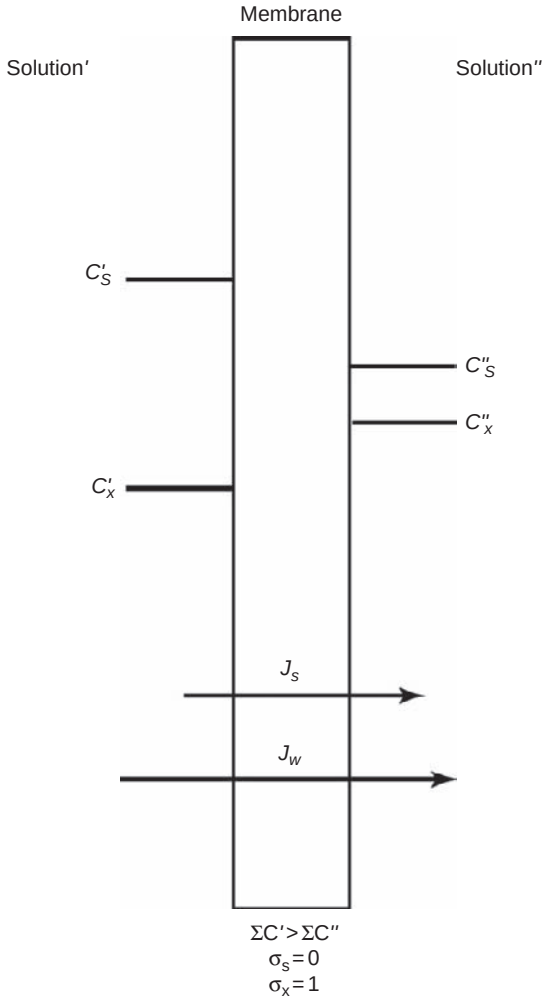

FIGURE 4.6 **Volume flow (J_v) between isosmotic solutions ($\sum C' = \sum C''$).** Solutes s and x gradients are of the same magnitude and opposite direction. Since the reflection coefficients differ, the effective osmolalities also differ, and there is a net J_v toward the side containing impermeant solute (i.e., $J_v = J_w + J_s$). *(Modified with permission from Reuss, L. (2000). General principles of water transport.* In *"The Kidney: Physiology and Pathophysiology," 321–340, Seldin, D. W. and Giebisch, G. (eds.). Raven Press, New York.)*

Porous Membrane

For a quantitative analysis of this complicated problem, see Anderson and Malone[3] and Finkelstein.[34] For large pores and solute particles larger than water particles, the solute is excluded from the periphery of the pore, that is, from a region slightly wider than the solute radius. In the pore axis, C_s is maximum (equal to

the concentration in the bulk solution) and C_w is less than at the pore periphery (where the solute is excluded). This generates a radial water concentration gradient within the pore. At equilibrium, this gradient is balanced by a fall in hydrostatic pressure in the periphery of the pore. In addition, there is a solute concentration gradient along the pore length, because of the transmembrane difference in C_s. These two gradients combine to generate a longitudinal hydrostatic pressure gradient along the pore's periphery, which causes water flow toward the high concentration side. The thickness of the ring subjected to this regime is directly proportional to the molecular size of the solute. When the solute is so large that it cannot enter the pore, J_v is maximum and $\sigma_s = 1$. When the solute has the same size as water, its distribution within the pore is identical to that of water, no pressure gradient develops, the water and solute net fluxes are purely diffusive and of equal magnitude and opposite direction, and $J_v = 0$. When the solute is smaller than water, J_v is greater than J_w, and J_v is in the same direction as J_s. Water is largely excluded from the periphery of the pore, and the pore hydrostatic pressure gradient is opposite to that generated by the impermeant solute.

We consider now the case of single file pores; the solution is dilute enough so that the number of solute molecules inside a pore can be only 0 or 1. Two pore populations will exist at any given time: pores containing water only, through which there is water flow toward the high-C_s side, and pores containing solute, in which solute and water are transported toward the low-C_s side by single file diffusion. When both water and solute permeation are single file, σ_s is[34,87]:

$$\sigma_s = 1 - \frac{P_{ds}\overline{V}_p^s}{P_{dw}\overline{V}_p} \tag{4.17}$$

where $\overline{V}_p$ denotes pore molar volume, solute-containing (superscript s) and solute-free (no superscript). Compare with Eq. (4.16).

In a system with more than one solute there can be net water and/or volume flows between solutions with the same total solute concentrations (and osmolalities). This will occur if the specific C_s values on the two sides of the membrane and the reflection coefficients differ. As shown in Figure 4.6, if , $\Delta C_s = -\Delta C_x$, $\sigma_s = 0$, and $\sigma_x = 1$, then there will be a net volume flow towards the right, although the solutions have equal total osmolalities. If the hydrostatic pressures are the same on both sides, then $J_v = L_p RT\ (\sigma_x \Delta C_x - \sigma_s \Delta C_s)$. Expressions such as σRTC denote "effective osmolality," in contrast with the "total osmolality" given by RTC. Effective osmolality is also referred to as *tonicity*. In epithelia, active transepithelial solute transport can generate asymmetries in the composition of the adjacent solutions. These asymmetries may in principle drive net water transport without differences in the total osmolalities of the bulk solutions, because of differences in the solute reflection coefficients.

Solvent Drag Can Account for Uphill Solute Transport

When there is net water flow (filtration and/or osmosis) across a porous membrane and a pore-permeant solute is present, there is a solute flux in the same direction as the water flow. This flux reflects water–solute frictional interaction within the pores. In the case of large pores, if $C'_s = C''_s$, and J_v is elicited by a hydrostatic pressure gradient or an asymmetrical addition of impermeant solute, the solute flux due to solvent drag is given by:

$$J_s = J_v C_s\ (1 - \sigma_s) \tag{4.18}$$

Uphill solute transport (i.e., transport in the absence of or against the prevailing electrochemical gradient) can be demonstrated, which is always in the same direction as the water flow. The energy is provided by the water flow, and conveyed to the solute by frictional interaction.

Demonstration of solvent drag is, in principle, a clear-cut argument for the existence of solute permeable water pores in membranes. However, many such demonstrations have been proven to be experimental artifacts. If there are unstirred layers, J_v will produce changes in solute concentrations at the membrane–solution interfaces; if the membrane is permeable to the solute, then a diffusive solute flux will occur (see Eq. (4.14)). This phenomenon is called "pseudo-solvent drag".[11] Putative demonstrations of pore-mediated water transport based on the observation of "solvent drag" must consider this possibility.

WATER TRANSPORT ACROSS THE CELL MEMBRANE

In this section we will first address some general issues pertinent to intracellular water, and then discuss in some detail the pathways and mechanisms for water transport across the cell membrane. Cell volume regulation is the subject of Chapter 5, and will not be addressed here.

Intracellular Water Behaves Similar to Water in Free Solution

The best direct assessment of the state of intracellular water was obtained from nuclear magnetic resonance (NMR) studies, which indicate that only a small fraction of cell water (< 5%) behaves as if it were

immobilized.[137] However, indirect arguments suggest that this may be an underestimate.[50] A related issue is whether the cytosol is a near-ideal aqueous solution or a gel, as suggested by numerous observations.[85] If this is the case, its higher viscosity may have a strong effect on enzyme catalysis rates.[100] In any event, the behavior of water fluxes in cells supports the idea that most of the intracellular water behaves as water in dilute solutions.

The Osmotic Behavior of Cells is not Ideal

Consider a cell at steady-state (constant volume) in suspension; then, the external concentration of an impermeant solute (and hence the external osmolality) are suddenly changed. If the cell is permeable to water, then water will flow until its osmolality becomes equal to the new medium osmolality. Numerically, $V_0 \cdot \pi_0 = V_t \cdot \pi_t$, where V is cell water volume and π is total solute concentration (or osmolality), and the subscripts 0 and t denote steady-state values before and after the solution change. The above equation assumes that there is no change in the amount of cell solute between 0 and t, and defines the ideal ("osmometric") behavior of cells. However, not all cells behave ideally. Non-ideal behavior can result from loss or gain of solute between times 0 and t (e.g., some cell solutes are permeable) or from changes in the osmotic coefficient of intracellular solute(s) secondary to the water flux. This appears to be the case in red blood cells, because of concentration dependence of the osmotic coefficient of hemoglobin. This and other issues relevant to non-ideal osmotic behavior of cells have been discussed by Hallows and Knauf.[50]

Another important point in quantifying cell volume changes in response to alterations in extracellular osmolality is the fact that although most of the cell volume is solvent water ("osmotically sensitive"), a fraction is nonsolvent volume (also referred to as "solids"). If one considers this factor, then the above equation becomes:

$$(V_0 - b)\pi'_0 = (V_t - b)\pi'_t \qquad (4.19)$$

where b is the nonsolvent volume. This is a modified form of the Boyle–Van't Hoff equation, and is very useful to interpret changes in cell volume. The plot of Eq. (4.19) is shown in Figure 4.7.

In experimental osmotic studies, the behavior of cells or membrane vesicles may not be linear, for the reasons given above. For instance, if the amount of cell solute changes during the experiment, then the slope will not be a constant.

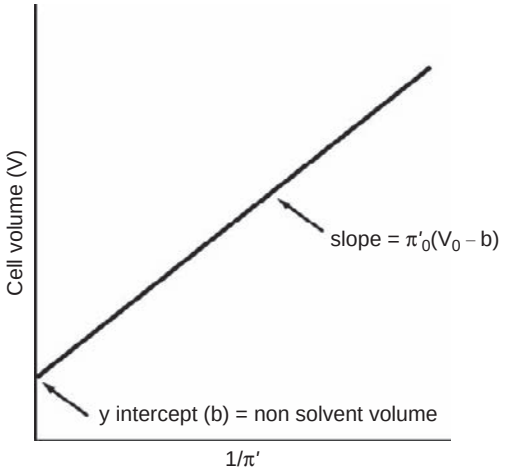

FIGURE 4.7 **Boyle–Van't Hoff plot for a theoretical cell.** The equation plotted is $V = (1/\pi')[\pi'_0(V_0 - b)] + b$ (see Eq. (4.19)). The y-axis intercept is b, the nonsolvent volume, and the slope is $[\pi'_0(V_0 - b)]$, that is, the amount of water-dissolved solutes in the cell. *(Copyright 1994 by CRC Press, Inc. Net Water Transport Across Membranes of Animal Cells is Osmotic

In plant cells, which have rigid walls, the intracellular hydrostatic pressure can vary over a considerable range. In animal cells, which have compliant plasma membranes, hydrostatic pressure differences are small. In contrast, small differences in concentration of impermeable or low permeability solutes across the cell membrane can result in sizable water flows by osmotic mechanisms. The water flow under these conditions can be via the phospholipid bilayer (solubility diffusion), driven by the difference in water chemical potential across the membrane or via pores driven by a hydrostatic pressure gradient inside the pore. This pressure gradient is caused by the difference between the water chemical potentials inside the pore and in the external solution (see Figure 4.2). It is generally assumed that under steady-state conditions *in vivo*, the osmolalities of the intracellular and extracellular compartments are equal. There is some experimental evidence supporting this,[94] but based on rather indirect estimations of intracellular osmolality. Also, it has been argued that, in order to balance a 1 mosmol/kg difference in osmolality (cell higher), the cell hydrostatic pressure would have to be ~19 mm Hg higher than the extracellular pressure, something that a soft-tissue cell membrane is extremely unlikely to support.[93] However, mechanical support of the cell membrane by the cytoskeleton and/or the exoskeleton may allow for the maintenance of transmembrane hydrostatic

pressure gradients.[50] This issue is unresolved, but it is unlikely that in the steady-state large gradients of osmotic or hydrostatic pressure exist across plasma membranes.

Quantitative treatment of water transport across the plasma membrane usually involves another assumption, namely that the cytoplasm behaves as a free solution, similar to the interstitial fluid. However, it is far more likely that the cytoplasm is a gel, as discussed above.[85] This problem is also unresolved.

The fact that animal cells lack rigid walls and do not develop sizeable transmembrane hydrostatic pressure differences determines that the only means to maintain or regulate cell volume is to change the cell content of osmotically-active solutes. This is the main theme of the next section.

Cell Volume is Determined by the Amount of Cell Solute and the Extracellular Osmolality

With the questionable exception of water co-transport (see below), net water transport between intracellular and extracellular compartments is the result of differences in effective osmotic pressure between these compartments. The effective osmotic pressure, in turn, is proportional to the total number of particles in solution, and their reflection coefficients. Hence, at the same total osmotic pressure, impermeant particles are more effective than permeant particles in generating water flow toward the side in which they are contained. This can be demonstrated experimentally by exposing cells to solutions of identical osmolalities, but different tonicities, by using solutes having different permeabilities. Depending on the relative permeabilities of the plasma membrane to water and the solute, cell volume can remain constant, increase or decrease. This phenomenon can be explained by the effect of the solute reflection coefficient on osmotic water flow.

A solution is defined as isotonic (with the cell interior) when exposure of cells to this solution results in no change in cell volume; hypertonic and hypotonic solutions elicit decreases and increases in cell volume, respectively. Therefore, a hypertonic solution has a greater effective osmolality, and a hypotonic solution a lower effective osmolality, than the isotonic solution. Because of the role of the solute reflection coefficient in determining the effective osmolality (see above), the terms hypertonic and hypotonic are not equivalent to hyperosmotic or hyposmotic; the latter expressions denote the total osmolality of the solutions, disregarding the reflection coefficients. The osmolalities of biological fluids are largely determined by their total salt concentrations, because low molecular weight salts are the solutes at highest concentrations, expressed as number of particles relative to water mass. Hence, the extracellular fluid osmolality is largely determined by Na^+ salts (mainly sodium chloride and sodium bicarbonate), and the intracellular osmolality is mostly determined by K^+ salts.

Under most physiological and pathophysiological conditions, the intracellular and extracellular compartments can be treated as two closed compartments separated by a semipermeable membrane (i.e., a membrane permeable to water and impermeable to the solute). This simplification is valid because, in the short-term, solute gains or losses by the whole system and solute fluxes between the compartments are slow relative to potential water fluxes. It follows that: (1) the amount of solute in each compartment can be considered constant; and (2) the steady-state osmolalities of both compartments must be equal. Therefore, the amount of cell water is inextricably related to the amount of cell solute and to the extracellular osmolarity:

$$V_w^c = \frac{S^c}{Osm_{ec}} \tag{4.20}$$

where V_w^c is the cell water volume (L), S^c is the amount of cell solute (mosmol), and Osm_{ec} is the extracellular osmolarity (mosm/L).

It follows from Eq. (4.20) that cell volume can change by two mechanisms, namely changes in the amount of cell solute or in the extracellular osmolality. From a homeostasis point of view, if pure water is added to the extracellular compartment, reducing its tonicity, then part of the water will flow across the cell membrane into the intracellular compartment, until the osmolalities are again equal. If pure water is lost from the extracellular compartment, then water will flow from the intracellular compartment until the osmolalities become equal. In contrast, if isotonic solution is added to or lost from the extracellular compartment, there will be no water flow across the cell membrane, because no osmotic pressure difference has been established, and in the body the ensuing changes in hydrostatic pressure will be very small. This analysis is rather qualitative; knowledge or assumption of the initial conditions allows for a highly quantitative analysis, essential for understanding the pathogenesis and planning the treatment of water and electrolyte disorders.

Water Permeability of the Plasma Membrane Varies Considerably Among Cell Types

Cell membranes are endowed with highly variable osmotic water permeability coefficients, ranging from practically zero (apical membrane of thick-ascending loop of Henle cells) to 400–600 $\mu m\ s^{-1}$ in red blood cells and renal proximal tubules. Most

nonepithelial cells display quite high osmotic water permeabilities. The best-studied case is that of the mammalian red blood cell, whose P_{os} is in the range of 50−400 μm s^{-1}.[39] In artificial lipid bilayers, P_{os} ranges from <1 to <100 μm s^{-1}, depending on the lipid composition. Bilayers of higher fluidity are more permeable to water, and increased bilayer cholesterol content decreases bilayer water permeability. Recent studies have shown that certain biological membranes that are highly water permeable contain water-selective pores (aquaporins).

The structural bases for the extremely low P_{os} of some cell membranes were recently discovered; others remain unknown. As detailed in Chapter 2, lipid rafts in membranes are microdomains rich in cholesterol and sphingolipids in the external leaflet and cholesterol and phospholipids with saturated fatty acids in the internal leaflet of the membrane. The surrounding bilayer is abundant in unsaturated fatty acids, and considerably more fluid than that in the raft.[71] Membrane rafts have low fluidity, and hence a low diffusional water permeability. Addition of cholesterol to liposomes formed by phosphatidylcholine produces a major decrease in water permeability.[6,7,116] In liposomes formed by mixtures of phosphatidylcholine, cholesterol, and sphingomyelin, which contain lipid microdomains similar to membrane lipid rafts, water permeability is significantly lower than that expected based on the lysis tension.[116]

Apical membranes of certain tight epithelia have an extremely low permeability to water. A case in point is the apical membrane of the urothelium, that is, the epithelium that lines the renal calices, pelvis, ureters, urinary bladder, and urethra. The apical membranes of the epithelial cells of the urothelium are covered by rigid plaques consisting of hexagonal arrays of particles.[14,57,156] The plaques contain four transmembrane domain proteins named uroplakins, of which there are four isoforms.[88,170,172] It has been suggested that uroplakins could influence the passive permeability of the apical membrane of the urothelium,[56] but evidence was lacking until the permeabilities of normal mice urinary bladders were compared to those of uroplakinIII (UPIII)-knockout mice.[64] The normal mouse bladder has high transepithelial electrical resistance, and low water permeability. The bladders from UPIII-knockout mice maintained the high transepithelial resistance, but their water permeability was 20-fold higher than in controls. These results strongly suggest that the low permeability of the tight junctions and the apical membrane to ions are preserved in the knockout mice, whereas the water permeability of the apical membrane is increased. This is the first instance in which expression of a transmembrane protein has been shown to decrease the permeability of a biological membrane. It has been speculated that the uroplakin crystals limit plasma membrane lipid mobility, reducing fluctuations in acyl chains, decreasing water permeability through the bilayer.[73,169] However, the UPIII-knockout mice urinary bladders display significant anatomical alterations, including the presence of small hyperplastic superficial cells,[63] and therefore other mechanisms for the decrease in water permeability cannot be ruled out.

The thick ascending limb of the loop of Henle also has an extremely low permeability to water[126] necessary for the operation of the urine concentration mechanism (see Chapter 43). The biophysical reasons for this low permeability are not entirely clear. Certainly there is no expression of water pores (AQP) in the apical membrane (see Chapter 41), and its surface area is small relative to that of the basolateral membrane,[126] but whether the composition of the membrane has a role is yet to be determined.

Pathways for Water Transport Across Cell Membranes

As explained above, water transport across biological membranes can be across the lipid phase of the membrane (solubility diffusion) or across membrane proteins. The mammalian aquaporin family consists of 13 members that form water pores and are expressed in the plasma membranes of numerous cell types. Their important role in water transport across cell membranes is unquestionable. It has also been suggested that other transport proteins may transport water, in addition to their substrates. Such suggestions have been made for both ion channels and carriers. We will discuss first aquaporins and then these membrane proteins in the context of water transport across cell membranes. The accepted water transport pathways across the cell membrane are illustrated in Figure 4.8.

Water Pores Determine High Cell-Membrane Water Permeability

The existence of water pores was first deduced from biophysical studies (reviewed in Macey[90] and Verkman[150]), and then elegantly confirmed by biochemical, molecular-biological, and structural studies (reviewed in Agre[1] and King et al.[75]). Over the years, several criteria were developed to ascertain the presence of water pores in membranes. The principal ones are discussed below.

HIGH P_{os}/P_d

If the membrane contains pores, then osmotic water flow does not occur via a diffusion-like mechanism, which obeys the independence principle. Instead, it

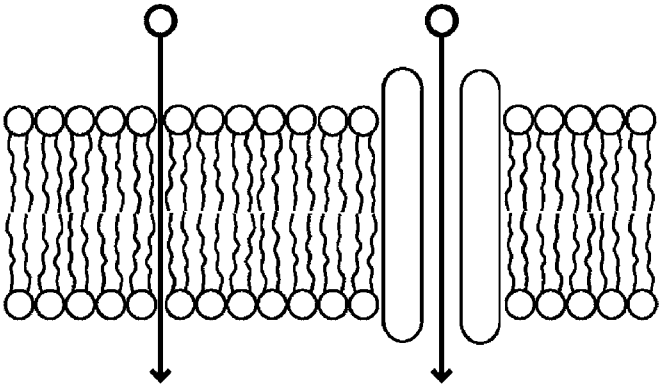

FIGURE 4.8 **Water transport pathways across plasma membranes.** Left arrow: Solubility diffusion across the phospholipid bilayer. The water permeability is directly proportional to the fluidity of the membrane. Right arrow: Permeation via pores. The water flux obeys Pouiseuille's Law in wide pores, and occurs by single-file diffusion in narrow pores such as those of aquaporins.

involves some form of interaction between water molecules, either Poiseuille-like (viscous) flow in thin capillaries or single file transport. As discussed previously, in both cases the flow of individual water molecules depends on the flow of other water molecules. It follows that the value of P_{os}/P_d is significantly greater than unity (the ratio is proportional to the square of the pore radius in case of viscous flow, and equal to the number of water molecules contained in the case of single file transport). However, unstirred-layer effects can cause a disproportionately large underestimation of P_d relative to P_{os}, with the end result of an artifactually large ratio. This error can be prevented by measuring the unstirred-layer equivalent thickness, and making appropriate corrections for P_{os} and P_d.[34] In conclusion, a correctly obtained $P_{os}/P_d > 1$ is strong evidence for water transport via pores. The value of P_{os}/P_d can denote either the pore radius or the number of water molecules in the pore. Resolving this issue requires additional experimental work, such as permeation studies with solutes of varying sizes to estimate the pore radius.

LOW ARRHENIUS ACTIVATION ENERGY

The activation energies (E_a) for water permeation via aqueous pores and for water self-diffusion are about the same (<5 kcal mol^{-1}), that is, much lower than the E_a for water permeation by solubility diffusion across a lipid membrane (<12 kcal mol^{-1}). This can be established by measuring the water permeability at different temperatures.

SENSITIVITY TO Hg

Water transport via proteinaceous pores is inhibited by $HgCl_2$ and organic mercurial compounds, an effect suggestive of a critical SH group in the protein underlying the pore function.[91,92] This was corroborated when the protein was identified.[113] The mercury sensitivity of water transport is conferred by a specific cysteine residue (Cys189 in human AQP1),[138] located ~8 Å above the NPA region.[59]

FLUX INTERACTIONS

In the case of large pores with finite solute permeability, there are frictional interactions between water and solutes (see above), with the end result of solvent drag and/or electrokinetic phenomena. Although this has been demonstrated for some membrane pores, it does not seem to take place with aquaporins, the water-selective pores in animal cell membranes. This suggests that these pores are impermeable to most solutes, and hence too narrow for solvent drag or electrokinetic phenomena.

Among cell membranes from epithelia, the best studied from a water-pore viewpoint is the apical membrane of the mammalian renal proximal tubule, where the above criteria have been clearly satisfied.[167] Water pores have been identified in numerous organs and cell types, and in the renal proximal tubule they are constitutively active; in contrast, in the collecting duct under resting conditions they exist in a cytoplasmic vesicular pool, and are inserted in the apical membrane after stimulation by vasopressin.[15,16]

Cell Membrane Water Pores are Aquaporins

The existence of water pores on cell membranes was demonstrated in red blood cells and renal tubules by the biophysical approaches described above (for reviews see Macey[90] and Verkman[150]). The pores were identified by the discovery of the red cell membrane protein first named CHIP28,[29,113] and now aquaporin 1 (AQP1). When expressed in amphibian oocytes or purified and reconstituted in liposomes, AQP1 forms Hg^{2+}-sensitive water pores with low activation energy, and no ion conductance (reviewed in Agre,[2] Engel et al.,[33] Heymann,[55] King et al.[75]). Later studies have shown three important facts: (1) AQPs are expressed in plant and animal cells, in both simple and complex organisms; (2) AQPs are expressed in the plasma and intracellular membranes of most cells, not just red cells and renal epithelial cells; and (3) there are 13 AQP isoforms in mammals, which have unique cellular and subcellular distributions.[43,70,75,151] Aquaporins are present in most cell types in the body, and there is reason to suspect that they are the predominant pathway for water transport across cell membranes.[75] In this section, we will discuss aquaporins largely from a molecular point of view. Aquaporins in the kidney are treated in Chapter 41, and aquaporins in other organs by King et al.[75] For excellent recent

reviews on AQPs, see Agre[1] and King et al.,[75] as well as more recent ones.[43,70,78,95,109,151,152,157] Peter Agre received the 2003 Nobel Prize in Chemistry for his work on aquaporins.

Based on their permeability properties, primary sequence, and gene structure, mammalian AQPs have been classified into three groups: Class 1, 2, and 3. Class 1 AQPs are permeated only by water (isoforms 0, 1, 2, 4, 5, 6, 8); class 2 AQPs, also known as aquaglyceroporins (isoforms 3, 7, 9, 10), are permeated by both water and small organic solutes such as glycerol; whereas class 3 AQPs are of unknown or unclear permeability properties (isoforms 11 and 12). AQPs in cell membranes are tetramers, with one subunit N-glycosylated.[72,135] Each monomer is ~30 kD, and contains a narrow aqueous pore surrounded by α helices. AQP monomers display N- and C-termini on the same side of the membrane (intracellular for plasma membrane AQPs), and the primary and tertiary structures clearly show an inverted symmetric pattern, each formed by three bilayer-spanning α helices. In each repeat, the loops B and E (C-terminal to the transmembrane helices 2 and 5), which contain the highly conserved signature motif Asn-Pro-Ala (NPA), form short hydrophobic α helices that reach halfway through the membrane from opposite sides to end facing each other. The overall fold has been described as an hourglass consisting of the two hemipores that face each other, with wider bases and a narrow area in the membrane center, lined by the two NPA-containing loops, which contribute to the pore selectivity.[65,75,113] The hourglass model was proposed from sequence analysis,[72] and has been confirmed by cryoelectron microscopy and X-ray crystallography studies.[37,41,60,103,119,142,158,159] A schema of this structure is shown in Figure 4.9.

The class 3 AQPs, AQP11, and AQP12, are located in intracellular compartments, and are closer to the SIP plant family (Small basic Intrinsic Proteins), displaying less than 20% homology with other members of the mammalian AQP family.[95] In AQP11 and AQP12, the highly-conserved NPA motif in the AQP N-terminal half is substituted with the sequences NPC and NPT, respectively, but they still have a conserved C-terminal half NPA motif.[69] The function of AQP11 is unknown, and that of AQP12 is unclear, without evidence for water permeability in frog-oocyte studies, but displaying water permeability when reconstituted in liposomes.[69,70]

Mechanism of Water Permeation in AQPs

The high selectivity of AQPs such as AQP1 for water – excluding even proton permeation – is consistent with the minimum width of the pore (2.8 Å), which limits the size of permeant molecules. The dipole moments of the two half-helices that contain the

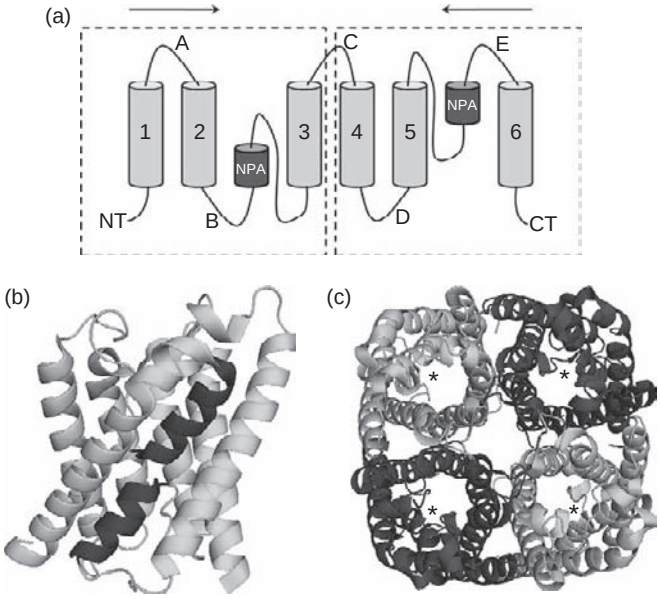

FIGURE 4.9 Membrane topology and structure of aquaporin 1 (AQP1). (a) Predicted secondary structure. AQP1 consists of two repeats of three transmembrane helices (1, 2, and 3; 4, 5, and 6). Amino and carboxy termini are on the cytoplasmic side. Loops B and E contain the Asn-Pro-Ala motifs (NPA) that form part of the water pore and are important to determine selectivity. Loop E contains Cys189, responsible for Hg^{2+} sensitivity. (b) Monomer structure (side view, ribbon representation). Transmembrane helices are shown in the same tone, whereas loops B and E, which contain the NPA sequences that meet approximately halfway into the membrane, are shown in a darker tone. (c) Tetramer structure (view from top). The monomers are functional *per se*, but AQP1 assembles into tetramers. Each monomer is shown in a tone different from that of the neighboring subunits. Asterisks denote the approximate location of the water pore in each subunit. Built with PyMol from PDB 1J4N.

NPA motifs are oriented on the center of the hydrophilic pore, creating an electrostatic barrier to H^+ movement, and inducing a complementary alignment of the water molecules' dipole moments as they pass the signature motif.[8,9,27,28,65,66,160] Interaction of the water molecules inside the pore with the NPA motifs dipoles prevents formation of hydrogen bonds between adjacent water molecules. In other words, similar to what happens to K^+ permeating K^+-selective channels, the water molecules in the AQP1 pore lose contact with other molecules. One could say that the water becomes "dehydrated," and permeates in single file. The lack of hydrogen bonding of water molecules inside the pore prevents proton conduction via "water wires".[142,144]

Water selectivity arises at a constriction located ~8 Å extracellular to the NPA region, the aromatic/arginine region (ar/R), which contains a conserved arginine.[65,66,160] The ar/R region acts as a selectivity filter that limits permeation based on size and hydrophobicity.[65] This region is wider and more hydrophobic in aquaglyceroporins, allowing permeation of small

TABLE 4.1 Permeability Characteristics and Predominant Distribution for Known Mammalian Aquaporins

Isoform	Permeability	Tissue Distribution	Subcellular Distribution[a]
AQP0	Water (low)	Lens	Plasma membrane
AQP1	Water (high)[b]	Red blood cell; kidney; lung; vascular endothelium; brain; eye	Plasma membrane
AQP2	Water (high)	Kidney; vas deferens	Apical membrane; intracellular
AQP3	Water (high); glycerol (high); urea (moderate)	Kidney; skin; lung; eye; colon	Basolateral membrane
AQP4	Water (high)[b]	Brain; muscle; kidney; lung; stomach; small intestine	Basolateral membrane
AQP5	Water (high)[b]	Salivary gland; lacrimal gland; sweat gland; lung; cornea	Apical membrane
AQP6	Water (low); anions ($NO_3^- > Cl^-$	Kidney	Plasma membrane; intracellular
AQP7	Water (high); glycerol (high); urea (high); metalloids[d]	Adipose tissue; kidney; testis	Plasma membrane
AQP8	Water (high)[c]	Testis; kidney; liver; pancreas; small intestine; colon	Plasma membrane; intracellular
AQP9	Water (low); glycerol (high); urea (high); metalloids	Liver; leukocytes; brain; testis	Plasma membrane
AQP10	Water (low); glycerol (high); urea (high)	Small intestine	Intracellular
AQP11	Water?	Testis; kidney; brain; heart; thymus; intestine; liver	Intracellular
AQP12	?	Pancreas	Intracellular

solutes such as glycerol.[65] In members of the AQP family such as the *Escherichia coli* GlpF channel, sequence tuning of the selectivity filter region allows permeation of small uncharged solutes.[65] In the case of GlpF, the minimum diameter of the pore is ~3.8 Å, allowing passage of glycerol. Both polarity and diameter of the selectivity filter are essential to determine the permeability properties of AQPs.[65,160]

Certain Aquaporins are Permeable to Solutes and Perhaps to Physiologic Gases

As shown in Table 4.1, five of the eleven AQP isoforms have been shown to display solute permeability, in addition to water permeability. It has also been claimed that AQP1 has ion-channel activity when stimulated by cGMP, but this is unclear at this time (see below). Class II AQPs (aquaglyceroporins, isoforms 3, 7, 9, and 10) are permeable to small, neutral, hydrophilic solutes. Of these, urea is critical for renal function (see Chapter 43). Recent observations also point to permeability to the trivalent metalloids arsenite, As(III), and antimonite, Sb(III) through aquaglyceroporins.[5] As(III) and Sb(III) are protonated at physiological pH, with the main species in solution being the undissociated trioxides of a molecular volume slightly smaller than that of glycerol, which may explain permeation through the aquaglyceroporins.[5,114]

From the point of view of permeability properties, AQP6 differs from other AQPs in that it displays low water permeability, and behaves as an anion channel selective for anions such as nitrate over Cl^-.[67,68] Lowering pH and reaction with Hg^{2+}, a known blocker of water permeation through AQPs, increase anion conductance.[67,68,109] AQP6 has been traditionally considered an intracellular AQP present in intracellular vesicles of α-intercalated cells of the renal collecting ducts,[68,70,109] but it has been more recently identified in other tissues, including the apical membrane of parotid acinar cells, where it seems to contribute to the anionic conductance of the membrane.[67]

A very interesting issue is whether AQPs are permeable to gases, in particular CO_2 and NH_3.[21,65,104,106] It was reported that AQP1 expression in *Xenopus* oocytes elicits an almost twofold, Hg^{2+}-sensitive increase in plasma membrane CO_2 permeability,[21,106] and an even larger effect (also Hg^{2+}-sensitive) was

obtained in *E. coli* membrane vesicles expressing AQP1.[112] Other aquaporins may also be permeable to gases.[104] However, the CO_2 permeabilities of red blood cells and alveolar epithelium of mice in which *Aqp1* was deleted were found to be no different from those of wild type mice.[171] The differences between these sets of studies remain unresolved (see [22,153]).

Regulation of AQP-Mediated Water Permeability

In principle, the water permeability of a cell membrane via AQP depends on the number of functional pores (N per cell or membrane surface area), the single-pore water permeability, and the pore open probability (the fraction of the time that it is water permeable). Changes in N have been clearly demonstrated to regulate AQP-mediated water permeability. The most striking example of this mechanism is the effect of vasopressin on the insertion of AQP2 in the luminal membrane of the cortical collecting duct (see Chapter 42). As discussed below, certain solutes decrease the water permeability of AQP pores, but there is no definitive evidence for a regulatory role of pore "gating" in the sense that this expression is used in ion channel function (see Chapters 2 and 8). However, there is some evidence for regulation of aquaporin opening through phosphorylation.[49,51,95,101,145]

The permeability of several AQP isoforms is modulated by the composition of the extracellular solution. The water permeability of AQP0 expressed in *Xenopus* oocytes was reported to be increased by lowering external pH and $[Ca^{2+}]$.[107] Both effects depend on the pore residue His40.[44] In another study, the water permeability of AQP3, also expressed in oocytes, was found to be reduced by external acidification, whereas AQP0, AQP1, AQP2, AQP4, and AQP5 were found to be pH-insensitive,[177] in contrast with the study quoted above. In oocytes or LLC-PK1 cells expressing heterologous AQP4, PKC agonists were reported to reduce cell membrane water permeability,[50,173] an effect abolished by deletion of Ser180.[173] However, when purified AQP4 was reconstituted in liposomes, its phosphorylation by PKC did not affect the water permeability (quoted in King et al.[75]). Finally, *Xenopus* oocytes expressing AQP1 develop an ion current after injection of cGMP, whereas this agent had no effect on oocytes expressing AQP5.[4] Further, the effect is dependent on specific charged residues in the C-terminal domain of AQP1.[13] It is not clear, however, that the pathways for water permeation and ion fluxes are the same: when the experiment was carried out with AQP1 reconstituted in planar bilayers, an organic mercurial compound inhibited water permeability, but not cGMP-induced ion conductance.[133] Further, the ratio of ion permeability to water permeability was extremely small, suggesting that only a minute fraction of AQP1 molecules would form cGMP-activated ion channels.[133] Calmodulin binds to AQP0 and AQ6 (acidification-induced anion channel AQP), in a calcium dependent manner, and it inhibits AQP0 permeability.[107,115,118,127] The mechanism of the decrease in water permeability and functional role of the interactions of Ca^{2+}−calmodulin with AQPs have not been established. In conclusion, contrary to statements in the literature, there is no evidence that the AQP water pore is gated, that is, opens and closes stochastically as an ion channel. The available information is consistent with modulatory effects, such as by H^+ or divalent cations that could simply block the water permeation pathway. It is also clear that the finding that expression of a membrane protein results in water and ion permeability does not mean that they occur through the same pathway.

Other Membrane Proteins May Contribute to Water Transport

Water permeation through narrow ion channels has been studied by molecular-dynamics simulations based in the atomic structure of the KcsA channel[129] (see also Chapter 2). In the narrow part of the pore (selectivity filter), K^+ is transported in single file; two adjacent ions are separated by a water molecule; therefore, the molar flux ratio (K^+/water) is unity. For "near-isosmotic" water transport, the flux of 1 ion has to be coupled to that of 157 water molecules. Therefore, direct coupling between ion and water transport in narrow ion channels contributes only a minute fraction of the water flux expected to be produced by the changes in the osmolality of the solutions adjacent to the membrane that are produced by the ion flux.

One would expect that wider ion channels, in which the ions permeate in a hydrated state, would result in larger water fluxes coupled to the ion flow, and perhaps also in water permeation in the absence of a net ion flux. Although there is no direct evidence for this, it was recently shown that blocking the volume-regulated anion channel (VRAC) decreased significantly the water permeability of endothelial cells.[108] This result suggests that these channels constitute a significant pathway for osmotic water flow in these cells.

Do Co-Transporters Perform Active Water Transport?

Experiments in the choroid plexus epithelium of *Necturus maculosus*[174,175] and retinal pigment epithelium of frog[176] suggested that water transport and solute transport (KCl and lactate, respectively) are directly coupled. Under energetically favorable conditions, water would move uphill in the direction of the net ion flux and by the same pathway, implying

molecular coupling (in the carrier molecule) between the solute and water fluxes. If this is correct, then the water is co-transported, that is, transported uphill by a secondary active mechanism. Several co-transporters have been suggested to perform this function when expressed in *Xenopus* oocytes: Na^+-glucose,[84,97,98] Na^+-glutamate,[89] Na^+-dicarboxylate,[99] and others.[80,175] The rate of water transport via these carriers would range between 40 and 600 molecules per cycle. The water/solute coupling ratio in the case of the human Na^+-glucose co-transporter[98] indicates that the transported fluid would be hyperosmotic, instead of near-isosmotic. Hence, near-isosmolality could result from the parallel operation of transcellular osmosis (see [175] for a recent review). The critical experimental result supporting the water co-transport hypothesis is that solute transport via a co-transporter is associated with a water flux much larger than that observed with a similar solute flux via ion channels,[83] an argument that would rule out the alternative explanation that the co-transporter-mediated solute flux increases the osmolality in the plane adjacent to the membrane, and that the resultant generated osmotic gradient is responsible for water flux across the plasma membrane,[79,80] and not necessarily the co-transporter itself. A careful study of water fluxes in *Xenopus* oocytes expressing heterologous proteins, including Na^+-glucose co-transporters, glucose transporters or the K^+-channel ROMK2, permitted another group to relate solute accumulation in the oocytes to water flow. Their conclusion is that the glucose accumulation quantitatively accounts for the water flux by simple osmosis, and therefore that there would be no need to postulate water co-transport.[20,42] A critical factor in the solute accumulation in these studies is the intracellular solute diffusion coefficient, which in the oocytes is about one-fifth of that in free solution.[19,20]

Summary and Conclusions

In conclusion, the osmotic behavior of cells is not ideal because of the presence of cell solids; water transport across the cell membrane occurs by osmosis; and the determinants of cell volume are the intracellular solute content and the extracellular osmolality. Water permeation across the plasma membrane occurs via AQP pores and/or the phospholipid bilayer. Other pathways contribute at most a small fraction of the water flow.

WATER TRANSPORT IN EPITHELIA

Two modalities of transepithelial water transport occur in renal tubules *in situ*: (1) net transport between isosmotic (or near-isosmotic) fluids (e.g., water reabsorption in the proximal tubule); and (2) net transport in the direction of a pre-existing osmotic gradient (e.g., water reabsorption in the collecting duct). Although other mechanisms have been proposed, the dominant view is that water transport is passive and driven by osmotic forces. Pinocytosis has also been suggested, but is considered highly unlikely.[167] Solute–water co-transport, discussed in the previous section, is also unlikely given recent experimental results.[42] Electro-osmosis[132] and mechano-osmosis[130] have also been proposed, largely on the basis of neglecting the presence of unstirred layers in theoretical or experimental analyses. The reader interested in these hypotheses should consult additional references.[32,36,82,102,130,132,167]

Characteristics of Transepithelial Water Transport

The main consequence of water transport across cell membranes of epithelial cells is to contribute to transepithelial transport, that is, fluid absorption or secretion. In addition, similar to most other cells, epithelial cells are endowed with mechanisms of maintenance and regulation of their own volume. Physiologic regulation of transepithelial transport may involve changes in solute transport rate at one of the two cell membranes. This causes an instantaneous imbalance between the transport rates of apical and basolateral membranes, and therefore a change in cell solute and water content. In most epithelial cells, there is a rapid readjustment of the transport rate by a complex process called intermembrane "cross-talk"[134,135] (see Chapter 2).

Epithelia Have Very Different Water Permeabilities

Epithelia differ widely in their osmotic water permeabilities (Table 4.2). From the points of view of magnitude and regulation of their osmotic permeability coefficient, epithelia can be classified in the following three groups:

1. *High constitutive osmotic water permeability.* In these epithelia the P_{os} is permanently high. This group includes most leaky epithelia (epithelia with high ionic paracellular permeability relative to the transcellular permeability), such as renal proximal tubule, descending limb of the loop of Henle, small intestine, gallbladder, and choroid plexus. The high value of P_{os} is in large part (or exclusively) attributable to high permeabilities of both cell membranes (apical and basolateral). The cell membranes express water pores, so that water is likely to permeate by both solubility diffusion (via the lipid bilayer) and osmosis (via the pores).

TABLE 4.2 Osmotic Water Permeability of Epithelial Cell Membranes

Epithelium	Apical	Basolateral	Transepithelial	Reference
ADH-INSENSITIVE				
Rabbit PST	4500	5000	4280	18
Necturus gallbladder	640	460	350	23
Rabbit/rat TALH	–	–	0–20[a]	117
ADH-SENSITIVE				
Rabbit CCD				
(−) ADH	70	450	–	141
(+) ADH	310	490	–	
Rabbit IMCD				38
(−) ADH	70	480	–	
(+) ADH	260	390	–	

P_f values are rounded and expressed in $\mu m\ s^{-1}$, without correction for membrane folding factors; that is, they are referred to an "idealized" epithelial surface. For P_f values considering membrane folding, see Tripathi and Boulpaep.[146]

[a]*Range of several studies.*

ADH: antidiuretic hormone (vasopressin); PST: proximal straight tubule; TALH: thick ascending limb of loop of Henle; CCD: cortical collecting duct; IMCD: inner medullary collecting duct.

It is also possible that part of the water flow is intercellular (or paracellular), as discussed below.

2. *Low constitutive osmotic water permeability.* In mammals the only epithelia with this property are the ascending limb of the loop of Henle and urinary tract epithelia. The P_{os} is extremely low and insensitive to hormonal action (vasopressin). Both the apical membranes and the junctional complexes are low permeability barriers. In the thick ascending loop of Henle, the basolateral membrane has a high water permeability, so that changes in peritubular fluid osmolality result in rapid cell volume changes, whereas changes in luminal (apical) solution osmolality are ineffective.[54,143] The transepithelial P_{os} is low, although there is a high junctional ionic permeability. This lack of correlation between permeability to ions and water is not unexpected. As discussed in the context of cell membrane water permeability, ion channels permeate little water, and their expression level is quite low, so they do not increase P_{os} by a large amount. The molecular explanations for the low P_{os} of the apical membranes and junctions of the ascending limb of loop of Henle cells are unknown. In the case of urinary tract epithelia, there appears to be a major role of apical membrane uroplakins (see previous discussion and Hu et al.[64]).
3. *Variable (regulated) water permeability.* The renal collecting duct and the anuran urinary bladder and epidermis have low baseline P_{os} values, which are elevated when plasma osmolality rises by a mechanism involving secretion of antidiuretic hormone (vasopressin) by the neurohypophysis. Vasopressin binds to the basolateral V2 receptor, and activates a signaling mechanism that involves an increase in intracellular cAMP, resulting in insertion and then retrieval of preformed water pores in the apical membrane by exocytosis and endocytosis, respectively. The cytoplasmic pool of pores is contained in subapical tubulovesicles.[16,38,52,53,150,154,155]

Two Types of Transepithelial Water Transport

It is not difficult to understand the mechanisms of water reabsorption in either the cortical or the medullary collecting duct (CCD and MCD, respectively) under the influence of vasopressin. The tubule fluid at the end of the distal tubule is hyposmotic to plasma (and to the renal cortex interstitial fluid). Hence, if the CCD is water permeable, then water will be reabsorbed down the osmotic gradient. A similar situation occurs in the MCD, where the entering lumen fluid is at most isosmotic to plasma and the osmolality of the surrounding interstitial fluid ranges in humans, from 300 mosmol/kg at the cortico-medullary junction to 1200 mosmol/kg at the papilla (Chapter 43). In the frog epidermis, water reabsorption occurs from the pond (osmolality <10) to the frog's extracellular fluid (200–250 mosmol/kg). Thus, in these three epithelia there is a pre-existing osmotic force, and whether water is absorbed or not depends on the P_{os} of the apical membrane of the epithelial cells. As discussed previously, P_{os} at this membrane is regulated by insertion and retrieval of AQP2 water pores in response to changes in extracellular osmolality, a process mediated by secretion of vasopressin (see also Chapters 42 and 43).

In the renal proximal tubule, small intestine, gallbladder, and other epithelia, the fluids bathing the epithelium are usually isosmotic or near-isosmotic, and transepithelial water transport can take place in the absence of a measurable driving force between the bulk solutions. Further, early experimental observations showed that water absorption can occur against the transepithelial osmotic gradient, that is, from the concentrated to the diluted solution.[25] This occurs both in small intestine and renal proximal tubule, and unquestionably demonstrates uphill water transport (see Whittembury and Hill[166] and Whittembury and Reuss[167] for detailed discussions). Of course, this does

not necessarily mean that there is a "water pump" (primary or secondary active water transporter) in the system. Studies in small intestine epithelium revealed that uphill water absorption occurs only together with net solute absorption and in the same direction, suggesting some form of "coupling" between water and solute fluxes.[25,161,162,163] Over the next 50 years, these puzzling observations elicited a great deal of experimental and theoretical work, which resulted in successive proposals to explain: (1) water transport between isosmotic bulk solutions; (2) uphill water transport; and (3) the nature of the coupling between solute and water flow.

Solute–Solvent Coupling

Passive mechanisms may exist that would couple salt to water absorption or secretion. Intuitively, active salt absorption by an epithelium (see Chapter 2) will create, at both apical and basolateral membranes, differences in the concentration of salt, with the side from which the salt is transported becoming "dilute" and the side toward which the salt is transported becoming "concentrated." The magnitude of the concentration changes in the fluids adjacent to the epithelial cells will depend on whether they are mixed (by convection) with the bulk solutions, and on the rates of solute diffusion into or away from these areas. Clearly, changes in concentration must be created inside the cell, in the surfaces immediately adjacent to the membranes, where the cytosol is not well mixed and the diffusion rates are much smaller than in free solution. In addition, in the extracellular surfaces adjacent to the cell membranes the solutions are not well mixed with the bulk, for two reasons: the existence of unstirred layers (see above); and the existence of anatomic restricted spaces in which good mixing cannot occur. In the case of the basolateral cell membrane of an epithelium, the histology indicates that there cannot be good mixing with the extracellular solution because of the complex architecture of the lateral intercellular spaces, the basal membrane infoldings, and the presence of the basement membrane, which is a barrier for hydraulic flow. At the apical membrane surface, fluid mixing is easier, but is also not ideal if there are microvilli. Hence, in a fluid absorbing epithelium at the steady-state one would expect a solute concentration profile in which there are salt concentration gradients across the apical membrane, with the lumen fluid diluted with respect to the cell interior, and across the basolateral membrane, with the cell diluted with respect to the extracellular solution.

The central points in this analysis of solute–solvent coupling in epithelia will be two. First, the functional anatomy of epithelia determines the existence of compartments (i.e., spaces that are "unstirred"); in these spaces osmotic coupling occurs, explaining the relationship (coupling) between salt and water transport. Second, the water permeability of the cell membranes is so high that the osmotic gradients required for near-isosmotic coupling are very small, and detectable only under rather artificial experimental conditions. This view is not universally accepted. As we discuss the details below, we will point out criticisms and alternative explanations.

Three-Compartment Models Define the Problem

An epithelial monolayer and the surrounding fluid compartments can be modeled as a three-compartment system with two barriers. The essence of these models is that the specific properties of the barriers and the compartments can account for solute–water flux coupling and explain apparently active water transport. Two proposals were developed based on this idea, namely the three-compartment model of Curran and MacIntosh[24] and the standing-gradient hypothesis of Diamond and Bossert.[31]

In the three-compartment model, illustrated in Figure 4.10, water transport occurs from the *cis* solution (A) to the *trans* solution (B), against the osmotic pressure difference between these two solutions [C_s (B) > C_s (A)]. The *cis* solution and *trans* solution are separated from the middle compartment (M) by barriers with different properties, semipermeable and porous, respectively. Active salt transport into an unstirred intraepithelial compartment renders it hyperosmotic to the *cis* solution (hyperosmotic middle compartment). Water then flows from A to M by osmosis (the membrane is semipermeable) and, as the hydrostatic pressure rises in M, solution flows from the M into B by bulk flow (the membrane is porous). The equivalent of this system in an absorptive epithelium would be as follows: the semipermeable membrane is constituted by the two cell membrane domains (apical and basolateral) in series, and the porous membrane by the distal end of the lateral intercellular spaces and the basement membrane, also in series. Compartment A is the lumen, compartment B the basolateral (interstitial) solution, and compartment M the lateral intercellular space. Water can be transported uphill (against the osmotic gradient between A and B) only while the middle compartment is hyperosmotic to the *cis* compartment. In addition, for this model to operate the absorbed fluid must be hyperosmotic to the *cis* solution. Experimental studies showed that the emerging fluid is virtually isosmotic with the *cis* solution,[30] requiring revision of the above theory. This resulted in the formulation of the standing-gradient hypothesis, explained below.

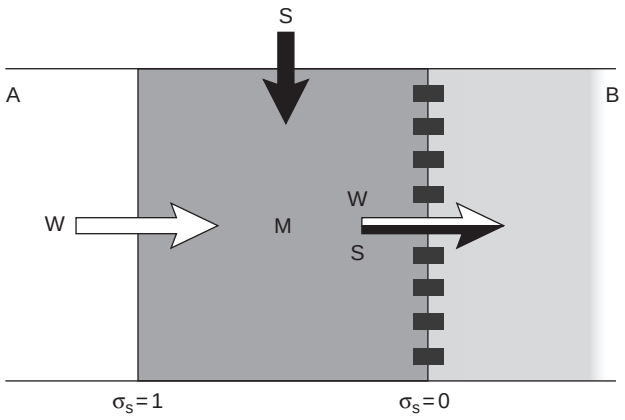

FIGURE 4.10 **Three-compartment model of Curran and MacIntosh.**[18] Solute entry (s, solid arrow) into the middle compartment (compartment M) causes osmotic *water* flow (w, open arrow) from compartment A to compartment M. The elevation of the hydrostatic pressure in compartment M causes *solution* flow from compartment M into compartment B (w/s open/solid arrow). Hence, there is water flux from A to B, although $C_s(B) > C_s(A)$. Darker tones in the compartment denote higher solute concentrations. See text.

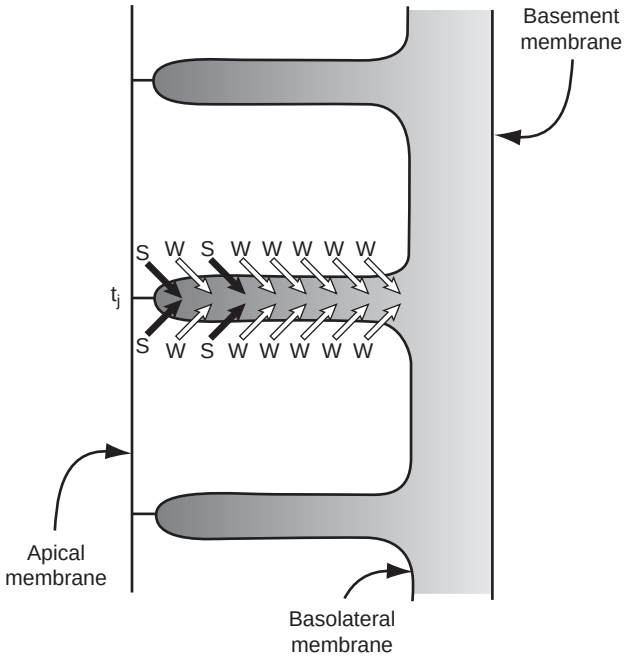

FIGURE 4.11 **Standing-gradient hypothesis of Diamond and Bossert.**[23] Solute transport (s, solid arrows) into the channel (lateral intercellular space) causes a local increase in osmolality; water flows osmotically across the bounding membranes (w, open arrows), "diluting" the solution in the channel. Transport toward the open end is by bulk flow and diffusion. See text.

Standing-Gradient Hypothesis Explains Near-Isosmotic Fluid Transport, but is Difficult to Reconcile with Current Experimental Knowledge

The standing-gradient hypothesis of Diamond and Bossert[31] is depicted in Figure 4.11. It is based on the following definitions and assumptions: (1) the lateral intercellular space is the hyperosmotic middle compartment; (2) the junctional complexes are impermeable to both solute and water; (3) solute transport from the cell to the *trans* solution takes place across the lateral membranes near the apical poles of the cells; (4) in contrast, secondary (osmotic) water flow occurs across the entire lateral membrane; (5) the lateral intercellular space solution is unstirred; (6) solute diffusion along the length of the lateral intercellular spaces is restricted by their geometry (the spaces are long and narrow). Under these conditions, the solution of the complicated mathematical model describing the system yields a continuously decreasing osmolality from the apical (blind) to the basolateral (open) end of the space. Also, the emerging solution is more likely to be near-isosmotic when the following conditions hold: long and narrow spaces, small solute diffusion coefficient, and high cell membrane P_{os} relative to the solute transport rate.

Direct and indirect observations demonstrated that some of the above assumptions are not correct. (1) In many instances the junctions have high permeability to ions[40,61,164,168] and perhaps to water.[165,167] (2) The Na^+, K^+-ATPase is distributed homogeneously in the lateral cell membrane,[99] not restricted to the apical region. (3) Both morphometric studies and electrophysiological computations yield short times for lateral space solute diffusion,[58,74,131,158,162] making longitudinal concentration gradients unlikely. (4) Realistic calculations based on geometry predict that the transported fluid must be hyperosmotic,[131] because the spaces are not sufficiently long and narrow. (5) The hypothesis predicted sizable hyperosmolality in the lateral intercellular spaces, but this was based on the early estimations of transepithelial P_{os}, which were in error due to unstirred-layer artifacts.[11,62] (6) Measurements of transepithelial voltage changes elicited by changes in solution osmolality revealed that the lateral intercellular spaces are in virtual osmotic equilibrium with the cell.[124,125]

An important point in this discussion is that for a constant fluid transport rate, the magnitude of the osmotic gradient and of the hyperosmolality of the transported fluid is inversely proportional to the effective P_{os} of the osmotic barriers. In fact, many of the above problems were solved with the development of methods to measure the osmotic water permeability of the cell membranes of leaky epithelia, which were demonstrated to be very large. On these bases, some of the above notions must be discarded, because they

were based on incorrect experimental data and a simpler mechanism of transepithelial water transport has emerged.

Near-Isosmotic Fluid Transport Model Solves the Difficulties of Three-Compartment Models

Measurements of P_{os} in high water permeability membranes give values ranging from 100 to 400 $\mu m\ s^{-1}$, that is, 10- to 100-fold greater than early estimates.[167] Hence, instead of a needed osmolality difference of about 20 mosmol kg^{-1}, as predicted from the standing-gradient hypothesis, a very small difference in osmolality, of only 1–2 mosmol kg^{-1}, quantitatively accounts for the measured water transport rates.[23,111,167] As explained previously, the primary event in transepithelial water transport is active salt transport. Inasmuch as solute is removed from the *cis* side and added to the *trans* side, there must be a decrease in *cis* fluid and an increase in *trans* fluid osmolality in the immediate vicinity of the respective membranes, as well as opposite changes in osmolality at the intracellular surface of the two membranes: an increase at the apical membrane and a decrease at the basolateral membrane. The magnitude of these changes will depend on the transport rate and geometry of the systems, and can be generally expected to be quite small. Measurements in fluid samples from isolated, perfused renal tubules reveal small differences, supporting this view.[10,46] In conclusion, recent studies support the notion that so-called isosmotic transepithelial water transport is not truly isosmotic, but near-isosmotic. Further, the osmotic driving forces required to account for water transport are quite small, and hence difficult to determine *in situ*, and substantial hyperosmotic compartments or sizable longitudinal standing gradients probably do not exist[121,141,167] (see Figure 4.12).

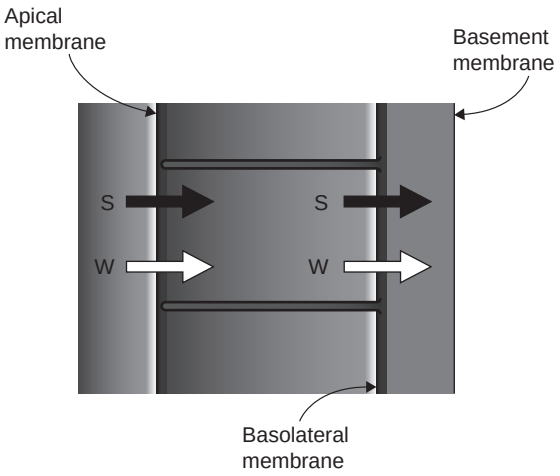

FIGURE 4.12 **Near-isosmotic transport model.** Because of the high osmotic water permeability of the cell membranes, the differences in solution osmolality needed to account for fluid transport are small, probably localized at epithelium–solution interfaces. Salt transport causes dilution of solution on *cis* side and concentration of the solution on *trans* side at the two cell membranes. In the case of fluid absorption, at the apical membrane the intracellular solution is hyperosmotic to the lumen solution; at the basolateral membrane, the intracellular solution is hyposmotic to the extracellular solution. These small differences in osmolality, denoted in the figure by shades of gray (hyperosmotic solution being darker), cause osmotic water flow into the cell across the apical membrane and out of the cell across the basolateral membrane. The magnitude of the paracellular water flow is uncertain. Because of the high surface area of the lateral membranes, and the small volume of the lateral intercellular spaces, the space osmolality is "clamped" by the cell osmolality, making longitudinal osmotic gradients in the spaces small at most.

Solute Recirculation in the Paracellular Pathway in Theory Explains Truly Isosmotic Transepithelial Fluid Transport

Truly isosmotic transepithelial water transport[147,148] may occur, in theory, if there is solute recirculation across the epithelium. In other words, it is argued that an epithelium cannot perform transepithelial truly isosmotic transport if it is bathed by identical solutions on both sides, and there are no differences in electrical potential or hydrostatic pressure, unless part of the transported solute recirculates to the solution of origin. In frog skin glands, there is transcellular Cl^- secretion (secondary active uptake at the basolateral membrane, channel-mediated downhill Cl^- extrusion across the apical membrane) and paracellular Na^+ secretion (driven by the lumen-negative transepithelial voltage generated by Cl^- transport). As such, this transport mechanism would cause secretion of a hyperosmotic fluid, but it was proposed that this fluid can become truly isosmotic. Larsen and co-workers[81,82] developed an interesting mathematical model for solute recirculation in the epithelium of the small intestine. The essential points are as follows: the primary transport event is active Na^+ transport across the lateral cell membrane (by the Na^+,K^+-ATPase). Water follows osmotically across the lateral cell membranes and the tight junctions. With appropriate geometric and transport parameters, the solution in the lateral intercellular spaces would be hyperosmotic by a small amount. The transported fluid would become isosmotic by uptake (recirculation) of salt across the basal membrane, via Na^+-K^+-$2Cl^-$ co-transport. This model has been criticized[140] on two main grounds: the use of experimental measurements of the Cs^+ flux ratio to assess transcellular and paracellular Na^+ fluxes, and the energetic cost of recirculation, namely the fact that about half of the pump work would be wasted. However, both sides agree that the model is amenable to further experimental testing.[81,140]

In Certain Epithelia Asymmetries in Solute Composition Play Significant Roles

It is possible that factors other than the total osmolalities of the solutions on either side of the epithelium contribute to transepithelial water transport. Three possibilities should be considered (see Whittembury and Hill[166] for a more detailed discussion). First is a colloid-osmotic force: transepithelial differences in protein concentration can result in colloid-osmotic pressure differences that can be significant in the case of epithelia with high permeability to water and small solutes. In the renal proximal tubule, this factor accounts for a small portion of water reabsorption.[48] Second is a difference in the effective osmolalities of the solutions: if the epithelium is exposed to solutions containing solutes of different reflection coefficients, then there could be transepithelial effective osmolality gradients, even if the solutions have the same total osmolality. Under the conditions described there will be osmotic water flow toward the side containing the higher concentration of low permeability (high reflection coefficient) solutes.[47] This has been proposed to occur in the late renal proximal tubule because of reabsorption of organic solutes such as glucose, and preferential reabsorption of HCO_3^-. Both have been claimed to have higher reflection coefficients than Cl^-. However, the notion of low reflection coefficients in epithelial cells has been disputed, and attributed to errors caused by uncorrected unstirred-layer effects.[154] Third are hydrostatic pressure differences: under most conditions, these differences are small and hence do not contribute significantly to water flow.

Pathways for Transepithelial Water Transport are also Controversial

Is water transport transcellular and/or paracellular? Epithelial transport pathways can be in series or in parallel. The cells consist of pathways in series (apical membrane, cytoplasm, and basolateral membrane), as does the intercellular (paracellular) pathway (junction in series with lateral intercellular space). In turn, the transcellular pathway and the paracellular pathway are in parallel with each other. A major problem in the phenomenological description of transepithelial transport has been to ascertain the portions of ion and water fluxes occurring across each pathway. In the case of ions, it has been clearly shown that in some epithelia most passive permeation is paracellular (leaky epithelia); whereas in others most passive permeation is transcellular (tight epithelia) (see Reuss[123] for a review). In the case of water, there is convincing experimental evidence demonstrating transcellular transport, but paracellular transport is controversial.[122]

Transcellular Osmotic Water Transport is Supported by High Cell-Membrane P_{os}

In high water permeability epithelia (mammalian renal proximal tubule, *Necturus* gallbladder), apical and basolateral membrane P_{os} values range from <500 to $5000\ \mu m\ s^{-1}$ (renal tubule [17,18,19,45,167]; gallbladder [23,111]). In both membrane domains, there can be considerable "amplification," by the presence of microvilli at the apical membrane and infoldings at the basolateral membrane. Hence, the P_{os} values expressed per unit surface area of membrane are much smaller than those relative to the idealized geometry of the tissue. Regardless of this, the water permeability of these epithelia is high, and attributable to the expression of water pores.

Paracellular Osmotic Water Transport is Supported by Indirect Arguments

The paracellular P_{os} can be estimated in principle from the transepithelial and cell membrane P_{os}. Given that the transcellular and paracellular pathways are in parallel:

$$P_{os}^t = P_{os}^c + P_{os}^p \tag{4.21}$$

where P_{os} denotes osmotic permeability, and the superscripts t, c, and p refer to transepithelial, cellular, and paracellular pathways, respectively. In the proximal tubule, P_{os}^t appears to be significantly higher than P_{os}^c, suggesting that P_{os}^p is sizable.[167] The problems with these calculations are the errors involved in the measurements of transepithelial and cell membrane P_{os} values.

Paracellular water transport is also supported by quantitative assessments of the effect of organomercurial compounds, presumed to be specific pore blockers, on P_{os}^t and P_{os}^c. An agent such as pCMBS inhibits P_f^c by more than 90%, but P_{os}^t is reduced by only 50%, which strongly suggests a finite parallel water permeation pathway.[167] These calculations imply a single site of action of pCMBS and other effects are, in principle, possible.

Another argument suggesting paracellular water flow is the observation of solvent drag and electrokinetic phenomena. If osmotic water flow takes place across large pores, which are also permeable to solute, then there will be a frictional interaction between water and solute, and the water flow will cause a solute flow in the same direction. This solute flux can occur in the absence of a favorable solute electrochemical gradient between the solutions. It is usually demonstrated using hydrophilic nonelectrolytes (e.g., small sugars such as mannitol); the mannitol and water fluxes correlate linearly, as predicted by Eq. (4.18). Results suggesting solvent drag have been reported for several epithelia.[167] The simplest electrokinetic

phenomenon to study is the streaming potential produced when, in the absence of a favorable electrochemical gradient, the solute is a permeant ion that flows in the same direction as water. Streaming potentials are generated if the water permeation pathway is ion-selective, that is, more permeable to that ion than to the counterion. The observation of this phenomenon has been interpreted as supportive of solute–water coupling in the paracellular pathway (reviewed in Tripathi and Boulpaep[146]).

The main problem with experiments purporting to demonstrate solvent drag or streaming potentials is the complication introduced by unstirred layers. Water transport in such a system causes changes in solute concentrations next to the membrane surfaces, raising the concentration on the *cis* side and lowering it on the *trans* side. Therefore, even if the concentrations of a given solute are the same in the bulk solution, there will be a concentration gradient at the membrane surfaces (unstirred-layer polarization), which explains the apparent solvent drag (pseudo-solvent drag). Pseudo-streaming potentials can be similarly caused by ion concentration changes elicited by the water flux. It is possible to distinguish true from apparent streaming potentials by comparing the time courses of the transepithelial voltage changes caused by the addition of nonelectrolyte or by a unilateral ionic substitution.[120,124,125] This criterion could help confirm or rule out the legitimacy of claimed true streaming potentials.

One recent approach to assess the role of the paracellular pathway in water permeation has been the use of genetic manipulation of claudins in mice and culture cells. Tight junctions are composed of several membrane proteins, including occludin and claudins.[77,136] Claudin-2 is frequently located at tight junctions of leaky epithelia that display high fluid transport rates, and seems to be responsible for the cation selectivity of the paracellular pathway in these tissues.[77,105] Recent studies have shown that expression of claudin-2 in an MDCK cell line increases water permeability,[128] and that the proximal tubules of mice deficient in claudin-2 display increased paracellular electrical resistance with loss of cation selectivity.[105] The decrease in net fluid transport in the claudin-2-deficient mice parallels the decreases in NaCl reabsorption, and cannot be unambiguously ascribed to a primary decrease in water permeability.[105,128]

In sum, the cellular pathway is certain to contribute to transepithelial osmotic water transport, and there are suggestions of a significant paracellular contribution. However, the latter is based on indirect evidence, and is questionable because of possible unstirred-layer artifacts. This problem will be definitively solved only by direct measurements of transcellular and paracellular water flows, which is a daunting task. Recent elegant fluorescence microscopy studies[76] suggest that there is no significant water flow across tight junctions of MDCK monolayers, relative to the transcellular flow. However, in these experiments the rate of transepithelial water flux was much smaller than observed in native epithelia. Sachar-Hill and Hill[130] have argued, on the basis of analyses of hydrophilic probe and water fluxes, that the paracellular water flux of several epithelia is quite high. However, the problem of unstirred layers was neglected in their analysis. Additional studies using genetic manipulations, in combination with sophisticated imaging studies, may shed light into the long-standing issue of the physiological role of water permeation through the paracellular pathway.

Summary and Conclusions

Water transport in leaky epithelia occurs in the same direction as solute transport and in near-isosmotic proportions. The available experimental evidence supports the view that the coupling between solute and water transport is not molecular, but thermodynamic, that is, osmotic. Solute transport by pumps, carriers, and/or channels elicits differences in solute concentration at the membrane surfaces, with a decrease in concentration on the *cis* side and an increase on the *trans* side. The establishment of osmotic gradients is favored because of the architecture of epithelia, which contain compartments that do not mix well with the surrounding fluids. The magnitude of the osmotic gradients is small and difficult to measure, but sufficient to account for the measured rates of fluid transport. Osmotic water flow takes place predominantly across the cell membranes, via both AQP pores and the phospholipid bilayer, with a small or nil contribution of other proteins. It is possible that part of the water flow is paracellular via the tight junctions, but this is likely to be relatively small.

Cell Volume Control

Florian Lang

Department of Physiology, University of Tübingen, Tübingen, Germany

Cells must avoid gross alterations of volume in order to survive. Obviously, excessive cell swelling will jeopardize the integrity of the cell membrane, and both cell swelling and cell shrinkage will interfere with cytoskeletal architecture. Moreover, cellular function critically depends on the hydration of cytosolic proteins. Proteins and protein-bound water occupy a large portion of the cell interior (macromolecular crowding), leaving only a small fraction of cellular volume to free water.[1–6] Abstraction or addition of only a few percentage points of cellular water thus has profound effects on protein function and cellular performance.

In most mammalian cells, the plasma membrane is highly permeable to water,[7,8] a property in large part due to virtually ubiquitous expression of water channels in the cell membrane.[9–11] In theory, driving forces for movement of water include hydrostatic and osmotic pressure gradients. However, the cell membrane is too fragile to withstand significant hydrostatic pressure gradients, and if extension of the cell is not prevented by extracellular constraints the movement of water is governed almost exclusively by osmotic gradients.[12–15] Thus, to avoid swelling or shrinkage, a cell has to achieve osmotic equilibrium across the cell membrane (Figure 5.1). At excessive intracellular osmolarity, water will enter following its osmotic gradient, and the cell will swell. Conversely, at excessive extracellular osmolarity, water will leave, and the cell will shrink. As outlined in this chapter a wide variety of factors modify intra- or extracellular osmolarity, and thus challenge osmotic equilibrium across the cell membrane.

For maintenance of volume constancy, cells employ a number of mechanisms, including metabolism and altered transport across the cell membrane. These mechanisms may also participate in the regulation of cell function. Hormones and mediators may influence cell volume regulatory mechanisms, and thus manipulate cell volume. Alterations of cell volume will in turn modify other cell volume-sensitive functions. The interplay among cell volume regulatory mechanisms, cell hydration, and cell function does not only contribute to physiological regulation of cellular function, but also participates in the pathophysiology of a wide variety of diseases.

In this chapter a description of cell volume regulatory mechanisms will be followed by a synopsis of factors challenging cell volume constancy, and a discussion on the impact of cell volume regulatory mechanisms on the physiology and pathophysiology of cellular function. Due to space constraints, many excellent original papers on cell volume regulation could not be cited, and the reader is referred to reviews instead. For more detailed analysis of the pertinent original literature, the reader is encouraged to consult previous reviews on cell volume regulation.[16–41]

CELL VOLUME REGULATORY MECHANISMS

Cell volume constancy is challenged by alterations of extracellular osmolarity, by intracellular metabolic generation of osmotically active solutes and by transport across the cell membrane.[31] To counteract those challenges, cells employ a variety of cell volume regulatory mechanisms.[32] Following cell swelling, these mechanisms decrease intracellular osmolarity and cell volume, thus accomplishing regulatory cell volume decrease (RVD). Upon cell shrinkage the mechanisms increase intracellular osmolarity and cell volume, thereby accomplishing regulatory cell volume increase (RVI). Upon slow changes of extracellular osmolarity, the volume regulatory mechanisms may be fast

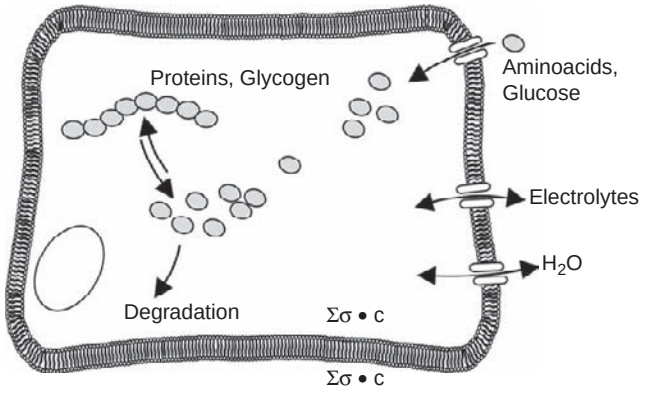

FIGURE 5.1 **Determinants of cell volume.** Water moves according to osmotic gradients across the cell membranes, that is, differences between intracellular and extracellular $\sum\sigma.c$, where σ is the reflection coefficient and c the concentration of each solute on either side. Even at constant extracellular $\sum\sigma.c$, an osmotic gradient is generated by transport of osmotically active solutes across the cell membrane and by metabolic generation or disposal of intracellular solutes.

enough to prevent significant alterations of cell volume, leading to isovolumetric volume regulation.[42]

The most powerful mechanisms of cell volume regulation are ion transporters in the cell membrane.[32] As outlined below, uneven ion composition of intracellular and extracellular fluid is one prerequisite for the establishment of osmotic equilibrium across the cell membrane. Furthermore, several ion transport systems in the cell membrane are modified upon alterations of cell volume. Following cell swelling they mediate cellular ion release; upon cell shrinkage they allow cellular ion accumulation to re-establish osmotic equilibrium across the cell membrane.

However, the use of ions in cellular osmoregulation is limited, since high inorganic ion concentrations interfere with the stability of proteins.[43] Beyond that, altered ion gradients across the cell membrane interfere with the function of gradient-driven transporters. For instance, an increase of intracellular Na^+ activity decreases the chemical gradient for Na^+ across the cell membrane, and reduces the driving force for Ca^{2+} extrusion via the Na^+/Ca^{2+} exchanger, which increases intracellular Ca^{2+} activity. To avoid excessive alterations of intracellular ion concentration, cells also utilize organic osmolytes for osmoregulation.[20,21,44] Moreover, cells adapt a variety of metabolic functions, and thus modify the cellular generation or disposal of osmotically active organic substances.

It should be pointed out that a single cell does not usually employ all cell volume regulatory mechanisms described in the following text. In most cases, it is not clear why a given cell selects a certain set of ion transporters and osmolytes without using other mechanisms. Presumably, the large repertoire of cell volume regulatory transporters and osmolytes available enables any given cell to regulate its volume with relatively little impairment of its particular function.

Cell Volume Regulatory Ion Transport

To counterbalance the intracellular osmolarity due to osmotically active organic solutes, such as amino acids and carbohydrates, cell volume regulatory mechanisms need to maintain intracellular concentrations of inorganic ions below extracellular ion concentrations. In addition, cell volume regulatory ion transport systems are employed to counteract alterations of cell volume by appropriate transport of ions across the cell membrane.

Ions in Cell Volume Maintenance

To compensate for the cellular accumulation of organic solutes, cells maintain a low intracellular Cl^- concentration.[31] In most cells, Cl^- may move across the cell membrane through Cl^- channels. Cl^- movement through those channels is governed by the cell's negative potential across the cell membrane, which is built up by asymmetric cation gradients[8]: the cells extrude Na^+ in exchange for K^+ by the Na^+/K^+-ATPase. The cell membrane is, on average, less permeable to Na^+ than to K^+. K^+ tends to leave the cell through K^+ channels following its chemical gradient. The exit of K^+ generates a cell-negative potential difference across the cell membrane, and thus establishes the driving force for the exit of anions such as Cl^-. At a cell membrane potential of some -18 mV, for instance, Cl^- is in equilibrium at a chemical gradient of 1:2. Accordingly, at an extracellular Cl^- concentration of 110 mmol/L, the intracellular Cl^- concentration is in electrochemical equilibrium at 55 mmol/L. In theory, such a Cl^- distribution would allow the excess accumulation of 55 mmol/L of organic solutes. In most cells the potential difference across the cell membrane is higher (more negative) than -18 mV, and intracellular Cl^- is even lower than 55 mmol/L.

As long as the cell membrane is perfectly impermeable to Na^+, cell membrane potential, cytosolic Cl^- concentration, and cell volume could be maintained constant without continued expenditure of energy. Maintenance of the asymmetric cation distribution requires, however, that any Na^+ entering the cell is subsequently extruded by Na^+/K^+-ATPase, an ATP-consuming process.

Ion Release Following Cell Swelling

Ion transport is not only crucial for the establishment of osmotic equilibrium across the cell membrane, but accomplishes rapid correction of any osmotic imbalance across the cell membrane. Following cell swelling, cells must release ions to decrease their osmolarity. Most cells release ions by activation of K^+ channels and/or anion channels (Figure 5.2). Cell volume regulation requires the operation of both ion channel types, since neither K^+ nor anions can leave the cells without the respective counterion. Several cell volume regulatory ion channels have been identified at the molecular level, including the K^+ channels Kv1.3,[45] Kv1.5,[46] Kv4.2, 3,[47] IsK or KCNE1/Q1,4,5,[26,48–51] TWIK1,[52] TASK2/KCNK5,[53] TREK1/KCNK2,[26] TRAAK/KCNK4,[26] intermediate or MaxiK (Kca),[26,54] and the anion channels ClC-2,[55–59] ClC-3,[60,61] phospholemman,[62] and bestrophins.[63] The role of other ion channels in cell volume regulation, such as I_{Cln},[64–66] P-glycoprotein (MDR) ,[67–70] and CFTR,[71,72] has been a matter of controversy. Clearly, many different ion channels are likely to contribute to cell volume regulation in various tissues, and the molecular identity of some of those channels is still elusive. Some anion channels not only allow the exit of Cl^-, but also of HCO_3^-, organic anions, and noncharged osmolytes.[73–80]

Swelling of some cells activates unspecific cation channels, including some transient receptor potential (TRP) channels.[15,32,81–87] Since the electrochemical gradient favors entry rather than exit of cations, these channels cannot directly serve cell volume regulation. Instead, the channels allow the entry of Ca^{2+}, which in turn activates Ca^{2+}-sensitive K^+ channels and/or Cl^- channels.

Besides ion channels, the most important mechanism contributing to regulatory cell volume decrease is KCl co-transport by one of the four members of the KCC family,[88,89,90–94] which allows coupled cellular release of both ions.

Some cells release cellular KCl via parallel activation of K^+–H^+ exchange and Cl^-–HCO_3^- exchange.[95,96] The H^+ and HCO_3^- thus taken up in exchange for KCl react via H_2CO_3 to produce CO_2, which can easily leave the cell again.

Water efflux during volume regulatory decrease could be fully accomplished by existing water channels. Nevertheless, aquaporins participate in cell volume regulation by modifying the activity of ion channels.[9]

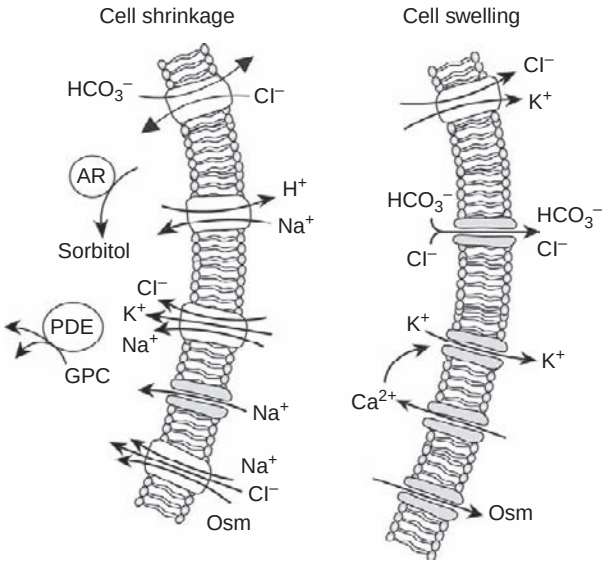

FIGURE 5.2 **Most widely employed mechanisms of regulatory cell volume regulation.** Left: Mechanisms of regulatory cell volume decrease. Cell swelling leads to activation of KCl co-transport, anion channels, K^+ channels, cation channels, and channels releasing organic osmolytes such as sorbitol, inositol, taurine, and betaine. The cation channels do not directly serve cell volume regulatory decrease, but rather increase of cytosolic Ca^+ activity that triggers activation of Ca^{2+} sensitive K^+ channels. Right: Mechanisms of cell volume increase. Cell shrinkage leads to parallel activation of Na^+/H^+ exchanger and Cl^-/HCO_3^- exchanger, $Na^+K^+2Cl^-$ co-transport, Na^+ channels, and Na^+-coupled accumulation of inositol, taurine, and betaine. Furthermore, cell shrinkage leads to cellular accumulation of glycerophosphorylcholine by inhibition of phosphodiesterase (PDE), and of sorbitol by activation of aldosereducase (AR).

Ion Uptake upon Cell Shrinkage

Cell shrinkage activates the Na^+–K^+–$2Cl^-$ co-transporters NKCC1, and NKCC2,[97–100] and/or the Na^+/H^+ exchangers NHE1,[101] NHE2[102] or NHE4[103] parallel to the $Cl^-HCO_3^-$ exchanger AE1.[36,104,105] The parallel activation of Na^+/H^+ exchangers and Cl^-/HCO_3^- exchangers leads to uptake of NaCl, while the H^+ and HCO_3^- lost in exchange for NaCl are replenished in the cell from CO_2 via H_2CO_3 (Figure 5.2). The epithelial Na^+/H^+ exchanger NHE3 is inhibited by cell shrinkage.[106] The Na^+ ions accumulated by either Na^+–K^+–$2Cl^-$ co-transport or Na^+H^+ exchange are extruded by Na^+K^+-ATPase in exchange for K^+. Accordingly, the transporters eventually lead to cellular KCl uptake.

Several cells activate Na^+ channels or unspecific cation channels following cell shrinkage.[107–112] The channels may include some members of the transient receptor potential (TRP) channel family or ENaC.[113–116,181] The resulting depolarization drives Cl^- into the cell, so that the net effect is cellular accumulation of NaCl. Other cells inhibit K^+ and/or Cl^- channels to avoid cellular ion loss.[32]

Osmolytes

The most important osmolytes are polyols such as sorbitol and myoinositol, methylamines such as betaine and glycerophosphorylcholine, as well as amino acids including taurine.[3,21,28,41,44,117,118] In contrast to inorganic ions, organic osmolytes do not destabilize proteins, but rather stabilize them. They counteract the destabilizing effects of inorganic ions, some organic ions (e.g., spermidine), and urea.[3,18] The stabilizing potency of the diverse organic osmolytes is not identical. The destabilizing effects of urea are counteracted most efficiently by betaine and glycerophosphorylcholine, and less efficiently by myoinositol.[18] The stabilizing effects of osmolytes may protect proteins against excessive ion concentrations, as well as against heat shock, freezing, desiccation, and presumably radiation.[119–123]

Osmolyte Accumulation by Metabolism

Sorbitol is generated from glucose under the catalytic action of aldose reductase.[124–126] Stimulation of the transcription rate of the aldose reductase during osmotic cell shrinkage leads to cellular accumulation of sorbitol. The expression of the protein takes many hours, and the appropriate increase of sorbitol concentration requires hours to days.[127]

Glycerophosphorylcholine (GPC) is produced from phosphatidylcholine under the catalytic action of a phospholipase A_2, which is distinct from the arachidonyl selective enzyme.[21,128] GPC is degraded by a phosphodiesterase to glycerol-phosphate and choline. Inhibition of the phosphodiesterase during cell shrinkage leads to cellular accumulation of GPC.[129]

Osmolyte Accumulation by Transport

Myoinositol (inositol),[28,130–133] betaine[134–136] and taurine[137] are taken up by specific Na^+-coupled transporters SMIT (inositol), BGT (betaine), and NCT (taurine), respectively. The carriers accumulate Na^+, the respective organic osmolyte, and in the case of BGT and NCT, Cl^- as well. Movement of excess positive charge by the carriers depolarizes the cell membrane, thus favoring entry of Cl^- via anion channels. The transporters thus mediate uptake of NaCl parallel to organic osmolytes. The transcription rate of the transporters and the cellular accumulation of the respective osmolytes are stimulated by osmotic cell shrinkage. Expression of the transporters is slow, and full adaptation requires hours to days. Moreover, volume regulation by activation of transport systems depends on the availability of osmolytes in the extracellular fluid.

Analogous to osmolytes, some amino acids are accumulated by cell volume-sensitive, Na^+-coupled transport.[138–140] In addition, amino acids could be generated by autophagic proteolysis, as discussed in the next section.

Osmolyte Release

Cell swelling stimulates the rapid release of GPC,[27,141] sorbitol,[142–144] inositol,[27,145] betaine,[27,145] and taurine.[77,146–150] The mechanisms mediating osmolyte release are still poorly understood. Clearly, several mechanisms are simultaneously operative. At least some of the release mechanisms are thought to be anion channels. As shown for taurine,[147] the osmolyte release could be triggered by oxidative stress.

Metabolic Pathways Sensitive to Cell Volume

Alterations of cell volume influence a variety of metabolic pathways. The effects of cell volume on metabolism are accomplished in part by activation and inhibition, and in part by altered expression of enzymes.[31]

Protein and Glycogen Metabolism

Cell shrinkage stimulates the breakdown of proteins to amino acids, and of glycogen to glucosephosphate.[24,151–154] Moreover, cell shrinkage inhibits protein and glycogen synthesis.[153,154] The sum of amino acids generated during proteolysis is osmotically more active than the osmolarity of the respective protein. Thus, net formation of macromolecules decreases, and net degradation of macromolecules enhances, cellular osmolarity. Cell swelling stimulates protein and glycogen synthesis, and inhibits proteolysis and glycogenolysis, thus decreasing the intracellular concentration of amino acids and glucosephosphate.

Glucose and Amino Acid Metabolism

In addition to affecting protein and glycogen metabolism, alterations of cell volume influence several pathways of glucose and amino acid metabolism.[154] Cell swelling inhibits glucose uptake and glycolysis, stimulates flux through the pentose phosphate pathway, and favors lipogenesis from glucose, effects reversed by cell shrinkage.[154–156] Transcription of phosphoenolpyruvate carboxykinase, a key enzyme for gluconeogenesis, is decreased by cell swelling. Cell swelling stimulates glycine and alanine oxidation and glutamine breakdown, as well as formation of NH_4^+ and urea from amino acids; these effects are reversed by cell shrinkage.[154]

Oxidative Metabolism

The stimulation of flux through the pentose phosphate pathway during cell swelling enhances NADPH production, which favors the formation of glutathione (GSH).[154,156] Cell shrinkage decreases NADPH production and GSH formation. Accordingly, cell swelling increases and cell shrinkage decreases cellular resistance to oxidative stress. On the other hand, cell swelling stimulates, and cell shrinkage decreases, the activity of NADPH-oxidase, thus modulating cellular O_2^- formation.[157,158] Accordingly, leukocyte oxidative burst, and thus immune response, is blunted by the high osmolarity of kidney medulla.[159,160]

Other Metabolic Pathways

Cell swelling stimulates ketoisocaproate oxidation, acetyl CoA carboxylase, and lipogenesis, and inhibits carnitine palmitoyltransferase I. It decreases cytosolic ATP and phosphocreatine concentrations, and increases respiration. Cell swelling stimulates RNA and DNA synthesis. All of these effects are reversed by cell shrinkage.[31]

Cell Volume-Sensitive Genes

Cell volume influences the transcription of a wide variety of genes,[31,44,117,161] leading to differential expression of a wide variety of proteins.[162,163] Transcription factors involved include AP1, c-FOS, cJUN, tonicity-response enhancer binding protein TONEBP, serum response factor (SRF), and myocardin related transcription factor.[26,161] Many of the cell volume-regulated genes are related to cell volume regulation. Accordingly, cell shrinkage stimulates expression of enzymes or transporters engaged in cellular formation or accumulation of osmolytes, such as aldose reductase, and the Na^+-coupled transporters for betaine (BGT), taurine (NCT), myoinositol (SMIT), and amino acids, as well as Na^+,K^+,$2Cl^-$ co-transport (see above). Moreover, cell shrinkage upregulates the expression of the ATPase α1-subunit.[164]

The products of other genes may be involved in the signaling of cell volume regulatory mechanisms, such as the kinases ERK1, ERK2, and JNK-1, which are expressed during cell swelling[165] or the serum and glucocorticoid inducible kinase SGK1[166,167] and cyclooxygenase-2,[168] which are preferably expressed in shrunken cells.[31]

Heat shock proteins serve to stabilize proteins, and their expression in shrunken cells may counteract the destabilizing effects of accumulated ions.[169–173] Several genes expressed in response to altered cell volume do not have obvious roles in cell volume regulation. Cell swelling stimulates the expression of the cytoskeletal elements β-actin and tubulin, the immediate early genes c-jun and c-fos, the enzyme ornithine decarboxylase, and the cytokine TNF-α.[165,174,175]

Cell shrinkage stimulates the expression of the channels CIC-K1, the transporter P-glycoprotein, the immediate early genes Egr-1 and c-fos, the GTPase inhibitor α1-chimaerin, the CDβ antigen, the enzymes phosphoenolpyruvate carboxykinase (PEPCK), arginine succinate lyase, tyrosine aminotransferase, tyrosine hydroxylase, dopamine β-hydroxylase, matrix metalloproteinase 9, tissue plasminogen activator, as well as matrix proteins including biglycan and laminin B_2.[31] Cell shrinkage stimulates both expression and release of ADH, which serves to eliminate water and thus increase extracellular osmolarity.[176]

The mechanisms mediating the altered gene expression are beginning to be understood. The promoter region of the genes encoding aldose reductase, BGT, TAUT, and SGK1 have been ascribed to contain osmolarity responsive (ORE), tonicity responsive (TonE) or cell volume-responsive (CVE) elements, which are required for osmolarity or cell volume-sensitive expression of the respective genes.[125,177,178] TonE has been shown to bind a tonicity-responsive element-binding protein (TonEBP) for stimulation of expression.[179–186] TonEBP is regulated by ataxia teleangiectasia-mutated (ATM) kinase.[181]

Signaling of Cell Volume Regulation

The stimulation of effectors of cell volume regulation requires that alterations of cell volume or osmolarity are perceived and trigger a signaling cascade, eventually leading to stimulation of cell volume regulatory mechanisms.

Little is known about sensors of cell size and hydration. Circumstantial evidence points to the ability of cells to determine cellular protein content or macromolecular crowding.[187] It has been speculated that macromolecular crowding directly or indirectly regulates kinases which in turn influence the activity of cell volume regulatory KCl and $Na^+-K^+-2Cl^-$ co-transport (see below).[31] Alternatively, alterations of ionic strength or the concentration of individual ions such as Cl^- modify volume regulatory mechanisms.[26] Moreover, alterations of cell size are thought to impose stretch on the cytoskeleton and/or cell membrane or change the curvature of the cell membrane,[188–190] again leading directly or indirectly to activation of cell volume regulatory mechanisms.[31,191,192] Cell swelling leads to unfolding of the cell membrane and, if this does not suffice, to endomembrane insertion. Alterations of cell volume could be further sensed by

cytokine[193] and Ca^{2+} sensing receptors,[194] as well as by integrins.[26]

A multitude of signaling pathways link the alterations of cell volume and cell volume regulatory mechanisms. The respective signaling varies considerably between different cells or a given cell in different functional states.

Intracellular Ca^{2+}

Cell swelling increases intracellular Ca^{2+} activity in many, but not all, cells. Ca^{2+} enters through Ca^{2+} channels in the plasma membrane, and/or is released from intracellular stores triggered by 1,4,5-inositol-trisphosphate. The channels involved include nonselective Ca^{2+} channels, Ca^{2+} permeable members of the TRP (transient receptor potential) channel family, such as TRPV4, and L-type voltage gated Ca^{2+} channels.[41,113,195,196] Ca^{2+} in turn activates some cell volume regulatory K^+ channels and Cl^- channels.[197–199] In addition to its involvement in regulatory cell volume decrease, intracellular Ca^{2+} may mediate some of the functional consequences of cell shrinkage.

Cytoskeleton

Alterations of cell volume modify the architecture of the cytoskeleton and the expression of cytoskeletal proteins.[200–204] Cell shinkage increases and cell swelling decreases actin polymerization. Both microtubules[200] and actin filaments[201] have been implicated in cell volume regulation. In several cells, disruption of actin filaments and/or the microtubule network have been shown to interfere with cell volume regulation.[31]

Protein Phosphorylation

Cell swelling and cell shrinkage have both been shown to modify the phosphorylation of a variety of proteins. Kinases reported to be activated during cell swelling include tyrosine kinases,[205–209] protein kinase-C,[210,211] phosphoinositide (PI) 3 kinase,[212] Jun-kinase, and extracellular signal-regulated kinases ERK-1 and ERK-2,[165,208,213–219] as well as focal adhesion kinase ($p121^{FAK}$).[212] Activation of PI3 kinase leads to stimulation of protein kinase B (Akt), and serum and glucocorticoid inducible kinase isoforms, which modify a wide variety of carriers and channels.[220] Expression of SGK1 is, however, downregulated by cell swelling, and thus SGK1 dependent signaling is disrupted.[220] In Jurkat lymphocytes, cell swelling leads to activation of the src-like kinase lck,[56] which in turn activates the cell volume regulatory Cl^- channel ORCC.[206]

Osmotic cell shrinkage stimulates WNK (with no lysine kinase) 1 and 4, which in turn activate Ste-20-related proline alanine rich kinase (SPAK) and oxidative stress responsive kinase (OSR1).[222–224] SPAK and OSR1 activate the Na^+-K^+-$2Cl^-$ co-transporters NKCC1 and NKCC2.[222,223,225] Conversely, WNK4 inhibits KCl co-transporters.[226] WNK1 activates SGK1, which in turn inhibits WNK4.[227,228] Osmotic cell shrinkage further triggers several MAP (mitogen-activated protein) kinase cascades, and activates SAPK, p38 kinase, myosin light-chain-kinase (MLCK), Jun kinase (JNK), p21-activated kinases PAKs Rho kinase, LIM kinase, and casein kinase.[193,229–239] MLCK may modulate the cytoskeleton, and thus cell volume regulatory ion transport. Moreover, the kinase cascades lead to activation of transcription factors governing expression of cell volume-regulated genes.[31] Hyperosmolarity activates the tyrosine kinase Fyn-dependent phosphorylation of caveolin,[240] which in turn inhibits volume-sensitive Cl^- channels.[241]

Phosphatidylinositol 4,5,-Bisphosphate

Cell swelling decreases and cell shrinkage increases the formation of phosphatidylinositol 4,5 bisphosphate ($PtdIns(4,5)P_2$)[242] by the phosphatidylinositol 4-phosphate 5-kinase beta isoform (PIP5KIbeta).[243] Among other effects, $PtdIns(4,5)P_2$ stimulates the transient receptor potential channel TRPV1, Na^+/H^+ exchanger NHE1, the Na^+/Ca^{2+} exchanger NCX, and the Na^+ channel ENaC, and inhibits the transient receptor potential channel TRPC6.[26,244] $PtdIns(4,5)P_2$ may further foster actin polymerization by inhibiting the monomer-binding protein profilin, the severing protein cofilin, the capping protein gelsolin, as well as the Wiskott–Aldrich syndrome protein (WASP).[26,245]

Phospholipase A_2 and Eicosanoids

Cell swelling activates phospholipase A_2 and subsequently stimulates the formation of the 15-lipoxygenase product hepoxilin A_3, and the 5-lipoxygenase product leukotriene LTD_4.[246] Phospholipase A2 is phosphorylated by casein kinases CK1 and CK2, protein kinase A, protein kinase C, and mitogen activated kinases.[247–249] In some cells the eicosanoids generated following ativation of phospholipase A_2 stimulate cell volume regulatory K^+,Cl^- channels, and/or taurine release.[246] Enhanced formation of leukotrienes parallels decreased formation of PGE_2, with subsequent decrease of Na^+ channel activity.[246,250] Conversely, osmotic cell shrinkage may stimulate formation of PGE_2, with subsequent activation of PGE_2-sensitive Na^+ channels.[251] In other cells PGE_2 may activate volume regulatory K^+ channels.[252] In erythrocytes, activation of phospholipase A_2 by hyperosmotic shock leads to release of platelet-activating factor PAF, which in turn activates a sphingomyelinase, thus stimulating ceramide formation.[253]

pH of Acidic Cellular Compartments

In all cells studied thus far, swelling alkalinizes and cell shrinkage acidifies acidic cellular compartments, presumably including endosomes, lysosomes, and secretory granules.[31,254] This effect is apparently mediated by the microtubules, since it is abolished by disruption of the microtubule network. The alkalinization of the acidic cellular compartments may contribute to the antiproteolytic action of cell swelling, since the pH optimum of lysosomal proteases is in the acidic range, and lysosomal alkalinization has indeed been shown to inhibit proteolysis.[255]

Others

Several G-proteins have been implicated in cell volume regulation including Rho, Rac, and Ras.[26,256,257] Hyperosmotic cell shrinkage further activates ezrin/radixin/moesin (ERM) proteins, which in turn mitigate the shrinkage-induced activation of NHE1, augment Rho activity, and presumably modify actin architecture.[258] Cell swelling may trigger release of ATP, which in turn leads to autocrine stimulation of purinergic receptors with the respective activation of cell volume regulatory ion channels.[259]

CHALLENGES AND FUNCTIONS AFFECTING CELL VOLUME

A wide variety of factors alters extracellular and/or intracellular osmolarity, and thus challenges cell volume constancy. Due to the exquisite sensitivity of cell function to even minor alterations of cell volume, those factors may modify a multitude of physiological functions and participate in several pathophysiological conditions.

Alterations of Extracellular Fluid Osmolarity and Composition

In mammals, most cells are usually bathed in well-controlled extracellular fluid. However, both extracellular osmolarity and composition could vary to an extent, challenging cell volume regulation.

Osmolarity

Excessive alterations of extracellular osmolarity are only encountered in kidney medulla, where extracellular osmolarity may approach 1400 mosmol/L in humans (see Chapter 40). Renal medullary cells are exposed to this excessive extracellular osmolarity during antidiuresis, and have to cope with rapid changes of extracellular osmolarity during transition from antidiuresis to diuresis. Blood cells passing the kidney medulla experience high medullary osmolarity and subsequent return to isoosmolarity within seconds (see Chapter 40).

During intestinal absorption, intestinal cells are exposed to anisosmotic luminal fluid, and liver cells to minor alterations of portal blood osmolarity. Other tissues are exposed to anisotonic extracellular fluid during deranged regulation of extracellular osmolarity (see Chapters 41 and 42). As Na^+ salts (mainly NaCl) contribute normally more than 90% to extracellular osmolarity, hypernatremia is necessarily paralleled by an increase in extracellular osmolarity (see Chapter 42). During hypernatremia, cells defend themselves against increased extracellular osmolarity by triggering regulatory cell volume increase involving cellular accumulation of osmolytes. Owing to cell volume regulation, cell volume may become normal despite enhanced extracellular osmolarity. Rapid correction of chronically enhanced osmolarity may then lead to deleterious cell swelling, since the organic osmolytes accumulated during hyperosmolarity cannot be rapidly released. The most serious consequence is cerebral edema.

Hyponatremia cannot be equated with hypoosmolarity, but may occur in isoosmolar or even hyperosmolar states, as in hyperglycemia of uncontrolled diabetes mellitus and ethanol poisoning (see Chapter 44). When hyponatremia reflects a decreased extracellular osmolarity, the cells must undergo regulatory cell volume decrease to escape cell swelling. Among other mechanisms, cells release organic osmolytes. Upon rapid correction of hyponatremia, cells are unable to rapidly accumulate the osmolytes, and the iatrogenic cell shrinkage may prove more harmful than the untreated hypoosmolarity.

Hypoosmolar hyponatremia is observed following burns, pancreatitis, and crush syndrome, which are generally paralleled by cell shrinkage.[24] In those conditions, the primary event may be cell shrinkage leading to ADH release with subsequent renal water retention and to cellular catabolism with enhanced release of organic solutes to the extracellular fluid.

Extracellular K^+ Concentration

The potential difference across the cell membrane is maintained by K^+ flux through K^+ channels, which in turn depends on the electrochemical driving force for K^+. An increase of extracellular K^+ concentration decreases the chemical gradient for K^+ ions, impedes K^+ efflux, depolarizes the cell membrane, and thus favors Cl^- entry into the cell. The cellular accumulation of KCl eventually leads to cell swelling. Conversely, a decrease of extracellular K^+ may lead to cell shrinkage secondary to cellular loss of KCl.[31]

H^+ and HCO_3^- Concentration

On increase of extracellular HCO_3^- concentration, cellular HCO_3^- release through anion channels and Na^+–HCO_3^- co-transport is blunted or even reversed, and the decreased efflux of negative charge hyperpolarizes the cell membrane, and thus decreases the electrochemical gradient for K^+ efflux. As a result, the cell may swell due to accumulation of K^+ and HCO_3^-.[260]

An increasing extracellular pH favors cellular H^+ elimination through the Na^+/H^+ exchanger, and the resulting cellular Na^+ accumulation may lead to cell swelling.[261] During hyperkapnea, cellular CO_2 dissociates to form H^+, which is subsequently extruded by the Na^+/H^+ exchanger. Again, cellular Na^+ accumulation is paralleled by cell swelling. Due to sensitivity of the Na^+/H^+ exchanger to intracellular pH, cellular acidification favors cell swelling, whereas cellular alkalinization has the opposite effect.[262]

Organic Acids

Some organic anions, such as acetate, lactate, and proprionate, may enter cells as unionized acids. Intracellular dissociation of the acids then leads to intracellular acidification, stimulation of Na^+/H^+ exchange, accumulation of Na^+ and organic anions, and subsequent cell swelling.[31] Isotonic replacement of Cl^- with impermeant gluconate, on the other hand, leads to cell shrinkage due to cellular loss of Cl^-.[31]

Urea, Drugs, and Toxins

Urea readily passes cell membranes, and does not usually create osmotic gradients across them. On the other hand, it has been shown that urea destabilizes proteins, and thus shifts the cell volume regulatory set point towards smaller cell volumes. Through activation of some cell volume regulatory mechanisms, such as KCl co-transport, urea shrinks cells, as shown for erythrocytes, hepatocytes, renal cells, and vascular smooth muscle cells.[31]

Beyond these mechanisms, cell volume is influenced by a wide variety of drugs and toxins, interfering with cell volume regulatory mechanisms.[31] For instance, inhibition of K^+ channels leads to cell swelling, and inhibition of Na^+–K^+2Cl^- co-transport and/or Na^+/H^+ exchanger leads to cell shrinkage.

Functional States Affecting Cell Volume Control

Even at normal extracellular osmolarity and composition, osmotic gradients across the cell membrane could arise from unbalanced transport across the cell membrane, and from intracellular generation or disposal of osmotically active solutes. Cellular conditions and functions affecting intracellular osmolarity thus impact on cell volume control (Figure 5.3).

Energy Depletion

Impairment of Na^+/K^+-ATPase function, such as during pharmacological inhibition, energy depletion or decrease of ambient temperature, eventually leads to cell swelling due to cellular Na^+ accumulation, dissipation of the K^+ gradient, depolarization, and subsequent accumulation of Cl^-.[31] In some cells, the

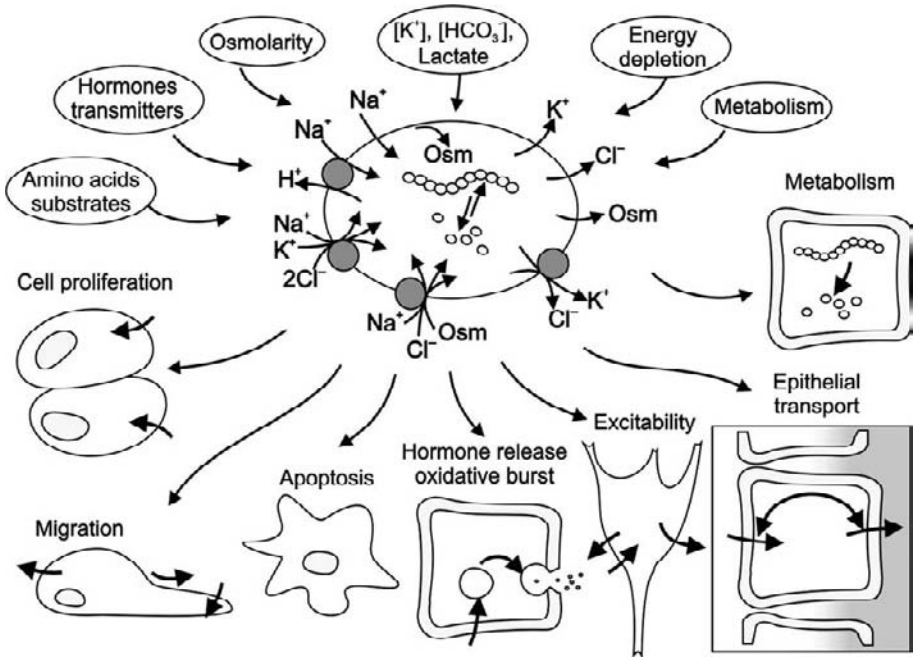

FIGURE 5.3 **Synopsis of challenges of cell volume constancy and functional significance of cell volume regulatory mechanisms.** Cell volume is altered by concentrative uptake of amino acids and additional substrates, alterations of ion transport by hormones and transmitters, changes of extracellular osmolarity, alterations of extracellular K^+, HCO_3^- and organic acid concentrations, energy depletion, and metabolic generation or disposal of osmolarity. Altered cell volume, as well as cell volume regulatory transport and metabolism, participate in the regulation of cell proliferation, migration, apoptosis, hormone release and oxidative burst, neuromuscular excitability, epithelial transport, and metabolism.

swelling is preceded by transient cell shrinkage.[263,264,265] The increase of intracellular Na^+ concentration reverses the driving force for the Na^+/Ca^{2+} exchanger; the increase of intracellular Ca^{2+} activity in turn leads to activation of Ca^{2+}-sensitive K^+ channels and/or Cl^- channels, as well as contraction of cytoskeletal elements.

Transport

Most epithelial cells are faced with large transcellular fluxes of osmotically active substances (see Chapter 2). To cope with transcellular transport, the cells have to coordinate the various transport systems at the apical and basolateral cell membranes. In both reabsorbing and secreting epithelia, cell volume participates in the coupling of those transport processes.

In proximal renal tubules[266] and intestine[267] for instance, Na^+-coupled transport of substrates such as amino acids or glucose across the luminal cell membrane leads to cellular accumulation of Na^+ and substrate. Moreover, the entry of excess positive charge leads to depolarization, impeding the exit of Cl^- and HCO_3^-, thus favoring cell swelling. In Na^+ reabsorbing epithelia, such as renal collecting duct and colon, entry of Na^+ via Na^+ channels similarly challenges cell volume constancy. Limitation of cell swelling during stimulated Na^+ transport requires the operation of cell volume regulatory mechanisms, including activation of K^+ channels, which in turn maintain the electrical driving force for Na^+ entry into the cell.[266,267] Activation of Cl^- and/or K^+ channels in several Cl^- secreting epithelia is paralleled by decrease of intracellular Cl^- activity and cell shrinkage, which in turn stimulate $Na^+{-}K^+{-}2Cl^-$ co-transport and/or Na^+H^+ exchanger with Cl^-/HCO_3^- exchanger.[268–271]

The influence of Na^+-coupled transport on cell volume is not limited to epithelial cells. In several epithelial and nonepithelial cells, concentrated uptake of substrates such as amino acids, glucose, taurine, and taurocholate increases cell volume.[31]

Deranged transport participates in disordered function of erythrocytes in sickle cell disease. In this disorder, a point mutation of hemoglobin (HbS) favors polymerization of desoxyhemoglobin, dramatically decreasing erythrocyte deformability and increasing blood viscosity.[272] The depolymerization of hemoglobin is critically dependent on cell volume. Cell shrinkage due to enhanced ambient osmolarity, activation of KCl co-transport by urea or activation of Ca^{2+}-sensitive K^+ channels by a rise in intracellular Ca^{2+} activity potentiates polymerization of HbS. The high osmolarity and urea concentration in kidney medulla thus contribute to the particular vulnerability of this tissue to ischemia in sickle cell anemia. Cell shrinkage and subsequent triggering of erythrocyte cell membrane scrambling (see below) presumably participate in accelerated erythrocyte turnover in various anemic conditions.[273]

Influence of Hormones and Transmitters on Cell Volume

A wide variety of hormones and other mediators have been shown to alter cell volume.[31] Insulin swells liver cells by activation of both Na^+/H^+ exchange and $Na^+{-}K^+2Cl^-$ co-transport, and glucagon shrinks hepatocytes, presumably by activation of ion channels.[274] The effect of insulin depends partially on the cell volume regulated serum and glucocorticoid inducible kinase SGK1.[275] The effect of the hormones on cell volume accounts for several of their metabolic effects (Figure 5.4). Notably, the swelling effect of insulin accounts for its antiproteolytic effect, and the shrinking effect of glucagon accounts for its proteolytic effect.[276,277]

Virtually all known growth factors increase cell volume by stimulation of Na^+/H^+ exchange, and in some cases by $Na^+K^+2Cl^-$ co-transport. As amplified below, an increase of cell volume appears to be required for cell proliferation.[35]

Several excitatory neurotransmitters, such as glutamate, activate Na^+ channels or nonselective cation channels, the entry of Na^+ and depolarization then favor cell swelling.[278–280] Other neurotransmitters, such as GABA, activate K^+ channels and/or anion channels, and thus induce cell shrinkage.[281]

Mediators and hormones regulating epithelial transport, such as ADH, adrenaline or acetylcholine, may either swell or shrink epithelial cells, depending on their effect on ion transport.[31] Stimulation of Na^+/H^+ exchange, $Na^+{-}K^+2Cl^-$ co-transport or Na^+ channels tends to swell epithelial cells, whereas prevailing stimulation of Cl^- and/or K^+ channels shrinks epithelial cells. Cell volume may in turn affect hormone and transmitter release. In a variety of cells, swelling stimulates and cell shrinkage inhibits the release of hormones.[282]

Neuromuscular Excitability

Cell volume could affect neuronal excitability by affecting ionic gradients, ion channel activity or cell volume regulatory release of neurotransmitters.[31] Dehydration enhances the neuronal expression of SGK1, which in turn regulates channels and transporters relevant for neuroexcitability.[283] Moreover, glial cell swelling may impede glial cell function.[284] In liver insufficiency, for instance, formation of urea is impaired, leading to accumulation of NH_3. NH_3 enters the brain and is taken up by glial cells, which then stimulates cellular formation and accumulation of glutamine, resulting eventually in glial cell swelling.[285,286] To counteract swelling, glial cells release inositol,

a mechanism, however, limited by the availability of inositol.[287,288] Inhibition of glutamine synthase has indeed been shown to protect against hepatic encephalopathy.[289]

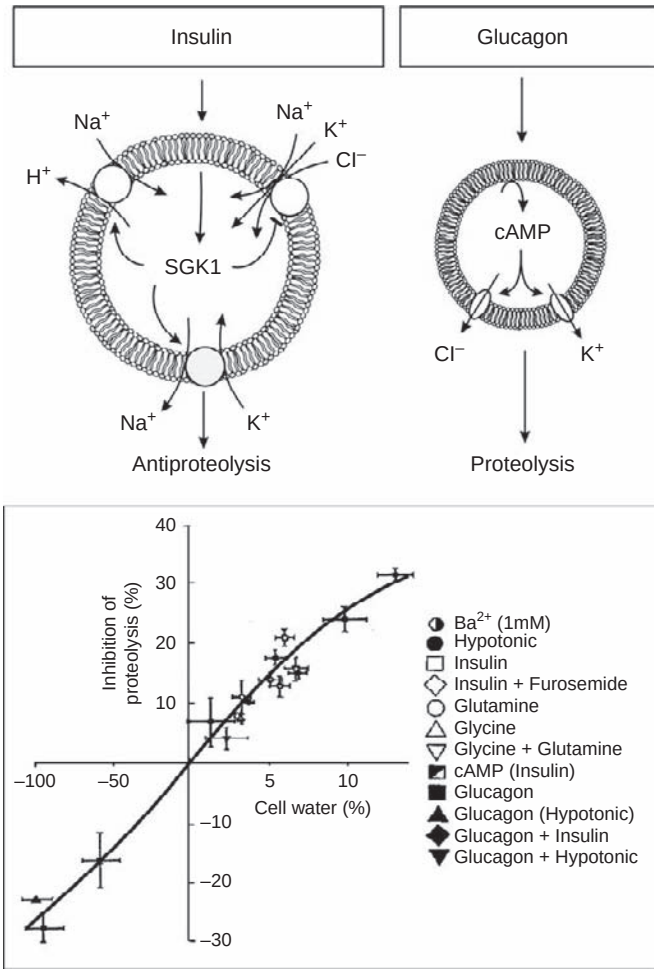

FIGURE 5.4 Cell volume in the regulation of metabolism by hormones. Insulin swells cells by KCl uptake via activation of Na^+/H^+ exchange, $Na^+–K^+–2Cl^-$ co-transport, and Na^+/K^+-ATPase. Glucagon shrinks cells by activation of K^+ and anion channels. The cell volume changes participate in the signaling of hormone action. Cell swelling stimulates protein synthesis, and cell shrinkage stimulates proteolysis. The diagram at the bottom illustrates the correlation between inhibition of proteolysis and hydration of hepatocytes. Cell swelling was induced by inhibition of K^+ channels (Ba^{2+}) decrease of extracellular osmolarity (hypotonic), insulin ± $Na^+–K^+2Cl^-$ co-transport inhibitor furosemide or concentrative uptake of amino acids (glutamine ± glycine). Cell swelling was counteracted or shrinkage accomplished by (additional) application of glucagon or cyclic AMP. The cell volume changes fully account for the effect of both hormones on proteolysis, and contribute to the other effects on macromolecule metabolism such as protein synthesis, as well as glycogen formation and breakdown *(modified from ref. [22]).*

Metabolism

Any reaction resulting in an increase of osmotically active solutes, such as degradation of proteins to amino acids, glycogen to glucose phosphate or triglycerides to glycerol and fatty acids, is expected to create intracellular osmolarity.[31] The degradation of the substrates to CO_2 and H_2O then decreases intracellular osmolarity.

Enhanced glycolysis, as it occurs during forced exercise for instance, leads to cellular accumulation of lactate and H^+, subsequent activation of Na^+/H^+ exchanger, and cell swelling.[290] Metabolic pathways may influence cell volume indirectly through alteration of transport across the cell membrane. A decrease of cellular ATP could activate ATP-sensitive K^+ channels, and thus shrink susceptible cells.[31] Similarly, cellular formation of peroxides may shrink cells through activation of K^+ channels, as shown for hepatocytes, pancreatic β-cells, and vascular smooth muscle cells.[31] In endothelial cells, peroxides inhibit $Na^+–K^+2Cl^-$ co-transport, an effect similarly expected to shrink the cells.[291] On the other hand, oxidation leads to inhibition of n-type K^+ channels in lymphocytes and IsK K^+ channels in a variety of tissues, effects that tend to favor cell swelling.[31]

In several hypercatabolic states, such as burns, acute pancreatitis, severe injury, and liver carcinoma, a decrease of muscle cell volume is observed that correlates with urea excretion, an indicator of protein degradation.[24] Since cell shrinkage is known to stimulate proteolysis, this correlation points to a causal role of altered cell volume in these hypercatabolic states. Conversely, hypercatabolism can be reversed by glutamine, which is known to swell cells by Na^+-coupled cellular accumulation.[24]

Diabetic ketoacidosis may be paralleled by cell swelling due to cellular accumulation of organic acids and enhanced Na^+/H^+ exchange activity in response to cellular acidosis.[221,261,292–294] Furthermore, the excessive glucose concentrations of hyperglycemia stimulate cellular formation and accumulation of sorbitol through aldose reductase.[17] As an attempt to counteract swelling, cells decrease other osmolytes such as myoinositol, an effect that can be reversed by inhibition of aldose reductase with sorbinil.[295–297] On the other hand, hyperglycemia is paralleled by hyperosmolarity, and intriguing evidence has been gathered pointing to cell shrinkage in hyperosmolar diabetes mellitus, which increases cellular Ca^{2+} concentration, and thus induces cell injury.[298,299] Obviously, more experimental information is needed to clarify the role of cell volume changes in the pathophysiology of diabetic complications.

In uremia, extracellular osmolarity is usually enhanced due to accumulation of urea, which interferes with protein stability and thus cell volume regulation (see previous discussion). The high urea concentrations in uremia stimulate the formation of methylamines, which counteract the perturbing effect of urea.[300] Rapid alterations in urea concentration such as during dialysis presumably do not allow full adjustment of osmolyte concentration, and are thus expected to disturb the balance of stabilizing osmolytes and destabilizing urea.[301] Alterations of cell volume may participate in the progression of renal failure: TGF-β1 has been postulated to accelerate renal fibrosis by inhibition of proteolysis and stimulation of protein synthesis, which both lead to enhanced deposition of matrix proteins.[299,302]

Cell Proliferation

Mitogenic factors are known to stimulate Na^+/H^+ exchange and $Na^+-K^+2Cl^-$ co-transport.[35] As shown in ras oncogene-expressing cells, activation of those carriers leads to a shift of the set point for cell volume regulation toward greater volumes (Figure 5.5). In addition, activation of Na^+/H^+ exchange leads to cellular alkalinization. Apparently, the increase of cell volume is one of the prerequisites for cell proliferation, which is impeded by pharmacological inhibition of Na^+/H^+ exchange and $Na^+-K^+2Cl^-$ co-transport, as well as osmotic cell shrinkage.[31,303] Cell volume changes parallel transition through the cell cycle,[304] and cell proliferation requires further timely activation of volume-sensitive Ca^{2+} channels, K^+ channels, and Cl^- channels.[305–307] Moreover, cell proliferation is substantially influenced by the cell volume-sensitive SGK1.[308]

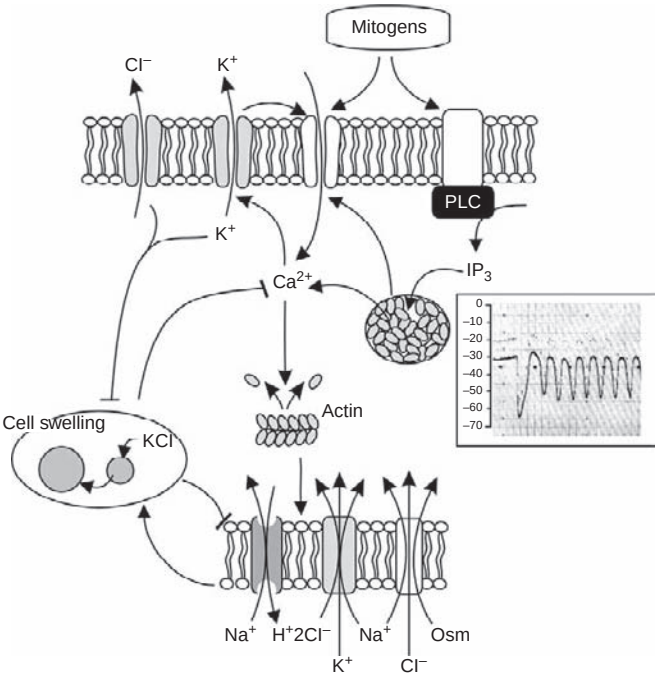

FIGURE 5.5 **Cell volume regulatory transport in regulation of cell proliferation.** The case of Ras oncogene expressing cells. Application of mitogenic factors in cells overexpressing Ras oncogene triggers intracellular Ca^+ release and Ca^+ entry, leading to oscillations of cytosolic Ca^+ activity and cell membrane potential (insert). Increased cytosolic Ca^{2+} activity stimulates Ca^{2+}-sensitive K^+ channels and triggers initial cell shrinkage. Ca^{2+} further leads to depolymerization of the microfilaments, which disinhibits the Na^+/H^+ exchanger and $Na^+-K^+-2Cl^-$ co-transporter. The activation of these carriers eventually leads to cell swelling, a prerequisite for cell proliferation *(from ref. [31])*.

Migration

Locomotion of cells requires alteration of cell shape, and thus of cytoskeletal architecture. At the leading edge actin filaments are polymerized, and at the rear they are depolymerized.[309,310] The movement of cells is paralleled by movement of water that is driven by osmotic gradients. Na^+/H^+ exchange and $Na^+-K^+2Cl^-$ co-transport drive water entry at the leading edge, and the activity of K^+ channels and anion channels drive water extrusion at the rear.[31,311–314] The respective water movement is facilitated by water channels.[315] Activation of cell volume regulatory mechanisms during migration is similar to that of cell proliferation (Figure 5.6). However, the elements are polarized, and cells undergo cell volume regulatory increase at the leading edge, and cell volume regulatory decrease at the rear.[31]

Apoptotic Cell Death

Cell shrinkage is one of the hallmarks of apoptotic cell death, and marked osmotic cell shrinkage ($>30\%$) has been shown to trigger this type of cell death.[193] Apoptotic cell shrinkage requires the participation of cell volume regulatory mechanisms (Figure 5.6). Apoptotic death of Jurkat T-lymphocytes following CD95 triggering is indeed paralleled by inhibition of the Na^+/H^+ exchanger, as well as activation of the anion channel ORCC and osmolyte release.[316] The release of ions, and subsequent cell shrinkage, are apparently a prerequisite for induction of apoptosis.[317–319] On the other hand, at an early stage of CD95 triggering, the cell volume-regulatory K^+ channel Kv1.3 is inhibited, and a moderate decrease of cell volume ($<30\%$) has been shown to blunt receptor (CD95)-triggered apoptotic cell death.[320] The cellular mechanisms triggered by moderate osmotic cell shrinkage apparently interfere with the signaling of the CD95 receptor, such as cellular O_2^--formation.

The triggering of cell death by hyperosmotic shock has been attributed to upregulation or clustering and subsequent activation of apoptosis-inducing receptors,

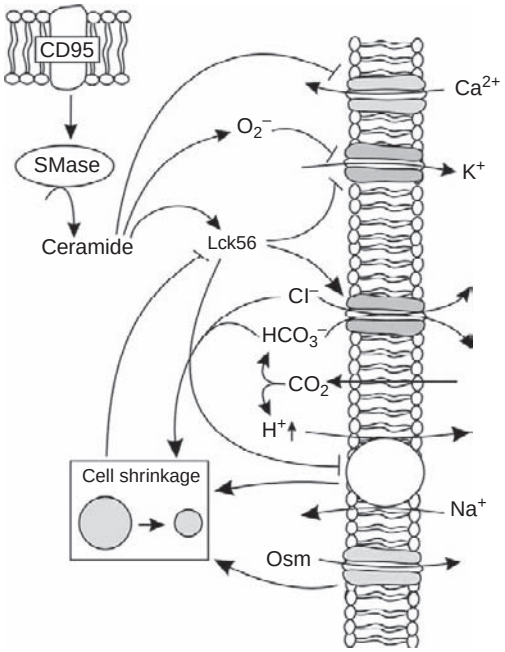

FIGURE 5.6 **Cell volume regulatory ion transport during CD95-induced apoptosis of lymphocytes.** CD95-induced apoptosis of Jurkat T-lymphocytes is paralleled by inhibition of the Na^+/H^+ exchanger, as well as activation of the anion channel ORCC and osmolyte release. The altered transport leads eventually to cytosolic acidification and cell shrinkage. Initially, CD95 stimulation leads to inhibition of the cell volume regulatory K^+ channel Kv1.3, thus preventing early cell shrinkage. At a later stage (not shown), additional activation of K^+ channels leads to apoptotic cell shrinkage. *(From Lang, F., Lepple-Wienhues, A., Paulmichi, M., Szabo, I., Siemen, D. and Gulbins, E. (1998). Ion channels, cell volume, and apoptotic cell death. Cell Physiol. Biochem. 8(6), 285–292.)*

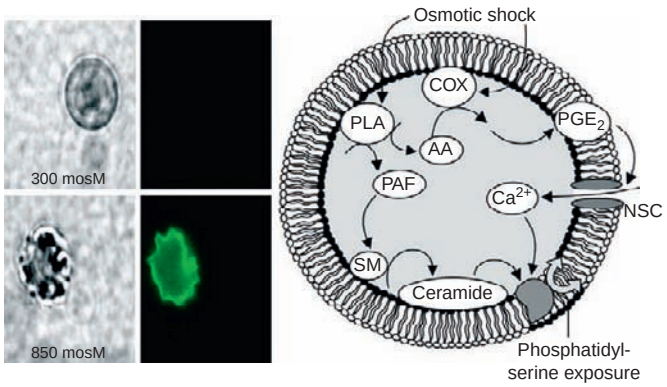

FIGURE 5.7 **Stimulation of erythrocyte death by osmotic cell shrinkage.** Osmotic shock activates a phospholipase A_2 leading to formation of platelet activating factor (PAF) on the one hand, and of arachidonic acid on the other. PAF stimulates a sphingomyelinase leading to formation of ceramide; arachidonic acid is converted by cyclooxygenase (COX) to PGE2 which activates a Ca and Na permeable cation channel. Ca entering through the cation channels activates a scramblase, leading to phosphatidylserine exposure at the cell surface (left), a typical feature of apoptotic cells. Ceramide sensitizes the scramblase for Ca, and thus contributes to the activation of this enzyme *(from ref. [273])*.

such as CD95 or TNFα-receptor[193,321–323] or to formation of their ligands, such as TNFα.[324] Beyond that, cell shrinkage could trigger cell death more directly, by activating a signaling cascade of rac, p38 kinase, p53, and subsequent upregulation of pro-apoptotic proteins Bax/Bid.[325] Conversely, osmotic shrinkage may downregulate signaling supporting cell survival, such as the PI3 kinase pathway leading to protein kinase B-dependent phosphorylation, and thus inactivation of Bad.[236] In erythrocytes, hyperosmotic shock stimulates a phospholipase A_2 with subsequent formation of PGE_2[251] and PAF.[253] PGE_2 stimulates a cation channel, allowing the entry of Ca^{2+} and subsequent triggering of Ca^{2+}-sensitive cell membrane scrambling.[251] PAF stimulates a sphingomyelinase that leads to formation of ceramide, which sensitizes the erythrocyte for the scrambling effect of Ca^{2+}.[253] Cell membrane scrambling leads to breakdown of phosphatidylserine asymmetry and exposure of phosphatidylserine at the outer surface of the cell membrane, a typical feature of apoptotic cells (Figure 5.7).

Necrotic Cell Death

As pointed out above, energy depletion impairs the function of the Na^+/K^+-ATPase, dissipates the Na^+ and K^+ gradients, depolarizes the cell membrane, and leads to cellular accumulation of Cl^-.[31] During ischemia, the cell membrane is further depolarized by increasing extracellular K^+ concentrations. Cellular Na^+ and Cl^- accumulation eventually lead to cell swelling. Moreover, the excessive formation and reduced clearance of lactate during ischemia induces cellular acidosis and enhanced Na^+/H^+ exchange activity, compounding cell swelling. In the brain, the depolarization triggers the release of glutamate, which activates unspecific cation channels and thus induces further cell swelling.[31]

INTRODUCTION

The kidney must reabsorb more than 99% of approximately 180 liters of water and 25,000 mmoles of Na^+ daily. To do this, the kidney consumes a large amount of energy. Although the kidney is only 0.5% of the total body weight, it utilizes approximately 7% of the oxygen consumed by the body.[1] In fact, the kidney is the second only to the heart in terms of the rate of energy consumption.[1] In this chapter, first we describe the energy consuming and production processes in the kidney. Second, the mechanisms of mutual relationships between energy consumption and production will be described. Significant advances have been made with regard to this issue, and AMPK (AMP-activated kinase) is considered to be the central for the regulation of energy consuming processes. Finally, we also refer to the pathophysiological states in which renal energy production is inhibited.

ENERGY CONSUMPTION

Na Transport and Energy Consumption in the Kidney

Na^+ Transport and O_2 Consumption

The energy utilized in the kidney is primarily required for the active reabsorption of Na^+ from the glomerular filtrate. This seems rational considering that the amount of Na^+ reabsorbed by the kidney is much higher than that of HCO_3^- (4,000 mmole/day), Ca^{2+} (210 mmole/day), other electrolytes, and organic substances. The active Na^+ transport also energizes the reabsorption of water and other solutes by the osmotic gradient generated by Na^+ transport, and by the electrochemical gradient of Na^+ across the plasma membrane.

The data shown in Figures 6.1 and 6.2 indicate another important point. Extrapolation of the regression line to the Y ordinate indicates the basal oxygen consumption (Figure 6.1). This value is identical to the energy used for cellular functions other than Na^+ transport, and was estimated to be between 3 to 18%,[2] while other studies indicated a higher value for this basal O_2 consumption in the kidney.

With regard to energy production, the kidney generates approximately 95% of the ATP produced via aerobic mechanism,[3] while in some nephron segments anaerobic metabolism also occurs efficiently. This is reasonable because of the highly efficient ATP production by mitochondrial oxidative phosphorylation compared to anaerobic glycolysis. Thirty-six moles of ATP are generated by the mitochondrial oxidative phosphorylation of one mole of glucose, whereas only two moles of ATP are produced via glycolysis in the absence of O_2. Thus, historically, the relationship between Na transport and O_2 consumption (QO_2) in renal tissues has been extensively investigated.

Several investigators have examined Na^+/O_2 stoichiometry in the kidney.[4–6] Thurau demonstrated a linear relationship between Na^+ transport and QO_2 with a ratio of 28 Na^+/O_2 in the whole dog kidney[6] (Figure 6.1). This stoichiometry is equal to a ratio of 4.6 for Na^+/ATP, which indicates more efficient transport in the kidney compared to that in the frog skin and toad bladder. The discrepancy has been studied by many investigators and is attributed to the following.[7]

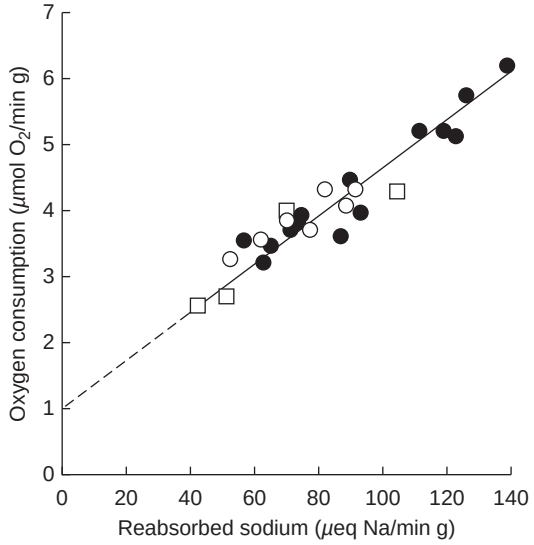

FIGURE 6.1 Oxygen consumption as a function of net sodium reabsorption in whole dog kidneys. *(Adapted from [6] with permission.)*

First, there are alternative pathways for Na^+ transport in the nephron. In the leaky epithelia, such as proximal tubule (PT), paracellular Na^+ transport occurs, while only transepithelial transport is possible in the tight epithelia in cortical collecting duct (CCD) cells. Second, coupling of Na^+ transport to that of other solutes occurs, such as bicarbonate transport in PT, and Na^+-K^+-$2Cl^-$ transport via NKCC2 in the thick ascending limb of Henle (TAL). These two mechanisms produce more efficient Na^+ transport in certain nephron segments compared to that observed in frog skin and toad bladder, where only cellular transport of Na^+ driven by Na^+,K^+-ATPase occurs. The different Na^+/O_2/ATP stoichiometry among individual nephron segments will be described below.

Heterogeneity in Na^+ Transport Efficiency among Nephron Segments

Proximal Tubule

In the PT, the Na^+/QO_2 was reported to be 24 to 30, corresponding to a Na^+/ATP ratio of 4 to 5. In the early portion of the PT (S1), preferential absorption of bicarbonate occurs,[8] resulting in a rise in the luminal Cl^- concentration, defined as axial anionic asymmetry.[9,10] In the basolateral membrane of proximal tubular cells, a Na^+-bicarbonate co-transporter (NBC) extrudes Na^+ with HCO_3^-[11] with a stoichiometry of 1: 2∼3.[12] The electrochemical gradient of HCO_3^- across the plasma membrane in the PT cells, which is generated by the coordinated function of carbonic anhydrase and H^+-ATPase or Na^+-H^+ exchanger, drives Na^+ efflux via NBC. Because PT is more permeable to Cl^- than to HCO_3^-, a driving force develops for isotonic fluid transport. It was suggested that 30%[13] to 50%[14] of Na^+ transport in the PT is passive, and not directly related to ATP consumption. In addition, in the early part of the PT, glucose, amino acids, and phosphate are actively reabsorbed by the Na^+-co-transport mechanism, thereby rapidly reducing their concentration in the lumen. This luminal hypotonicity also contributes to the solvent drag which involves Na^+. Thus, in the PT, more than 3 Na^+ could be transported via the hydrolysis of one mole of ATP.

Thick Ascending Limb of Henle

In the TAL, the most efficient sodium transport occurs, with the Na^+-K^+-$2Cl^-$ co-transporter (NKCC2) playing an important role. The transport by NKCC2 is electrically neutral, and the K^+ reabsorbed by NKCC2 in the TAL is leaked back into the tubular lumen via the ROMK channel in the apical membrane. This K^+ leakage results in a positive electrical potential difference in the lumen, which drives paracellular transport of Na^+ from the lumen to the plasma (Figure 6.3). Although no direct measurement has been made of the Na^+/O_2/ATP stoichiometry in the TAL, the results obtained in the rectal gland[15] and tracheal epithelium[16] indicated that the Na^+/ATP ratio could theoretically be up to 6 in the TAL.

CCD

In the CCD, the efficiency of Na^+ transport is the lowest among the nephron segments. In this segment, the junction between the epithelia is very tight, and paracellular transport is minimal. In addition, Na^+ entry from the luminal side into CCD cells is mediated only by ENaC, which is not associated with any coupled transport other than that of Na^+. Thus, the Na^+: ATP ratio in the CCD is estimated to be 3.

Energy Cost of Primary Active Transport

The cellular transport of electrolytes and organic substances is classified into three types, namely, primary active, secondary active, and tertiary active transport. Primary active transport refers to that which directly utilizes ATP hydrolysis energy to accomplish transepithelial transport. The primary active transporter in the plasma membrane of mammalian cells is further subdivided into three subtypes, i.e., P-type-ATPase, V-type-ATPase, and ABC transporter. The secondary active transporters utilize the Na^+ gradient across the plasma membrane generated by the Na^+,K^+-ATPase. Na^+-coupled co-transporters (e.g., Na^+-glucose co-transporter, Na^+-amino acid co-transporter) transport substrates with Na^+ in the same direction, while Na^+-exchangers (e.g., NHE: the Na^+-H^+ exchanger) transport substrate

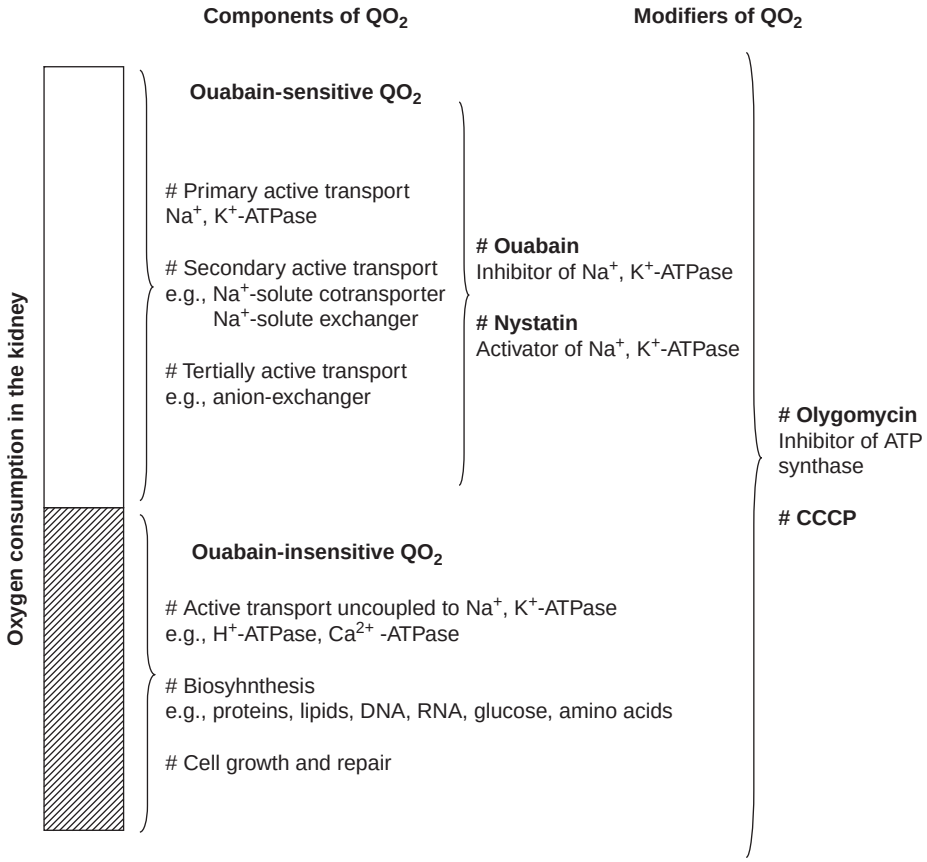

FIGURE 6.2 **Cellular components of oxygen consumption (QO_2).** Cellular QO_2 is divided primarily into two components. The first is ouabain-sensitive QO_2, which is identical to the sum of Na^+,K^+-ATPase, secondary active and tertiary active transport coupled to the Na^+ gradient. The other is an ouabain-insensitive portion, which is related to transport processes uncoupled to Na^+,K^+-ATPase (e.g., H^+-ATPase and Ca^{2+}-ATPase) and catabolic processes (e.g., biosynthesis and cell growth and repair). Ouabain-sensitive QO_2 is markedly different among nephron segments. In the PCT, 60% of QO_2 is ouabain-sensitive, whereas in OMCD, only 8% of QO_2 is ouabain-sensitive. These differences reflect the activities of Na^+,K^+-ATPase among nephron segments.

and Na^+ in opposite directions. In addition, there exist the tertiary active transporters. One example of this is the anion exchangers (AE: Cl^-/HCO_3^- exchanger). The proton gradient generated by the coordinated function of Na^+,K^+-ATPase (primary active transporter) and NHE (secondary active transporter) is used as the driving force for the exchange of Cl^- and HCO_3^- by AE (tertiary active transporter).

The energy cost for secondary and tertiary active transport processes is attributed to the active transport via Na^+,K^+-ATPase, which alone is accompanied by hydrolysis of ATP. Primary active transporters other than Na^+,K^+-ATPase are also related to the energy consumption processes in the kidney. In general, the expression level of ATPases along the nephron segments correlates well with the transport activity of each solute.

P-type-ATPases

P-type-ATPases (Figure 6.4), including Na^+,K^+-ATPase, H^+,K^+-ATPase, and Ca^{2+}-ATPase, share several common features: (1) they possess a seven amino acid motif with aspartate to which ATP binds; (2) they are transiently phosphorylated during the cation transport cycle (the term P-type derives from this transient phosphorylation); and (3) they catalyze cation transport between E_1 and E_2 conformations (P-type-ATPase was previously called E_1-E_2-ATPase). The transport activity of P-type-ATPases is commonly inhibited by vanadate.

Na^+,K^+-ATPase

Na^+,K^+-ATPase extrudes 3 Na^+ and takes up 2 K^+ across the plasma membranes through the hydrolysis of one ATP molecule in the presence of Mg^{2+}. Na^+,K^+-ATPase generates an inwardly-directed Na^+ gradient and inside a negative electrical gradient. Na^+,K^+-ATPase accounts for approximately half of the total Na^+ reabsorption in the kidney.[17]

Na^+,K^+-ATPase is a heterodimeric integral membrane protein, with a minimal composition of α- and

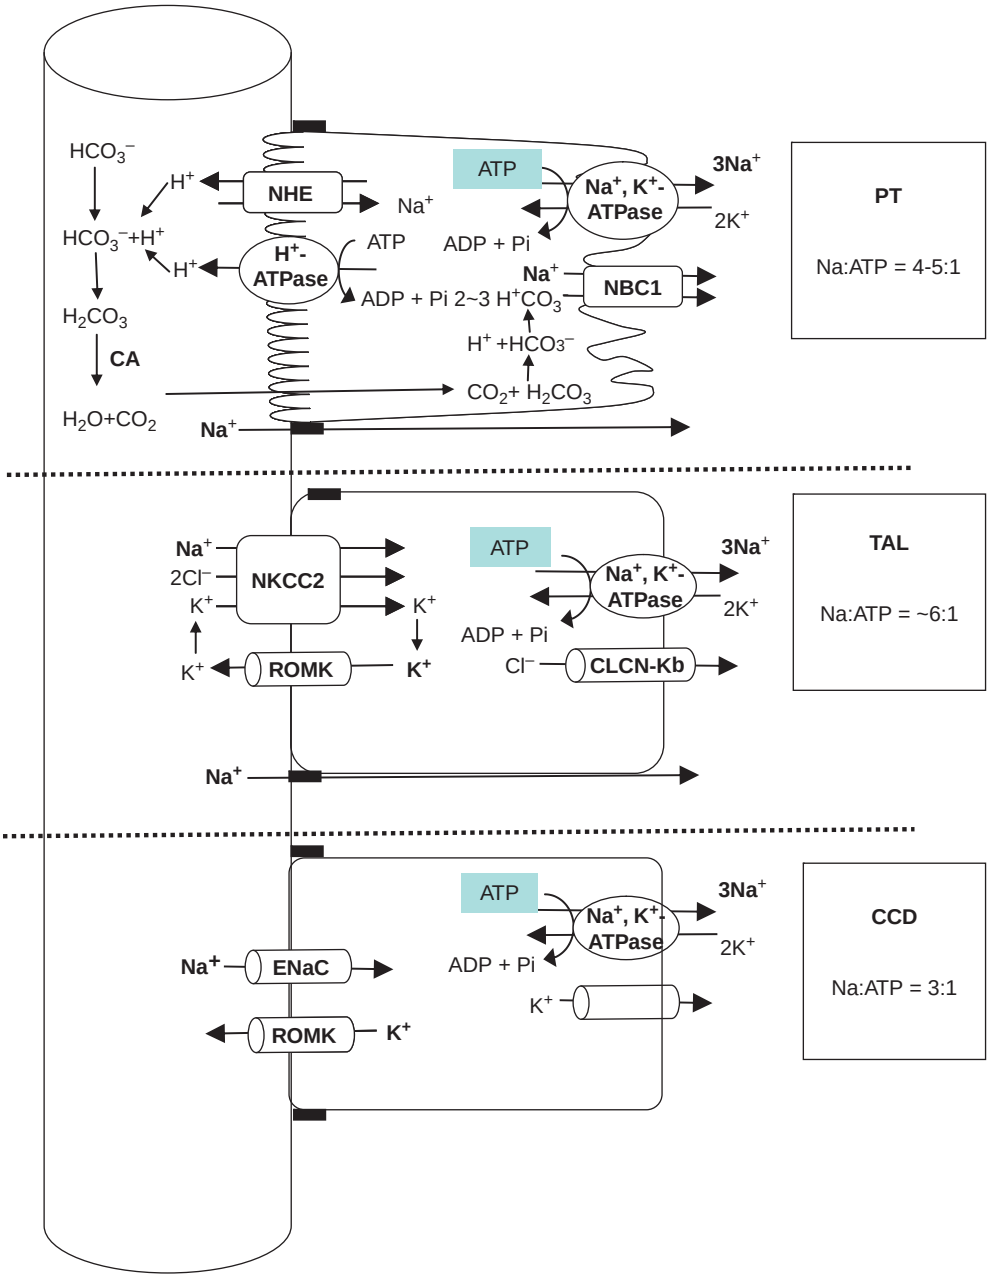

FIGURE 6.3 Heterogeneity of Na^+ transport/O_2/ATP along nephron segments.

β-subunits. The α-subunit possesses ten membrane-spanning domains with a molecular mass of approximately 100 kDa. The β-subunit is a glycosylated type II membrane protein with a molecular weight of approximately 55 kDa.[18] In mammalian genomes, four α-subunits and at least three β-subunits of Na^+,K^+-ATPase have been identified.[19,20] In addition, a γ-subunit, a member of the FXYD family of type II transmembrane proteins, constitutes an Na^+,K^+-ATPase.[21] In the kidney, two γ-subunit isoforms are expressed.[19,20] The combination of each isoform comprises a number of Na^+,K^+-ATPase isozymes that are expressed in a tissue- and cell-specific manner to evolve distinct properties to respond to cellular requirements.[19] In the kidney, α1β1 is predominantly expressed.[20,22,23]

The α-subunit is the catalytic subunit of the Na^+, K^+-ATPase, and α1, α2, and α3 isoforms differ in their affinities for ATP, Na^+ and K^+.[24] β-subunits are suggested to facilitate the correct membrane integration and packing of the α-subunit, and β-subunits also participate in the determination of the intrinsic transport properties of Na^+,K^+-ATPase.[25] The γ-subunit was

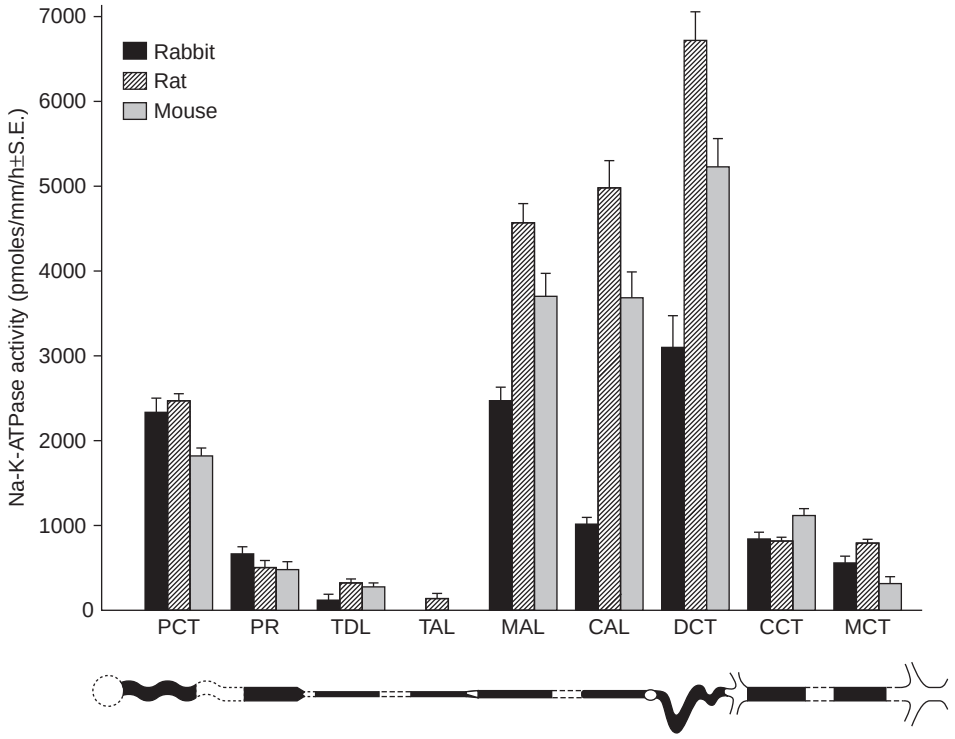

FIGURE 6.4 Na^+,K^+-ATPase activity in individual nephron segments measured using hydrolysis activity. *(Adapted from [34] with permission.)*

shown to be a specific regulator of renal $\alpha1\beta1$ isozymes.[26] A putative dominant-negative mutation in the gene encoding the γ-subunit (FXYD2) which leads to defective routing of the protein in a family with dominant renal hypomagnesaemia indicates the physiological importance of the γ-subunit.[27] The overall structure of the α-subunit of Na^+,K^+-ATPase determined by electron crystallography using two-dimensional crystals is similar to the X-ray structure of Ca^{2+}-ATPase.[28,29]

The pump activity of Na^+,K^+-ATPase has been investigated using direct measurement of hydrolysis activity, and axial heterogeneity in the nephron segments was demonstrated[30–34] (Figure 6.4). Na^+,K^+-ATPase hydrolysis activity was high in the TAL, distal convoluted tubule (DCT), and proximal convoluted tubule (PCT), and low in the pars recta (PST) and collecting tubule (CT).[30–34] Ouabain binding studies show the highest density of Na^+,K^+-ATPase (20–30 fmol/mm length of tubule) in the DCT and the MTAL, intermediate density (10 fmol/ mm) in the PCT and connecting tubule (CNT), and lowest density (2–7 fmol/mm) in the PST, CTAL, and CT.[35] The pump activity was proportional to the number of catalytic units. $\alpha1\beta1$ has a maximum turnover rate of 7,700/min.[36] The measurement of Na^+,K^+-ATPase hydrolytic activity at V_{max}, and initial rates of ouabain-sensitive Rb uptake indicated that in intact cells the pump works at approximately 20–30% of its V_{max}.[37] Western blotting analysis,[38,39] RT-PCR using microdissected nephron segments,[39] *in situ* hybridization,[23,40] and immunohistochemical analysis[41–43] demonstrated similar intranephron heterogenetic localization of Na^+,K^+-ATPase consistent with those observed in the studies on pump activity.

Regulation of Na^+,K^+-ATPase by dexamethasone,[44] deoxycorticosterone,[45] intracellular Na concentration,[46] cAMP,[47] potassium depletion,[48] aldosterone and vasopressin[49,50] was demonstrated. Many of these modulations influence the cell surface expression of Na^+,K^+-ATPase,[49,50] while MEK1/2 inhibitors changed the intrinsic activity rather than cell surface expression.[51]

Ca^{2+}-ATPase

Renal calcium transport is comprised of two processes: a paracellular, passive process that predominates in most nephron segments; and a transcellular, energy-dependent step in the DCT. Transcellular calcium transport involves: (1) entry into the DCT cell via a Ca^{2+} channel (ECaC) across the luminal membrane; (2) intracellular Ca movement facilitated by the presence of the vitamin D-dependent calcium-binding protein (calbindin D); and (3) extrusion by the Ca^{2+}-ATPase located at the basolateral membrane.[52]

The extrusion of Ca^{2+}, the final step in the transcellular transport of Ca^{2+}, is mediated by the plasma membrane Ca^{2+}-ATPase (PMCA), which is a P-type-ATPase.

PMCA is a monomeric protein consisting of approximately 1,220 amino acids with a molecular mass of 140 kDa.[53,54] The sequence contains the calmodulin-binding domain, and two domains resembling calmodulin, one of which may play a role in the binding of Ca^{2+}.[54] There are at least four isoforms of PMCA, and isoforms 1 and 4 are more widely distributed than 2 and 3.[55–57] The activity of renal PMCA showed two saturable components: a high-affinity component with a Km of 33 μM ATP, and a low-affinity component with a Km of 0.63 mM ATP.[58] PMCA is regulated by calmodulin,[55] estrogen and dihydrotestosterone,[59] protein kinase C or A,[55] extracellular ATP,[60] and pathophysiologic states such as hypercalciuria.[61] RT-PCR,[62,63] immunohistochemical analysis,[64] and Western blot analysis[53] demonstrated high expression of PMCA in the DCT. PMCA was also detected in Madin–Darby canine kidney (MDCK) cells.[65] Doucet and co-workers examined sodium azide-insensitive plasma membrane Ca^{2+}-ATPase activity. The Ca^{2+}-ATPase was maximally activated by Ca^{2+} concentrations with an apparent Km of 0.3–0.4 μM. Ca^{2+}-ATPase activity was found in all segments of the nephron: activity was highest in the DCT and CCT, intermediate in the PCT and MTAL, and lowest in the PST, CTAL and MCT.[66]

In addition to PMCA, there exists another distinct Ca^{2+}-ATPase, the sarco/endoplasmic reticulum Ca^{2+}-ATPase (SERCA), which also belongs to the P-type-ATPase. The SERCA family includes three gene products, SERCA1 (ATP2A1), SERCA2 (ATP2A2), and SERCA 3 (ATP2A3),[67] which function in the removal of free cytosolic Ca^{2+} into the sarco/endoplasmic reticulum. Although thapsigarigin is known to be a specific inhibitor of the endoplasmic reticulum Ca^{2+}-pump,[68] no study has been reported on the relative energy consumption rate of SERCA in the kidney.

H^+,K^+-ATPase

H^+,K^+-ATPase was originally characterized in a study of gastric mucosa. The gastric H^+,K^+-ATPase is located in the apical membrane of stomach parietal cells, and mediates electroneutral exchange of K^+ and H^+. Gastric H^+,K^+-ATPase activity is independent of extracellular sodium, and is inhibited by vanadate.[69]

Molecular cloning identified two types of H^+,K^+-ATPase: gastric and colonic type H^+,K^+-ATPase. H^+,K^+-ATPase is comprised of α- and β-subunits. The catalytic α-subunit of gastric H^+,K^+-ATPase shows structural similarity to that of Na^+,K^+-ATPase, and the greatest homology occurs in the phosphorylation site region, and domains presumably involved in nucleotide binding and energy transduction.[70] The α-subunit of colonic H^+,K^+-ATPase exhibits 63% amino acid identity to that of the gastric H^+,K^+-ATPase.[71] The β-subunit of H^+,K^+-ATPase shows 41% amino acid sequence identity to the β2-subunit of Na^+,K^+-ATPase in the rat.[72]

In the kidney, the existence of both gastric H^+,K^+-ATPase[70] and colonic H^+,K^+-ATPase[71] was demonstrated. Gastric H^+,K^+-ATPase is expressed constitutively along the length of the collecting duct, is responsible for H^+ secretion and K^+ reabsorption under normal conditions, and may be stimulated with acid–base perturbations and/or K^+ depletion.[73] The level of expression of colonic H^+,K^+-ATPase is much lower in the kidney than in the distal colon.[71]

Using *in vitro* microperfusion, Wingo and colleagues provided evidence of the existence of omeprazole-sensitive acidification and a K^+-absorptive mechanism in OMCD in rabbits.[74] By enzymatic analysis, Doucet[75] and Garg[76] quantified the K^+-stimulated, Na-insensitive ATPase activity in the nephron segments. K^+-stimulated ATPase activity was identified in the CNT, CCT, and MCT, although the activities were very low compared to those of other P-type-ATPases in the kidney.[76] The renal K^+-ATPase had a high affinity for K^+ (Km of approximately 0.2 ~ 0.4 mM) and was inhibited by vanadate, omeprazole, and SCH 28080, specific inhibitors of gastric H^+,K^+-ATPase, but was insensitive to ouabain.[75,76] A correlation between the magnitude of enzymatic activity and the percentage of intercalated cells in a given segment suggested that K^+-ATPase activity originates in intercalated cells.[75]

Immunohistochemical analysis revealed H^+,K^+-ATPase in intercalated cells in the CCD and OMCD. In all segments studied, except for the CCD, the percentage of H^+,K^+-ATPase-immunoreactive cells corresponded to the percentage of intercalated cells.[77] The RT-PCR technique demonstrated the gastric H^+,K^+-ATPase α-subunit in the CCD and IMCD, and a specific hybridization signal for the gastric H^+,K^+-ATPase α-subunit cDNA was demonstrated.[78] The colonic H^+,K^+-ATPase α-subunit is specifically expressed in the CCD and OMCD in K^+-depleted rats.[79] An increase in the H^+,K^+-ATPase activity,[75] and enhanced expression of gastric H^+,K^+-ATPase α-subunit[80] and colonic H^+,K^+-ATPase[73] in K^+ depletion, suggests the physiological adaptation of renal H^+,K^+-ATPase.

V-type ATPases

V-type (vacuolar) ATPases represent the second family of ATP-dependent ion pumps. Vacuolar H^+-ATPase is primarily responsible for the acidification of intracellular compartments such as endosomes, lysosomes, Golgi apparatus, and clathrin-coated vesicles.

H^+-ATPase is also expressed in the plasma membrane, and functions in acid–base transport in epithelia. In the kidney, vacuolar H^+-ATPase mediates H^+ secretion, mainly in the PT and CCD.[81,82]

H^+-ATPase is a multi-subunit complex composed of two functional domains.[83,84] The V(1) domain is a 570 kDa peripheral complex composed of eight subunits of molecular mass 73–14 kDa (subunits A–H) that is responsible for ATP hydrolysis. The V(o) domain is a 260 kDa integral complex composed of five subunits of molecular mass 100–17 kDa (subunits a, d, c, c′, and c″) that is responsible for proton translocation.

H^+-ATPase is insensitive to vanadate or ouabain, but inhibited by bafilomycin A, N,N′-dicyclohexylcarbodiimide (DCCD: Ki = 50 μM) and N-ethylmaleimide (NEM: Ki = 20 μM). Physiological experiments indicated the existence of H^+-ATPase in the PT. DCCD caused a fall in CO_2 absorption by 15% under eucapnia, and by 30% during acute hypercapnia in the PT.[85] In other experiments, the S_3 segment was shown to possess plasma membrane H^+-ATPase activity.[86]

The relative contribution of H^+-ATPase to ATP consumption by the kidney was examined by Noel et al. In dog proximal tubules incubated under control conditions, 81% of the respiration was directly related to oligomycin-sensitive ATP synthesis, and 29% of this amount was inhibited by bafilomycin A. In rabbit and hamster PT, the bafilomycin-sensitive ATP requirement involves only 5 and 10%, respectively, of the total ATP turnover. Thus, the metabolic cost of H^+-ATPase in PT varies significantly among species.[87]

Ait-Mohamed et al. examined the localization of NEM-sensitive ATPase in all the segments of the rat nephron; its activity was highest in the PCT; intermediate in the PST, TAL and CCT; and lowest in the OMCD.[88] Immunocytochemical analysis demonstrated localization of rat H^+-ATPase in the PCT, the initial part of the thin descending limb, TAL, DCT, and CT[89] consistent with the aforementioned H^+-ATPase activity.

Garg and co-workers examined the effect of acid-base balance[90–92] and aldosterone[93] on NEM-sensitive ATPase activity, and demonstrated the modulation of NEM-sensitive ATPase activity by metabolic acidosis and administration of aldosterone, and these effects were observed mainly in the CT.

The significance of H^+-ATPase in final urinary acidification along the collecting system has been confirmed by hereditary defects in H^+-ATPase. Mutations in the gene encoding the B1-subunit of H^+-ATPase cause distal renal tubular acidosis with sensorineural deafness, and defects in the 116 kDa subunit ATP6N1B cause recessive distal renal tubular acidosis with preserved hearing.[94–96]

ABC Superfamily

The third subgroup of primary active transporters is the ABC (ATP-binding cassette) transporter family. The prototype ABC transporter is the P-glycoprotein (P-gp) encoded by the MDR gene. P-gp was originally isolated as a drug extrusion pump in cancer cells which confers multiresistance to antineoplastic drugs.[97,98] Later, P-gp was also shown to be expressed in normal tissues such as the kidney, intestine, and brain capillary cells, where it acts as a functional barrier to xenobiotics by extruding them from the tissues. Then, a subfamily of ABC transporters, the MRP (multidrug-resistance-associated protein) family, was identified, and the number of its isoforms is expanding rapidly.[99]

The common molecular structure of ABC transporters is as follows; they possess two transmembrane (TM) domains, each with six TM segments and two nucleotide-binding domains, both of which can hydrolyze ATP.[100] The stoichiometry of two ATPs hydrolyzed per molecule of drug transported was proposed.[97]

Although the molecular properties of the members of ABC transporters, such as tissue distribution and substrate selectivity, have been extensively characterized, their significance in energy consumption in the kidney remains to be investigated, and to date no information is available.

Comparison of Ion Transporting ATPase Activities and QO_2 along the Nephron

In the upper panel of Figure 6.5 a comparison of the ion transporting ATPase activities is shown. In the lower part, relative distribution of QO_2 along the nephron segments is depicted.

METABOLIC BASIS IN THE KIDNEY

Energy Production Pathway in the Kidney

ATP synthesis in the kidney is mainly performed by mitochondrial oxidative phosphorylation, and a variety of energy fuels, such as glucose, fatty acids, and ketone bodies, are metabolized. Anaerobic glycolysis also occurs in certain nephron segments. Because of its heterogeneity in structural and functional properties, metabolic pathways and preferred substrates are distinct among the nephron. In this section, metabolic basis in the kidney and individual nephron segments are described.

Mitochondrial Oxidative Phosphorylation

Mitochondrial oxidative phosphorylation (Figures 6.6, 6.7) is comprised of the following three steps: (1)

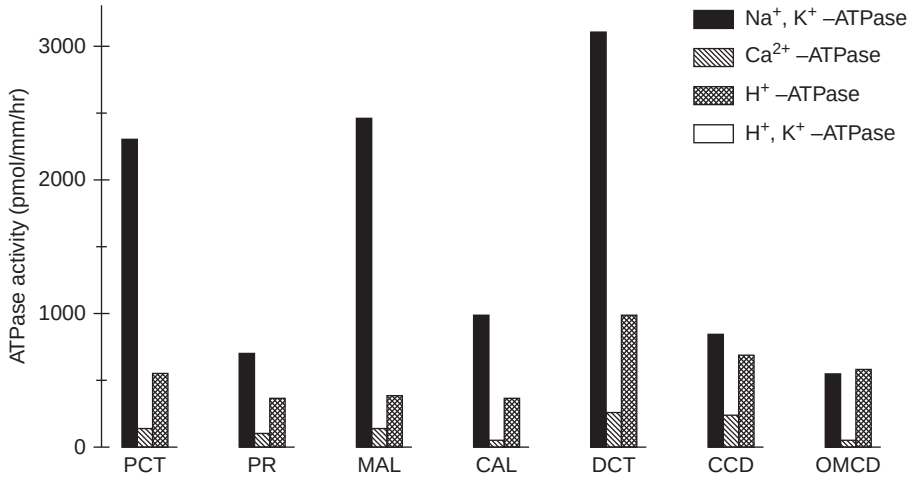

FIGURE 6.5 Comparison of ATPase activities employed from representative studies. *(Upper part adapted from [101] with permission; lower part from [102] with permission.)*

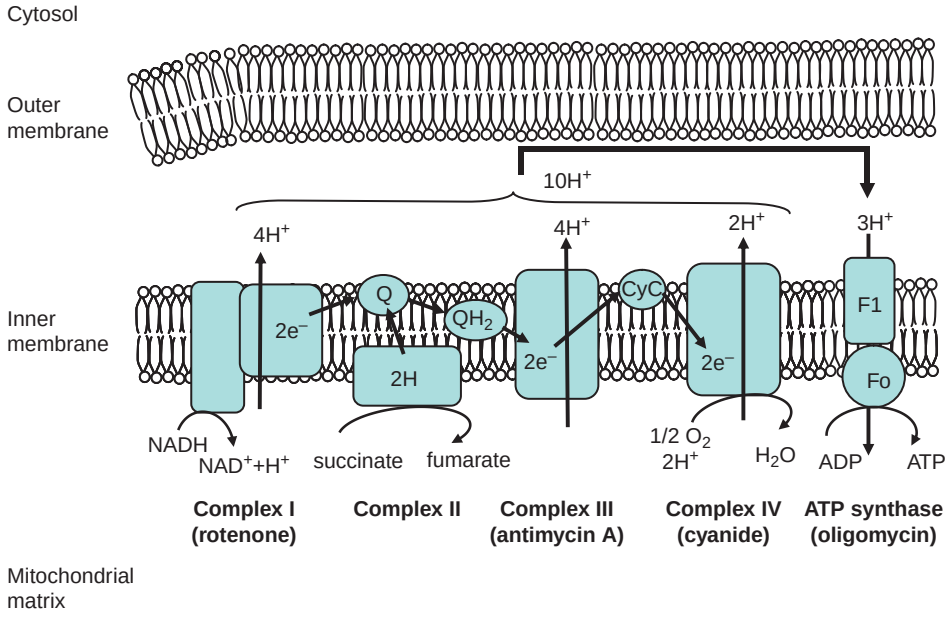

FIGURE 6.6 **Schematic representation of mitochondrial oxidative phosphorylation.** In the inner membrane of the mitochondria, four large multimeric membrane proteins complexes (complex I, II, III, and IV) catalyze electron transfer and proton extrusion. Two relatively small mobile proteins (Q and CytC) also mediate electron transport. Finally, ATP synthase produces ATP using the electrochemical gradient generated across the inner membrane of the mitochondria. Rotenone, antimycin A, cyanide, and oligomycin are representative inhibitors for the complexes I, III and IV, and ATP synthase, respectively.

production of reduced equivalents, i.e., NADH and $FADH_2$, mostly by the TCA cycle in the matrix of mitochondria; (2) electron transfer via the mitochondrial respiratory chain in the inner membrane of mitochondria, associated with proton extrusion across the inner membrane of mitochondria; and (3) ATP production by F_0F_1-ATPase using the proton gradient generated[103] (Figures 6.6 and 6.7). The mitochondrial respiratory chain catalyzes electron transfer via four large multimeric integral membrane protein complexes (complex I to IV), ATP synthase (alternatively called complex V), and two relatively small hydrophobic proteins, i.e., ubiquinone (Q: Coenzyme Q) and cytochrome c.

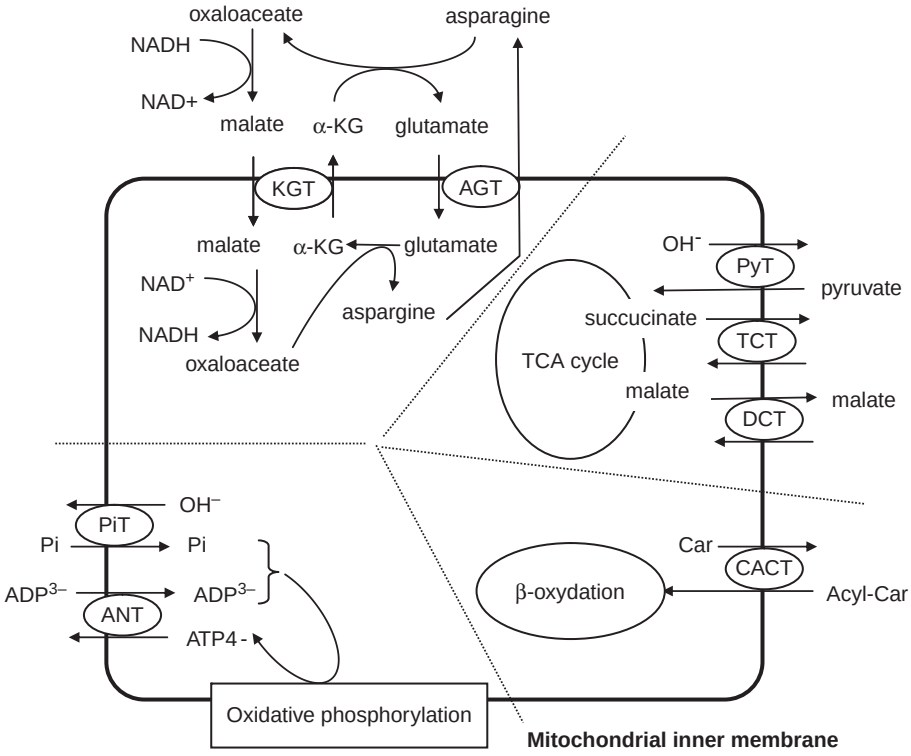

FIGURE 6.7 **Mitochondrial solute transporters located in mitochondrial inner membrane.** These transporters are divided into four groups from the functional viewpoints. The lower left part indicates the interchange of ADP, Pi, and ATP between the inner membrane by ANT and PiT. The left upper part indicates the malate-asparagine shuttle transporting the reducing potential from the cytosol to the matrix. The right upper part indicates the transport of substrates of the TCA cycle. The right lower part indicates the acyl-CoA transport to the mitochondrial matrix. Acyl-CoA is used for β-oxidation. In this figure, the ornithine transport system is not depicted.

Tricarboxylic Acid Cycle

The tricarboxylic acid (TCA) (Figure 6.8) cycle is present in all mammalian cells, except those lacking mitochondria such as mature red blood cells. The TCA cycle oxidizes acetyl CoA derived from carbohydrates, fatty acids, amino acids, and ketone bodies, and produces NADH and $FADH_2$. In addition, the TCA cycle provides intermediates that are utilized for the formation of glucose, lipids, and amino acids. Thus, the TCA cycle is central for metabolism, and is regulated to meet a variety of cellular metabolic demands.

Le Hir et al. assayed three TCA cycle enzymes, i.e., oxoglutarate dehydrogenase, citrate synthase and isocitrate dehydrogenase, in dissected rat nephron segments. The activities of the enzymes were higher in distal segments (TAL and DCT) than in the PT. The distal versus proximal ratios of activities were about 1.5, 2.5, and 2 for oxoglutarate dehydrogenase, citrate synthase, and isocitrate dehydrogenase, respectively. Oxoglutarate dehydrogenase showed the lowest activity along the entire nephron segments, and appeared to catalyze the rate-limiting step of the TCA cycle.[104] Marver et al. determined citrate synthase levels in isolated rabbit nephron segments. The order of relative citrate synthase activities in normal rabbit nephron segments (per kg of dry tissue) was as follows: DCT > PCT > CTAL > CCD > PST. The activity in CCD was regulated by aldosterone.[105]

β-Oxidation of Fatty Acids

Fatty acid is a major energy fuel in the kidney. β-Oxidation of short-, medium- and long- chain fatty acids (Figure 6.8) occurs in mitochondria, and that of very long-chain fatty acids in peroxisomes. The 3-hydroxyacyl-CoA dehydrogenase activity, which mainly represents the mitochondrial β-oxidation pathway, is similarly distributed in all cortical proximal and distal segments, and is much lower in glomeruli and collecting ducts. The peroxisomal fatty acyl-CoA oxidase is restricted to the PT, with a capacity comparable to that in liver cells.[106]

Ketone Body Metabolism

The kidney, as well as the muscle and brain, utilizes ketone bodies as metabolic fuel, while the liver cells do not. Acetoacetate and β-hydroxybutyrate are converted to acetyl CoA in the mitochondrial matrix. In this process, three enzymes, i.e., D-3-hydroxybutyrate

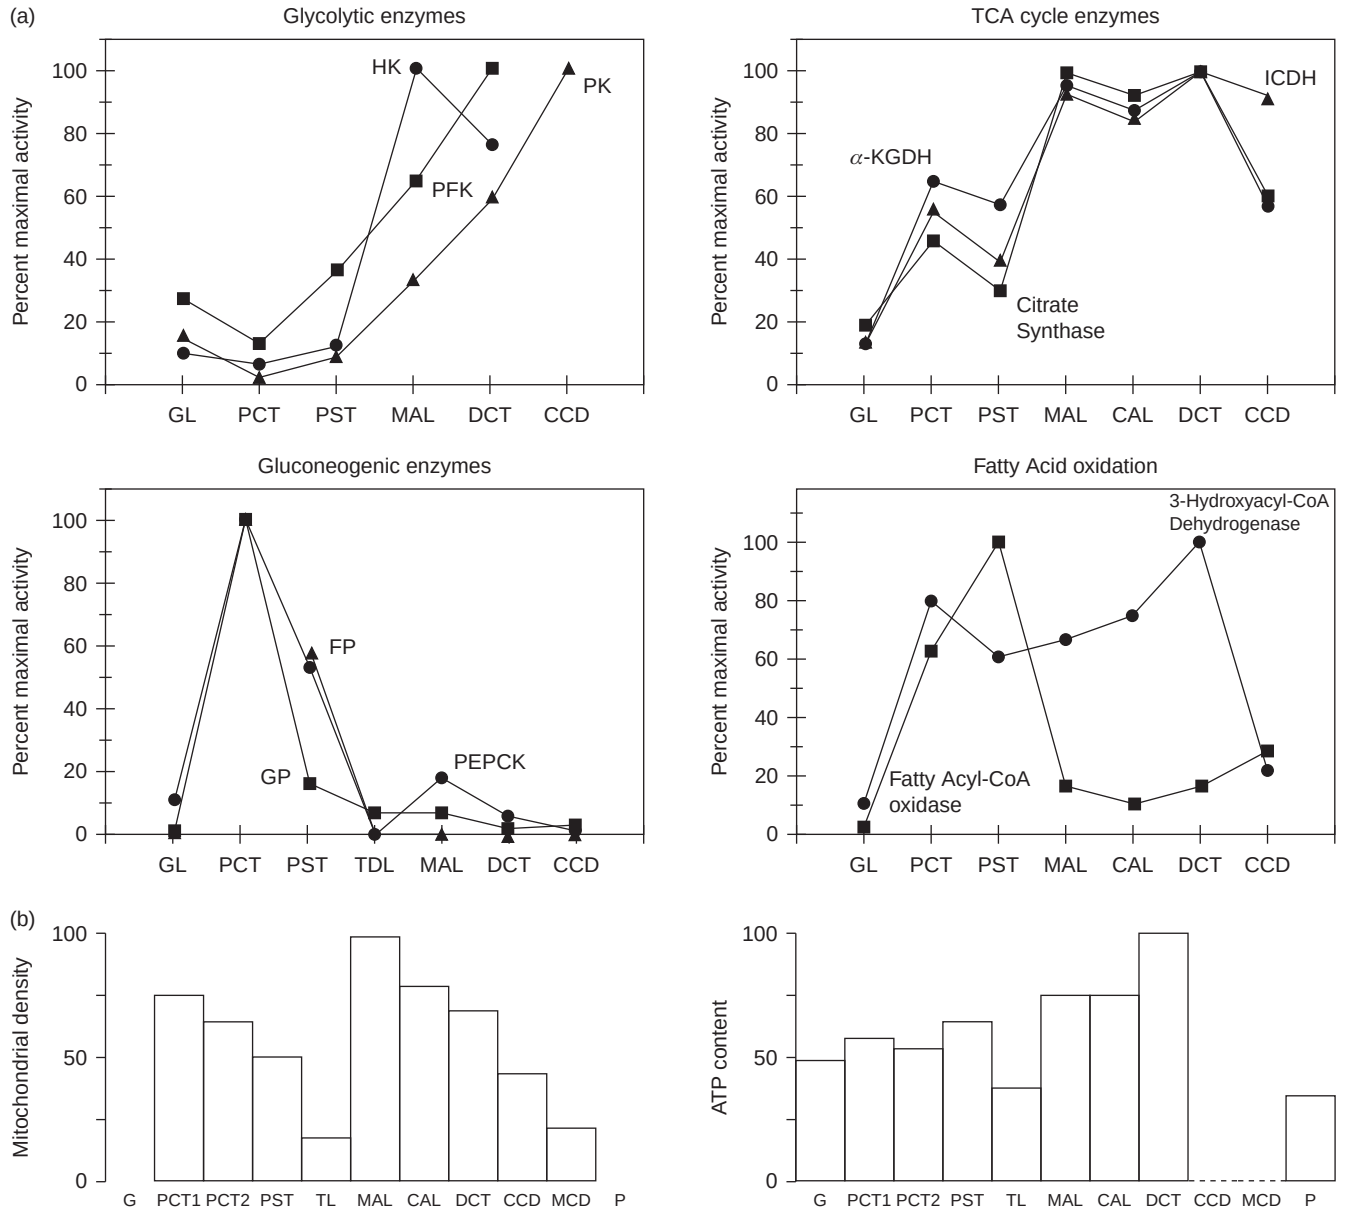

FIGURE 6.8 **(a) Distribution of enzymes involved in four major metabolic pathways:** TCA cycle, β-oxidation of fatty acids, glycolysis and gluconeogenesis. *(Adapted from [101] with permission.)* (b) Mitochondrial density distribution and ATP content along nephron segments. *(Adapted from [3] with permission.)*

dehydrogenase, 3-ketoacyl CoA transferase (3-oxoacid CoA- transferase), and acetoacetyl CoA thiorase, are involved.

Guder and co-workers measured 3-oxoacid CoA-transferase, and D-3-hydroxybutyrate dehydrogenase in mouse nephron. The activities of these enzymes were high in TAL and DCT, but decreased to nearly 20% in the CCD. In the PCT and PST, the 3-oxoacid CoA-transferase activity was almost equal, while the 3-hydroxybutyrate dehydrogenase activity was five-fold higher in PST than in PCT. In glomeruli and thin descending limbs of Henle's loop, the enzymatic activities were markedly low. These results indicate that 3-hydroxybutyrate and acetoacetate can be metabolized in all of the mouse nephron segments with different capacities. The enzymatic activity for ketone body oxidation mirrors the distribution of mitochondria along the nephron segment.[107]

Glycolysis

The role of glycolysis (Figure 6.8) as a metabolic pathway is different among cells and the state of oxygen supply. In the kidney, glycolysis occurs primarily from glucose, since the storage of glycogen is

minimal.[108] The hexokinase activity in single microdissected rabbit nephron segments was the lowest in the PCT, and increased along the nephron segments. It was the highest activity in the CNT.[109] The activities of phosphofructokinase and pyruvate kinase in the rat nephron were ten-fold higher in the distal nephron than in the proximal portion.[110] Thus, the glycolytic activity in the kidney is mostly distributed along the distal part of the nephron. Lactate production from glucose, with and without antimycin A, was investigated in the rat nephron.[111] PT produced no lactate, and the distal segments all produced lactate. Antimycin A, an inhibitor of mitochondrial oxidation, increased lactate production significantly in all of the distal segments. The increase was the largest in the MTAL (1400%), cortical (798%), and outer medullary collecting ducts (357%). Increments were smaller in CTAL (98%) and DCT (98%), and were the lowest in the IMCD (28%). Thus, anaerobic glycolysis is important, particularly in the distal segments of the nephron.

Gluconeogenesis

The capacity of the kidney to conduct gluconeogenesis (Figure 6.8) was demonstrated more than 50 years ago. Actually, the glucose synthesis rate of the kidney is higher than that of the liver when they are compared using the same tissue amount.[112] The release of glucose by the kidney has been reported to account for ~20% of all glucose released into the circulation in postabsorptive healthy humans.[113] Sustained hypoglycemia enhances the renal extraction of circulating precursors for gluconeogenesis, and stimulates renal glucose production, which may represent an important additional component of the body's defense mechanism against hypoglycemia in humans.[114,115]

Among the nephron segments, the PT is the only site where net glucose synthesis occurs.[101,116] The gluconeogenic enzyme PEPCK was exclusively found in the PT, and the PST exhibited 50% of the enzyme activity in the PCT.[109] All other renal structures exhibited only negligible PEPCK activity.[109] Thus, the activities of glycolysis and gluconeogenesis are a mirror image. Meyer et al. demonstrated that lactate is the most important precursor in renal gluconeogenesis, which exceeded the sum of renal gluconeogenesis from glycerol, glutamine, and alanine.[113] Gluconeogenesis from these substrates accounts for ~90% of renal glucose release.

Kondou et al. demonstrated that renal gluconeogenesis is stimulated by short-term ischemia.[117] They suggested that such stimulating gluconeogenesis supplies an energy fuel for further regeneration in nephron segments other than the PT.

There are several studies indicating a reciprocal relationship between Na^+ transport and gluconeogenesis.

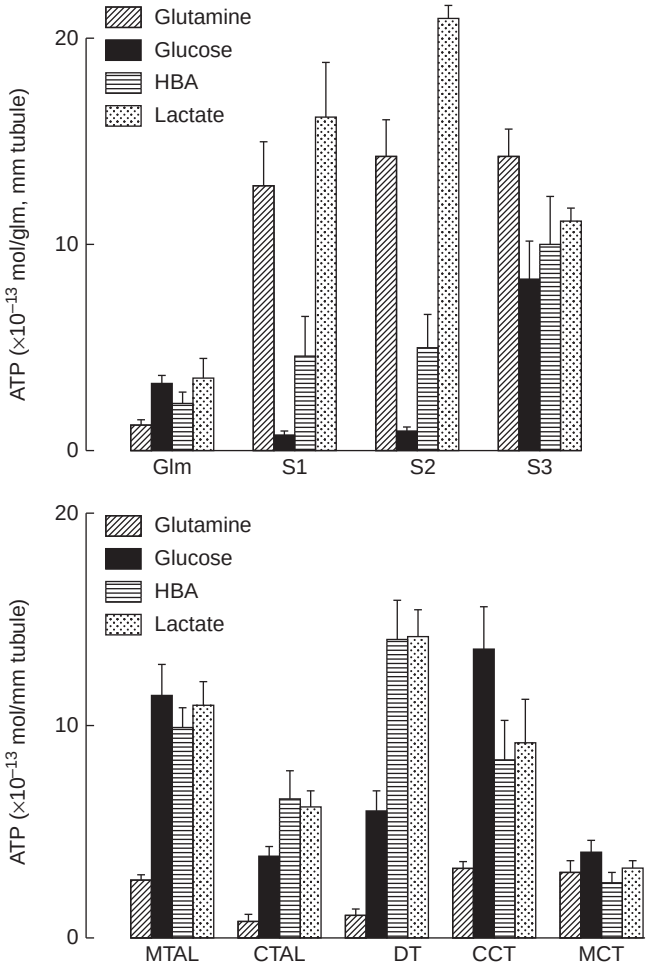

FIGURE 6.9 ATP content in nephron segments in the presence of several metabolic substrates. *(Adapted from [127] with permission.)*

The inhibition of Na^+,K^+-ATPase by ouabain stimulated gluconeogenesis.[118–120] In contrast, the stimulation of Na^+,K^+-ATPase by nystatin and monesin inhibited gluconeogenesis.[119,121] Silva et al. suggested that under certain circumstances, gluconeogenesis competes with Na^+ reabsorption in an intact kidney.[122,123]

Metabolic Parameters along Nephron Segments

As described, aerobic and anaerobic metabolisms are different among the nephron segments (Figure 6.8). This difference is in good accord with the distribution of mitochondria along the nephron. Pfaller and colleagues investigated the density of mitochondrial volume (mitochondrial volume per unit volume of cytoplasm) by stereoscopic analysis, and demonstrated PCT (33%), PST (22%), thin limb (6–8%), MTAL (44%), DCT (33%), CCD (20%), and MCD (10%)[124,125] (Figure 6.8).

Intracellular ATP contents in various nephron segments were measured by several investigators.[111,126,127] Uchida and Endou demonstrated that the cellular ATP

(b)

	Preferred substrates	
PT	Lactate glutamine citrate fatty acids	Glutamine pyruvate acetate ketone bodies
TAL	Glucose fatty acids acetate	Lactate ketone bodies
DCT	Glucose β-OHB	Lactate
CCD	Glucose pyruvate β-OHB	Lactate fatty acids
OMCD	Glucose glutamine	Lactate β-OHB
IMCD	Glucose	Lactate

FIGURE 6.10 **Metabolic pathways and substrates used to fuel renal transport.** (a) Boxed substances are typical substrates used in nephron segments. (b) Substrate preference of each nephron segment.

content is largely dependent on the exogenous substrates available (Figure 6.9).When appropriate exogenous substrates are present, the cellular ATP content is high in the PT, MTAL DT, and CCD, whereas it is low in glomerulus, CTAL, and MCD.

Preference of Metabolic Substrates in Nephron Segments (Figure 6.10a,b)

Substrate Preference Along the Nephron Segments

Ever since Gyoergy et al. identified differences in metabolisms between the renal cortex and medulla in 1928,[128] numerous studies identified different metabolic profiles along the nephron. In the previous section, the activities of metabolic enzymes in the nephron were described. However, preferred substrates for each segment do not always correlate well with the distribution of specific enzymes. The substrate preference in a specific nephron segment depends on several factors other than the enzymatic activities, such as the cellular uptake systems for substrates, oxygen supply, hormonal stimuli, and the demand for metabolic end products.

Knowledge of the preferred substrates for each segment has accumulated, especially from studies using microdissected nephrons. The determination of $^{14}CO_2$ production from distinct labeled substrates, in conjunction with the effects of the substrate on cellular ATP level, QO_2, redox state (NADH fluorescence), and active ion transports provide evidence that a variety of metabolic fuels, such as lactate, glucose, pyruvate, fatty acids, ketone bodies, amino acids, and TCA cycle intermediates energize cellular metabolism.

In this section, we briefly summarize the data on the substrate preference in each nephron segment.

Proximal Tubule (PT)

Numerous studies examined the metabolic profiles of the PT, and consistently indicated that the PT metabolizes a variety of substrates, such as fatty acids, ketone bodies, lactate, pyruvate, glutamine, glutamate, and TCA cycle intermediates. One notable exception is glucose: the PT, especially proximal convoluted tubule (PCT), poorly metabolizes glucose.

Glucose: PT poorly metabolizes glucose, and there is a difference in the utilization of glucose between PCT and the proximal straight tubule (PST). $^{14}CO_2$ production from glucose in the PT was low,[129–131] and glucose was poorly converted to lactate under both aerobic and anaerobic conditions.[111] Uchida and

Endou measured cellular ATP contents in mouse nephron segments in the presence of several exogenous substrates. When only glucose was supplied to the PT, the cellular ATP content significantly decreased in the S1 and S2 segments, while it was sustained in the S3 segment (PST).[127] A study using rabbit PCT or PST suspensions demonstrated a similar metabolic profile for glucose: the addition of glucose to the rabbit PCT did not increase QO_2, whereas that to the rabbit PST increased it by 57%.[130] The differences in glucose utilization do not correlate with the distribution of glycolytic enzymes between the PCT and PST,[132] suggesting that a metabolic regulation mechanism other than that by glycolytic enzymes may determine the ability of each segment to utilize glucose. It should be noted that the gluconeogenic activity is high in the PT.

Fatty acids: Short-chain fatty acids are important fuels in the PT. Balaban and Mandel examined the effects of various short-chain fatty acids, carboxylic acids, and amino acids on NADH fluorescence and QO_2 in the rabbit PT.[133] The short-chain fatty acids (butyrate, valerate, and heptanoate) were the most effective in increasing NADH fluorescence and QO_2, followed by the carboxylic acids and amino acids. Butyrate supported mitochondrial respiration to a greater degree than lactate, glucose, and alanine when the Na^+,K^+-ATPase activity was maximally stimulated by nystatin.[134] Butyrate was also shown to enhance the volume regulation of the isolated nonperfused PST under hypoosmotic conditions by activating Na^+ Cl^- transport.[135] Ruegg et al. demonstrated that PT exhibits maximal QO_2 and ATP content when incubated in culture medium with 2 mM heptanoate.[130] In contrast, palmitate oxidation occurs minimally in the PCT.[129] Thus, short-chain fatty acids are one of the best substrates, especially when active sodium transport is stimulated.

TCA cycle intermediates: The PCT demonstrated marked $^{14}CO_2$ production from labeled succinate, 2-oxoglutarate, glutamate, glutamine, and malate (approximately 10 to 45 pmoles/mm/hr), and moderate $^{14}CO_2$ production from citrate (approximately 3 pmoles/ml/hr).[129] Gullans et al. demonstrated that succinate stimulates gluconeogenesis, and the hyperpolarization of the plasma membrane potential, and promotes intracellular K^+ without altering Na^+,K^+-ATPase activity.[136] Since TCA cycle intermediates are highly hydrophilic substances, cellular metabolisms of TCA cycle intermediates require specific transporters in the plasma membrane. The sodium-dicarboxylate co-transporters, NaDCs encoded by the *SLC13* family, are expressed mainly in both the luminal and basolateral membrane of the PT.[137–140]

Ketone bodies: Guder et al. reported that ketone bodies, i.e., acetoacetate and β-hydroxybutyrate, are presumably the most preferred substrate as kidney fuel.[141] In a study using kidney slices, acetoacetate was estimated to support up to 80% of renal energy demands.[131] β-hydroxybutyrate supported ATP levels to the same extent as lactate and glutamine in isolated mouse S3, while S1 and S2 had a low capacity to metabolize β-hydroxybutyrate. These results correlate with the high enzyme activities for ketone bodies such as 3-hydroxybutylate dehydrogenase in this segment.[101]

Lactate: Lactate is also a preferred substrate for the PT. Goldstein et al. investigated the extraction of substrates from the blood by the rat kidney in normal, acidotic, and diabetic ketoacidotic conditions, and demonstrated that lactate accounts for 78% of the total amount of substrates extracted in normal control rats.[142] Exogenous lactate maintained the cellular ATP content in the mouse PT.[127] However, Kline et al. indicated that a negligible amount of $^{14}CO_2$ was released from the labeled lactate as well as glucose in the rat PCT.[129]

Thus, the proximal tubule metabolizes a wide range of substrates. This seems to be, at least in part, due to the existence of cellular transport systems for various substrates in the PT. PT cells possess Na-dependent transport systems for most of the nutrients across the luminal membrane. Nutrient transporters also exist in the basolateral membrane of the PT. Recent molecular studies have revealed the exclusive distribution of these transporters in the PT.

In the rat PT, preferred substrates are ketone bodies, short-chain fatty acids, lactate, and TCA cycle intermediates. However, there are species differences: the rabbit PT has a limited capacity to oxidize ketone bodies.[133]

The PT normally conducts transport work at 50 to 60% of its maximal respiratory capacity, and has significant amounts of endogenous fuels, probably neutral lipids, which support about half of the energy in the absence of exogenous substrates. Metabolism of endogenous fuel is suppressed when there is an adequate supply of exogenous substrates. The preferred substrates differ under different physiological conditions.[142]

Thin Descending Limb of the Loop of Henle (TDL)

The data available regarding the metabolic profile of the TDL is insufficient. The mitochondrial density of this segment is low, and its oxidative metabolism is limited. Jung and Endou measured the cellular ATP content in the rat short loop of TDL (SDL) and the rat long loop of TDL (LDL) in the presence of alanine, glucose, glutamine, β-HBA, lactate, and pyruvate.[143] They demonstrated that the substrate preference in SDL is pyruvate = glucose > glutamine = lactate = β-HBA

> alanine, and that in the LDL is pyruvate- = glucose = glutamine > alanine = β-HBA = lactate. They also demonstrated that ATP is depleted when the TDL is incubated in the absence of exogenous substrate, indicating a limited store of endogenous fuels in this segment.

Cortical Thick Ascending Limb of the Loop of Henle (CTAL)

In the TAL, the rate of Na^+ transport and QO_2 are high, and the mitochondria are enriched, suggesting there is active oxidative metabolism in this segment. Klein et al. measured $^{14}CO_2$ production from ^{14}C-labeled substrates in the rat MTAL and CTAL.[129] MTAL and CTAL oxidized glucose, 2-oxoglutarate, lactate, glutamate, and glutamine, but not malate, succinate, and citrate. Palmitate oxidation occurred in MTAL and CTAL.[129] Lactate production from glucose in the rat nephron indicated that the distal segments produce a significant amount of lactate from glucose, and under anaerobic conditions (with antimycin A), lactate production increased significantly in all of the distal segments. The increase was the largest in the MTAL (1400%), CCD (798%), and OMCD (357%), whereas increments were smaller in CTAL (98%) and DCT (98%), and were the lowest in the IMCD (28%).[111] Thus, CTAL possesses modest anaerobic glycolysis capacity. The ATP content in the mouse CTAL is maintained in the presence of glucose, β-OHB or lactate, but not with glutamine.[127]

Wittner et al. investigated the substrate preference by measuring the short circuit current (Isc) in the isolated rabbit CTAL perfused *in vitro*.[144] They further examined which sides, i.e., luminal or basolateral, substrates were taken up from. Isc rapidly decreased to 50% after 3 minutes and to 27% after 10 minutes without any exogenous substrates, indicating that Na^+ transport is strictly related to the presence of substrates in CTAL segments.[144] When substrates were added from the luminal side, only butyrate sustained Isc, while all other substrates tested (pyruvate, acetate, β-OHB, D-glucose, and L-lactate) showed a marked decrease in Isc. When the substrates were added from the basolateral side, D-glucose, D-mannose, butyrate, β-OHB, acetoacetate, L-lactate, acetate, and pyruvate sustained the Isc, but citrate, α-ketoglutarate, succinate, glutamate, glutamine, propionate, caprylate, and oleate did not. This study clearly indicates that the cellular uptake system is an important determinant in the substrate metabolisms in the CTAL. In the CTAL, most substrates, except for butyrate, are taken up by basolateral nutrient transporters. In fact, cytochalasin B and phloretin, inhibitors of the facilitated glucose transporter (GLUTs), inhibited the sustained Isc by glucose.[144]

Regarding fatty acids, the CTAL possesses mitochondrial β-oxidation activity (3-hydroxyacyl-CoA dehydrogenase),[106] and $^{14}CO_2$ is produced from palmitate,[129] while oleate (C-18) does not sustain Isc in the CTAL.[144] Taken together, glucose, lactate, pyruvate, ketone bodies, and fatty acids are the preferred exogenous substrates for the CTAL.

Medullary Thick Ascending Limb of the Loop of Henle (MTAL)

Chamberlin and Mandel measured QO_2 in MTAL suspensions.[145] In the absence of exogenous substrates, the control QO_2 decreased only by 15%. Torikai et al. demonstrate a similar result in the rat MTAL.[146] These results indicate that endogenous substrates support most of the energy required for the MTAL under normal conditions. However, nystatin-stimulated QO_2 was inhibited 36% in the absence of exogenous substrates, indicating that the oxidation of endogenous substrates cannot meet the ATP demand when Na^+ transport is fully stimulated. They also investigated the role of endogenous substrates in the MTAL. The inhibitors of fatty acid, carbohydrate or amino acid metabolisms further inhibited QO_2, revealing that endogenous fatty acids, glycogen, and amino acids (or proteins) contribute to energy production in the MTAL. The addition of fatty acids or acetoacetate increased QO_2 in 10 mM glucose, indicating that the MTAL oxidizes exogenous fatty acids and ketones in addition to glucose. In the MTAL, organic acids failed to enhance QO_2, possibly due to the absence of transport systems for organic acids. The rat MTAL generated $^{14}CO_2$ from glucose, lactate, palmitate, glutamate, glutamine, and α-ketoglutarate. $^{14}CO_2$ from succinate, citrate, and malate was minimal. Glucose, β-hydroxybutyrate, and lactate maintained the intracellular ATP content, whereas the effect of glutamine on the ATP content was partial.[127] The tight coupling of Na transport and QO_2 was demonstrated in the MTAL. Furosemide inhibited oxygen consumption by 43%, and ouabain inhibited it by 42%[147]; 50% of the oxygen consumption of the MTAL cells is related to the transport of Na^+ and Cl^-.[148]

In the MTAL, anaerobic glycolysis is also an important energy source.[149] Ten mimutes of anoxia led to only a 15% decrease in potassium content in the rabbit MTAL, and an anaerobic metabolism maintained 73% of cellular ATP during 10 minutes of anoxia. The exposure of anoxic tubules to iodoacetate produced a 57% decrease in ATP level, and a 33% decrease in potassium content. Lactate production was remarkably enhanced in MTAL (1400%) under anaerobic conditions with antimycin A.[111]

Distal Convoluted Tubule (DCT)

Although studies have examined the metabolic and transport properties in DCT, such as the mitochondrial density, Na^+,K^+-ATPase activity, and enzymatic activities, data regarding its substrate preference is limited. The ATP content of the DCT was maximal in the presence of β-OHB or lactate, and somewhat lower in the presence of glucose. Glutamine did not increase the ATP content in the DCT.[127] The lactate production rates from glucose under aerobic conditions were comparable to that observed in the CTAL, whereas under anoxic conditions, the glycolytic lactate production rate was increased two-fold as observed in CTAL.[111] These results indicate that DCT utilizes both oxidative metabolisms and anaerobic glycolysis.

Cortical Collecting Duct (CCD)

Torikai demonstrated that substrate deprivation for 30 minutes does not change the cellular ATP content in the rat CCD and OMCD. However, a marked decrease in the PT and medullary TDL, and a slight decrease in CTAL and MTAL were observed, suggesting that CCD and OMCD possess sufficient amount of endogenous fuels.[146] Hering-Smith et al. demonstrated the dependence of CCD on oxidative metabolisms in the Na^+ reabsorption and bicarbonate transport in the rabbit CCD.[150] There was no significant glycolysis or any difference in substrate-dependence of solute transport in the CCD. Na^+ reabsorption was optimally supported by a mixture of basolateral metabolic substrates (glucose, acetate, and fatty acid), whereas bicarbonate secretion was fully supported by either glucose or acetate. This result indicates that principal cells and intercalated cells differ not only in their morphology and function, but also in their metabolism. Alanine was not effective in the CCD. Nonaka and Stokes examined the effects of substrates on Na^+ transport in the rabbit CCD, and concluded that the majority of the energetic support of Na^+ transport appears to come from an oxidative metabolism. Glucose supports transport better than the other substrates tested, and lactate, pyruvate and some organic acids also provide near maximal support.[151]

The CCD synthesized modest amounts of lactate from glucose under aerobic conditions, which increased eight times under anaerobic conditions.[111] The addition of glucose, β-hydroxybutyrate or lactate, but not glutamine, restored the cellular ATP content, and glucose was the best substrate in CCD for maintaining the ATP level.[127] Natke showed that the rabbit nonperfused CCD regulates the cellular volume against extracellular hypertonic solution when exogenous butyrate is available,[152] although rat CCD possesses a relatively low enzymatic activity for β-oxidation.

Outer Medullary Collecting Duct (OMCD)

The OMCD cells play an important role in the final acidification of urine, which is mediated by apical H^+-ATPase.[89] The OMCD has a relatively low QO_2, which is inhibited only by 8% by ouabaine.[153] Several studies indicated the importance of anaerobic glycolysis in this segment. The ATP content in the OMCD did not significantly change with the addition of antimycin A.[146] Lactate production from glucose was significantly increased in the outer medullary collecting ducts by 357% under anaerobic conditions.[111] Under aerobic conditions, the ATP content was supported equally well by glucose, glutamine, lactate or β-hydroxybutyrate. Thus, glucose appears to be a preferred substrate for this segment, particularly under hypoxic or anoxic conditions, but other alternative substrates, such as glutamine, lactate or β-hydroxybutyrate, can be metabolized under aerobic conditions. The uptake of glucose by the OMCD, as well as that by the TAL cells, is mainly through a facilitated basolateral diffusion.[154] Studies of H^+ transport[155] and ATP content[127] also indicated the existence of a significant amount of endogenous fuel, most likely glycogen in the OMCD.

Inner Medullary Collecting Duct (IMCD)

Substrate metabolism in IMCD cells has not been sufficiently analyzed. QO_2 in IMCD is lower than that in other nephron segments.[156–158] Glycolysis under aerobic and anaerobic conditions was examined by several investigators. Addition of glucose to IMCD cells stimulates both QO_2 and lactate production, indicating that glucose can be readily metabolized to both CO_2 and lactate under aerobic conditions.[111,156,157,159] Lactate production in the IMCD under aerobic conditions was three- to five-fold greater than that in other nephron segments in the outer medulla, such as the TAL or OMCD.[111]

To evaluate the relative contributions of aerobic and anaerobic metabolism in the IMCD, the effects of specific inhibitors of mitochondrial oxidative phosphorylation and glycolysis were examined. Stokes et al. examined metabolism in rat renal papillary collecting duct cells, i.e., IMCD cells.[157] In the presence of rotenone, glycolysis increased by 56% and maintained the cellular ATP level at 65% of the control. Without any exogenous substrates, IMCD respiration was normal, and had a nearly normal ATP content, but lactate production was markedly decreased. At normal PO_2 and in the presence of D-glucose, the IMCD cells showed a substantial amount of aerobic glycolysis, although their mitochondrial respiration was not rate-limiting. In the absence of glucose, the cells acquired the majority of their energy from an endogenous substrate.[157]

Kone and co-workers showed that the addition of glucose to IMCD cells results in the accumulation of 12% more intracellular K^+, even in the presence of lactate and glutamine.[159] The data indicates that glucose is a preferred substrate in IMCD.

COUPLING OF TRANSPORT AND METABOLISM IN THE KIDNEY

As described in the section "Energy Consumption," Na transport and QO_2 show a linear relationship in the kidney. The nature of the cellular mechanism linking active transport to energy production is a fundamental physiological question. Alterations in the rate of active transport cause changes in the mitochondrial state and/or concentrations of adenine nucleotides in epithelia.[7] Conversely, the cellular respiration rate and/or ATP concentration affects active transport. This section focuses on the coupling mechanism of transport and energy production in the kidney.

The Effect of Active Transport on Metabolism

Whittam Model: Intracellular Signaling Between Transport and Energy Production

Whittam and co-workers primarily proposed a simple model indicating the coupling of active transport and mitochondrial respiration[160,161](Figure 6.11). In this model, the rate of active cation transport is a pacemaker for cellular respiration in the renal cells: increased ATP hydrolysis and elevated cytosolic levels of ADP and Pi by Na^+,K^+-ATPase activity would activate mitochondrial oxidative phosphorylation and oxygen consumption. Conversely, decreased Na^+,K^+-ATPase activity would induce the opposite result (Figure 6.11).

The validity of this model has been examined by: (1) direct measurement of ATP, ADP, Pi; and/or (2) monitoring of the mitochondrial redox state, in various states of transport. Early investigations into the intracellular nucleotide concentration failed to detect a change in the intracellular ATP levels.[162,163] This was probably due to the rapid ATP turnover in the renal cortex; the half-life of ATP in the anoxic state was estimated to be as low as 3.3 seconds.[164] Balaban and co-workers measured the cellular ATP/ADP concentrations and the QO_2 of a rabbit cortical tubule suspension under ideally designed conditions. They demonstrated that: (1) ouabain caused a 54% inhibition of QO_2 and a 30% increase in the ATP/ADP ratio; and (2) the addition of K^+ (5 mM) to K^+-depleted tubules caused an initial 127% stimulation of QO_2, followed by a new steady-state QO_2 50% above the control, and a 47% decrease in the cellular ATP/ADP ratio.[165]

The monitoring of the redox state by optical measurements also demonstrated appropriate "mitochondrial state of transition." Stimulation of Na^+,K^+-ATPase activity stimulated QO_2 and decreased NADH fluorescence (in whole kidney and proximal tubules). Inhibition of Na^+,K^+-ATPase with ouabain decreased QO_2 and increased NADH. Addition of rotenone to proximal tubules decreased QO_2, and ATP content net fluid transport with increase of NADH fluorescence.[165]

Regulation of Mitochondrial Respiration

The precise mechanism by which the rate of mitochondrial oxidative phosphorylation is regulated is of major interest in the field. There is much evidence suggesting the importance of cytosolic ADP concentration. Chance and Williams first proposed that the availability

of ADP determines the mitochondrial respiration rate.[166–168] The respiratory state of mitochondria was classified into five states according to the supply of ADP, Pi, substrates, and O_2.[7,166] The addition of ADP to the mitochondria with a sufficient amount of substrates and O_2 induces the maximal rate of respiration, called "state 3 (active)" respiration. When all of the ADP is phosphorylated to ATP, QO_2 and ATP production decrease (the phase called "state 4 resting" respiration). The ratio of QO_2 in state 3 and state 4 is termed the "*respiratory control index*." This change in respiration was also demonstrated in proximal tubules permeabilized to ADP by digitonin, in which QO_2 was stimulated by four- to five-fold by the addition of ADP.[169] Nevertheless, the predominant parameter, (e.g., only [ADP] itself, [ATP]/[ADP] ratio or [ATP]/[ADP][Pi] ratio), should be determined by further studies using mitochondria, and two conflicting hypotheses on mitochondrial phosphorylation have been proposed.

The first hypothesis indicated that the [ATP]/[ADP] ratio is the rate-limiting step in oxidative phosphorylation.[170] This hypothesis is founded on kinetic considerations of adenine nucleotide translocase. Addition of atractyloside, an inhibitor of ATP/ADP translocase, caused inhibition of ADP influx into the mitochondrial matrix and oxidative respiration.[171] However, the data from intact tissues with high oxidative phosphorylation capacities, i.e., heart, brain, and kidney, indicated that the cytosolic concentration of ADP and Pi do not change significantly with work.[172]

The second hypothesis, called the "near-equilibrium theory," stated that oxidative phosphorylation is dependent on the phosphorylation potential.[173,174] This hypothesis suggested that oxidative phosphorylation is regulated thermodynamically by four factors: (1) [ATP]/[ADP][Pi] ratio; (2) intramitochondrial [NAD^+]/[NADH] ratio; (3) respiratory chain components, especially cytochrome c oxidase; and (4) oxygen concentration. This theory was partially correct, however, oxidative phosphorylation is not always close to equilibrium, at least in isolated mitochondria.[175]

Furthermore, both of these hypotheses should be re-evaluated by the determination of the cytosolic concentration of ATP, ADP, and Pi by nuclear magnetic resonance (NMR) spectroscopy. NMR spectroscopy is a method by which the radiofrequency signal of specific molecules (P, N, C, and H) in a strong magnetic field can be recorded and quantified. There are particular features of this technology which can be applied to the measurement of biological events as follows: (1) the ability to define the chemical nature of phosphorus-containing molecules and follow their transition in time; (2) completely nondestructive and repeated determination is possible; (3) rapid determination over a few seconds; and (4) wide application from isolated mitochondria to intact kidney *in vivo*.[176,177] Freeman and colleagues quantified inorganic phosphate (Pi) and high-energy phosphates in the isolated, functioning perfused rat kidney. Compared with enzymatic analysis, 100% of ATP, but only 25% of ADP and 27% of Pi were visible by NMR spectroscopy,[178] indicating that a large proportion of both ADP and Pi are bound to proteins in the intact kidney. The data obtained by NMR spectroscopy, in conjunction with biochemical assays, estimated the free concentration of cytosolic ADP as approximately 30 μM[178,179] and Pi as 0.6 mM.[178] As a consequence, the [ATP]/[ADP][Pi] ratio (phosphorylation potential) and [ATP]/[ADP] ratio should be at least one order of magnitude higher than previously estimated values.

There are several other theories on the regulation of mitochondrial respiration. One claimed that the interplay of all aspects of oxidative phosphorylation affects respiration control.[180] Another new hypothesis implies the regulation of respiration and ATP synthesis via allosteric modification of respiratory chain complexes, in particular of cytochrome c oxidase by metabolites, cofactors, ions, hormones, and the membrane potential.[181,182] At the moment, there seems no simple answer to the question "what controls respiration?" The answer varies with: (1) the size of the system examined (mitochondria, cells or organs); (2) the conditions (rate of ATP use, level of hormonal stimulation); and (3) the particular organ examined.[175]

The Effect of Metabolism on Active Transport

Intracellular ATP and Cation Transport

The intracellular ATP content was reported 2∼8 mM,[165,183–187] and the Km value of α-subunits for ATP was estimated to be 0.1 to 0.4 mM.[188] Therefore, Na^+,K^+-ATPase should be saturated for ATP under physiological conditions. However, intact renal cells normally function at almost half of their maximal respiratory capacity.[189] Harris measured cellular QO_2 during stimulation and inhibition of the Na^+,K^+-ATPase in mitochondria released from the rabbit renal tubules by digitonin shock. In the presence of NADH-linked substrates and fats, isolated renal cells respired at 50 to 60% of the maximum occurring in state 3 respiration, and addition of ouabain resulted in a decline in respiration to 25 to 30%. Stimulation of Na^+,K^+-ATPase by nystatin resulted in increased respiration with increased oxygen consumption.[134] Gullans and colleagues demonstrated that partial inhibition of oxidative metabolism with rotenone caused proportional reduction in QO_2, ATP content, and absorption rates of fluid and phosphate.[190] The effect of inhibition of oxidative metabolism on transport systems was also

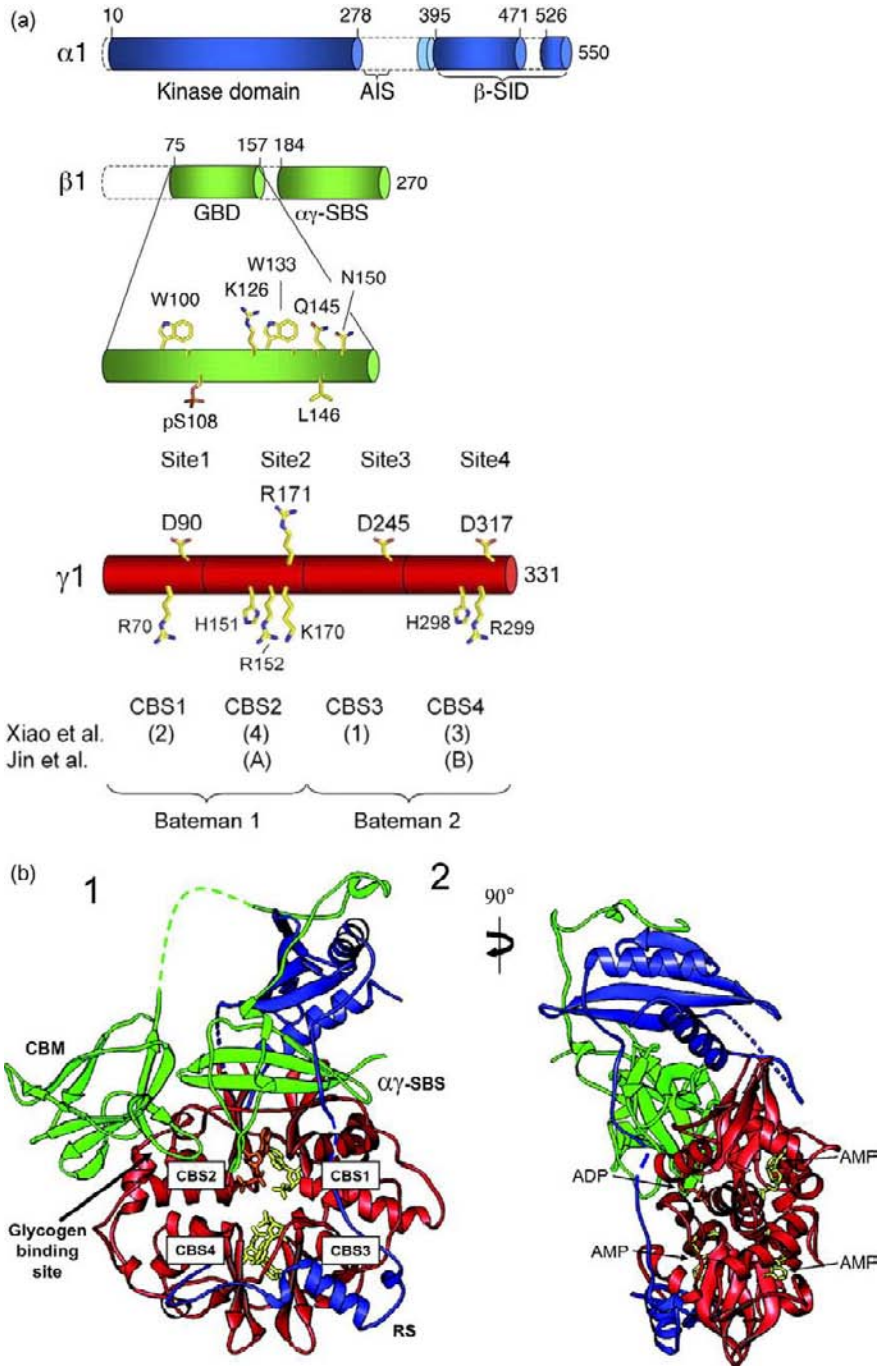

FIGURE 6.12 **Structure and function of AMPK.** (a) AMPK subunit composition. Details are described in the text. (b) Tertiary structure of AMPK. *(Adapted from [195] with permission).*

demonstrated using arsenate, which uncouples oxidative phosphorylation.[191]

This inconsistency was explained through a study by Soltoff and Mandel. In the membrane fraction of the PT, Na^+,K^+-ATPase hydrolytic activity showed saturated kinetics with a Km value of 0.4 mM for ATP. In contrast, Na^+,K^+-ATPase activity was demonstrated to have a linear, nonsaturating dependence on the ATP concentration in the intact proximal cells (Figure 6.11).[186] The authors speculated that unknown cytosolic factors in the intact renal cell, such as local concentration of ADP, Pi, and Mg in the vicinity of Na^+,K^+-ATPase may be different, which might account for the discrepancy between the two

measurements. In contrast to Na^+,K^+-ATPase, decreased concentration of cytosolic ATP does not significantly alter the Ca^{2+}-ATPase activity, probably due to its relatively high affinity for ATP.[192]

AMPK-Activated Protein Kinase (AMPK): A Regulator of Energy Consumption and Generation

For the last decade, numerous experimental data have indicated the significant role of AMP-activated kinase (AMPK) in the regulation of the energy consuming and producing process in the living cells. AMPK appears to be the molecular entity which Whittam had proposed as "the pacemaker of respiration." AMPK has been extensively analyzed in the regulation of metabolism of carbohydrate, lipid, protein, and other cellular functions, such as cell polarity and growth; several studies have demonstrated its critical roles in solute transport in the kidney. In this section, we will review AMPK, and thereafter describe its role in the kidney.

AMP-Activated Protein Kinase (AMPK)

The AMP-activated protein kinase is an evolutionarily conserved heterotrimeric kinase acting as an ultrasensitive cellular energy sensor.[193–195] AMPK is activated by increased levels of cytoplasmic AMP, and controls various energy-dependent cellular processes. Recent studies have shown that the activities of membrane proteins, such as epithelial Na^+ channel (ENaC), Na^+-K^+-$2Cl^-$ co-transporter (NKCC2), cystic fibrosis transmembrane conductance regulator (CFTR), and vacuolar H^+-ATPase, are regulated by AMPK.[193] This evidence strongly suggests that energy sensing by AMPK would be a physiologically relevant mechanism by which renal tubular cells maintain tight coupling between energy metabolism and tubular transport.[193] AMPK appears to be the molecule which couples cellular respiration and solute transport proposed by Whittam and colleagues (Figure 6.11). In this section the biological basis of AMPK is briefly reviewed, and the current information on AMPK in solute transport in the kidney will be described.

Discovery of AMPK as an Ultrasensitive Cellular Energy Sensor

In 1980, Yeh et al. demonstrated that the rate of phosphorylation and inactivation of rat liver acetyl-CoA carboxylase (ACC) was stimulated by AMP and inhibited by high levels of ATP[196]. In 1988, Munday and colleagues demonstrated that the enzyme formerly called acetyl-CoA carboxylase kinase-3 (ACC kinase-3) reduces the maximum velocity of ACC, and they proposed the name of AMP-activated protein kinase for ACC kinase-3.[197] Mammalian AMPK was first purified and sequenced by two groups from porcine or rat liver.[198,199] Subsequent studies revealed that AMPK acts to balance energy status by stimulating pathways leading to ATP synthesis and inhibiting those leading to ATP consumption.

One of the best characterized pathways and substrates regulated by AMPK is 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase, the rate-limiting enzyme for cholesterol synthesis.[195] Other than enzymatic activities, diverse biological processes have been reported to be regulated by AMPK, such as cellular nutrient uptake, protein synthesis, gene transcription, inflammation, autophagy, cellular polarity, and nitric oxide synthesis.[195] In addition to these metabolic processes, recent studies have indicated that solute transport is also regulated by AMPK.[193]

Structure and Regulation of AMPK

Mammalian AMPK is a heterotrimeric protein that comprises of two α-subunits, two regulatory β-subunits, and three regulatory γ-subunits allowing for the generation of 12 different heterotrimeric complexes[193,195,200] (Figure 6.13). γ-Subunits have several spliced variants.[193] The AMPK α1- and α2-subunits are approximately 550 residue proteins, and comprise an N-terminal kinase domain, followed by an auto-inhibitory sequence (AIS), and a β-subunit interacting domain. Phosphorylation at Thr^{271} in the α-subunit kinase domain is essential for activation of AMPK, and significantly increases its kinase activity.[201] β-Subunits have a carbohydrate-binding domain (CBM) in their central region, which binds glycogen and regulates AMPK activity. The C-terminus of β-subunits is necessary for the formation of αβγ AMPK heteromer. γ-Subunits possess the binding sites for AMP, which is the key process for the regulation of AMPK activity. In the c-terminus of γ-subunits, there are four cystathione-β-synthase (CBS) domains, and two CBS domains form one Bateman domain which bind AMP or ATP.[202] The Bateman domain has higher affinity for AMP than ATP, and the Kd for ATP is 3.3-fold higher than that for AMP.[202] The activity of AMPK is regulated by the concentration of AMP and an increase in the AMP/ATP ratio. As AMP levels rise, there is a resulting AMP binding to the Bateman domain of the regulatory γ-subunit.[202]

When ATP is utilized and its intacellular level decreased, cellular concentrations of AMP increase drastically, which leads to activation of AMPK, and activated AMPK regulates the energy homeostasis by

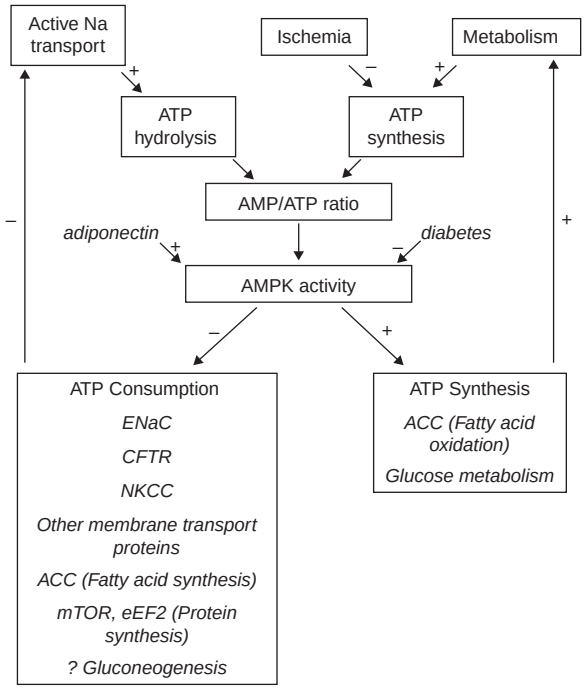

FIGURE 6.13 **Proposed role for AMPK.** Deduced role of AMPK in the kidney. Catabolic pathway requiring ATP hydrolysis (primarily sodium transport) and metabolic pathways leading to ATP synthesis (primarily fatty acid and glucose oxidation) are depicted. (*Adapted from [193] with permission.*)

stimulating energy production and minimizing energy consumption. AMPK activity is regulated by three mechanisms.[194] First, AMP allosterically activates AMPK complex in mammalian cells.[194] Second, AMP binding to the Betaman domain of the γ-subunit activates phosphorylation of Thr^{271} by upstream AMPK kinases. The third is that AMP binding to AMPK significantly reduces the dephosphorylation of Thr^{172} by 2Cα dephosphorylation phosphatase.[200] These three mechanisms make AMPK very sensitive to energy status, i.e., changes of cellular AMP and ATP concentration.

So far, three physiological kinases upstream of AMPK have been identified, namely LKB1, CaMKKβ (Ca^{2+}/calmodulin-dependent protein kinase kinase β), and TAK1 (a member of the mitogen-activated protein kinase kinase family).[200]

Expression of AMPK in the Kidney and Localization along the Nephron Segment

Expression of the AMPK catalytic α-subunit and its enzymatic activity was examined in various tissues.[203] In the rat, mRNA of the α1-subunit of AMPK was ubiquitously expressed among tissues including heart, brain, spleen, lung, liver skeletal muscle, and kidney, whereas the α2-subunit is strongly expressed in the heart, liver, and skeletal muscle, but its expression was comparatively weak in the brain, lung and kidney. Expression of α1- and α2-subunit protein showed similar patterns to those of mRNA: mRNA of the α2-subunit in the kidney was very weak. In terms of kinase activity, AMPK activity was highest in the kidney, followed by liver, lung, heart, and brain. Taken together, the kidney possesses very high AMPK activity, and its main α-subunit is α1.

Localization of AMPK subunits along the nephron segments has been investigated in the rat.[204,205] Immunoprecipitation and Western blot of protein lysates from whole rat kidney showed that the α1 catalytic subunit is expressed in the kidney, associated with the β2- and either γ1- or γ2-subunits. Phospho-Thr^{172} AMPK ($pThr^{172}$) was expressed on the apical surface of the cortical thick ascending limb of the loop of Henle, including the macula densa, and some parts of the distal convoluted tubule. α1-$pThr^{172}$ AMPK was also expressed on the basolateral surface of the cortical and medullary collecting ducts, as well as some portions of the distal convoluted tubules.[204] In another study, AMPK catalytic α2-subunits were expressed in the isolated distal tubule.[205] There seems some species difference as to which isoform(s) of each subunit are predominantly expressed in the nephron segment.[193] At the moment, there is limited information on the expression of AMPK isoforms in the kidney. Further studies are required to elucidate the significance of AMPK in the kidney, because there are remarkable differences in the metabolic profile among the nephron segments, as described in this chapter.

Regulation of Solute Transport by AMPK

Recently, regulation of renal solute transport by AMPK has been examined in several important transport and channel proteins. Low sodium and low chloride conditions activate AMPK in the murine macula densa cells indicating a potential role of AMPK in salt homeostasis in the body.[204] As is been expected, AMPK regulates the solute transport in accordance with the energy status in the kidney cells.

NA^+,K^+-ATPASE

Considering the relationship between the cellular energy status and solute transport activity, Na^+,K^+-ATPase is the membrane protein whose regulation by AMPK should first be elucidated in the kidney. So far, no definite information on this relationship in the kidney has been reported, while it was examined in the

lung cells. Woollhead and colleagues examined the effect of AMPK on Na^+,K^+-ATPase using H441 lung cells.[206,207] H441 human lung epithelial cells express α1 and α2 catalytic subunits of AMPK, and additional activators of AMPK, phenformin and 5-aminoimidazole-4-carboxamide-1-beta-D-ribofuranoside (AICAR), to H441 cells increased AMPK activity in a dose-dependent fashion. Both agents significantly decreased basal ion transport (measured as short circuit current) across H441 monolayers by approximately 50% compared with that of controls. Phenformin and AICAR significantly reduced amiloride-sensitive transepithelial Na^+ transport compared with controls. This was a result of both decreased Na^+, K^+-ATPase activity and amiloride-sensitive apical Na^+ conductance.

Vadász et al. examined the mechanisms regulating CO_2-induced Na^+,K^+-ATPase endocytosis in alveolar epithelial cells (AECs).[208] They showed that elevated CO_2 levels are sensed by AECs, and that AMPK mediates CO_2-induced Na^+,K^+-ATPase endocytosis. Elevated CO_2 levels caused a rapid activation of AMPK in AECs. Activation of AMPK was mediated by a CO_2-triggered increase in intracellular Ca^{2+} concentration and Ca^{2+}/calmodulin-dependent kinase kinase-β (CaMKK-β). Chelating intracellular Ca^{2+} or abrogating CaMKK-β function prevented the CO_2-induced AMPK activation in AECs. Activation of AMPK or overexpression of constitutively active AMPK was sufficient to activate PKC-zeta and promote Na^+,K^+-ATPase endocytosis. Inhibition or downregulation of AMPK using dominant-negative AMPK-α1 prevented CO_2-induced Na^+,K^+-ATPase endocytosis.

The Epithelial Na^+ Channel (ENaC)

Oocytes microinjected with mouse ENaC (mENaC) with either active AMPK protein or an AMPK activator inhibited mENaC currents relative to controls, as measured by two-electrode voltage-clamp studies.[209] In addition, pharmacological AMPK activation or overexpression of an activating AMPK mutant in mpkCCD (c14) cells inhibited amiloride-sensitive short circuit currents via ENaC. However, AMPK did not bind ENaC or phosphorylate ENaC *in vitro*.[209] Furthermore, they demonstrated that AMPK promotes ENaC-Nedd4-2 interaction, thereby inhibiting ENaC by increasing Nedd4-2-dependent ENaC retrieval from the plasma membrane. The results indicated that AMPK-dependent ENaC inhibition is mediated through a decrease in the number of active channels at the plasma membrane, presumably due to enhanced Nedd4-2-dependent ENaC endocytosis. This regulation of ENaC by AMPK was confirmed by AMPK α1-KO mice.[210] Almaça et al. demonstrated AMPK-α1 KO mice showed enhanced electrogenic Na^+ absorption, and that AMPK uses the ubiquitin ligase Nedd4-2 to inhibit ENaC by increasing ubiquitination and endocytosis of ENaC, leading to the enhanced expression of ENaC detected in the colon, airways, and kidney of AMPK-α1 KO mice.

Bhalla et al. examined the effects of AMPK activation on ENaC currents in *Xenopus* oocytes co-expressing ENaC and wild-type (WT) or mutant forms of Nedd4-2. ENaC inhibition by AMPK was blocked in oocytes expressing either a dominant-negative or constitutively active Nedd4-2 mutant, suggesting that AMPK-dependent modulation of Nedd4-2 function is involved.[211] Moreover, cellular AMPK activation significantly enhanced the interaction of the β-EnaC-subunit with Nedd4-2, as measured by co-immunoprecipitation assays in HEK-293 cells.

Na^+-K^+-2Cl^- Co-transporter 2 (NKCC2)

It has been known that renal-specific NKCC2 (Na^+-K^+-2Cl^- co-transporter 2) is regulated by changes in phosphorylation state, however, the phosphorylation sites and kinases responsible have not been fully elucidated. Fraser et al. demonstrated a physical association between AMPK and the N-terminal cytoplasmic domain of NKCC2 by immunoprecipitation experiments.[212] Activation of AMPK in the mouse macula densa-derived 1 cell line resulted in an increase in Ser126 phosphorylation of NKCC *in situ*, suggesting that AMPK may phosphorylate NKCC2 *in vivo*. When exogenously expressed in *Xenopus laevis* oocytes, S126A mutated NKCC showed a marked reduction in co-transporter activity. Thus, Ser^{126} in the N-terminus of NKCC2 was identified as a novel activating phosphorylation site by AMPK.

The Vacuolar H^+-ATPase (V-ATPase)

V-ATPase subcellular localization in intercalated cells by PKA and AMPK was examined in rat kidney tissue slices *ex vivo*.[213] Immunofluorescence labeling of kidney slices revealed that the PKA activator induced V-ATPase apical membrane accumulation in collecting duct intercalated cells. Pre-incubation of kidney slices with an AMPK activator blocked V-ATPase apical membrane accumulation induced by PKA activator, suggesting that AMPK antagonizes cAMP/PKA effects on V-ATPase distribution.

The Cystic Fibrosis Transmembrane Conductance Regulator (CFTR)

The cystic fibrosis transmembrane conductance regulator is an ATP-gated Cl^- channel that regulates other epithelial transport proteins. Using a yeast two-hybrid

screening technique, the α1- and α2-subunit of AMPK was identified as a novel interacting protein. AMPK phosphorylated full-length CFTR *in vitro*, and AMPK co-expression with CFTR in *Xenopus* oocytes inhibited cAMP-activated CFTR whole-cell Cl^- conductance by approximately 35−50%.[214]

Other Transport Proteins and Channels Regulated by AMPK

Other than the above-mentioned transporters and channels, several membrane proteins have been reported to be regulated by AMPK. These include a Na^+-coupled glucose carrier SGLT1[215] and an ATP-sensitive K^+ (K_{ATP}) channel.[216]

Other Factors Linking Transport and Cellular Metabolism

ATP-Sensitive Cation Channels

ATP-sensitive K^+-channels (K^+-ATP channels), the activity of which are inhibited by micromolar to millimolar concentrations of ATP, contribute to the potassium balance by coupling cellular metabolism with K^+ transport.[217–219] Tsuchiya of the Welling laboratory identified K^+-ATP channel activity at the basolateral membrane in the PT, which is a major determinant of the macroscopic K conductance.[220] The open probability of K^+-ATP channel determined by the intracellular ATP concentration altered the extent of K recycling: a decrease in intracellular ATP by stimulation of Na^+, K^+-ATPase activity increased the macroscopic K conductance, and intracellular ATP loading uncoupled the response. Wang and Giebisch demonstrated the effect of ATP on the small-conductance potassium channel in the apical membrane of CCD using the patch-clamp technique.[221] A dual effect of ATP was observed: low concentrations of ATP (0.05−0.1 mM) restored channel activity in the presence of cAMP-dependent PKA, while high concentrations of ATP (1 mM) and ADP (1.2 mM) blocked it completely. The dual effect of ATP was explained by assuming: (1) ATP-dependent PKA-mediated phosphorylation of the potassium channel under physiological conditions; and (2) direct inhibitory action of high concentrations of ATP on the channel activity. ATP-sensitive K^+ channels, the open probability of which was downregulated by ATP concentrations greater than 0.1 mmol/l, were also identified in the TAL.[222] These studies indicate that ATP acts as a coupling modulator between cellular metabolism and K^+-ATP channel activity, and regulates the transepithelial transport of K^+. Tsuboi and co-workers investigated the molecular effect of ATP on a Kir6.2, a K^+-ATP channel. ATP inhibits the channel activity by binding to a specific site formed by the N- and C-termini of the pore-forming subunit. The structural changes associated with the interaction of ATP with Kir6.2 were as follows: (1) the interaction between the N- and C-terminal domains was altered; (2) both intra-subunit and intersubunit interactions were probably involved; (3) ligand binding and not channel gating was affected; and (4) these effects occurred in intact cells when subplasmalemmal ATP concentrations changed in the millimolar range.[223]

The regulation of cation transport by intracellular ATP was also identified in a stretch-activated nonselective cation channel in the basolateral membrane of the PT.[224] This cation channel is primarily regulated by stretching (membrane deformation), depolarization, and hypotonic swelling. In addition, intracellular ATP reversibly blocks this cation channel (Ki approximately 0.48 mM). Thus, this cation channel activity is coupled to the metabolic state of the cell, particularly when intracellular ATP is depleted, as occurs during increased transepithelial transport or ischemia.

Purinergic Receptors

ATP and its metabolites, ADP, UTP, and UDP, act as extracellular signaling molecules via purinergic P2 receptors.[225–227] ATP is readily released from epithelial cells across their luminal membrane when the cells are damaged by ischemia or the toxic effects of exogenous compounds. ATP released from the cells is metabolized by ecto-nucleotidases, and thereby acts on the epithelial cells as paracrine and autocrine regulators. Mammalian P2 receptors are subdivided into P2Y (G-protein-coupled) and P2X (ligand-gated channels). In the kidneys, P2 receptors are expressed both in the basolateral and luminal membranes, and induce a variety of biological effects. In the distal nephron, luminal nucleotides inhibit Ca^{2+} and Na^+ absorption and K^+ secretion via the $P2Y_2$ receptor. In steroid-sensitive cells, luminal ATP/UTP inhibits epithelial Na^+ channel-mediated Na^+ absorption. Adenosine generated by ecto-nucleotidases may introduce further effects on ion transport, often opposite to those caused by ATP. Bailey demonstrated that activation of the $P2Y_1$ receptor impairs acidification in the PT through inhibiting the reabsorption of bicarbonate.[228] As well as having effects on solute transport, P2 receptors also modulate cellular metabolism. Cha and Endou demonstrated that renal gluconeogenesis was increased via P2Y stimulation.[229] The suggested functions of luminal P2 receptors include: (1) an epithelial "secretory" defense; (2) the regulation of cell volume when transcellular solute transport is out of balance; and (3) autocrine/paracrine regulators mediating cellular protection and regeneration after ischemic cell damage.[225]

Nephrons are also equipped with adenosine/P1 receptors, which have been further subdivided into

four subtypes, A1, A2A, A2B, and A3, all of which couple to G-proteins.[226] Adenosine is produced by biochemical reactions, and by the extracellular cAMP-adenosine pathway, in which cAMP effluxed from cells is converted to adenosine by the serial actions of ecto-phosphodiesterase and ecto-5′-nucleotidase.[230] Adenosine modulates Na^+,K^+-ATPase via A1 and A2 adenosine receptors.[231]

Nitric oxide (NO)

In the kidney, nitric oxide participates in several regulatory processes, including those for the glomerular and medullary hemodynamics, the tubuloglomerular feedback, renin release, and the extracellular fluid volume.[232,233] NO is formed from L-arginine by NO synthases (NOSs), a family of related enzymes encoded by separate unlinked genes. Three isoforms of NOS, i.e., nNOS (or NOS I), eNOS (or NOS III), and iNOS (or NOS III) were shown to be expressed in the kidney with distinct localization.[232,234] NO affects transporters and channels, such as Na^+,K^+-ATPase, NHE3, NKCC2, H^+-ATPase, and K^+-channels, in a segment-specific manner.[233] For examples, NO inhibited Na^+,K^+-ATPase in PT cells, while it did not change Na^+,K^+-ATPase activity in the TAL and CCD.[233] NO also affects mitochondrial QO_2. Granger and Lehninger initially observed an inhibition of mitochondrial electron transport in a murine cell line exposed to endotoxin-stimulated macrophages,[235] and subsequently NO was suggested to mediate this phenomenon.[236] NO inhibits QO_2,[237] and conversely nitro-L-arginine, a NO synthesis inhibitor, increases QO_2.[238] The inhibitory effect of NO on QO_2 appears to occur reversibly through the direct inhibition of the mitochondrial electron transport chain.[239,240] Adler et al. investigated the effects of renal NO production on QO_2 using eNOS KO mice.[241] Basal QO_2 in the renal cortex was higher in eNOS KO mice than in the heterozygous control mice. NO production stimulated by bradykinin or ramiprilat decreased QO_2 to a lesser extent in eNOS KO mice than in the control mice. These results indicate that NO production via eNOS regulates the renal QO_2. Laycock and colleagues indicated that NO plays a role in maintaining a balance between QO_2 and sodium reabsorption in the dog.[242] The administration of nitro-L-arginine decreased sodium reabsorption, and increased renal QO_2.

PATHOPHYSIOLOGICAL STATES IN ENERGY PRODUCTION IN THE KIDNEY

Pathophysiological states, in which energy production is inhibited, lead to significant alterations in renal function. In this final section, we focus on these pathophysiological states.

Mitochondrial Cytopathies

Mitochondrial cytopathies are metabolic diseases caused by mutations in nuclear DNA or mitochondrial DNA encoding the proteins involved in the mitochondrial oxidative chain. These genetic lesions alter mitochondrial oxidative phosphorylation, with a reduction in energy produced for cell activity.[243] The manifestation of mitochondrial cytopathies occurs in tissues where energy requirement is high, such as skeletal muscle and brain. Given the high energy utilization in the kidney, it is not surprising that mitochondrial cytopathies cause dysfunction of renal transport, and various renal involvements in mitochondrial diseases have been reported.

In most cases of Fanconi syndrome, a generalized dysfunction of proximal tubular cells results in glucosuria, aminoaciduria, and phosphaturia.[244–249] In patients manifesting Fanconi syndrome, defects in complex IV (CCO) activities are most commonly detected.[247] Bartter syndrome,[250] acute renal failure,[251] chronic renal failure,[252] and chronic tubulointerstitial nephritis[253,254] were also reported. The renal tubule in patients with mitochondrial disease may be susceptible to renal hypoxic injury and acute renal failure. In the renal tissues of patients with mitochondrial cytopathies, giant and degenerated mitochondria are observed by electron microscopy.[255,256] Glomerular involvement was occasionally reported.[245,257–261]

Renal Ischemia

Ischemia-induced renal dysfunction involves multifactorial events, and there are two effects regarding tubular damage due to ischemia: effects that occur during ischemia; and those occurring during reperfusion (reoxygenation), although these two factors are not always separable.[262] If the ischemic damage is severe, tubular cells undergo necrosis and/or apoptosis.

Necrosis is characterized by the progressive loss of cytoplasmic membrane integrity, rapid influx of Na^+, Ca^{2+}, and water due to the disturbance of several ATP-dependent ion channels, which results in cytoplasmic swelling, the disruption of the actin cytoskeleton, nuclear pyknosis, and eventual collapse of the cells.[263,264] Necrosis is considered to be mediated by ATP depletion,[265] the redistribution of Na^+,K^+-ATPase,[266] an increase in free cytosolic Ca^{2+},[267] reactive oxygen species generation,[268] and activation of several enzymes, such as proteases, phospholipases,

and endonucleases. Apoptosis is a highly coordinated process mediated by active intrinsic mechanism or extrinsic factors.[264]

Both apoptosis and necrosis occur simultaneously in acute renal failure (ARF),[269] and the relative contribution of the two mechanisms depends on the severity of the injury and the cell type.[270] Lieberthal et al. investigated the effect of graded ATP depletion ranging from 2 to 70% of control levels induced by either antimycin or 2-deoxyglucose in mouse PT cells.[271] The cells subjected to ATP depletion to less than 15% of the control level developed necrosis uniformly. In contrast, the cells subjected to ATP depletion to between 25 and 70% of control levels developed apoptosis. A narrow range of ATP depletion exists (15 to 25% of control level), representing a threshold that determines whether cells die by necrosis or apoptosis. The degree of cellular GTP depletion plays also a crucial role in determining the mode of cell death.[272]

ATP Depletion during Acute Ischemia and its Consequence

After one minute of ischemia, whole kidney ATP content decreased by 70%,[273] and after 10 minutes renal ischemia ATP levels fall quickly to less than 10% of control values.[274] During ischemia, tubular cells should maintain ATP content by anaerobic metabolisms, and the vulnerability of each nephron segment depends partly on the glycolytic properties. The S3 (PST) segment of the PT is extremely susceptible to ischemic injury, because of its low glycolytic capacity, and severe ATP depletion leads to necrotic cell death in this segment. In the rabbit PT, hypoxia (1% O_2) induced lactate production, whereas anoxia (0% O_2) failed to stimulate glycolysis. The addition of ouabain during rotenone treatment reduced lactate production by 50%, indicating that glycolytic ATP can be used to fuel the Na^+,K^+-ATPase when mitochondrial ATP production is inhibited. In addition, this study suggested that mitochondrial inhibition is not obligatorily linked to the activation of glycolysis.[275]

Weinberg and colleagues investigated anaerobic metabolism other than glycolysis in the PT during ischemia.[276,277] A severe mitochondrial energy deficit in the PT subjected to hypoxia/reoxygenation was prevented, and reversed by supplementation with α-ketoglutarate (α-KG) and aspartate. The anaerobic metabolism of α-KG and aspartate generated ATP, and maintained the mitochondrial membrane potential. Malate and fumarate were also effective singly or in combination with α-KG, while succinate showed a protective effect only during reoxygenation. In other studies, Weinberg and co-workers further demonstrated that the events upstream of complex I are important for the energetic deficit in the PT during hypoxia.[278]

The TAL possesses a relatively greater glycolytic capacity than the PT, and is less vulnerable to ischemic injury.[279,280] In a suspension of rabbit MTAL under anoxic conditions, anaerobic metabolism maintained 73% of cellular ATP during 10 minutes of anoxia, and exposure of anoxic tubules to iodoacetate, an inhibitor of glycolysis, resulted in a 57% decline in ATP levels, indicating that glycolysis is an important pathway in supplying energy during anaerobiosis in MTAL.[149] The cellular damage of the TAL by ischemia is influenced by cellular transport. The TAL develops a specific structural lesion during perfusion of the isolated rat kidney. The fraction of the TAL showing severe damage was reduced by furosemide, but not by acetazolamide, and the lesion was also eliminated by perfusion with ouabain or by preventing glomerular filtration.[281]

Mitochondrial Injury during Reperfusion

It is known that cell death following ischemia-reperfusion is closely related to functional changes in the mitochondria. Liu et al. revealed that apoptotic programmed death is associated with the release of cytochrome c (cyt c) due to caspase (cysteinyl aspartate-specific proteinase) activity.[282] Cyt c release is dependent on the site and the type of mitochondrial injury. Isolated mouse PT was subjected to mitochondrial oxidative phosphorylation inhibitors, rotenone and antimycin A or hypoxia. Antimycin A caused a significantly higher level of cyt c release from the PT than rotenone or hypoxia.[283] The efflux of cyt c and other apoptosis-related compounds, such as apotosis-inducing factor (AIF) and pro-caspases-2, -3, and -9, is mediated by the disrupted mitochondrial membrane or MPT (mitochondrial permeability transition).[284] Although the precise molecular mechanism of MPT remains to be elucidated, MPT occurs by a multiprotein channel composed of a voltage-dependent anion channel (VDAC), which comprises a nonselective channel for any substances with a molecular mass less than 15 kDa,[285] and adenine nucleotide translocase (ANT).

ATP depletion causes an increase in cellular free Ca^{2+},[286,287,288] and this phenomenon causes mitochondrial injury and apoptosis in renal tubular cells. Tanaka and colleagues demonstrated that voltage-dependent Ca^{2+} channels are involved in cellular and mitochondrial accumulation of Ca^{2+} due to ATP depletion.[289]

Chronic Ischemia

Recently, accumulating evidence has emphasized the effects of chronic hypoxia on renal structure and function.[290] In the advanced stage of renal dysfunction with tubulointerstitial damage, peritubular capillaries

are lost, and the development of interstitial fibrosis decreases oxygen diffusion to tubules. As a consequence, nephron segments are exposed to chronic hypoxia, and this in turn exacerbates renal insufficiency. Diffuse cortical hypoxia was demonstrated in the puromycin aminonucleoside-induced nephrotic syndrome and focal and segmental hypoxia in a remnant kidney model.[291]

When cells are exposed to hypoxia, the activation of hypoxia-inducible factor-1 (HIF-1) occurs, which is a primary defensive mechanism against hypoxia.[292,293] HIF-1 transcriptionally regulates many factors associated with hypoxia, such as the increased expression of VDGF,[294] erythropoietin,[295] a glucose transporter (Glut-1),[296] and PGK,[297] thereby chronic hypoxia alters the cellular transport and metabolism via HIF-1 activation. It is suggested that the induction of the HIF signal, which adapts the renal cells to hypoxia, may be a therapeutic option against the development of renal dysfunction.

Nephrotoxicants

Several nephrotoxic drugs, such as certain cephalosporins,[298] tacrolimus and sirolimus,[299] cadmium metallothionein,[300] probenecid,[301] prednisolone and azathioprine,[302] and cyclosporine A,[303] were shown to impair mitochondria and cellular metabolism. Ochratoxin A, a mycotoxin, also inhibits mitochondrial oxidative phosphorylation in the PT.[304] In contrast, enalapril and losartan attenuate mitochondrial dysfunction.[305]

A Novel Technology Analyzing Renal Blood Oxygenation

Recently, a novel technique called the Blood Oxygen Level-Dependent (BOLD) MRI method has been applied to renal physiology. The BOLD MRI method measures blood deoxyhemoglobin, and indirectly estimates intrarenal oxygenation in a noninvasive fashion, allowing sequential measurements in humans as well as animals in response to a variety of physiological or pharmacological stimuli with high reproducibility.[306,307] The effects of diuretics on renal oxygenation were investigated using the BOLD method. Furosemide, but not acetazolamide, increased medullary oxygenation by inhibiting active transport and QO_2 in the medullary thick ascending limb, consistent with their separate sites of action in the nephron.[308] The effect of furosemide on medullary oxygenation was absent or slight in an elderly human population.[309] Moreover, the BOLD method was applied to changes in intrarenal oxygenation in a variety of pathophysiological states, such as an acute reduction in RBF,[310] the diabetic state,[311] and the administration of NO synthase inhibitor.[312] BOLD-contrast imaging appears to predict the tissue at risk from ischemia by revealing information on the balance between tubular workload and delivery of oxygen.[311] Refined methods with improved visualization and more precise quantification have been developed.[313]

CONCLUSIONS

Most of the energy produced in the kidney is primarily utilized for the active reabsorption of Na^+, which further drives the cellular and paracellular transport of water and solutes. Renal metabolism for energy production is regulated by transport activity, and conversely, transport is affected by the cellular energy status. The intracellular adenine nucleotide level is an important regulatory factor for metabolism and transport; however, the interactions of these two processes are diverse and complex. For the last decade, AMPK was identified as the critical molecule for the regulator of cell metabolisms in various cells. Although the current information on its importance in the kidney is not abundant, emerging evidence has demonstrated its significance in the kidney, especially in energy metabolism in several solute transports. Other regulators, such as ATP-sensitive cation channels, NO, and purinergic receptors, should play some roles. Futher studies are required to elucidate the fine regulatory mechanisms for renal transport and cellular metabolisms. A novel methodology, BOLD MRI, will provide some progress in this field.

From pathophysiological viewpoints, the susceptibility of the kidney to ischemia and agents affecting energy production are critical clinical issues. Not only the role of acute ischemia, but also that of chronic ischemia in the kidney is now beginning to be a novel research subject.

INTRODUCTION

In this chapter we discuss electrophysiological approaches to the study of renal function. The purpose is to provide an overview of the available techniques, with particular emphasis on what can be learned using the latest methods. However, the chapter is neither a technical manual nor a comprehensive review of the literature. For this, we refer the reader to other sections of the book which deal with specific nephron segments and transport mechanisms. Finally, we will not derive mathematical equations from first principles. Those equations that are essential to the text are provided in the main body of the chapter, while the more detailed formulae are described in the appendices.

We have arbitrarily divided the field of epithelial electrophysiology into three major sections. The first describes measurements of transepithelial electrical properties. The second section focuses on the use of intracellular microelectrodes to discriminate apical and basolateral membrane properties. The final section deals with the technique of patch clamping to investigate the functional characteristics of individual ion channels, and in some cases their molecular identification.

The interpretation of electrical signals from epithelia is complicated by the geometry of the tissues. At least three structures within an epithelium contribute to its electrical properties: the apical plasma membrane; the basolateral plasma membrane; and the paracellular pathway. The individual cell membrane properties will, in turn, be determined by various conductive pathways, including those of passive or dissipative pathways, through which ions flow driven by their own electrochemical potential differences, and active transport, which can use metabolic energy to drive ions against these potential differences. The paracellular pathway, in turn, consists of the tight junctions connecting the epithelial cells and the lateral interspaces between the cells.

The electrical properties of this complex structure can be most easily understood in terms of equivalent circuits. A comprehensive equivalent circuit of a generic reabsorbing epithelium is illustrated in Figure 7.1. Electrolyte diffusion across the apical membrane can be separated into its constituent ionic pathways, as shown by the expanded view of the apical membrane in Figure 7.1. Each ionic pathway is associated with an electromotive force (EMF) or battery representing the chemical potential for each ion. Electrogenic carriers such as the Na-glucose co-transporter can also be represented by an additional resistor (R_{glu}) and EMF (E_{glu}) in parallel with the diffusional elements. All of the batteries and resistors can be lumped respectively into a single apical EMF (E_{ap}) and a single resistance R_{ap} as shown in the center diagram. The basal membrane has a similar set of elements: R_b and E_b which represent a dissipative ion pathway in parallel with an active transport pathway, represented by a resistor (R_{ap}) and an EMF (E_p). Thus:

$$E_x = -\frac{RT}{z_i F} Ln \frac{[X_1]}{[X_2]} \tag{7.1}$$

where $[X_1]$ and $[X_2]$ are the concentrations of ion X on the two sides of the membrane, and z_i is the charge on the

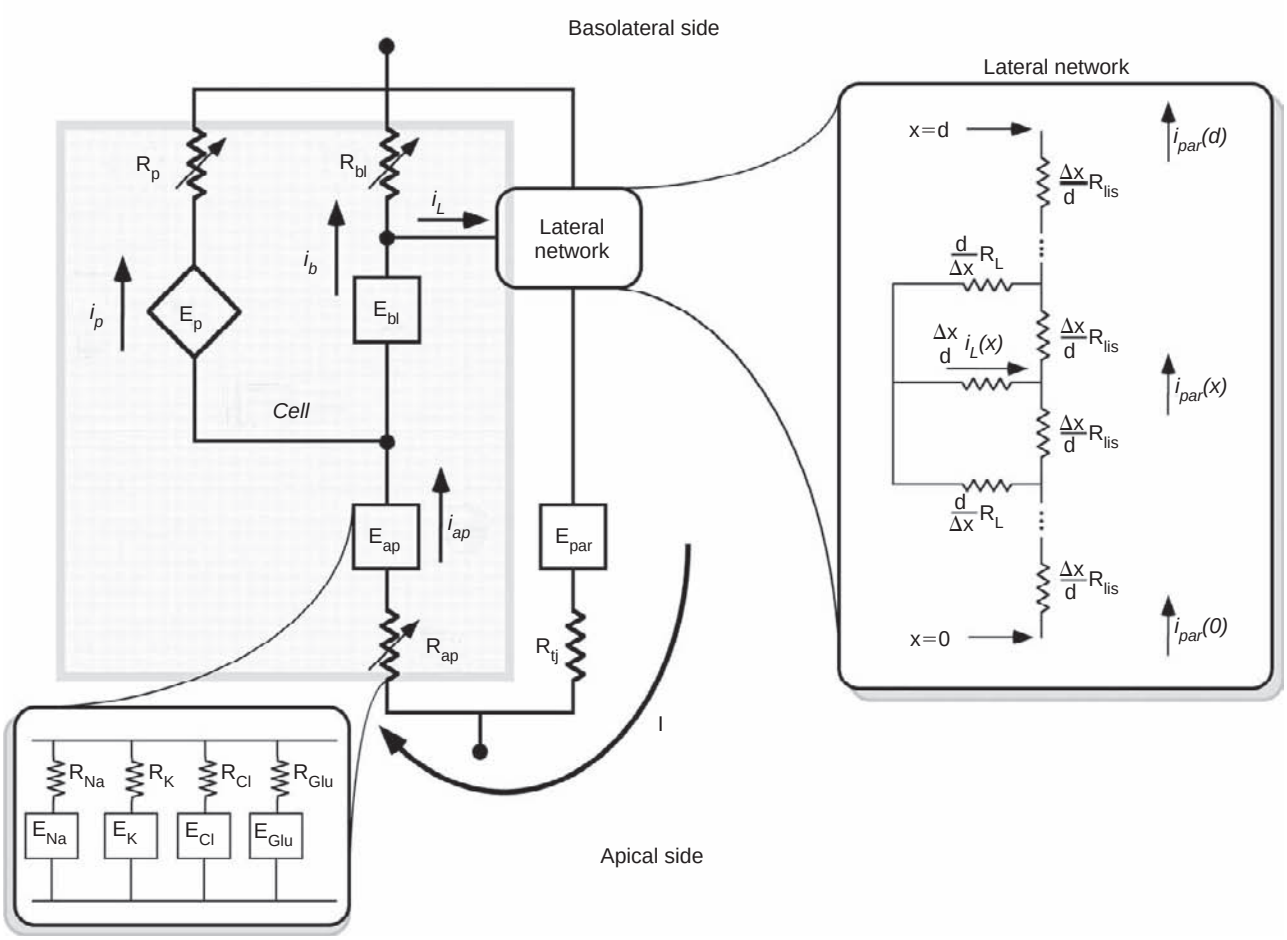

FIGURE 7.1 **Electrical equivalent circuit for a general epithelium.** Each membrane or barrier is associated with an electromotive force (**E**) that represents the weighted average of the ionic diffusion potentials at that barrier. Electrogenic carriers (such as the apical Na-glucose co-transporter) and electrogenic pumps (such as the basolateral Na,K-ATPase) can also be formally represented by a series resistor and an associated EMF. The lateral network takes into account the nonzero electrical resistance of the lateral intercellular spaces.

ion. The weighting factor for each ion is the transference number, t_x, which expresses the fraction of membrane conductance that is attributable to that particular ion:

$$t_x = \frac{g_x}{g_{tot}} \tag{7.2}$$

where g represents the conductance of the individual ion pathways and g_{tot} is the total ionic conductance of the membrane. In most cases g_{tot} will simply be the sum of the Na, K, and Cl conductances of the barrier. Hence, the total EMF can be generally expressed by the equation:

$$\begin{aligned} E &= t_{Na}E_{Na} + t_K E_K + t_{Cl}E_{Cl} \\ &= -\frac{RT}{F} \sum_{x=Na,K,Cl} \frac{t_x}{z_x} Ln \frac{[X_1]}{[X_2]} \end{aligned} \tag{7.3}$$

The overall goal of classical electrophysiology, described in the first two sections of this chapter, is to evaluate the different elements of this equivalent circuit, to quantify the various resistances and EMFs, and to describe the extent to which they change during regulation. To this end, it has often been desirable to use reductions of the main equivalent circuit of Figure 7.1, and to work under conditions in which these reduced circuits are applicable. Such simplifications are discussed in more detail in the sections entitled, "Transepithelial Measurements" and "Intracellular Measurements." Finally, the section entitled, "Measurements of Individual Ion Channels" describes application of the patch clamp technique to epithelia, and permits a description of ion transport in more molecular terms.

The rationale for representing the pump by a resistance and an EMF is discussed further in the section entitled "Intracellular Measurements." Briefly, the E_p represents the maximum amount of energy that the pump derives from splitting ATP or, alternatively, the maximum electrochemical potential difference against which the pump can operate. The pump pathway

must also include a non-zero internal resistance. The magnitude of this internal resistance is determined by the actual current–voltage relation for the membrane bound Na-K-ATPase. To maintain generality, all membrane resistances are shown as variable resistors to include the possibility of intrinsic or extrinsic regulation of ion channels.

Although the paracellular pathway is not a membrane barrier, it can also be modeled by resistive (R_{tj}) and electromotive elements (E_{par}). A lateral network (indicated to the right of the main circuit) is also included in the model. This network takes into consideration the finite resistance of fluid in the lateral spaces. This aspect of the circuit becomes important for calculation of individual membrane resistances from voltage deflection experiments (see Section entitled "Intracellular Measurements").

TRANSEPITHELIAL MEASUREMENTS

Measurements of transepithelial electrical properties are by far the simplest to perform, and the most difficult to interpret. They are easy to carry out because they are non-invasive; only extracellular electrodes are employed. They are difficult to interpret because the parameters which can be measured reflect, in most cases, a combination of many of the circuit elements shown in Figure 7.1. In this chapter we will describe how transepithelial techniques are used to measure three basic parameters that characterize an epithelium: transepithelial voltage; transepithelial resistance; and short-circuit current. We will then discuss a number of special extracellular approaches which have been employed to gain additional insights into epithelial properties.

Measurement of Transepithelial Voltage

Methods of measuring transepithelial voltage (V_{te}) are conceptually simple. In principle, the potential difference between two electrodes placed on either side of the epithelium is simply determined with an appropriate electrometer. With flat epithelia that can be mounted in Ussing chambers, the transepithelial electrodes are placed in the two bathing compartments.[1] In cylindrical epithelia such as the renal nephron, classical measurements of transepithelial potential have been performed *in vivo* using micropuncture techniques. In this technique, a pipette filled with electrolyte is introduced into the lumen of the tubule, and voltage is measured relative to another electrode placed in a capillary. Here, the presumption is that the voltage reflects the properties of the impaled tubule, and is not greatly influenced by those of neighboring segments. Under most conditions this should be a reasonable assumption. For a lumen of 10 μm diameter and an isoosmotic saline solution with a resistivity of around 60 Ω•cm, the axial resistance of the tubule will be about 8×10^7 Ω/cm. This is much larger than the value of the transepithelial resistance of around 100 Ω•cm^2 (Table 7.1), which for the same 10 μm lumen is equivalent to 3×10^4 Ω/cm. Thus, each part of the nephron will be effectively electrically isolated from other parts of the high resistance of the luminal pathway. If the nephron segment can be isolated and perfused *in vitro*, the perfusion and/or collection pipette can be used to monitor the intraluminal voltage with respect to the bath potential. This is illustrated in Figure 7.2.

Measurement of Transepithelial Resistance

For measurements of transepithelial resistance (R_{te}), current must be injected across the epithelium to perturb V_{te}. This is most easily accomplished when the epithelium can be mounted in Ussing chambers, where current flow and voltage changes are assumed to be uniform in the plane of the tissue. Resistance can then be computed from Ohms law as the ratio of the change in V_{te} to the amount of current passed:

$$R_{te} = \frac{\Delta V_{te}}{\Delta I} \tag{7.4}$$

Epithelia can be studied in open-circuited or voltage-clamped conditions. In open circuit the tissue is allowed to maintain its spontaneous transepithelial voltage. In this case the resistance is determined from the change in voltage produced by passing a known amount of current. Under voltage-clamp conditions a current is passed across the epithelium to maintain the transepithelial voltage at a predetermined level. In the case where this level is zero, so that the transepithelial voltage is abolished, it is called the "short-circuited" state. If the epithelium is voltage-clamped, resistance is determined from the change in current produced by a controlled voltage step. In open-circuited tubular epithelia, transepithelial current flow is not constant along the length of the tubule. In this case, cable analysis must be used to estimate the transepithelial resistance (see below).

Measurement of Transepithelial Resistance in Open Circuited Renal Tubules

The measurement of overall transepithelial resistance, R_{te}, in renal tubules under open circuit conditions is best carried out with a double-barreled perfusion pipette system similar to the one illustrated in Figure 7.2. In this technique, the tubule is cannulated at both the perfusion and collection ends. The

TABLE 7.1 Transepithelial Properties of Renal Epithelia

Tissue	V_{te} (mV)	R_{te} (Ωcm^2)	R_{par} (Ωcm^2)	P_{Na}/P_{Cl}	Reference
Amphibians					
Proximal tubule (*Ambystoma*)	−10	70	70	0.25	4

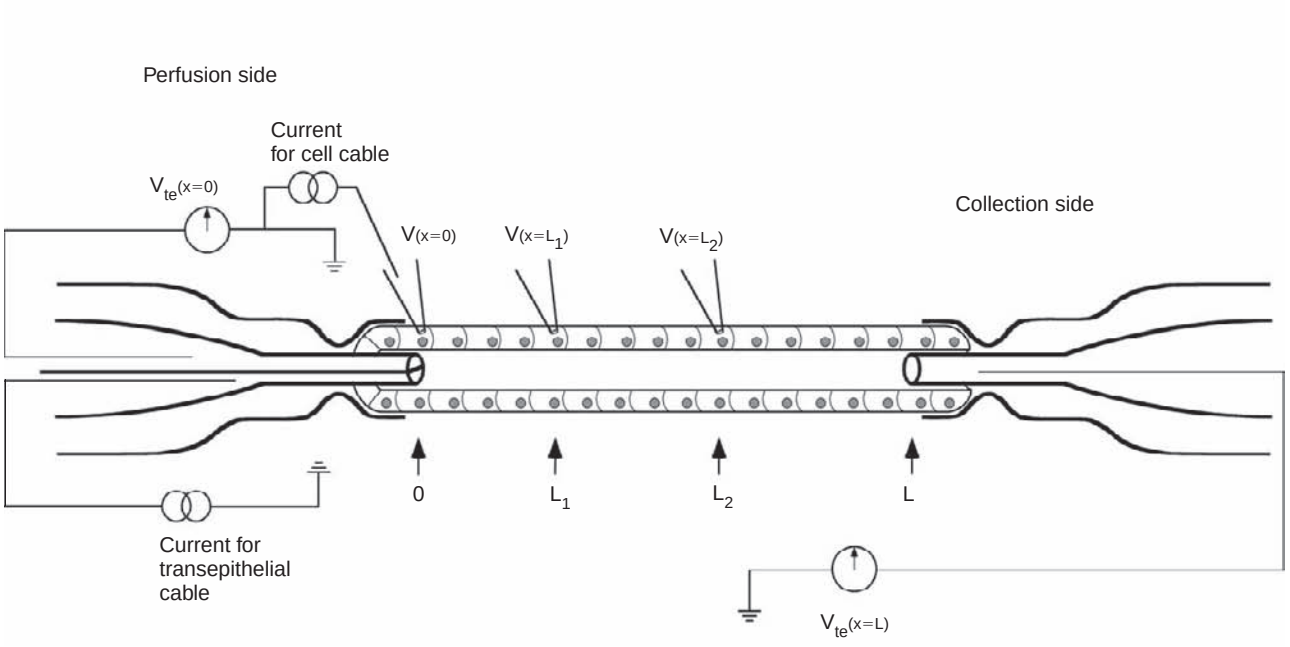

FIGURE 7.2 **Experimental apparatus for determining electrophysiological properties of renal epithelia.** The segment of isolated renal tubule is held at both ends by constriction pipettes. The tubule perfusion pipette is fabricated from "theta" glass and has separate pathways for both current injection and transepithelial measurement, $V_{te}(x = 0)$. The transepithelial potential, $V_{te}(x = L)$, can also be determined at the collection side of the tubule. For determination of cell membrane resistance, current is passed into the cell layer via the microelectrode at location $x = 0$ and the resultant voltage deflections are measured by intracellular microelectrodes at locations $x = 0$, L_1, and L_2.

double-barreled perfusion pipette, fabricated from *theta* glass[2–4] creates separate pathways for current flow and voltage recording. An alternative technique uses the same single-barreled pipette for both current injection and voltage measurement. This is not nearly as accurate as the double-barreled technique, because the voltage deflection arising from the internal resistance of the perfusion pipette must be nulled with a bridge circuit. The microelectrodes in Figure 7.2 are for evaluation of individual cell membrane resistances. This will be discussed in the section entitled, "Intracellular Measurements."

A thin fluid-exchange tubing (not shown) can be inserted into one barrel of the perfusion pipette of Figure 7.2 to permit rapid exchange of the perfusion solution while measuring the transepithelial potential $V_{te}(x=0)$. Current is passed from a chlorided silver wire glued into the other barrel of the pipette. The transepithelial length constant of the tubule λ_{te} is determined from the voltage deflections at the perfusion, $\Delta V_{te}(x=0)$, and collection, $\Delta V_{te}(x=L)$, sides of the tubule, resulting from a transepithelial current pulse, I_{te}, through the current side of the perfusion pipette. For a doubly cannulated, isolated tubule of length L, λ_{te} is given by Eq. (7.5) from Sackin and Boulpaep[5]:

$$\frac{L}{\lambda_{te}} = cosh^{-1}\left[\frac{\Delta V_{te}(x=0)}{\Delta V_{te}(x=L)}\right] \tag{7.5}$$

The transepithelial resistance R_{te} in Ωcm^2 is given by Eq. (7.6):

$$R_{te} = 2\sqrt{\pi \lambda_{te}^3 R_{in} R_i}\sqrt{tanh(L/\lambda_{te})} \tag{7.6}$$

In the above equation, R_{in} is the input resistance measured in ohms (Ω). It is operationally defined as the voltage deflection at the perfusion end $\Delta V_{te}(x=0)$ divided by the total injected current I_{te}. Typical injected currents for proximal tubules are 100 nA pulses of 1 to 5 seconds duration. Ideally, none of the current injected into the lumen from the perfusion pipette enters the compressed region of tubule within the holding pipette, which presumably acts like an electrical insulator when compared to the relatively low resistance of the tubule. However, artifacts may still arise from current leaks at either the perfusion or collection ends of the tubule. These can be detected by a "mismatch" between the calculated electrical radius (r_e) of the tubule and its measured optical radius (r_o).

$$r_e = \frac{2\, R_i \lambda_{te}^2}{R_{te}} \tag{7.7}$$

Use of a double-barreled perfusion pipette (Figure 7.2) eliminates much of the uncertainty in R_{in}. Double-barreled perfusion pipettes have the additional advantage that R_{te} can be measured during changes in the perfusion solution. This is practically impossible with a single-barreled perfusion pipette, because the bridge circuit is unstable during solution changes. Finally, the term R_i ($\Omega \bullet cm$) is the volume resistivity of the perfusion solution, as measured with a standard conductivity meter.

Measurement of Transepithelial Resistance in Voltage Clamped Renal Tubules

There have been a number of early attempts to elucidate the electrical properties of renal tubules using voltage clamp techniques similar to those originally developed for flat epithelia. The basis of these methods is to isolate a segment of tubule (usually with oil droplets) that is short enough to permit a uniform current distribution across the epithelium. To accomplish this, metallic axial electrodes are directly inserted into the lumen of the tubule.[6] These axial electrodes can also be used for AC impedance analysis.[7,50] However, one important problem with metal electrodes is the release of ions into a restricted space during continuous current flow.

An alternative technique employs segments of isolated, perfused tubules that have been shortened to such an extent that the current distribution within the lumen is virtually homogeneous.[8] In this case R_{te} is essentially determined from the input resistance according to Eq. (7.8):

$$R_{te} = 2\pi r_o L \cdot R_i \tag{7.8}$$

where r_o is the optical radius, and R_{te} has units of $\Omega \bullet cm^2$.

Typical Results

Measurements of V_{te} and R_{te} in some representative epithelia are shown in Table 7.1. The range of both these parameters is large, with values of V_{te} ranging from ± 2 mV in the proximal tubule to as much as -60 to -80 mV in the CCT. R_{te} values vary from less than 10 Ωcm^2 in proximal tubule to more than 5000 Ωcm^2 in urinary bladder. Despite the range of values observed, the transepithelial voltages in all cases reflect two factors: the conductance of the epithelium to the major ions and the active transport of ions. In general, a high value of V_{te} indicates that active transport is taking place across a high resistance epithelium, whereas low values of V_{te} can reflect either a low R_{te} or a low rate of active transport.

Traditionally, epithelia have been divided into the categories "tight" and "leaky," according to their transepithelial resistances. In leaky epithelia the low value of R_{te} is thought to largely reflect the low resistance of the tight junctions which constitute the major electrical resistance of the paracellular pathway between the epithelial cells.[9] In tight epithelia the tight junctional resistance, and therefore the transepithelial resistance, is much higher. However, the resistance above which an epithelium is considered "tight" is not precisely defined.[10] Even though the amphibian proximal tubule and the mammalian collecting duct have similar absolute values of paracellular resistance, the proximal tubule is considered a leaky epithelium, whereas the collecting duct is usually referred to as "tight." Thus, a better definition of a leaky epithelium is one in which the paracellular resistance is low relative to that of the cell membranes. For example, in Table 7.1 it can be

seen that in leaky proximal tubules R_{te} is virtually equal to R_{par}, which is small compared to the parallel transcellular resistance R_c. In tight epithelia R_{par} is significantly larger than R_{te}. This implies that R_{par} is of the same order of magnitude as R_c or even much larger in the case of the urinary bladder. Another feature of a tight epithelium is its ability to separate two fluid compartments with very different ion compositions. High resistance tight junctions slow the "backleak" of ions and other solutes down their concentration gradients. Thus, in a tight epithelium it is harder to dissipate the ion gradients established by active transport processes.

Interpretation of Measurements of V_{te} and R_{te}

As discussed above, transepithelial measurements of voltage and resistance are difficult to interpret because they lump together information from many different electrical pathways arranged in parallel. To analyze such data, it is often useful to use a simplified equivalent electrical circuit.

The terms R_c and E_c represent the resistance and electromotive forces across the transcellular pathway, whereas R_{ti} and E_{par} are respectively the resistance and electromotive forces across the paracellular pathway. If the potential differences V_{te}, E_c, and E_{par} are all defined with respect to the bath or serosal side, the overall measured transepithelial values R_{te} and V_{te} are related to this circuit by Eqs (7.9) and (7.10):

$$R_{te} = \frac{R_{tj}R_c}{R_{tj} + R_c} \tag{7.9}$$

$$V_{te} = \frac{E_cR_{tj} + E_{par}R_c}{R_{tj} + R_c} \tag{7.10}$$

The dissection of the measured parameters into the appropriate contributions from cellular and paracellular pathways can sometimes be accomplished by using maneuvers that affect only one of the pathways or cause one pathway to dominate the other. Some of these perturbations and special conditions will be discussed below.

Contribution of Active Transport to V_{te}

The major effect of the pump is to establish transmembrane ionic gradients, i.e., to keep cell Na low and cell K high. As was first pointed out by Koefoed-Johnsen and Ussing in their classic paper of 1958,[11] the permeability properties of the apical and basolateral membranes of the frog skin are quite different. Since the apical membrane is selectively permeable to Na, and the driving force for this ion is inward, the entry of Na will tend to make the cell voltage positive with respect to the mucosal solution. Conversely, the basolateral membrane is selectively permeable to K. This ion will tend to flow out of the cell, making the cell voltage negative with respect to that of the serosal fluid. The EMFs E_{ap} ($=RT/F\ \Delta\ln$[Na]) and E_{bl} ($=RT/F\ \Delta\ln$[K]) will be in the same direction with respect to the epithelium and the transepithelial EMF, and hence V_{te}, will reflect their sum (Figure 7.4).

Although the Na-K-ATPase is ultimately responsible for the transepithelial potential in many Na-reabsorptive epithelia, the magnitude of V_{te} does not correlate with the magnitude of active transport when different tissues are compared. In general, the effect of active ion transport will be shunted by the paracellular resistance. This shunting is least in the tight epithelia such as frog skin and toad urinary bladder, where V_{te} can be over 100 mV. In leaky epithelia such as the proximal tubule the shunting is considerable, and the values of V_{te} are much lower.

In leaky epithelia, E_{par} will be much smaller than E_c (Figure 7.3), since ion gradients across the tight junction are relatively small. In tight epithelia where ion gradients can be significant, $R_{tj} > R_c$ so that the term $E_{par}R_c$ will be small compared to E_cR_{tj}, and Eq. (7.10) becomes:

$$V_{te} = \frac{E_c}{1 + R_c/R_{tj}} \tag{7.11}$$

The implication of Eq. (7.11) is that if $R_{tj} >> R_c$, V_{te} will approach E_c, a quantity which is limited by the EMF of the Na-pump. In general, V_{te} will be reduced according to the ratio R_c/R_{tj}. The contribution of active transport to cell membrane potential is discussed in the section entitled, "Estimation of renal Na,K pump current and electrogenic potential."

The mammalian TALH, and its amphibian counterpart the diluting segment, have lumen-positive V_{te} despite the fact that they are also Na-reabsorbing epithelia (Table 7.1, Figure 7.4). This turns out to be the exception that proves the rule. As discussed in detail by Greger,[12] Na does not enter the TALH cell through a conductive mechanism, as in the frog skin and other epithelia, but through an

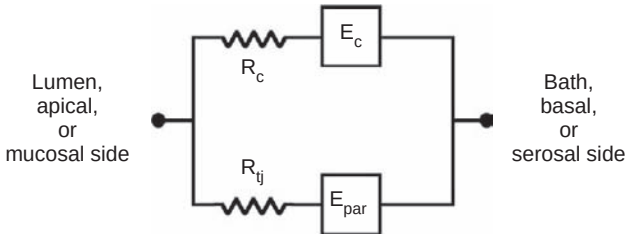

FIGURE 7.3 **Simplified equivalent electrical circuit for an epithelium.**

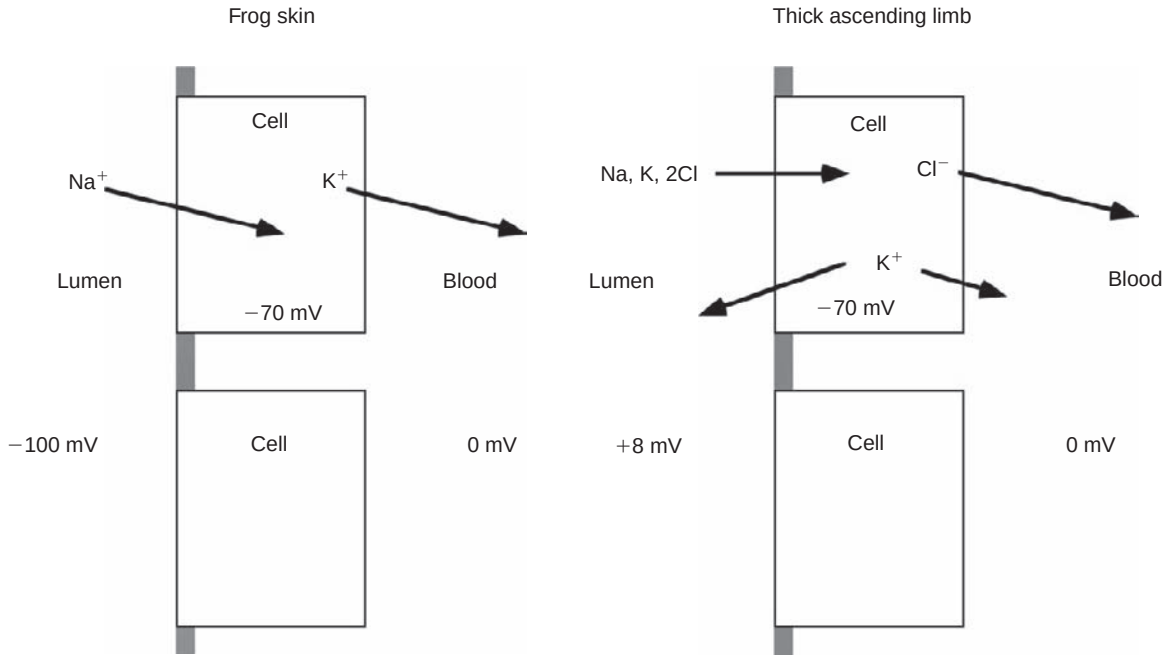

FIGURE 7.4 **Contribution of transcellular potentials to the transepithelial potential.** On the left is a tight epithelium such as the frog skin or cortical collecting duct (CCD). Influx of Na across the apical membrane and efflux of K across the basolateral membrane create a lumen-negative voltage which is not significantly shunted because of the high tight-junctional resistance. Consequently, most of the transepithelial potential arises from diffusion potentials for Na and K that are established across the cell membranes by active transport, and by the different ion-selectivities of the apical and basolateral membranes. The figure on the right is a model of a TALH cell. Here Na entry across the luminal membrane is electrically silent. The dominant electrodiffusive ion movements are K efflux across both apical and basolateral membranes, and Cl efflux across the basolateral membrane. The basolateral Cl conductance makes the cell less negative relative to interstitial fluid versus luminal fluid.

electrically neutral co-transport system along with K and Cl. Thus, Na entry does not contribute to a lumen-negative voltage, and in fact the membrane is more permeable to K than to Na. Furthermore, the basolateral membrane has a rather high permeability to Cl. This makes the lumped EMF E_{ap} less negative than E_{bl}, and the potential difference between the cell and the blood side is less negative than the potential difference between the cell and the lumen. Hence, the mechanism for the lumen-positive potential in the TALH is accounted for by the different permeability properties of the two membranes, just as in the frog skin.

Contribution of Diffusion Potentials to V_{te}

Paracellular diffusion potentials can contribute significantly to the overall transepithelial potential, especially when V_{te} is small. For example, in the mammalian proximal tubule the early portion of the segment has a lumen-negative V_{te} *in vivo*, which is thought to reflect active Na reabsorption. Farther down the nephron, however, the lumen becomes positive with respect to the blood. Preferential luminal reabsorption of HCO_3^- relative to Cl^- establishes opposing gradients for Cl^- and HCO_3^- across the tight junction (Figure 7.5). This results in a lumen-positive potential since Cl^- diffuses more rapidly across the junctions than HCO_3^-.[13]

Diffusion potentials may also contribute to the normal lumen-positive V_{te} in the mammalian TALH (Table 7.1). In this segment NaCl is reabsorbed but water is not, leading to a dilution of the luminal fluid. Since the tight junctions of the mammalian TALH are cation-selective, Na diffuses back more rapidly than the Cl, contributing to a lumen-positive diffusion potential[12] (Figure 7.5).

Contribution of Circulating Current to V_{te}

The different equivalent EMFs at the apical and basolateral sides of the cell produce a circulating current (I) which traverses both cell membranes in series, and returns via the paracellular shunt (Figure 7.1). The magnitude of this current depends on the relative resistances of paracellular versus cell pathways, as well as the active transport rate for the particular epithelium.[14,15] For example, in renal proximal tubules, the low shunt resistance (compared to transcellular resistance) characterizes this nephron segment as a leaky epithelia with large circulating current.[13,16] On the other hand, tight epithelia like the urinary bladder or the frog skin have shunt resistances comparable to or larger

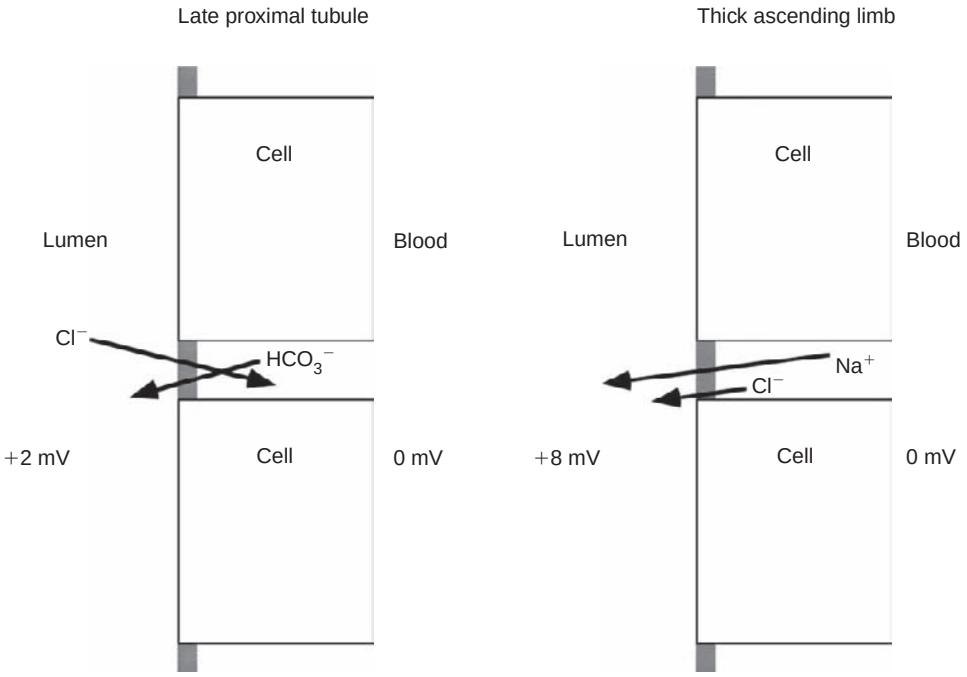

FIGURE 7.5 **Contribution of paracellular potentials to the transepithelial potential.** The figure on the left corresponds to the late proximal tubule. Preferential reabsorption of HCO_3^- in the early proximal tubule produces opposite gradients for Cl^- and HCO_3^- across the tight junction of late proximal tubule. Since the junctions are more permeable to Cl^- than to HCO_3^-, a lumen-positive diffusion potential develops. The paracellular contribution in the TALH is illustrated on the right. Here, reabsorption of NaCl across the water-impermeable epithelium results in an accumulation of NaCl within the interspaces between the cells, producing a similar gradient for both Na^+ and Cl^- across the tight junction. Since the junctions in this epithelium are more permeable to Na^+ than to Cl^-, a lumen-positive diffusion potential develops.

than the transcellular resistance, so that the circulating current is small in comparison with proximal tubule.[17]

The effect of circulating current on renal transepithelial potentials can be understood qualitatively by considering the electrical profiles depicted in Figure 7.6. In this figure, the serosal or blood side of the epithelium is considered at ground and the voltage at any point is displayed as a function of distance from mucosa to serosa. For the sake of simplicity, we have assumed that the apical membrane is primarily selective to sodium, the basolateral membrane is primarily selective to potassium, and the interior of the cell is isopotential. Therefore, in the absence of circulating current, there is a "staircase" voltage profile through the epithelium determined by the respective diffusion potentials across the mucosal (or apical) membrane and across the serosal (or basolateral) membrane (Figure 7.6a). Under these conditions the measured V_{te} (mucosa minus serosa) would actually be more negative than the basolateral cell membrane potential (E_K).

In most epithelia the diffusion potential steps of Figure 7.6a would be modified by the effect of circulating current (I) across the resistance of the mucosal and serosal barriers. Specifically, the mucosal to cell step will be raised by an amount: $I \bullet R_{ap}$ due to the circulating current crossing the mucosal membrane resistance (Figure 7.6b). The same current crossing the basolateral side of the cell will decrease the size of the cell-to-serosal step by $I \bullet R^*_{bl}$, where R^*_{bl} is the effective basolateral resistance. The final values of V_{te} and V_{bl} can be calculated by considering the complete equivalent circuit (Appendix 7.1).

In most epithelia, the resistance of the apical membrane is larger than the resistance of the basolateral membrane, and the effect of the circulating current is to transform the staircase potential (Figure 7.6a) into a "well-type" potential (Figure 7.6c), where the intracellular region is the most negative space and V_{te} is directly dependent on the magnitude of the current and the tightness of the epithelial cell layer. In some tight epithelia (*Necturus* urinary bladder) with high paracellular resistance and low circulating current, the "staircase" potential profile is still maintained despite "IR drops" at both membranes.[18]

Short-Circuit Current

It is also possible to measure transepithelial currents while controlling the transepithelial voltage. A special case of this voltage-clamp approach is the short-circuit current technique[1] in which V_{te} is maintained at zero.

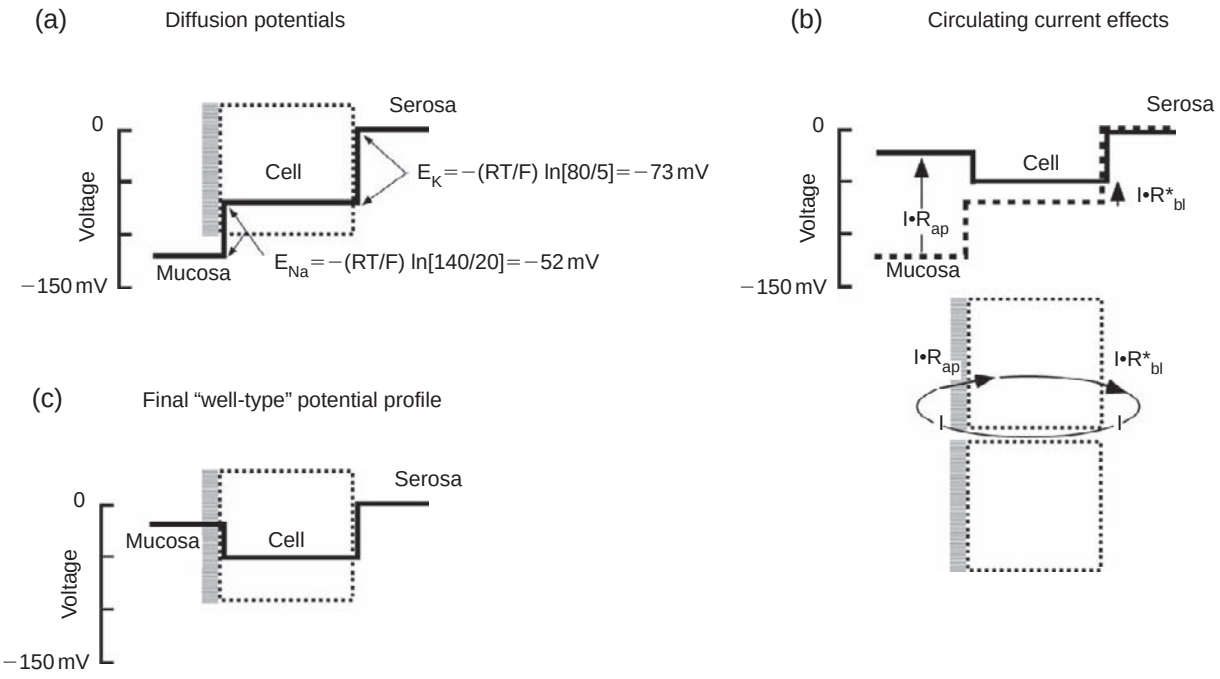

FIGURE 7.6 **Electrical potential profiles across a simple epithelium.** (a) In the absence of circulating currents, the electrical potential from serosal to mucosal sides would be largely determined by the Na diffusion potential at the apical membrane, and the K diffusion potential at the serosal membrane. (b) Circulating currents that arise from a net (open-circuit) EMF produce additional voltage drops across both the apical membrane ($=I \bullet R_{ap}$) and across the basolateral membrane ($=I \bullet R_{bl}$). (c) This changes the "staircase" potential profile to a "well-type" potential, where the cell is more negative than either the mucosal or serosal sides.

If the solutions on both sides of the epithelium are identical, there is no net movement of ions through the paracellular spaces, since both electrical and chemical driving forces are reduced to zero. The current across the tissue, which must also pass through the external circuit and can thus be readily measured, results only from active transport processes (defined as those which take place against an electrochemical activity gradient). Thus this current (called the short-circuit current), will equal the sum of all active ion transport processes.

The particular ion being actively transported can be identified rigorously by measuring net fluxes at the same time as the short circuit current. For some cases, such as the frog skin and toad bladder,[19,20] the short-circuit current can be accounted for by the active transport of only one ion species, namely Na (Table 7.2). In general, the short-circuit current will represent the sum of the net transport of Na, K, H, Cl, and HCO_3. Another way to identify actively transported ions is to eliminate them from the bathing media and measure the resulting effects on short-circuit current. This approach is often experimentally much simpler, but it is less rigorous since the apical and basolateral solutions will not be identical. Furthermore, changing the external environment of the tissue can lead to secondary changes in cell composition and volume. In any case, once the transported species have been identified, the technique becomes a very convenient way to analyze the regulation of the active transport systems.

TABLE 7.2 Equivalence of Net Na + Fluxes and Short-Circuit Current in Model Epithelia, Transepithelial fluxes (nEq/cm^2/min)

Type of Epithelium	Mucosal to Serosal	Serosal to Mucosal	Net	Short-circuit Current
Frog skin	24.6	1.5	23.1	23.6
Toad urinary bladder	35.7	9.5	26.2	26.8

Data are from [1] for frog skin and from [19] for toad bladder.

An important limitation of the short-circuit current technique is that it often requires unphysiological conditions. For example, short-circuiting high resistance epithelia like frog skin will reduce the normally large V_{te} to values near zero. This will necessarily affect the transmembrane voltage of one or both cell membranes, which may in turn affect the ionic conductances of those membranes.

The short-circuit technique also involves bathing the apical side of the tissue with a solution that has an electrolyte composition close to that of the blood. This is a highly unphysiological condition for many tight epithelia like the frog skin, which is normally in contact with pond water, and the toad bladder, which is

normally in contact with dilute urine. Another important problem with short-circuit experiments is that short-circuited tissues do not have to maintain the electroneutrality of the transported species. For example, in Na-transporting epithelia, such as the frog skin, Na ions can be reabsorbed only if another cation (e.g., K, H) is secreted or if an anion (Cl) is also reabsorbed. Under physiological conditions these other ionic pathways can be rate-limiting for Na reabsorption.

Finally, the uniform current distribution required by the short-circuit technique has largely restricted its use to flat epithelia which can be mounted in Ussing chambers. However, in some cases it has been possible to voltage-clamp large-diameter amphibian tubules.[21] Attempts have also been made to circumvent these technical problems by defining an "equivalent short-circuit current" for renal epithelia. In this method, the current at $V_{te} = 0$ is estimated by dividing the spontaneous value of V_{te} by the transepithelial resistance R_{te}. This approach assumes that R_{te} is constant; i.e., that the current voltage relation of the epithelium is linear. Even when this condition is satisfied, it is not always possible to attribute the equivalent short-circuit current to specific ion species, since net fluxes of the ions must be measured under true short-circuited conditions.

Technical Problems

For epithelia that can be studied as flat sheets *in vitro*, the major technical problem with transepithelial measurements is avoiding edge damage to the tissues, particularly when these tissues are mounted in Ussing chambers.[22,23] On the other hand, for renal micropuncture experiments performed *in situ*, the major technical problem is localization of the microelectrode tip within the tubular lumen.[13]

The most important general problem in the measurement of transepithelial resistance is the choice of the magnitude and duration of the applied perturbations. Currents (or voltage changes) which are too large can result in changes in the electrical properties of the membranes due to voltage-dependent ion conductances. Perturbations which are either too large or too long can lead to redistribution of ions across the cell membranes, which can also alter electrical properties. For example, in toad urinary bladder modest changes in V_{te} in the order of 10 mV under voltage-clamp conditions can result in time-dependent changes in the tissue resistance.[24] On the other hand, if perturbations are too small they are difficult to measure accurately, and if they are applied for too short a time the capacitative, as well as the resistive, properties of the epithelium will affect the response. There are no generally accepted rules for determining the size and duration of the perturbations.

Estimation of Membrane Parameters from Transepithelial Measurements

Measurement of transepithelial electrical properties does not, in general, give any direct, quantitative information about the circuit elements of greatest interest, namely the conductances of individual membranes to specific ions. As emphasized throughout this section, R_{te} is a lumped parameter determined by R_{ap}, R_b, R_{tj}, and in some cases R_{lis} (see Figure 7.1). V_{te} is determined by all the R_s and EMFs in the circuit. Clearly, measuring two parameters is insufficient to determine seven or eight unknowns.

However, in some cases it has been possible to either use conditions which simplify the equivalent circuit or to use experimental perturbations that selectively change only one electrical parameter. These methods have provided a good deal of information about epithelial properties from purely transepithelial measurements. Some examples are given below.

Paracellular Resistance and Selectivity

When the paracellular (tight junction) resistance is low compared to the transcellular resistance, the transepithelial resistance is dominated by the resistance of the paracellular pathway. This happens in a leaky epithelium like the proximal tubule. This condition can also be produced in some tight epithelia by blocking the major conductive pathways at the apical membrane. The most frequently used blockers are amiloride, for the Na conductance, and Ba, for the K conductance. In both of these cases the paracellular resistance can then be estimated from transepithelial measurements (Table 7.1), although intracellular recordings are usually required to prove that the transcellular resistance is high.

The ion selectivity of the paracellular pathway can also be evaluated under these circumstances. This involves measurement of the transference numbers for various ions across the tight junction (see Eq. (7.12)). The most important ions in this case are Na and Cl, and their transference numbers can be estimated by reducing the concentration of NaCl on one side of the junction by diluting one of the bathing solutions. If the transcellular resistance is sufficiently high (i.e., $R_{ap} >> R_{tj}$, see Eq. (A2.3) in Appendix 2) and is unaffected by the dilution, the measured change in V_{te} will approximately reflect the change in E_{par} where:

$$\Delta E_{par} = -\frac{RT}{F}(t_{Na} - t_{Cl}) Ln \frac{[NaCl]_1}{[NaCl]_2} \qquad (7.12)$$

If sodium and chloride are the only conducting ions in the external solutions, the absolute transference numbers can be calculated from Eq. (7.12) and the requirement that $t_{Na} + t_{Cl} = 1$. Some measurements of

paracellular selectivity in renal epithelia are listed in Table 7.1. This parameter is of considerable physiological interest. The results range from a significant selectivity for anions (Cl) over cations (Na) in the amphibian proximal tubule, to a cation selectivity in the thick ascending limb of Henle's loop or its counterpart, the diluting segment, in the amphibian kidney. If ions moved through the tight junctions as if they were in free solution, a permeability ratio P_{Na}/P_{Cl} of 0.8 would be expected. The variations in selectivity result from differences in the expression of specific members of the tight-junction proteins claudins.[25]

Membrane Selectivity

If the paracellular or tight junction resistance is much greater than the transcellular resistance, it is possible to determine the ion selectivity of the individual cell membranes. Specifically, if R_{tj} is very large compared to $R_{ap} + R_{bl}$, there will be negligible current through either the paracellular pathway or the cell pathway under open-circuit conditions. Under these conditions, the circuit of Figure 7.1 predicts that changes in E_{ap} will parallel changes in V_{ap} which, in turn, can be estimated from the measured changes in transepithelial potential ΔV_{te} (see Equations (A1.8) and (A1.11)–(A1.13) of Appendix 7.1). Such a situation was studied by Koefoed-Johnsen and Ussing[11] in their classic paper on the frog skin, where pre-treatment of the skins with low concentrations of Cu^{+2} produced very high values of R_{te} and V_{te}.

This permits evaluation of individual membrane selectivities from transepithelial measurements alone if the concentration of just one ion on one side of the epithelium is replaced with an impermeant species, and the conditions associated with Eq. (A1.13) (Appendix 7.1) are satisfied. If this is the case and Na is partially replaced on the apical side, then:

$$\Delta V_{te} = \Delta E_{ap} = -\frac{RT}{F} t_{Na} Ln \frac{[Na]_{ap}^{exp}}{[Na]_{ap}^{con}} \quad for\ R_{tj} >> R_{ap} + R_{bl}^{*} \tag{7.13}$$

where the change in potential is measured as experimental minus control. $[Na]^{exp}$ and $[Na]^{con}$ represent the concentrations of Na under experimental and control conditions, i.e., after and before the solution change.

Koefoed-Johnsen and Ussing[11] found that changes in mucosal Na produced changes in V_{te} close to those which would be expected if $t_{Na} = 1$. From this they inferred that the apical membrane was primarily conductive to Na ions. Similarly, changes in serosal K concentration produced changes consistent with the idea that the basolateral membrane conducted only K. The elegant conclusions of this study depended upon the rather unusual conditions achieved, namely a very high paracellular resistance and the absence of other "leak" pathways due to other cell types. Except for the case of the urinary bladder, such conditions are difficult to achieve in renal epithelia where paracellular pathways are usually leakier than in the frog skin.

Selectivity of the epithelial basolateral membrane has also been studied by using pore-forming polyene antibiotics to reduce apical membrane resistance[26] so that V_{te} becomes a reasonable estimate of the basolateral potential V_{bl} (see Equation A1.16 of Appendix 7.1). For example, in the turtle colon, Germann et al.[27] were able to characterize two different conductances for K across the basolateral membrane using the amphotericin-B permeabilized epithelium. This approach has also been used mostly in flat epithelia rather than renal tubules.

Impedance Analysis

Impedance analysis permits estimation of the electrical properties of individual membranes using transepithelial measurements.[28] In principle, transepithelial impedance can be measured from the time-course of the response to any electrical perturbation. In practice, it is usually obtained either under "current-clamp" conditions, using sine wave current perturbations at different frequencies or under voltage-clamp conditions by applying voltage perturbations. Since the apical and basolateral membranes will each have an associated complex impedance that depends on frequency, it is possible to distinguish contributions from the two membranes if they have very different time constants ($\tau = RC$, where R is the resistance and C the capacitance).

Typically four parameters (consisting of the amplitudes and time-constants of the two membrane components) are measured to fit a circuit with five parameters (resistance and capacitance of apical and basolateral membranes and the paracellular resistance). To fully solve the system one model parameter (e.g., the paracellular resistance) usually must be determined independently.

Impedance analysis has also been used to derive detailed information about the paracellular pathway, including the distribution of resistance across tight junctions and along intercellular spaces. In this regard, it has been used to estimate individual resistances and capacitances of the apical and basolateral membranes of flat epithelial sheets obtained from frog skin, amphibian and mammalian urinary bladder, colon, and cultured epithelial cells.[29–32] The elegance of the technique is that it is non-invasive, yielding information about individual membranes without the need for intracellular probes or electrodes. Because of the

requirement of uniform currents or voltage fields, its application to renal tubules has been very limited.[7,33]

CONCLUSIONS

Many important epithelial properties can be determined from transepithelial measurements alone. In fact, the original Koefoed-Johnsen/Ussing model for Na transport by the frog skin was based entirely on transepithelial electrical and flux measurements, and the ingenious use of special simplifying conditions. Thus, a number of important physical and thermodynamic properties of epithelia are still estimated from transepithelial measurements, particularly in renal tissues. These include the magnitude and selectivity of the paracellular shunt pathway, the ion selectivity of cell membranes (qualitatively in most instances), and the currents and EMF's associated with active transepithelial transport. On the other hand, the quantitative description of membrane properties requires detailed intracellular measurements to specifically characterize the apical and basolateral membrane components, as well as the contribution of the paracellular pathway. These measurements will be discussed in the next section.

INTRACELLULAR MEASUREMENTS

Intracellular measurements with voltage-sensitive and ion-sensitive microelectrodes permit a more detailed evaluation of individual membrane parameters than transepithelial measurements. This has been essential to our understanding of ion transport in epithelia. Three important membrane characteristics that are amenable to study with intracellular techniques are: (1) ionic selectivity; (2) membrane conductance; and (3) estimation of pump current. Although there are significant differences in the methodology of these measurements depending on the particular tissue involved, much of the underlying theory is similar in both flat epithelia and renal tubules. The emphasis of this section will be on describing the simplest and most straightforward methods for evaluation of single-membrane parameters with emphasis on renal epithelia, although much of the theory is applicable to flat epithelia as well.

Cell Membrane Potentials in Epithelia

An epithelium is a sheet of polarized cells joined together to function as a selective barrier between two compartments. Epithelia not only structurally define two compartments, but also maintain the composition of those compartments via the specific transport of electrolytes, non-electrolytes, and water. The electrical voltage measured across either the apical or basolateral membrane of an epithelium is the sum of the ionic diffusion potentials across the membrane, and the voltage drops arising from current flow across the resistance of that membrane. This current flow (depicted by the thick arrow in Figure 7.1) arises in part from the differences in membrane ionic diffusion potentials and the sum of epithelial barrier electrical resistances (Appendix 7.1).

In practice, cell membrane potentials are determined by impaling the cell with fine tipped glass microelectrodes, filled with a highly conductive electrolyte solution (1 M or 3 M KCl). Uniform filling is often accomplished by starting with glass tubing that contains a thin glass filament, allowing solution to flow smoothly from the back to the tip of the finished electrode. The microelectrode is then mounted on a stable micromanipulator. Given the elasticity of most cell membranes, impalement usually requires a rapid forward movement of the tip that can be accomplished either mechanically or with piezoelectric headstage. Sometimes a high frequency alternating current is briefly applied to the tip to permit entry into the cell with minimum damage.

A major technical problem with microelectrode measurements is the damage to the cell that may be produced by impalement. For a discussion of this topic see Higgins et al.[18] and Nelson et al..[34] Cell damage can be minimized by utilizing epithelia with large cells (e.g., *Necturus*; *Amphiuma*), and by recording from the basolateral rather than the apical membrane. This will result in less electrical shunting of the membrane potential, since in many cases the basolateral membrane has a much lower resistance than the apical membrane and an additional leak conductance at the basal side will have a smaller overall effect.[18] Furthermore, epithelia like the proximal tubule, whose cells are electrically coupled, are less sensitive to impalement artifacts, since the effective cell membrane area is larger. Finally, the use of very fine-tipped micropipettes can minimize membrane damage during intracellular measurements. However, such pipettes are more likely to produce artifacts due to changes in the liquid-junction potentials ("tip potentials") when the tip enters the cytoplasm.

Use of microelectrodes to measure cell potential may result in KCl leakage into the cell. Although these tips are extremely small ($< 0.2\ \mu m$), the use of concentrated KCl in the electrode to minimize liquid junction potentials can lead to KCl influx into the cell, alterations in cell composition, and cell swelling.[34] Thus, the choice of a filling solution is a trade-off between a concentrated KCl solution, which yields low tip potentials

but possible KCl leakage, versus a low salt pipette solution, which results in higher tip potentials but less salt leakage into the cytoplasm.

Intracellular potential can also be measured with relatively large diameter patch-clamp pipettes. In a "whole-cell clamp" experiment, a high resistance seal is formed between the pipette and the cell membrane. This permits direct electrical contact between the recording electrode and the cell interior with negligible impalement damage. If the amplifier is used in the voltage-clamp mode, the holding potential that reduces the membrane current to zero becomes a good measure of the cell potential. One disadvantage of using the whole-cell clamp to measure cell potential is that the cell is dialyzed with the pipette solution.[35] The exchange of vital cell constituents with the pipette solution may alter the intracellular ion composition, as well as change the normal cell membrane permeabilities through the loss of regulatory factors. The latter effect can be minimized by using the "perforated-patch" technique, in which the patch is permeabilized by the addition of pore-forming substances such as nystatin to the pipette solution.[36]

Evaluation of Individual Membrane Resistances from an Equivalent Circuit Analysis

The simplest technique for determining individual cell membrane resistance is to measure intracellular and transepithelial potential during an experimental maneuver that produces only a single perturbation in the parameters of the equivalent circuit. These techniques have been particularly useful in mammalian proximal tubules where multiple microelectrode impalements are difficult or in nephron segments that are not electrically coupled.

When only one microelectrode is used, the circuit of Figure 7.1 must be simplified to permit an indirect evaluation of the cell membrane resistances. This type of reduction is illustrated in Figure 7.7, and is permissible when most of the paracellular resistance is contributed by the tight junction resistance (i.e., when $R_{par} \approx R_{tj}$), which is equivalent to the assumption that R_{tj} is $>>$ lateral interspace resistance ($=R_{lis}$). This is particularly appropriate for mammalian proximal tubule, where basal interdigitations of adjacent cells greatly reduce the lateral space resistance, and most of the paracellular resistance is contributed by the tight junction resistance.

The circuit of Figure 7.7a can be further reduced to the simpler form of Figure 7.7b by defining an effective basolateral EMF (E^*_{bl}) and an effective basolateral resistance (R^*_{bl}), as described in Appendix 7.1. Although the electromotive forces or EMFs (E_{ap}, E_{bl}, E_{par}) in the circuit cannot be measured directly, the potential differences across each barrier can be measured with intracellular or transepithelial electrodes. These are defined as transepithelial potential (lumen-bath) $= V_{te}$, apical cell membrane potential (lumen-cell) $= V_{ap}$, and basolateral potential (cell-bath) $= V_{bl}$.

An important consequence of the circulating epithelial current in Figure 7.7 is that alterations in any of the electrical parameters on one side of the cell will produce changes in the measured electrical potentials on the contralateral side. This actually provides an indirect method for evaluating those resistances that remain constant during a change in loop current, I. Individual cell membrane resistances R^*_{bl} and R_{ap} can be evaluated by any experimental maneuver that changes only the parameters at one membrane. For example, rapid addition of amiloride or glucose to the apical solution presumably alters only the resistance and/or the EMF of the apical membrane by blocking Na channels or stimulating Na-glucose co-transport, respectively.

Amiloride causes a hyperpolarization of V_{bl} by both increasing the measured apical resistance (R_{ap}) and decreasing the contribution of the Na gradient to the value of E_{ap} (see Appendix 7.1, Eq. (A1.7)). On the other hand, addition of glucose to the luminal solution depolarizes V_{bl} by stimulating Na-glucose co-transport, which effectively increases both the apical Na conductance and the relative contribution of the Na gradient to the apical diffusion potential. Since the primary effect of both amiloride and glucose occurs at the apical membrane, the ratio of basolateral to apical resistance is directly related to the measured ratio of basolateral to transepithelial voltage deflections according to Eq. (7.14), which applies for addition of either apical-side amiloride or apical-side glucose:

$$\frac{R^*_{bl}}{R_{tj}} = -\frac{\Delta V_{bl}}{\Delta V_{te}} = \beta \tag{7.14}$$

This equation implicitly assumes that neither glucose nor amiloride affect the paracellular pathway, and that the potential measurements can be performed before any changes in cell composition have occurred that would affect E_{ap}, E_{bl}, and R_{bl}.

Similarly, measurement of the ratio of apical to transepithelial potential change following addition of barium to the basolateral solution permits estimation of the apical membrane resistance via Eq. (7.15):

$$\frac{R_{ap}}{R_{tj}} = -\frac{\Delta V_{ap}}{\Delta V_{te}} = \frac{\Delta V_{bl}}{\Delta V_{te}} - 1 = \alpha \tag{7.15}$$

Again, it has been assumed that basolateral application of barium has no effect on the paracellular pathway, and that the measurement can be performed rapidly enough to avoid changes in cell composition.

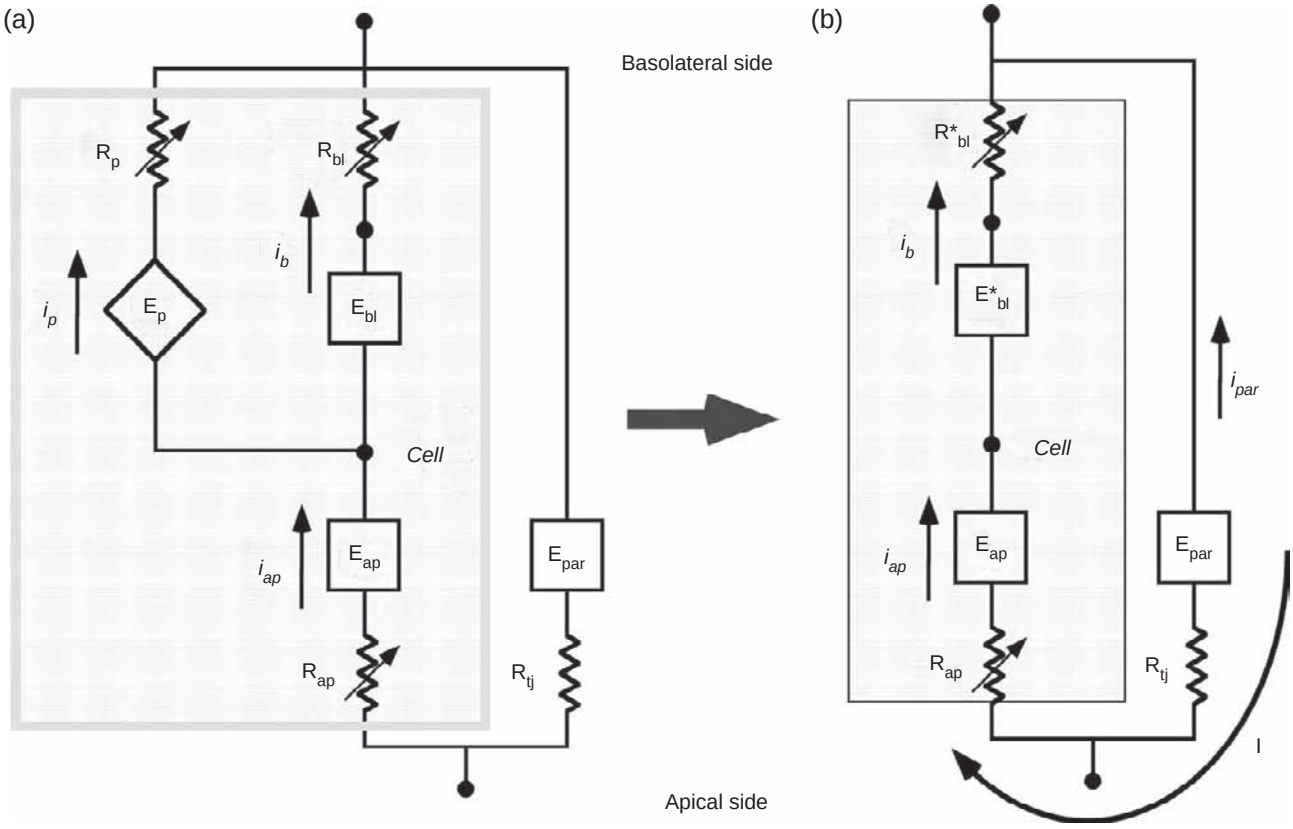

FIGURE 7.7 (a) Reduced form of the general equivalent circuit, where the lateral resistive network has been neglected because most of the paracellular resistance is assumed to reside at the tight junction (i.e., $R_{tj} >> R_{lis}$). This situation applies in a number of epithelia and greatly simplifies the equivalent circuit. (b) Reduced circuit in which the parallel diffusive and active transport paths across the basolateral membrane have been combined into an effective basolateral EMF (E^*_{bl}) and an effective basolateral resistance (R^*_{bl}). "I" denotes direction of positive net circulating current under open-circuit conditions.

Finally, in cases where it is feasible to make changes on only one side of the epithelium, the voltage divider ratio can be used instead of either Eq. (7.14) or Eq. (7.15). When current is injected into the tubule lumen via the perfusion pipette, a certain fraction of that current will cross the apical and basolateral cell membrane in series, producing voltage deflections ΔV_{ap} and ΔV_{bl}. If the lateral and basal resistances of Figure 7.1 are combined into a single effective resistance R^*_{bl} (defined in Appendix 7.1, Eq. (A1.4)) the ratio of apical to basolateral resistance during transepithelial injection of current is given by Eq. (7.16):

$$\gamma = \frac{R_{ap}}{R^*_{bl}} = \frac{\Delta V_{ap}}{\Delta V_{bl}} = \frac{\Delta V_{te}}{\Delta V_{bl}} - 1 \qquad (7.16)$$

The term "γ" is sometimes referred to as the voltage divider ratio. An alternative to Eq. (7.16) is to define the "fractional resistance" of either the apical (fR_{ap}) or basolateral membranes (fR_{bl}), according to Eqs. (7.17a), (7.17b):

$$fR_{ap} = \frac{R_{ap}}{R_{ap} + R^*_{bl}} = 1 - \frac{\Delta V_{bl}}{\Delta V_{te}} \qquad (7.17a)$$

$$fR^*_{bl} = \frac{R^*_{bl}}{R_{ap} + R^*_{bl}} = \frac{\Delta V_{bl}}{\Delta V_{te}} \qquad (7.17b)$$

Since γ, α, β, and R_{te} are all measured quantities, the individual resistances: R^*_{bl}, R_{ap}, R_{tj}, can be evaluated by using any three of the four equations Eqs. (7.14), (7.15), (7.16), and Eq. (A1.5).

An example of these methods is illustrated by the experiment depicted in Figure 7.8.[37] In this experiment, changes in transepithelial (V_{te}) and basolateral potential (V_{bl}) are shown during addition of 1 mM barium to the bath (Figure 7.8a), followed by addition of 8 mM glucose to the lumen (Figure 7.8b). The superimposed smaller deflections are due to periodic current injection for evaluating "γ" from Eq. (7.16).

In both these experiments, ΔV_{bl} and ΔV_{te} were taken as the initial changes in voltage resulting from a particular maneuver. For example, in the barium experiment, only changes in V_{bl} and R^*_{bl} were presumed to occur, and ΔV_{bl} was taken as the difference between the baseline V_{bl} and the V_{bl} at the inflection point (asterisk). The origin of the slow secondary depolarization of V_{bl} in Figure 7.8a is not known.

The above methods have been used to determine individual cell membrane resistance in mammalian proximal tubule. Some of these results are summarized in Table 7.3. Although there are some differences in the absolute values of cell resistances, there is general agreement that in proximal tubule the resistance of the cellular pathway is between 20 and 30 times higher than the resistance of the shunt pathway. This factor is even higher in amphibian proximal tubule.

Determination of individual membrane parameters from Eqs. (7.14)–(7.16) involves certain practical problems. These methods require measurement of ΔV_{te} and ΔV_{bl} in the same tubule at the same axial distance along its length. As indicated in Figure 7.8, the small magnitude of the change in transepithelial potential renders the two ratios α and β in Eqs. (7.14) and (7.15) particularly susceptible to errors in ΔV_{te}. Measurements of ΔV_{te} obtained by advancing a microelectrode into the lumen are unreliable, because damage to the epithelium can produce artificially low values of ΔV_{te}. Since transepithelial potential is measured only at the perfusion or collection ends of the tubule, the value of ΔV_{te} must be calculated from the electrotonic voltage spread along the tubule using a terminated cable analysis (see section entitled, "Transepithelial Measurements").

Evaluation of Individual Membrane Resistances Using Multiple Intracellular Recordings

In the relatively large cells of amphibian proximal tubule (30 μm diameter), direct electrical measurement of cell membrane resistance is possible. Exploiting the property of electrical coupling between adjacent proximal cells,[16] it is possible to pass current from an intracellular microelectrode through an annular syncytium, with an outer specific resistance of R^*_{bl} and an inner specific resistance of R_{ap}. This cannot be done in nephron segments like the collecting duct, where adjacent cells are not electrically coupled.[38]

The use of cellular cable analysis to evaluate the individual resistances R^*_{bl}, R_{ap}, and R_{tj} still depends on the definition of transepithelial resistance (Eq. (A1.5)) and the "voltage-divider" ratio (Eq. (7.16)) that were discussed in the section entitled, "Cell Membrane Potentials in Epithelia." However, instead of relying on the ratio $\Delta V_{bl}/\Delta V_{te}$, obtained during application of barium or amiloride, the parallel resistance of the cell layer (R_z) is computed directly from the electrotonic voltage spread along the double core cable, where R_z is defined by Eq. (7.18).

$$1/R_z = 1/R_{ap} + 1/R^*_{bl} \tag{7.18}$$

In practice, R_z is evaluated by injecting current I_o into the cell layer at x = 0 via a microelectrode and measuring the voltage deflection ΔV_x at two or more locations "x," downstream from the injection site. The arrangement of microelectrodes is illustrated in Figure 7.2. If x is at least twice the diameter of the tubule, the electrotonic voltage spread along the cable will be given by Eq. (7.19), where λ_c is the cellular length constant of the tubule[5]:

$$Ln[\Delta V_x] = Ln\left[\frac{R_z I_o}{4\pi r \lambda_c}\right] - \frac{1}{\lambda_c}x \tag{7.19}$$

The best fit for the two unknown parameters λ_c and R_z is determined by evaluating Eq. (7.19) at a number of locations along the tubule. The radius of the tubule, r_o, is measured with an optical micrometer. Combining Eqs. (7.16), (7.18), (7.19), and (A1.5), the individual membrane resistances R_{ap}, R^*_{bl}, and R_{tj} are uniquely determined by the two parameters R_z, γ, and the measured value of R_{te} according to Eqs. (7.20)–(7.22):

$$R_{ap} = R_z[1 + \gamma] \tag{7.20}$$

$$R^*_{bl} = R_z\left[1 + \frac{1}{\gamma}\right] \tag{7.21}$$

$$R_{ti} = \frac{R_{te}[R^*_{bl} + R_{ap}]}{R_{ap} + R^*_{bl} - R_{te}} \tag{7.22}$$

The transepithelial resistance of the tubule, R_{te}, is determined by passing current and measuring voltage through a doubled-barreled perfusion pipette according to the methods described in the section entitled, "Transepithelial Measurements" and Figure 7.2.

In amphibian proximal tubule, most measurements of individual cell resistances have been performed using a cellular cable analysis with two or more intracellular microelectrodes. On the other hand in mammalian tubules, the method of relative voltage deflections (Eqs. (7.14) and (7.15)) have been used exclusively. However, in *Ambystoma* proximal tubule, a direct comparison of the two methods has been made under similar conditions. These results are summarized in the first two rows of Table 7.4. As indicated, the absolute values of resistance are quite close considering the propagation of errors that occur with both types of measurements. The remaining rows of Table 7.4 summarize additional resistance measurements in amphibian renal epithelia.

As with the mammalian proximal tubule, the ratio of shunt to cell resistance clearly establishes the amphibian proximal tubule as a "leaky" epithelium. In contrast, the *Necturus* urinary bladder (a "tight" epithelium) possesses a shunt resistance that is several times larger than the cell resistance pathway. Neither the diluting segment nor the collecting tubule of the *Amphiuma* fall neatly into the "tight" or "leaky" category, since both of these segments have cellular

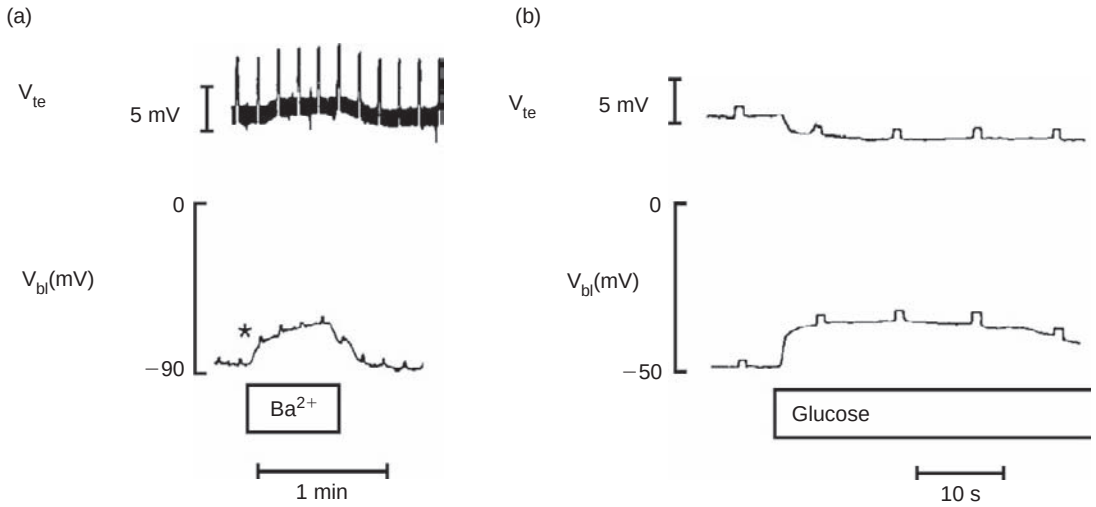

FIGURE 7.8 **Effect of barium and glucose on membrane voltages in rabbit proximal convoluted tubule (from [37]).** (a) Reversible depolarization of both the transepithelial (V_{te}) and the basolateral membrane potential (V_{bl}) produced by addition of barium to the basolateral side of isolated proximal tubules. (b) Simultaneous depolarization of the transepithelial (V_{te}), and hyperpolarization of the basolateral membrane potential (V_{bl}) produced by addition of glucose to the apical side of isolated proximal tubules. In both panels the superimposed periodic voltage deflections were produced by current pulses injected through the perfusion pipette.

TABLE 7.3 Cell Membrane Resistances in Mammalian Tubules (Ωcm^2 Epithelium)

Segment	Apical Resistance	Basolateral Resistance	Shunt Resistance	Method	Species	Reference

and paracellular resistances that are in the same order of magnitude. Interestingly, both the diluting segment and collecting duct have higher shunt resistances and lower cellular resistances than the corresponding membrane of the proximal tubule. Mammalian collecting ducts and diluting segments also have higher shunt resistances than mammalian proximal tubules, although differences in cell resistance are less dramatic along the mammalian nephron.

The resistances quoted for the *Amphiuma* diluting segment in Table 7.4 assumed a single cell type throughout the cable analysis.[39] This greatly simplified the calculation of membrane resistance. Unfortunately, subsequent experiments indicated that this nephron segment actually consists of two different cell types with dissimilar conductive properties.[40] One cell type has a high basal K and Cl conductance (HBC), whereas the other cell type (LBC) has a low basolateral conductance for both ions.[40] There is also some evidence that mammalian TALH may exhibit a certain amount of cell heterogeneity as well.[41] Since it is unlikely that different cell types in the same nephron segment are directly coupled to each other, a unique value of cell membrane resistance cannot be determined from cable analysis on these nephron segments unless all recordings are made from the same cell type.

The cellular cable equations (Eqs. (7.18) and (7.19)) were originally derived for *in situ* proximal tubules, in which the cables are effectively infinite in length.[16] However, they should be reasonably valid for isolated perfused tubules as long as the voltage recording microelectrodes are several tubule diameters from either end of the tubule. Under these conditions the electrotonic voltage spread would be effectively the same as for an infinite cable. The problem of "cross-talk" or interactions between the transepithelial and cellular cables has been suggested as a source of error in these measurements.[42] The complication of cable−cable interactions would only be significant if current injected into the cell layer leaks into the lumen and then re-enters the cell layer at the some point downstream. A thorough analysis by Guggino et al.[16] for *Necturus* proximal tubule suggests that cross-talk will be negligible if intracellular voltage deflections ΔV_x are recorded at locations $x > \lambda_c$.

Evaluation of cell membrane resistance via Eqs. (7.14)−(7.16) is only as accurate as the equivalent circuit of Figure 7.7. An important aspect of this electrical model is the assumption that the tight junction constitutes the principal resistance of the paracellular pathway, or $R_{par} \approx R_{tj}$. This is probably true in tight epithelia like the urinary bladder, where the lateral intercellular space has a negligible resistance compared to that of the tight junction. However, the low transepithelial resistance of the proximal tubule raises the possibility that the resistivity of free solution in the lateral space contributes significantly to overall shunt resistance. In this case, evaluation of the divider ratio is complicated by the lateral resistive network shown in Figure 7.1. Current flow through a distributed network of this kind will cause the measured value of $\Delta V_{ap}/\Delta V_{bl}$ to *underestimate* the actual value of R_{ap}/R^*_{bl} by an amount that depends on the ratio of lateral space resistance, R_{lis}, to paracellular resistance R_{par} (see Figure 7.9).

As illustrated in Figure 7.9, the larger the contribution of the fluid-filled interspace to the total paracellular resistance (i.e., the larger the ratio R_{lis}/R_{par}), the more the measured voltage ratio will underestimate the actual resistance ratio, γ. In epithelia where the paracellular resistance is essentially determined by the resistance of the tight junction and $R_{lis}/R_{par} < 0.01$, the resistance ratio (γ) will be correctly given by Eq. (7.16). On the other hand, if the lateral interspace is long and narrow and constitutes a non-negligible electrical resistance, R_{par} will be related to R_{te} according to a complicated function (see Eqs. (31−40)) of reference[6] with $R_3 = R_{par}$). As can be seen in the figure, significant deviations from Eq. (7.16) occur even if R_{lis} is as little as 10% of R_{par}. A detailed analysis regarding the effect of lateral resistive networks on measurement of cell membrane resistance has also been presented by Weber and Frömter.[43]

Determination of individual cell membrane resistances involves a number of technical difficulties. In addition to those indicated above, positioning of the intracellular electrodes is particularly tedious. If the first cell voltage electrode is within one cell length constant of the cell current electrode there may be significant cross-talk between cell and luminal cables. If the second cell voltage electrode is too far from the current injection electrode, the size of the deflection will be immeasurably small. Use of a third voltage recording electrode gives a better definition of the electrotonic voltage spread, but is often impractical. If sequential voltage impalements are used, the first recording should be made at the farthest distance from the current electrode. In this manner, intracellular recording at $x = L_1$ will be insignificantly affected by cell damage at $x = L_2$, as long as $L_2 > L_1$, and the current electrode is maintained at $x = 0$ (see Figure 7.2).

A significant source of error in cellular cable measurements arises from voltage-dependent membrane conductances. These can result from asymmetry of the electrolyte composition on the two sides of the membrane ("Goldman rectification"). Furthermore, patch-clamp experiments have indicated that a number of renal channels are voltage-gated. The specific magnitude and type of gating varies with each nephron segment. Since the current injections used for determination of cell membrane resistance often

TABLE 7.4 Cell Membrane Resistances in Amphibian Tubules (Ωcm^2 Epithelium)

Segment	Apical Resistance	Basolateral Resistance	Shunt Resistance	Method	Species	Reference

[b]*The basolateral conductance of this segment is strongly inward rectifying and quoted value applies only at a membrane potential of −60 mV.*

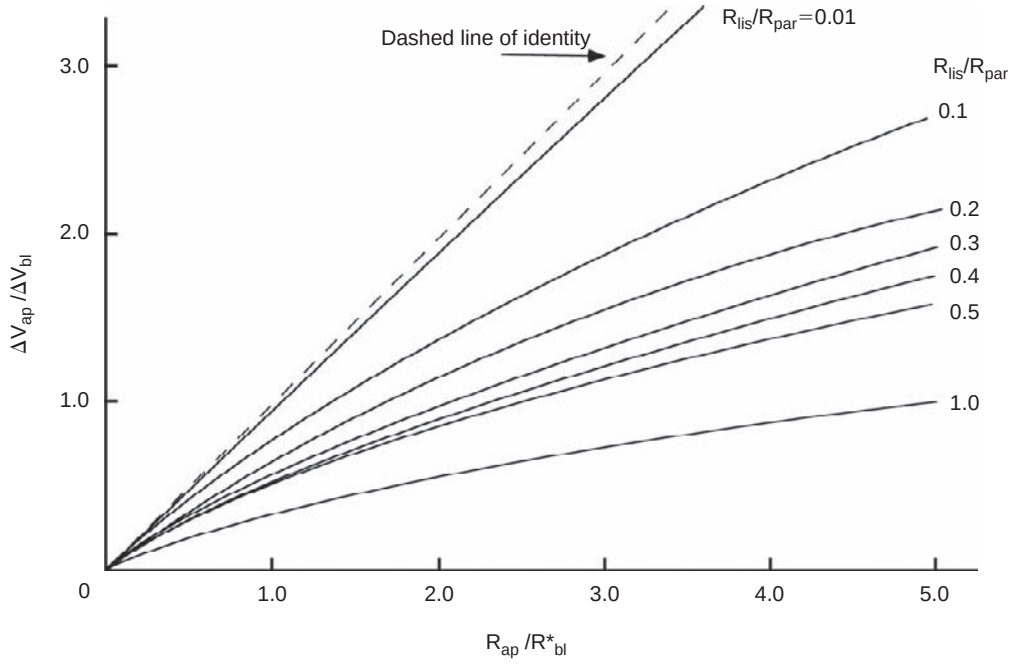

FIGURE 7.9 **Relationship between the measured voltage divider ratio ($\Delta V_{ap}/\Delta V_{bl}$) and the actual ratio of apical to basolateral resistance (R_{ap}/R_{bl}) at different values of fractional interspace resistance (R_{lis}/R_{par}).** Negligible values of R_{lis} result in the voltage divider ratio being a good measure of R_{ap}/R_{bl} (line of identity). In epithelia where R_{lis} is a significant fraction of the paracellular resistance, the voltage divider ratio is not a good measure of the apical to basal resistance ratio.[179]

produce 10 to 15 mV voltage deflections across the basolateral membrane, the conductance could be affected by the process of measurement. One solution to this difficulty has been to take the average value of ΔV_{bl} determined from both positive and negative going currents.

Evaluation of Ion Selectivities from Ion Substitution Experiments

One of the most important membrane properties that can be determined from electrophysiological measurements is membrane selectivity. The basic equation that defines the transference number of the membrane for ion x is obtained by rearranging Eq. (7.3) to yield Eq. (7.23) below:

$$t_x = -\frac{\Delta E}{\frac{RT}{z_x F} Ln\left[\frac{[X^{expt}]}{[X^{con}]}\right]} \tag{7.23}$$

Eq. (7.23) can then be used to evaluate the ion selectivity of the individual epithelial membranes from changes in the total EMF ΔE (expt − control) produced by replacement of a specific *apical* ion X by an impermeant ion. In Eq. (7.23), X^{expt} and X^{con} respectively refer to the extracellular ion concentration of the apical solution under experimental (expt) or control (con) conditions. If ΔE is produced by a change in *basolateral* composition, the transference numbers would be calculated from the negative of Eq. (7.23). As indicated in Figure 7.7b, the circulating current, I, prevents a simple equivalence between the measured change in potential difference (ΔV) and the actual change in the EMF of the membrane (ΔE). The effects of circular current flow on the actual changes in EMF resulting from ion substitution, ΔE, are described in detail in Appendix 7.2. These equations are essential for evaluating membrane selectivities from ion substitution experiments.

The partial conductance of the membrane for any ion "x" (G_x) can be determined from the transference number for the membrane and the total ionic conductance of that membrane (G_{tot}), according to Eq. (7.24):

$$G_x = t_x \cdot G_{tot} \tag{7.24}$$

There is no simple relation between the partial ionic *conductance* and the *permeability* of the membrane to a particular ion. However, it is possible to develop a general relation between the conductance and the permeability of a particular ion (X). This is given by Eq. (7.25), where $\langle X \rangle$ is a weighted average of the concentrations of X on both sides of the membrane. Its value depends on the particular assumptions about ion permeation across the membrane.

$$G_x \approx P_x \frac{z^2 F^2}{RT} \langle X \rangle \tag{7.25}$$

In the constant field assumption, $\langle X \rangle$ is a complicated function of both the membrane potential and the ion concentrations on both sides of the membrane. Explicit forms of Eq. (7.25) are discussed in Appendix 7.3. However, if the membrane is assumed to be permeant to only three ions: Na, K, and Cl, the permeability ratios P_{Na}/P_K and P_{Cl}/P_K can be evaluated from a two parameter fit to the general form of the Goldman–Hodgkin–Katz equation.[44] This procedure has not been used extensively for renal epithelia because of uncertainties in a simultaneous evaluation of P_{Na}/P_K and P_{Cl}/P_K.

On the other hand, if the membrane is primarily selective to two rather than three ions, a closed form expression can be obtained for the permeability ratio:

$$\frac{P_K}{P_{Na}} = \frac{[Na]_o - [Na]_i \exp\left(\frac{E_{rev}}{RT/F}\right)}{[K]_i \exp\left(\frac{E_{rev}}{RT/F}\right) - [K]_o} \tag{7.26}$$

In Eq. (7.26) the term, E_{rev}, is the potential difference, inside (i) minus outside (o), associated with zero current across the membrane. The principle disadvantage of Eq. (7.26) for kidney tubules is that determination of E_{rev} requires voltage-clamping the individual cell membranes of the epithelium. So far this has really only been accomplished for the *Amphiuma* collecting tubule.[21]

Since the specific conductance of a membrane for ion X is generally a function of the concentration of that ion (Eq. (7.25)), the values of t_x obtained from Eq. (7.23) only apply to the concentration range over which the ion replacement is actually performed. Consequently, any determination of normal transference numbers requires that the ionic replacement: $X^{con} - X^{expt}$ be as small as possible, but still produce a measurable ΔE. On the other hand, the permeability ratio of Eq. (7.26) should (in theory) be less dependent on external ion concentrations.

Estimation of Renal Na-K Pump Current and Electrogenic Potential

The 3Na/2K stoichiometry and electrogenic nature of the Na/K pump has been demonstrated in a number of non-epithelial tissues.[45,46] Most studies on red cells,[47,48] squid axon,[49] and Purkinje fibers[50] indicate a fairly consistent Na/K coupling ratio of 3/2 for the Na-K-ATPase. This electrogenicity not only causes the pump to contribute to total membrane potential, but also requires that the pump itself be dependent on membrane potential.

Mullins and Noda[51] and Ascher (cited in [52]) have derived an expression for the electrogenic contribution to the membrane potential of nerve and muscle cells which predicts a steady-state contribution of no larger than about 11 mV. This theory depends on the observation that electroneutrality conditions on symmetric cells require that there be no net macroscopic current under open-circuit, steady-state conditions. The estimate of 11 mV maximal electrogenic hyperpolarization also depends on the assumption that the membrane permeabilities are voltage independent, which is somewhat of an approximation, even for nonexcitable tissues.

In epithelial tissues, where current circulates around a cellular and paracellular path (see Figure 7.7), the electrogenic contribution to the membrane potential may be larger than in symmetric cells, but it is also more difficult to quantify. Early estimates of pump current and electrogenic potential in epithelial tissues were determined by comparing the observed change in basolateral potential ΔV_{bl} to the potential changes predicted from the measured ion gradients and electrical resistances, during rapid return of K to the basolateral solution[5] or application of cardiac glycosides.[21,53] These experiments clearly demonstrated net transfer of charge by the pump, but uncertainty about the potassium concentration in unstirred layers outside the cell made it difficult to determine pump stoichiometry from these types of experiments.

In general, the calculation of the electrogenic potential in epithelial tissues requires explicit knowledge of both membrane and pump resistances, which may themselves be a function of pump activity (see Appendix 7.4). This significantly complicates the situation, and the electrogenicity of the pump is better characterized by evaluating its I–V relation than by evaluating its contribution to the open-circuit potential.

Since electrogenicity requires that pump current be sensitive to membrane potential, the I–V relation for the pump must intersect the voltage axis at some reversal potential E_p. The reversal potential of the pump should correspond to the membrane potential against which the pump can no longer translocate a net charge (i.e., 3Na for 2 K). The value of E_p can be calculated from Eq. (7.27) using estimates of the free energy of ATP hydrolysis (E_{ATP}) and the concentration work involved in moving "m" sodium ions (mE_{Na}) and "n" potassium ions (nE_K) per molecule of ATP split.[54]

$$E_p = EMF_{pump} = \frac{E_{ATP} + mE_{Na} - nE_K}{m - n} \tag{7.27}$$

where E_{ATP} is the free energy of ATP hydrolysis (about −600 mV for m − n = 1, from ref [14]), and E_{Na}, E_K, are respectively the Na and K Nernst potentials across the membrane. For amphibian tubules, E_{Na} is about 55 mV and E_K is about −80 mV at room temperature. According to Eq. (7.27), the predicted value of E_p is about −275 mV for a net translocation of one (m − n) positive charge. This value of E_p corresponds to the reversal potential of the current–voltage relation for the pump.

The existence of a pump reversal potential defined by Eq. (7.27) provides no information about the sensitivity of pump current to membrane voltage. This sensitivity is determined by the specific shape of the current–voltage (I–V) relation of the pump. For example, if the pump I–V relation exhibits a low angle slope in the region of normal membrane potential, the pump would be best represented as a (Norton equivalent) constant current source. On the other hand, if the I–V relation is linear between zero voltage and the pump reversal potential, the pump would be best represented as a (Thevenin equivalent) constant voltage source (Figures 7.1 and 7.7). Four examples of I–V relations for the Na,K-ATPase are illustrated in Figure 7.10.

These pump, current–voltage relations were determined by measuring either the strophanthidin (a, c) or the ouabain (b, d)-sensitive currents at different voltages. Figure 7.10a and 7.10b are I–V relations from symmetric cell preparations, whereas Figure 7.10c and 7.10d were measured in renal epithelia. In both isolated guinea-pig ventricular myocytes[55] and *Xenopus* oocytes,[56] pump current is linearly dependent on membrane voltage with a reversal potential of at least −150 mV. Saturation of current, with decreasing slope, was only evident at positive membrane potentials.

On the other hand, voltage-clamp studies in amphibian (*Amphiuma*) collecting tubules[21] indicate a curvilinear I–V relation (Figure 7.10c), which would imply that (in this tissue) the Na,K pump behaves as a constant current source at normal membrane potentials (− 20 mV to −75 mV). Differences in the I–V curves of Figures 7.10a, 7.10b, and 7.10c may indicate true distinctions between Na pumps of different preparations or may simply reflect differences in experimental technique. The final I–V relation (Figure 7.10d)[57] indicates that the pump current in the mammalian CCD, like that of symmetric cells, is sensitive to voltage in the physiological range.

The variability in the shape of the I–V relations for the Na,K-ATPase (Figure 7.10) implies some uncertainty as to whether the Na pump of a particular tissue behaves more like a constant current or a constant voltage source. Nonetheless, we have chosen to represent the Na pump in the equivalent circuits of Figures 7.1 and 7.7 as a voltage source (E_p) in series with an internal resistance (R_p), because this is a somewhat more general form than a constant-current source.

CONCLUSIONS

With the use of microelectrodes to record intracellular voltages and voltage changes, it has been possible to characterize renal epithelia according to the equivalent circuit in Figure 7.1. Overall conductances of apical and basolateral membranes can be computed, and the contribution of various ions to these conductances can be estimated. Our understanding of the major nephron segments at this level is fairly secure. In the next section we discuss how measurements at the single-channel level have yielded a more detailed description of renal ion transport processes.

Patch-Clamp and Single-Channel Analysis

Defining a Channel

The ability to measure currents through individual ion channels in small "patches" of biological membranes has, over the course of the last 25 years, increased enormously the type of information that can be gleaned about ion channels and the details of our knowledge of how these transport proteins work. With this technique we can find out how many different types of channels there are in a membrane, and how many of each type is present, without the need for specific pharmacological agents. It is possible to determine what gene produces a given membrane conductance by comparing the properties of the channels in that membrane with those of the gene product when it is heterologously expressed in another cells type. In other cases a gene can be specifically deleted using genetic techniques, and the disappearance of a channel type from the membrane can be followed. The patch-clamp technique can also be very useful to determine what agents or second messengers directly or indirectly regulate ion channels.

An ion channel is defined in physical terms as a membrane protein which forms a continuous pathway for the diffusion of an ion from one side of the membrane to the other. In contrast to active transporters, the direction of movement of the ion is determined by the electrochemical energy difference across the membrane. Unlike more complex "carriers" (including facilitated transporters and co- and countertransporters) a conformation change in the channel protein is not required for the translocation of the ions. This permits ions to move quite quickly through the channels. While co-transporters or exchangers generally have maximal turnover rates of about 10^5/sec, and metabolically driven pumps are even slower, channels can achieve rates of 10^8/sec or more through individual units.[58]

Most channels exhibit gating; they switch between distinct open and closed states, producing abrupt transitions in current under voltage-clamp conditions. Patch-clamp recording can generally resolve currents of around 10^6/sec or 0.15 pA. Thus, the ability to see an individual transport unit using the patch-clamp is a reasonably good operating definition of a channel. Although the appearance of current transitions is a good operational definition of channel activity, this is actually too restrictive since some channels may have a low turnover rate. Nevertheless the definition is a useful one, and most channels that we know about have currents large enough – at least under optimal conditions – to be seen by patch-clamp.

Most biologically important channels will also have a density high enough to be observed frequently. For a moderate membrane conductance of 1 mS/cm^2, a single channel conductance of 40 pS and an open probability of 0.5, the density of channels will be 5×10^7/cm^2 or 0.5/μm^2. If a patch contains 5 μm^2 it will have on the average 2 to 3 channels. This simple calculation illustrates that a patch pipette of average diameter will usually contain at least one channel, making this technique a highly efficient method for studying the characteristics of individual ion channels.

High resolution patch-clamp recording was developed in the early 1980s by Neher, Sackmann, and colleagues.[35] The patch methodology consists of four major configurations, three of which can be used to study single channels. As illustrated in Figure 7.11, the cell-attached patch consists simply of forming a seal on the surface of a cell, and studying the resulting piece of membrane *in situ*. This is obviously the most physiological condition. The same patch can be excised from the cell membrane, forming an inside-out patch in which the cytoplasmic surface of the membrane now faces the bathing medium. This is useful for studying the effects of second messengers and other cytoplasmic components which can be added back to the medium to test for their ability to regulate the channels. A cell-attached patch can also be broken with suction, to form a whole-cell voltage-clamp. This is a very convenient method for studying the total current from the entire cell membrane. It is usually not possible to resolve single-channel events in this configuration, although noise analysis of whole-cell recordings can give information about single-channel properties (see below). Finally, withdrawing the pipette from the cell under the whole-cell condition often gives rise to the outside-out configuration, in which a new patch is formed with the former extracellular surface of the membrane facing the bath. This can be used to study the effects of hormones, drugs, and other ligands which interact with the external face of the channel.

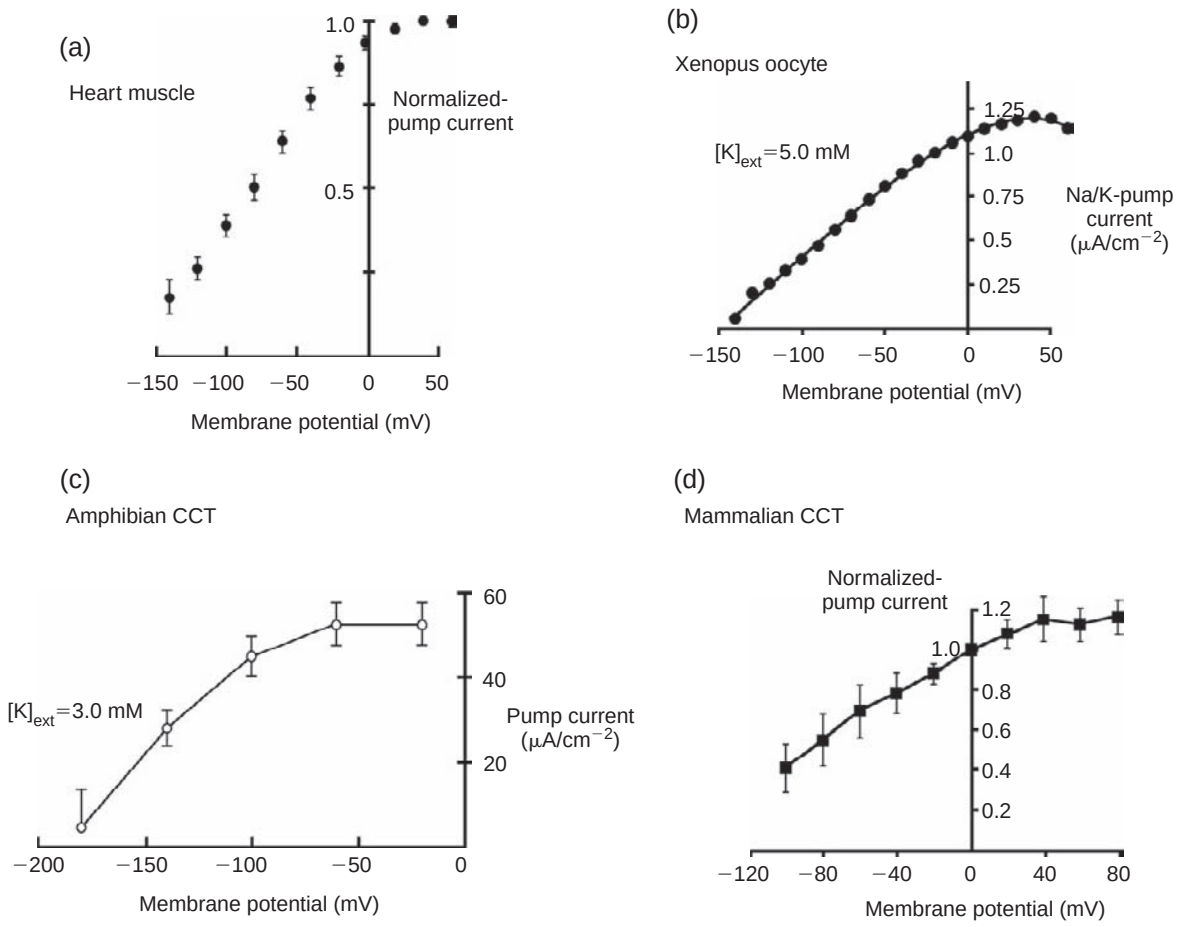

FIGURE 7.10 (a) Current-voltage relation of the cardiac Na-K-ATPase as determined from the strophanthidin-sensitive pump current in a whole-cell recording from a single isolated ventricular myocyte. Dissipative current pathways were blocked with Cs, Cd, TEA, and Ba (from [55]). (b) Current-voltage relation for the Na/K pump of *Xenopus* oocytes, bathed in a 90 mM Na, 5 mM K solution. Pump current was determined as the difference between current measured at 5 mM external K and current measured in K-free solutions (from [180]). (c) Current-voltage relation of the basolateral Na pump of *Amphiuma* collecting tubule as determined from the strophanthidin-sensitive current in short segments of voltage-clamped tubules (from [150]). (d) Current-voltage relation of the rat principal cell Na-K-ATPase. Ouabain-sensitive currents were normalized to their values at zero mV (from [57]).

PARAMETERS MEASURED ON SINGLE CHANNELS

Single-Channel Current

The simplest measure of channel electrical activity is the single-channel current (Figure 7.12). This is the change in current under voltage-clamp conditions which occurs when a channel opens or closes. It is generally quite reproducible for a given set of conditions, but varies with ion concentration, temperature, and voltage. It is common to characterize channels by their single-channel conductance. This is defined as the slope of the current versus the voltage relationship. For some channels this conductance is roughly independent of voltage. Many others, however, have highly non-linear current-voltage relationships. In the latter case, the voltage at which the conductance was measured must always be specified.

Normally, the lowest single channel conductance that can be reliably measured is in the neighborhood of 1 pS. This would correspond to measuring a 0.1 pA current at an electrical driving force of 100 mV. Most channels can conduct much larger currents; an upper limit of about 33 pA has been estimated from limitations of diffusion rates.[58] Eukaryotes have channels with conductances up to about 400 pS.

Some channels have more than one conducting state. Usually the largest one is chosen as the characteristic conductance, and smaller ones are referred to as "subconductance" states. Presumably these reflect different conformations of the channel protein. In one special case of the Cl channel CLC-0, the channel has two conductance states, with one being precisely half of the

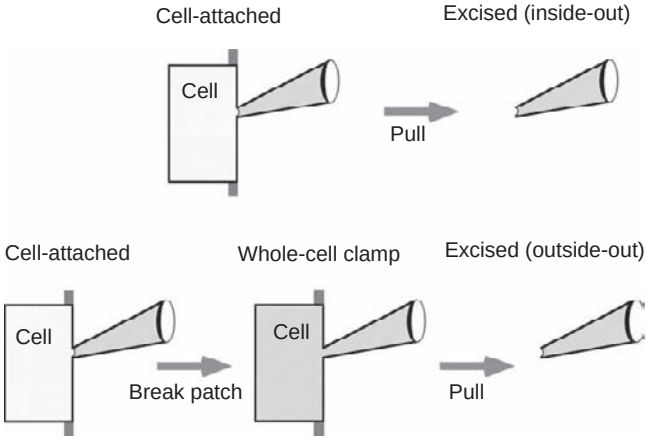

FIGURE 7.11 **Schematic of the patch-clamp technique, applied to the apical membrane of an epithelium.** Patch-clamping the basolateral membrane involves a similar procedure. In a cell-attached recording, the cell retains its original composition. Formation of a (conventional) whole-cell clamp causes most of the cell contents to be replaced by pipette solution. Withdrawal of the pipette from the whole-cell configuration often produces an excised, outside-out patch.

other.[59] The interpretation of these results was that two identical conducting pores are linked together such that they can close either separately or together. The "full" conductance state represents both pores conducting simultaneously, and the "sub" conductance state reflects the opening of just one of them. In general, the structural basis of subconductance states – which can have any fraction of the full conductance – is not well-understood.

Channel Selectivity

In addition to conductance, the ionic selectivity of the channel can also be determined from single-channel i-V plots under appropriate conditions. As in the case of macroscopic currents discussed in the last section, the selectivity of an individual ion channel can be defined and measured in different ways. Inside-out and outside-out patches are particularly well suited for measurements of permeability ratios, since the ions on both sides of the membrane can be set to known concentrations.

The ionic transference numbers for a channel can be evaluated using the same relationships discussed previously (see Eq. (7.23)). However, instead of perturbing the concentration of an ion across the membrane, it is simpler in a patch-clamp experiment to change the transmembrane voltage (see Eq. (7.26)). The reversal potential (E_{rev}) is then defined as the voltage at which current flow through the channel changes direction. Measurement of E_{rev} is easiest to interpret in excised patches, where ionic concentrations can be precisely controlled. For measurement of cation versus anion selectivity, dilution conditions are normally used, with a single salt at different concentrations (S1 and S2) on both sides of the membrane. For the case of a monovalent salt:

$$E_{rev} = (t_+ - t_-)\frac{RT}{F} Ln\ \frac{S_1}{S_2} \tag{7.28}$$

where t_+ and t_- are the transference numbers for ion movement through the individual pore, and S_1 and S_2 are the salt concentrations on either side of the membrane. This is equivalent to Eq. (7.12). Thus, if a channel has perfect selectivity for cations (or for anions) the reversal potential will shift by 59 mV for a 10-fold concentration gradient (at 25°C).

The permeability ratio is a common measure of the selectivity among ions of the same charge. In general, the permeability ratio can be computed from a constant-field equation similar to Eq. (7.26). This equation reduces to a particularly simple and useful form under bi-ionic conditions, with two different salts at the same concentration on either side of the membrane (e.g., NaCl and KCl for an exclusively cation-selective channel):

$$E_{rev} = \frac{RT}{F} Ln\ \frac{P_x}{P_y} \tag{7.29}$$

where P_x and P_y represent the permeabilities of the two ions x and y. A selectivity (permeability ratio) of 10 will give rise to a reversal potential of 59 mV at 25°C. Notice that Eq. (7.29) does not involve the actual salt concentration, as long as the concentration of salt X on one side is the same as the concentration of salt Y on the other side.

The relative permeability of a channel to different ions can be measured in cell-attached patches, even when the intracellular ion composition is not precisely known, from changes in the single-channel reversal potential associated with different patch pipette solutions. When the highly selective renal K channel, ROMK2, is expressed in K-depolarized *Xenopus* oocytes, the single-channel (cell-attached) i-V curve intersects the origin at a reversal potential of zero (solid line, Figure 7.13). When the same experiment is performed with Rb (rather than K) in the patch pipette, the single channel i-V relation becomes less steep, and the reversal potential shifts in a negative direction by 14 mV (dashed line, Figure 7.13). Using Eq. (7.29), this change in reversal potential implies a permeability ratio, $P_{Rb}/P_K = 0.63$ for ROMK2, expressed in *Xenopus* oocytes.

Ionic selectivity can also be estimated from single-channel conductance ratios determined under different ionic conditions. These can be compared with selectivity ratios derived from the permeability ratios described above. In general, the conductance ratio will

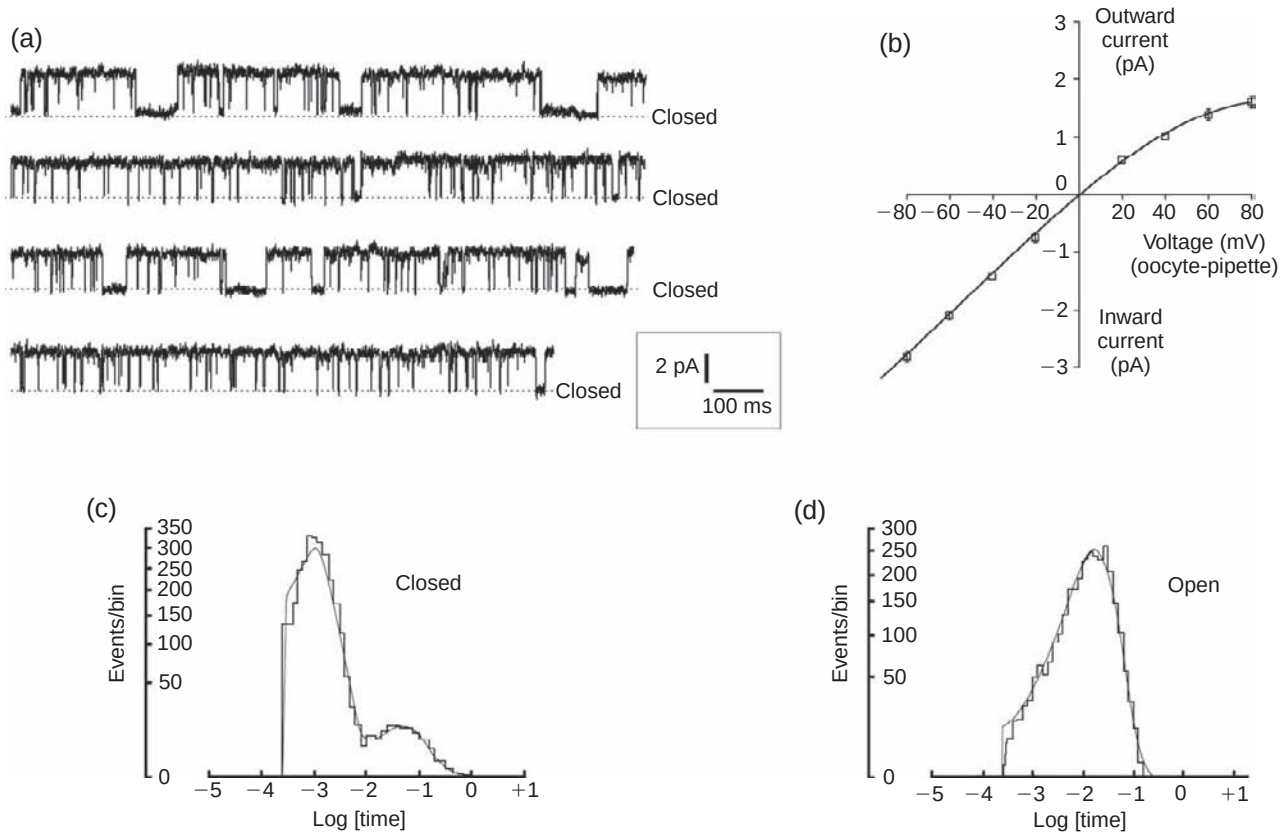

FIGURE 7.12 **Example of single-channel current records and associated analysis.** ROMK2 was expressed in *Xenopus* oocytes, and currents were recorded from a single channel in a cell-attached patch. The oocyte membrane potential was reduced close to zero by 100 mM KCl in the bath. The patch pipette also contained 100 mM KCl. Neither divalent ions nor specific chelating agents like EDTA were added to the pipette. (a) Currents recorded with the membrane potential clamped at −80 mV (cytoplasm relative to pipette). Upward deflections from the closed state correspond to inward K currents. (b) Current voltage relation for ROMK2, constructed by recording currents at different (clamped) membrane potentials. (c) Closed time distribution at −80 mV, showing two discrete closed states with time constants of 1.2 msec and 47 msec. (d) Open time distribution at −80 mV, with mean open time of 19 msec (from [60]).

differ from the permeability ratio, derived from reversal potentials and Eq. (7.29). For example, using the data of Figure 7.13, the ratio of inward Rb conductance to inward K conductances is $g_{Rb}/g_K = 0.36$. This differs significantly from the permeability ratio, $P_{Rb}/P_K = 0.63$ determined from reversal potentials. The discrepancy is even larger when the selectivity of K versus NH_4 is considered. Here the shift in reversal potential implies $P_{NH4}/P_K = 0.1$. However, the conductance to NH_4 at large negative potentials is equal to or higher than that to K at voltages driving inward currents, giving $g_{NH4}/g_K \geq 1$.[60,61] Discrepancies of this kind may indicate an interaction between the permeant ions and the channel. Rb may bind tightly a particular site within the pore, thus passing slowly through the channel. However, this binding will displace K from the channel, also reducing K conductance. The permeability ratio will reflect the relative affinity of the binding site for the two ions. Conversely, NH_4 may bind less tightly than K within the conduction pathway.

Open Probability

A second fundamental parameter of an ion channel that can be measured directly using single-channel recording is the open probability (P_o) or the fraction of time the channel spends in the open state. If there is only a single channel in the patch, P_o is determined by dividing the amount of time spent in the open state by the total recording time. P_o can also be measured in patches with more than one channel, provided that the number of channels (N) is known. This requires identification of the states with all channels open and with all channels closed, as discussed below.

A useful measure of overall channel activity in multichannel patches is the mean number of open channels, defined by Eq. (7.30):

$$NP_o = \sum_{n=1}^{N} nP_n \tag{7.30}$$

where P_n equals (the dwell time with n channels open)/(total time); and N is the total number of

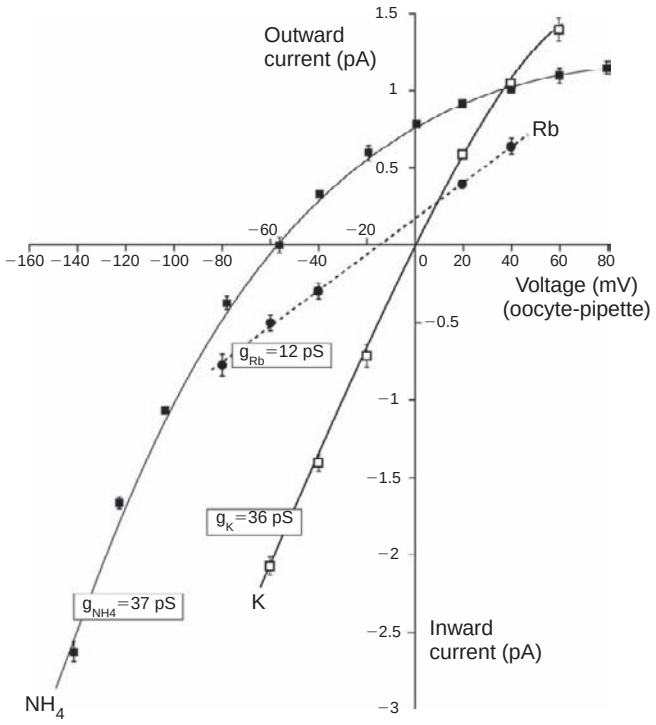

FIGURE 7.13 **Differences between relative conductances and relative permeabilities.** When R_b replaces K as the permeating cation of ROMK2, there is a shift in both the reversal potential (x intercept) and single-channel conductance (slope) of the i-V relation. The Rb/K permeability ratio calculated from the change in reversal potential was 0.63, which is significantly larger than the Rb/K conductance ratio of 0.36 determined from the inward slopes of the i-V curves. Similarly, the NH_4/K permeability ratio calculated from the change in reversal potential was 0.12, compared to a NH_4/K inward conductance ratio of unity (from [60]).

channels in the patch. Single-channel open probability (P_o) can be readily determined from Eq. (7.30), if the number (N) of channels in the patch is known. One caveat is that channels whose kinetics are very slow relative to the recording time may not be counted by Eq. (7.30).

An alternative method for estimating open probability is to compare the total macroscopic current (I) resulting from N channels to the single channel current (i), using Eq. (7.31), assuming that the number of channel proteins (N^*) can be measured independently. Under these conditions, the open probability would be given by (P^*_o):

$$P^*_o = I/N^*i \tag{7.31}$$

In *Xenopus* oocytes expressing ENaC channels, P^*_o was estimated to be 0.05 with Eq. (7.31) (Table 7.5). This is an order of magnitude lower than the P_o of about 0.5 that was determined by conventional electrical methods.[62] Presumably, this difference reflects a large number of silent channels, which are electrically invisible and therefore do not contribute to patch-clamp determinations of P_o. Equations (7.30) and (7.31) yield comparable estimates of P_o only for the special case where all channels in the membrane are active during the electrical measurements.

NUMBER OF CHANNELS

The number of channels in a patch (N) divided by the area of the patch will reflect, on average, the density of channels in the membrane. In principle, N can be observed. In practice, not all the possible current levels will be visited during the lifetime of the recording. This is particularly problematic when the P_o of the channels is either very low or very high. Sometimes this difficulty can be mitigated by maximally activating or deactivating channels at the end of a recording by applying voltage or chemical regulators.

If the properties of all channels are identical and are independent of each other, then the percentage of time spent in each state (e.g., 1 channel open, 2 channels open, etc.) should follow the binomial distribution. Fitting the measured distribution of times with a binomial function can then be used to estimate channel number.[63] This method is less biased than that of counting current levels, as the latter will always be an underestimate. However, the assumption that channels have identical kinetics is probably not always valid.

In some cases the kinetics of the channels can be used to estimate N. If all channels have a high P_o such that the state with all channels open is clearly defined, and a reproducible mean open time t_{open} (see below), then the mean time that an ensemble of N channels will stay in the all-open state will be t_{open}/N. Thus, N can be estimated even if the current level with all channels closed is never directly identified.[64] A similar procedure can be used on channels with a low P_o if the mean closed time is reproducible. This procedure works only if the channels have a single open (or closed) state (see below).

The area of patches is also difficult to quantify precisely. When the membrane patch can be seen in the light microscope, it often appears to be drawn a considerable distance into the patch-clamp pipette by the process of seal formation.[65,66] A typical patch geometry might correspond to a membrane area of about 5 μm^2. Areas estimated from electrical capacitance measurements varied from about 1 μm^2 to over 15 μm^2.[65] The area will depend on both the size of the micropipette and the cell type. Perhaps the surest way of estimating single-channel density is to combine single-channel measurements with a macroscopic measurement. For example, the number of Na channels in the apical membrane of the rat CCD has been estimated from the whole-cell, amiloride-sensitive conductance, and the

TABLE 7.5 Open Probability of Na Channels Expressed in *Xenopus* Oocytes[a]

Direct measurement: $P_o = 0.42$	Patch-clamp
Macroscopic current: I = 0.94 μA (100 mV)	TEVC
Single-channel current: i = 0.60 (− 100 mV)	Patch-clamp
Channel number $N^* = 1.7 \times 10^8$/cell	Ab binding (assume 4 subunits/channel)
Open probability: $P_o^* = I/N^*i = 0.04$

average single-channel conductance and open probability measured under similar conditions (Table 7.6).

OPEN AND CLOSED TIMES

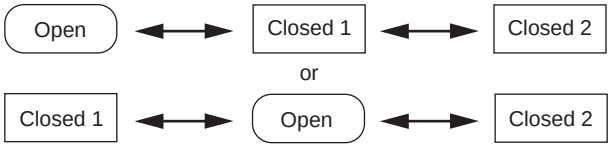
All channels that open and close can be characterized, not only by the percent time in the open state (P_o), but also by the mean times spent in these states or, equivalently, the rates of transition between them. The mean lifetimes of the open and closed states can range from less than 1 msec to more than 1 second. The lifetimes of a given state are presumed to be exponentially distributed, similar to those of radioactive isotopes. The transition rates can be estimated by plotting the number of open (or closed) events of a given duration as a function of that duration.

In the simplest kinetic scheme, a channel that has just one open and one closed state can be diagrammed as follows:

This will result in open- and closed-time histograms which are monotonically decreasing functions of interval length, and which can be fitted by a single exponential decay curve.

In practice, the kinetic parameters of a particular channel are usually estimated by fitting the open and closed dwell time distributions with multiple exponential components. In this regard, it has proved most useful to generate event histograms with a logarithmic time axis and a square root transformation of the ordinate.[67] This greatly simplifies interpretation and fitting of distributions that contain multiple exponential components. Examples of two such fitted distributions are shown in Figure 7.12c and Figure 7.12d, respectively, for the closed and open times of single ROMK2 channels expressed in *Xenopus* oocytes. In this type of representation, the peaks of each of the skewed, bell-shaped curves correspond to time constants for the open and closed states of the channel.

Even after the number and duration of closed and open states have been determined, the exact kinetic scheme for the channel may still be ambiguous. Both of the models depicted below are consistent with two closed states and one open state. The first model corresponds to transitions between a single open state and a long-lived closed state (closed 2) that can only be reached by passage through a short-lived closed state (closed 1). In the second model, both the short and long-lived closed states are accessible from the open state. Even with this modest degree of complexity these two patterns cannot readily be distinguished, and the rate constants among the states cannot always be unequivocally derived.



Channels can have multiple open states as well as multiple closed states. In Ca-activated BK channels, for example, models with 50 different states are required to portray channel kinetics.[68] As the number of possible open and closed states increases, the difficulty of the analysis increases as well, making it difficult to assign values to individual rate constants or to distinguish alternative kinetic schemes.

The situation can be even more complicated if the channel exhibits bursts of activity that are themselves part of a larger pattern of activity. This behavior requires even more states. Alternatively, a kinetic scheme based on fractals has been proposed[69] on the basis that a burst within a burst pattern will continue to be observed as the time domain over which

measurements are made becomes smaller or larger. The relative merits of fractal models as opposed to the more conventional discrete-state models are discussed in detail elsewhere.[70–72] Although the fractal approach is mathematically elegant, it is rarely used in practice since discrete-state models more closely correspond to the simple physical picture of a channel protein having several alternative conformations. It emphasizes, however, that the kinetic models are based on measurable time scales determined by technical limitations. Events of <0.1 msec duration are difficult to resolve with current instrumentation. On the other side of the spectrum, it is difficult to record a sufficient number of events of duration >10 sec to analyze accurately.

In some cases multiple gating "modes" have been distinguished from different kinetic states.[73,74] Here a channel will shift abruptly from one pattern of gating to another. This can be thought of as preserving the same open and closed states, but changing the rate constants for moving from one state to another. In some cases, changes in gating mode could reflect a chemical modification of a channel, such as a change in the phosphorylation state. However, reversible mode switches have also been observed with channels reconstituted into planar lipid bilayers.[75] In these cases the modes must be intrinsic to the channel proteins themselves.

Channel Pharmacology

Another defining characteristic of a channel type is its response to pharmacological agents, usually those which block the channel. If a specific blocker can be identified, it is also quite useful to compare single-channel data with macroscopic currents, similar to what was shown above for estimation of channel density. Amiloride is a commonly used blocker for epithelial Na channels, whereas Ba, TEA or Cs, block K channels. The dihydropyridines and certain divalent cations such as Cd^{+2} block Ca-selective channels, disulfonic stilbenes as well as a variety of organic anions block Cl channels, and gadolinium inhibits stretch-activated cation channels. A variety of naturally produced toxins work by blocking ion channels; most are directed against voltage-gated channels in excitable epithelia. However, tertiapin, a component of honey-bee venom, is a potent and fairly selective blocker of the renal K channel ROMK.[76,77] In addition, high-throughput screening has been used to identify novel inhibiters of specific ion channels. This approach has identified small-molecule blockers of ROMK channels that may be useful for *in vivo* or clinical applications.[78]

Channel blockers can affect either the open probability of the channel or its (apparent) single-channel conductance. The effect depends on the rates of association and dissociation of the blocker with the channel. In particular, if the off-rate is *slow* relative to the bandwidth of the recording device and the duration of the spontaneous open and closed states, the blocking action will be revealed as a new long-lived closed state. Block of the maxi-K channel by Ba^{+2} on the cytoplasmic side is an example of this type of interaction (Figure 7.14a). On the other hand, if the blocking action is *fast* relative to the bandwidth, it will show up as a decrease in the apparent single-channel conductance. Block of the maxi-K channel by extracellular TEA is a good example (Figure 7.14b).

Often the on-rates for blocking ions are diffusion-limited, i.e., very roughly in the range of $10^8\ sec^{-1}\ M^{-1}$. In this case, the rates of unblocking are inversely related to the affinities of block. For blockers with affinities in the nM range, the off-rate will be 10^{-1}/sec. This is a slow block, with a mean lifetime of the blocked state of 10 sec. For blockers with affinities in the μM range the mean lifetime could be 10 msec, corresponding to an intermediate blocking speed in which the blocking events are readily observed in patch-clamp recordings. For blockers with affinities in the mM range, the mean lifetime of the closed state would be 10 μsec, too fast to be resolved under most conditions.

There are at least two basic mechanisms of block, regardless of the blocking kinetics. In one, the blocker enters the pore part way, and sticks there by binding to a site within the pore. This type of block is usually voltage-dependent, particularly if the blocker is charged, since the transmembrane electric field will tend to either pull it into the pore or push it out. Voltage dependence may also arise if the blocker displaces permeant ions from the electric field. Examples of this type of block include those of Mg^{+2} and polyamines in inward-rectifier channels,[79] Ba^{+2} on several types of K channels,[80] and amiloride on the epithelial Na channel.[81] Another type of block involves an allosteric interaction with the channel protein. This changes the conformation of the protein to one in which the pore is closed or stabilizing a spontaneously occurring closed conformation. A well-studied example of this type of block is that of dihydropyridines on voltage-dependent Ca-channels.[73] The second type of block may be voltage-independent. However, a voltage-dependence could arise if the conformational change involves a movement of charge on the channel protein with respect to the electric field across the membrane.

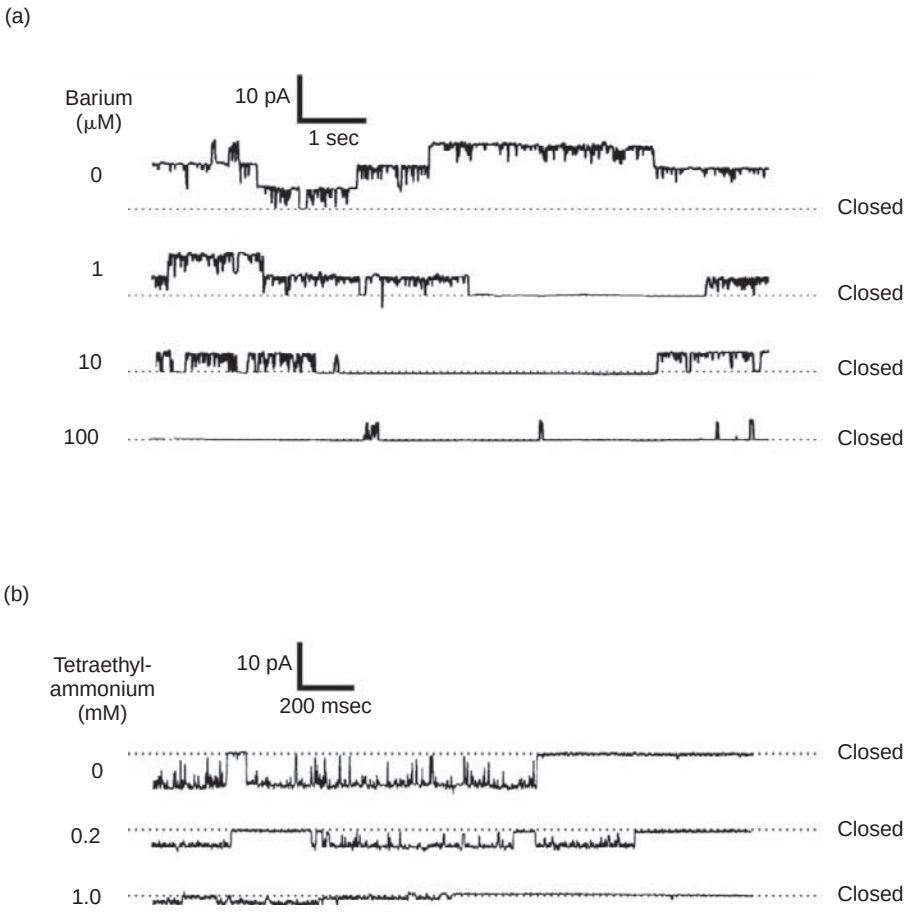


FIGURE 7.14 Comparison of (a) block of maxi-K channels by a slow blocker, Ba, which is effective at micromolar concentrations and reduces the open probability, with (b) block by tetraethyl ammonium, which is effective at mM concentrations and reduces the apparent single channel conductance (from [181]).

APPLICATION TO EPITHELIA

One of the major difficulties in the application of the patch-clamp technique to renal epithelia has been gaining access to the plasma membranes. Different methods have been used for both apical and basolateral membranes.

Apical Membranes

One successful approach to gaining access to the apical membrane is to split the tubules mechanically and flatten them onto their basolateral surfaces.[82,83] The use of a transparent, non-toxic, molluscan adhesive (Cell-Tak, Becton-Dickinson, Bedford, MA) has greatly improved attachment of the basement membrane to the bottom of the chamber and increased the stability of the patch-clamp recording.[82,84] An example of a split, flattened proximal tubule from *Necturus maculosus* is shown in Figure 7.15. Absence of staining with Trypan blue, except around the edge of the tissue, indicates viability of most of the hexagonal cells. Gigaohm seals can be formed on the apical surface of this preparation (shadow of a patch pipette can be seen near the center of the field). Although splitting individual nephron segments works best in large, amphibian tubules,[82,84–86] it has also been successfully used in mammalian CCD and TALH.[83,87,88]

A second approach to patch-clamping the apical surface of renal tubules has been to insert a micropipette into the open lumen of a perfused tubule.[89] This has the advantage of maintaining the tubule in the perfused state, and theoretically permits independent control of the solution on both sides of the tubule. However, this technique significantly increases the complexity of the patch-clamp procedure and decreases cell visibility, making it difficult or impossible to be absolutely sure which cell type is actually being studied within a given nephron segment.

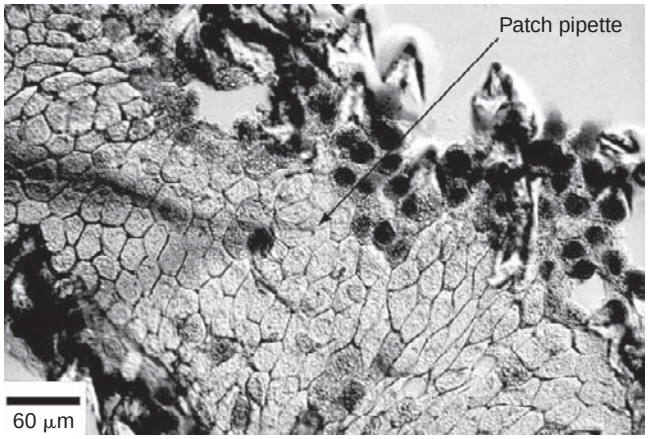

FIGURE 7.15 **Light micrograph of split-open *Necturus* proximal tubule (apical side up), viewed from below with modulation contrast optics.** The tissue was attached with Cell-Tak. Nuclei of damaged cells at the periphery are readily identified by their uptake of Trypan blue. Undamaged cells are approximately hexagonal in shape and exhibit well-defined boundaries with a diagonal diameter of about 30 μm. The tip and shadow of a patch pipette are visible at the left of the figure.

Another technique that preserves the separation of apical and basolateral solutions entails the eversion of the entire tubule, which can then be perfused with the luminal surface on the outside.[90–92] This approach has the advantage of maintaining the integrity of the entire tubule, but is technically demanding.

Finally, renal cells can be studied in culture, taking advantage of the tendency of epithelial cells to attach to a suitable substrate with their basolateral side down, leaving the apical membranes facing up and accessible for patch-clamping. Both continuous cell lines[93–95] and primary cultures of renal tubules[34,84,86,96–98] have been used. A problem with this approach is the difficulty of preserving the properties of the original cells in culture. One cell line which does appear to closely resemble native epithelial cells from the distal nephron is the A6 line from *Xenopus* kidney.[99] This has been a particularly useful preparation for studying epithelial Na channels.[93,100–102] A mammalian cell line that also preserves a distal nephron phenotype and has been used for patch-clamp is the mouse line mpkCCDc14.[95,103]

Basolateral Membranes

Basolateral channels are difficult to study because the basal surface is covered with a basement membrane that must be removed to allow access to the plasma membrane. With isolated amphibian tubules it has been possible to gain access to the basolateral membrane by manually removing a small segment of basement membrane.[84,104] This process has also been applied to the mammalian collecting tubule.[105] However, most patch-clamp studies on mammalian basolateral membranes have used pre-treatment of the tubules with a collagenase solution to remove enough of the basement membrane to permit formation of a high resistance patch-clamp seal.[105–109]

In an effort to circumvent the possible problems associated with enzymatic digestion, the lateral cell membranes of mammalian nephron segments have been patch-clamped either on the open end of a perfused tubule[89] or by mechanically removing an adjacent cell in an otherwise intact epithelium. The latter method was used to study basolateral channels on the lateral membrane of principal cells of rat CCD.[110] Here, a suction pipette is used to remove an entire intercalated cell from a split-open rat collecting tubule. This exposes a clean, lateral surface of an adjacent principal cell on which a high resistance seal can be formed with a standard patch pipette (Figure 7.16).

Isolated Cells

Another way of gaining access to either the apical or basolateral cell membranes is to use isolated, polarized cells, derived by a brief collagenase or trypsin treatment of the epithelium. This weakens the basement membrane sufficiently so that individual, undamaged cells can be obtained by moderate mechanical agitation. A number of studies have been carried out using isolated cell preparations of proximal tubules, since these cells often retain their polarity for extended periods.[111–115] Detailed cytochemical studies on isolated cells of this type have confirmed the stability of markers normally associated with either the apical or basolateral membranes of intact epithelia.[115] An example of an isolated amphibian proximal tubule cell is illustrated in Figure 7.16.[112,115] These cells maintain their polarity by assuming a bi-spherical,

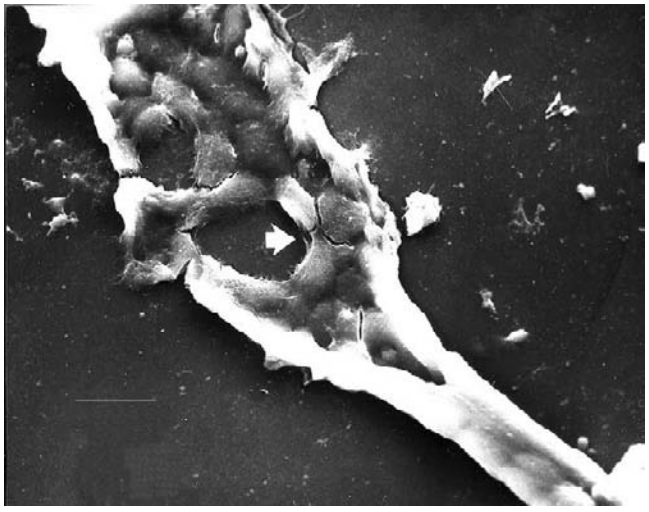

FIGURE 7.16 **Scanning electron micrograph of split open CCD.** Arrow shows lateral membrane of a principal cell. The intercalated cell adjacent to the principal cell was removed by mechanical suction, leaving the principal cell intact (from [110]).

minimum energy configuration. In this picture the apical surface, with brush border, is clearly visible as the smaller hemisphere, whereas the larger spherical surface consists of basolateral membrane.

NOISE ANALYSIS

Noise or fluctuation analysis provides an alternative approach to obtaining information at the level of single channels. In this technique the mean current level, as well as the variations about the mean, is used to infer single-channel properties. The principle behind the measurement is that random openings and closures of channels within a population will give rise to appreciable fluctuations in the overall number of open channels. The amplitudes of the fluctuations depend on the number channels, their open probability, and the single-channel current (see below). For a given mean current level, the fluctuations will be larger for a small number of channels (with large single-channel currents) than for a large number of channels (with smaller single-channel currents), since opening or closing one channel will produce a larger change in the mean current. A major disadvantage of this approach versus that of patch-clamp is that the single-channel events are not observed directly, but need to be extracted from the data using kinetic models, Fourier transforms, and curve fitting. A second drawback is that information on variations in channel behavior may be lost, and only the mean properties of an ensemble of the channels are obtained. This loss of information can sometimes be a blessing in disguise, particularly when the overall performance of the whole population of channels needs to be assessed, by focusing attention on the quantitatively important aspects of channel function. Another advantage is that the sampling of channel properties is not biased by those of a few "good" patches which may be easy to analyze, but are not necessarily representative. A third advantage of noise analysis over direct recording of single-channel events is that it can resolve smaller single-channel currents. For example, the inward-rectifier K channel Kir7.1 has a single-channel conductance of $\sim$50 fS estimated from noise analysis.[116] Single-channel openings and closings associated with this conductance would be impossible to see using patch-clamp recordings.

Like single-channel recordings, noise analysis depends on abrupt changes in currents which occur when channels open or close, giving rise to fluctuations. Although it is possible to analyze noise due to spontaneous opening and closing, in practice most uses of noise analysis in epithelia have made use of blocker-induced noise in which the fluctuations are promoted by addition of blocking ions to the medium. This has two advantages. First, if the blockers interact with the channel through a first-order process, the kinetic scheme is particularly simple:

In the frequency domain, such a scheme predicts fluctuations which follow the form of a simple Lorentzian equation[117]:

$$S = S_o/[1 + (f/f_c)^2] \quad (7.32)$$

Where S is the power associated with a given frequency f, S_o is the plateau power approached at low frequencies, and f_c is a constant called the corner frequency, and is the frequency at which the power is reduced to half that of the plateau (Figure 7.17). Furthermore, f_c is determined by the kinetics of the blocking interaction:

$$2\pi f_c = [B]k_{on} + k_{off} \quad (7.33)$$

where [B] is the blocker concentration, and k_{on} and k_{off} are the on and off rate constants, respectively for the blocking reaction.

A second advantage of studying blocker-induced noise is that both the blocker and its concentration can be chosen to optimize the frequency of the fluctuations. This is important because technical problems can often limit the frequencies over which the noise can be reliably measured. For example, although amiloride-induced noise was originally used to study properties of epithelial Na channels,[117] recordings could be improved by using a lower affinity analog which produced fluctuations at higher frequencies.[118]

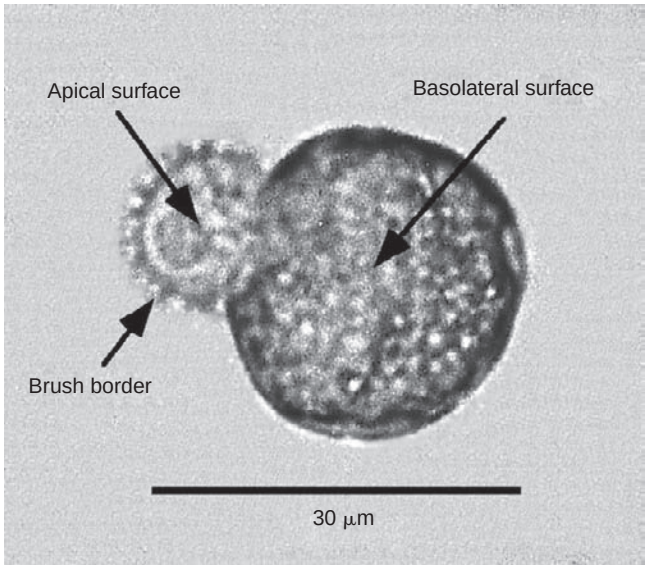

FIGURE 7.17 Isolated *Necturus* proximal tubule cell. The cell is bi-spherical in shape and about 30 microns in diameter. Evidence of a brush border is apparent on the smaller apical sphere. The larger spherical side of the cell consists of basolateral membrane. Isolated amphibian proximal tubule cells retain their polarity much longer than mammalian isolated epithelial cells. Patch-clamp recordings from both apical and basal surfaces indicate channel types similar to those found in native tubules.

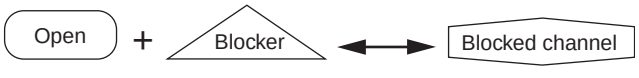
The simplest piece of information that can be extracted from the noise analysis is the single-channel current[117]:

$$i = S_o 2\pi f_c / 4IF_B \tag{7.34}$$

Where F_B represents the fraction of blocked channels and I is the total (mean) current through the ensemble of channels measured in the presence of the blocker. F_B can be determined from the ratio of k_{on}/k_{off}, noting that $F_B = 1/(1 + k_{off}/k_{on}\bullet[B])$. F_B can also be estimated from the macroscopic dose-response curve (Figure 7.18a), although this may give different results if the blocker increases the number of channels contributing to the noise. The quantity N_o (=mean number of open + blocked channels) can be calculated from:

$$N_o = I/[i(1 - F_B)] \tag{7.35}$$

In general, N_o will be smaller than the total number of active channels N, since closed channels are not included. Helman and colleagues have made use of this discrepancy, and the finding that N_o increases as the concentration of blocker is increased, to assess P_o, the open probability of unblocked channels. This was analyzed in terms of a three-state model [118]:



Assuming that closed channels cannot be blocked, the number of open + blocked channels is increased by the blocker through the principal of mass action.

A second approach to estimate P_o is to measure the fluctuations associated with the spontaneous opening and closing.[119] Again a simple model is assumed:

In which the variance (σ^2) of the current is given by[58]:

$$\sigma^2 = Ni^2P_o(1 - P_o) = I(1 - P_o)i \tag{7.36}$$

Therefore, the three measurements of blocker-induced noise, mean current, and variance in the absence of blocker can be used to estimate the three variables i, N, and P_o.

Most noise analysis studies have used flat epithelia in which the transepithelial voltage is clamped. Both native tissues[44,117,120,121] and cultured cells[118,122] have been successfully studied. In these instances blockers have been added to the apical side of the epithelia to measure properties of Na channels (using amiloride or its analogs as blockers) or K channels (using Ba^{+2}). More recently, fluctuation analysis has been applied to whole-cell recordings of renal epithelia, particularly the CCD, where the cells are not electrically coupled to each other.[38] Na channel fluctuations similar to those of flat epithelial can be measured in this way.[119] Another application involved characterization of basolateral K channels which, as described above, are difficult to study directly.[123] Similar techniques were also used to examine cell-attached patches in which channel density was too high to resolve single-channel events directly.[124]

Molecular Identification of Channels

Detailed information about channel properties obtained from patch-clamp analysis can, in some cases, be used to establish the molecular identity of the channels. Ideally this identification is corroborated using biochemical and genetic techniques. Table 7.7 provides a list of such channels for the mammalian nephron.

ROMK (Kir1.1), the apical K^+ channel of the TAL and CNT/CCD, provides a good example of this process. The channel was observed characterized in both of these segments[125,126] before the cDNA encoding it was cloned.[127] Subsequent detailed comparison of the biophysical properties of the native and cloned channels made it highly likely that the two were identical.[61] This was supported by immunocytochemical evidence demonstrating expression of the channel protein in the luminal membrane of the appropriate segments of the rat kidney.[128–130] Finally, genetic deletion of ROMK

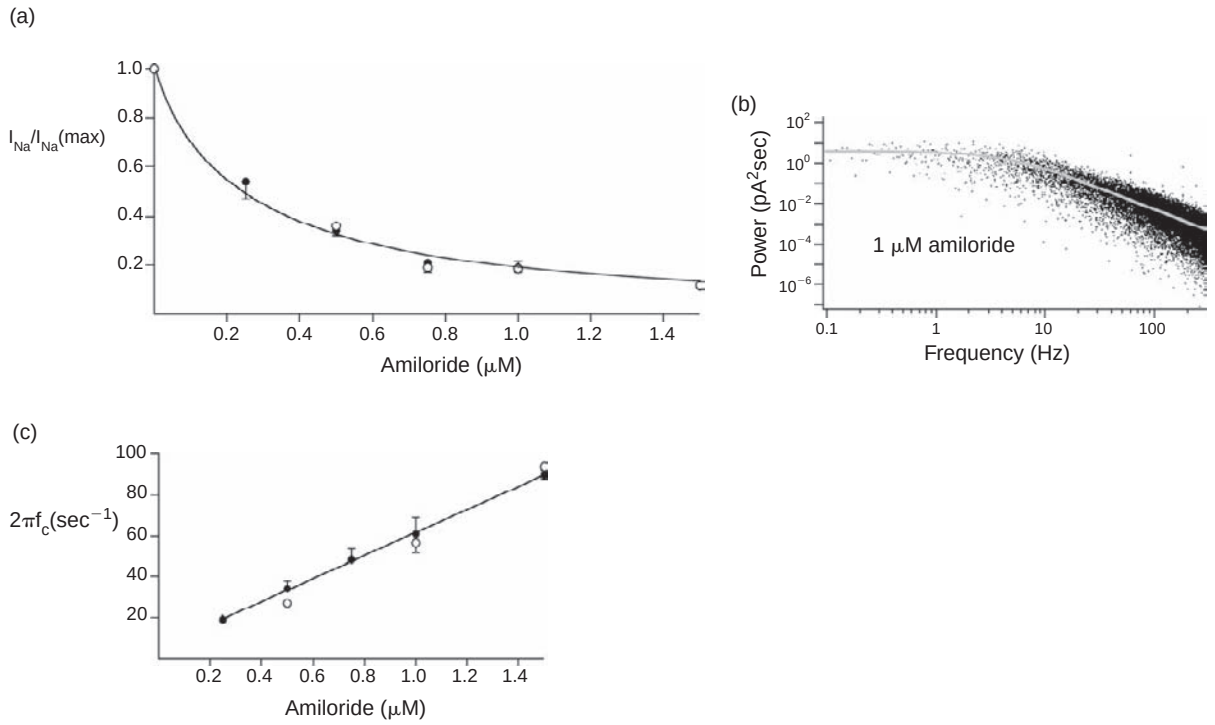


FIGURE 7.18 Noise analysis of whole-cell currents in a principal cell of the mouse CCD. The power density spectrum was obtained with 1 μM amiloride in the bath. The line represents a fit to a Lorentzian function with So = 3.06 pA^2 sec and f_c = 3.8 Hz (from [119]).

in the mouse led to the disappearance of the channels from the apical membranes of both the CCD and TALH.[131]

Although few channels have been examined as fully as ROMK, the list of fully and partially identified conductances is growing. In some cases, the genetic identification cited in Table 7.7 entails the analysis of phenotypes of human mutations such Bartter's[132] and SESAME/EAST[133,134] syndromes rather than a knock-out line. This is a less direct approach, but one that increases the pathophysiological relevance of the channel.

CONCLUSIONS

The patch-clamp approach has made it possible to study renal ion channels one molecule at a time. Insights into ion transport mechanisms that have emerged from these studies have greatly expanded the information that was previously available from equivalent circuit analysis. Although single-channel measurements provide details about how ion *channels* work, they do not provide complete information about how an *epithelium* works. Achieving this goal requires measurements of transepithelial, intracellular, and single channel properties.

APPENDIX 1. THE BASIC EQUATIONS FOR THE GENERAL EQUIVALENT CIRCUIT

The lateral resistive network in the circuit of Figure 7.1 makes it difficult to obtain a closed form solution for the electrical parameters of interest. However, if the lateral network is neglected, Figure 7.1 reduces to the simpler circuit of Figure 7.7a, which can be evaluated as follows.

Since the pump and diffusional EMFs are in parallel, the effective electromotive force of the cellular pathway is the sum of the individual EMFs weighted by their relative conductances:

$$E_{bl}^{*} = \frac{R_{bl}}{R_p + R_{bl}} E_p + \frac{R_p}{R_p + R_{bl}} E_{bl} \qquad \text{(A1.1)}$$

where E_p is the reversal potential of the pump and E_{bl} is the total ionic diffusion potential across the basolateral membrane, as given either by the mosaic membrane equation (Eq. (A1.2)) or the constant field equation (Eq. (A1.3)):

$$E_{bl} = -\frac{RT}{F}\left[t_{Na} Ln \frac{[Na]_c}{[Na]_b} + t_K Ln \frac{[K]_c}{[K]_b} + t_{Cl} Ln \frac{[Cl]_b}{[Cl]_c}\right] \qquad \text{(A1.2)}$$

TABLE 7.7 Molecular Identification of Ion Channels in Renal Tubules

Channel			Identification	
		Function	Protein	Genetic
PROXIMAL TUBULE				
Basolateral	K: K_{ATP} (Kir6?)	106, 107, 109, 155	–	–
TALH				
Apical	K: Kir1.1 (ROMK)	126	128, 130, 156	131
Basolateral	Cl: CLCK1(A)/2(B)	108, 157	158-160	132, 161
DCT				
Basolateral	K: Kir4.1/5.1	162	163, 164	133, 134
	Cl: CLCK2(B)	165, 166	159	–
CNT/CD PRINCIPAL CELL				
Apical	Na: ENaC	87, 167	168, 169	170
	K: Kir1.1 (ROMK)	125, 171	128, 130, 156	131
	K: mSlo (BK)	83, 172	–	–
Basolateral	K: Kir4.1/5.1	173	173	–
	K: Kir4.1	110, 123	173	–
	Cl: CLCK2(B)	174	159	–
CNT/CD INTERCALATED CELL				
Apical	K: mSlo (BK)	175, 176	177	–
Basolateral	Cl: CLCK2(B)	174, 178	158, 159	–

$$E_{bl} = -\frac{RT}{F} Ln \frac{P_{Na}[Na]_c + P_K[K]_c + P_{Cl}[Cl]_b}{P_{Na}[Na]_b + P_K[K]_b + P_{Cl}[Cl]_c} \quad \text{(A1.3)}$$

The effective basolateral resistance R^*_{bl} is the parallel sum of pump resistance (R_p) and the passive resistive elements of the membrane (R_{bl}):

$$R^*_{bl} = \frac{R_p \cdot R_{bl}}{R_p + R_{bl}} \quad \text{(A1.4)}$$

Transepithelial resistance (R_{te}) is a function of the other resistances in the network as defined by:

$$\frac{1}{R_{te}} = \frac{1}{R_{tj}} + \frac{1}{R_{ap} + R^*_{bl}} \quad \text{(A1.5)}$$

Considering the circuit of Figure 7.7b, the total circulating current (I) can be calculated from the total EMF of the circuit divided by the total resistance according to the equation:

$$I = \frac{-E^*_{bl} - E_{ap} + E_{par}}{R^*_{bl} + R_{ap} + R_{tj}} \quad \text{where } E^*_{bl} \text{ and } E_{ap} < 0 \quad \text{(A1.6)}$$

Under these conditions, the measured basolateral potential will be given by:

$$V_{bl} = E^*_{bl} + I \cdot R^*_{bl} = \frac{E^*_{bl}(R_{ap} + R_{tj}) + R^*_{bl}(E_{par} - E_{ap})}{R^*_{bl} + R_{ap} + R_{tj}} \quad \text{(A1.7)}$$

The measured apical membrane potential will be given by:

$$V_{ap} = E_{ap} + I \cdot R_{ap} = \frac{E_{ap}(R^*_{bl} + R_{tj}) + R_{ap}(E_{par} - E^*_{bl})}{R^*_{bl} + R_{ap} + R_{tj}} \quad \text{(A1.8)}$$

and the measured transepithelial potential will be given by:

$$V_{te} = E_{par} - I \cdot R_{par} = \frac{E_{par}(R_{ap} + R^*_{bl}) + R_{tj}(E_{ap} + E^*_{bl})}{R^*_{bl} + R_{ap} + R_{tj}} \quad \text{(A1.9)}$$

Equations (A1.7)–(A1.9) can be evaluated for the limiting cases of very tight and very leaky epithelia. In the case where the cell (rather than the interspace) is the primary conductive pathway:

$$Lim\ V_{bl} = E^*_{bl} \qquad \text{for } R_{tj} >> R_{ap} + R^*_{bl} \text{ (very tight epithelium)} \quad \text{(A1.10)}$$

and:

$$Lim\ V_{ap} = E_{ap} \qquad \text{for } R_{tj} >> R_{ap} + R^*_{bl} \text{ (very tight epithelium)} \quad \text{(A1.11)}$$

If perturbations are confined to the apical membrane, the additional limiting case is sometimes useful when only transepithelial measurements can be performed:

$$Lim\ \ \Delta V_{ap} = \Delta E_{ap} = \Delta V_{te} \qquad \text{for } R_{tj} >> R_{ap} + R^*_{bl} \quad \text{(very tight epithelium)} \tag{A1.12}$$

since:

$$Lim\ \ V_{te} = E_{ap} + E^*_{bl} \qquad \text{for } R_{tj} >> R_{ap} + R^*_{bl} \quad \text{(very tight epithelium)} \tag{A1.13}$$

At the other extreme, if the paracellular pathway has a much higher conductance than the cellular pathway:

$$Lim\ \ V_{te} = E_{par} \qquad \text{for } R_{ap} + R^*_{bl} >> R_{tj} \quad \text{(very leaky epithelium)} \tag{A1.14}$$

Finally, two other limiting cases of the general circuit equations permit determination of cell membrane properties from transepithelial measurements under special conditions. First, application of a high K solution to the serosal side of an epithelium having a predominantly K selective basolateral membrane reduces both R^*_{bl} and E^*_{bl} to values close to zero. Under these conditions, Eqs. (A1.8) and (A1.9) imply the following simple relation between V_{ap} and V_{te}.

$$V_{ap} = V_{te} = \frac{R_{tj}}{R_{ap} + R_{tj}} E_{ap} + \frac{R_{ap}}{R_{ap} + R_{tj}} E_{par} \tag{A1.15}$$

(K depolarized tissue)

Second, protocols that involve selective permeabilization of the apical membrane reduce both R_{ap} and E_{ap} to values near zero, and Eqs. (A1.7) and (A1.9) imply a simple relation between V_{bl} and V_{te}:

$$V_{bl} = V_{te} = \frac{R_{tj}}{R^*_{bl} + R_{tj}} E^*_{bl} + \frac{R^*_{bl}}{R^*_{bl} + R_{tj}} E_{par} \tag{A1.16}$$

(permeabilized apical membrane)

APPENDIX 2. RELATION BETWEEN THE REAL CHANGE IN EMF AND THE MEASURED CHANGE IN POTENTIAL

Circular current flow in polarized epithelial cells produces important discrepancies between the real change in EMF at a particular barrier, ΔE, and the change in voltage, ΔV, that can actually be measured with electrodes (see Figure 7.7). In order to evaluate individual ion selectivities, some assumption must be made about the equivalent circuit of the epithelium. In the simple model of Figure 7.7a, luminal replacement of Na, K or Cl with an impermeant ion will produce changes in the measured basolateral ΔV_{bl} and transepithelial potentials ΔV_{te} that are related to the change in apical membrane EMF according to:

$$\Delta E_{ap} = \Delta V_{te} - \Delta V_{bl}\left[1 + \frac{R_{ap}}{R_p} + \frac{R_{ap}}{R_{bl}}\right] \tag{A2.1}$$

where R_{ap}, R_{bl}, and R_p respectively refer to the apical membrane resistance, the lumped basolateral membrane resistance, and the intrinsic resistance of the basolateral Na-K pump. In Eqs. (A2.1)–(A2.3), it is assumed that the external ion replacements are performed rapidly enough so that the resistance ratios (R_{ap}/R_p, R_{ap}/R_{bl}) are constant, and the ion composition of the cell is essentially unchanged. The equations were derived by noting that the total current entering the cell across the apical membrane must equal the total current leaving the cell across the basolateral membrane.

Basolateral replacement of Na, K or Cl with an impermeant ion yields an analogous expression for the relation between the change in basolateral EMF and the measured potentials ΔV:

$$\Delta E_{bl} = \Delta V_{bl}\left[1 + \frac{R_{bl}}{R_p} + \frac{R_{bl}}{R_{ap}}\right] - \frac{R_{bl}}{R_{ap}}\Delta V_{te} \tag{A2.2}$$

Finally, the paracellular EMF would be given by Eq. (A2.3) for experiments involving basolateral replacement of Na, K or Cl by an impermeant ion.

$$\Delta E_{par} = \Delta V_{te}\left[1 + \frac{R_{tj}}{R_{ap}}\right] - \frac{R_{tj}}{R_{ap}}\Delta V_{bl} \tag{A2.3}$$

Equations (A2.1)–(A2.3) would be used together with Eq. (7.23) of the text to evaluate the ionic transference numbers of the apical, basolateral, and paracellular barriers.

APPENDIX 3. EQUATIONS FOR PARTIAL IONIC CONDUCTANCE

Specific expressions for the partial conductance G_x can be obtained by differentiating the Goldman–Hodgkin–Katz flux equation with respect to voltage:

$$G_x = \frac{\partial I_x}{\partial V} = \frac{\partial}{\partial V}\left\{P_x \frac{z^2F^2}{RT} V \cdot \left[\frac{[X]_o - [X]_i e^{zFV/RT}}{(1 - e^{zFV/RT})}\right]\right\} \tag{A3.1}$$

In the limiting case of zero membrane potential, the complicated form of Eq. (A3.1) reduces to the

arithmetic average of the concentrations on both sides of the membrane. This equation does not depend on the ion being distributed near its electrochemical equilibrium:

$$G_x \approx P_x \frac{z^2F^2}{RT}\frac{1}{2}(X_o + X_i) \tag{A3.2}$$

At large negative membrane potentials, positive ions will be driven from outside to inside, and the limiting conductance will be:

$$G_x \approx P_x \frac{z^2F^2}{RT} X_o \tag{A3.3}$$

Conversely, at large positive potentials, negative ions will be driven from inside to outside, and the limiting conductance will be:

$$G_x \approx P_x \frac{z^2F^2}{RT} X_i \tag{A3.4}$$

Although the above relations reduce the complicated general equation (Eq. (A3.1)) to a manageable form, neither the assumption of zero membrane potential (Eq. (A3.2)) nor the assumption of very large membrane potentials (Eqs. (A3.3), (A3.4)) are terribly physiological.

For ions like K and Cl, which are often distributed close to their electrochemical equilibrium, it is possible to simplify the algebraic form of the 'X' term in Eq. (7.25) of the text. Under these conditions, the conductance would be given by the equation:

$$G_x \approx P_x \frac{z_x^2F^2}{RT}\left(\frac{[X]_i[X]_o}{[X]_o - [X]_i}\right)\mathrm{Ln}\frac{[X]_o}{[X]_i} \tag{A3.5}$$

If more than one ion (X and Y) is distributed close to equilibrium across the membrane, the ratios of transference numbers, conductances and permeabilities are given by the equation:

$$\frac{t_x}{t_y} = \frac{G_x}{G_y} \approx \frac{P_x}{P_y}\cdot\frac{[X]_o}{[Y]_i} = \frac{P_x}{P_y}\cdot\frac{[X]_i}{[Y]_o} \tag{A3.6}$$

APPENDIX 4. CONTRIBUTION OF THE ELECTROGENIC Na-K PUMP TO THE MEMBRANE POTENTIAL

The contribution of the Na-K pump to the cell membrane potential of epithelial tissues is different than its contribution to the membrane potential of symmetric cells. The existence of circulating currents in the open-circuited state places a different set of constraints on the magnitude of the cell potential. This can be derived from the reduced equivalent circuit of Figure 7.7b. In this circuit, the electrogenic and diffusive ion pathways are combined into an effective EMF of the basolateral membrane (E^*_{bl}), and an effective basolateral resistance (R^*_{bl}). These lumped quantities are directly related to the individual parameters of the pump and the basolateral diffusion potential according to standard equations of linear circuit theory:

$$R^*_{bl} = \frac{R_{bl}\cdot R_p}{R_{bl} + R_p} \tag{A4.1}$$

$$E^*_{bl} = \frac{R_{bl}}{R_{bl} + R_p}E_p + \frac{R_p}{R_{bl} + R_p}E_{bl} \tag{A4.2}$$

If the circulating currents of Figure 7.7b are also considered, the measured membrane potential (V_{bl}) can be described by Eq. (A4.3), which indicates the specific contribution of the electrogenic pump (E_p), the ionic diffusion potential (E_{bl}), and the apical and paracellular diffusion potentials (E_{ap}, E_{par}).

$$\begin{aligned} V_{bl} = {} & f\left[\frac{R_{bl}}{R_{bl} + R_p}\right]E_p \\ & + f\left[\frac{R_p}{R_{bl} + R_p}\right]E_{bl} + g\left[E_{par} - E_{ap}\right] \end{aligned} \tag{A4.3}$$

where the factors "f" and "g" arise from the circulating current "I" in the model of Figure 7.7b:

$$f = \frac{R_{ap} + R_{tj}}{R^*_{bl} + R_{ap} + R_{tj}} \tag{A4.4}$$

$$g = \frac{R^*_{bl}}{R^*_{bl} + R_{ap} + R_{tj}} \tag{A4.5}$$

Equations (A4.3)–(A4.5) are the general equations for the relative contributions of the electrogenic pump (denoted by E_p), ionic diffusion (denoted by E_{bl}), and circulating current (denoted by $E_{par} - E_{ap}$) to the observed basolateral membrane potential (V_{bl}). As indicated by Eq. (A4.3), the membrane potential depends critically on the relative magnitude of the pump resistance (R_p) versus the diffusion resistance of the membrane R_{bl}.

The term R^*_{bl} can be determined from cable analysis (as described in the text). This value can then be used to calculate R_{bl} from Eq. (A4.1), assuming that the internal resistance of the pump (R_p) can be estimated from its I–V relation (see Figure 7.10).

If the internal pump resistance (R_p) is high compared to the ionic resistance (R_{bl}), the ratio $R_{bl}/(R_{bl} + R_p)$ will be low, and the measured membrane potential V_{bl} (given by Eq. (A4.3)) will be dominated by the diffusional EMF term involving E_{bl}. Conversely, if the

internal pump resistance is low, V_{bl} will be dominated by the pump term involving E_p.

CHAPTER

8

Renal Ion Channels, Electrophysiology of Transport, and Channelopathies

James D. Stockand

Department of Physiology, University of Texas Health Science Center, San Antonio, TX, USA

The purposes of this chapter are to explain what an ion channel is and how it works, provide an overview of the contribution ion channel proteins make to renal transport, and suggest how changes in the structure and biophysical properties of renal ion channels cause disease. Emphasis is placed on recent information gained from the latest techniques. This chapter is neither a technical manual nor a comprehensive review. Its goal, rather, is to demonstrate how appreciation of renal physiology is expanded by considering the structure and biophysical properties of ion channels. Important equations are provided only in their simplest forms to demonstrate how the understanding of channel biophysics informs us about the role played by these proteins in the kidney. The goals of this chapter necessitate coverage of a wide subject matter. Several topics are introduced here in brief but are covered in more depth in other chapters of this book and elsewhere.[1,2,3] This chapter is about how we move from understanding channel biophysics and structure to understanding how changes in them cause disease.

Ion channels are central to renal transport. A diverse group of ion channels, including Ca^{2+}, Cl^{-}, K^{+}, Mg^{2+}, Na^{+}, and non-selective cation channels, are expressed along the length of the renal tubule and collecting duct system. Figure 8.1 and Table 8.1 report the expression profile for ion channels in the kidney at sites where their functions have been firmly established. Channels act as selective and regulated gateways, conducting ions down electrochemical gradients via restrictive diffusion. This enables channel proteins to serve as physical conduits for the movement of ions across epithelial cell membranes. In addition to functioning as gateways during transport, channel activity sets the electrical and chemical forces driving the movement of ions and coupled molecules, such as water and glucose, through and between renal epithelial cells. As such, the activities of renal ion channels often serve as the final arbiters of the electrolyte content of urine and plasma. This is true for Ca^{2+}, K^{+}, Mg^{2+}, and Na^{+}. Ion channels in the kidney, consequently, are targets for hormones and pharmacological agents to affect plasma ion content and volume. Aberrant regulation of renal ion channels or dysfunction of these proteins, moreover, cause kidney disease with compromised tubule transport. For instance, renal Mg^{2+} excretion is fine-tuned in the early distal convoluted tubule (DCT). Inactivating mutations in the Mg^{2+}-selective transient receptor potential (TRP) channel, TRPM6, causes hypomagnesemia with secondary hypocalcemia (HSH). This is a familial form of an autosomal recessive renal Mg^{2+}- and Ca^{2+}-wasting tubulopathy that ultimately leads to neurological damage and dysfunction.[4,5,6,7,8,9] Figure 8.2 shows models of epithelial cells in different segments of the nephron, and emphasizes the location of transport proteins and ion channels.

Renal ion channels also play important roles in cell signaling. They set membrane potential that modulates intracellular signaling. They also allow access to the ions involved in cell signaling, as typified by Ca^{2+}. Involvement of renal channels in cell signaling is highlighted by the role played by TRPC6 channels in podocytes of Bowman's capsule. Here, gain-of-function mutations in TRPC6 facilitate Ca^{2+} entry, leading to prolonged changes in the dynamics of Ca^{2+} signaling ultimately causing a familial form of focal segmental glomerulosclerosis (FSGS[10,11,12,13]).

Over the last few decades, the application of contemporary molecular genetics and gene knockout technology to cell biology and physiological questions

has revealed much about the roles played by renal ion channels, and the diseases caused by their dysfunction. An improvement in electrophysiological methods has allowed the detailed study of single ion channel proteins. Furthermore, the resolution of the crystal structures for several different channels has contributed greatly to determining the mechanisms by which channels gate and are regulated, facilitating our understanding at the atomic level of structure–function relations in these proteins. This allows the rationalization of how mutations in the genes encoding renal channels and channel regulators lead to disease, and how agents used in the clinic to modulate renal channel activity exert their pharmacological actions. For instance, it is recognized now that the renal phenotype resulting from decreased activity of the luminal Na^+,K^+,Cl^--co-transporter (NKCC2) in the thick ascending limb (TAL) shares many common features with those arising from inactivation of the luminal renal outer medullary K^+ (ROMK) channel responsible for K^+ recycling across the apical membrane of TAL epithelial cells and serosal ClC-Kb channels responsible for Cl^- exit from these cells, in that they all cause Bartter syndrome (BS) with hallmark NaCl wasting and compromised urine-concentrating ability.[14,15,16,17,18] Smilar salt- and water-wasting stems from the inhibition of NKCC2 in the TAL by furosemide and bumetenide loop diuretics. Both are important clinical tools used in the treatment of high blood pressure and heart failure.

As stated above, this chapter applies understanding of channel biophysics to the understanding of physiology, focusing on the role played by channels in renal transport, and rationalizes how compromises in channel properties cause channelopathies and tubulopathy. Important concepts are reinforced with specific examples. To facilitate discussion, a general appreciation of the structure and functional properties of the renal epithelium to include routes of transport, types of transport proteins common to epithelial cell membranes and forces driving transport are first developed. These are covered in greater detail in Chapters 1 and 2. What an ion channel is, and the biophysical explanation and atomic origins of gating, selectivity, and permeation are also addressed. Again, this material has some overlap with that presented in Chapter 7. The rich understanding of renal ion channels that has emerged over the last two decades makes it reasonable to describe briefly the roles played by these channels in transport and disease, and to discuss how the biophysical properties of renal channels determine their function in the kidney (see also Chapters 30, 31, 47, 62 and 80). The number of crystal structures now available for different types of channels makes it feasible to include a brief review of channel structure, and to discuss how this determines channel properties. Examples then can be examined where known changes in the biophysical properties of specific renal channels cause tubulopathies.

STRUCTURE–FUNCTION OF TUBULE EPITHELIUM

The renal tubule is a single epithelial cell thick. It is linear with ultrafiltrate and pro-urine separated from interstitial fluid by epithelial cells coupled together with tight junctions to form the epithelium. Fluid flows down the tubule in one direction from Bowman's space to the collecting duct system, ultimately into the ureter. Fluid flows down the tubule driven by hydrostatic pressure renewed by constant filtration at the glomerulus.

The Tubule is a Barrier

The structure of the tubule provides a barrier function separating fluid compartments; pro-urine from interstitial fluid. The electrical properties of the tubule and transport across the tubule can be understood in terms of equivalent circuits, such that ions cross a resistive barrier driven by electrochemical forces

TABLE 8.1 Renal Ion Channels with Recognized Function

Channel	Alternative Names	Expression	Gene Pore/ Accessory	Chromosome Location	Function	References
CALCIUM						
TRPC3	TRP3	podocyte + CD (ubiquitous)	*TRPC3*	4, 123.02-123.09	Receptor operated Ca^{2+} entry pathway in podocytes.	10, 11, 12

through conductive pathways. Figure 8.3 shows a simplified equivalent circuit representing tubule epithelium. In this regard, ion channels and tight junctions serve as conductive pathways across epithelial cell membranes and the epithelial barrier, respectively, with voltage and concentration gradients existing across these membranes and the barrier. Because channels, which are gated, make a significant contribution to membrane resistance, epithelial cell membranes are best described as variable resistors. Accordingly, channels affect the resistance of the epithelial cell membrane and electrochemical driving forces across these membranes and the epithelium.

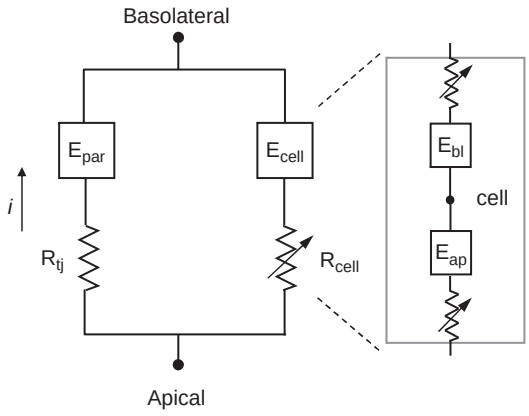

FIGURE 8.3 **Tubule epithelium can be represented by an equivalent circuit.** (Abbreviations: ap: apical; bl: basolateral; par: paracellular; tj: tight junction.)

Routes of Transport across the Tubule

Two different routes of transit from one fluid compartment to the other exist across the renal epithelial barrier. Movement through the epithelial cell is termed transcellular, and between epithelial cells across tight junctions is termed paracellular. Transcellular movement, as depicted in the simple equivalent circuit shown in Figure 8.3, includes crossing both the apical and basolateral membranes. Channels facilitate the crossing of these membranes by ions. Tight junctions serve a similar function for paracellular movement

across the epithelium. Tight junctions, like channels, are selectively permeable. Nothing to date, though, suggests that tight junctions act in a gated manner; rather, they function as doorways of fixed resistance that are selective in what they let pass. Diffusion through tight junctions is passive, driven by electrochemical gradients.

Epithelial Cells are Polarized

Tubule epithelial cells, and thus the tubule epithelium, are polarized with distinct membranes facing the pro-urine, the apical membrane, and the interstitial fluid, the basolateral membrane. These distinct membranes have different protein profiles, including the expression of ion channels. The net result is that each cell membrane has different capability, selectivity, and capacity for moving ions and other molecules. This, combined with the barrier function of the epithelium, provides epithelial cells with the ability to transport in a directional manner. This process is often termed vectoral transport.

Types of Transport and Transporters

Epithelial transport and specific transport proteins are covered in more detail in Chapters 1 and 2. In brief, transport across an epithelial cell can be divided into those that do not require a protein, and those that are protein-mediated. The former is termed simple diffusion and is passive, being dependent on the concentration gradient and surface area. If a molecule is capable of permeating the cell membrane, it will cross according to its chemical gradient. Molecules that move using this form of transport are exclusively small and non-polar, and are capable of crossing a lipid bilayer. Simple diffusion cannot be saturated and is not regulated. The movement of NH_3 in parts of the tubule is a good example of this form of transport. Mediated transport, in contrast, is capable of being saturated, and is dependent on the presence of specific proteins. Moreover, it often is regulated by cell signaling. Figure 8.4 shows models representative of the different classes of transport proteins common to renal epithelial cells. Forces driving protein-mediated transport are discussed in more detail below, but they can include the concentration difference of the molecule to be transported across the membrane or barrier, electrical potential differences, and the activity of transport proteins.

Facilitative diffusion, similar to simple diffusion, is passive, allowing molecules to move down concentration gradients. Facilitative transporters translocate molecules across membranes. An example of a facilitative transport protein in the kidney is the proximal tubule glucose transporter, GLUT2.

Ion channels allow restrictive diffusion, a unique form of passive transport. Channels form selective pores in the membrane, allowing ions to cross the membrane through permeation rather than being translocated across the membrane. Restrictive diffusion through ion channels is driven by electrochemical gradients.

The two remaining types of transport proteins allow active transport: the active movement of molecules against gradients. This type of transport is directly, in the case of primary active transport, and indirectly, in the case of secondary active transport, tied to the consumption of energy. Primary active transporters require ATP to transport molecules against their concentration gradients. As discussed below, this ultimately energizes all transport across the renal tubule. The Na^+,K^+-ATPase is a notable primary active transporter in the tubule and

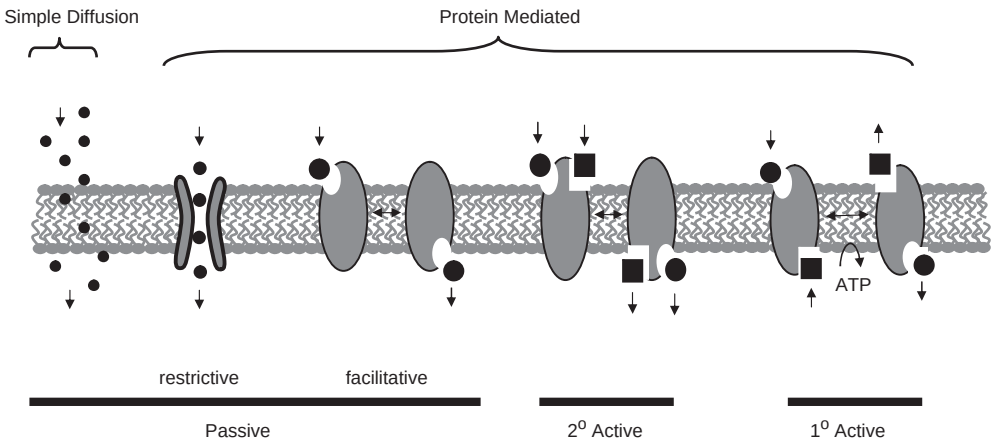

FIGURE 8.4 **Representative models of the different types of renal transport proteins.**

collecting duct system. Secondary active transporters use gradients established by primary active transporters. They couple the movement of one molecule against its gradient to the movement of another molecule down its gradient. NKCC2 in the TAL and the thiazide-sensitive Na^+,Cl^--co-transporter (NCC) in the DCT are prominent secondary active transporters in the kidney. The latter couples the inward movement of Cl^- into the cell against its gradient to the inward movement of Na^+ into the cell with its gradient. Thus, Na^+ entering the cell downhill on this transporter pulls Cl^- uphill with it.

Forces Driving Transport across the Tubule: The Importance of Disequilibrium

Filtration at the glomerulus, as discussed in Chapter 21, is governed by Starling forces. The difference in hydrostatic pressure between plasma in the glomerular capillary and ultrafiltrate in Bowman's space, the beginning of the tubule, drives filtration. The difference in oncotic pressure between these fluids impedes filtration. The net result of filtration is that ultrafiltrate entering the renal tubule is similar in content to plasma minus blood cells and proteins. Electrolytes or other small molecules, therefore, have little gradient initially to cross the epithelial barrier, leaving pro-urine for interstitial fluid or *vice versa*. The activity of the Na^+,K^+-ATPase pump localized to the basolateral membrane of all tubule epithelial cells changes this by providing the motivation, ultimately, for all transport. This protein consumes ATP to generate disequilibrium for Na^+ and K^+ across cell membranes. Because epithelial cell membranes are effective at separating fluid compartments, this disequilibrium can be maintained and converted into voltage differences and differences in ion concentrations by the activities of ion channels, other transport proteins, and the capacitive nature of cell membranes. Similarly, because epithelial cells, coupled together by tight junctions, effectively separate fluid compartments, disequilibrium across the tubule epithelium is maintained. Urine flowing in only one direction down the tubule also helps maintain disequilibrium, by moving processed fluid too quickly for equilibrium to be reached. Ion channels and other transport proteins tap these electrochemical gradients to transport molecules across the epithelium. Thus, disequilibrium enables modification of urine by tubule epithelial cells. Renal transport ultimately, then, is the movement of molecules through channels and other transporters, tending towards an equilibrium that is kept beyond reach by the continuous activity of the Na^+,K^+-ATPase.

The Tubule Epithelium has Emergent Properties

The importance of the structure of the epithelial barrier and state of disequilibrium maintained across this barrier to transport is apparent when considering the similar Ca^{2+}- and Mg^{2+}-wasting phenotypes arising from inactivation in the TAL of NKCC2, ROMK, claudin-16, and claudin-19.[19,20,21,22,23,24] Dysfunction of claudin-16 and -19 cause familial hypomagnesemia, with hypercalciuria and nephrocalcinosis (FHHNC[25,26,27,28]). These claudins are critical components of the tight junction in the TAL, where they provide cation-selectivity, allowing Na^+ back-flux into tubular fluid more rapidly than Cl^-, contributing to a lumen-positive diffusion potential. The lumen-positive potential that results from the combination of this Na^+ back-flux with apical K^+ recycling mediated by the coordinated activities of luminal ROMK channels and NKCC2 drives paracellular Mg^{2+} and Ca^{2+} transport. Claudin dysfunction, like dysfunction of ROMK or NKCC2, then compromises the electrochemical gradient responsible for divalent cation reabsorption in the TAL. This illustrates that a break in function of any of several components of the whole leads to the same disease. This is an important concept: epithelial cells and epithelial barriers have emergent properties that are dependent on the proper functioning of each component part, including ion channels.

Urine Flows down the Tubule

An additional point important to recognize about renal transport is that urine flows in the tubule in one direction; what happens upstream affects transport downstream. This is so because the modification of urine in upstream segments determines the constituents of urine in downstream segments. For instance, inhibition of NKCC2 in the TAL by loop diuretics, in addition to compromising urine-concentrating ability by destroying the axial corticomedullary hyperosmotic gradient, also leads to an increase in K^+ secretion at the collecting duct (CD), and ultimately to K^+ excretion by the kidney. This is due to increased urine flow and Na^+ delivery to the CD. Increased urine delivery to the CD promotes flow-induced K^+ secretion by BK_{Ca} channels, which are activated by mechanical stimuli.[29,30] Increased Na^+ delivery drives increased Na^+ reabsorption via the epithelial Na^+ channel (ENaC) across principal cells of the CD, due to a change in the electrochemical gradient for Na^+ across the apical membrane. This increase in Na^+ reabsorption in turn affects the electrochemical gradient across the apical membrane, driving additional K^+ secretion through ROMK channels.[31,32] For the same reasons, any inactivating mutation in a TAL transport protein

involved in NaCl reabsorption, including NKCC2, ClC-Kb, and ROMK channels, causes the renal K^+ wasting associated with Bartter syndrome.[15,16,17,18] Moreover, disease resulting from inactivation of NCC and the ClC chloride channel beta subunit barttin, and diuretics such as thiazide inhibitors of the NCC co-transporter that decrease NaCl reabsorption in the DCT, also cause renal K^+ wasting by this common mechanism.

Transport does not Happen in a "Vacuum"

Another concept emerging from the above discussion is that the transport of one type of ion through renal ion channels influences the movement of different ions through other distinct channels. This coupling is a manifestation of ion channel activity influencing electrochemical driving forces. An example of this, as discussed above, is the electrogenic Na^+ reabsorption via ENaC influencing ROMK-mediated K^+ secretion in the CD. This will be touched upon again in more detail below. Similarly, as mentioned earlier, Mg^{2+} and Ca^{2+} reabsorption in the TAL are positively coupled to NaCl reabsorption with K^+ recycling across the luminal membrane via ROMK channels and paracellular Na^+-back flux via claudin proteins, setting the electrochemical driving forces moving these divalent cations.[21,22,26,31,33]

ION CHANNELS: BIOPHYSICAL PROPERTIES

An ion channel is an integral membrane protein or protein complex that forms a continuous conductive pore through a membrane. The pore spans the entirety of the membrane with the conduction pathway perpendicular to the plane of the lipid bilayer. The mouths of an ion channel pore are in contact with the aqueous solutions on both sides of the bilayer. As ions enter the permeation pathway of a channel pore and reach the selectivity-filter, they become partially dehydrated, moving through the channel only after losing surrounding water molecules. Binding sites within the pore then mimic solvation by water as ions permeate across the membrane through the channel.

Channel pores are selective and gated. The basis of selectivity is usually a defined sequence of residues at the narrowest part of the pore. Residues in the selectivity-filter are highly conserved across a channel family, and generally across a class of channels. Most, if not all, K^+-selective channels, for instance, share the common signature selectivity sequence TXGYG.[32,34,35,36] Moreover, all known

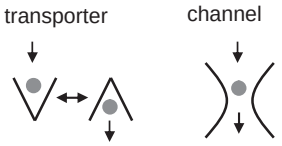

FIGURE 8.5 **Simplified modes of transport used by transporters versus ion channels.** Translocation of molecules across the membrane by transporters entails relatively large changes in conformation compared to ion permeation across the membrane through ion channels.

K^+ channels with this selectivity-filter use a common mechanism of permeation to conduct K^+ through the pore, as discussed in greater detail below.

Ion Channels Provide a Unique Form of Passive Diffusion

As emphasized in the simplified forms of transport shown in Figure 8.5, ion channels differ from other transport proteins, in that they form a physical hole through the membrane. No other type of transport protein does this. Rather, the molecule to be translocated by transport proteins other than ion channels interacts with a binding site on one face of the protein, but does not actually move across the membrane until a change in conformation takes place where the initial entry site closes as the exit site opens to allow the bound molecule to be released and egress out across the opposite face of the protein from which it entered. Ion channels also contain binding sites for permeant ions. Ions transiently bind to these sites during permeation, with the electrochemical gradient driving the direction of transport. In conjunction with properties of the pore and charge repulsion between permeant ions, this gradient determines the magnitude of ion flow.[36,37,38] Because channels are pores that allow ions to permeate through the membrane, they facilitate crossing of the membrane with relatively little change in overall conformation. Transporters, in comparison, typically require greater relative changes in conformation to translocate molecules across the membrane. The result is that single-channel proteins move a far greater number of molecules per unit of time (10^7 to 10^8 ions/second) compared to any other single-transport protein.

Recording Ion Channel Activity with Patch-Clamp Electrophysiology

When open, a channel conducts the movement of ions across the cell membrane. This manifests as a decrease in resistance the membrane has to the permeant ion. Current through an ion channel is dependent on the electrochemical driving force, whether

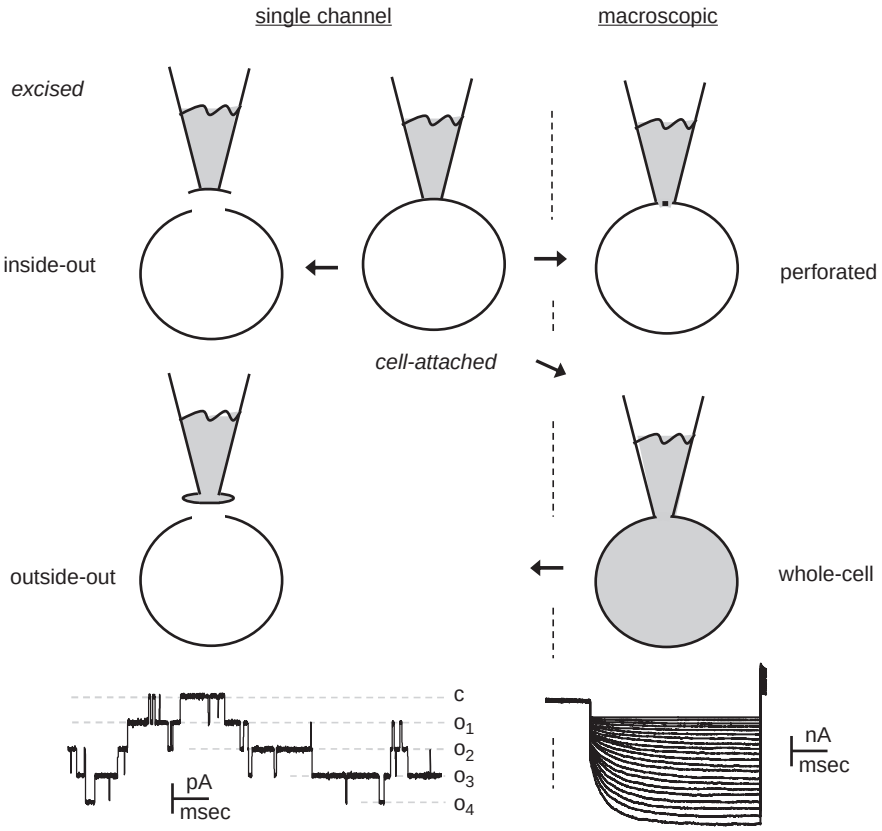

FIGURE 8.6 **Patch-clamp configurations.** This illustration depicts the five different seal configurations available for patch-clamp analysis: three are amenable to single channel recording, cell-attached, excised inside-out and excised outside-out; and two for macroscopic current recording, perforated and whole-cell. In this figure, the cell is represented as a circle and the recording pipette as a V. Gray shading defines continuity between the solution in the recording pipette and intracellular solution. Arrows represent transition steps during seal formation taken to establish the distinct types of seals. Shown below are representative current data from configurations with single channel (left) and macroscopic (right) resolutions. Closed (C) and open (O) states are noted in the single channel trace. *(Data from J.D. Stockand or published previously in ref. [39].)*

the channel is open or closed and the selectivity of the channel, and how well a certain ion moves through, or rather permeates through, the conduction pathway. The activity and biophysical properties of ion channels can be assayed in experiments with electrophysiological tools, including sharp electrodes and two-electrode voltage clamping. The most sophisticated tool used to probe the biophysical properties of channels is patch-clamp electrophysiology. Erwin Neher and Bert Sakmann were awarded the Nobel Prize in Physiology or Medicine in 1991, in part for this development.[3] Patch-clamp electrophysiology enables the study of both macroscopic and single-channel currents. It has a high degree of precision and fidelity, allowing the resolution of the activity of a single protein in real-time. Figure 8.6 shows the different patch configurations available for the study of ion channels, and sample data from experiments investigating the single-channel properties of wild-type ENaC (left) and macroscopic currents from a mutant form of ENaC (right) that activates upon hyperpolarization due to the voltage-dependent block of the pore by intracellular Na^+.[39]

Adaptation of Ohm's Law to Biological Systems: Explaining Current Carried by Ion Channels

Current flow in an electrical circuit obeys Ohm's Law which, when reordered, states $I = gE$, where current (I) equals the product of the conductance (g) and voltage difference (E) across the conductor, which in biological systems is an ion channel protein. This simple formula was adapted to $I_x = g_x\ (E-E_x)$ by Hodgkin and Huxley, in their seminal electrophysiological studies (as explained by Hille and Cole in their books[2,40]) to fit biological reality better where current through an ion channel crosses a capacitive membrane that separates fluid compartments of different ionic activities. The gradient across the membrane acts like a battery represented by an equivalent circuit with an

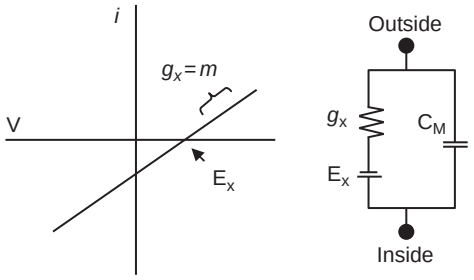

FIGURE 8.7 **An idealized I–V relation and equivalent circuit describing a channel obeying Ohm's Law.** Conductance (g) is equal to the slope of the I–V line. E_x is the reversal potential, and C_M is membrane capacitance.

electromotive force, E_x, in series with a channel resistor, g_x. This conductive branch is in parallel with the capacitor representing the membrane. In this modified equation, E remains voltage across the membrane, and the net driving force on ion X is now $E - E_x$. Thus, current in biological systems is driven by an electrochemical gradient rather than by voltage alone.

Figure 8.7 shows a graphical representation of an idealized current–voltage relation for an equivalent circuit describing an open ion channel obeying this modified Ohm's Law. When voltage, E, is equal to E_x, no net current flows through the channel. When $E < E_x$, current flows into the cell. If this represents a cation channel, for instance ENaC, and extracellular $[Na^+]$ is greater than intracellular $[Na^+]$, as is the normal case in physiological systems, this inward current flow would be carried by Na^+ entering the cell through ENaC. This represents the normal conditions under which ENaC functions in CD principal cells, allowing Na^+ to enter the cell across the apical membrane during electrogenic Na^+ reabsorption.[41,42] The typical concentration of ions in urine and intracellular fluid combined with the activities of K^+ channels in the apical and basolateral membranes set the potential (E) across the apical membrane lower than E_{Na}. This facilitates Na^+ influx through ENaC. In contrast, when $E > E_x$ current flows outwards, Na^+ exits the cell. This explains the consequences of the electrochemical gradient driving Na^+ through ENaC. Sodium movement through ENaC across the membrane, in turn, influences electrochemical gradients. If no other parameter changed, Na^+ moving through ENaC would dissipate the $E - E_{Na}$ difference, eventually arriving at equilibrium where E and E_{Na} are equalized. Restated, net flux through a channel occurs only as long as the system is out of electrochemical equilibrium. This is where the Na^+,K^+-ATPase and separation of fluid compartments with different ionic activities by cell membranes come into play. They enable epithelial cells to remain out of equilibrium.

The Nernst Equation

In the above description, E_x is the equilibrium potential (or reversal potential) for ion X, a state where the tendency for further change vanishes, and all existing forces on X are in balance. This would be where voltage across the membrane containing the channel permeable to ion X equals the diffusion potential developed by the ionic gradient for ion X across this membrane. Mathematically, as noted above, this is where $E = E_x$. Equilibrium potentials are easily measured in the laboratory with electrophysiology. Moreover, they can be calculated empirically using a formula developed by Nernst in 1888.[40,43] This led to the equilibrium potential sometimes being referred to as the Nernst potential. The Nernst equation states $E_x = (RT/zF)\ln([X]_o/[X]_i)$, where R and F are physical constants having the usual meanings of Universal Gas constant and Faraday's constant, T is temperature in kelvin, z accounts for the charge and valence of ion X, ln indicates natural logarithm, and $[X]_o$ and $[X]_i$ are the concentrations of ion X outside and inside the cell, respectively. Accordingly, the equilibrium potential falls to zero in the absence of a gradient, reverses signs as the direction of the gradient is reversed (e.g., that for Na^+ compared to K^+) and as the charge of the ion is reversed, for example Na^+ versus Cl^-. Equilibrium potentials across cell membranes for ions common to physiological solutions are $\sim$130, $-$98 and 67 mV, respectively, for Ca^{2+}, K^+, and Na^+ [2]. The equilibrium potential for Cl^- is more variable, because $[Cl^-]_i$ varies more widely with cell type, but it usually is close to the resting membrane potential of the cell, often being slightly above or below that level. Calculating equilibrium potential across tubular epithelial cell membranes is complicated by the luminal and serosal membranes facing different solutions. The apical membrane may have a different equilibrium potential for Na^+ as compared to that across the basolateral membrane, because the concentration of this ion in urine may be greater or less than that of plasma, depending on Na^+ and water transport along the length of the nephron.

The Goldman–Hodgkin–Katz Voltage Equation

Work performed by Hodgkin, Huxley, and Goldman and others led to the realization that cell membrane potential reflects the equilibrium potentials of all permeant ions at a given time, and that this can be mathematically represented.[2,40] When calculating membrane potential (E_{mem}), the magnitude of ion movement through any given class of channel, for example K^+ versus Na^+ channels, is accounted for by using weighted averages of each ion's equilibrium potential. These weighted averages convey the relative

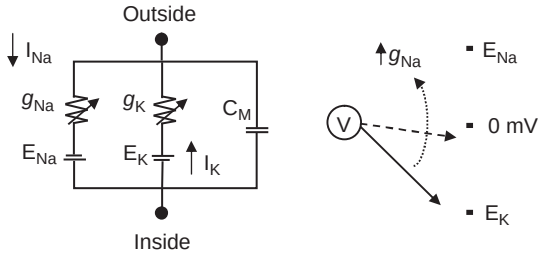

FIGURE 8.8 **A simplified equivalent circuit of a cell containing Na^+ and K^+ channels contributing to membrane potential.** Shown to the right is the change in membrane potential resulting from activation of Na^+ channels.

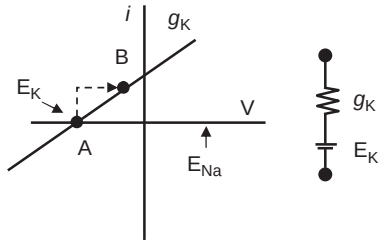

FIGURE 8.9 **Changes in membrane potential influence current through open channels.** Shown are an idealized I–V relation (left), and associated equivalent circuit (right) for a K^+ channel. Movement from point A to B notes the effect on current through this channel as the membrane becomes depolarized in response to the activation of Na^+ channels.

permeability (P_x) of each ion to total ion permeability (P_{tot}). By using the simplified condition of only considering flux of monovalent cations through channels, which is not too distant from reality, the Goldman–Hodgkin–Katz (GHK) equation is $E_{mem} = (P_K/P_{tot})E_K + (P_{Na}/P_{tot})E_{Na}$. Figure 8.8 shows an equivalent circuit representing the cell membrane and individual ionic conductances contributing to this membrane potential. Because K^+ channel activity predominates at rest with P_K approaching P_{tot}, membrane potential is closest to E_K. An increase in the activity of Na^+ channels, which increases the relative permeability of this ion, causes the membrane to become more depolarized, as represented by the volt meter in Figure 8.8 moving E_{mem} towards E_{Na} as ENaC becomes active.

What do Ohm's Law, the Nernst Equation, and the GHK Equation Tell us About Transport?

Reconsidering now Figure 8.7 and the scenario described earlier, inward Na^+ flow through ENaC depolarizes the apical membrane, moving E_{mem} towards E_{Na}. Because the ionic gradient for K^+ across the apical membrane is the reverse of that for Na^+, depolarizing the apical membrane would move E_{mem} further away from E_K, driving more K^+ out of the cell through apical K^+ channels, for instance, through ROMK channels in the apical membrane of principal cells.[32] Figure 8.9 shows an idealized current–voltage relation for an open K^+ channel, and notes the influence of membrane depolarization (moving from A to B) on K^+ current through this channel as the apical membrane is depolarized by Na^+ reabsorption through ENaC, activated perhaps by the addition of aldosterone. There is greater outward K^+ current and greater K^+ secretion. The idealized graphs of cumulative K^+ secretion, membrane voltage, and relative K^+ and Na^+ permeability shown in Figure 8.10 expand on this concept. Basolateral leak K^+ channels, which provide the majority of ion permeability at rest, sets E_{mem} of CD principal

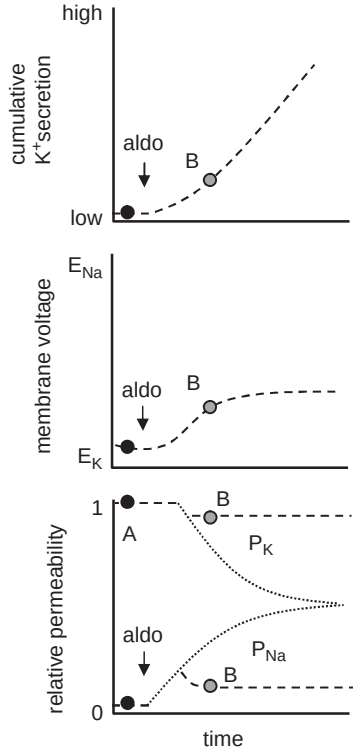

FIGURE 8.10 **Activation of ENaC depolarizes the apical membrane driving K^+ secretion through ROMK.** Shown are idealized graphs representing changes in K^+ secretion (top); apical membrane potential (middle); and relative permeability (bottom) as ENaC becomes activated by aldosterone to drive K secretion through ROMK, moving from point A to point B.

cells to near E_K. There is little electrochemical force, therefore, for K^+ to exit the cell through ROMK under these conditions. This resting condition is time A, with little K^+ secretion across the apical membrane. The introduction of aldosterone to the system activates ENaC, increasing the relative permeability of Na^+ and allowing this ion to enter the cell down its electrochemical gradient. This begins to depolarize the apical membrane, as E_{mem} moves towards E_{Na}. As E_{mem} moves

towards E_{Na}, K^+ exits the cell at an increased rate across apical ROMK channels. This is time B.

Another consequence of ENaC opening is that the relative permeability of K^+ begins to fall as that of Na^+ rises; however, as K^+ exits the cell through ROMK, a new steady-state is reached where membrane potential has increased, and P_{Na} and P_K have stabilized with constant K^+ secretion. Neither the K^+ nor Na^+ concentration gradients change substantially across the apical membrane, due to the constant activity of the Na^+,K^+-ATPase pump. These gradients are also protected by the constant flow of urine, bringing Na^+ to the cell and washing away K^+ that has been secreted through ROMK. This scenario is simplified compared to the real-life situation, but it shows how the equations described above can be used to understand the role played by renal ion channels better. This simplified description, moreover, reveals the mechanistic underpinnings of why K^+ secretion from CD principal cells is tied in a positive manner to Na^+ reabsorption by these cells, as initially raised in earlier sections. In addition, it explains why diuretics, such as amiloride and triemterene, which block ENaC, also have K^+-sparing action.[41,44] They retard the development of the normal electrochemical driving forces favoring K^+ secretion from the CD, because they block the entry of Na^+ across the apical membrane necessary to drive K^+ from the cell. Because the CD is the final site along the nephron where urinary $[K^+]$ is fine-tuned, decreased secretion here leads to K^+ retention in plasma.

Channels are Selective

Ion channels need to be selective to perform their role of converting chemical disequilibrium into electrical signals. In epithelial cells, moreover, they need to be selective to facilitate vectoral transport. The chemistry of selectivity (often called the selectivity sequence), for a channel can also be empirically determined using the GHK Voltage Equation discussed above. The extended equation is $E_{rev} = (RT/F)\ \ln\ \{(P_K[K]_o + P_{Na}[Na]_o + P_{Cl}[Cl]_i)/(P_K[K]_i + P_{Na}[Na]_i + P_{Cl}[Cl]_o)\}$.[2] This equation allows one to calculate permeability ratios by measuring reversal potential, but it does not allow the determination of absolute permeabilities. Bi-ionic conditions, where only one permeant ion is presented to either side of the -channel, are the simplest when testing selectivity. Under such conditions, the equation reduces to $E_{rev} = (RT/zF)\ \ln\ \{(P_x[X]_o)/(P_y[Y]_i)\}$. Figure 8.11 shows predicted results from a hypothetical excised inside-out patch-clamp experiment with bi-ionic conditions used to determine that the channel within the patched membrane is selective for Na^+ over K^+. With Na^+ in

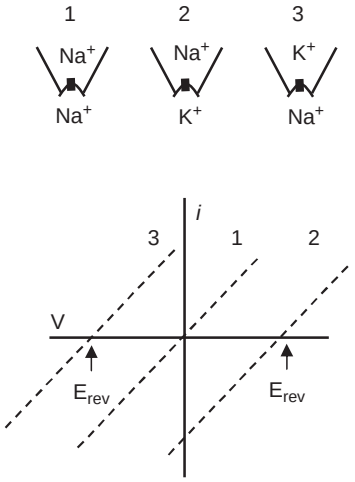

FIGURE 8.11 **A channel's selectivity sequence can be experimentally determined by quantifying how different ionic gradients influence reversal potential.** Shown at top are three different experimental conditions with distinct Na^+ and K^+ concentrations in the bath and pipette solutions for an excised inside-out patch containing an ion channel. Below is the predicted I–V relation for a Na^+ channel in this patched membrane under the three conditions.

the bath and recording pipette, there is no gradient across the membrane, and reversal potential is 0 mV (condition 1). Next, when the bath contains K^+ as the sole cation, condition 2, the reversal potential moves to E_{Na}, which is $\sim$70 mV. Similarly, when the cations in the pipette and bath are reversed, the equilibrium potential again moves to E_{Na}, which is ~ -70 mV with condition 3.

What provides a channel with selectivity? In the simplest sense, it is how capable binding sites within the pore are at coordinating an ion permeating through the pore. If we view a channel pore as a tunnel with consecutive constrictions followed by recesses, as shown in Figure 8.12a, then the selectivity-filter is the tightest constriction. A pore can also be understood by considering thermodynamics. As shown in Figure 8.12b, there would be energy wells followed by energy barriers along the length of the pore. The selectivity-filter then is the greatest barrier that a permeant ion must cross to move through the channel. Using equivalent circuits to describe ion channels, as shown in Figure 8.12c, a change in selectivity would be observed as a change in the electromotive force driving current across the channel upon ion substitution.

The physical basis of selectivity is set by the selectivity-filter defining an internal diameter within the pore, which prohibits molecules larger than this diameter from crossing. This represents the idea that ion channel pores are sieves, selecting on size. With such a description, a selectivity-filter that passes large ions, presumably, would also pass smaller ions, but clearly this is not the case. There are, obviously, other

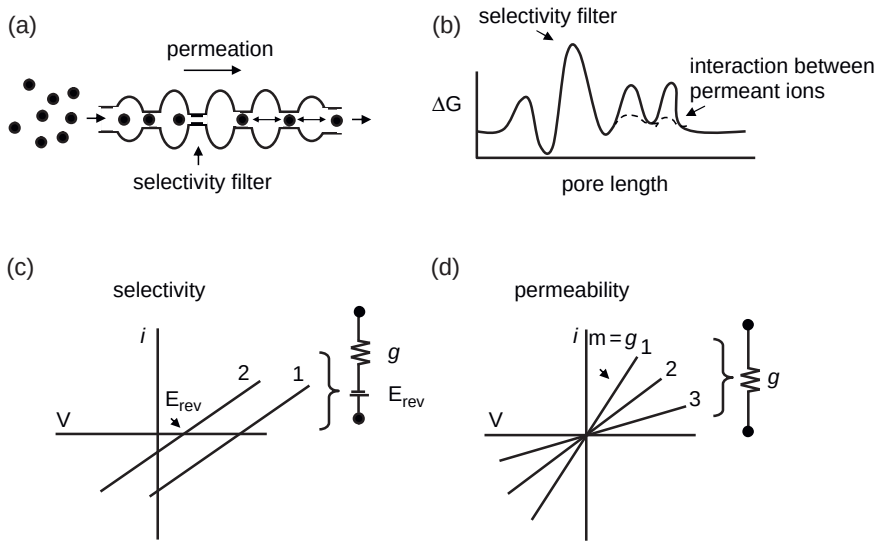

FIGURE 8.12 **Selectivity and permeation.** Shown in (a) is an illustration of a channel pore acting as a filter selecting on size. Ions permeating through the channel pore are shown as black balls. Shown in (b) is a representation of a channel pore as understood by thermodynamics. The I–V relation and equivalent circuit shown in (c) emphasize that selectivity is calculated experimentally by measuring changes in reversal potential resulting from changes in ionic gradients. The I–V relation and equivalent circuit shown in (d) emphasize that permeation is measured in experiments by calculating conductance in the presence of different permeant ions. The two-headed arrows in (a) indicate charge repulsion between permeant ions within the pore. The dashed lines in (b) show decreases in energy barriers along the pore and also indicate the effects of charge repulsion on permeation.

factors contributing to selectivity. Ions move through channel-selectivity filters only after they shed their layer of surrounding water.[35,36,37,45,46] So, it is the dehydrated diameter of an ion, and its ability to shed surrounding water molecules, that are important when moving through a selectivity-filter. Moreover, selectivity-filters also select on the basis of charge: side chains of amino acids defining or near the selectivity-filter present as a charge barrier. The side chains and backbone carbons of residues within or near the selectivity-filter also form transient bonds with the permeant ion and, thus, there is a chemical component to selectivity. Selectivity, then, is a culmination of several factors, including size and charge, and the ability to shed solvating water molecules and interact with residues at or near the selectivity-filter. The precision of selectivity among ion channels varies widely from ENaC having a $P_{Na}/P_K > 100$ being at the highly selective end of the spectrum, to some TRP channels with $P_{Na}/P_K \approx 1$ being at the other end of the spectrum of non-selective channels.[11,47,48,49]

It is easiest to view selectivity as fixed and immutable. However, this is not exactly the case. Channel selectivity can be influenced by experimental conditions, and even the presence or absence of permeant ions in the pore.[50,51] Moreover, the selectivity-filter can be involved in channel gating, as it is in ROMK and ClC channels.[32,52,53,54,55] Gating is discussed in more detail below.

Ions Permeate Through Channels

Selectivity and permeation are related, but they are not exactly the same thing. Selectivity, as emphasized in Figures 8.12a and 8.12b, is set by the physical properties of ion-binding sites within the pore, and how well they coordinate permeant ions when bound. Permeation refers to how fast or rather how many ions move through the pore per unit of time, and speaks of how well an ion surmounts energy barriers within the pore. Stated another way, selectivity can be viewed as a filter with certain physical properties, and permeation is how well molecules cross this filter. Experimentally, as shown in Figure 8.12d, permeation is measured as conductance, where a channel passing a more permeant ion has a higher conductance relative to when it passes a less permeant ion. Ions permeate through the narrowest portions of a channel pore in a single-file manner.[34,35,36,45,56] One then might expect a channel that is less selective to have a higher conductance compared to a highly selective channel. In general, this rule is only loosely obeyed. The reasons for this are discussed below. One might also expect that the ion for which a channel is most selective would permeate through the channel best. This is most often the case, but it is not absolute.

Permeation is a result of how easily an ion surmounts every energy barrier within the pore, as well as interactions between permeant ions with each other

when occupying the pore. Ions occupying the pore can exert a pushing effect on each other, impeding and propelling progression depending on the relative order of these ions within the pore and opposing energy barriers each ion is facing. Repulsion between ions within a pore is indicated in Figures 8.12a and 8.12b with two-headed arrows and decreases in the size of energy barriers, respectively. Such repulsion contributes to highly selective channels passing large numbers of ions per second. For instance, charge repulsion between the Cl^- ions occupying the pore of ClC channels makes a significant contribution to the conductance of these channels.[53,57] In addition, most channels have large aqueous vestibules lined by polar residues at the extracellular and intracellular mouths of their pores.[36,37,45,46,58] The vestibules act as reservoirs concentrating the permeant ion, increasing conductance.

The pores of ClC and ENaC channels contain three binding sites for permeant ions.[37,52,55,58] In ENaC, sites immediately adjacent likely are not occupied simultaneously, due to charge repulsion between permeant ions within the pore. This is also the case for K^+ channels, such as Kv and Kir, which use a single-file mode of multiple ion permeation with four pause/binding sites within the pore.[35,36,45,56] As illustrated in Figure 8.13, only two sites are occupied at any one time, with the occupied pairs always separated by an empty site filled with water.[35,36,45,56]

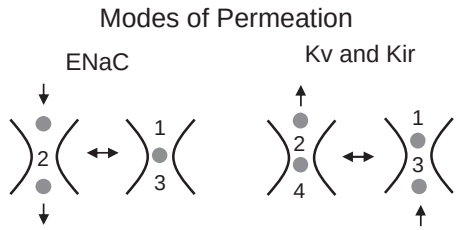

FIGURE 8.13 **Modes of permeation.** Shown here are representative modes of ion (represented by gray balls) permeation through ENaC (left); and Kv and Kir (right) channels. Ions permeate through channel pores in a single-file manner with several ions occupying different binding/pause sites along the length of the pore at any one time. However, charge repulsion often precludes neighboring sites from being occupied by permeant ions simultaneously. Such mechanisms of permeation allow highly selective channels to have large conductance.

Channels Gate

Channels transition between closed and open states as they gate.[2,3] By definition, no current flows through a closed channel. Upon opening, current flows through the channel obeying $i = g_x(E-E_x)$. The open current level of a single channel then is a determinant of its conductance, which is measured by taking the slope of i−V curves for single-channel currents captured with a voltage-clamp recording (see Figure 8.12d). Current flow through a channel, as shown in Figure 8.14, is an all-or-nothing event: with no change in driving force, the channel transitions from closed to open and back again, always the same as defined by a normally distributed Gaussian curve unitary step in single-channel current.

Channels gate in a stochastic manner: a new and random pattern of openings is observed for each trial period.[2] The stochastic nature of gating makes it possible to describe gating in terms of probabilities, where the sum of the probability of a channel being in either the open (P_o) or closed (P_c) state is equal to 1. Channel open probability is calculated from single-channel activity (NP_o) defined as $NP_o = \sum(t_1 + 2t_2 + \ldots\ nt_n)$, where N and P_o are the number of channels in a patch and the mean P_o of these channels, and t_n is the fractional open time spent at each of the observed current levels. P_o is calculated by dividing NP_o by the number of active channels (N) within a patch, as defined by all-point amplitude histograms. Another common way of representing this is:

$$NP_o = \sum_{i=0}^{N_A} \frac{it_i}{T}$$

where T is the total recording time, N_A is the observable number of current levels corresponding to channel number as established with all-point histograms, i is the number of channels open, and t_i is the time during which i channels are open. P_o can be calculated as above, by dividing NP_o by the channel number.

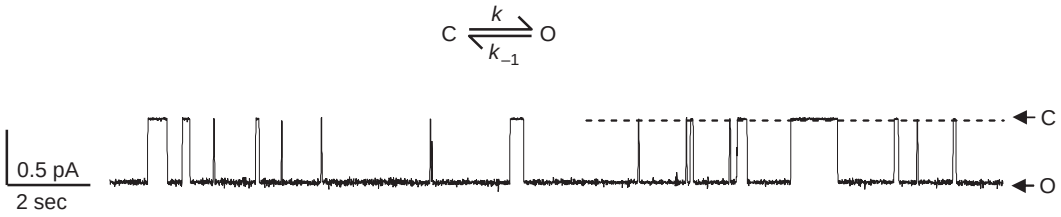

FIGURE 8.14 **Channels gate in a stochastic manner.** Shown here is a typical single-channel current trace for ENaC in an excised outside-out patch containing a single channel. Open and closed states are indicated with O and C, respectively. Shown above is a kinetic scheme describing gating. At a fixed driving force, the channel opening is always to the same unitary current level, and gating is stochastic.

Macroscopic channel current is related to unitary current by $I = iNP_o$, where i is unitary single-channel current at a given voltage. Similarly, macroscopic conductance is $G = gNP_o$. This provides another means for estimating NP_o from experimental data where NP_o can be estimated as I/i. This latter estimation is often used in experiments where N cannot be fixed with certainty, but i can be or when N and I (and i) are measured independently of each other.

All channels have inherent gating activity: with time, they transition between open and closed states in a random manner driven by thermal energy. So, all channels have at least one gate. The physical nature of a channel gate, though, may be different among different kinds of channels. Moreover, channels often have more than one distinct gate. This seems to be the rule rather than the exception. For example, ClC channels are double-barreled channels containing two proto-pores, each having an independent gate .[53,57,59,60] Both proto-pores, moreover, are also covered by a common gate. For the channel to be open, both the gate of the proto-pore and the common gate must be open. Similarly, Kir channels, such as ROMK, have fast and slow gating, showing the effects of at least two different gates.[32,34,35,45,56]

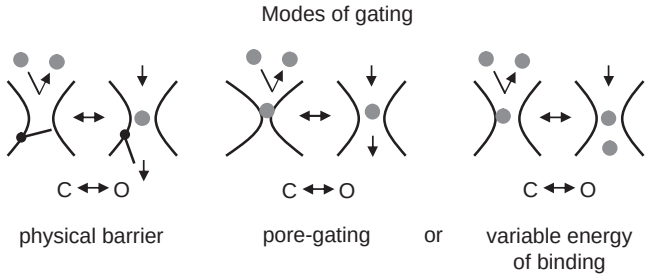

FIGURE 8.15 **Two different general types of gates are known to exist in channels.** Illustrated are the two different types of channel gates identified to date. The left shows a representation of a physical barrier functioning as a gate where the barrier is a side chain, residue or domain of the channel (represented by a black line connected to a small black circle on the wall of the pore) that occludes the pore in the closed state. The regulated common gate and slow gate in ClC and Kir channels, respectively, are this type of gate. The middle and right illustrations represent two different understandings of a pore-gate where the pore collapses around a permeant ion (middle) or the permeant ion sticks to a binding site within the pore (right) to occlude the pore in the closed state. Fast gating of Kir channels and fast gating of proto-pores in ClC channels represent gating of this type. Closed-to-open transitions are shown below, and movement of the permeant ion (gray ball) through the pore is indicated by arrows.

Types of Gates

We typically think of a channel gate as a domain or residue that occludes or covers the pore in a dynamic manner. This may be the case for gates in many types of channels typified by the regulated gate in Kv channels, the slow-gate in Kir, and the common gate in ClC channels.[37,52,61] The crystal structures of many ion channels have recently advanced the understanding of gates. As depicted in Figure 8.15, at least two types of gates are now known to exist. Several channels contain both types of gates, as typified by the fast and slow gates in Kir channels.[32] These two types of gates share some properties, such as they both prevent further permeation of the conductance pathway, but also have important differences albeit sometimes subtle. In addition to a physical gating particle that may obstruct the pore, collapse of the pore around a permeant ion prohibiting further permeation has also been identified as a means of gating.[32,35,36] During pore-gating, the channel is open when the pore is open, and closed when the pore is collapsed. So, there is no true gate with a pore-gating mechanism, rather the physical diameter of the pore is the gate.

In the pore-gating model, the selectivity-filter or another portion of the pore is the working part. This is the case for the fast gating seen in the ROMK channel, where K^+ occupancy of the pore has a profound influence on the structure of the selectivity-filter.[32] Fast gating is characterized by the rapid transition between the open and shortest-lived closed states. The role of pore-gating and the selectivity-filter in this fast-gating process was noticed because the rate of entering the shortest-lived closed state varies as a function of K^+ concentration, and is proportional to current amplitude.[50,51,62–64] The crystal structures of bacterial Kir channels, sharing structure with ROMK as discussed below, provides additional support for this mechanism, showing how a pore may collapse around a permeant ion to gate the channel. A similar relation between extracellular Cl^- and gating of ClC channels has also been noticed.[65–68] This has led to speculation that the proto-pores of ClC channels may also use a pore-gating mechanism. This is supported by the crystal structure of ClC channels.[37,46,53,57]

An alternative to mechanical collapse of the pore/selectivity-filter around the permeant ion to explain pore-gating is a variable energy-of-binding model. Simply put, in some instances, such as that during the shortest-lived closed state of ROMK channels, K^+ may be bound so tightly to the pore that it briefly plugs the permeation pathway.[63] This latter mechanism shares similarities with a traditional gate, in that it is a manifestation of a particle physically clogging the pore to prevent further permeation, but here the gating particle is also the permeant ion rather than a distinct part of the channel. It is different from a pore-collapse mechanism, in that the pore remains in an open state

in the variable energy-of-binding model, merely being clogged. Both the mechanical pore collapse and variable energy-of-binding modes of gating result from interactions between the ion permeating the pore and pore residues.

Regulation of Gating

The inherent activities of gates can be influenced by factors that change the kinetics and equilibrium between the closed and open states. This change can be reversible or irreversible. Only the former is involved in the dynamic regulation of channel activity. The latter permanently changes the gating state. Factors that influence gating assume many forms. They can be extracellular and intracellular ligands that bind the channel, for instance Ca^{2+} binding to calcium bowls and RCK domains in the intracellular portions of BK_{Ca} channels.[69,70] They can be enzymes, for instance kinases and proteases, which chemically modify channels or change channel structure. For instance, ROMK is activated and maintained in a high-P_o state by PKA phosphorylation, and inhibited by intracellular acidification.[32] Voltage also can influence the gating of some channels. This represents a special case as discussed below in the section titled "Some Channels Rectify." Channel oligomerization and association with accessory subunits can also influence gating. Barttin plays such a role for ClC-Ka and ClC-Kb channels.[71] As shown in Figure 8.16, the presence of barttin reverses the voltage-dependence of the rat ClC-Ka ortholog, ClC-K1, switching it from being activated by membrane depolarization to being activated by membrane hyperpolarization. Such regulation of gating allows ClC-Ka and ClC-Kb channels to be active under physiological conditions, facilitating NaCl reabsorption in both the TAL and DCT.[72,73]

Many factors that influence gating to change P_o work through an allosteric mechanism, using a binding or effector site that is away from the pore. With such a mechanism, the effector molecule or influence of voltage affects an allosteric site where the free energy of interaction at this site is translated into a change in conformation that alters gating kinetics, equilibrium or both. As discussed further below, channel subunits in the Kv channel family have a core structure containing six transmembrane domains with an extracellular pore-forming loop between S5 and S6. In these channels, S4 is the voltage-sensor. This transmembrane domain contains conserved positive charged residues that sense voltage and move the S4 domain in response to a voltage-change across the membrane. In this sense, S4 is a molecular voltmeter. Movement of S4 is conveyed to the gate to change its position. BK_{Ca} channels contain intracellular Ca^{2+}-binding sites that also act as allosteric regulators of gating.[69,70] Occupancy of these sites by Ca^{2+} increases P_o by making it more likely that the channel will be in an open state.

Pore-gates, like those in ClC channels, can also be influenced by modulators to change gating. For instance, ClC channels are also voltage-dependent (see Figure 8.16). Because of the nature of the gate in these channels, regulation of ClC gating by voltage, though, is not allosteric. Rather, voltage directly influences the interaction of Cl^- with residues in the pore.[37,46,61]

The Consequences of Regulation of Gating

Regulation of gating determines how active a channel is, and the magnitude of the current through the channel. For instance, the regulation of gating, as noted above, enables ClC channels to be active under physiological conditions. Because gating can be regulated, channels act as variable resistors in equivalent circuits: their mode of gating can change, which causes P_o to be able to be changed in a dynamic manner. Recall that $I = iNP_o$ and $G = gNP_o$. In experiments quantifying macroscopic current, like the idealized results shown in

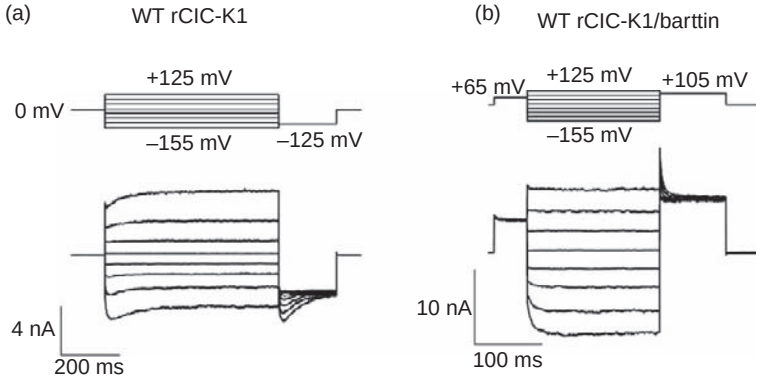

FIGURE 8.16 The regulatory subunit, barttin, reverses the voltage-dependence of ClC-K channels, allowing them to be active under physiological conditions. (*Adapted from Figure 1 in* [72].) Voltage-step protocols and representative current responses for cells expressing rat ClC-K1 alone (a) or together with barttin (b).

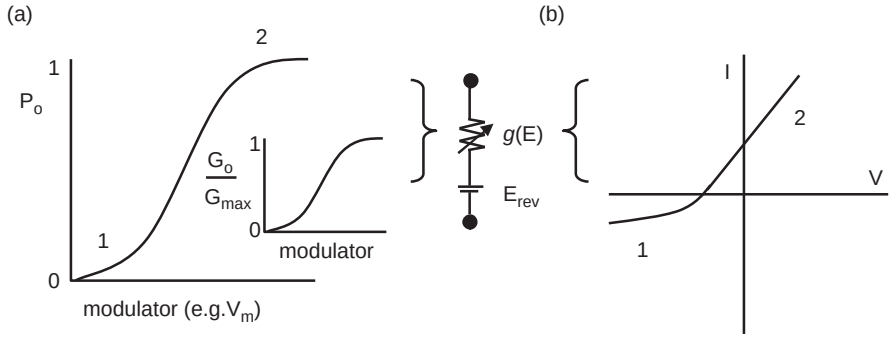

FIGURE 8.17 Changes in gating influence channel activity. The idealized graph in (a) shows P_o as a function of the effects of a modulator of gating, which changes the resistance of the channel shown in the idealized equivalent circuit shown to the right. (The inset in (a) shows the effects of a gating modulator on channel conductance.) The I–V relation in (b) shows the effects of the gating modulator changing P_o on macroscopic current, with point 1 being when the channel has low P_o and point 2 when P_o is approaching 1.

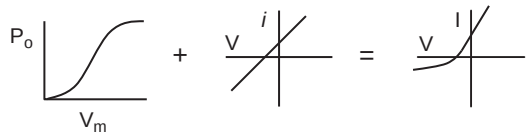

FIGURE 8.18 A channel's macroscopic I–V relation is a determinant of the effects of gating modulators on P_o and its single-channel *i*–V relation.

Figure 8.17, conductance changes as P_o changes, as a result of effectors influencing gating. The importance of this to physiology is clear when considering that voltage-dependent activation of BK_{Ca} channels enables them to conduct more current at depolarizing potentials, which in turn prevents further membrane depolarization by driving the membrane potential toward E_K. As noted previously, feedback activation of BK_{Ca} channels is critical to nearby TRPC6 channels functioning as Ca^{2+} entry pathways in podocytes.[11]

Some Channels Rectify

Rectification is when the macroscopic I–V relation of a channel deviates from strictly obeying Ohm's Law.[2] A macroscopic I–V relation, as detailed in Figure 8.18, is the sum of the single-channel i–V relation, and effects of gating modulators on channel P_o. Our discussion of ion channels has been simplified, in that we have presumed that they all rigorously follow Ohm's Law. This is not actually the case. As the concentration gradient of the permeant ion across the membrane increases, and as the concentration of the permeant ion approaches 0, all channels show some degree of rectification. This is referred to as Goldman rectification, and is a manifestation of the asymmetrical distribution of permeant ions across the membrane.[2] As such, it can be described by the GHK current equation. Further discussion of this, though, is beyond the scope of our discourse. Rectification that is of relevance here is that caused by voltage-dependent gating, because it can influence (as discussed immediately above) how active a channel is under physiological conditions.

Modulation of gating by voltage represents a special case. In this case, voltage has two affects. It influences P_o and the unitary current i of the channel. As such, macroscopic I–V relations for voltage-gated channels show rectification. Channels that rectify exhibit greater conductance at either positive or negative potentials applied across the membrane, meaning that they facilitate the movement of ions in a particular direction (into the cell or out of the cell). Macroscopic I–V relations for such channels are illustrated in Figures 8.17 and 8.18. The voltage-dependence of gating is routinely described with a Boltzmann function where $P_o = 1/[1 + e^{-V-V1/2zF/RT}]$.[2] All symbols in this equation have their usual meaning as described in previous sections, and $V_{½}$ is the voltage at which P_o is 0.5 or, if used to describe macroscopic conductance, the voltage at which conductance is half of the maximum. In most cases, when fitting the voltage-dependence of macroscopic conductance, G is normalized to maximum conductance (G_{max}), giving $G = G_{max}/[1 + e^{-V-V1/2zF/RT}]$. Fitting with a Boltzmann function provides two important pieces of information describing the effects of voltage on gating. It provides the voltage at which half the channels are open, telling us about the threshold for activation by voltage. It also describes the degree to which a channel responds to voltage. This is the slope of the fit, and informs us about the range over which the channel responds to voltage and how tightly channel gating is linked to changes in voltage: a steeper slope indicates a tighter association.

Modeling Channel Gating

Gating of an ion channel is akin to an enzyme transitioning between an unbound and substrate-bound active state, with rate constants determining the state

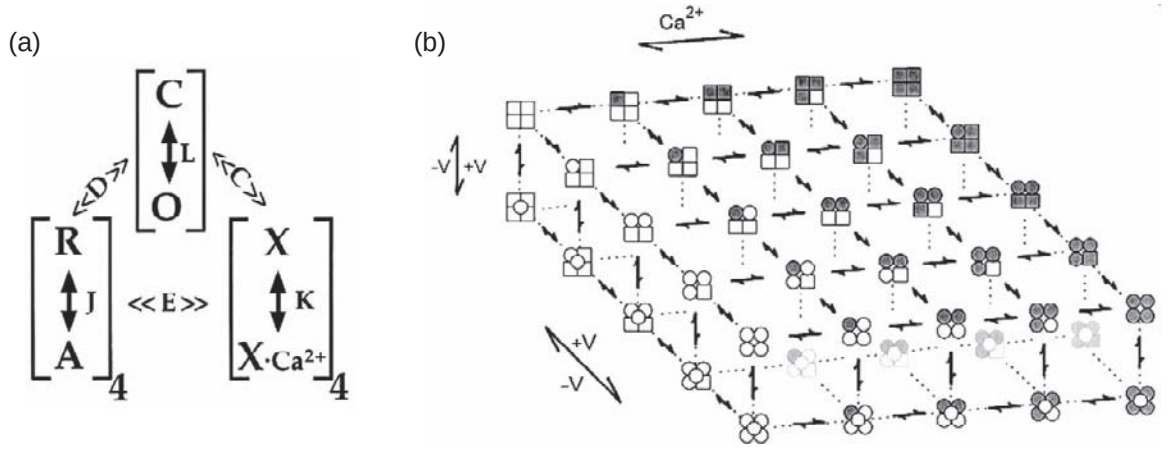

FIGURE 8.19 Channel gating can be described with kinetic models and state diagrams. The kinetic model (a) and state diagram (b) describing BK_{Ca} channel gating are from [69] and [70], respectively. The gating mechanism involves an allosteric interaction between channel opening (C−O) and voltage sensor activation (R−A). L is the C−O equilibrium constant when all voltage sensors are in the resting (R) state. J is the R−A equilibrium constant when channels are closed. D is the allosteric interaction factor where the C−O equilibrium constant increases D-fold for each voltage sensor activated, and the R−A equilibrium constant increases D-fold when the channel opens. Subscripts for closed and open states denote 0−4 activated voltage sensors of the tetrameric channel. The Ca^{2+}-binding transition (X−XCa) for each subunit has an equilibrium constant $K = [Ca^{2+}]/K_D$ when channels are closed and voltage sensors are not activated. Allosteric interactions of Ca^{2+}-binding with channel opening and voltage sensor activation are determined by the allosteric factors C and E, respectively. In the state diagram, a change in subunit conformation is indicated by the square-to-circle transition. The effects of voltage and Ca^{2+} are noted on the axes, with Ca^{2+}-binding indicated with gray shading. The open channel state is noted by a white circle in the center of the tetramer.

occupied. This allows gating to be viewed as a biochemical reaction, where standard analysis of reaction rates and kinetics can be used to describe the gating process. The simplest mode of gating is one containing forward and backward transitions between a single closed and open state. Such a gating scheme with associated kinetic constants is shown above the current trace in Figure 8.14.

Kinetic models and state diagrams have explained much about how factors influence gating. As we learn more about the biophysical properties of channels, these models have been becoming more complex, but also they are better at explaining the features and caveats of how channels transition and gate. Figure 8.19 shows a kinetic model and state diagram explaining the effects of voltage and Ca^{2+} on BK_{Ca} channel gating. Both models assume allosteric interaction between the voltage-sensor and Ca^{2+}-binding site(s) with the channel gate. When expanded, these models contain at least 50 different states. The kinetic model originated from the investigation of macroscopic currents under extreme conditions used to isolate specific effects of voltage and Ca^{2+} away from intrinsic gating events.[69] The state diagram was derived from single-channel data, including the analysis of single-channel gating kinetics.[70] These models have common features, and do a good job of predicting the voltage- and Ca^{2+}-dependence of BK_{Ca}-channel gating over a range of $[Ca^{2+}]$ and voltages, justifying their continued use for explaining BK_{Ca}-channel activity and regulation.

Such models have important ramifications for how we think about renal ion channels and understand their role in physiology. BK_{Ca} channels are critical to protecting membrane potential in podocytes during TRPC6-mediated Ca^{2+} influx, and are involved in K^+ secretion from the CD.[10,11,12] A detailed understanding of how BK_{Ca} channels gate in response to voltage and Ca^{2+} then is critical to appreciating these processes.

Pore Block

Although not a true change in gating in that the gate is not affected, a block of the pore by a factor other than the permeant ion or gating particle may also alter single-channel and macroscopic currents. For instance, the blocking of the ENaC pore by amiloride decreases the mean P_o these channels have with channels spending briefer periods in the open state.[47,48,74,75] In experiments, this appears as frequent transitions between the open and open-blocked state, with the latter appearing as a closed state. Block of a pore can also be voltage-sensitive if the blocker interacts with the blocking site in a voltage-dependent manner. For instance, rectification of Kir channels results from voltage-dependent block of the pore by Mg^{2+} and polyamines. This appears as an effect on gating.[43,76,77] Because such factors influence P_o and the time channels spend in the open state, their actions can also be assessed with standard kinetic analysis and measurements of voltage-dependence.

FUNCTION OF RENAL ION CHANNELS

Interpreting experimental results from a biophysical perspective, as developed above, has been instrumental in defining the roles of many channels in the kidney. In the next section, expression patterns are discussed in terms of where function has been established with some degree of certainty from experimental results (see Figures 8.1 and 8.2 and Table 8.1). Two channel proteins in the ClC transporter/channel family are expressed in the kidney: ClC-Ka in the basolateral membrane of ascending thin limb (ATL) and TAL cells, and CLC-Kb in the basolateral membrane of TAL and DCT cells.[60,78,79] Barttin, a regulatory subunit obligatory for ClC-Ka and ClC-Kb activity, is expressed along with these channel proteins in the nephron.[71,72,73] K^+ channels from at least four different families are functionally expressed in the kidney. The inward rectifiers Kir1.1 and 4.1 are expressed in the apical membranes of TAL, DCT, CNT and CD, and the basolateral membrane of DCT cells, respectively.[20] BK_{Ca} channels are expressed in podocytes and the apical membranes of CD cells.[11,19,29,30,31,33] Proximal tubule epithelial cells express the TWIK-related acid-sensitive K^+-2 (TASK-2) channel, a member of the two-pore K^+ channel family, in their basolateral membranes.[80] Kv1.1 is expressed in the luminal membrane of DCT cells.[20] A single type of Na^+ channel, ENaC, is expressed in the kidney in the apical membrane of CD principal cells.[41,81,82,83] Several members of the TRP channel family are expressed in the kidney. TRPC6 is expressed in podocytes.[11,13] The nonselective TRPV4 channel is expressed in the apical membranes of cells lining the water-impermeable segments of the tubule, including the ATL, TAL, and DCT.[12] TRPP2 is expressed in the apical membranes of TAL and DCT cells, as well as in other segments of the nephron.[12] Inactivating mutations in the gene encoding this channel protein cause autosomal dominant polycystic kidney disease. Coverage of this area of research is broad and beyond the scope of the current chapter. Chapter 80 discusses polycystic kidney disease, and TRPP2. The Mg^{2+}-selective TRPM6 channel is expressed in the apical membrane of early DCT cells.[9,10,19,20] The epithelial Ca^{2+} channel, TRPV5, is expressed in the apical membrane of late DCT and CNT cells.[49,84,85,86]

CLC (CLCN) Channels and Barttin (BSND)

The ClC proteins are members of a large family of Cl^- transport proteins that serve diverse functions (Chapter 31).[59,60] These proteins are widely expressed in every animal and most, if not all, bacteria. The ClC family is divided into two branches depending on function; three if sequence identity is the discriminator. Members of one branch (two if using identity) function as electrogenic anti-porters, moving $2Cl^-$ and H^+ in opposite directions in a secondary-active manner. This branch is likely to be the older for most, if not all, ClC proteins identified in bacteria belong to it. The younger branch contains proteins that have lost their need for H^+ to move Cl^- in a coupled manner, and now function as voltage-gated ion channels with anions moving through the ClC channel pore via restrictive diffusion.

ClC-Ka and ClC-Kb proteins form anion channels selective for Cl^- with similar biophysical properties. ClC-Ka and ClC-Kb have overlapping, but not identical, function in the kidney. This was revealed by the different tubulopathies arising from the inactivation of ClC-Ka (diabetes insipidus) versus ClC-Kb (Bartter's syndrome type III), and the realization that inactivation of barttin (BS type IV with sensorineural deafness) recapitulates the entirety of the phenotype resulting from loss of both ClC channels.[14,18,71,87] In the TAL, ClC-Ka and ClC-Kb serve as basolateral exit pathways for Cl^- brought into the cell along with Na^+ and K^+ by apical NKCC2. ClC-Kb, but not ClC-Ka, serves a similar function in the DCT, with the caveat that Cl^- enters these cells along with Na^+ across the apical membrane on NCC. Because ClC-Kb functions as a basolateral Cl^- exit gateway in both the TAL and DCT, inactivating mutations in this gene sometimes can appear to result in a mixed Bartter–Gitleman's phenotype.[14,18,88] Moreover, because both ClC-Ka and ClC-Kb are expressed in the TAL, the phenotype resulting from inactivation of ClC-Kb is not as severe as that seen with inactivation of barttin (BS type IV) or NKCC2 (BS type I).

Barttin, as indicated above, is required for ClC-Ka and ClC-Kb activity, making mutations in this accessory subunit also capable of causing disease.[72,73] The effect of barttin on ClC-K channels is complex and not fully-understood. What is clear is that ClC-K channels are the only members of the ClC family not to contain the critical E166 gating moiety at the extracellular mouth of the pore. Rather, these channels have a Val residue here.[46,57,61,72] This may contribute in part to why these channels are not functional in the absence of barttin, for this gating moiety enables other ClC channels to sense and respond to voltage with activation. Mutagenesis studies have shown that the transmembrane core of barttin is necessary and sufficient to promote ClC-K trafficking to the plasma membrane, a short cytoplasmic segment following the second transmembrane domain modifies the unitary conductance of ClC-K channels, and the entire COOH-terminal cytoplasmic domain is

involved in affecting channel P_o.[73] The biophysical mechanism whereby barttin affects ClC-K channel P_o involves locking the common gate covering the two proto-pores open: in the presence of barttin, ClC-Ka and ClC-Kb channels can reach full activity with their proto-pore gates primarily modulating P_o.[72] The physiological importance of this is clear. Without barttin, there is no ClC-K channel activity, concomitant K^+ recycling across the apical membrane of TAL cells or dependent NaCl reabsorption, resulting in the compromise of the axial corticomedullary hypertonic gradient necessary to concentrate urine.

KCNA (Kv) Channels

The Kv1.1 channel is expressed in the luminal membrane of DCT cells.[20] Kv1.1 is best known as the first cloned mammalian fast delayed rectifier channel belonging to the Shaker subfamily, named so because flies lacking the Shaker channel shake their legs while under ether anesthesia.[89,90,91] There is little difference between the intracellular and extracellular concentrations of ionized Mg^{2+} in the renal tubule. The electrochemical force driving cell entry of Mg^{2+} as a consequence is mostly a result of the apical membrane being hyperpolarized. Kv1.1 is K^+-selective and voltage-gated, rapidly activating upon membrane depolarization. Activation of Kv1.1 stabilizes the potential across the luminal membrane hyperpolarized near E_K. This function makes Kv1.1 well-qualified to facilitate Mg^{2+} reabsorption in the DCT. Inactivation of Kv1.1 leads to autosomal dominant hypomagnesaemia resulting from decreases in Mg^{2+} reabsorption in the DCT.[20,92]

KCNM (BK_{Ca}) Channels

BK_{Ca} channels are expressed in both podocytes and the apical membrane of CD epithelial cells. In podocytes, BK_{Ca} channels co-localize with TRPC6 channels, where they serve in a feedback capacity to facilitate and fine-tune receptor-operated Ca^{2+} influx mediated by TRPC6.[11] The Ca^{2+} and voltage-sensitivity of BK_{Ca} channels, as well as their selectivity and the influence that activating these channels have on membrane potential, makes them well-suited for such a task. This function, though, is not definitive; rather it is extrapolated from co-localization with TRPC6, and the biophysical properties of BK_{Ca} and TRPC6 channels. It has not been determined yet whether BK_{Ca} channel mutation causes any type of proteinuric glomerulopathy akin to the FSGS arising from the mutation of TRPC6.[13]

BK_{Ca} channels are also expressed in the apical membrane of CD epithelial cells. Here, they function as one of two discrete apical exit gateways for K^+ secretion in the distal nephron.[23,29,31,33] ROMK, as discussed below, serves a similar function in the parallel secretory pathway. Although both pathways mediating K^+ secretion in the distal nephron coexist and provide some redundancy and protection, they do not have a complete overlap of function. The ability of BK_{Ca} channels to respond to mechanical stimuli with changes in gating and P_o makes them particularly well-suited to mediate flow-induced K^+ secretion.[29,30] In comparison, ROMK activity is not sensitive to flow. Decreases in K^+ excretion in electrolyte-balance studies during states of high K^+ intake in animals with compromised BK_{Ca} channel activity resulting from gene deletion of the critical β1 regulatory subunit recapitulate findings testing the actions of BK_{Ca} channel blockers on K^+ secretion in isolated perfused tubules.[93]

KCNJ (Kir) Channels

ROMK (Kir1.1) is the founding member of the inward-rectifying K^+ channel family.[94] Inward-rectifying K^+ channels exhibit a non-linear I−V relation characterized by a larger inward current than outward current. ROMK, though, is only weakly inwardly rectified. ROMK is active at physiological potentials with electrochemical gradient, rectification, and other regulatory factors fine-tuning the amount of outward current carried by this channel. Under normal conditions, activated ROMK is well-suited for K^+ secretion, having a P_o approaching 0.9.

ROMK channels serve a dual role in the kidney. In the TAL, ROMK channels provide the majority of apical membrane K^+ conductance. This activity enables K^+ recycling across the apical membrane, to facilitate NaCl entry along with K^+ on the NKCC2 driving NaCl reabsorption by this segment of the tubule and, ultimately, creation of the axial corticomedullary hyperosmotic gradient necessary for concentrating urine.[31,32,33] This function of ROMK was revealed upon discovery of the genetic basis of Bartter syndrome.

ROMK is also an essential component of one of two parallel K^+ secretory pathways in the CNT and CD.[31,32,33,95] As discussed above, BK_{Ca} channels replace ROMK in the ROMK-independent K^+ secretory pathway. This explains how K^+-wasting can happen in BS type II, even in the absence of ROMK. In the same way, upregulation of ROMK channels preserves K^+ secretion in BK_{Ca} channel knockout mice. It has been speculated that this redundancy is a protective mechanism to ensure high-capacity K^+ excretion to guard against fatal hyperkalemia.[32]

Kir4.1 is another member of the inward rectifier family of K^+ channels expressed in the kidney.[92,96,97,98] Compared to ROMK, less is known about the function of this channel in the kidney, but emerging evidence supports that it acts as an important basolateral K^+ exit pathway in DCT cells. Potassium exiting through this channel contributes to the extracellular pool of K^+ immediately available to serosal Na^+,K^+-ATPases. This is necessary for Mg^{2+} reabsorption in the DCT, because Mg^{2+} entry across the apical membrane is intimately tied to membrane potential and NaCl reabsorption where maximal Na^+,K^+-ATPase activity is required to maintain the electrochemical gradients driving Mg^{2+} across the luminal membrane. Proper Kir4.1 function in the DCT is critical, in that the loss of this channel's function causes disease, SeSAME, with notable renal Mg^{2+}-wasting.[92,96,97,98] Clearly, the unique biophysical properties this channel provides to the basolateral membrane of DCT cells cannot be compensated for by the presence of other K^+ channels.

KCNK (K_{2P}) Channels

TASK-2 is a member of the alkaline-activated TALK sub-family within the larger two-pore K^+ channel family.[80] TASK-2 is expressed in the basolateral membrane of PT epithelial cells. As revealed in TASK-2 $-/-$ mice, this channel functions as an alkali-activated counterbalance to the depolarizing influence of the electrogenic Na^+,3-HCO_3^--co-transporter also in the basolateral membrane of PT cells.[80,99] Outward K^+ conductance through TASK-2 counteracts the depolarizing effects of this co-transporter by hyperpolarizing membrane potential back towards E_K. This function makes TASK-2 a key component of a positive feedback pathway maximizing HCO_3^- reabsorption in the PT. Loss of TASK-2 function causes metabolic acidosis, as expected but also modestly increases Na^+ and water excretion by the kidney.[99,100] These effects on pH and renal salt and water handling are akin to those seen with diuretic inhibitors of carbonic anydrase, which promote a weak diuresis by decreasing bulk fluid reabsorption in the PT due to decreased $NaHCO_3^-$ reabsorption. Although the role of TASK-2 in the mouse is clear, it remains to be determined whether mutations in this channel account for familial forms of proximal renal tubule acidosis in humans.

SCNN (ENaC) Channels

ENaC is a member of the ENaC/Degenerin channel family.[101–103] Acid-sensing ion channels (ASIC) are also in this family. ENaC/Deg channels are widely distributed in epithelial and nervous tissues. These channels are Na^+- or non-selective cation channels. Some of the non-selective ENaC/Deg channels also conduct Ca^{2+}. ENaC, which is highly selective for Na^+, though, does not.[41,83,104,141] The activity of ENaC in the CNT and CD is limiting for electrogenic transcellular Na^+ reabsorption here.[41,82,83] This reabsorption fine-tunes urine and plasma Na^+ content. Consequently, ENaC is a physiologically important target for hormones that control blood pressure through feedback regulation of systemic Na^+ and water levels, including those in the renin–angiotensin–aldosterone system. As such, ENaC mutation resulting in gain- and loss-of-function cause improper Na^+ retention and excretion, respectively, leading to increases and decreases in blood pressure.[83,106,107] The prior is Liddle's syndrome, and the latter is pseudohypoaldosteronism (PHA) type-I. Because the electrochemical gradients driving Na^+ reabsorption and K^+ secretion across the apical membrane of CD principal cells are intimately tied to each other, factors that change ENaC activity, including the steroid hormone aldosterone, also affect renal K^+ excretion.

TRP Channels

The TRP protein family is a diverse group of cation channels that participate in a wide range of physiological processes. The mono- and divalent cation conductance of TRP channels enables them to influence both membrane potential and intracellular Ca^{2+} signaling, allowing them to function as important signal transduction switches and gateways for Ca^{2+} and Mg^{2+} entry into the cell during transcellular transport. Mammalian TRP proteins are organized into six subfamilies based on sequence identity. These are C (Canonical, TRPC1-TRPC7 with TRPC2 being a pseudogene in humans), V (Vanilloid, TRPV1-TRPV6), M (Melastatin, TRPM1-TRPM8), A (Ankyrin, TRPA1), P (Polycystin, TRPP1-TRPP3), and ML (Mucolipin, TRPML1-TRPML3).

TRPC6

TRPC6 is a non-selective cation channel with finite Ca^{2+} permeability.[10–12] This channel is expressed in the foot processes of podocytes of Bowman's capsule in the vicinity of the slit diaphragm, as well as in the cell body and major processes of these cells. TRPC6, possibly oligomerized with TRPC3, functions as a receptor-operated Ca^{2+} entry channel in podocytes, where activation leads to cell entry of Ca^{2+} capable of modulating a host of secondary cascades. TRPC6 is only Ca^{2+} permeable under hyperpolarizing conditions. During depolarization Ca^{2+} binds to an

inhibitory site within the pore. Binding to this site results in the block of the pore, with a dependent decrease in P_o and inward rectification of macroscopic TRPC6 currents.[108,109,110] Pore block of TRPC6 by a permeant ion is accurately described by a standard single binding site, two-barrier pore model, where the binding site has a two-fold higher affinity for Ca^{2+} than it does for monovalent cations.[108] Consequently, binding to the inhibitory site impedes Ca^{2+} permeation, causing a relative increase in permeation of monovalent cations. The result is that, in the presence of membrane depolarization, TRPC6 converts from a Ca^{2+} entry channel that affects cell signaling to a channel that depolarizes the membrane. BK_{Ca} channels colocalize with TRPC6 channels in the foot processes and other major structures of podocytes.[11] This suggests a tight relation between the function of these channels with TRPC6 allowing Ca^{2+} to enter the cell, which in turn activates nearby BK_{Ca} channels to facilitate or fine-tune further Ca^{2+} entry through TRPC6 channels. Gain-of-function mutations in TRPC6, leading to increased activity and plasma membrane expression, cause familial forms of FSGS.[10,11,12,13] Mutation of other proteins in the podocyte, including nephron and podocin, that interact with TRPC6 also cause FSGS-like proteinuric glomerulopathies.[10,11] Similarly, the mutation of PLC-ε, an important regulator of DAG-sensitive TRPC6 channel activity, causes an FSGS-like disease.[10]

TRPM6

TRPM6 functions as a Mg^{2+}-selective channel in the apical membrane of early DCT cells.[4,19,20,24] TRPM6 may possibly oligomerize with the more widely-expressed TRPM7 to perform this function. Nevertheless, it is clear that TRPM6 brings a unique component to the channel for inactivating mutations in the gene encoding TRPM6 leading to HSH and, thus, TRPM7 does not fully recapitulate the properties of TRPM6.[4,10,12,19,20,24] Macroscopic current through channels containing TRPM6 is both outwardly and inwardly rectified, and activated by deceases in intracellular Mg^{2+}. This activation serves as a feedback mechanism favoring Mg^{2+} reabsorption. In addition to inactivating mutations in TRPM6, mutations in the genes encoding regulators of this channel cause hypomagnesemia.

Inactivation of the gene encoding pro-epidermal growth factor (EGF), for instance, causes isolated autosomal-recessive hypomagnesemia.[9,10,19,20,24] EGF is a magnesiotropic factor that controls the expression of TRPM6 in the apical membrane of DCT cells. Cetuximab, which is an inactivating monoclonal antibody inhibitor of the EGF receptor used in the treatment of colorectal cancer, causes pronounced renal Mg^{2+}-wasting, also resulting from decreased TRPM6 expression, an acquired form of isolated renal hypomagnesemia.[20,111,112] Magnesium reabsorption via TRPM6 is dependent on NaCl reabsorption and membrane potential in the DCT mediated by the coordinated activities of the apical membrane thiazide-sensitive NCC co-transporter and basolateral Na^+,K^+-ATPase. Mutation of the *FXYD2* gene, which encodes the γb splice variant of the Na^+,K^+-ATPase γ-subunit expressed in this segment of the tubule, causes isolated dominant hypomagnesemia.[9,19,20] Similarly, one component of the complex renal salt-wasting phenotype arising from the inactivation of NCC (Gitleman's syndrome) is Mg^{2+}-wasting.[9,12,19,20,88]

TRPV4

TRPV4 was originally described as an osmotically-responsive monovalent cation-selective cation channel/current with the different names of OTRPC4, VR-OAC, TRP12, and VRL-2.[12] This channel is activated by hypotonic stimuli, resulting in an increase in $[Ca^{2+}]_i$. Increases in Ca^{2+} are secondary to membrane depolarization, rather than Ca^{2+} flux through the channel. TRPV4 is expressed in the water-impermeable segments of the nephron and circumventricular nuclei of the CNS, which governs vasopressin release. The osmotic sensitivity of this channel and its expression in the part of the CNS controlling AVP release led to the idea that TRPV4 contributes to the sensing of osmotic stress and plasma osmolarity. Such a function is supported by findings that AVP release is dysregulated in TRPV4 knockout mice.[113,114] The expression pattern of this channel in the kidney is also consistent with it acting as a cellular-level osmoreceptor that enables epithelial cells to adapt and respond to changes in osmolarity with a change in NaCl transport. Again, findings in the knockout animal are consistent with this.[114,115]

TRPV5

The activity of TRPV5 is voltage- and Ca^{2+}-dependent. This channel is active at physiological potentials and $[Ca^{2+}]_i$ concentrations, but quickly inactivates in response to feedback regulation from intracellular Ca^{2+}.[12,49,84,85] TRPV5 is permeable to Ca^{2+}, and is selective for this divalent cation over monovalent cations. The relative permeability of Ca^{2+} versus Na^+ for channels containing TRPV5 is greater than 100. This is fairly unique for TRP channels, with TRPV6 being the only other TRP channel to share this preference for Ca^{2+}. The selectivity and activity of TRPV5 allows it to function as the apical gateway for Ca^{2+} entry into late DCT and CNT epithelial cells. As such, TRPV5 activity is rate-limiting for Ca^{2+} reabsorption in the nephron beyond the Loop of Henle, where urine and plasma $[Ca^{2+}]$ are fine-tuned. Inactivating mutations of TRPV5 or proteins that regulate the activity

of this channel, such as Klotho, cause hypercalcuria and renal Ca^{2+}-wasting in mice.[12,49,84] It has not been established yet if mutations in human TRPV5 cause a similar renal phenotype.

ION CHANNEL STRUCTURE

Ion channels are multimeric, made of component subunits. There are two general types of channel subunits: those that form the pore, termed pore-forming or α-subunits, and those that do not directly contribute to the pore, but rather modify the properties of the channel proper or pore-forming subunits; these routinely are labeled accessory or β-subunits, but also have been called auxiliary and regulatory subunits. Pore-forming subunits must span the lipid bilayer to create the conductive pore. As depicted in the idealized models of the different subunits making renal channels shown in Figure 8.20, pore-forming subunits contain two or more membrane-spanning domains. Many, but not all, accessory subunits are also integral membrane proteins. (These are not represented in Figure 8.20.) The presence or absence of an accessory subunit has significant consequence to the biophysical and physiological function of a channel. For instance, the activities and properties of the human ClC channels, ClC-Ka and ClC-Kb, are greatly changed by interaction with their β-subunit, barttin.[71,72,73]

Families of pore-forming channel subunits are comprised of homologous proteins that share amino acid identity. The degree of similarity determines how much overlapping function members within a family have. The consequence of a channel family being composed of homologous subunits is that they often differentially assemble into homomeric and heteromeric channels containing a single type of subunit or one with many different but related subunits. The biophysical ramifications of this ability to assemble differentially are profound, leading to differences in channel gating, expression, and regulation to name just a few. This greatly broadens the functional range of channels within the same family. It also can impact the ability to use redundancy to circumvent pathological consequences when one subunit is compromised. Moreover, it can confound the understanding of the specific role played by a particular channel protein within a channel family.

Pore-forming subunits oligomerize into one of three general quaternary structures, as represented in Figure 8.20. ClC family members dimerize into channels containing two subunits, with each subunit encompassing an independent pore.[53,57,116] Most often, as is the case for the renal ClC-Ka and ClC-Kb channels, these dimers are made of identical subunits,

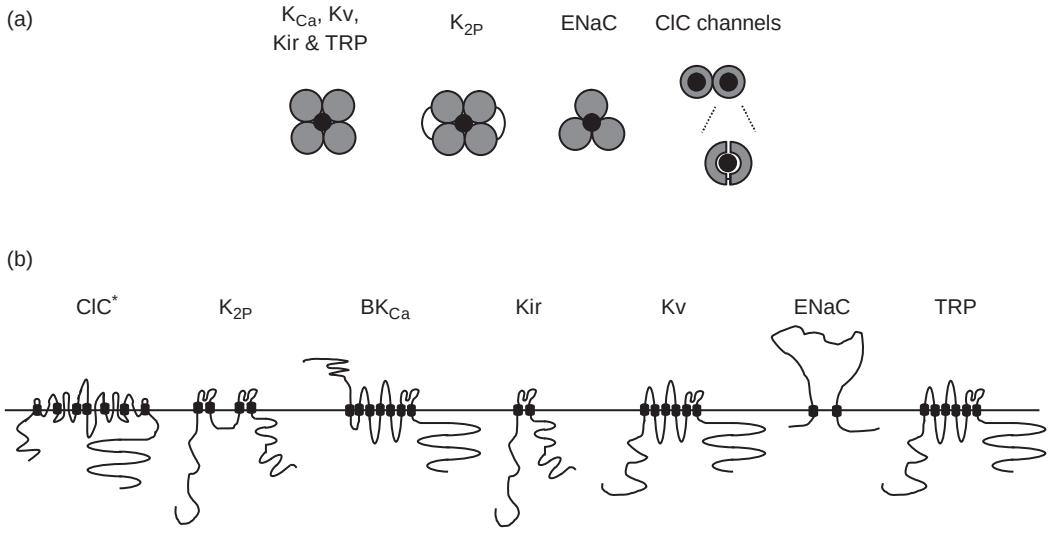

FIGURE 8.20 **Channel structure.** The idealized illustrations in (a) indicate how renal ion channel subunits assemble to form pores. Subunits are indicated by gray circles or half circles with black lines representing the connection between the two subdomains within each monomer of dimeric K_{2P} and ClC channels. The position of the pore is represented by a black circle. Views are parallel to the plane of the membrane. The idealized illustrations in (b) represent the topology of pore-forming subunits of renal ion channels. These views are perpendicular to the plane of the membrane, which is represented by a solid black horizontal line. Transmembrane domains are represented by small black barrels. Extracellular and cytoplasmic portions of these channel subunits are shown above and below the line representing the plasma membrane, respectively, and only loosely correspond to the real structure of these domains. It is difficult to represent the structure of ClC subunits faithfully using such a diagram, as many intra-membrane helices in this channel do not fully span the membrane. Refer to Figures 8.21 and 8.23 for a better understanding of the secondary and tertiary structure of transmembrane helices in ClC channel subunits.

being homodimers. ENaC is an obligatory heterotrimeric channel containing one α-, β-, and γ-subunit surrounding a central pore.[117,118] (The Greek letters referring to the subunits in ENaC are not indicative of whether they contribute to formation of the pore or not for they all do; rather, they reflect the order of cloning.) In comparison, K^+-channel subunits and TRP subunits assemble into tetramers with identical or like subunits forming homotetramic and heterotetramic channels with a central pore. K_{2P} channels are a slight variation on this theme. These channels are homodimers, with each component subunit containing two pore-forming domains that contribute to a central pore that has four-fold symmetry.[119] Thus, K_{2P} subunits oligomerize into a channel with structure that is reminiscent of that formed by Kir channel subunits. Because good structural information exists for ClC, ENaC, and Kir channels or channels closely related to them, discussion in the next section focuses on these channels as representative of the three types of general structure renal channels assume.

The Architecture of ClC Channels

Every ClC protein, including both transporters and channels, shares a conserved molecular architecture consisting of a complex transmembrane transport domain and soluble regulatory domain. Representative crystal structures for both domains are available: the transmembrane domains of two bacteria ClC homologs, ClC-ec1 and ClC-st1, and a cyanobacterial ClC protein, ClC-sy1, and the regulatory domains of three eukaryote family members, ClC-0, ClC-Ka, and ClC-5.[53,57,116,120–122] ClC channels are unique for ion channel proteins, probably reflecting their evolutionary roots as transporters, in that many of their intramembrane helices are of unequal size not completely crossing the membrane. This places several intramembrane helices of ClC proteins at acute angles, rather than right angles as is more common for channels, to the plane of the lipid bilayer. This is clear in the crystal structure for ClC-ec1 shown in Figure 8.21.[52]

Also clear in this structure is that the assembled ClC channel is a homodimer containing two similar

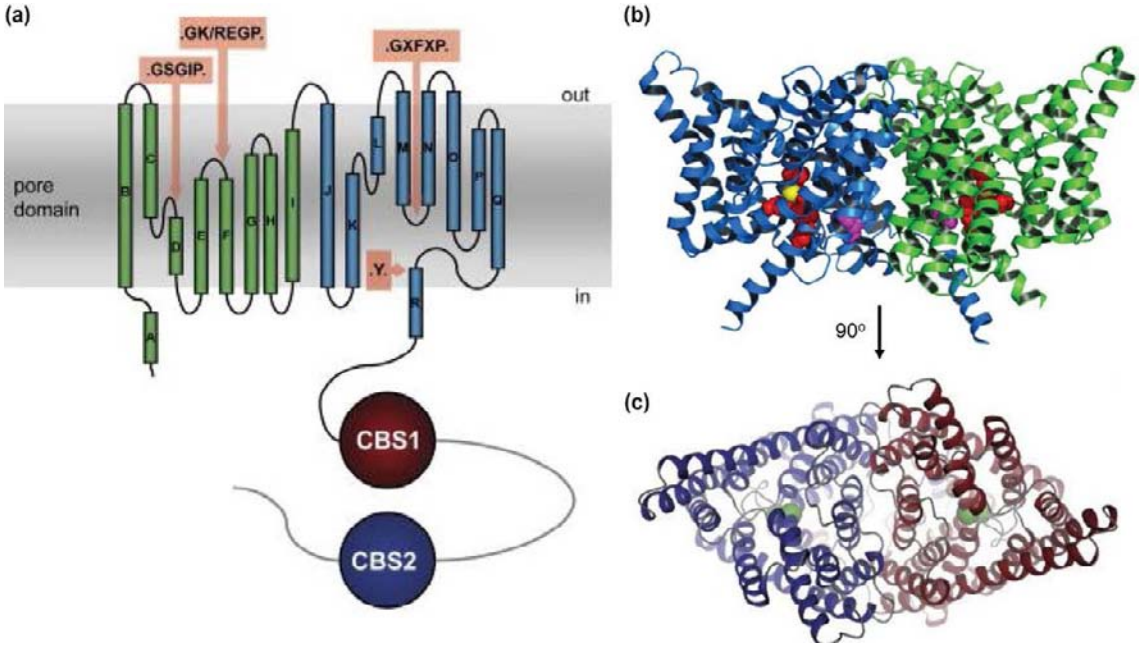

FIGURE 8.21 **Topology and structure of ClC proteins.** (a) *(Figure from [52].)* Schematic representation of ClC channel proteins with topology inferred from the known structure of the bacterial homolog ClC-ec1. The 18 α-helices in these proteins are labeled A–R. The two similar halves within the transmembrane domain (α-helices B–I and J–Q), which have anti-parallel orientation, are colored in green and cyan, respectively. The sequence and position of conserved residues that contribute to the Cl^- selectivity filter are noted with arrows and peach highlighting. The two cytoplasmic CBS domains are shown as red and blue spheres. (b) *(Figure from [79].)* Crystal structure of the *Salmonella enterica* serovar *typhimurium* ClC protein viewed parallel to the plane of the lipid bilayer. One subunit of the dimeric protein is shown in blue and the other green. Cl^- ions in the pore are shown as yellow spheres. Residues comprising the selectivity filter (S106, E1148, and Y445) are shown as red spheres. (c) *(Figure from [52].)* Structure of the *Escherichia coli* ClC protein, ClC-ec1, viewed from the extracellular side. The two subunits of the homodimer are colored red and blue, with ions in the selectivity filter of each subunit represented as green spheres. See color section at the back of the book.

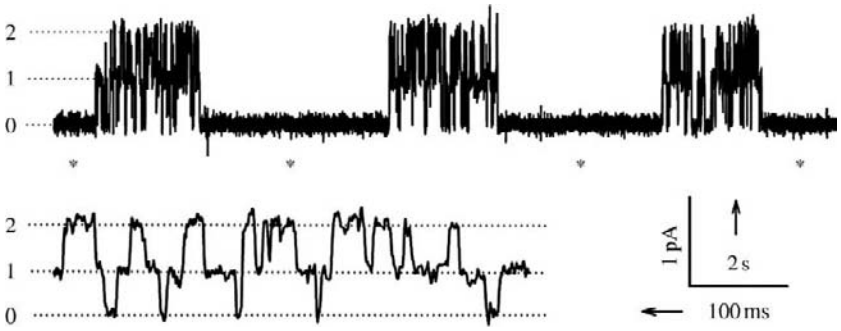

FIGURE 8.22 **ClC subunits form double-barreled Cl^- channels.** *(Figure from [61].)* Shown here is a representative single-channel current trace of a ClC-0 channel. Slow gating by the common gate is noted by asterisks. Fast gating of the proto-pore gates occurs between slow-gate closures: conductance level 0, both pores closed; conductance level 1, one pore closed, one pore open; conductance level 2, both pores open. Below is part of the current trace shown with an expanded timescale.

monomers, each having two topologically related halves, which span the membrane in opposite directions in an antiparallel arrangement. Despite their similarity in structure, the two antiparallel halves of each monomer share only weak conservation at the 1° amino acid sequence level. The two monomers within the channel are structurally related by an axis of two-fold symmetry perpendicular to the membrane plane. When viewed looking down on the plane of the extracellular leaflet of the membrane, the two monomers appear triangular, with a subunit interface at the bases of these triangles. A pore is completely contained within the center of each triangular subunit. That the assembled ClC homodimeric channel contains two independent pores with separate but identical ion permeation pathways has led to these channels being referred to as double-barreled channels. This is consistent with early electrophysiological work on the ClC-0 channel predicting this double-barreled architecture.[52,61,79] Each pore, sometimes termed proto-pore, has its own gate that functions independently gating in a fast manner. Both pores also are covered by a common gate that gates, in comparison, slower. These types of gating are clear in the representative single-channel current trace of homodimeric ClC-0 shown in Figure 8.22. In comparison to this fully assembled channel, the limiting functional unit of a ClC pore, as recently proven by Jayaram and colleagues using a molecularly "designed" ClC-ec1 protein mutating it from a transporter to channel, is a monomer containing the two antiparallel halves capable of conducting Cl^- through a single pore.[123] Experiments on this designed ClC-ec1 channel, moreover, addressed the line separating ClC channels from ClC transporters: it was shown to be thin, involving replacement of only two amino acids. Although the limiting functional unit is a monomer, binding sites critical to regulation of gating, for instance that for Ca^{2+}, are formed at the interface between the two monomers of the homodimer.[124]

The Cl^- Permeation Pathway in ClC Channels: The Molecular Basis of Selectivity

All known ClC channel subunits use a conserved permeation pathway through the protein and common binding sites to conduct Cl^-.[37,46] This vestigal pathway is also present and used in ClC anti-porters to translocate Cl^-. The permeation pathway for anions was unexpectedly revealed by the presence of Cl^- ions bound within each pore in the first crystal structures of bacterial ClC transporters.[53,57] As recognized now from this early work, and reflected in the ribbon structures shown in Figure 8.23, the permeation pathway contains three Cl^--binding sites: an external binding site, S_{ext}; a central binding site, S_{cen}; and an internal binding site, S_{int}. The external binding site can be occupied by Cl^- or the side chain of a conserved Glu residue, E148 in bacterial ClC homologs.[46,52,79] This observation generated many of the initial hypotheses regarding the molecular basis of fast gating in ClC channels. This will be addressed further below.

Formation of a complete permeation pathway containing a selectivity-filter with three Cl^--binding sites, as depicted in Figure 8.23, is possible because the two structurally related antiparallel halves of a monomer are arranged in opposite directions, giving rise to a pseudo two-fold axis of symmetry in the center of the membrane. This makes it possible to bring together loops at the end of helices from different parts of the structure to form the pore in the center of the triangular monomer. Moreover, in this arrangement, the positive ends of the helix dipole point toward the ions entering the pore and stabilize them by electrostatic interactions. Interestingly, nature seems to have conserved this means of pore formation, because an antiparallel architecture also forms the pore of the unrelated aquaporins.[125,126]

Although scattered across the entire subunit, the signature sequences defining the three Cl^--binding sites, as noted in Figure 8.21, are conserved throughout all ClC proteins.[46–52] This speaks to the functional importance of conserving key residues at critical sites in the three-dimensional structure of the protein. The pore of ClC channels is hourglass in shape, bound by aqueous vestibules on the extracellular and intracellular end narrowing in the middle at the selectivity-filter. The intracellular Cl^--binding site is located at the interface between the intracellular vestibule and

Ion-binding sites in the pore are labeled. See color section at the back of the book.

selectivity-filter. The Cl^- ion occupying S_{int} is only partly desolvated, and still hydrated where it is exposed to the aqueous environment of the vestibule. The desolvated surface of this Cl^- ion is coordinated by backbone amide groups on the loop preceding the D helix. The Cl^- ion at S_{cen} has completely shed its water shell, and is now coordinated by partial positive charges from backbone amide nitrogen groups in residues preceding the N helix. In addition, key interactions are made here with selectivity-filter side chain hydroxyls of S107 in the conserved GSGIP sequence and of Y445 located at the beginning of the R helix. When S_{ext} is occupied by E148, not only is the pore physically blocked by the residue side-chain, but a negative charge is also placed within 4 Å of the Cl^- ion occupying S_{cen}. This provides two alternatives to explain gating: a physical occlusion of the pore and a repulsion mechanism involving pore-gating. When the channel is conducting, E148 has moved from S_{ext}, opening this binding site to the Cl^- ion. Supporting this are findings showing that, upon substituting E148 with either an Ala or a Gln, a Cl^- ion is bound to this site coordinated by free backbone amide NH groups of residues in the NH_2-termini of the N and F helices.[37,46,57]

ClC Channel Gating

The gating of ClC channels is complex and incompletely understood. More is understood about the mechanisms underpinning fast gating of proto-pores, as compared to gating by the common gate. Gating of both the fast and common gates is inextricably linked to ion permeation.[37,61,127] In addition to being modulated by extracellular $[Cl^-]$ where increases in $[Cl^-]_{ex}$ increase P_o, fast gating (and also slow gating) is modulated in a positive manner by depolarizing voltages and decreases in pH.[61,67,128,129] Dependence on pH is thought to be a remnant from its days as a transporter. Compelling evidence has emerged that E148 mediates the effects of pH on the fast gate. There is a real possibility also, as supported by experimental evidence, that the effects of voltage on the fast gate are felt by the permeant Cl^- ion and/or modulatory H^+.[61,130] This likely arises from the fact that proto-pores use some form of a pore-gating mechanism, with the interaction between the permeant ion and permeation pathway doing the "gating." Working in combination with this is the charged side chain of E148, which also may be sensitive to voltage or even extracellular $[Cl^-]$ and pH in a voltage-dependent manner.

An important point to note is that ClC-Ka and ClC-Kb do not have a Glu at the position corresponding to 148, which is 166 in ClC-Kb, but rather have a Val at this site, yet both channels show fast gating.[46,79,131] This suggests that, while E148 and the corresponding Glu residues in other ClC channels may be involved in gating, it is not functioning in isolation. In addition, ClC-K1 channels are voltage-sensitive where interaction with the accessory subunit barttin reverses the voltage-activation profile (see Figure 8.16[72,73]). Chimeras of ClC-K1 and ClC-Kb retain this barttin-dependent switch in voltage-sensitivity, suggesting that ClC-Kb channels are also voltage-sensitive in the absence of barttin and E148. The importance of E148 to gating in most ClC channels, though, is not trivial for mutation of the homologous residues in ClC-0, ClC-1, and ClC-2 to neutral residues abolishes voltage-dependent gating.[57,132,133]

The Architecture of ENaC/Deg Channels

The three-dimensional structure of ENaC awaits elucidation, but much can be inferred with a degree of certainty from the known structure of chicken ASIC1.[58,117] As discussed below, we can make predictions about the selectivity-filter and permeation pathway of ENaC and how the channel gates, which are supported by electrophysiology studies.[104,105,134–136]

Subunits forming ENaC/Deg channels share a common topology, which is shown in Figure 8.24, containing a large extracellular domain with much secondary structure bound by two transmembrane (TM) domains, TM1 and TM2, with intracellular NH_2- and COOH-termini.[58,117] As noted above, ENaC is an obligatory heterotrimer containing one α-, one β-, and one γ-subunit contributing to a central pore.[118] These orthologs are encoded by different genes.[101,102] The relative order of subunits within ENaC has yet to be determined. Oligomerized ENaC likely appears as a "chalice," similar to that shown in Figure 8.25, with extracellular domains forming the cup, the transmembrane domains the stem, and intracellular domains the base.[117,137] In comparison to K^+ channels, the ENaC/Deg pore and selectivity-filter, as defined by the cASIC1 crystal, are not made of P-loops diving back into the membrane, but rather are formed by the TM2 domains of the three component subunits as they run in a linear manner through the membrane. The pore as defined by TM2 domains is "hourglass" in shape, with wide extracellular and intracellular facing vestibules and a narrowing in the middle. The extracellular mouth of the pore is coupled to the extracellular domain by short linker sequences in the wrist of the channel. TM1 domains lie just outside TM2 domains within the same subunit as they run the length of the pore sheltering TM2 residues, with TM1 making most of the contact with the lipid bilayer. There are extensive interactions between residues in the adjacent TM1 and TM2 helices within the same subunit, and also between TM domains in neighboring subunits.

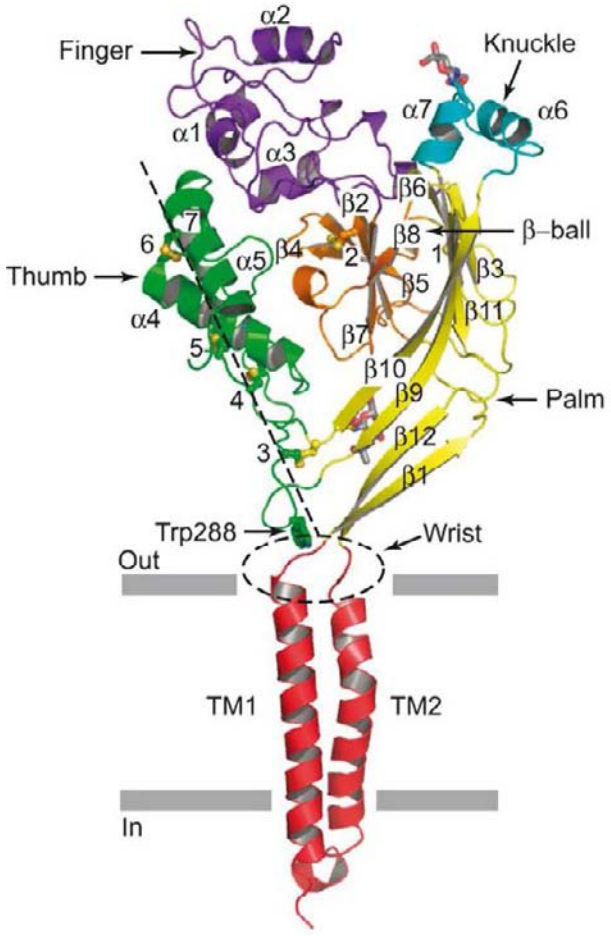

FIGURE 8.24 **The topology of ENaC/Deg channel subunits.** *(Figure from [117].)* This cartoon shows the topology of a monomer within the homotrimeric cASIC1 channel, as defined by the crystal structure. The view is perpendicular to the plane of the membrane. Transmembrane helices (TM1 and TM2) are shown in red. Location of intra-subunit disulphide bridges are labelled 1–7. See color section at the back of the book.

The Permeation Pathway in ENaC/Deg Channels: Selectivity and Ion-Binding Sites

Similar to cASIC1, the ENaC pore likely has pseudo three-fold symmetry around the central axis of the pore, perpendicular to the plane of the lipid bilayer. Ions enter the extracellular mouth of the pore proper through a large vestibule that has profound negative electrostatic potential where the lower half of this molecular "basket" sits within the membrane plane. The negative electrostatic potential of the vestibule allows it to act as a cation reservoir, concentrating cations around the mouth of the pore, contributing to robust channel conductance.[58] The bottom of this vestibule in cASIC1 is defined by D433 corresponding to N530 in γ-ENaC, which when substituted as discussed below causes disease.[58,138] D433 has been proposed to contribute to the desensitization gate in cASIC1 in response to H^+.[58] The cytoplasmic mouth of the pore, similarly, is bound by a large vestibule, shaped like an inverted cone. This vestibule is lined by residues with negatively charged side chains, again possibly allowing the vestibule to act as a cation reservoir. Substitution leading to charge neutralization of these negatively charged residues in ENaC eliminates conductance through the channel.[136]

Figure 8.26 shows the three-dimensional structure of cASIC1, including the radius of a possible conduction pathway along the three-fold axis. The cASIC1 pore, and likely that in ENaC, contains three Na^+-

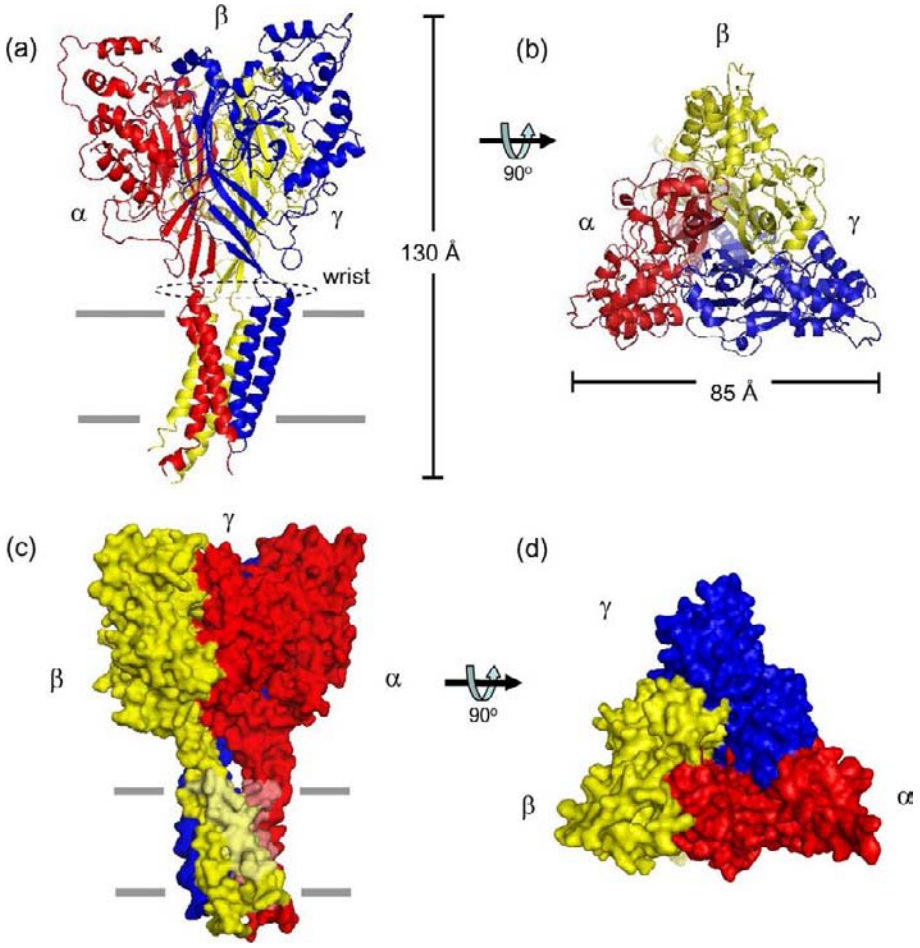

FIGURE 8.25 **Predicted structure of ENaC.** *(Figure adapted from Figure 3 in [137].)* View of the predicted ribbon and space-filled structure of heterotrimeric ENaC perpendicular (a and c) and parallel (b and d), from the extracellular side, to the molecular three-fold axis. binding sites that are occupied during permeation. Adjacent sites are unlikely to be occupied at the same time due to charge repulsion (see Figure 8.15[58]). In open cASIC1, main chain carbonyl oxygen atoms from the symmetry-related G436, G439, and G443 residues coordinate Na^+ permeating through the pore. As shown in Figure 8.27, permeant ions are bound by six ligands arranged in a trigonal antiprism geometry arising from the three ligands on the upper triangular plane being staggered in comparison to those in the lower triangular plane. This geometry provides the appropriate number of partial negative charges for coordination of a Na^+ ion, while perfectly accommodating the underlying molecular symmetry of the trimeric channel.

Several of the coordinating Gly residues in cASIC1 are replaced by Ser residues in ENaC subunits (see Figure 8.27a). ENaC is about 10-fold more selective for Na^+ than ASIC.[47,48,58,139] Although Gly and Ser are structurally similar, the latter is larger, containing an extra carbon and hydroxyl moiety. Thus, Ser occupies a larger volume. Perhaps this larger volume introduces a steric constraint that allows better accommodation of Na^+ in the permeation pathway over other cations. This awaits experimental testing. Nevertheless, the geometry and atomic volumes of the pore in cASIC1 suggest that Na^+ sheds its hydration shell to permeate through the channel. Electrophysiology findings for ENaC support this. Mutations in and near the ENaC selectivity-filter reduce both the Na^+ conductance and Na^+ to K^+ selectivity, possibly because of a perturbation of precise channel-ion hydration geometry.[104,105,140]

The trigonal antiprism coordination of Na^+ in the pore of ENaC/Deg channels, as exemplified by cASIC1, has been proposed to be the archetypal molecular basis of permeation through cation-selective ion channels containing three component subunits.[58] The crystal structure of the P2X4 channel, which also was recently solved, agrees with this position.[58,141] The P2X4 channel is cation-selective, and has 2°, 3°, and 4° structures similar to those in ENaC/Deg channels, but little 1° amino acid sequence identity. Yet, both use identical modes and means of permeation and coordination of permeant ions. The ideal ion-to-ligand distance in the trigonal antiprism arrangement in

Asterisks indicate residues thought to contribute to binding sites within the permeation pathway of the pore. "d" indicates the degenrin site.[144,145] (b) View of the cASIC pore from the extracellular side of the membrane, with the position of selected side chain residues shown. (c) Key interactions between Cs^+ ions, shown as purple balls, in the cASIC1 pore with main chain and side chain oxygen atoms of Gly 432 and Asp 433, respectively. (d) Trigonal antiprism coordination of a Cs^+ ion in the cASIC1 pore by the symmetry related Gly 432 carbonyl and Asp 433 carboxyl oxygens in the three momomers. Oxygen atoms are shown as red spheres. See color section at the back of the book.

ENaC/Deg channels, where six partial-charge ligands coordinate cation binding, is stereochemically analogous to the eight-fold square antiprism coordination of larger K^+ ions in K^+ channels containing four subunits.[36,58] In both ENaC/Deg and K^+ channels, the symmetry of the pore and number of subunits contributing to the pore are matched to the optimal coordination requirements of the permeant ion.[142,143] Moreover, although the linear pore of ENaC/Deg channels lined by the three TM2 domains of component subunits differs in general construction from the pore of K^+ channels, which is formed by the four-component P-loops dipping back into the membrane, the basic chemistry and physical tenets underpinning the coordination of permeant ions within these pores are conserved. This speaks to conservation by nature of a workable blueprint.

The Gate in ENaC/Deg Channels

Compared to ASIC channels, which activate and inactivate in response to H^+ binding to an extracellular allosteric site, ENaC is held to gate in a constitutive manner, with gating modulated by regulatory factors.[41,58,81,117] In cASIC1, a constriction formed by the crossing of TM2 domains at D433 occludes the pore acting as an inactivation gate. The channel is thought to open by TM domains untwisting around the central axis of the pore perpendicular to the plane of the lipid bilayer, partially uncrossing TM2 domains and relieving obstruction of the pore by the inactivation gate. The *degenerin* mutation that constitutively activates ENaC/Deg channels by locking them in long-lived open states is at 432 in cASIC1, one position upstream of the crossing site of TM2 domains.[144,145] Placement of an amino acid larger than Gly at this site sterically clashes with symmetry-related TM2 domains, providing a mechanism whereby mutations at the *degenerin* site perturb gating.

It is interesting that Asn residues, as clear in the alignment shown in Figure 8.27, occupy the positions in ENaC subunits homologous to D433 in cASIC1. This appears to be a signature feature of ENaC, as most other non-ENaC subunits in the ENaC/Deg family have Asp at this position. Moreover, it is likely to be of biophysical importance, for Asn is the uncharged derivative of Asp. This may explain why ENaC constitutively gates and does not inactivate. In ENaC, TM2 crossing at this Asn, for instance, may not be as stable as that in cASIC1 and, thus, transient or it may not obstruct the pore. In addition to an inactivation gate, the crystal structure of cASIC1 suggested that ENaC/Deg channels use a pore-gating mechanism.[58] This possibly explains constitutive gating of ENaC.

The Architecture of K^+ Channels and TRP Channels: ROMK as a Representative

Subunits that form K^+ channels have either two, four, six or six-plus-one transmembrane domains, as typified by Kir-, K_{2P}-, Kv-, and BK_{Ca}-subunits, respectively (see Figure 8.20). Whereas at first glance the apparently different 2° and 3° structures of these subunits may suggest that they assemble into channels of different 4° structure, the fact is they do not, but rather all form channels having a similar core structure surrounding a central pore with four-fold symmetry .[35,36,45,56,146,147] The canonical K^+ channel pore is formed by transmembrane domains and the P-loop, as defined by the two transmembrane domains of Kir channels. The crystal structures of the bacterial KvAP, MthK, KirBac1.1, KirBac3.1, and KcsA channels (and chimeras of KcsA-Kv1.3 and Kir3.1-prokaryotic Kir channel) show slight variations of a common K^+ channel pore, informing on the molecular basis of selectivity, permeation, and gating.[35,36,45,56,146,147] Segments defining this core pore structure are repeated as a pair in the four transmembrane domains of K_{2P} channels. This explains why these channel subunits form a dimeric channel with a central pore that has four-fold symmetry.[80] Moreover, this core pore-forming structure is retained in Kv and BK_{Ca} channels as the S5-P-loop-S6 domains.[2] BK_{Ca} channels mirror the general structure of Kv channels, with the exception that they have one additional transmembrane domain placing their NH_2-terminus outside the cell. TRP channels are also thought to assume this basic structure, often being modeled on the six transmembrane Kv channel.[2,119] The formal structure of TRP channels, however, awaits crystallization studies.

To facilitate discussion of the molecular basis of selectivity, permeation, and gating of the common K^+ channel pore, we focus on ROMK. The reason for this is that the ROMK channel is made of subunits having two transmembrane domains containing all the components comprising the core K^+ channel pore and a regulated gate.

The ROMK Channel Pore: Selectivity and Permeation

Welling and Ho,[32] in a recent review article, reported a compelling atomic model for ROMK based on known Kir channel structures, including regions defined in the crystal structures of the bacterial KirBac1.1 channel, a chimeric Kir3.1-prokaryotic Kir channel, the pore region of the mammalian GIRK1 channel, and the cytoplasmic domains of Kir2.1 and Kir3.1.[35,56,146,147] This model is shown in Figure 8.28.[32] ROMK contains the canonical transmembrane pore common to all K^+ channels, but also a unique central

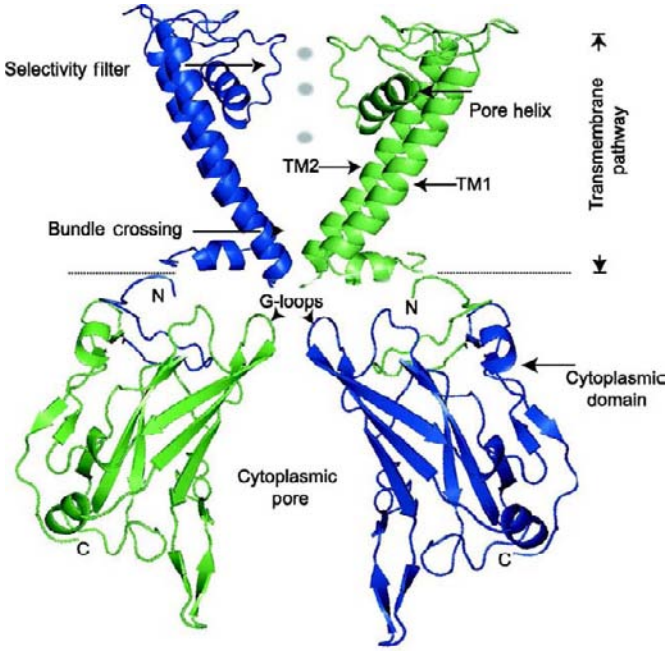

FIGURE 8.28 **Predicted structure of ROMK.** *(Figure from [32].)* An atomic model of ROMK was developed from known K_{ir} channel structures and an iterative optimization algorithm. Shown are two subunits, one green and the other blue, of the tetrameric channel.

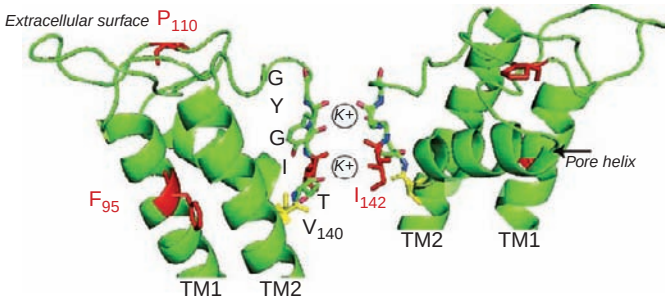

FIGURE 8.29 **The selectivity filter of ROMK.** *(Figure from [32].)* Backbone carbonyl oxygens of selectivity-filter residues T_{141}IGYG point into the pore, mimicking the hydration shell of potassium. Rapid conformational movement of $T_{141}I_{142}$ likely underpins fast gating in ROMK. Residues in red are mutated in Bartter's syndrome type II. See color section at the back of the book.

cavity contained by a large cytoplasmic domain, which is characteristic of Kir channels.[148,149]

The four component subunits of ROMK assemble around a central pore that has four-fold symmetry. The helices of TM2 domains span the membrane at a tilt, narrowing at the intracellular base of the pore. The four TM2 helices of the component subunits frame the pore as it spans the membrane, with TM1 domains running along but outside TM2 domains of the same subunit. The narrowest part of the open conduction pathway is defined by P-loops of the four subunits. These P-loops are linker regions that connect TM1 to TM2 and contain short helical domains that dip back into the mouth of the pore. The symmetry related linkers contain the conserved K^+-selectivity sequence, T[V/I]GYG.[35,36,45,56,146] This motif adopts a strand conformation, as depicted in Figure 8.29, where the NH_2-terminal end is deepest in the pore and COOH-terminal end at the mouth of the pore. The backbone carbonyl oxygen of these T[V/I]GYG residues projects into the central axis of the open pore. Similar to all K^+ channels, the carbonyl oxygen of residues in this selectivity sequence from each symmetry-related subunit form four equally spaced K^+-binding sites in the pore. Four oxygen atoms at the top and bottom of each binding site cage a K^+ ion with eight-fold square antiprism coordination. Such coordination is similar to the way water molecules surround K^+ ions in solution.[36,142,143] This mimicry of water solvation at the selectivity-filter creates an energetically favorable means for K^+ to diffuse into binding sites as they shed their surrounding water shell. Because the volume and ion coordination of these binding sites do not accommodate smaller ions in a dehydrated state, like Na^+, this molecular structure provides high-fidelity K^+-selectivity.

The sequential arrangement of the four equally spaced K^+-binding sites in the linear ROMK pore facilitates a single-file multiple-ion conduction mechanism in agreement with findings from early biophysical measurements.[150–152] As revealed in the crystal structure of the KcsA channel, K^+ ions are simultaneously absorbed to two binding sites at a time, with an empty site positioned between the two occupied sites due to electrostatic charge repulsion between permeant ions.[36,45,151,152] Conduction by K^+ channels then, as depicted in Figure 8.13, is the rapid jumping of K^+ ions in a pair-wise manner from one to the other paired-binding sites within the pore. Such movement involves several rounds of dehydration and rehydration, as the K^+ ion moves into the pore and is absorbed and released from each binding site, and as it exits the pore. The energetics of this sequential dehydration and rehydration as counterbalanced by electrochemical driving forces and electrostatic repulsion between ions within the pore sets conductance. Such a structure enables K^+ ions to move through the pore with high-throughput, but yet with remarkable selectivity.[151,153]

Molecular Basis of Rectification in ROMK Channels

A unique feature of ROMK and other inward rectifier K^+ channels, as their name suggests, is that they have larger inward currents compared to outward currents.[32] The molecular basis of this rectification

involves a pore-block mechanism, where Mg^{2+} and polyamines enter the pore at depolarizing voltages through the intracellular mouth of the channel.[76,77] Once in the pore, Mg^{2+} and polyamines interact with a binding site near the selectivity-filter, plugging the pore. This gives rise to inward rectification, which actually is a decrease in P_o as a function of a voltage-dependent block of the pore where channel P_o is higher at hyperpolarizing potentials compared to depolarizing potentials, allowing greater inward as compared to outward current flow. The degree of rectification is different between distinct members of the Kir channel family, depending on subtle differences in the binding sites for blocking Mg^{2+} and polyamines. ROMK only marginally rectifies. This rectification phenotype is largely a factor of N171 in the pore lining TM2 domain of ROMK or its equivalent in other Kir channels. This is supported by the observation that the N171D substitution in ROMK produces strong rectification. The reverse mutation, D172N, in the strong inward-rectifying Kir2.1 channel weakens rectification, making it more akin to that of ROMK.[154] Figure 8.30 reports the relative position of N171 in ROMK showing that its side chain projects into the aqueous environment of the pore, a position consistent with it being involved in an intra-pore binding site for large blocking cations like Mg^{2+} and polyamines.

Molecular Basis of ROMK Gating

ROMK channels have, at least, two different types of gates. The fast gating of ROMK, as discussed above, involves a pore-gating mechanism. Potassium in the pore of ROMK has profound influence on the structure of the selectivity-filter and pore-binding sites.[151,152] As K^+ binds to a particular position in the selectivity-filter of ROMK (as seen in Figure 8.29), the energetics of binding to this site cause a conformational change at T141-I142, briefly shuttling the channel into a nonconducting conformation.[50,51] An alternative to this physical mechanism, as mentioned above, is a chemical mechanism where the pore does not change conformation but rather K^+ binding affects the energy of binding where the permeant ion is briefly stuck and is unable to move along the pore.[63]

In addition to using a pore-gating mechanism for fast gating, ROMK channels also use a distinct type of gating mechanism that is slower and is regulated. As shown in Figure 8.30, the side chain of L179 in the TM2 domain of ROMK subunits projects into the mouth of the pore and obstructs permeation. It is widely held that regulated K^+ channel opening involves the movement of the pore helixes (TM2) away from the bundle-crossings (with TM1) at the intracellular base of the pore, with extracellular G167 and G176 or their equivalents acting as flexible "hinges" allowing this opening pivot. This movement carries the putative L179 gate at the base of TM2 away from the pore, physically removing this obstruction. Replacement of L179 with small or charged residues stabilizes the open state, just as would be predicted if this residue acts as a regulated gate to obstruct the conduction pathway during the closed state.[155,156] Moreover, such a gating movement is consistent with the differences identified in the crystal structure "snap-shots" of KirBac3.1 in the open and closed state.[35] Figure 8.31 shows these structures. The Y132 gating residue in KirBac3.1 corresponds to L179 in ROMK.

The regulated gate is actually a larger structure involving complex interactions between residues in TM2 and TM1, where an ε-nitrogen of K80 in TM1 forms a hydrogen bond with the backbone carbonyl oxygen of A177 to control the energetics of gating as performed by L179. Such a gating structure provides the molecular basis for regulation, with information arising from conformational changes in intracellular domains translated to the gate via K80. K80 sits at the base of TM1 at the bundle-crossing, which is positioned immediately above the G-loops of the cytoplasmic domains. The idea is that allosteric sites in the

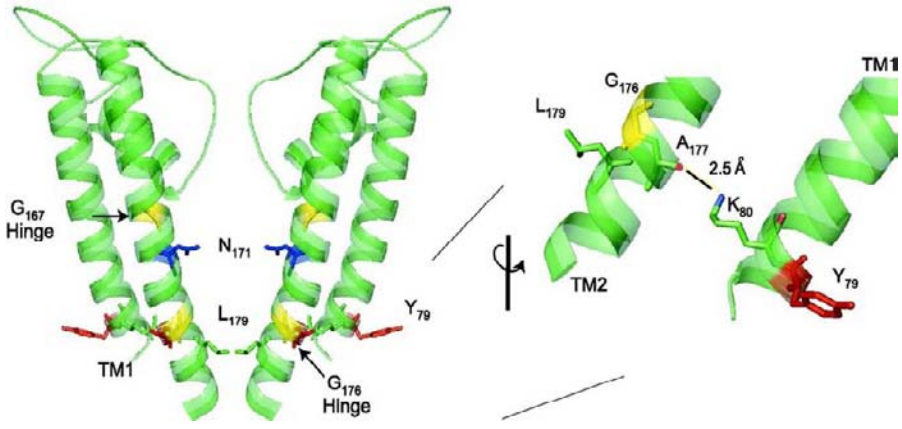

FIGURE 8.30 **The molecular determinants of regulated gating and rectification of ROMK.** *(Figure from [32].)* ROMK gating is thought to involve the twisting of membrane helices pulling L179, the putative gate, out of the pore. Hydrogen bonds between K80 at the base of TM1, and A177, in TM2 stabilizes the gate. Y79 is mutated in Bartter's syndrome. The side chain of N171 projects into the pore and is a key determinant of inward rectification.

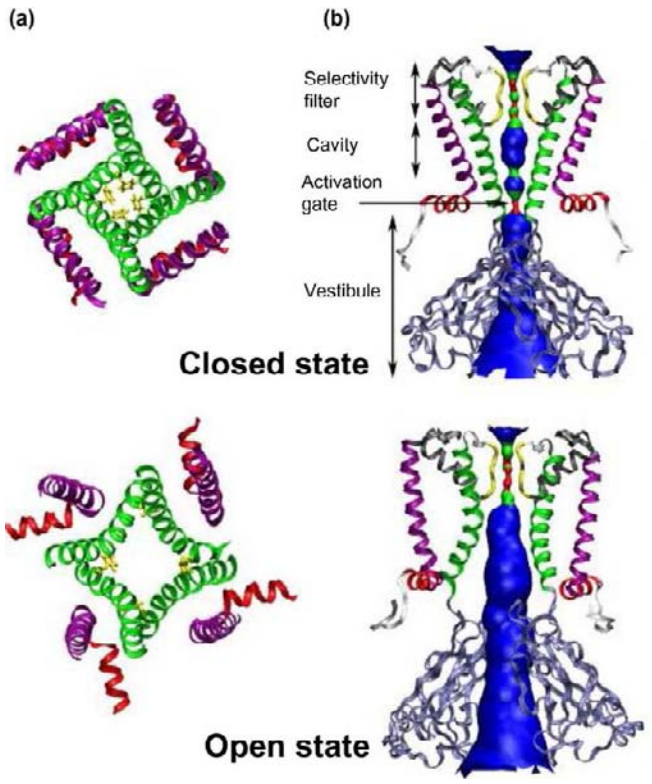

FIGURE 8.31 **"Snap-shots" of KirBac3.1 in the closed and open state.** *(Figure from [35].)* (a) View of the transmembrane section of KirBac from the extracellular side of the membrane in a closed (top) and open (bottom) conformation. Helices are shown as ribbons with outer helices, purple; inner helices, green; and the slide helices, red. The activation gate is displayed as yellow sticks. (b) Two monomers of the closed (top) and open (bottom) channel are shown superimposed on a representation of the diameter of the central ion conduction pathway. Structural elements are colored as in (a). Red coloring in the central conduction pathway indicates that there is not enough space to allow a water molecule to pass; green shows where one or two water molecules could fit; and blue where many water molecules can fit. See color section at the back of the book.

intracellular portion of the channel communicate to the gate through the G-loop positioned just below the intracellular mouth of the pore, although this remains an open question.[32]

The cytoplasmic domains of ROMK assemble just below the canonical transmembrane pore to form a long water-filled cavity extending the length of the conduction pathway. The characteristics of secondary structures and position of side chains of residues lining this water-filled cavity are consistent with it being a pathway for permeation. For instance, this intracellular pore is lined by residues that provide an electrostatic environment favorable for efficient K^+ transport and cation-blocker binding.[157] In addition, there is a high degree of concordance between residues contributing to the electrostatic field, favoring transport and binding with residues known from mutagenesis studies to affect cation block and single-channel conductance.[43] Moreover, studies on the chimeric ROMK-Kir2.1 channel, in addition to other mutagenesis studies, revealed that residues lining the inner wall of this intracellular pore, with N259 in ROMK playing the most significant role, directly influence single-channel conductance. This effect is independent of structures in the transmembrane selectivity-filter, suggesting that the symmetry related cytoplasmic domains provide additional energy barriers to the flow of K^+ through the channel.[157–159] The putative gate for this intracellular pore is thought to be at the narrowing created by the four G-loops as they coalesce just below the mouth of the membrane-spanning pore. This gate is believed to create a flexible diffusion barrier between the cytoplasmic and transmembrane pores. Supporting this are findings that mutations in this region of Kir2.1 and Kir3.1 alter channel gating and inward rectification.[160]

TUBULOPATHIES RESULTING FROM CHANGES IN CHANNEL BIOPHYSICAL PROPERTIES

The majority of channelopathies, including those causing tubulopathy, result from loss of expression or changes in the expression level of functional channels at the membrane. These are not covered here. Less common are channelopathies resulting from mutations that affect the biophysical properties of an ion channel. The latter are informative about residues and structures critical to function. Such mutations, as listed in Table 8.2, are a focus of this discussion.

ClC-Kb: Barrter Syndrome Type III

Mutations in the gene *CLCNKB* encoding the ClC-Kb Cl^- channel cause Bartter syndrome type III, characterized by hypokalaemic metabolic alkalosis, renal salt-wasting, and hyper-reninaemic hyperaldosteronism.[14,18,161] The root cause of BS type III is abberant transport in the TAL and DCT, stemming from pathological changes in membrane voltage and diffusion potentials resulting from loss of the basolateral exit pathway for Cl^-. Although several missense mutations resulting in amino acid substitutions in ClC-Kb are known to cause BS type III, the effects of these mutations on the biophysical properties of this channel are largely unexplored. The R351W Bartter mutation in ClC-Kb is an exception.[162]

Homodimeric ClC-Ka and ClC-Kb channels contain extracellular regulatory Ca^{2+}- and H^+-binding sites at inter-subunit interfaces.[124] Increases in extracellular $[Ca^{2+}]$ and extracellular alkalinization increase ClC-K

channel activity: Ca^{2+} binding is stimulatory, whereas H^+ binding is inhibitory.

The R351W substitution in ClC-Kb abolishes sensitivity to extracellular [Ca^{2+}], and markedly reduces activation by alkaline pH.[162] The consequence of these changes in biophysical properties is that mutant ClC-Kb is less active under physiological conditions. The mechanism whereby mutation of R351 affects Ca^{2+}- and pH-regulated gating has not been determined. R351 is positioned at the COOH-terminal end of the linker coupling helices K and L. This positions the residue near the extracellular surface of the

channel. Perhaps R351 plays a role in coupling Ca^{2+}- and H^+-binding to the channel gate or it is an essential component of an allosteric regulatory binding site, or integral to the structure of the gate itself. The importance of this position to ClC channel function is underscored by the fact that mutations in this region of ClC-1, for instance F413C and A415V corresponding to two and four positions downstream from R351 in ClC-Kb, cause myotonia.[163,164]

In addition to R351W, a host of other point mutations, as listed in Table 8.2, decrease ClC-Kb channel activity to cause BS type III.[161,165] As yet, no experimental information is avaliable about how these Bartter mutations cause ClC-Kb dysfunction. There is circumstantial evidence, though, that some may affect the biophysical properties of the channel, for they involve nonconservative substitutions of residues highly conserved across paralogs and orthologs. For instance, L139 is conserved in most ClC proteins across species ranging from *C. elegans* to man, and S297 and S337 are conserved in all mammalian ClC-K channels. The P124L substitution changes a conserved residue in the first Cl^--binding site in the permeation pathway, predicting a change in conductance, selectivity or even gating, considering ClC channels use a pore-gating mechanism.[55,161,166] The S123P mutation in this region of the ClC-0 channel, that corresponds to three residues upstream of P124 in ClC-Kb, increases nitrate permeability.[167] Moreover, covalent modification by sulfhydryl reagents of a P126C mutant in ClC-0, which corresponds to P124 in ClC-Kb, markedly reduces P_o.[168] The Y432H mutation, similarly, is four positions downstream of residues forming the third Cl^--binding site, suggesting that it may also impact permeation. Additional support comes from the fact that several Bartter mutations in ClC-Kb occupy the same sites or are near residues in ClC-1 that when mutated, cause myotonia. For instance, the A349D mutation in ClC-Kb is two positions downstream of the F413C, and homologous with the A415V myotonia causing mutations.[161,163,164] The Bartter mutation H357Q is one position upstream of the myotonia mutation I424M. Futher investigation of these Bartter mutations is of importance, moreover, for they cause disease with varying degrees of severity, and several of them, as typified by mutation of R438 and the P124L substituion, appear in unrelated families of different ethnic origin in different geographical locations.[161,165]

The cytoplasmic COOH-terminal domains of all mammalian ClC proteins contain two interacting cystathionine-β-synthase CBS domains that form intrasubunit dimers.[121,122] CBS domains regulate ClC channel gating. For instance, ATP binding is coordinated at the CBS1/CBS2 interface, as shown in the ClC-5 crystal structure,[169] and ATP is known to modulate gating of ClC-1 and ClC-2 channels.[170,171,172] The Bartter mutations K560M and S573Y substitutions in ClC-Kb are within the first CBS domain, predicting that they may influence regulated gating.[121]

Barttin: Bartter Syndrome Type IV

Barttin is an obligatory accessory subunit for human ClC-K channel activity.[71] Inactivating mutations in barttin cause corresponding loss of ClC-K channel function, leading to BS type IV.[18,71,173] This form of Bartter syndrome has the hallmark renal salt-wasting phenotype, but also a sensorineural deafness phenotype. The reason for the additional phenotype in BS type IV is that, similar to their roles in renal epithelial cells, ClC-K channels also serve as Cl^- exit pathways in strial marginal cells.[87] Barttin is required for this activity, which in turn is required for active K^+ secretion into endolymph. In the ear, loss of ClC-Ka or ClC-Kb individually can be compensated for by the presence of the other protein; however, the loss of both channel proteins or of barttin cannot be.[87] Compensation also explains why loss of ClC-Kb, but not ClC-Ka, causes BS type III without accompanying deafness.[14,87] Although ROMK mediates apical K^+ secretion in TAL epithelial cells, KCNQ1 oligomerized with KCNE1 mediates apical K^+ secretion in marginal cells.[87] This explains why BS type II, which results from loss-of-function of ROMK, as discussed below, is not associated with deafness.

Several missense mutations causing substitutions in barttin change the biophysical properties of ClC-K channels to cause disease. The Bartter mutations R8L, R8W, and G10S in barttin eliminate ClC-Ka and ClC-Kb function, as shown in Figure 8.32, but they do not prevent channel insertion into the membrane (not shown[71,173]). This identifies changes in either channel gating or permeation as the disease-causing defects. It is not clear yet which of these two alternatives is correct. However, investigation of chimeric hClC1-ClC-Kb channels, as shown in Figure 8.33, revealed that these mutations influence voltage-dependent activation, with channels containing mutant barttin having less activity at hyperpolarizing potentials. This is most consistent with an effect on gating.

The Bartter's mutation G47R in barttin produces a mild renal phenotype.[71,173] The G47 residue is at the intracellular COOH-terminus of the second transmembrane domain of barttin. This position, and the fact that barttin containing the G47R substitution interacts less effectively with ClC-Kb, suggests that association of the accessory subunit with the pore-forming subunit is compromised in some manner. Such interpretation is consistent with the recent finding that the

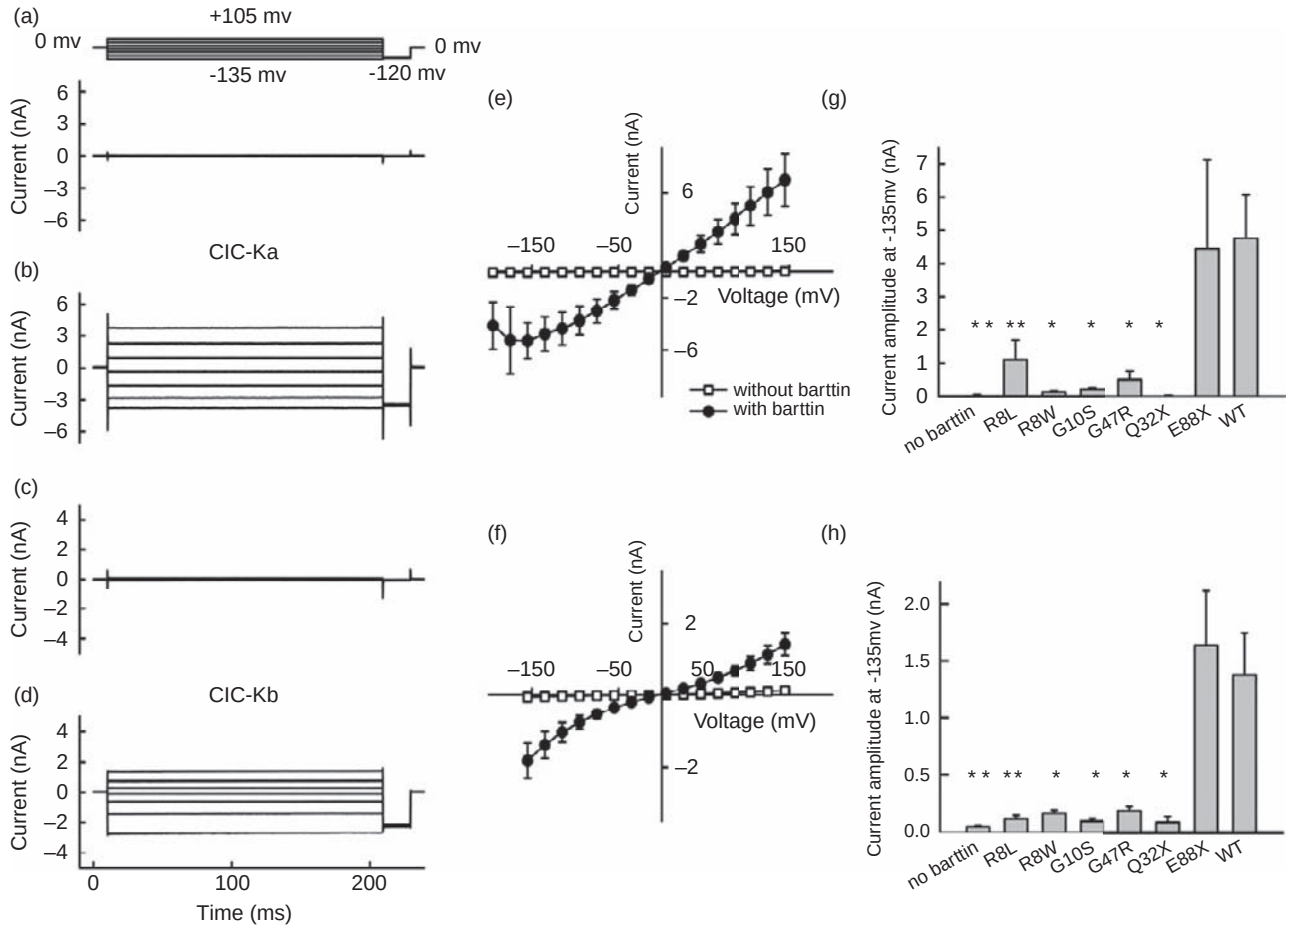

FIGURE 8.32 **Some disease-causing mutations in barttin decrease ClC-Ka and ClC-Kb channel activity.** *(Figure from[173].)* (a)–(d) Representative macroscopic ClC-Ka ((a) and (b)) and ClC-Kb ((c) and (d)) currents with ((b) and (d)) and without ((a) and (c)) barttin. Corresponding I–V relations for ClC-Ka and ClC-Kb with and without barttin are shown in (e) and (f), respectively. Steady-state currents at −135 mV for ClC-Ka and ClC-Kb expressed with wild-type and barttin containing Bartter mutations are shown in g and h, respectively.

transmembrane core of barttin is necessary and sufficient to promote ClC-K channel trafficking.[73] Moreover, the fact that the G47R phenotype is milder compared to that seen with complete loss or inactivation of barttin demonstrates that the physiological effects of barttin can be titrated, indicating that there is some finite threshold at which the loss of barttin activity causes disease.

ENaC

ENaC activity, as mentioned above, is the final arbiter of renal Na^+ reabsorption setting urinary and plasma $[Na^+]$[82,83,106]. This function makes ENaC an important end-effector of feedback systems controlling blood pressure. As such, ENaC activity is a critical determinant of blood pressure in all mammals, including humans. Loss- and gain-of-function mutations in ENaC and modulators of this channel then cause a host of diseases having pathological changes in renal Na^+ handling and blood pressure.

PHA-I: Loss of ENaC Function

Pseudohypoaldosteronism is a group of rare genetic diseases presenting with hallmark hyperkalemia and renal Na^+ wasting in the presence of high aldosterone.[107,174] Renal Na^+ wasting is a consequence of decreased Na^+ reabsorption in the CNT and CD. Such a phenotype represents end-organ resistance, identifying ENaC or cellular regulators of this channel as dysfunctional.

Compared to ROMK, less is known about the structure of the cytoplasmic portions of ENaC. Therefore, we do not have precise structural information to guide the interpretation of recent electrophysiology findings relevant to PHA. The missense mutation, G37S, in human β-ENaC nonetheless causes PHA type-I.[134,174] This Gly residue is in an absolutely conserved HG motif located in the intracellular NH_2-terminal portions of all

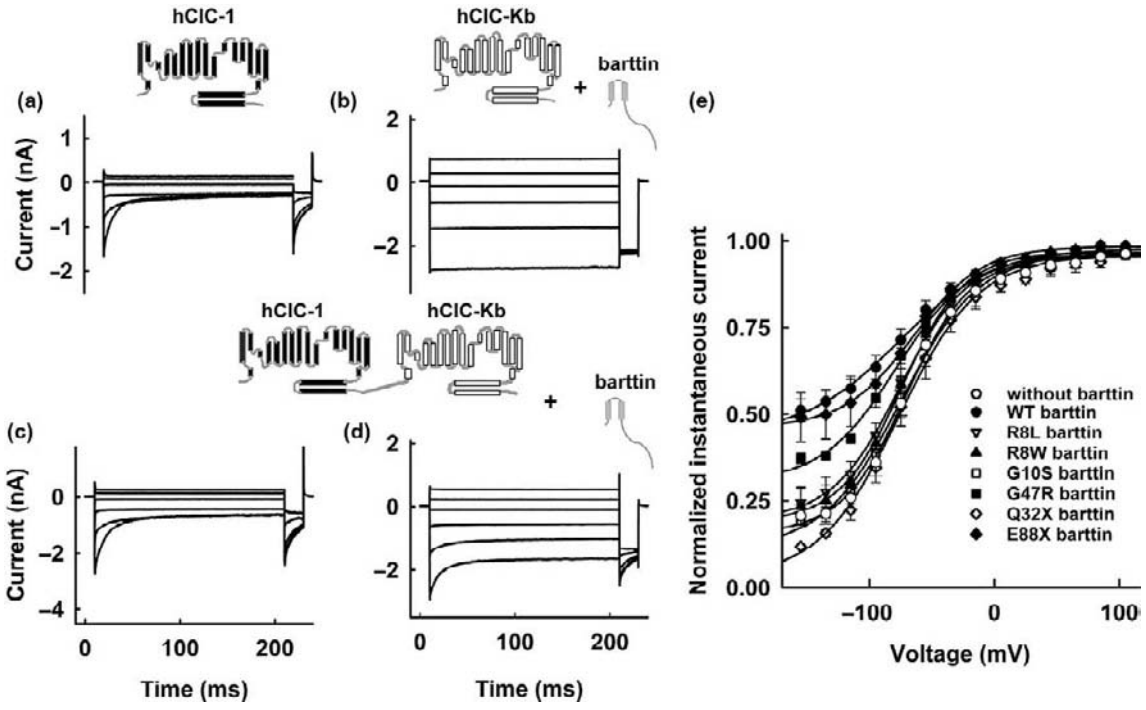

FIGURE 8.33 **Some disease-causing mutations in barttin affect ClC-K channel gating.** *(Figure from [173].)* (a)–(d) Representative macroscopic currents from human ClC-1 alone (a), ClC-Kb with barttin (b), and concatameric hClC-1-ClC-Kb without barttin (c), and with barttin (d). (e) Normalized instantaneous macroscopic currents as a function of voltage for hClC-1-ClC-Kb concatamers alone and together with wild-type and mutant barttin. The action of voltage on normalized current indicates that these mutations in barttin affect ClC-K channel gating.

ENaC/Deg subunits. The HG motif is required for normal gating.[134,135,174] The molecular mechanism whereby the HG motif influences the gate is unknown, but in the primary sequence of ENaC, the motif is in the NH_2-terminal cytoplasmic domain just preceding TM1. As shown by the results in Figure 8.34 from whole-cell and outside-out single-channel patch-clamp experiments probing the effects on gating, substituting either the H or G residue decreases P_o to where ENaC is not active under physiological conditions.[175] Decreases in P_o, as supported by results shown in Figure 8.35, arise from the voltage-dependent block of the pore by the permeant ion where the block is from the intracellular side and relieved by hyperpolarization.[39] A possible explanation for this is that ENaC gates through a pore-gating mechanism, and mutation of the HG motif destabilizes the pore to where Na^+ sometimes sticks to a binding site in the permeation pathway or the pore collapses around a Na^+ ion moving through the pore. More study is needed to determine if this is the case, but the crystal structure of cASIC1 is consistent with ENaC/Deg channels using a pore-gating mechanism.[58] Moreover, the biophysical consequences of substituting a Trp residue (W112 in α-mENaC) at the base of TM1 mimic the effects of substituting HG motif residues.[39] Like the HG motif, this Trp is conserved in all ENaC/Deg subunits. It is unknown at this time if mutation of this key Trp also causes PHA-I.

Many ion channels contain similar interfacial Trp residues at the intracellular bases of transmembrane domains.[176–178] Such Trp residues often modulate gating. In cASIC1, the side chain of the homologous Trp at the base of TM1 projects into the aqueous environment of the pore.[58] Interestingly, M_2 proton channels also contain a critical Trp residue at the intracellular base of the transmembrane domain lining the pore. The side chain of this Trp, akin to that in ENaC/Deg channels, projects into the aqueous mouth of the pore. Through Pi-bond interactions with a nearby His, the critical Trp in a M_2 proton channel stabilizes the gating state.[176,179,180] Perhaps the homologous Trp in ENaC interacting with the His in the HG motif serves a similar function. This possibility seems to reconcile the parallel findings that substitution of the HG motif and interfacial Trp residues cause identical changes in ENaC biophysical properties. Although further research is required to clarify the structure–function relation between the conserved HG motif and interfacial Trp in ENaC if there is any, it is clear that a pathological consequence of mutating the HG motif is that ENaC gating becomes voltage-dependent, with P_o being extremely low at physiological voltages.

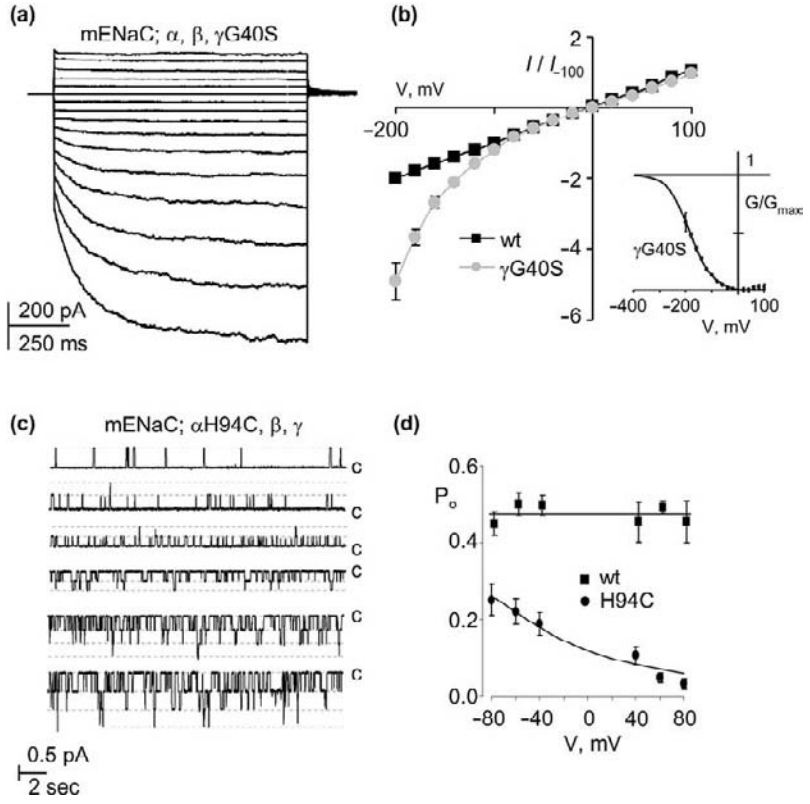

FIGURE 8.34 **Some disease-causing PHA-I mutations in ENaC affect channel gating.** *(Figure from [175].)* (a) Representative macroscopic Na^+ currents for a mouse ENaC channel containing the γG40S PHA-I mutation. (b) Macroscopic current-voltage (*I*−V) relations for CHO cells expressing wild-type (black lines) and mutant mENaC (gray lines) containing the γG40S mutation. For presentation, current normalized to current at −100 mV. The inset shows the G−V relation for mutant ENaC. Inward Na^+ current is downwards and closed states noted with (c). (d) Plot showing ENaC open probability (P_o) as a function of voltage for wild-type (black squares) and mutant mENaC containing αH94C. Data fit with a Boltzman function.

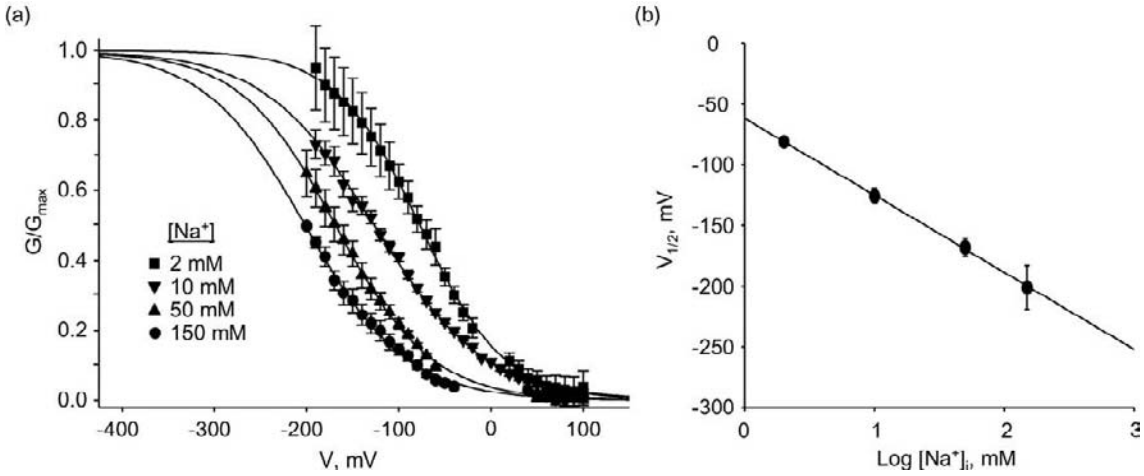

FIGURE 8.35 **Intracellular Na^+ can block mutant ENaC in a voltage-dependent manner to decrease macroscopic conductance.** *(Figure from [39].)* (a) Summary G−V curves for steady-state currents from mutant ENaC, containing the αW112C mutation, acquired in symmetrical 150, 50, 10, and 2 mm $[Na^+]$. (b) Summary graph showing the voltage resulting in half-maximal activity at steady-state, as established from G−V curves, for mutant ENaC as a function of $[Na^+]_i$.

Decreased ENaC P_o, then, is the biophysical cause of this form of PHA-I.

A missense mutation, S562P, in α-ENaC also causes familial PHA-I.[181] S562 occupies the third position in the selectivity-filter, GSS, sequence.[104,105,136] Little electrophysiology information is available for this mutant, but understanding that channel function is determined by its structural and biophysical properties makes it reasonable to predict that the S562P substitution disrupts permeation, resulting in a disease-causing loss-of-function.

Liddle's Syndrome: Gain of ENaC Function

Gain-of-function mutations in ENaC cause an inheritable form of hypertension, Liddle's syndrome, marked by high blood pressure in the presence of low plasma renin and aldosterone, and uncontrolled Na^+ reabsorption in the distal nephron.[106] This also represents end-organ resistance, where ENaC activity is inappropriately high in the presence of low aldosterone. Amiloride, an inhibitor of ENaC, reverses the high blood pressure and renal phenotype of Liddle's syndrome. The majority of mutations in ENaC that cause Liddle's syndrome retard retrieval of the channel from the apical membrane of CNT and CD principal cells.[182–184] An exception to this common mechanism is the Liddle mutation N530S in γ-ENaC, which increases channel activity but not membrane expression level.[138] Detailed biophysical experiments have yet to be performed on this mutant. Its position in the channel when considering the three-dimensional structure of cASIC1,[58] and previous findings from the study of the activating *Degenerin* mutation in *C. elegans* homologs,[144,145] though, are informative. N530 is one position downstream of the *Deg* position in the primary structure of ENaC (see Figure 8.27). This places it at the extracellular apex of the TM2 pore-lining transmembrane domain. This region of ENaC/Deg channels is thought to be important for ion permeation and gating. It is widely held that the *Deg* mutation locks open ENaC/Deg channels, because it occupies such a position. Perhaps the N530S Liddle mutation does the same thing in ENaC. ENaC locked in an open state would maximize Na^+ reabsorption in the distal nephron, moving it beyond the control of feedback regulation, explaining the salt-sensitive hypertension in this form of Liddle's syndrome even in the presence of low aldosterone. Supporting such a role are findings that covalent modification by sulfhydryl reagents of a N530C mutant in γ-ENaC and modification of Cys substitutions of the corresponding residues in α- and β-subunits increase activity of ENaC within the membrane.[140] In fact, this region of ENaC is particularly sensitive to alteration. Modification of cysteines substituted for residues throughout this region consistently affect channel activity.[105,136,140]

ROMK: Bartter Syndrome Type II

A constellation of mutations in *KCNJ1* leading to loss-of-function of ROMK causes BS type II.[14,15,23,185,186] Several of these mutations, as listed in Table 8.2, affect channel gating and conductance. It is possible, with our current understanding of ROMK structure and biophysical properties, to rationalize how these Bartter mutations affect channel function to change physiology and cause disease. Bartter mutations in ROMK that change biophysical properties can be placed into several groups. First are those that immediately disturb the gate based around the interaction of K80 at the intracellular base of TM1 with A177 at the intracellular base of TM2 as it couples to the putative L179 gate. This structure is held to be the regulated gate responsive to pH, PKA phosphorylation, and PIP_2-binding.[32] The remaining types of Bartter mutations that change the biophysical properties of ROMK interrupt regions in cytoplasmic domains to affect gating. They include those that disrupt PIP_2 binding sites, critical PKA phosphorylation sites, domains important for a response to pH, and inter- and intra-subunit salt-bridges required for normal structure. In addition to these are Bartter mutations that affect a distinct gate in the cytosolic portion of the channel, and one that affects a key residue in the selectivity-filter.

Mutation of the Regulated Gating Structure at the Bundle-Crossing

A hallmark feature of ROMK, as emphasized in Figure 8.36, is its sensitivity to intracellular pH, where P_o

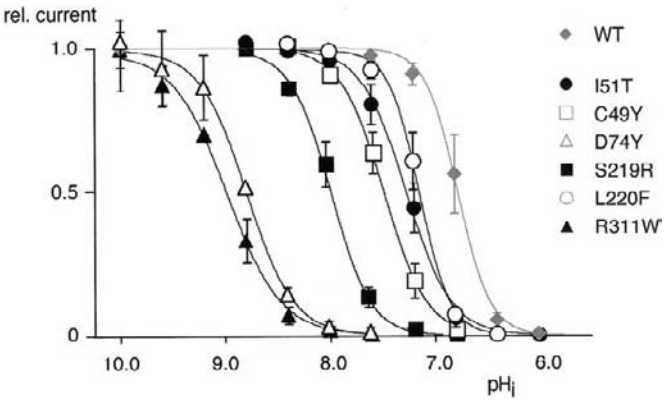

FIGURE 8.36 **ROMK gates in a pH-dependent manner with some Bartter mutations changing the apparent pK_a of activation.** *(Figure from [194].)* Current-pH_i relations are shown for wild-type ROMK and channels containing Bartter mutations.

increases as a function of increasing pH_i with intracellular acidification inducing a long-lived closed-state.[187,188] Residues and domains in ROMK involved in sensing pH are yet to be identified. Nevertheless, sensitivity to pH is routinely measured using titration experiments plotting relative current as a function of pH, and fitting the data with a modified Hill equation, such as $I/I_{max} = 1/(1 + ([H^+]/K_a)^{nH})$, where K_a is the half-maximal inhibitory proton concentration and n_H is the Hill coefficient.[148] As noted above, the influence of pH on gating is manifested by the regulated L179-gate coupled to A177 and K80.[32,148] The A177T Bartter mutation disrupts this interaction, and causes a marked alkaline-shift in the pH sensitivity of ROMK gating effectively turning the channel off at physiological pH_i.[15,189] The biophysical and physiological consequences are that, although the driving force remains for K^+ efflux across the apical membrane of TAL cells through ROMK, it cannot be harnessed, with the result that NKCC2 cannot run at full capacity. This compromises NaCl reabsorption in the loop of Henle, and breaks down the axial corticomedullary hyperosmotic gradient, causing a pathological decrease in the ability to concentrate urine. Substitution of K80 with residues unable to form an H-bond with A177, in addition, alters gating in a similar manner.[190] Additional support for this mechanism of pathology is the finding that the Bartter mutation Y79H also disrupts regulated gating.[15] The side chain of Y79 projects into the lipid bilayer, possibly stabilizing the interaction of K80 with A177 and ultimately the L179 gate. Interestingly, mutations in comparable residues in the Kir6.2 K_{ATP} channel alter ATP-dependent gating, and cause neonatal diabetes.[191] Such results summate to suggest that the energetics of regulated K^+ channel opening are strongly influenced by H-bonds formed between residues at the base of TM1 and TM2, and between interactions of residues in TM1 with the inner leaflet. Disruption of this gating structure, then, is one cause of ROMK channel dysfunction in BS type II.

Mutation Leading to Loss of pH-Sensitivity

ROMK gates in a high P_o state at normal intracellular pH_i, with a pK_a near neutral pH making the channel especially susceptible to pathological changes in pH_i. Interestingly, the pK_a for activation of ROMK is under physiological control, and can be dynamically changed by PIP_2 binding and PKA phosphorylation of the channel.[192,193] Bartter mutations disrupting the normal regulation of pK_a shift the pH_i of activation.[194] Moreover, a Bartter mutation causing a frameshift at T332 interrupts pH-dependent gating, moving the apparent pK_a at which ROMK opens markedly in the alkaline direction outside the physiological range.[148,186,185] The biophysical consequence of this is that the channel enters long-closed states for prolonged periods of time, greatly decreasing K^+ exit across the apical membrane. The structural basis for this effect remains to be determined, but clearly, this mutation involves changes in the intracellular domains of ROMK likely resulting in destruction or uncoupling of allosteric sites from the regulated gate.

Mutation of the Intracellular Gating Structure

The narrowing at the apex of the cytoplasmic pore of ROMK where G-loops coalesce is also involved in gating.[32] The Bartter mutation A306T disrupts K^+ conductance by ROMK.[15] This residue is located in the G-loop, possibly affecting the intracellular gate. Underscoring the importance of this intracellular resistance barrier to channel structure and function are findings that disease (Andersen–Tawil syndrome)-causing mutations in other Kir channels cluster in G-loops.[196,197] The Y314C, V315G, and A198T Bartter mutations, as discussed below, may also affect gating that involves the interactions of intracellular domains of the channel with the bundle-crossing.[15,185,198]

Mutation of the PIP_2-Binding Site

Phosphoinositide 4,5-*bis*phosphate (PIP_2) is an important physiological regulator of Kir channel gating, including ROMK, which it stabilizes in a high P_o state.[32,199,200,201] A comprehensive investigation of ROMK mutants and mutants of its homolog, Kir2.1, combined with the study of Kir1.1-Kir2.1 chimeric channel proteins, identified several basic amino acids corresponding to R48, K181, K184, K186, R188, R217, K218, and R311 in ROMK that are required for PIP_2-dependent gating.[201–203] Substitution that neutralizes these charged residues reduces channel activity. That the side chains of these residues carry a positive charge is consistent with them contributing to a *bona fide* allosteric PIP_2-binding site. This was reinforced by findings that a portion of ROMK containing four of these basic residues (aa. 183–221) has the capacity in solution to bind PIP_2.[204] Although these four basic residues are in a portion of Kir for which structure has not been resolved, their position in the linear sequence suggests that they reside at the apex of the cytoplasmic domains near the intracellular face of the lipid bilayer.[32] Moreover, modeling clusters R48, R217, and R218 at the top of the cytoplasmic domain where they are predicted to face the inner lipid leaflet. Considering findings from functional studies and lipid-binding studies, this position is consistent with these residues having the capacity to interact in a direct manner with membrane phospholipids. That ROMK and other Kir channels contain a PIP_2-binding site capable of signaling to a gate becomes important

when recognizing that a group of Bartter mutations, C49Y, I51T, A214V, and L220F, disrupt PIP_2-dependent gating.[15,186,194] In three-dimensional ROMK models, all of these residues cluster on the membrane-facing surface of the cytoplasmic domain near the putative PIP_2-binding pocket, suggesting that they modulate binding to this site or transduction of information from this site to the gate. Importantly, similar observations made for Kir2.1, which when dysfunctional causes the familial Andersen–Tawil form of long QT syndrome, have been interpreted to indicate that the disruption of PIP_2-binding underlies many Kir channelopathies.[200,201,205]

Mutation of Salt-Bridges Critical to Structure

The cytoplasmic domain of ROMK is stabilized by inter- (R311–E302) and intrasubunit (R41–E318) salt-bridges. Compromise of these bridges uncouples ligand binding in cytoplasmic domains from the regulated gate.[15,194] This is underscored by the dramatic alkaline-shift in apparent pK_a of activation for ROMK containing the R311W or R311Q Bartter mutation. A shift in pK_a leads to these channels being in a prolonged closed state at physiological pH_i.

Mutation of PKA Phosphorylation Sites

Similar to the secretory channel in native tissue, ROMK in heterologous expression systems is also responsive to PKA phosphorylation.[206,207] In concert with physiological pH_i and PIP_2 levels, PKA phosphorylation sets ROMK to a high P_o state.[32] Biochemical studies identified three discrete PKA phosphorylation sites in the cytoplasmic NH_2- and COOH-termini of ROMK: S44, S219, and S313.[208,209,210] Each of these must be phosphorylated for full channel function. The site in the NH_2-terminus is an absolute requirement for expression at the membrane. Those in the COOH-terminus are necessary for the high P_o state, modulating regulated-gating in response to pH, PIP_2, and ATP.[192,211] These latter two phosphorylation sites are strategically positioned in the channel to modulate the effects of regulators of gating. S219 is positioned between a PIP_2-binding site, the G-loop, and an intersubunit (E311–E302) salt-bridge. In comparison, S313 is sandwiched between an intrasubunit (R41–E318) and intersubunit (E311–E302) salt-bridge. Such positions provide a structural explanation for how phosphorylation may be involved in the functional coupling of gating factors. As such, phosphorylation of S219 and S313 provoke an acidic shift in the apparent pK_a activating ROMK at physiological pH_i.[192] The Bartter mutations S219R and S313C remove these critical phosphorylation sites; consequently, ROMK containing these mutations has decreased activity, being in a low P_o state under physiological conditions.[186,194] Two other Bartter mutations, Y314C and V315G, are one and two positions downstream of the critical Ser at 313.[198] It is not clear yet, but the Bartter mutations L220F and R311W may also influence the phosphorylation state or be involved in coupling PIP_2 binding and PKA phosphorylation. These are reasonable expansions on the possibility that the L220F mutation impacts PIP_2 binding and R311W is critical to salt-bridge formation, and is also possibly involved in PIP_2 binding as discussed above.

Mutation of a Selectivity-Filter Residue

ROMK channels, similar to all K^+ channels, contain the signature K^+-selectivity sequence T[V/I]GYG in the P-loop linking TM1 to TM2 (see Figure 8.29). The Bartter mutation I142T substitutes the critical second residue in this selectivity sequence, disrupting K^+ permeation significantly and decreasing conductance.[15] I142 is also involved in pore-gating of ROMK channels, as discussed above.[50,51] Therefore, this mutation may also affect gating. Regardless, as a result of this mutation, the ability to reabsorb NaCl in the TAL is compromised, destroying the axial corticomedullary hyperosmotic gradient necessary to concentrate urine.

Loss-of-Function Mutations with Undefined Mechanism

There are several other mutations in ROMK that also possibly change the channel's biophysical properties to cause disease. For instance, the Bartter mutations W99C, A103V, P110L, and N124K act in a dominant negative manner. When co-expressed with wild-type subunits, these mutant subunits decrease channel activity.[185] This is consistent with channels containing both wild-type and mutant subunits making it to the membrane, but having abnormal biophysical properties. Similarly, ROMK channels containing the T71M, F95S, A156V, and R324L Bartter mutations also traffic in a normal manner to the plasma membrane in some expression systems, but have decreased activity.[15] Again, this points to a change in biophysical properties as the disease-causing mechanism.

TRPM6: Hypomagnesemia with Secondary Hypocalcemia

Genetic studies in patients with hereditary HSH identified disease-causing mutations in TRPM6.[9,10,19,20,24] The missense substitution, P1017R, in TRPM6 is one such mutation.[4,10] Although a crystal structure for TRP channels is currently not available, it is accepted that these channels contain six transmembrane domains and assume a tetrameric structure similar to voltage-gated K^+ channels, with extracellular P-loops diving into the

membrane to form the pore. Using the structural coordinates of the KvAP channel to model the putative S5-S6 segment of TRPM6, including the putative P-loop, places P1017 in the predicted pore region of the channel.[4,212] A recent study by Chubanov and colleagues showed that co-expression of wild-type TRPM6 with TRPM7 significantly increases current through the channel.[4] In contrast, co-expression of TRPM6 containing the P1017R mutation with wild-type TRPM7 suppresses channel activity. Consistent with this dominant-negative effect, co-expression of TRPM7 containing a homologous P-to-R mutation decreases wild-type TRPM6 activity. This action is restricted to changes in the biophysical properties of the channel, for the P1017R mutation has no effect on channel assembly or trafficking. These results strongly suggest that the P1017R mutation affects either permeation through the channel or channel gating to decrease activity. Decreases in TRPM6 channel activity would reduce Mg^{2+} reabsorption by the kidney, leading to the disease phenotype.

Acknowledgments

I thank Drs. John Johnson (Dept. Physiology, UTHSCSA), Kishore Kamaraju (Dept. Physiology, UTHSCSA), Volodymyr Kucher (Dept. Physiology, UTHSCSA), Steve Sansom (Dept. Cellular and Integrative Physiology, UNMC), and Bin Wang (Dept. Physiology, UTHSCSA) for critically reading this chapter.

CHAPTER

9

Microvascular Permeability and the Exchange of Water and Solutes Across Microvascular Walls

C. Charles Michel

Department of Bioengineering, Imperial College, London, UK

INTRODUCTION

Exchange through microvascular walls is both the initial and the final step of transport of materials by the circulation. In most tissues, microvascular exchange is a passive process, driven by differences in hydrostatic pressure and solute concentration between the circulating plasma and the interstitial fluid that flank microvessel walls. Lipophilic molecules and small water-soluble molecules and ions can exchange rapidly in most vascular beds, but microvascular walls are a barrier to macromolecules, severely impeding their exchange. The consequent differences in macromolecular concentration across microvascular walls are responsible for differences in osmotic pressure, which were identified over a century ago to play an essential role in the balance of fluid between the circulating blood and the tissues.[121]

Although small hydrophilic molecules can exchange rapidly between the blood and the tissues, it is wrong to assume that microvascular walls are no barrier to them. The rate at which changes of concentration of a solute in the blood can be reflected as changes in interstitial fluid (ISF) concentration depends both on the blood flow to the capillary beds, and on the permeability of the capillary walls to the solute. It is often assumed that for small molecules only blood flow is important, but once flow has exceeded a certain minimum range of values, the rate of equilibration of blood and ISF becomes limited by permeability.

Microvascular exchange and microvascular permeability are sometimes regarded as synonymous but this in incorrect and it is important to distinguish between them. Microvascular permeability to a substance is the conductivity of the microvessel wall and the permeability coefficients which describe permeability in functional terms are determined by the structure and properties of the pathways through which its molecules traverse the vessel wall. Microvascular exchange rates and net transport through microvascular walls for a particular substance are determined by microvascular permeability to that substance and also by the value and direction of net fluid flow through the vessel wall and by differences in concentration of the substance between plasma and ISF. The difference between microvascular exchange and microvascular permeability is important when interpreting methods that claim to demonstrate changes in permeability. Many of these methods involve the measurement of changes in net transport of macromolecules between blood and tissues, without controlling the transcapillary differences in hydrostatic pressure and macromolecular concentration. We shall consider the potential errors later in this chapter.

First, we consider microvascular permeability, and then microvascular exchange. Not included in this chapter is a consideration of transport through the walls of microvessels of the central nervous system. The low permeabilities of these vessels and the specialized transport mechanisms for certain solutes constituting the

Seldin and Giebisch's The Kidney, Fifth Edition.

blood–brain barrier are atypical of other microvessels, and resemble those of tight epithelia.

MICROVASCULAR PERMEABILITY

Microvascular Ultrastructure

Capillary walls consist of a single layer of flattened endothelial cells, the endothelia, and these cells constitute the barrier between the blood and the ISF. Electron microscopy has revealed that endothelial cells in different tissues are of two distinct types: "continuous" and "fenestrated" (Figure 9.1). Continuous endothelium is found in microvessels of skin, muscle, lung, and connective tissues. Here, the endothelial cells are joined together by tight junctions to form a continuous layer surrounded by a continuous basement membrane. The plasmalemmal membranes of the continuous endothelia retain their integrity; even in areas where the cells are flattened, reducing their thickness to less than 0.1 μm, the distinct luminal and abluminal membranes are separated by a thin layer of cytoplasm.

Fenestrated endothelium is found in microvessels associated with secretory and absorptive epithelia, e.g., the capillaries of the intestinal mucosae, glomerular, and peri-tubular capillaries of the kidney. The walls of fenestrated microvessels are also made of a single continuous layer of endothelial cells joined by tight junctions and surrounded by a continuous basement membrane, but in these vessels attenuated areas of cells appear to be penetrated by circular openings 40 to 70 nm in diameter. These are the fenestrae (or fenestrations), and in most cases the fenestrations are closed by a thin electron-dense diaphragm, which appears to be arranged as a series of broad spokes with central "hub"[14] (Figure 9.2).

Covering the luminal surface of endothelial cells is a layer of glycoprotein called the glycocalyx or endocapillary layer (ECL). First identified by Luft in 1966[68] using ruthenium red staining, its importance has only come to be widely appreciated in the past 15 years. Although both continuous and fenestrated endothelia have been found to contain the various inclusions common to most cells (e.g., mitochondria, rough and smooth endoplasmic reticulum) the dominating ultrastructural feature seen in transmission electron micrographs is the large number of small endoplasmic vesicles (Figure 9.3). The majority of vesicles are arranged in fused clusters that communicate with each other and with flask like pits on either the luminal or abluminal surfaces of the cells called the caveolae

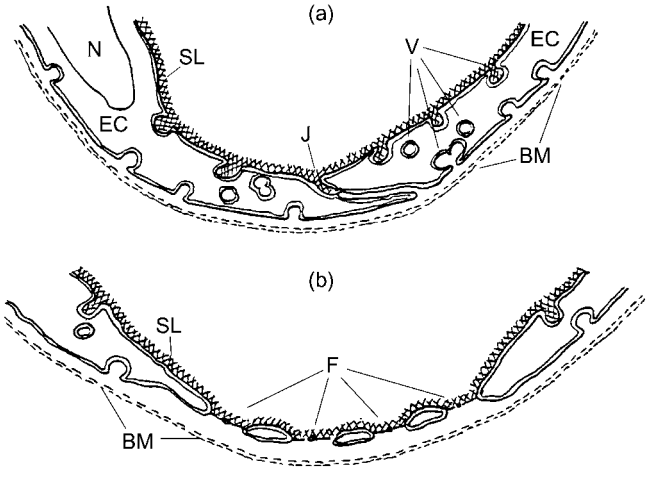

FIGURE 9.1 **Diagrams showing the ultrastuctural features of microvascular walls in transverse section: (a) Vessel with continuous endothelium; (b) Vessel with fenestrated endothelium**. The basement membrane (BM) forms a continuous layer around the outside of both vessel types and the luminal surfaces of both endothelia are covered with a negatively charged glycocalyx (SL) (EC: endothelial cell; J: junction; F: fenestration (fenestra); N: endothelial cell nucleus).

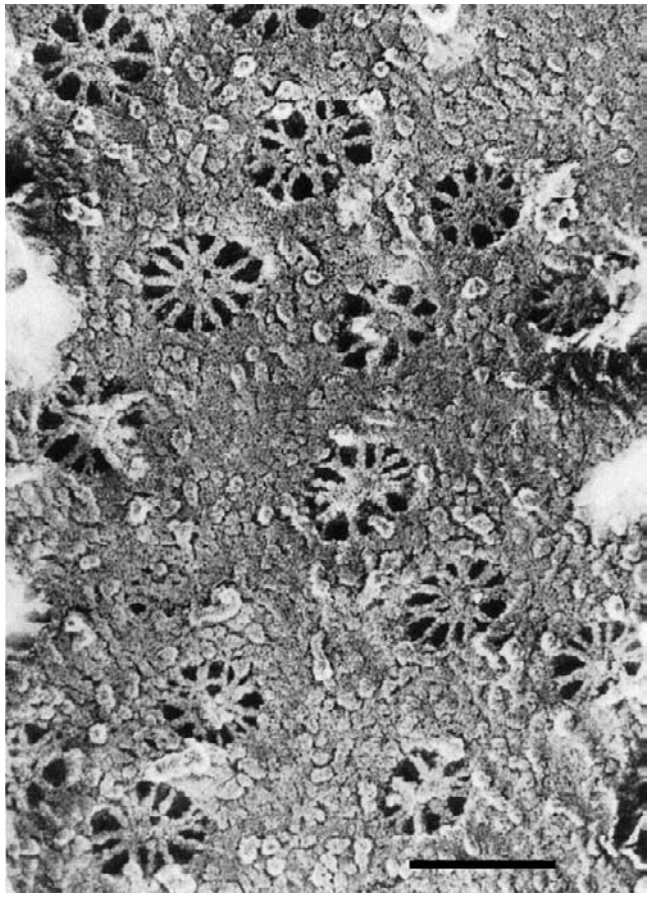

FIGURE 9.2 ***En face*** **view of fenestrated endothelium of peritubular capillary of the kidney in a rapid freeze deep etch preparation**. Scale bar = 0.1 μm. *(From ref. [14].)*

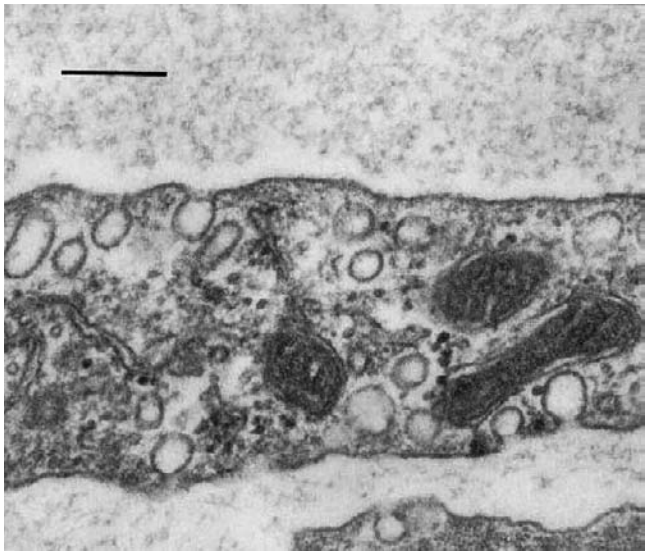

FIGURE 9.3 **Electron micrograph of microvascular endothelium of frog.** There are three mitochondria in the central part of the cell and large numbers of plasmalemmel vesicles. Scale bar = 0.2 μm. *(Electron micrograph by H.Moffitt.)*

intracellulares. Chains of fused vesicles forming channels that pass through endothelial cells[119] appear to be relatively rare occurrences in unstimulated endothelium, but are a feature of endothelium activated by certain mediators.[34,35]

The intercellular clefts of continuous endothelia, the fenestrae of fenestrated endothelia, and the small vesicles have all been implicated as pathways through the endothelia as a result of experiments using electron-dense tracers. Controversy surrounded the interpretation of many of these experiments, but progress has been made over the past 20 years as physiological evidence clarified their interpretation. For this reason, the ultrastructural basis of permeability is considered after we have defined the permeability coefficients by considering the principles of passive transport and have discussed their values in different endothelia to different types of molecules.

Passive Transport and Permeability Coefficients of Porous Membranes

The mechanisms of transport are convection and diffusion. Convection is equivalent to bulk flow of solutions and the solutes within them. Thus, if a solution flows from a reservoir A at a high pressure to a second reservoir, B, at a lower pressure, there is bulk flow of the solution and transport of the solutes by convection. If J_V ml sec^{-1} is the rate at which the solution flows from A to B, it is proportional to the difference in hydrostatic pressure, ΔP, between A and B as follows:

$$J_V = K\Delta P \tag{9.1}$$

where K is the conductance of the system between A and B.

If A and B are separated by a porous membrane, K is proportional to the area of the membrane, A_m, through which fluid can flow. Thus:

$$J_V = L_P A_m \Delta P$$

and

$$L_P = (J_V / A_m \Delta P) \tag{9.2}$$

where L_P is the hydraulic conductivity or hydraulic permeability of the membrane. L_P is one of several membrane permeability coefficients. It describes the ease with which fluid flows through a unit area of membrane when driven by a unit difference in pressure. It can be thought of as describing the frictional interactions between the membrane molecules and the molecules of the solution (principally water), and like the other permeability coefficients its value depends on the structure of the membrane. If small water-filled pores penetrate the membrane, L_P is proportional to the number of pores per unit area of membrane, to the fluid viscosity, and to a function of the dimensions of the pores. This function depends on the size and shape of the pores and the nature of flow through them.

Equation (9.2) describes the flow of a solution through a membrane only if the solute molecules can pass through the membrane as easily as the water molecules. If movement of solute is hindered to a greater extent than the water, filtration of the solution leads to the development of a solute concentration difference across the membrane as water enters compartment B faster than solute. The difference in solute concentration gives rise to a difference in osmotic pressure which opposes filtration of the solution across the membrane. The force driving solution through the membrane is no longer just ΔP, but ΔP minus the effective osmotic pressure between the solutions in A and B. The magnitude of this osmotic pressure difference is related not only to the concentration difference itself, but also to the degree to which the membrane hinders the movement of solute relative to water. This is described by a second membrane coefficient, σ_d, referred to as the osmotic reflection coefficient. If the channels in the membrane are permeable to water but not solute molecules, filtration of a solution of this solute through the membrane will separate the solute from the water, with pure water leaving the membrane and concentration of the solution upstream. Since all

the solute molecules are reflected at the membrane, σ_d has a value of 1.0. The osmotic pressure exerted by differences in its concentration across this particular membrane should be close to that calculated from Van't Hoff's law, i.e., $\Delta\Pi = RT\Delta C$, depending on the "ideality" of the solution. If, alternatively the solute molecules are able to pass through the membrane as easily as the water molecules, σ_d has a value of 0, as none of the solute molecules are reflected. If the solute passes the membrane more easily than water, σ_d has a negative value. If only a fraction of the solute molecules are "reflected" during ultrafiltration of the solution, σ_d has a value between zero and one.

Only those molecules that are reflected at the membrane during ultrafiltration can exert an osmotic pressure across it. Thus, the osmotic pressure difference, $\Delta\Pi$, is related to the concentration difference, ΔC, through the universal gas constant, R, and the absolute temperature, T:

$$\Delta\Pi = \sigma_d\, RT\Delta C$$

and

$$\sigma_d = \frac{\Delta\Pi}{RT\Delta C} \tag{9.3}$$

At microvascular walls, macromolecules such as plasma proteins have high values of σ_d and σ_f (0.8–0.999), whereas small ions (e.g., Na^+, K^+, Cl^-) and small hydrophilic molecules (e.g., glucose, lactic acid, amino acids, urea) have values of σ less than 0.2 in most vessels.

Net fluid flow through microvascular walls carries dissolved solutes by convection. The rate of solute transport by convection from A to B depends on J_V, and also upon the value of σ for the particular solute at the membrane. If σ has a value of zero, then J_S is equal to $J_V C$ (in moles per second), where C is the solute concentration in the solution (in moles per ml), i.e., the solution flowing out of the membrane into B has the same concentration as that entering the membrane from A. If, however, σ has a value between zero and one, then the solution emerging from the membrane into B will have a lower solute concentration than that entering the membrane at A. Convective transport of solute through the membrane is now described by the relation:

$$J_S = J_V(1 - \sigma_f)C \tag{9.4}$$

where C now refers to the concentration entering the membrane from A. Note that in Eq. (9.4) σ is written as σ_f, whereas in describing the effective osmotic pressure σ is written as σ_d. For "an ideal solute" $\sigma_f = \sigma_d$, but solutions of macromolecules deviate from "ideal" behavior and σ_d is often measurably greater than σ_f. Rearrangement of Eq. (9.3) provides a definition of σ_f:

$$\sigma_f = 1 - \frac{J_S}{J_V C} \tag{9.5}$$

If the only pathway for both water and solutes through the membrane is a population of equally sized channels, σ_d and σ_f are determined only by the ratio of the dimensions of the solute molecules to those of the channels, and are independent of the number of channels per unit area of membrane.

A second mechanism of transport through porous membranes is diffusion. This is most important for the transport of small molecules across microvascular walls. In contrast to the stately progression of molecules by convection, diffusion results from the random jostling of all molecules in a solution that represents their thermal energy. Diffusion is a mixing process, and where there are differences in concentration in a solution diffusion is responsible for the spontaneous net transport of solute from regions of high to regions of low concentration. On a macroscopic scale, Fick's first law of diffusion describes net transport of solute by diffusion:

$$J_S = DA\left(\frac{-dC}{dx}\right) \tag{9.6}$$

where D is the diffusion coefficient of the solute in the solution, A is the area through which diffusion occurs, and the derivative $(-dC/dx)$ is the concentration gradient of solute down which diffusion occurs. The negative sign of the derivative is to indicate that diffusion occurs from a region of high concentration (low value of x) to a region of lower concentration (higher value of x), i.e., the diffusion of a solute is directed down its concentration gradient.

Diffusion coefficients of solutes in aqueous solutions reflect the ability of solute molecules to slip past adjacent molecules of water. They are measured and defined in terms of net movements of solute under conditions in which there is no overall movement of the solution. Thus, diffusion in solution is a displacement process whereby the displacement of a solute molecule in one direction is accompanied by the displacement of an equal volume of water in the opposite direction. Because the rate at which displacement occurs is dependent on the thermal energy of the solution, the diffusion coefficient is directly proportional to temperature. It is also inversely proportional to the frictional interactions between the solute and water molecules.

When diffusion of a solute occurs through a thin porous membrane, the diffusional permeability of the membrane to the solute, P_d, is defined in terms

of the net solute flux, J_S, the solute concentration difference across the membrane, ΔC, and the membrane area, A_m, under conditions where there is no volume flow through the membrane. Thus:

$$P_d = \left(\frac{J_S}{A_m \Delta C}\right)_{J_V=0} \tag{9.7}$$

P_d has units of velocity (cm sec^{-1}), and like L_P and σ_f, it has meaning in terms of the interactions between the solute molecules, the molecules of the membrane, and the water within the membrane. Such interactions depend critically upon the ultrastructure of the pathways for solute and water through the membrane, particularly when the width of the pathways is comparable to the diameter of the diffusing molecules.

Diffusional permeability coefficients are defined under conditions where there is no net volume flow through the membrane. In measuring P_d of microvascular walls, it is often convenient to use radioactive isotopes or fluorescent tracers, because their fluxes can be detected when their concentration differences are in the micromolar range. Larger differences in concentration may set up significant differences in osmotic pressure, which may complicate the estimation of P_d by giving rise to net fluid flows in the opposite direction to those of the diffusing molecules.

Permeability to Lipophilic Solutes

Solutes that can dissolve to a significant extent in lipids have high cell membrane permeabilities, and very high microvascular permeabilities. It is assumed that these molecules diffuse directly through the entire microvascular wall. This group of solutes includes gas molecules, including O_2 and CO_2, as well as N_2, the inert gases, and molecules of general anesthetics, although recent evidence suggests CO_2 and NH_3 may cross membranes additionally through specialized channels.[15]

So rapidly can small lipophilic solutes cross microvascular walls that, under physiological conditions, their transport between the blood and the tissues is always limited by their rate of delivery or clearance by blood flow through the microcirculation, and it has been impossible to estimate their microvascular permeability coefficients with accuracy with values for some greater than 10^{-2} cm.sec^{-1}.

Microvascular permeability to lipophilic molecules is, however, sensitive to temperature. Renkin[101] showed that antipyrene, which is fat-soluble at body temperature, could exert substantial osmotic pressures across the walls of capillaries in cat hind limbs when the tissue was cooled to 15°C, but not when the tissue was at 37°C. A similar phenomenon has been demonstrated by Curry[25] in single mesenteric capillaries.

Permeability Coefficients to Small Hydrophilic Molecules

Microvascular permeability to macromolecules is usually considered separately from permeability to hydrophilic molecules smaller than serum albumin, as different mechanisms of transport appear to be involved. Evidence for this emerged in 1956 from studies on the passage of a range of dextran polymers between plasma and lymph.[45] Some of the original data are shown in Figure 9.4, where it is seen that the steady-state concentrations of the smaller dextrans in the lymph draining hind limb tissues of anesthetized dogs relative to the plasma levels fall rapidly as their molecular radii increase up to 4–5 nm; for the larger molecules the decline of lymph concentration with molecular size is so small as to appear barely significant in these data.

This two-component relation between P_d and molecular diameter is seen in nearly all microvascular beds, suggesting that small molecules use different mechanisms or pathways to cross microvascular walls from those used by macromolecules.[78,108,123]

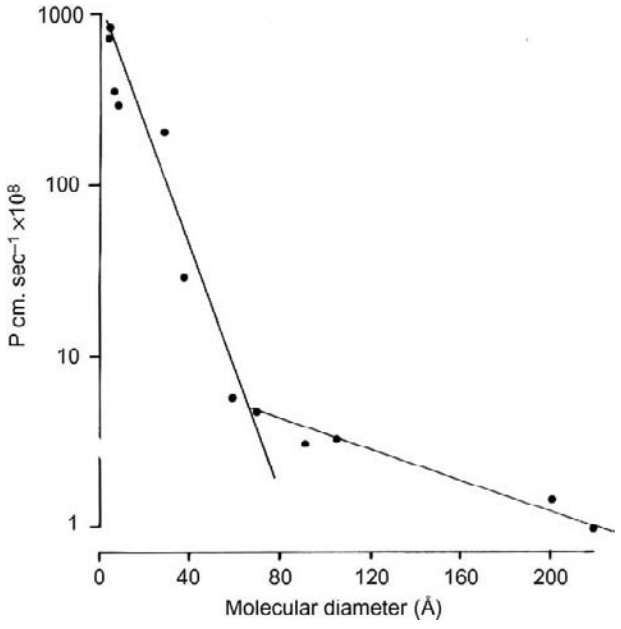

FIGURE 9.4 **Relations between permeability (P) of dog hind limb microvessels to hydrophilic solutes and the molecular diameter of the solutes.** The endothelium of these vessels is continuous and P has been calculated assuming they have a surface area for exchange of 7000 cm^2 $100g^{-1}$ of tissue. Note that P, which has been plotted on a logarithmic scale, declines sharply as molecular diameter increases up to 70 Å (7 nm), which is approximately the diameter of serum albumin. A less steep relation is seen for larger molecules. *(From ref. [78]. With permission)*

Permeability Coefficients to Small Hydrophilic Molecules

In Figure 9.5, the values of P_d measured in microvascular beds of skeletal muscle and single mesenteric microvessels to some small water soluble solutes have been plotted against solute molecular radius. In mesenteric capillaries, values for P_d to the smallest molecules and ions (e.g., Na^+, K^+, urea) are ten times greater than values of P_d for the same solutes in muscle capillaries. To make the comparison easier, both the P_d values and values for molecular radius are shown on logarithmic scales. The decline of P_d with molecular radius for both types of microvessel is much greater than the decline of diffusion coefficient (D) for the same molecules in open aqueous solution. The more rapid decline of P_d can be accounted for if molecules were diffusing through water-filled channels whose widths were comparable to their own diameters.[94] The smooth curves, which have been fitted to the data, converge as molecular radius increases. If the channels were cylindrical pores, the convergence implies that the radii of the pores is very similar in mesenteric and muscle capillaries, but there are ten times more pores penetrating per unit area of the walls of mesenteric capillaries than of muscle capillaries. The value of molecular radius at which the curves intersect provides an estimate of the pore radius – in this case between 3.5 and 4 nm.

This pattern of declining P_d to small hydrophilic solutes with increasing molecular diameter is seen in all microvessels where it has been sought, and curves based on the theory of diffusion through pores of radii between 3.5 nm–5 nm can be fitted to these data.

The values of P_d to a particular small hydrophilic solute (e.g., Na^+, K^+, sucrose, and inulin) in different microvascular beds correlate with the values of hydraulic permeability (L_P). This is shown in Figure 9.6, where each point represents the mean value of L_P plotted against the mean value of P_d to Na^+ or K^+ in the same microvessel or microvascular bed, different points representing values for vessels in different tissues. The data have been plotted on logarithmic scales so that values covering two orders of magnitude can be compared. The slope that has been drawn through the points has been given a value of unity, to indicate that direct proportionality is a reasonable description of the relationship. The correlation is strong circumstantial evidence for believing that the same pathways through the endothelium serve both for the rapid exchange of small hydrophilic solutes, and for most net fluid movements. Furthermore, because Na^+ ions are likely to follow an extracellular route, it seems likely that this shared pathway is extracellular. This line of reasoning is greatly strengthened by the demonstration of similar linear correlations between L_P and P_d values for other extracellular solutes, such as sucrose and inulin[81] in different microvascular beds.

Although the exchange of small hydrophilic molecules occurs through the same channels that account for most of L_P, some water may also cross microvascular walls of continuous endothelium by channels not available to solutes. This additional route has been

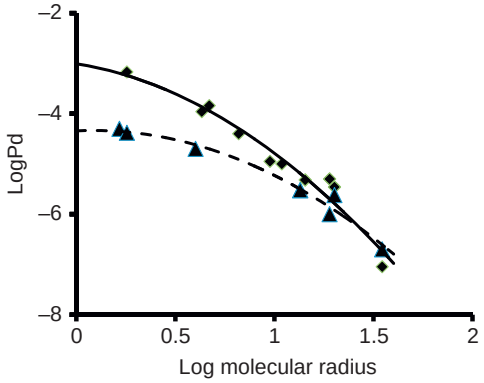

FIGURE 9.5 **Relations between the logarithms of P_d and molecular radius for small to intermediate sized hydrophilic solutes in capillaries of frog mesentery (filled circles) and cat skeletal muscle (filled triangles).** Data for frog obtained from measurements made in single perfused microvessels *in situ*. Data from cat based on measurements on perfused vascular bed. Both types of vessel have continuous endothelium. Note whereas P_d for the smallest solutes is 10 times greater in mesentery than in muscle (1 $\log_{10}$ unit = 10 ×), values for P_d converge as molecular size increases.

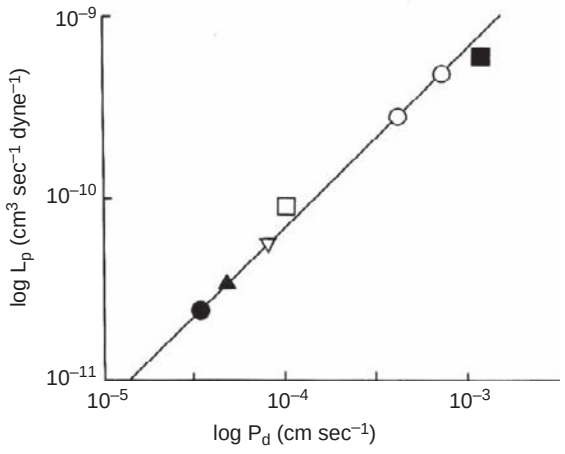

FIGURE 9.6 **Variations in L_P and P_d to small ions (Na^+ and K^+) in different microvascular beds.** The scales are logarithmic to include values covering two orders of magnitude, and the line has a slope of 1.0, indicating direct proportionality. Each point represents the value for L_P and P_d for one vascular bed; where several values of P_d are available the largest has been used to minimize errors resulting from flow-limited transport. ○, frog mesentery; ∇, frog muscle; ●, mammalian skeletal muscle; ϒ, mammalian heart muscle; ▲, dog lung; ■, cat salivary gland. *(From ref. [74]. With permission)*

identified by Pallone et al.[92] as channels formed by the membrane protein aquaporin-1, AQP-1.[6] The first real evidence for a "water only" pathway was indicated by Yudilevich and Alvarez from measurements of the rates of diffusion of triated water and Na^+ through dog heart capillaries. From measurements of σ to small hydrophilic solutes, Curry and colleagues[29] estimated that in single perfused capillaries between 5 and 10% of the pathways responsible for L_P were available only to water, and not to small solutes. More recently, Turner and Pallone[126] have shown that "water only" channels account for a similar proportion of the L_P of descending vasa recta of rat kidney. It is worth emphasizing that although fluid movements through AQP-1 channels of the descending vasa recta are of physiological importance, the channels contribute no more than 5 to 10% to the total L_P of these vessels. Although it has been suggested that AQP-1 channels might contribute to as much as 30% of the L_P of skeletal muscle capillaries,[137] the strong correlation between P_d and L_P shown in Figure 9.6 indicates that the contribution of AQP-1 channels to the L_P of most exchange vessels is small.

Although absolute values of L_P and P_d to small hydrophilic solutes vary greatly from one microvascular bed to another, the reflection coefficient to large molecules are remarkably similar in different vessels when the tissues are undamaged (or unstimulated). This is shown in Figure 9.7, where the mean values of σ to serum albumin have been plotted against the mean value of L_P for various tissues. Whereas L_P varies over three orders of magnitude, σ to albumin is usually in the range of 0.8 to 1.0. There is no trend in the relation between $\sigma_{albumin}$ and L_P. Vessels with high values of L_P have mean values of $\sigma_{albumin}$ that are as high, if not higher, than in vessels with low values of L_P. This means that the channels or pores that are largely responsible for the L_P of vessels in different tissues all restrict the passage of albumin to a similar extent. Thus, both the variations of P_d with molecular size and the variations in $\sigma_{albumin}$ and L_P in different capillary beds lead to the same conclusion: individual channels for exchange of water and small hydrophilic solutes are similar in different capillary types, but the density of these channels in vessel walls varies considerably.

Permeability Coefficients to Macromolecules

Apart from the sinusoids of the liver and spleen, microvascular walls have high reflection coefficients and low permeabilities to macromolecules. These permeability properties are essential if the circulating blood is to be retained within the vascular system. Although their permeabilities are low, macromolecules do cross the walls of all microvessels at slow but finite rates. Table 9.1 compares estimates of σ and P_d made from the transport of macromolecules between blood and lymph in the dog paw and the cat intestine.[106] Although it is possible that the values given in this table are actually overestimates of the permeability coefficient of macromolecules, there are three important points to note here. First, the values of P_d for serum albumin are more than 3000 times less than the permeabilities of the same vessels to Na^+ and urea. The diffusion coefficient of albumin in aqueous solutions is only 20 times less than those of Na^+ and urea. This means that the diffusion of albumin molecules through microvascular walls is hindered 150 times more than the diffusion of Na^+ ions or urea molecules. Second, compared with the changes seen for small molecules, there is a relatively small decrease in P_d and rise in σ with increases in molecular size. The third point is the similarity of the values of P_d to the same macromolecule at the predominantly continuous endothelium of the dog paw capillaries, and also at the predominantly fenestrated endothelium of vessels in the small intestine. The values of L_P and P_d to small hydrophilic solutes in these two microvascular beds differ by nearly two orders of magnitude. This would seem to be further evidence supporting the belief that the transport pathways through microvascular walls are different for macromolecules from those responsible for water small hydrophilic solutes.

TABLE 9.1 Reflection Coefficients (σ) and Permeability Coefficients (P_d) to Macromolecules of Selected Molecular Radii (a_{ES}, nm) in Microvascular Beds of Dog Paw and Cat Ileum

		Dog Paw		Cat Ileum	
Molecule	a_{ES} (nm)	σ	$P_d \times 10^8$ (cm sec^{-1})	σ	$P_d \times 10^8$ (cm sec^{-1})
Serum albumin	3.55	0.89	1.0–4.7	0.9	3.0
Transferrin	4.3	0.89	6.3	–	–
Haptoglobin	4.6	0.91	3.1	–	1.4
Immunoglobulin	5.6	0.91	3.3	0.95	–

Renkin, E. M. (1988). Transport pathways and processes. In "Endothelial Cell Biology," 51–68, Simionescu, N., and Simionescu, M., (eds.) Plenum Publishing, New York.[104]

It is possible that some of the values for P_d in Table 9.1 are overestimates and those for σ are underestimates because, in calculating vascular permeability coefficients from plasma to lymph transport, it is assumed that a steady-state has been established between the newly formed filtrate surrounding the microvessels and the ISF entering the lymph. Simple calculations suggest that in some tissues the time taken to reach a steady-state after a change in microvascular filtration rate can be many hours.[78] This can be understood by considering the events that follow an increase in microvascular filtration. A rise in filtration rate is accompanied by a rise in lymph flow and a fall in the concentrations of macromolecules in the newly formed interstitial fluid. It may, however, take several hours before the lymph has the same composition as this new filtrate, and if the lymph is sampled prematurely its concentration of macromolecules will be greater than that in the ultrafiltrate. The lymph flow, however, may reach its new steady-state level before the lymph concentration of macromolecules, and if flux of macromolecules is estimated from values for the product of lymph flow and lymph concentration of macromolecules at this stage, its value will exceed the real rate of transport into the tissue. Not only is macromolecular transport overestimated, but the mean concentration differences across the microvascular walls are also underestimated.[107]

Since 1990, much work has been conducted on the passage of macromolecules through monolayers of culture endothelial cells. In many of these studies, changes in permeability to macromolecules have been investigated, and relative rather than absolute values of permeability coefficients have been reported. In most but not all studies, absolute values for P_d of monolayers of cultured endothelial cells to albumin lie in the range of 10^{-6} cm sec^{-1}, about 100 times greater than the values of P_d to albumin at microvascular walls *in situ*.[9] In a few laboratories, values in the range of 10^{-7} to 10^{-6} cm sec^{-1} have been reported, but even these values are at the very high end of the range found in microvessel walls *in vivo*. The reasons for this difference are not understood at present. Although studies on cultured endothelial cells have provided essential information of intracellular processes, conclusions from them relating to macromolecular permeability should be viewed with caution.

Like smaller hydrophilic molecules, the microvascular permeability coefficients to macromolecules decrease as molecular size increases, although the decline is considerably less steep. Molecular charge is also more important as molecular size increases. Evidence for the charge-selective nature of ultrafiltration in the renal glomerular capillaries is well-known, but in other microvessels, charge selectivity has been investigated in less detail. Areekul[8] first provided evidence for charge selectivity in systemic capillaries. Working on the isolated perfused rabbit ear, he showed that σ_d to sulfated dextran (which is negatively charged) was always greater than σ_d to neutral dextran of the same molecular weight. Work on single perfused capillaries[2] and on microvascular beds in rat hind limbs also supported the view of microvascular walls as a negatively-charged barrier.

This picture was temporarily confused by studies on the transport of charged macromolecules between plasma and lymph. Negatively-charged macromolecules appeared more rapidly in the lymph and at higher concentration than positively-charged molecules, suggesting a positively-charged barrier. It was then appreciated that the large number of fixed anionic sites in the interstitium (see [49]) would reduce the volume of distribution of the negatively-charged molecules relative to cationic or neutral molecules of the same molecular size. Parker and co-workers[95] showed that the greater volume of distribution of neutral and cationic molecules increased the time for these molecules to reach a steady-state concentration in the ISF. This delay accounted for the apparently more rapid transport of the anionic molecules, a conclusion reinforced by the recent study of

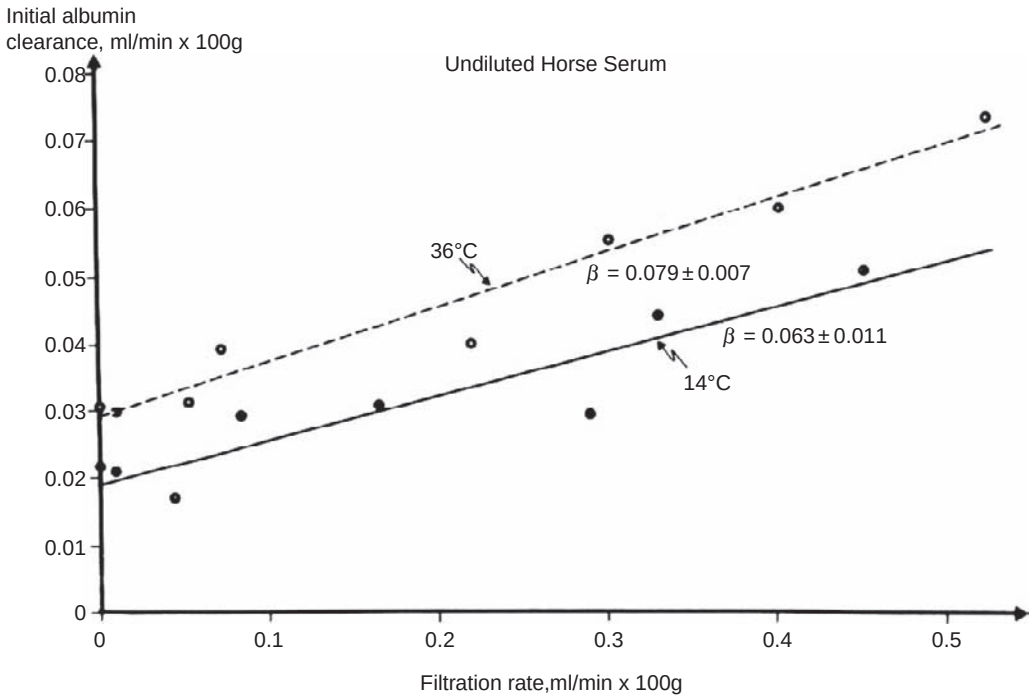

FIGURE 9.8 **The clearance of serum albumin from perfusate into tissues of rat skeletal muscle at different filtration rates in experiments conducted at 36°C and 13–15°C.** β is the slope of the relation. *(From ref. [107]. With permission.)*

Gyenge and her co-workers[49] on albumin distribution in skin and muscle tissue. With this point clarified, the evidence once again supports the concept of a negatively-charged barrier at microvascular walls hindering the transport of negatively-charged macromolecules greater than 3.0 nm in diameter.

The decline of P_d (and an increase in σ) with an increase in molecular size led to the suggestion that macromolecules cross the endothelium through a system of large pores with radii in the range of 20–40 nm. These pores would be few in number compared with the small pores that act as a pathway for small hydrophilic solutes.[45] Calculations suggest that individual capillaries in skeletal muscle may have an average of only three large pores[81] and with the usual variation between microvessels this indicates that many vessels will have no large pores at all. In a comprehensive review, Taylor and Granger[123] showed that microvascular permeability to macromolecules in different tissues could be described by transport through a population of small pores (radii 3.5–5 nm) and a set of large pores (15–30 nm radii). If large pores do exist, then transport of macromolecules through them will be largely convective, sensitive to microvascular pressure, and increase with fluid filtration rate. Experiments by Rippe and his colleagues[109] showed that this is the case for the transport of labelled albumin from capillaries in skeletal muscle of an isolated perfused rat limb preparation. Defining the clearance of tracer from the blood into the tissue as the rate of its accumulation divided by the perfusate concentration, they not only showed that clearance of albumin increased linearly with fluid filtration into the tissues, but also that cooling the tissue from 36° to 14°C reduced albumin clearance by only 40%. This was similar to the reduction of the apparent hydraulic permeability of the microvessels. The results of this classic experiment are shown in Figure 9.8. A 40% reduction in L_P would be expected because the filtrate flow through the water-filled channels through the vessel walls is inversely proportional to fluid viscosity, and the viscosity of water at 36°C is approximately 60% of that at 14°C. Because albumin transported is proportional to filtration rate and is reduced in parallel to J_V as the viscosity of water is increased, Rippe and his colleagues[109] concluded that albumin is transport through water-filled channels in the microvascular walls. Figure 9.8 shows that the clearance of albumin from plasma to tissue is significant when fluid filtration is zero. Rippe and his colleagues[109] accounted for this by pointing out that, because the hydrostatic pressure difference across microvascular walls is greater than zero under these conditions, there would still be fluid filtration through the large pores, and consequent transport of albumin because σ_d to plasma proteins here is low. This filtration through the large pores

would not be detected in whole tissue, because it would be balanced by an equal and opposite uptake of fluid through the "small pores" where σ_d to plasma proteins is high. As we shall see, the steady uptake of fluid from tissues into capillary blood may peter out and become a low level of filtration in tissues such as muscle.

Ultrastructural Basis of Permeability

Small Hydrophilic Solutes and Water

If the molecular sieving properties of microvascular endothelia are determined by pores or channels of similar dimensions, one might expect to find common structural features in all endothelia that are more frequent in the more permeable vessels. Unfortunately, electron micrographs of endothelia do not reveal an obvious structure that might fill this role.

The endothelia of the vessels with the four highest values of L_P in Figure 9.9 are fenestrated, while those with the seven lowest L_P values are continuous. In some others (e.g., small intestine) values of L_P and σ represent those of a microvascular bed where there are both fenestrated and non-fenestrated vessels. In a quantitative analysis of permeability of fenestrated vessels, Levick and Smaje[66] found that variations in L_P and P_d to small hydrophilic solutes in fenestrated vessels can be correlated with the number of fenestrations per unit area of endothelium. From their analysis they estimated the mean hydraulic conductance per unit increment of area for fenestrations in a variety of microvascular beds as $0.38\,\mu m.sec^{-1}$ $mmHg^{-1}$ (2.8×10^{-5} $cm.sec^{-1}$ cmH_2O^{-1}). This means that the addition of a single fenestration (diameter = 60 nm) to one μm^2 of the endothelium of a skeletal muscle microvessel increases the L_P of that area approximately 2.6 times. Although fenestrations appear as large pores passing through the endothelium, the fenestrations themselves are much too large to account for molecular sieving and their high reflection coefficients to macromolecules. Molecular sieving is now thought to be achieved by the endothelial glycocalyx, with significant contributions to the hydraulic resistance from the fenestral diaphragms and the basement membrane.

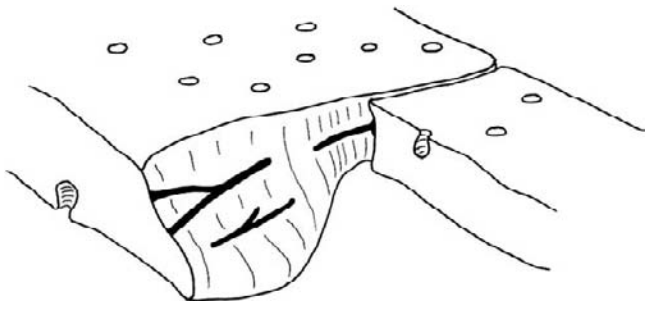

FIGURE 9.9 **Diagram of the ultra-structure of an intercellular cleft based on reconstructions from serial ultrathin sections (A&M).** Part of the cell in the foreground has been removed to expose the interior of the cleft showing the junctional strands (heavy lines), which correspond to points of close apposition between the cells (tight junctions) in single sections. Lanthanum ions cannot diffuse through the junctional strands, but pass through breaks in the strands. Because there is usually only one continuous strand in the junctions of mesenteric microvessels, each break provides a direct pathway through the cleft.

The luminal glycocalyx was proposed by Curry and Michel[30] as the structure responsible for molecular sieving in microvessels with continuous endothelia. Its wide acceptance came after direct observations of the exclusion of macromolecules from the luminal surface of living microvessels had been demonstrated 16 years later by Vink and Duling.[129] Whereas variations in L_P of fenestrated vessels results from variations in the number of fenestrae per unit area of vessel wall, the variations in L_P and P_d to small hydrophilic molecules in vessels with continuous endothelia appears to correlate with the numbers of breaks and complexity of the junctional strands of the intercellular clefts. Although evidence for this concept was available in 1978 from the work of Wissig and Williams,[136] progress was hindered by the beliefs that: (1) the molecular sieve consisted of pores or narrow openings in the tight junction strands; and (2) that the breaks forming a pathway through the junctional strands were too few in number to account for permeability to water and small hydrophilic solutes. Thus, Bundgaard[19] reconstructed the intercellular clefts of rat heart capillaries from ultrathin serial sections and confirmed the presence of a tortuous pathway through the cleft, but rejected this as the route taken by water and small hydrophilic solutes on the grounds that the dimensions of the openings through the junctional strands were too great to filter plasma proteins, and the number of breaks per unit length of junction were too few to account for water and small solute permeabilities.

The question was clarified by Adamson and Michel.[4] Working on frog mesenteric capillaries *in situ*, they perfused single capillaries briefly with solutions containing lanthanum ions, before the tissues were fixed for electron microscopy. Micrographs of serial sections of the walls of the perfused vessels demonstrated that lanthanum ions were only able to pass through the intercellular clefts at breaks in the junctional strands. In a second series of experiments, they measured L_P in individual capillaries *in situ* before fixing the tissue for electron microscopy (EM). The three-dimensional structures of the intercellular clefts of that capillary were then reconstructed from long runs of ultrathin sections of the vessel. Although the breaks only represented 3–10% of the length of the strands, Adamson and Michel[4] used a mathematical

model of Parker and colleagues to show that this was more than sufficient to account for permeabilities that were three times greater than those they had measured. The mathematical model provided a rigorous argument for believing that a small break in the junctional strands has a much greater effect upon L_P than its size might suggest. The pressure gradient driving fluid flow through the intercellular cleft is steepest across the tiny distance through the break in the strand, and is much greater than that calculated for the entire cleft. More detailed mathematical models have been developed by Weinbaum and his colleagues[38,55,133] and more recently, Adamson et al.[3] have shown that the fine structure of the tight junction in intercellular clefts of rat mesenteric venules is very similar to that seen in frog vessels.

The L_P of mesenteric vessels is approximately three times greater than the L_P of heart muscle capillaries, which is approximately three times greater than the L_P of capillaries in skeletal muscle. These differences in permeability appear to correlate with the complexity of the pathway through the tight junction in these different types of capillary. This is illustrated in Figure 9.10 for pathways through the intercellular clefts of mesenteric, cardiac, and skeletal muscle capillaries. It seems most probable that the wide variations in permeability to fluid and small hydrophilic solutes that is found in microvessels with continuous endothelium are determined by the complexity of the tight junctional architecture within the intercellular clefts.

As mentioned earlier, the glycocalyx on the luminal surface of the endothelium that covers the entrances to intercellular clefts and fenestrae is now considered to be the barrier to macromolecules. When this was first proposed[30] there was indirect evidence to support it, and more evidence of this kind accumulated during the 1980s.[81] In 1990, Adamson[1] showed that the L_P of single vessels was doubled by brief perfusions of pronase that disrupt the glycocalyx without having any other detectable effects on endothelial ultrastructure

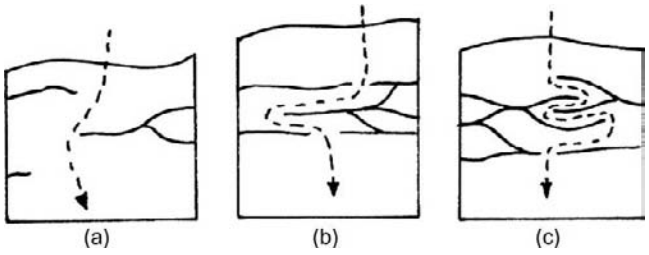

FIGURE 9.10 **Variations in the complexity of arrangement of junctional strands in intercellular clefts of microvessels with different hydraulic permeabilities.** The dashed lines with arrows indicate potential pathways through the breaks in the strands. (a) Mesenteric capillary (based on [4] and [5]); (b) Cardiac muscle capillary (based on [19]); (c) Skeletal muscle capillary (based on [136]).

when electron micrographs of the same vessels were inspected. General recognition of the concept of the glycocalyx barrier resulted from some remarkable *in vivo* observations of Vink, Duling, and their colleagues.[52,128,129] Using confocal microscopy to visualize capillaries in rat cremaster muscle, these authors observed that FITC dextrans were excluded from the endothelial cell membranes by a distance of 0.5 μm. The exclusion layer was diminished or even abolished by prolonged exposure to UV light and after perfusion with hyaluronidase. Observations of this kind continue to bolster the view of the glycocalyx as a barrier.

Direct evidence for how its structure acts as a molecular filter comes from the analysis of electron micrographs of glycocalyx.[9,120] Examining very differently prepared specimens, including some made by the rapid freeze-deep etch technique in the absence of chemical fixatives, Squire et al.[120] have concluded that the glycocalyx may be regarded as a regular cubic lattice with side length of 20 nm and a cubic internal space of side length 8 nm (see Figure 9.11). Since serum albumin molecules have diameter of 7−7.2 nm, the dimensions of this internal space are consistent with the glycocalyx acting as the molecular filter in microvascular walls. The initial observations were all made on the glycocalyx of continuous endothelia of the frog, but more recent work has revealed very similar structural features to the glycocalyx covering both continuous and fenestrated endothelia, including that over fenestrae in mammalian microvessels in a wide range of tissues.[9]

In summary, the main permeability pathways through microvascular walls to water and small hydrophilic solutes are located in the fenestrations of fenestrated endothelium, and through the intercellular clefts in vessels with continuous endothelium. In both types of endothelia, the molecular filter that forms the barrier to macromolecules at most microvascular walls is in the luminal glycocalyx of the endothelial cells.

Macromolecules

Just how macromolecules cross the walls of small blood vessels remains a controversial subject. Two apparently conflicting hypotheses emerged from very different lines of evidence more than 40 years ago, and the question of which is more correct has not been finally resolved. As summarized earlier, a purely functional approach has led to the proposal that microvascular walls were penetrated by a small number of "large pores" (30−80 nm in diameter) through which macromolecules pass from plasma to interstitial fluid (ISF).[45] The large pores are estimated to occur so infrequently that their contribution to the P_d of small hydrophilic solutes would be negligible, although they might make a 5 to 10% contribution to L_P. The large pores, however, would be entirely responsible for the permeability of

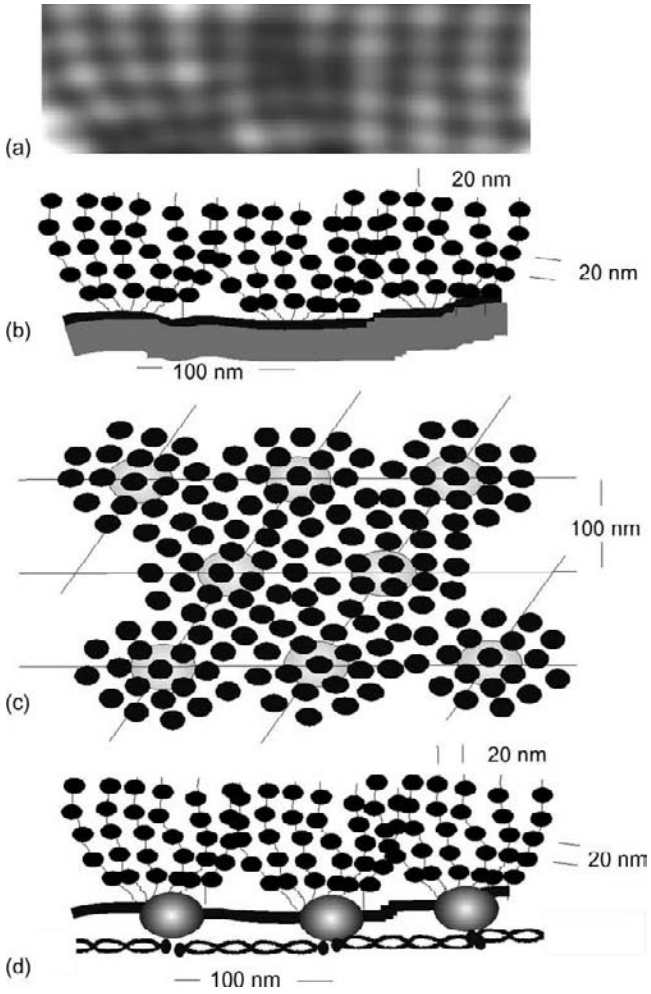

FIGURE 9.11 Models of glycocalyx based on image analysis of electron micrographs. (a) An autocorrelation function of the glycocalyx indicating the underlying regularity of structure with a periodicity of approximately 20 nm both parallel and perpendicular to the cell membrane. (b) A molecular interpretation of (a). It consists of clusters of fibrous strands projecting perpendicular to the luminal cell membrane with periodicity along the strand provided by equally spaced globular proteins. It is suggested that adjacent clusters are separated by approximately 100 nm (consistent with a longer range periodicity) where they linked to the cortical cytoskeleton of the cell. Figures 9.11(c) and (d) show luminal surface and saggital views of the proposed structure. *(From ref. [118].)*

macromolecules, and transport through them would be largely by convection.

The alternative arises from electron microscopy, and proposes that macromolecules cross endothelial cells by transcytosis via the small vesicles.[17,18] After their injection into the blood, electron-dense macromolecules have been found labeling caveolae and small vesicles of the endothelia. Initially it was suggested that the vesicles acted as ferries, equilibrating with plasma when they opened as caveolae at the luminal surface, then budding off as small vesicles to travel across the cell where they fused with the abluminal surface of the endothelium and equilibrated with the ISF. In the absence of evidence for active transport of macromolecules through microvascular walls, it was suggested that equal fluxes of vesicles occurred in opposite directions across the cells, and the vesicles moved as a result of Brownian motion.[22] The size dependence of macromolecular permeability arises in vesicular transport from volume exclusion of the macromolecules by the walls of the vesicles.[103] The exclusion effect is considerably enhanced if the caveolae and small vesicles are lined with glycocalyx.[67,118]

A detailed examination of the labeling of vesicles with ferritin molecules led to a more complicated model, in which neighboring vesicles periodically fused transiently for long enough for their contents to equilibrate.[23] It was also shown that cooling the tissue inhibited the labeling of vesicles with ferritin.[24] This fusion–fission hypothesis was consistent with the detailed structural analysis showing the vesicles to be arranged in fused clusters communicating with caveolae at either the luminal or the abluminal cell membranes.[20,36] One extreme form of the fusion–fission hypothesis is for the joined vesicles to form channels through the endothelium. Evidence for such vesicular channels has been reported,[119] and these could act as large pores.

Direct evidence for transport by vesicles through normal endothelium has been reported by Wagner and Chen,[130] who demonstrated caveolae emptying terbium label at the abluminal endothelial surface at points distant from intercellular clefts. The demonstration of membrane binding sites for transferrin,[56] insulin,[59] ceruloplasmin,[122] and albumin[42] on endothelia suggested that the vesicle pathway might be involved in receptor mediated transport. A series of papers by Schnitzer and colleagues[113–117] seemed to bolster the idea of vesicular shuttling or fusion–fission as an important mechanism of macromolecular transport through endothelium. The cholesterol scavenger, filipin, removes caveolae in cultured endothelial cells and in rat lung microvessels, and was also reported to reduce the clearance of albumin from perfusate to tissue in the isolated perfused rat lung.[113] It was also reported that N-ethylmaleimide (NEM), which inhibits fusion processes of vesicles and vacuoles in yeast, in synaptic vesicles, and in transport vesicles operating between the Golgi stacks and the endoplasmic reticulum, inhibited transendothelial transport of macromolecules in microvessels of mouse heart and rat lung.[114] Schnitzer and colleagues[117] have reported that endothelial caveolae from rat lung capillaries can bud away from their anchorage in the presence of GTP and extracts of cytosol. Critical studies by Rippe and his colleagues, however, have cast serious doubt on the relevance of these findings to

macromolecular permeability.[21,111] They found that both filipin and NEM increased albumin transport in the isolated perfused rat lung. NEM was found to reduce σ to albumin. Reducing the tissue temperature from 35° to 22°C, however, lowered both albumin clearance and L_PS in rough proportion to increased water viscosity. NEM also increased both albumin clearance and L_PS in the microcirculation of rat muscle,[21] and increased precapillary vascular resistance in both rat lung and rat muscle. The authors suggested that increased resistance would reduce microvascular perfusion, and this could account for the earlier studies where NEM appeared to reduce albumin clearance. Rippe and colleagues have recently reviewed the controversy,[110] and provided further less direct evidence against endothelial transcytosis of macromolecules from studies of peritoneal dialysis.[112]

Rippe's arguments for convective transport of macromolecules via large pores are convincing. At present it seems that whereas there is strong evidence favoring convective transport of macromolecules (i.e., the large pore hypothesis), evidence that transcytosis makes a significant contribution to transendothelial transport of macromolecules is lacking. It is possible that the caveolae/small vesicle system is important for the transport of specific molecules. The blood−tissue transport of insulin, for example, appears to be anomalous for a protein of its size,[53] and is more consistent with receptor-mediated transport.[59] As mentioned already, the large pores carrying most macromolecules could be trans-endothelial channels formed by the fusion of vesicles. At normal tissue temperatures they might be continually forming and re-forming, accounting for the progressive labeling of the vesicle system with tracer macromolecules. On cooling the tissues, the open channels would remain open, but no new channels would form, consistent with both the effects of cooling on albumin transport, and the reduced vesicle labeling reported by electron microscopists.

The question of whether macromolecules are transported mainly by convection through large pores in the walls of microvessels in normal healthy tissue has implications for our understanding of fluid exchange between the blood and the tissues.

THE EXCHANGE OF FLUID AND SOLUTES BY CONVECTION AND DIFFUSION THROUGH MICROVASCULAR WALLS

Coupling of Fluid and Solute Transport during Ultrafiltration

In most tissues, ISF is formed by the ultrafiltration of plasma, a process that is driven by the greater hydrostatic pressure inside the microvessels than in the surrounding tissues. As fluid begins to be filtered through the vessel walls, its composition is determined by the rates at which the different plasma solutes can move with the filtrate by convection and diffusion. If one considers the transport of a solute past a point at a distance x cm along a pathway within the microvascular wall, and of cross-sectional area, A, the net flux of solute, J_S, can be described by adding together the contributions of convection and diffusion. Thus from Eqs. (9.4)−(9.6):

Total transport = Convective transport + Diffusive transport

$$J_S = J_V(1-\sigma_f)C + D'A(-dC/dx) \tag{9.8}$$

where C is the solute concentration of the solute at x, D' is solute diffusion coefficient, and $(-)$ is the direction of the concentration gradient (from plasma to ISF). The first term on the right hand side of Eq. (9.8) is the convective component of transport, and the second term is the diffusive component. The concentration gradient that is responsible for net transport by diffusion is equal to the solute concentration difference between the plasma and the ISF, divided by the length of the pathway through the wall only when fluid filtration is zero and there is no convection of solute. When net fluid movements are present they distort the concentration gradients in the channels within the vessel walls. Once a steady-state is established so the solute flux, J_S, is the same at all points along the diffusion pathway (i.e., the rate of solute entry equals the rate of its exit from the channels), then the extent of the distortion can be inferred by integrating Eq. (9.8). This leads to a form of the Patlak expression[96] which here relates J_S through an area of vessel wall, A_m, to the plasma concentration of solute, C_p, and the concentration emerging from the vessel walls into the peri-capillary ISF, C_i :

$$\frac{J_S}{A_m} = \frac{J_V}{A_m}(1-\sigma_f)\frac{(C_p - C_i e^{-Pe})}{(1-e^{-Pe})} \tag{9.9}$$

where

$$Pe = \frac{J_V(1-\sigma_f)}{P_d A_m}$$

Pe is a dimensionless number, called the Péclet number, which expresses the ratio of solute velocities by convection and diffusion, P_d being the diffusional permeability coefficient. Curry[26] has recast Eq. (9.9) in a form that allows the convective and diffusive components of transport to be recognized:

$$\frac{J_S}{A_m} = \frac{J_V}{A_m}(1-\sigma_f)C_p + P_d(C_p - C_i)\left(\frac{Pe}{e^{Pe}-1}\right) \tag{9.10}$$

Equation (9.10) is analogous to Eq. (9.8), with the first term on the right-hand-side describing convective transport, and the second term describing diffusion. The expression $Pe/(e^{Pe}-1)$ describes the effects of solute convection upon the mean concentration gradient within the diffusion pathway by convective flow in the same direction as net diffusion.

Earlier it was noted that ultrafiltration through microvascular walls is driven by the hydrostatic pressure difference, ΔP, between the plasma inside the vessels and the surrounding ISF. If, initially, all the solutes were at the same concentration in plasma and ISF, the filtration rate per unit area of vessel wall (J_V) is $L_P A_m \Delta P$, as in Eq. (9.2). The process of ultrafiltration, however, soon leads to differences in solute concentration between the plasma and the newly formed ISF, as a consequence of the differences in σ and the Péclet numbers of the different solutes. These concentration differences give rise to osmotic pressure differences that oppose ΔP. In this way, the rate of fluid filtration per unit area of vessel wall becomes the product of L_P and the difference between ΔP and the sum of all the osmotic pressures opposing it. Thus:

$$\frac{J_V}{A} = L_P\left(\Delta P - \sum_n \sigma_{d_n}\Delta\Pi_n\right) \tag{9.11}$$

where $\sigma_{dn}\Delta\Pi_n$ is the effective osmotic pressure set up across the vessel wall by the n^{th} solute.

Equation (9.9) can be used to calculate the contribution of different plasma solutes to the osmotic term in Eq. (9.11). When the filtration rate is steady, C_i becomes equal to the ratio of the rate of solute transport to the filtration rate i.e., $C_i = J_S/J_V$. Combining this relation with Eq. (9.9) leads to the following expressions for C_i and $\Delta C = C_p - C_i$:

$$C_i = \frac{J_S}{J_V} = C_P\frac{(1-\sigma_f)}{(1-\sigma_f e^{-Pe})} \tag{9.12}$$

and:

$$\Delta C = C_p - C_i = C_p\sigma_f\frac{(1-e^{-Pe})}{(1-\sigma_f e^{-Pe})} \tag{9.13}$$

Differences in concentration (and hence differences in osmotic pressure) can only be sustained for those solutes that have low permeabilities. If permeability is high, concentration gradients are dissipated by diffusion, and for differences of concentration and osmotic pressure to be maintained both reflection coefficient and Péclet number of the solute must be high. The implication of this is that when Pe is zero (e.g., when $J_V = 0$) the concentration differences will dissipate, even for those solutes that have very low permeabilities.[75]

The message of Eq. (9.13) can be appreciated by evaluating *Pe* for urea and serum albumin during slow filtration (at a rate of 2×10^{-7}cm^{-2}sec^{-1}) through the walls of skeletal muscle capillaries.[75] For urea, P_d is 2.7×10^{-5} cm sec^{-1} and σ is 0.1, so that *Pe* is 0.0074; for serum albumin with P_d at 10^{-8} cm sec^{-1} and σ at 0.95, *Pe* is 1. Thus, C_i would be more than 99.9% C_p for urea, and ΔC is therefore 0.1% C_p, so that urea makes a negligible contribution to $\sigma_{ds}\Delta\Pi$ (about 0.1 cmH_2O). For serum albumin, however, C_i is only 7.6% of C_p and ΔC is 92.4% C_p accounting for the major contribution of albumin to $\sigma_{ds}\Delta\Pi$ (about 19 cmH_2O). Similar calculations can be made for microvessels in most other tissues (the exception being those of the brain), and it is therefore the osmotic pressure of the macromolecules that constitute the osmotic pressure difference that acts as a break on fluid filtration and holds the plasma in the vascular system. The osmotic pressure of the macromolecules of plasma and other body fluids is often referred to as the *oncotic pressure*.

Equations (9.12) and (9.13) indicate the close coupling between microvascular fluid exchange and microvascular solute permeability. The concentration of plasma proteins in the ISF (and hence the ISF oncotic pressure) is almost an inverse function of ultrafiltration rate. This relation is of considerable significance in interpreting microvascular fluid exchange, and its consequences are discussed further below.

Fluid Movements through Microvascular Walls

General Approximation: Starling Forces

The principle that fluid is held in the vascular system by a balance of hydrostatic and oncotic pressures across capillary walls was recognized over a century ago by Ernest Starling.[121] Since then it has been demonstrated to apply in a large number of vascular beds in different animals, including humans, using a variety of techniques. It remains the basis for understanding fluid exchange between the blood and the tissues.[65,77,79,81,83]

For most purposes, Eq. (9.11) can be written in a simplified form, in which the effective osmotic pressure term becomes the effective oncotic pressure difference across microvascular walls, $\sigma_m(\Pi_c - \Pi_i)$, i.e.:

$$\frac{J_V}{A} = L_P(\Delta P - \sigma_m\Delta\Pi) = L_P[(P_c - P_i) - \sigma_m(\Pi_c - \Pi_i)] \tag{9.14}$$

The reflection coefficient, σ_m, refers to the mean (or effective) reflection coefficient of microvascular walls to macromolecules and the pressures, P_c, P_i, Π_c, and Π_i are often referred to as the *Starling pressures*.

Equation (9.14) is a clear statement of Starling's principle of fluid movement between the plasma and the ISF. Under suitable experimental conditions it is possible to compare fluid movements through microvascular walls when ΔP is varied as $\Delta\Pi$ is held constant. This has been achieved most unambiguously in single perfused microvessels (e.g., Figure 9.12). Essentially similar results have been obtained by less direct methods in perfused vascular beds[93]; see [79] for review).

Experiments such as that shown in Figure 9.12 reveal several general features of the permeability of microvascular walls.[74] The linearity of the relation between fluid flux and pressure suggests that the pathways conducting fluid through the vessel walls are not stretched or deformed over this range of pressures. If the channels were stretched and widened, their conductivity, L_P, would be raised and this would be seen as an increase in the slope of the relation between J_V/A and ΔP (which is L_P) with increasing pressure. Furthermore, the value of L_P is the same during fluid absorption (negative values of J_V/A) as it is during filtration, indicating that there is no significant rectification of flow within the conducting channels. (With less careful experimental design, however, rectification of flow may appear to occur.) A third feature of importance is the effect of changing the concentration of macromolecules in the perfusate. The consequent change in oncotic pressure results in a parallel shift of the relation between J_V/A and fluid pressure. The magnitude of the displacement is equivalent to 70% of the perfusate oncotic pressure, as measured in a membrane osmometer. This indicates that σ_d is greater than or at least equal to 0.7 in this vessel. Overall, the experiment reveals that the permeability coefficients L_P and σ_m, can be regarded as independent of the Starling forces. Although permeability can be modulated, a background of constant permeability provides a basis to discuss fluid movements that occur physiologically as a result of changes in the Starling pressures.

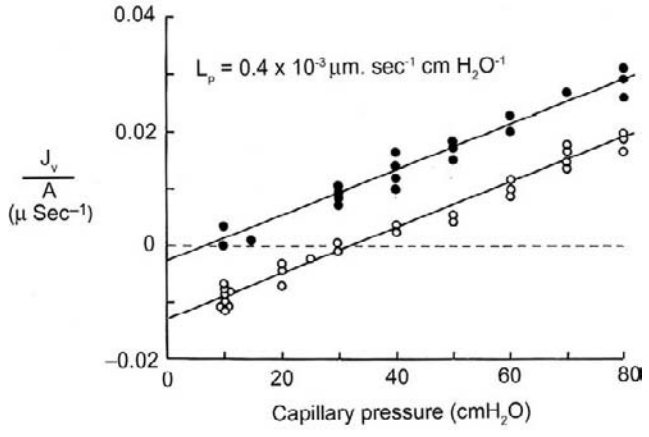

FIGURE 9.12 **Relation between net fluid movement per unit area of microvascular wall (JV/A) and capillary pressure in a single frog mesenteric capillary perfused with Ringer's solution containing high (o) and low (●) concentrations of serum albumin.** Positive values of JV/A indicate fluid filtration from vessel to tissue and negative values show movement from tissue into vessel. *(From ref. [72]. With permission.)*

Changes in Microvascular Pressure

Although textbooks so often say that P_c has a mean value that approximates to plasma oncotic pressure, this is true only for systemic microvessels of small mammals, and for systemic pressures at heart level in larger mammals. In the pulmonary microcirculation of all mammals investigated, mean P_c is more often closer to a third of the value of plasma oncotic pressure. In larger mammals, such as humans, mean P_c varies with the vertical height between the vessel and the heart. When a human subject lies horizontally, mean P_c in most systemic microcirculations may approximate to plasma oncotic pressure, but as soon as the subject sits or stands, P_c in vessels below the heart increases, and that in vessels above the heart decreases. The changes in P_c above and below the heart are not symmetrical; the decrease in P_c in vessels in the upper parts of the body is checked as the local venous pressure falls below atmospheric and the veins collapse. Measurements of P_c in skin suggest that once this happens, P_c becomes independent of position.[60] Below the heart, arterial and venous pressures increase in proportion to their vertical distance beneath the heart providing the subject remains still, and mean P_c in the feet also increases but to a lesser extent than arterial and venous pressures (see Figure 9.13). Movements of the legs increase venous return from the feet, reducing the local venous pressures and P_c.

The smaller increase in P_c than arterial and venous pressure in tissues below heart level (see Figure 9.13) suggests how P_c may be regulated. For blood to flow through a vascular bed there must be a lower pressure in the veins than in the capillaries, and in the capillaries than in the arteries. The fall in pressure from arteries to capillaries, $P_a - P_c$, is the product of the blood flow from arteries to capillaries, and the resistance of the vessels between them (i.e., the pre-capillary resistance, r_a). Similarly, the fall in pressure between the capillaries to the veins, $P_c - P_v$, is the product of the blood flow and the post-capillary resistance, r_v. Providing the blood flows into and out of the circulation are equal, P_c can be related to P_a and P_v through r_a and r_v:

$$\frac{(P_a - P_a)}{(P_c - P_v)} = \frac{r_a}{r_v}$$

which can be rearranged in the form derived by Pappenheimer and Soto-Rivera[93]:

$$P_c = \frac{P_a + P_v(r_a/r_v)}{1 + r_a/r_v} \qquad (9.15)$$

Equation (9.15) reveals how the value of P_c between P_a and P_v is determined by the ratio of r_a/r_v, and since local blood flow is regulated in most vascular beds by alterations in r_a, it also suggests how P_c might be regulated. Even if P_a and P_v remain constant, arteriolar vasodilatation, which reduces r_a/r_v, increases P_c and enhances fluid filtration. Arteriolar vasoconstriction, which increases r_a/r_v, reduces P_c consequently promoting fluid absorption from the tissues. A sudden loss of a substantial volume of blood (e.g., by hemorrhage or blood donation) is followed by intensive vasoconstriction, increasing r_a/r_v and leading to a shift of fluid from ISF to plasma (largely in skin and muscle). It is seen as a fall in hematocrit, and is usually complete within 30 minutes of the cessation of bleeding.[91]

In most tissues a local increase in P_v is associated with constriction of the local arterioles, increasing r_a/r_v and tending to minimize the increase in P_c. This phenomenon has been called the veno-arteriolar response, and appears to be a local response dependent on the presence, but not the central connections, of the sympathetic nerves.[51] It is largely responsible for the smaller increase in P_c than either P_a or P_v in the skin of the human foot as the subject moves from a supine to a standing position (Figure 9.13). Although P_c has to remain above P_v, it approaches P_v very closely when the subject is standing still. As soon as the subject moves, P_v falls. With an efficient muscle pump acting on the veins in the leg, P_v may be reduced from 120 to 130 cmH_2O when the person is standing still, to less than 30 cmH_2O in within a few seconds of starting to walk, and P_c presumably is reduced.

Landis[61] argued that P_c was the most variable of the Starling pressures in human subjects, drawing attention to the large changes in its value that followed changes in posture. P_c is also the one Starling pressure that can be regulated quickly in parallel with the local blood flow, inducing fluid shifts between the circulation and the ISF that appear to improve the chances of the organism's survival.

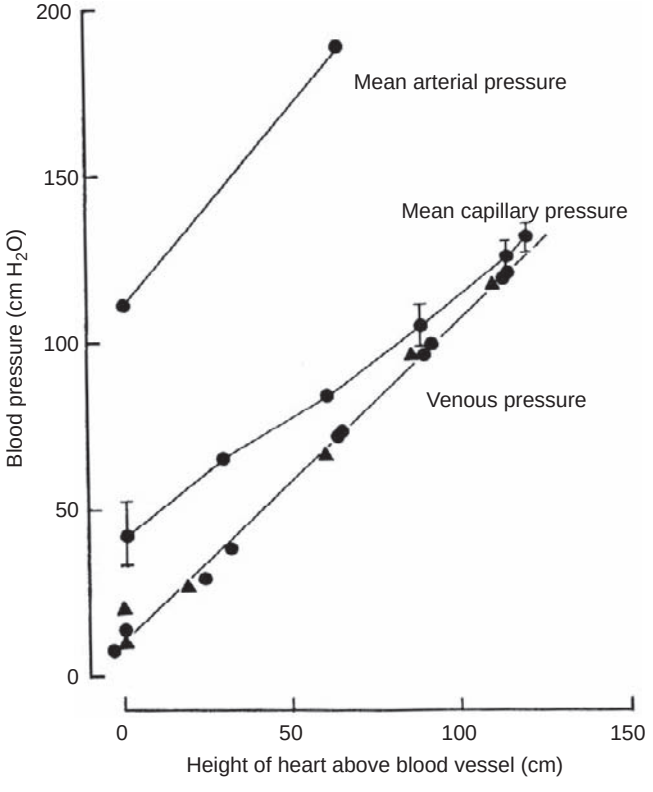

FIGURE 9.13 **Relation between the local blood pressure in the feet and the height of the heart above the feet in two normal subjects in supine, sitting, and standing positions.** Mean values for capillary pressure were based on direct measurements (by micropuncture) of capillary loops in the nail fold of the great toe. *(From ref. [62]. With permission.)*

Plasma Oncotic Pressure

Although reduced levels of circulating plasma proteins may be associated with edema, the steady-state relations between edema formation and plasma protein concentration are complicated by adjustments of microvascular pressures, and of ISF hydrostatic and oncotic pressures.[90] There is evidence to suggest that the oncotic pressure difference may be adjusted by atrial natriuretic peptide regulating the transport of proteins from plasma to ISF.[31,127]

In normal healthy subjects, oncotic pressure of the arterial plasma may be regarded as constant in the short-term. The plasma oncotic pressure, however, may increase considerably as blood flows through the microcirculation under conditions where the filtration rate becomes a significant fraction of the plasma flow. In most microvascular beds, L_P is too low for this to be significant, but it does occur in the renal glomerular capillaries, where L_P is very high,[16] and in the microcirculation of the feet of human subjects during prolonged standing or sitting, where P_c is high and plasma flow is very low.[40,87,89] In the glomerular capillaries it underlies the dependence of glomerular filtration rate upon renal blood flow (see Chapter on Glomerular Filtration).

Interstitial Hydrostatic Pressure

Before 1963, P_i was believed to approximate to atmospheric pressure in non-edematous tissues and steady fluid filtration, which expanded ISF volume, was thought to increase P_i proportionately. In this way, the increase in P_i would reduce the difference in hydrostatic pressure across microvascular walls, and so limit the rate of filtration protecting the tissues from edema.

The pioneering work of Guyton and colleagues showed that P_i of subcutaneous tissues and many others was 4 to 7 mmHg below atmospheric pressure.[46,47,48] After much controversy, sub-atmospheric or negative values for P_i in non-edematous tissues have been confirmed using a series of different techniques. There is some variation from tissue to tissue, most negative values being found in the lung and positive values being found in the kidney with the subcutaneous tissues of many mammals being in the range of -0.5 to -2.0 mmHg.[10,99]

At an early stage in his investigations, Guyton[47] showed that expansion of the ISF by filtration from the microvasculature quickly raised P_i to atmospheric pressure. Further expansion of the ISF volume, however, was accompanied by little change of P_i in most tissues. These relations between P_i and ISF volume have been extended and confirmed by others (see Figure 9.14 and [134]). Whereas there have been minor differences in some of the absolute values reported by different investigators, the general picture of a steep relation between P_i and ISF volume (low interstitial compliance) at normal and at low ISF volumes, and a flat relation between P_i and ISF volume (high compliance) when ISF volume is slightly expanded and P_i has risen to atmospheric pressure, has been widely confirmed (see Figure 9.14). The renal interstitium appears to be an exception to this general pattern. In the kidney, P_i is $+4$ to $+6$ mmHg, and increases and decreases linearly with ISF volume.[41] It has been argued that, in the kidney, P_i does fulfill the role of limiting the expansion of ISF volume, and promotes the uptake of fluid and solutes (including macromolecules) by the microcirculation.[10,69,70] For a more detailed discussion of the role of P_i in trans-capillary fluid exchange the reader is referred to the recent review of Reed and Rubin.[100]

Interstitial Oncotic Pressure

Measurements of ISF oncotic pressure are usually global values for a particular tissue. The values of importance for microvascular fluid exchange, however, are those for the newly formed ISF in contact with the abluminal surface of the ultrafilter within walls of the microvessels. Here, we have to be guided by theory. Equations (9.12) and (9.13) argue that if microvascular permeability of a solute is finite, the concentration of that solute in the ISF ultimately depends on its permeability and the rate of fluid filtration through the microvascular walls. If the Péclet number is zero (net filtration = 0), the concentration of a protein such as serum albumin in the interstitial fluid, C_i, will rise until it equals its plasma concentration. In the presence of net filtration from plasma to ISF, the concentration of plasma protein in the newly formed ISF will fall, reaching a plateau when C_i approximates to $C_p(1 - \sigma_f)$, as shown in the upper panel of Figure 9.15. The effective osmotic pressure difference exerted by albumin (and other large plasma protein molecules) across microvascular walls ($\sigma\Delta\Pi$) under conditions of steady fluid filtration varies with the filtration rate. This variation is shown in the lower panel of Figure 9.15. It can be estimated as follows:

$$\sigma\Delta\Pi = \sigma(\Pi_c - \Pi_i) = \sigma_d RT(\gamma_c C_c - \gamma_i C_i) \qquad (9.16)$$

The symbols γ_c and γ_i are the osmotic coefficients of albumin at its concentrations in capillary plasma and ISF. If they are approximated by a single value γ, Eq. (9.16) can be developed using Eq. (9.13)[75]:

$$\sigma_d\Delta\Pi = \sigma_d RT\gamma(C_c - C_i) = \sigma_d\sigma_f RTC_c\left(\frac{1 - e^{-Pe}}{1 - \sigma_f e^{-Pe}}\right) \qquad (9.17)$$

Equation (9.17) provides an explicit statement of the effective osmotic pressure difference exerted by a plasma protein across microvascular walls in terms of the filtration rate and through the Péclet number, the permeability coefficients P_d and σ_f of the vessel walls to the protein. Increases in J_V increase Pe and as e^{-Pe} approaches zero, $\sigma_d \Delta\Pi$ approaches a limit of $\sigma_d \sigma_f \Pi_c$, or approximately $\sigma^2 \Pi_c$.

Both P_i and π_i change[75] with fluid filtration rate, and since they themselves influence J_V, after a step change in P_c, an initial change of J_V is likely to be followed by a further changes as P_i and Π_i adjust to their new steady-state values. Thus, we should expect there to be differences between the initial transient changes in J_V and the steady-state values, and we shall consider these differences next.

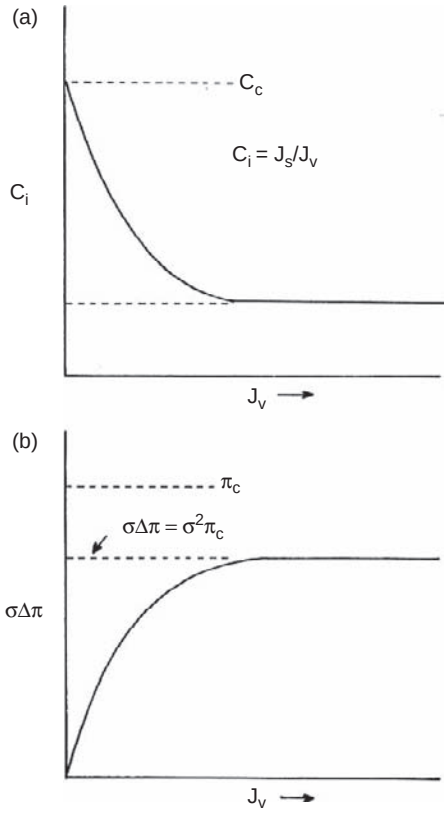

FIGURE 9.15 (a) Steady-state relations between the concentration of proteins (C_i) in capillary ultrafiltrate and the capillary filtration rate, J_V. The limiting value of C_i is $C_c(1 - \sigma)$ where C_c is the concentration of protein in the capillary. (b) Steady-state relations between the effective oncotic pressure across the walls of the microvessel ($\sigma\Delta\Pi$) consequent to changes in C_i and J_V. The oncotic pressure of the plasma, Π_c, is indicated as is the maximum value of $\sigma\Delta\Pi$. *(From [77]. With permission.)*

Transient and Steady-State Fluid Movements through Microvascular Walls

Figure 9.16 shows the results of an experiment on a single mesenteric capillary perfused with a Ringer solution containing serum albumin and the macromolecule Ficoll 70.[84] Both the immediate (transient) and steady-state values of fluid filtration were measured following step changes in capillary pressure. The transient changes (open circles) were measured after the vessel had been perfused at high pressure (35–50 cmH_2O) for several minutes, and then the pressure lowered to a predetermined value. The steady-state measurements (solid circles) were made after the vessel had been perfused for several minutes at that pressure, and preliminary measurement suggested a steady-state had been achieved. The transient values of J_V/A are related to P_c in the same linear fashion predicted by the standard Starling equation (Eq. (9.14)), and as shown by a similar experiment in Figure 9.12. This is the expected relation between ΔP and J_V/A when ΔP is varied and $\sigma_d \Delta\Pi$ remains constant. The steady-state measurements (solid circles) can be described by a non-linear (hockey stick) curve which can be predicted using Eq. (9.17) to calculate $\sigma_d \Delta\Pi$.

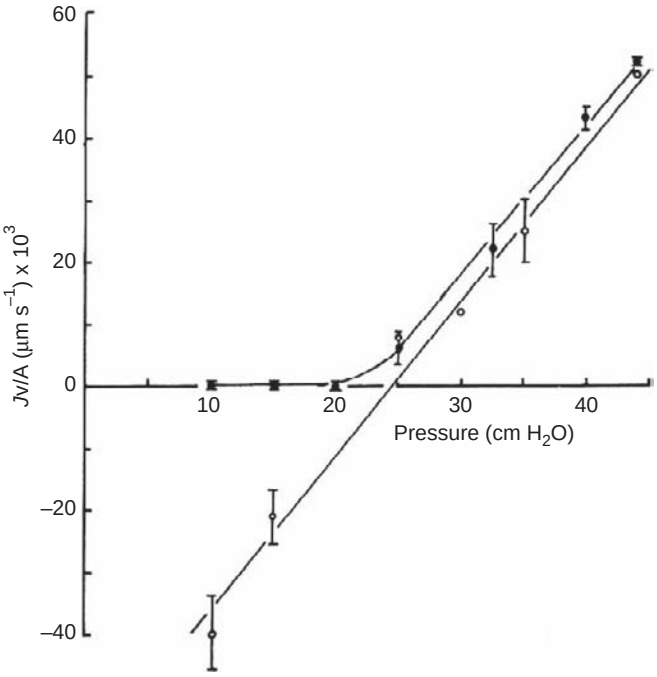

FIGURE 9.16 **The relations between fluid filtration and absorption (J_V/A) and microvascular pressure in a single frog mesenteric microvessel under transient (o) and steady-state (●) conditions.** Perfusate oncotic pressure was 32 cmH_2O. The oncotic pressure difference was the same at all values of J_V/A under transient conditions, but varied with J_V/A in the steady-state in the way indicated in Figure 9.15b. Note that absorption of fluid from the tissues is seen only under transient conditions. *(From ref. [82]. With permission.)*

Here, Π_c is constant, but Π_i varies with J_V, which changes *Pe*.

When P_c is greater than the effective osmotic pressure opposing filtration, both transient and steady-state values lie close together, and the linear portion of the steady-state relation at these higher values of ΔP has a slope of L_P, and is described by the following expression:

$$\frac{J_V}{A} = L_P(\Delta P - \sigma_m^2 \Pi_c) \tag{9.18}$$

At low values of P_c the transient and steady-state values of J_V/A deviate considerably with no fluid uptake from the tissue occurring under steady-state conditions. Not only are these results consistent with the theoretical picture, but analysis of the steady-state data also allows estimates to be made for both σ_m and P_d (the macromolecular permeability), which agree quantitatively with other determinations.[84] One surprising observation made during the measurement of the steady-state relations on single mesenteric capillaries was the relatively short time (2–5 minutes) required for a new steady-state to be established after capillary pressure had been changed.[84] This drew attention to the importance of the value of Π_i in the small volume of ISF in contact microvessel, and the relative lack of importance of the value of Π_i for the ISF of the entire tissue.

Figure 9.17 summarizes the transient and steady-state changes in fluid filtration and absorption in a microvessel of constant permeability, perfused at a rate sufficient to keep the plasma oncotic pressure constant. The dashed lines are drawn with a slope = L_P for the vessel. The solid line indicates the steady-state relations between J_V/A and ΔP. If P_c initially has a value, A, which is less than the plasma oncotic pressure, and remains constant for long enough for a steady-state to be established (at point T), a subsequent increase in P_c from A to B leads to a rapid increase in filtration (T→W). J_V then attenuates (to X), as Π_i is reduced and P_i increases. If P_c is then returned to A, fluid uptake from the tissues occurs (X→S), and the rate of absorption diminishes as Π_i increases returning J_V to its initial level of T.

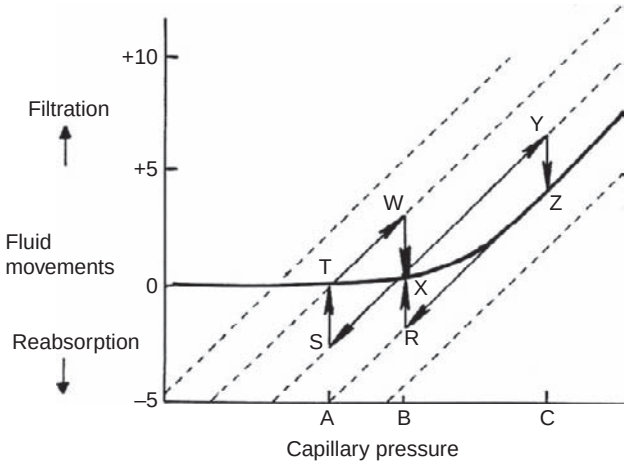

FIGURE 9.17 **Transient and steady-state relations between fluid movements and microvascular (capillary) pressure.** The dashed lines have slopes equal to L_P. The arrowed straight lines show transient changes in fluid movements with changes in pressure. The OTXZ (heavy line) represents the steady-state relation between J_V/A and capillary pressure. *(From ref. [81]. With permission.)*

In the pulmonary microcirculation, mean values of P_c are usually well below Π_c, and fluid movements fluctuate around a point half-way along the flat part of the steady-state relationship. Small changes in P_c lead to changes in filtration or absorption that are rapidly checked as a new steady-state is established. So long as $P_c - P_i$ is greater than $\Pi_c - \Pi_i$, there is a low level of fluid filtration into the tissues that is balanced by lymph drainage.

The steady-state analysis predicts that when the exchange vessels are finitely permeable to macromolecules, and there is no source of ISF other than the ultrafiltrate from these vessels, fluid absorption from the tissues is transient, and low levels of fluid filtration from blood to the tissues maintain the differences in oncotic pressures between the plasma and the ISF. The sustained levels of fluid filtration are matched by lymphatic drainage from the tissue, so that ISF volume remains approximately constant. Providing that the time-averaged mean P_c in most tissues approximates to the plasma oncotic pressure, this picture is consistent with blood–tissue fluid balance. It is not consistent, however, with the popular representation of the Starling Principle, which depicts fluid being filtered into the tissues from the arterial end of a capillary and absorbed from the tissues at its venous end. Quite apart from the lack of evidence for this picture, the steady-state analysis predicts that rising concentrations of macromolecules around the venular regions of the vessel would bring absorption to a halt. The experimental and theoretical arguments against this textbook picture of the filtering-absorbing capillary have been forcefully expressed in a series of publications by Levick.[62,63]

Steady-State Fluid Uptake into Microvessels Associated with Absorptive Epithelia

Continuous uptake of fluid into the microcirculation does occur in tissues such as intestinal mucosa, the post-glomerular capillaries of the renal cortex, and the ascending vasa recta of the renal medulla. Here, however, the bulk of the ISF is not formed by filtration from the capillaries, but by the secretion of

protein free fluid from the adjacent epithelia. In intestinal mucosa and in renal cortex, the large fluid uptake from the ISF into the blood capillaries is accompanied by a very much smaller flow of ISF into the lymphatics.[43,44] Although only a fraction of the fluid is absorbed from the ISF, the lymph flow is sufficient to clear proteins and keep their ISF concentrations low.

The renal medulla, however, has no lymphatics and special mechanisms appear to operate here. The continuous addition of protein free fluid into the medullary ISF is matched by the uptake of fluid into the ascending vasa recta (AVR). The AVR have relatively low σ to plasma proteins (0.7 to albumin). This allows the absorbed fluid to carry protein from the ISF into the blood. The uptake of labeled proteins from medullary ISF into the blood has been demonstrated directly,[125] and estimates of P_c, P_i, Π_c, and Π_i in and around the AVR indicate that these favor fluid uptake.[70] Theoretical studies have supported this "bootstrap" mechanism, whereby plasma proteins are carried up their own concentration gradient by the osmotic flow that arises from that same gradient.[70,131,138] In addition, unusual structural features of the ascending vasa recta, and the low compliance of the renal interstitium, ensure that fluid uptake is maintained even if Π_i increases. The low compliance means that P_i is high, and rises if ISF volume expands to levels that may equal or even exceed the pressure in the ascending vasa recta. When this occurs the vessels do not collapse as there are fine projections from their endothelial cells, which are inserted into the basal laminae of neighboring vessels and tubules, holding them open.[69] Because L_P of these fenestrated vessels is very high, an increment of P_i over P_c of only 1.0 to 2.5 cm H_2O is sufficient to account for the clearance of all fluid entering the medullary ISF from the loops of Henle and collecting ducts.[69] A more detailed discussion of the special features of the extra-glomerular renal microcirculation is given elsewhere in this volume.

Starling Pressures and Local Lymph Flow

In most tissues, ISF volume is maintained by a low level of filtration from the microcirculation being matched by an equal efflux of fluid from the tissue in the lymph. From this, one would anticipate that the magnitude of the lymph flow from a tissue could be estimated from the mean Starling pressures, the L_P, and the exchange surface area of the microcirculation. In an incisive review, Levick[62] pointed out that where the mean Starling pressures have been measured, they predict much greater filtration rates than the lymph flow and the lymph protein concentration would indicate. From 15 sets of data, he estimated P_0, the net pressure opposing filtration from the following relation:

$$P_0 = \sigma_m(\Pi_c - \Pi_i) + P_i \tag{9.19}$$

When values of P_0 are compared with direct measurements of pressure in post-capillary venules, P_{Vc}, it is found that P_{Vc} is nearly always greater than P_0, and in several cases P_{Vc} exceeds P_0 by 5 to 10 mmHg (Table 9.2). Net driving pressures for filtration of this magnitude would be expected to result in high lymph flows, but in most of the tissues concerned (e.g., subcutaneous tissue, muscle, and mesentery), the basal lymph flows are so low that they are difficult to measure.

To account for these discrepancies, Levick[62] suggested that vasomotion, the spontaneous contraction and relaxation of arteriolar smooth muscle, might be responsible for large variations in P_c, and that P_c measurements tended to be made in vessels where there was brisk flow and a higher than average P_c. The few direct estimates of P_c during vasomotion, however, suggest that the fluctuations are relatively small.

An alternative hypothesis was put forward by Michel[79] and Weinbaum.[132] Independently, they both realized that if the filtrate leaving the "small pores" was uncontaminated by fluid containing the higher concentration of macromolecules, the effective $\sigma\Delta\Pi$ opposing filtration may approximate to that across the small pores. This would be considerably greater than that calculated from global values of Π_i, and would increase the force opposing filtration (P_0), reducing filtration rates to levels consistent with basal rates of lymph flow. The significant deviations between P_0 and P_{Vc} reported by Levick[62] are found in microvessels with continuous endothelium, where the small pores are the interstices of the glycocalyx lying above the intercellular clefts. The downstream side of the

TABLE 9.2 Starling Pressures in Muscle, Mesentery, and Subcutaneous Tissues at Heart Level

Species and Tissue	Π_c	Π_i	P_i	P_o	P_c	$P_c - P_o$
Dog, skeletal muscle	26.0	11.0	−2.0	13.0	12–20	−1 + 7
Cat, mesentery	19.1	6.1	0	13.0	23.5	10.5
Human, chest subcutis	26.8	15.6	−1.5	9.7	>15.0	>5.3

P_o is calculated from Eq. (9.17) assuming that $\sigma = 1$ and thus is an overestimate. P_c is based on direct measurements in venules or venular capillaries, and is therefore an underestimate of mean P_c. The difference ($P_c - P_o$) is consequently the minimum difference based on available data. From Levick, J. R. (1991). Capillary filtration–absorption balance reconsidered in light of dynamic extravascular factors. *Exp. Physiol.* **76**, 825–85.[60]

microvascular ultrafilter is therefore the abluminal surface of the glycocalyx, which is separated from the ISF immediately outside the microvessel by the intercellular cleft with its tortuous pathway through the tight junctions. The pathway for macromolecules (the large pores) is either through the endothelial cell vesicles (via channels or by a fission–fusion mechanism) or by the very occasional leaky intercellular cleft. For the high protein concentration of this large pore filtrate to mix with that emerging from the small pores, protein molecules would have to diffuse back through the intercellular clefts to the site of ultrafiltration at the glycocalyx. Although this pathway is short, diffusion has to occur against the flow of fluid from the vessel lumen. The velocity of this filtrate is increased ten-fold or more as it passes through the breaks in the tight junctions. Rough calculations[79] and a detailed mathematical model[55] both indicate that, even with filtration rates driven by pressure differences across the glycocalyx as small as 1–2 cm H_2O, the fluid velocity through the breaks in the tight junctions impose a major barrier to the diffusion of proteins through the clefts in the luminal direction. These levels of filtration, nevertheless, are consistent with basal rates of lymph flow.

The hypothesis has been examined experimentally in single frog mesenteric capillaries[54] and in rat mesenteric venules.[3] In these studies, it was found that even when the interstitial concentration of serum albumin in contact with the outside wall of a vessel was the same as that in the perfusate, fluid movements through the vessel wall were opposed by oncotic pressures much greater than those estimated from global values of Π_i. The authors concluded that these observations were consistent with the oncotic pressures opposing fluid filtration from continuous (non-fenestrated) capillaries are developed across the glycocalyx, and that global values of Π_i do not determine fluid exchange directly. Some of their data are shown in Figure 9.18.

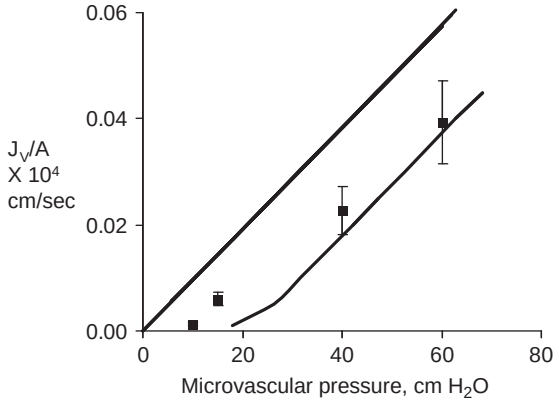

FIGURE 9.18 **Steady-state relations between microvascular filtration (J_V/A) and pressure in rat microvessels when the interstitial oncotic pressure is varied by superfusion.** The vessel is perfused with a 5% serum albumin solution (Π_c = 21.25 cmH_2O). The points are mean values from four experiments in which the ISF concentration of albumin in contact with the outside of the vessel was equal to the perfusate concentration. The curve on the left is the relation predicted when the interstitial concentration of albumin in contact with vessel is the same as the perfusate concentration; that on the right shows the relations when no albumin is added to the superfusate. Note that at high P_c, J_V/A has values comparable with those expected with no albumin present outside the vessel. Only at low J_V/A, when P_c is less than Π_c, does Π_i appear to influence the steady-state. *(From ref. [3].)*

Transient and steady-state fluid exchange and their relations to local lymph flow have been reviewed recently by Levick and Michel.[64]

Microvascular Blood Flow and Solute Transport

The rate of delivery of molecules, and the rate of their clearance to and from a tissue, depends on both microvascular blood flow and microvascular permeability. Where permeability is very high, transport depends on blood flow alone and is said to be "flow limited." Where solute permeability is low, increasing blood flow increases transport to a progressively smaller extent, and when further increases in blood flow no longer increase transport, transport is said to be "*diffusion limited*" or "*permeability limited*." Renkin set out the general principles of blood–tissue exchange in a series of papers between 1955 and 1970.[101,102,104,105] Figure 9.19 is taken from Renkin's work, to illustrate *flow limited* transport of antipyrene and *permeability limited* transport of urea between the microcirculation of skeletal muscle tissue. Both solutes are usually considered to have high permeabilities, but it is seen that as flow increases, the transport of urea becomes independent of flow. This maximum level of transport is determined by the product of P_d to urea and the surface area of the exchange vessels. Antipyrene is lipid soluble and has a much higher permeability than urea. Its transport remains proportional to flow over the range investigated.

Insight into the relations between blood flow and solute transport can be gained by considering the plasma or blood concentrations of a diffusible solute as it flows along an exchange vessel. If the Péclet number for the solute is low (as it is for most small solutes), its unidirectional transport through the vessel wall from a small volume of plasma, ΔV, flowing along the vessel is proportional to the product of its concentration, C, in that volume and its permeability, P_d (Figure 9.20). It is also proportional to the surface area, ΔS, with which ΔV makes contact as it flows along the vessel.

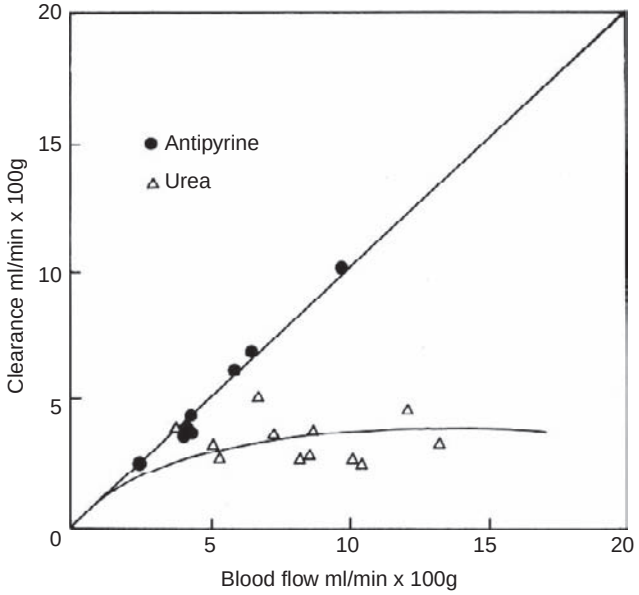

FIGURE 9.19 **Relations between blood–tissue clearance and blood flow for a small lipid soluble solute (antipyrene) and a small hydrophilic solute (urea) in skeletal muscle.** Whereas the clearance of antipyrene is limited only by blood flow over the range of flows investigated, clearance of urea is limited by its microvascular permeability, and is independent of flow when this exceeds 5 ml min − 1 100 g − 1 tissue. *(Re-plotted from ref. [102]. With permission.)*

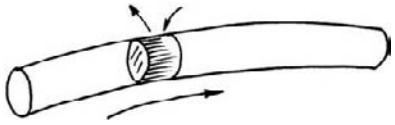

FIGURE 9.20 **Model illustrating the principles of diffusion and flow in microvascular exchange.** Exchange of solute is considered to occur from a small volume as it flows along a cylindrical microvessel.

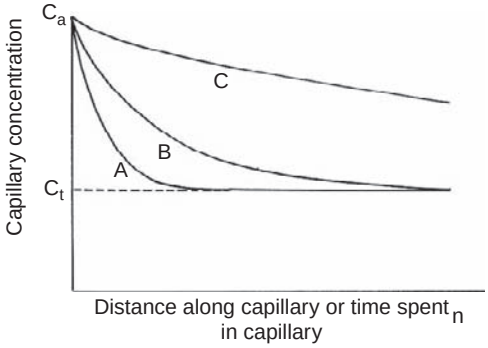

FIGURE 9.21 **Decrease in plasma concentration of three solutes as they equilibrate with the tissues during their passage along a microvessel.** The vessel is more permeable to A than to B, and more permeable to B than to C. Because equilibration is achieved for A and B before the blood leaves the vessel, net transport for these substances can only be increased by increasing the flow (cf. curve for antipyrene in Figure 9.20). Substance C does not equilibrate, and its transport is said to be permeability- or diffusion-limited (cf. with curve for urea in Figure 9.20). *(From ref. [71]. With permission.)*

The changes in C resulting from unidirectional loss of solute from ΔV are given by the following equation:

$$-\Delta V\frac{dC}{dt} = P_d \Delta A.C \tag{9.20}$$

For a cylindrical vessel, the ratio of $\Delta A/\Delta V$ is constant and is equal to the ratio of surface area to volume for the entire vessel, A/V. Thus:

$$C_{(t)} = C_0 \exp\left(\frac{-P_d A.t}{V}\right) \tag{9.21}$$

where $C_0 = C$ at time = 0, that is the concentration of solute at the point of entry to the vessel, and this would usually be the arterial concentration, C_a. When $t = \tau$, the transit time through the vessel, $C = C_v$, the venous concentration of the solute. Furthermore, V/τ is equivalent to the flow through the vessel, F, so that Eq. (9.19) can be rewritten as:

$$C_V = C_a e^{-P_d A/F} \tag{9.22}$$

The net transport of solute from blood to tissue is equal to J_S:

$$J_S = F(C_a - C_v) = FC_a(1 - e^{-P_d A/F}) \tag{9.23}$$

Since the clearance of solute from blood to tissue is J_S/C_a, clearance becomes:

$$Clearance = F(1 - e^{-P_d A/F}) \tag{9.24}$$

Renkin used expressions such as Eq. (9.24) to describe data such as those shown in Figure 9.19.

Equation (9.21) can be used to give additional insight into the nature of flow-limited and permeability limited transport. In Figure 9.21, Eq. (9.21) has been used to calculate the changes in concentration that occur in a bolus of blood flowing along a single vessel. The three curves represent the concentrations for three solutes that have different values of P_d. It is assumed that the flow is constant, so that distance and time are directly proportional to one another. The three curves start from the same value of C_a and finish at three different points, the venous concentrations. From Eq. (9.23), the net transport of solute from blood to tissue, J_S, for each solute is $F(C_a - C_v)$. F varies inversely with τ so that if F is doubled, τ is halved. Because solute A reaches its end capillary concentration before it has spent half its residence

time in the vessel, doubling F will not change $(C_a - C_v)$. Doubling F will therefore double J_S and the relation between clearance and blood flow is linear so that transport is flow-limited over this range of flows, and will resemble that for antipyrene in Figure 9.19. By contrast, for solute C, halving τ almost halves $(C_a - C_v)$, so that the product, F $(C_a - C_v)$ remains almost constant as flow is increased. Transport is now "permeability-limited," and the relation between clearance and flow resembles that shown for urea at high blood flows in Figure 9.19. In theory, the transport of all solutes is limited by permeability if blood flow is high enough. In practice, the permeability of microvascular walls to some substances is so high that transport is always flow-limited.

Although so far we have discussed only solute transport from blood to tissue, equivalent expressions describe the clearance of substances from tissues to blood, so long as the barrier to diffusion through microvascular walls is greater than the resistance to diffusion through the tissues. The latter is certainly not true when the clearance of highly diffusible lipid soluble solutes is being considered. For these molecules, transport between blood and tissues is determined more by the gradients of their concentration in the tissues.

The Renkin expressions (e.g., Eqs. (9.22) and (9.24)) have provided the basis of understanding blood tissue exchange, but Renkin himself has drawn attention to their limitations.[105] Considerations of heterogeneity of microvascular flow and permeability in different vessels in a microvascular bed have led to sophisticated models for the analysis of blood tissue exchange in intact tissues.[13,105] These models may well have to be revised in the light of observations on the relations between flow and transport of small hydrophilic solutes in single capillaries *in situ*. Indications that P_d may itself vary with flow have been confirmed, and greatly extended in a series of measurements on single microvessels of frogs and rats.[57,58,86] The increase in P_d with flow can be inhibited in rat vessels with NO-synthase blockers, and by procedures that raise intracellular cAMP levels. The effects of flow P_d are largest for small ions and hydrophilic molecules. They appear to involve a pathway more selective than the traditional small pores, and therefore make little contribution to fluid exchange.[86]

The implications of these findings for blood−tissue transport in the intact animal have yet to be assessed, but it could mean that increases in P_dA that, in the past, have been interpreted as the consequence of increases in A, are the result of changes in P_d, and a common set of control mechanisms regulate the permeability and the perfusion of the microcirculation.

Increased Microvascular Permeability

Over 50 years ago Majno and Palade[71] demonstrated that the classical mediators of acute inflammation (e.g., histamine, serotonin) increased vascular permeability by inducing openings in the endothelia of the post-capillary venules. The openings were believed to lie between the endothelial cells, and Majno[72] suggested that they were formed by the contraction of adjacent endothelial cells away from each other. This view, however, was controversial, and continues to be so.[5]

Two groups working in the mid-1990s, reconstructed openings in endothelium from electron micrographs of ultrathin serial sections of venules exposed to a range of mediators to increase their permeability. Whereas with some stimuli (e.g., substance P and PAF), the openings were predominantly paracellular with other stimuli (e.g., VEGF and A23187), they passed through the body of one cell close to the intercellular cleft, but clearly separate from it.[35,88] It seems that transcellular openings may be derived from vesicles or vacuoles in the endothelium.[88] Dvorak and her colleagues identified fused clusters of vesicles and vacuoles, the vacuolar-vesicular organelles (VVOs) in the highly permeable vessels of tumors as transcellular pathways.[33] Subsequent work revealed that VVOs were present in normal (healthy) vessels, but did not form a pathway for macromolecules until the tissues were stimulated by mediators, when they develop into transcellular openings.[34]

Considerable progress has been made unraveling the signaling events that follow the binding of an agonist with its receptor on the venular endothelial cell and the appearance of openings in the vessel wall.[27,28] From studies both in cultured endothelial cells and in intact vessels, it is clear that the early stages of signaling involve a steep rise in the intracellular activity of free Ca^{2+}. The agonist molecules, such as histamine and ATP, bind to endothelial cell membrane receptors linked to G-proteins, which then activate phospholipases (particularly β and γ isoforms of phospholipase-C) that release inositol tri-phosphate (IP_3) and di-acyl glyceric acid (DAG) from the membrane lipids. IP_3 releases Ca^{2+} from the intracellular Ca^{2+} stores, and this in turn leads to the opening of Ca^{2+} channels in the cell membrane so that the Ca^{2+} activity of the cytosol is rapidly raised by the combined influx of Ca^{2+} from both the stores and ISF (for review see [28]). Agonists such as VEGF bind to a tyrosine kinase receptor that phophorylates PLC-γ, and activate a DAG signal that opens membrane Ca^{2+} channels directly.[11,97] With VEGF, the rise in cytostolic Ca^{2+} is achieved entirely by influx from the ISF, and is independent of its release from the intracellular Ca^{2+} stores.

The sequence of events that follows the rise of cytostolic Ca^{2+} activity remains less clear, and this is particularly true of the final stages when the endothelial openings are formed. Several different studies have shown that, in intact venules, there is cascade involving NO and cGMP downstream from the initial peak of intracellular Ca^{2+} activity.[12,27] The effects of PAF and VEGF on permeability are prevented or greatly attenuated if the enzymes of the NO-synthase − cGMP cascade are blocked.[50,135] The details of other events are continually changing as new investigations are published, and the reader is referred to a recent review of Curry and Adamson,[28] and other contributors to the same issue of *Cardiovascular Research*.

Measuring Increases in Vascular Permeability

To assess the role of different molecules in signaling or in the mechanics of increased permeability, it is necessary to have trustworthy methods for measuring permeability. Earlier we have seen that the permeability coefficients, L_P, σ, and P_d provide quantitative estimates of the permeability properties of microvascular walls. Figure 9.22 shows the results of an experiment on a single rat venule where values of J_V/A were measured at two different microvascular pressures before and after exposure to histamine.[82] From this experiment, the values of L_P and σ can be estimated and interpreted in terms of endothelial openings forming and closing.

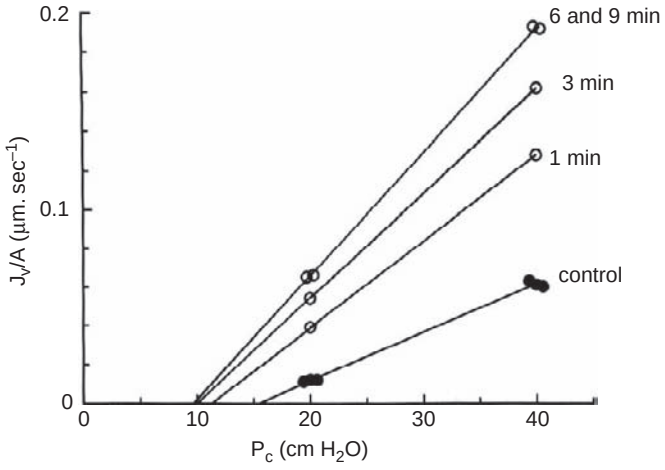

FIGURE 9.22 **Relations between fluid filtration (J_V/A) and microvascular pressure (P_c) before and following addition of histamine to the solution washing a single venule in rat mesentery.** Note how the slope of the relation between J_V/A and P_c (L_P) increases rapidly and the intercept with the P_c axis ($\sigma\Delta\Pi$) falls over the first 6min of exposure to histamine. *(From ref. [80].)*

While this practice of measuring permeability coefficients to chart increases in vascular permeability is used by some investigators, and provides reliable information, the great majority of reports of increased permeability are based on estimates of the rates of transport of macromolecules through endothelia. In the latter case the results should be viewed critically until the reader is satisfied that changes in permeability really have been demonstrated. In this final section, we discuss how results from two frequently used assays of changes in permeability can be easily misinterpreted.

A comparison of the rates of labeled serum albumin transport through monolayers of cultured endothelium *in vitro* in the absence and presence of various concentrations of a potential mediator are frequenty used to assay the latter's potency in increasing permeability. The most important question to ask of these studies is the absolute value of the permeability of the monolayer under control conditions. This is often unavailable, as authors have expressed their results as relative increases in permeability. The reason for questioning these assays is that most published control values of P_d for endothelial monolayers to serum albumin are high[7] ($>10^{-6}$ cm.sec^{-1}). This leads one to suspect that endothelial monolayers form leaky barriers to macromolecules. Strengthening this criticism is the finding that thrombin, which increases permeability of endothelial monolayers by inducing large openings between the cells, has no effects on unstimulated microvascular endothelium *in vivo*.[1] Thrombin will increase permeability in microvessels that are already in a pre-inflammatory state.[32]

Other studies compare transport rates of labeled macromolecules into tissues *in vivo*. Many of these derive from the method described by Miles and Miles[85] in 1952. Here, labeled protein is injected into the circulation of an experimental animal (rat, mouse, guinea pig or rabbit) in which a relatively large area of its dorsal skin has been shaved. Small volumes of varying concentrations of a potential mediator, suitably diluted in physiological salt solution, are injected into the skin. To act as a control, a similar volume of the physiological salt solution containing no mediator is also injected. If the potential mediator does increase vascular permeability to macromolecules, label will accumulate in the area where the injections have been made, and these are then compared with the accumulation of label at the control site over the same period. Initially the labels used were blue dyes that bound to plasma proteins, and the degree of accumulation was estimated from the mean diameter of blue area around the injection site. Later, the technique was made more quantitative by extracting the dye from the tissue or by using radioactive agents. A further refinement was

measurement of the plasma concentration of labeled macromolecule during the period that it was accumulating in the tissue. From these data it was possible to estimate the clearance of label from the plasma in the test and control areas.

Although methods such as these are very widely used, the belief that changes in the flux of macromolecules from blood to tissues reflect changes in permeability quantitatively is only valid when all other factors determining the flux rate are constant. It is apparent from Eq. (9.10) that net transport has a convective component, and while an increase in L_P and a fall in σ might both be responsible for increasing J_V, the increase will only be proportional to the permeability change if $P_c - P_i$ is unchanged. Many of the molecules that increase permeability also cause vasodilatation of the arterioles, so that by reducing r_a/r_v they will also raise P_c (see Eq. (9.15)). A vasodilator might also open previously unperfused microvessels, increasing the area available for exchange in Eq. (9.10). In these ways, changes in local blood flow compromise the quantitative relation between changes in net macromolecular flux from blood to tissue and changes in permeability, and mean that permeability assays based macromolecular leakage can only be used as qualitative guides of changes in permeability unless additional evidence is available. Sometimes molecules that are vasodilators and have no action on vascular permeability are erroneously reported as amplifying or potentiating increased permeability. This error was exposed in experiments by Williams and Peck,[135] who showed that the effects of prostaglandins E_1 and E_2 in enhancing protein leakage in inflammation were due to its action as a vasodilator. Not only did the effectiveness of the prostaglandins to enhance protein leakage correlate with their potency as vasodilators, but similar enhancement of protein leakage could be produced by other vasodilators not associated with inflammation. Finally, it is worth emphasizing that if σ to a macromolecule is high in non-stimulated endothelium, quite a modest fall in its value can have a large effect on the convective transport to that macromolecule. For example, if under control conditions σ to serum albumin at the wall of a venule is 0.98, and after exposure to a possible mediator σ falls to 0.80 (a reduction of σ of less than 20%), the convective component of albumin transport increases ten-fold in the presence of the mediator, even if P_c and L_P (and hence J_V) are unchanged. This is because the convective component is proportional to $(1 - \sigma)$, which increases from 0.02 to 0.2.

In conclusion, large changes in the net flux of macromolecules from blood to tissues usually indicate increased vascular permeability, but information obtained in this way is qualitative and should be treated as such unless strict control of J_V has been maintained. If one wants to measure changes in vascular permeability one should measure the changes in the permeability coefficients, for these are the functional measures of the properties of the endothelial barrier.

CHAPTER

10

External Balance of Electrolytes and Acids and Alkali

Man S. Oh

State University of New York, Downstate Medical Center, Brooklyn, NY, USA

This chapter will cover discussions on principles of external balance for electrolytes, and for acids and bases. The first section will deal with discussions on principles of electrolyte balance in general, and the second section discusses the acid–base balance.

PRINCIPLES OF ELECTROLYTE BALANCE

Introduction

Prolonged imbalance between input and output of most quantifiable elements in a living organism is incompatible with life. The duration of imbalance varies, but eventually balance must be restored for maintenance of survival. This rule applies to all quantifiable elements *in vivo* as well as *in vitro*. Red cell destruction equals red cell production. Oxygen uptake equals oxygen utilization. Sodium intake must equal sodium output, and water input must match water loss. Yet transient discrepancies occur regularly in living organisms, but balance is ultimately achieved. The same rule applies to the balance of any quantifiable elements in nature. The duration of imbalance is usually quite short in living organisms, because protracted imbalance results in death. However, not limited by survival, the duration of imbalance in nature could be more protracted.

The main aim of this chapter is to describe the underlying principles for eventual restoration of balance in nature, and then to extrapolate these principles to the understanding of human physiology, particularly the principles of fluid and electrolyte balance.

WHY IS BALANCE ALWAYS RESTORED?

The underlying mechanism that allows eventual restoration of balance is perfect and foolproof. As an example, the kidney is a central player in the restoration and achievement of fluid and electrolyte balance in living organisms, but the smartness of the kidney is not the reason for perfect balance. The kidney merely accelerates the process by utilizing a principle ubiquitous in nature, but it does not determine its ultimate outcome. The most crucial element of the control system that restores ultimate balance is that a discrepancy between intake and output inevitably leads to a change in total content of the element in the system, and the uncorrected imbalance is cumulative. When input is greater than output the content increases, and the continued imbalance keeps increasing the content. When output is greater than input the content decreases, and the continuing imbalance keeps decreasing the content. In a system with a limited capacity, a change in content of a substance alters its concentration; this invariably affects output, and sometimes also input. The key points here are: (1) an uncorrected balance invariably leads to a change in content; (2) a change in content leads to a change in concentration; (3) an altered concentration affects output or input; and (4) these effects are cumulative.

IS THE CAPACITY OF ANY SYSTEM ALWAYS LIMITED?

Is the capacity of any system always limited? The answer is yes. We often say: the sky has no limit. Yet

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00010-0

there is a limit even to the capacity of atmospheric air volume. The apparent air volume is about 4.08×10^{21} liters. (The apparent air volume is calculated considering that air is denser at sea level, and density declines progressively with rising altitude until there are no more air molecules. Thus, the apparent air volume is the theoretical volume that would be required if all the gases in the air were contained at the same concentrations as those at sea level at a pressure of 760 mmHg when the 1 mole of gas is contained in 22.4 liters.)

In recent years, the rising CO_2 concentration of the atmosphere and its impact on global warming is the source of a great deal of public concern. The rising CO_2 concentration implies that the amount of CO_2 added to the atmosphere is more than the amount eliminated from the atmosphere. However, the discrepancy will not and cannot remain permanent, because the CO_2 concentration in the atmosphere has a positive influence on the rate of its removal from the atmosphere. The main source of CO_2 addition to the air is the burning of fossil fuels (oil, gas, and coal). The total amount of CO_2 added is about 30 billion tons per year.[1] This amount added to the air volume of 4.08×10^{21} liters would increase atmospheric CO_2 concentration by about 3.74 ppm per year. Currently, the actual rise in CO_2 concentration is about 2 ppm per year. The difference, 1.74 ppm, is absorbed by the oceans, mostly by direct diffusion and some by diffusion into rain water entering the ocean. In the ocean, CO_2 is in equilibrium with bicarbonate and carbonate.[2] As the atmospheric CO_2 concentration increases, the amount entering the ocean would increase progressively. Since the industrial revolution, the atmospheric CO_2 level has been rising rapidly, because the rate of CO_2 addition has been increasing rapidly with the progressively greater consumption of fossil fuel worldwide. Once the rate of fossil fuel consumption stops increasing further, the rate of CO_2 removal will eventually equal the rate of CO_2 addition. Of course, it is quite likely that at the time of new balance, the earth could be much warmer and the ocean much more acidic, with major ecological changes. Nevertheless, imbalance does not last forever, because imbalance always leads to a new balance.

Many substances in the human body utilize the same principles to reach a state of balance. For example, if creatinine production is doubled in the absence of any change in GFR, serum creatinine would exactly double, at which point the renal excretion of creatinine would also double. At this point a new balance is reached between production and excretion. For some substances, a new balance is accelerated by physiological control mechanisms. For example, if sodium intake is doubled, renal sodium excretion will also double, but doubling of renal sodium excretion does not require doubling of serum sodium or total body sodium content, only a slight increase in sodium content of the body, because of the excellent renal regulation of sodium balance. By the same token, a reduction in sodium intake to 1/10 of the usual amount does not require sodium content of the body to decrease to 1/10 of normal when the balance is restored.

In the human body, the capacity for most substances is quite limited, and daily variations for most electrolytes are quite large in relation to total body content. Furthermore, there is a limit to which the organism can tolerate a deviation in the content of these substances. Therefore, survival of the organism demands the existence of certain physiological mechanisms to accelerate the compensation processes, to prevent a deviation from occurring to a lethal level.

Following is the sequence of events in the control system: a certain amount of an element is contained in a compartment, if input of the element into the compartment exceeds its output, the content will increase. The higher content influences the control mechanisms to reduce input or to increase output. As long as the discrepancy remains, the content will keep increasing, because the consequence of discrepancy is cumulative; the higher the content, the greater the effect on input or output. A cumulative change stops only when input equals output. When input is less than output, the opposite sequence of events restores the balance (Figure 10.1).

Restoration of salt balance will be used as an example. A person in a state of sodium balance has been ingesting 10 g of salt per day, and excreting 10 g of salt per day. Now, assume that a diuretic is given to this person. On the first day of diuretic therapy, salt output is 20 g per day, with net loss of 10 g of salt. The next day, although the diuretic dosage remains unchanged, salt excretion has to be less, for example, 15 g a day, because the reduction in effective vascular volume caused by the previous day's salt loss has activated salt-retaining mechanisms, and has reduced salt losing hormones. Still, the overall result is an additional negative balance of 5 g of salt. Although the negative balance is less on the second day, the cumulative loss (15 g) is greater on the second day than on the first, and the effective vascular volume is even lower on the second day than the first. The lower effective volume reduces salt output further to 12 g per day on the third day, with an additional negative balance of 2 g. The overall cumulative loss is now 17 g, resulting in a further decrease in effective vascular volume. As long as the salt output remains greater than salt intake, cumulative salt loss becomes larger and larger, albeit less steeply than before. Cumulative salt loss stops only when salt output equals salt intake. Indefinite net salt loss is theoretically impossible, because continued salt loss will ultimately cause such severe volume depletion that the

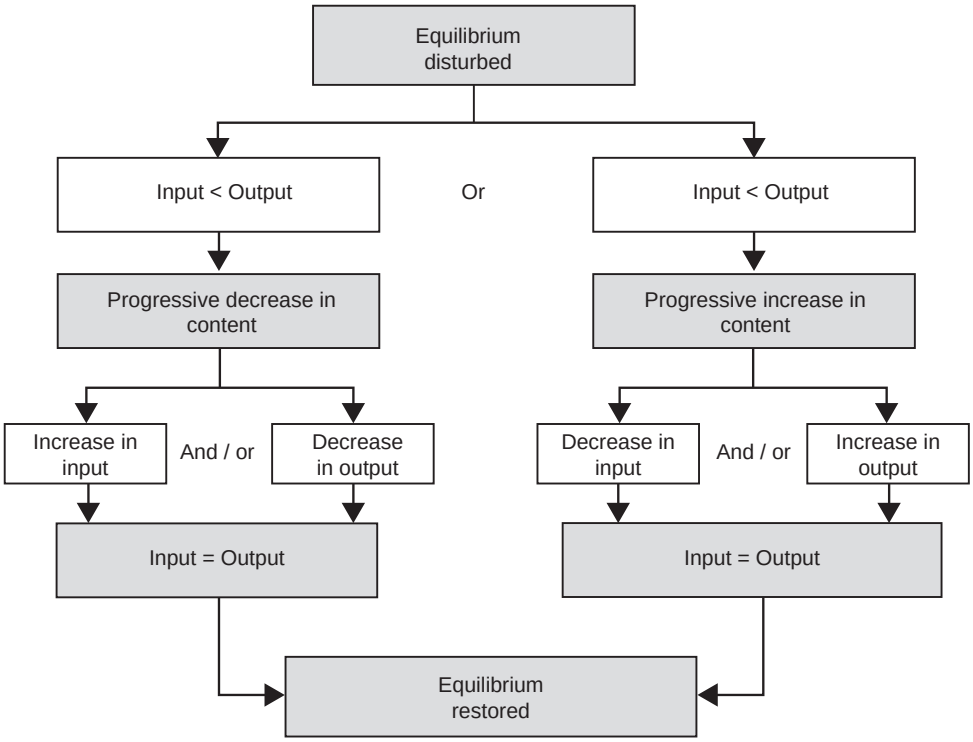

FIGURE 10.1 **Mechanisms by which balance is restored.**

person will become hypotensive, and salt excretion would stop completely. Of course, long before reaching such an extreme state, renal excretion of salt would decrease to a level equaling intake.

In the example given, what causes restoration of balance is not the smartness of the kidney or the cleverness of humoral mechanisms, but the principle of balance restoration, which is ubiquitous in nature. For example, sodium balance in a person on chronic diuretic therapy would still be restored in the absence of aldosterone, in which case the person could be quite sick with dehydration when balance is attained.

The same control mechanism explains why urinary excretion of potassium does not remain greater than intake in patients with primary hyperaldosteronism. With increased aldosterone, K output will initially exceed K intake. The resulting negative K balance causes hypokalemia, which in turn reduces urine K excretion. As long as K excretion exceeds K intake, serum K will decrease progressively until K excretion equals K intake. Occasionally, a patient dies of a cardiac arrhythmia before balance is attained. In the vast majority of cases, balance is achieved before the patient dies.

SPEED OF BALANCE RESTORATION

In a living organism, the speed of restoration of balance is teleologically determined. If an organism can tolerate protracted imbalance of a particular element without death or severe disability, balance need not be restored promptly. If quick restoration of balance is vital for survival, a mechanism for rapid restoration of balance is necessarily acquired in the process of evolution. Thus, the acceptable duration of discrepancy or alternatively speed with which restoration of balance is achieved, depends on the importance of maintaining the content of an element within a narrow range, in order to prevent the demise or serious disability of the organism. Four main factors influence the speed of balance restoration (Table 10.1).

For example, an adult of average size has about 40 liters of total body water, and daily intake and output of water is about 2 liters. Obviously, water output exceeding water intake by one liter a day would lead to fatal dehydration in 10 days to two weeks. Conversely, water intake exceeding water output by the same magnitude would lead to water intoxication and death. An opposite example is calcium balance. The total body calcium content of an average adult man is about 1,200,000 mg (60,000 mEq), and net daily external flux is about 150 mg (7.5 mEq). A daily negative balance of calcium of 100 mg for one year would reduce total body calcium by mere 36,500 mg; 3% of total body calcium content. Obviously, a negative calcium balance of such a magnitude, even for a protracted period, is not incompatible with life. Indeed, during the period of development of osteoporosis,

TABLE 10.1 Factors Influencing the Speed of Balance Restoration

1. Magnitude of flux.
2. Basal store.
3. Capacity for additional storage.
4. The physiological limit for deviation of the body content.

a substantial negative balance of calcium for 10 years or longer is a common occurrence. Similarly, a positive caloric balance of 500 calories a day for a year will result in a total positive balance of 182,500 calories ($500 \times 365 = 182{,}500$). This amount would result in an increase in adipose tissue weight of about 50 lbs, an undesirable situation, but with no immediate effect on survival.

A large storage capacity does not guarantee a protracted imbalance. A quantitative analysis must be applied before that conclusion is reached. Once it was widely accepted that a large store of alkali of the bone was responsible for the maintenance of stable serum bicarbonate concentrations in chronic renal failure, despite a substantial daily positive balance of acid.[3,4] However, this conclusion was reached without quantitative analysis. The bone content of alkali is indeed very large, but it is not sufficiently large to provide 19 mEq of alkali per day for six years in chronic renal failure. Since the total content of acid in the bone is about 25,000 mEq, a quick calculation would indicate that at a rate of consumption at 19 mEq per day, the entire bone content of alkali would be gone in about 3.6 years. Clearly, uremic patients with metabolic acidosis are in states of good or near acid–base balance, i.e., acid production equals acid excretion.

The cumulative net loss of a substance from the body cannot exceed the total amount of that substance contained in the body (Table 10.2). For example, one can conclude with certainty that a person who has total body sodium content of 3500 mEq could not have been in daily negative balance of sodium by 10 mEq per day for one year, since the total loss of 3650 mEq ($10 \times 365 = 3650$) would exceed the total body store of sodium. Even before exceeding the total body content, one cannot exceed a physiological limit of deficit for the substance. For example, potassium loss in excess of a third of the body store (3000 mEq) is usually fatal. Hence, you would reject a claim that a patient with Conn's tumor has been losing 20 mEq of potassium daily for three months, since loss of such an amount ($20 \times 30 \times 3 = 1800$ mEq) would certainly be lethal. In contrast, the body can tolerate a greater fraction of sodium loss. A person who loses half of the body's sodium would be gravely ill, but still alive.

While the total stored amount sets the absolute upper limit on losses, the amount that can be gained depends on the additional storage capacity, which varies widely with electrolytes. In the case of sodium, the storage capacity for additional Na^+ in the body is enormous. In certain edema-forming states, the Na^+ content may increase by 300% of the basal amount. Caloric balance is another example. In a normally-built adult, the total stored in fat and protein is about 130,000 calories. At the caloric consumption rate of 1200 calories per day, about 50% of the stored calories would be consumed in 55 days. In contrast, a person can gain as much as 500 lbs of fat, which are equal to 4,500,000 calories, about 35 times the normal caloric storage.

TABLE 10.2 Major Elements of Human Body: Total Body Content, Daily Turnover Rate, and Days Required for 50% Turnover

Body Elements	Total Body Content	Usual Daily Turnover	Days for 50% Turnover
Na	3500 mEq	4%	12
K	3000 mEq	2.3%	22
Ca	60,000 mEq	0.01%	2700
Mg	2000 mEq	0.5%	100
P	18,000 mmol	0.17%	290
Water	40 L	5%	10
Alkali	28,000 mEq	0.2%	250
Calories	130,000 kcal	1.5%	33
Creatinine	400 mg	400%	0.12
Urea-N	4000 mg	250%	0.2

MECHANISM OF BALANCE RESTORATION

All control mechanisms are activated by the introduction of a new influence into a system that causes imbalance between input and output of an element, and this leads to an alteration in a parameter of the element in the system. In biological systems, parameters that are most often disturbed are concentrations of elements in the plasma. Other disturbed parameters include pressure, volume, temperature, and body weight. Alterations in a parameter affect either input or output, which in turn affects the parameter directly or indirectly. Examples of an element that is directly responsible for a change in a parameter are balance of potassium (element) affecting plasma potassium concentration (parameter), and balance of magnesium (element) affecting the plasma magnesium

concentration (parameter). Examples of an element that is indirectly responsible for a change in parameter include the balance of sodium (element) affecting the effective vascular volume (parameter), and the balance of calories (element) affecting body weight (parameter).

The effectiveness of the compensation mechanism determines the degree of deviation of a parameter from the baseline value when the balance is restored. A poor compensation mechanism restores balance with the parameter greatly deviated from the baseline value. An example of a poor compensation mechanism is a change in plasma urea concentration with a change in the rate of urea production. When urea production doubles, the renal excretion will eventually also double and equal the increased production rate. However, at equilibrium the plasma urea concentration will be twice the baseline value. An example of a good compensation mechanism is a change in a sodium content of the body in response to a change in sodium intake. When salt intake is doubled, renal excretion of salt will eventually double; at this point the total body sodium content would be very slightly greater than the baseline value.

MODELS OF EXTERNAL BALANCE

The pattern of restoration of new balance for control of various elements in the human body is broadly classified into three models. The main source of input for most electrolytes in our body is oral intake and the main output the renal excretion, with some additional output through the GI tract.

Model A

This model is depicted in Figure 10.2 as a cylinder filled with water. Water enters from a faucet into the cylinder, and leaves through a hole at the bottom. The height of the water column depends on water input and water output, and water output in turn depends on the size of the hole at the bottom and the hydrostatic pressure. The hydrostatic pressure in turn depends on the height of water column. Under these conditions, only two factors can change the height of the water column permanently; the rate of water input and the size of the hole. If the rate of water input is doubled while the size of the outlet hole is kept constant, water output will also double when the balance is restored.

With the same size outlet hole, doubling of water output would require doubling of hydrostatic pressure, which in turn requires doubling of the water column height. Before balance is restored, the water column height rises, because water input exceeds water output. The rise in the water column height gradually increases the hydrostatic pressure, and therefore the water output. Hence the discrepancy between the water input and the water output gradually lessens. However, as long as water input remains greater than water output, the water level will keep rising, and the rise will stop only when the water output equals the water input; this occurs when the water column height is exactly doubled.

Conversely, decreasing the size of the outlet hole to double the resistance to water flow, with an unchanged rate in the water input, would initially reduce the water output to half. The ensuing imbalance between the water output and the water input would cause a rise in the water column height. A higher hydrostatic pressure resulting from the rise in the water column would allow more water to come out through a narrower hole. Thus, in this example, doubling of the water column height will restore the water output to the baseline value.

The main characteristic of this type of compensation is that the alteration in content or concentration caused by a disturbance is directly or inversely proportionate to the magnitude of the alteration in input or output function. For example, if the input of a substance is doubled, the content or concentration of the substance will be doubled when balance is restored. If input is increased three-fold, the content or concentration will be tripled. Similarly, if the output function is halved, the content or concentration will be doubled when balance is restored. If the output function is reduced to one tenth of the baseline, the content or concentration will be increased ten-fold when balance is restored.

Many substances in the body follow this pattern of compensation mechanism in order to achieve a new balance. When a substance follows this pattern of compensation, the body must have a high degree of tolerance for a large deviation in the body content or concentration for the substance. For example, if creatinine clearance diminishes to half of the baseline value with an unchanged creatinine production rate, serum creatinine concentration will double in order to achieve the same rate. Similarly, if creatinine production is reduced to half of the baseline value with the same renal creatinine clearance, serum creatinine concentration will be half of the original value. Likewise, if urea production is doubled, with unchanged kidney function, serum urea concentration is doubled when balance is restored.

Model B

In this model, the cylinder has a wedge-shaped slit on its side instead of a hole at the bottom (Figure 10.3). Water enters the cylinder from a faucet, and leaves through the slit. As in model A, water output depends on the height of the water column. But, because of the

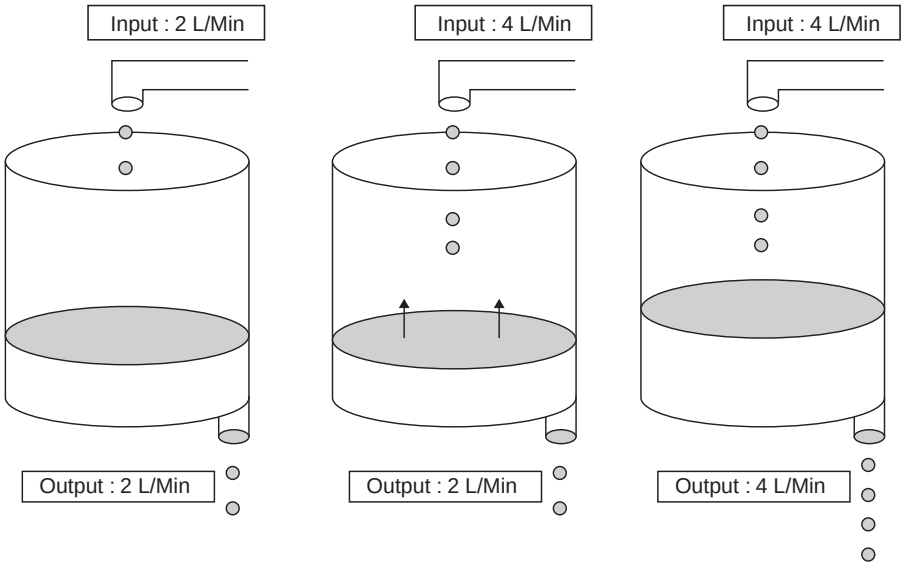

FIGURE 10.2 **Model A.** The input and output determines the balance, but the output changes in proportion to the height of the water column. When the water input doubles while the size of the output hole remains unchanged, the only way for the output to increase to the same level as the input is to double the height of the water column. At this point, a new balance is struck between input and output. For example, if creatinine production doubled while creatinine clearance remained unchanged, serum creatinine concentration will be doubled when a new balance is achieved between creatinine production and creatinine excretion

wedge shaped slit, the effect of a rise in water level on water output is exponential. Therefore, when water intake doubles, doubling of water output does not require doubling of the water column height. Depending on the shape of the slit, the water level may rise only slightly before a new balance is restored. In other words, an increase in water output in response to a change in the height of water column is magnified in this system. Furthermore, unlike model A, when the water level drops below the lowest part of the slit, water output stops altogether.

The regulation of the body content or plasma concentration of most electrolytes and other essential body elements utilizes this type of compensation. For example, when potassium intake is increased five-fold, plasma potassium concentration does not increase five-fold when balance is restored. In the presence of normal renal function and normal aldosterone response, plasma potassium concentration will increase only slightly. Likewise, a five-fold increase in sodium intake causes only a slight increase in body sodium content or plasma sodium concentration; when sodium intake is greatly reduced, the body sodium content decreases only slightly before renal sodium excretion ceases.

Model C

The pattern of water excretion in model C (Figure 10.4) is similar to model A, but in this model two cylinders, one big (A) and the other small (B), are connected at the bottom. Water enters only into cylinder A, but once it enters, it equilibrates with cylinder B. Ordinarily, because cylinder A has a bigger hole than cylinder B, the water output is determined primarily by the size of hole A. However, as the size of hole A decreases, the role of hole B increases. When water input is doubled, the height of the water column will have to be doubled in order to permit establishment of a new steady-state. On the other hand, when the resistance to flow through hole A is doubled, the height of the water column will be less than doubled when balance is restored, provided that the size of hole B is unchanged.

When the excretion rate through hole A decreases, the excretion through hole B becomes more important. The regulation of plasma concentration of uric acid follows the pattern in model C. Uric acid is cleared by the kidney, and is also cleared metabolically by colonic bacteria. The renal clearance of uric acid is normally about 8 liters per day, and the colonic clearance is about 4 liters per day. Thus, 2/3 of the uric acid produced is cleared by the kidney and 1/3 by the colon.[5] If the plasma concentration of uric acid is 5 mg/dl (50 mg/L), renal excretion of uric acid would be 400 mg per day (uric acid clearance of 8 liters per day), and the amount cleared by the colonic bacteria would be 200 mg, with a total uric acid removal rate of 600 mg per day. If chronic renal disease reduces the renal clearance of uric acid to 4 L a day (half of normal), total uric acid clearance would now be 8 liters

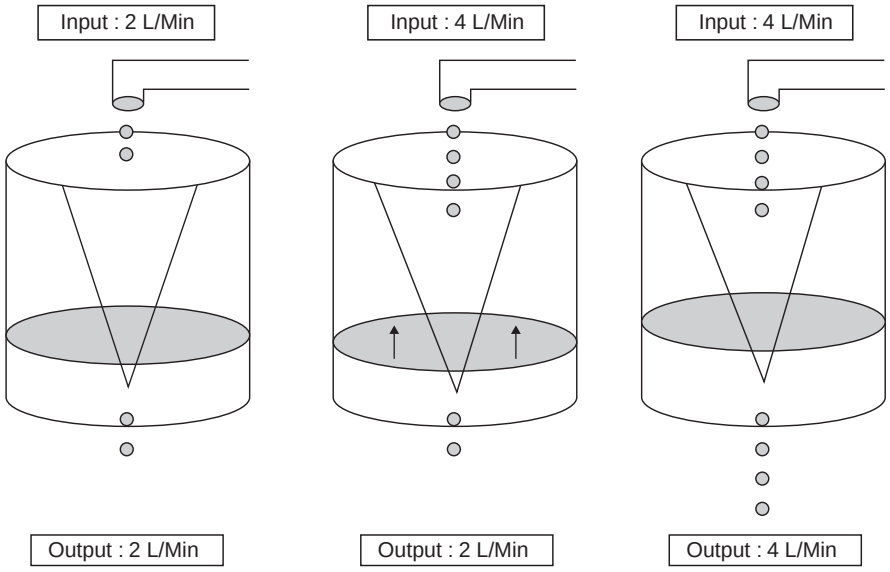

FIGURE 10.3 **Model B.** As in model A, input and output determines the balance, and output depends on the height of water column. However, unlike model A, a change in water output by the change in the height of water column is magnified. When the height of water column increases slightly, water output increases greatly, and a decrease in its height reduces water output markedly. Furthermore, when the height of the water column decreases below a certain level, output ceases completely. Thus, doubling of input from 2 liters per minute to 4 liters per minute requires increases in water level only slightly before output also increased to 4 liters a minute.

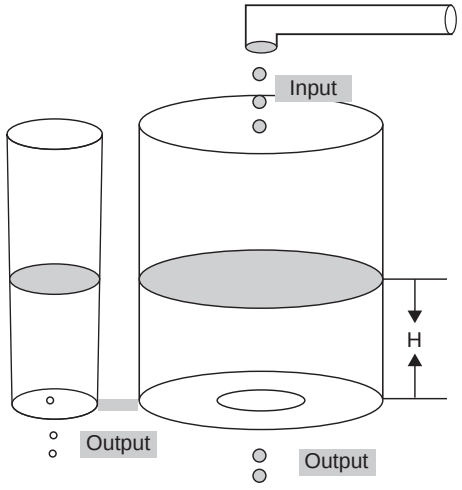

FIGURE 10.4 **Model C.** Two compartments A and B are connected to each other, and each has an outlet hole. Water output from both compartments depends on the height of water column. Because hole A is much larger than hole B, the bulk of water output occurs through hole A. When hole A becomes smaller, output through hole B plays a greater role in water output.

per day, if the colonic clearance remained unchanged at 4 liters per day. If the rate of production remained the same (600 mg/day), plasma uric acid concentration would not double to 10 mg/dl, but would increase to 7.5 mg/dl, because total body uric acid clearance would be 8 liters per day (4 + 4 = 8 liters); at this concentration, the total amount of uric acid cleared would be 600 mg/day (75 mg/L × 8 L/day = 600 mg/day).

The regulation of plasma creatinine concentration follows the same type of compensation as shown in model C. Normally, creatinine is cleared mainly by the kidney, with a daily clearance of about 180 liters, but the colonic bacteria also remove a small amount of creatinine, providing about 3 liters of creatinine clearance per day.[6] Thus, normally the colonic clearance, which constitutes less than 2% of the total creatinine clearance, has little impact on the plasma concentration of creatinine. However, in the presence of advanced renal failure, which does not diminish the colonic clearance of creatinine, it could have a substantial impact on plasma concentration of creatinine. For example, in a person who has 5 ml/min of renal creatinine clearance (7.2 liters per day), 3 liters of colonic clearance would now represent about 30% of the total creatinine clearance. For these reasons, the rate of rise in serum creatinine in advanced renal failure is not exactly inversely proportionate to the reduction in renal clearance of creatinine.

INFINITE GAIN CONTROL MECHANISM

The ultimate aim of all compensation mechanisms is restoration of balance between input and output, after balance is disturbed by introduction of an abnormality. In most instances restoration of balance is possible only when the abnormality persists. For example, increased renal excretion of potassium by primary hyperaldosteronism will result in imbalance between input and

output, with output exceeding input. Development of hypokalemia is needed for output to decrease to match input, and hypokalemia is the price that must paid in order to restore balance. Similarly, an increase salt intake would result in chronic volume expansion, in order for salt excretion to increase to equal the increased intake. The infinite gain control mechanism, to be discussed below, is unique in that the abnormality is corrected completely when a balance is restored.

This principle is well illustrated in Figure 10.5. In this model system, water enters the tank from a faucet at the top, and leaves the tank through a hole at the bottom. The input is independently regulated, but the water output depends on two factors, the size of the outlet hole and the hydrostatic pressure. The hydrostatic pressure in turn depends on the water level, which is determined by the balance between the water input and water output. At equilibrium, the water input is equal to the water output. What would happen if the capacity of the tank is suddenly altered at this point by, for example, placing a brick in the tank, without a change in the water input or the size of outlet hole (i.e., output function)? Initially, the water level would rise and hydrostatic pressure at the bottom of the tank would be increased. The higher pressure with the same size outlet hole would cause the output of water to exceed water input. The consequent imbalance between the input and output would cause a gradual decline in the water level. But, as long as the water level is higher, even slightly, than the baseline value, the water output will exceed the water input. Only when the water level decreases to the original level, will the water input equal the water output. A sudden increase in the capacity of the tank, for example by creating a pouch on the tank, would cause an imbalance between the water input and the water output because of the initial reduction in the water level and the hydrostatic pressure, but the discrepancy would be only transient. At equilibrium, the water level will return to the original level.

This type of compensation mechanism is ubiquitous in various physiological and pathological states in the human body, but the importance of this mechanism was first recognized by Guyton, who presented the concept in his discussion of the regulation of arterial blood pressure.[7–10] He boldly predicted that in the absence of an altered function of renal excretion of salt, no abnormality will sustain hypertension chronically. This prediction was made on the basis of the observation that the arterial blood pressure is normally a powerful regulator of renal salt excretion, and that a minute increase in blood pressure results in a large increase in salt excretion, and salt excretion in excess of salt intake will continue until the blood pressure returns to normal[9].

Suppose hypertension develops as a result of increased systemic vascular resistance, while the responsiveness of the kidney to changes in blood pressure to influence salt output (i.e., renal function curve in response to blood pressure) remains unchanged; the higher the pressure, the higher the renal salt output. Increased salt output caused by a higher blood pressure in the absence of commensurate increase in salt intake would lead to a negative salt balance. The negative salt balance would reduce effective vascular volume, circulating blood volume, and eventually cardiac output. A lower cardiac output will reduce blood pressure to a lower level, but as long as the blood pressure is still higher than the baseline, salt output will remain greater than the basal salt output. The salt output in excess of salt intake progressively reduces the salt content of the body. Only when blood pressure returns to the original value will the renal salt output return to the baseline value. At this point, balance is restored between salt intake and salt output, and the abnormality in blood pressure is completely dissipated.

In Guyton's use, the term "gain" is defined as the fraction of abnormality that has been corrected divided by the fraction yet to be corrected.[8] For example, if an abnormality causes an increase in blood pressure, and a control system brings it back halfway to the original value, the feedback gain is one ($0.5/0.5 = 1$). Gain is zero if a control system does not correct at all ($0/1 = 0$). Gain is infinite if the abnormality is almost all corrected completely with virtually nothing left to be corrected, because division of a number with an infinitely small number results in an infinitely large number.

What is the reason why an abnormality disappears completely in the infinite gain control mechanism, but not in other control mechanisms? The main difference is in the nature of the influence that causes disturbances in the system. When the disturbance affects either input or responsiveness of the system to change in a parameter for the output (i.e., output function), the abnormality will not be corrected completely, and the compensation mechanism does not involve the infinite gain control mechanism. On the other hand, when the disturbance introduced is not one of these two kinds, the compensation mechanism is an infinite gain control mechanism.

COMMON MISCONCEPTIONS AND NEW INSIGHTS

A series of topics discussed in the following section deals with widespread misconceptions regarding principles related to restoration of balance states.

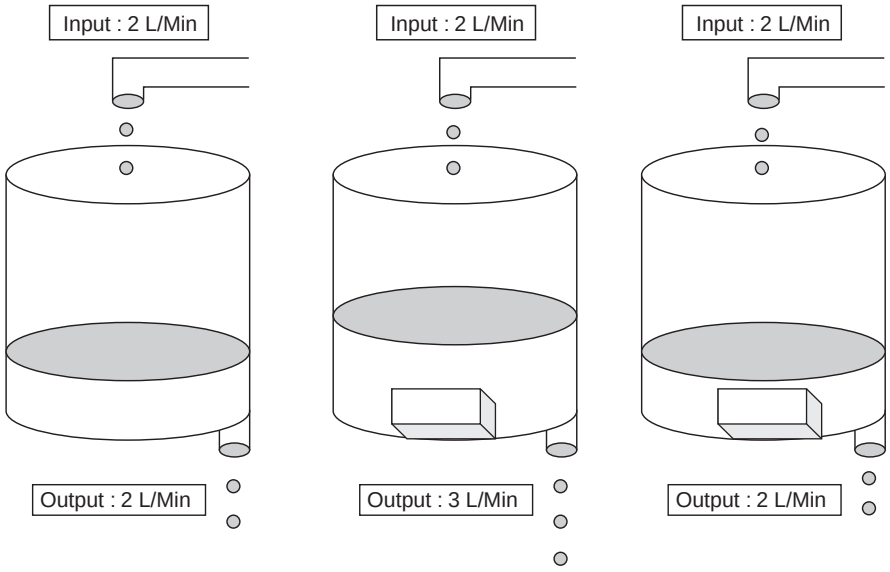

FIGURE 10.5 **An example of infinite gain control mechanism.** Water input and water output determine the balance, but water output is determined by the size of the hole at the bottom and the height of the water column. If water input and the size of the hole at the bottom remain unchanged, any change in the capacity of the tank will alter the height of water column only temporarily. For example, putting a brick into the tank reduces the capacity of the tank. This will increase the water column height only transiently. A higher level of water column with the same size of outlet hole will increase water output. Water output in excess of water input gradually decreases the height of the water column. Only when the height of the water column returns to the original level, is a balance restored between input and output.

There is no Set Point for Renal Salt Excretion

Hollenberg, citing the earlier writing on the same subject by Straus and colleagues[11] proposed a hypothesis for the existence of a set point for the regulation of body sodium content by the kidney. The set point is defined in his writings as the level of sodium content in the body that the kidney tries to maintain as the normal and desirable level. Henceforth, this hypothesis will be called the *set point hypothesis*. The evidence for the set point hypothesis follows.

First, when sodium intake is suddenly reduced, the rate of decrease in urine sodium excretion is exponential. The authors of the hypothesis consider the exponential decline thermodynamically unsound. If the decline were in response to progressive volume depletion, the authors argued, the decline should be accelerating, not declining exponentially. Second, when patients in sodium balance on a low sodium diet (10 mEq/day) were given a small amount of extra sodium (e.g., 30 mEq), the extra sodium was promptly excreted. It is further argued that if the patient had been volume depleted at the time, he should not have excreted the extra sodium. Finally, when a patient who was volume depleted by chronic diuretic therapy was given sodium, no sodium diuresis occurred until the body sodium content was brought back to the level that was achieved on zero sodium intake.

On the basis of these observations, the set point for renal sodium excretion was defined as the amount of sodium in the body when the subject is in balance on a salt-free diet. Accordingly, most humans are in a state of sodium excess, and hence the unloading of excess sodium diminishes the stimulus for sodium diuresis, producing an exponential decrease in renal sodium excretion. It was further argued that the absence of a set point would lead to chaos, and a control system without a reference point is unimaginable. The possibility of a set point being higher or lower than the level defined above was dismissed; the exponential decrease in sodium excretion on a salt-free diet is considered to be evidence against a higher set point, whereas the absence of sodium diuresis upon salt administration in patients pretreated with a diuretic was thought to be evidence against the existence of a lower set point. The set point hypothesis has been debated in the public forum previously[12,13] - but the uniqueness of the current argument against the hypothesis is that it is advanced by the use of counter examples (three counter examples follow).

1. When water intake is suddenly stopped after a period of normal water intake, the pattern of urine water output follows the same pattern as the renal salt output after sudden curtailment of salt intake. With increasing water deficit on a zero water intake, urine output declines exponentially, not accelerating, despite progressive water deficit and progressive activation of the water-conserving mechanism. Clearly, the water content of the body

on zero water intake cannot be the desirable water content.

2. When a patient is on a potassium-free diet, urinary excretion of potassium declines exponentially, not accelerating, despite a progressive increase in potassium deficit. Again, no one would argue that the potassium content of the body on zero potassium intake is the desirable body potassium content.
3. The arterial pCO_2 declines exponentially with increasing severity of metabolic acidosis, despite metabolic acidosis becoming more and more severe.

These counter examples indicate that the finding that urinary sodium declines exponentially neither supports nor argues against the existence of a set point, as previously defined. When sodium intake is stopped, urine sodium decreases progressively because effective vascular volume declines progressively, and as a result sodium reabsorption mechanisms in the kidney are activated progressively. Whether the body sodium content at usual sodium intake is normal or excessive is not a question that can be decided by the pattern of renal sodium excretion, just as we cannot decide the normal plasma potassium concentration by the pattern of renal potassium output in response to a change in potassium intake.

In an attempt to define a normal value in the set point hypothesis, a special meaning has been attached to the pattern of renal sodium excretion. However, normalcy of any physiological values must ultimately be decided by their relation to morbidity and mortality. Given the well-known effects of the body salt content on blood pressure, it may be more advantageous to have a salt content that is achieved on a near salt-free diet than the content attained on the current usual salt intake. The fact that the body's sodium content attained on a near salt free diet is more advantageous to human health is, in my opinion, pure chance, but may have contributed to the set point hypothesis. At different times in human history, a slight excess in sodium content might have been beneficial to survival, when salt was not readily available in many parts of the world and salt loss was a common occurrence from gastroenteritis and sweating. This scenario seems more plausible when one realizes that the main adverse effect of excess salt content in the body is increase in blood pressure, and hypertension was not the main cause of death when the average lifespan was 30 to 40 years. Normally, urine sodium excretion decreases when effective vascular volume declines. Thus, the relationship between effective vascular volume and renal sodium excretion can be summed up in one sentence: the lower the effective vascular volume, the lower the renal sodium output, and the higher the effective vascular volume, the higher the renal sodium output.

As explained in model B (Figure 10.3), the relationship between renal sodium excretion and effective vascular volume is not continuous; below a certain level of effective vascular volume, renal sodium output virtually disappears, and this happens before any overt signs of clinical dehydration. When effective vascular volume decreases further, renal sodium excretion cannot decrease further because renal sodium excretion cannot be a negative number, even though the sodium retaining mechanisms are even more activated. Administration of sodium in such a state would not cause sodium diuresis until effective vascular volume increases to a higher level. The proponent of the set point hypothesis asks the question: "if a subject is volume depleted on 10 mEq per day sodium diet, why would he excrete the administered sodium?" The simple answer would be "because he is less volume depleted now."

It is the central core of the set point hypothesis that the kidney stops excreting sodium at the set point, i.e., the salt content attained at near zero sodium intake, in order to preserve the most desirable value of body sodium content. However, that is not the consistent behavior of the kidney. Urine output never becomes zero until the kidney is completely shut off, despite progressive water deficit and clear clinical evidence of dehydration. Likewise, renal potassium output does not cease on a zero potassium intake, despite clinically evident hypokalemia.[14]

Renal Salt Output Does Not Exceed Salt Intake in Salt Losing Nephropathy

An often-cited diagnostic criterion for salt losing nephropathy is urine sodium excretion in excess of sodium intake.[15] This is obviously impossible on a chronic basis, just as chronic diuretic therapy cannot produce persistent net sodium loss. Salt intake must equal salt output in the long run, but transient imbalance often occurs. Salt output exceeds intake while volume depletion develops, but the reverse occurs when volume depletion is being corrected. If a patient with salt-losing nephropathy who had been on a high-salt diet reduces salt intake because of an illness, the patient will develop volume depletion, and during this period urine salt output exceeds salt intake, and hence a negative salt balance occurs. On the other hand, when the same patient resumes his usual salt intake or receives intravenous fluid, salt balance will be positive during the period of recovery. The diagnosis of salt losing nephropathy requires documentation of inappropriate urinary salt excretion in the presence of volume depletion.

Mechanism of Low Urea Nitrogen Concentration in Liver Disease

It is often stated that serum urea nitrogen level is very low in chronic liver disease because urea is produced in the liver, and the diseased liver cannot produce urea at the normal rate.[16] It is obvious that a low serum urea concentration without increased urea clearance must be due to reduced production, but impaired liver function is not the reason for reduced production. Once ingested protein is broken down to individual amino acids, and is absorbed into the bloodstream, it has three metabolic pathways: (1) metabolism to urea to be excreted in urine; (2) metabolism to non-urea nitrogen compounds to be excreted in urine; and (3) protein synthesis. Patients with chronic liver disease are not in a state of net protein synthesis, i.e., an anabolic state. Major non-urea nitrogen compounds normally excreted in urine include ammonia, amino acids, creatinine, and uric acid, and urinary excretion of these compounds is not increased in chronic liver disease. One might suggest that nitrogen could accumulate as ammonia in the blood as metabolic conversion of ammonia to urea is impaired in liver disease. In severe liver disease, ammonia concentration in plasma is indeed increased, but the total amount of nitrogen that can accumulate in the body in the form of ammonia without fatal consequences is extremely small. The concentrations of ammonia in plasma are expressed in micrograms per dl, whereas those of urea are in milligrams per dl. Accumulation of only 10% of ingested nitrogen as ammonia instead of its conversion to urea would lead to fatal hyper-ammonemia within hours.

The only logical explanation for low urea production, therefore, is reduced protein intake. Chronic alcoholics often have persistently low protein ingestion, and they have low plasma urea nitrogen. However, any normal person ingesting a low protein diet will also have low urea nitrogen production, and therefore low plasma urea nitrogen. A strict vegetarian often has a low urea nitrogen concentration, for these reasons. When a patient with a liver disease has a G-I hemorrhage, serum urea nitrogen concentration rises promptly, indicating that the diseased liver can produce urea rapidly when substrate is available. If a person with severe liver disease ingests a normal amount of protein, urea production will be normal, but plasma ammonia will be higher.

It is a general rule that an impaired metabolic pathway does not reduce the output of its metabolic product unless there is another pathway to which the precursor of the product can be shunted. In the absence of another pathway, at equilibrium the concentration of the precursor will be increased, and the rate of output of the metabolic product will return to the baseline. The situation is analogous to the quantity of creatinine excretion in chronic renal failure. When the kidney function is impaired, the amount of creatinine excreted in the urine does not decrease, as long as creatinine production remains unchanged. The amount excreted will decrease at the onset of renal failure, but at equilibrium it will return to baseline. One does not measure the rate of urinary creatinine excretion as a means of determining renal function; one looks at serum creatinine concentration instead. Likewise, the rate of production of urea by the liver does not offer any clue to the level of liver function, but serum ammonia level does.

Sodium Intake and Sodium Balance are Poor Predictors of Effective Vascular Volume

The assessment of effective vascular volume by urinary sodium excretion is a widely used and useful clinical tool. Most physicians, however, believe that knowledge of both sodium intake and urine sodium output provides a better clue to the status of effective vascular volume. The following example explains why this reasoning is flawed.

Question: Two subjects, A and B, have been admitted to the hospital with unknown status of their effective vascular volume. Subject A is given a diet containing 100 mEq of sodium per day, and subject B gets a sodium intake of 20 mEq a day. In the next 24 hours, subject A excretes 60 mEq of sodium per day, and subject B excretes 40 mEq of sodium per day. On the basis of this information, which subject do you believe has a higher effective vascular volume? You should assume that neither subject has any renal or hormonal disorder that would affect renal sodium excretion.

Answer and discussion: The most common answer is that A has a lower effective vascular volume than B. The reasoning for the answer: person A is in positive sodium balance because the "smart kidney," sensing volume depletion, retains sodium, whereas person B is in negative sodium balance because the "smart kidney," sensing the volume expansion, compels him to excrete the excess sodium. It is true that the balance data indicates that A is in a state of sodium retention and B in a state of sodium loss. However, sodium retention need not indicate the presence of volume depletion, and sodium loss not does prove the state of expanded volume. The following examples will make these points obvious.

A person in salt balance while ingesting 100 mEq of sodium per day suddenly increased sodium intake to 200 mEq per day. Salt excretion will eventually increase to the same level as intake, but not on the

first day. If adjustment in salt excretion matched intake immediately, there would be no retention of sodium, and there would be no harmful effect of a high salt intake. Instead, there would be some sodium retention. On the first day he may excrete only 150 mEq, causing net retention of 50 mEq of sodium. The positive sodium balance in this instance is due to increased intake, not to reduced excretion. Furthermore, a positive sodium balance increases the effective vascular volume to a higher level than the previous day, and the higher effective vascular volume is indeed the reason for the greater urinary sodium excretion. Clearly, positive sodium balance does not necessarily mean low effective vascular volume.

In another example, a patient with intractable heart failure is ingesting 50 mEq of sodium per day and excretes only 10 mEq per day. He is retaining sodium avidly, and hence the term renal sodium retention would be appropriate in this setting, as positive sodium balance in this instance is due to low effective vascular volume. Frustrated by relentless sodium retention, the physician prescribes a salt-free diet, and urine sodium drops further to 5 mEq per day. At this point, however, his overall sodium balance is −5 mEq per day. Can we say, then, that his effective vascular volume is no longer diminished, since he is no longer retaining sodium?

Sodium intake itself has no direct effect on renal sodium output. Any influence of sodium intake on renal sodium output is always mediated through effective vascular volume, because balance between sodium intake and sodium output influences effective vascular volume. If we think of renal sodium output in terms of model B (Figure 10.3), the height of the water column represents effective vascular volume. Just as the only factor that influences water output in model B is the height of water column, the only factor that influences renal sodium excretion directly is effective vascular volume. The higher the effective vascular volume, the higher is the urine sodium; the lower the effective vascular volume, the lower is the urine sodium. Once this relationship is understood, the question regarding subjects A and B is easy; subject A has higher effective vascular volume, because he is excreting more sodium in urine than subject B.

The reason for the widespread belief that sodium intake and output is a better predictor of effective vascular volume is likely to be due to the misuse of the term renal sodium retention. The train of logic goes as follows. First, sodium intake in excess of sodium output represents sodium retention. Second, sodium retention in most clinical situations is due to reduced renal excretion of sodium. Third, reduced renal excretion of sodium is most often due to low effective vascular volume. Fourth, therefore sodium retention is most often due to low effective vascular volume. Finally, any sodium retention, i.e., positive sodium balance, signifies low effective vascular volume. Although the fatal error in reasoning is in the final step, the major mistake occurred in the thinking that sodium retention is always due to reduced renal sodium output, instead of thinking that it is *usually* due to reduced renal sodium output.[17]

Does Overflow Mechanism Explain Ascites Formation?

The overflow theory of ascites formation states that an important mechanism of sodium retention in ascites formation in cirrhosis of the liver is primary renal sodium retention due to a diseased liver. The argument is based on the data from drug-induced cirrhosis of the liver in dogs, which developed ascites and salt retention in the absence of signs of reduced effective vascular volume, such as elevated PRA and plasma aldosterone concentration. On the basis of these observations, the authors of the study concluded that renal sodium retention could not have been a response to volume depletion caused by loss of fluid to the peritoneal cavity (i.e., under-filling), and therefore renal salt retention was a primary event that led to increased effective vascular volume resulting in the ascites formation (i.e., overflow).[18,19] Two major errors were made in this line of thinking.

The first error is the assumption that the proof of salt retention (i.e., positive salt balance) due to the under-filling mechanism requires the presence of overt volume depletion. The following example will demonstrate how effective vascular volume could remain "normal" during the period of positive salt balance by an under-filling mechanism. Assume that a person, who has been in salt balance while ingesting 15 g of salt a day and excreting 15 g a day, develops chronic diarrhea and loses 5 g of salt in the stool daily. The net GI absorption of salt after subtracting the amount lost in the stool would then be 10 g per day, and he would excrete 10 g of salt in the urine per day. His effective vascular volume during diarrhea will be lower than it was before the start of diarrhea, but not lower than that of a person ingesting only 10 g of salt per day without diarrhea. Likewise, if a person ingesting 15 g of salt per day develops ascites slowly, and sequesters 5 g of salt daily in the peritoneal space, his effective vascular volume would not be lower than a person who ingests 10 g of salt a day without development of ascites. In both cases, ingestion of 15 g of salt, in the absence of abnormal salt loss, would have resulted in excretion of 15 g of salt. With ascites formation or diarrhea, the kidney excretes 10 g instead of 15 g, because the effective vascular volume is slightly lower than in

a person without ascites formation or diarrhea. In both cases, the reduction in renal sodium output clearly was in response to "under-filling," even though there would be no discernible volume depletion. In both examples, effective vascular volume was maintained sufficiently high to allow renal excretion of 10 g of salt a day. If plasma renin activity were measured during the period of sodium retention in these examples, it would have been normal. The absence of apparent volume depletion in any edema-forming conditions does not prove that the kidney did not retain sodium in response to a volume stimulus.

The second error is the failure to recognize that the infinite gain control mechanism operates in ascites formation by the under-filling mechanism. If the salt intake and the function curve for renal salt output remain unchanged, effective vascular volume would return to the baseline when steady-state is achieved. The sequence of events would be as follows. Ascites formation by the transudation of fluid from the vascular space into the peritoneal cavity would reduce effective vascular volume, which reduces renal salt output. The normal salt intake with reduced renal salt output causes salt retention, which would tend to increase effective vascular volume. However, as long as effective vascular volume remains lower than the baseline value, renal salt output will remain lower than the baseline, and the positive salt balance will continue. Only when effective vascular volume returns to the baseline, will renal salt output return to the baseline, and the salt retention will stop. Thus, at equilibrium, effective vascular volume in any patient with ascites would be normal, unless he is treated with a low-salt diet or a diuretic.

Main Mechanism of Nephrotic Edema: Low Oncotic Pressure versus Primary Renal Salt Retention

It has been suggested that primary renal salt retention plays a more important role in the formation of nephrotic edema than low oncotic pressure which would cause secondary renal salt retention.[20] This belief is based on the observation that in untreated subjects with nephrotic syndrome, plasma renin activity is often reduced. The reasoning goes this way: if low oncotic pressure is the primary cause of edema formation, transudation of fluid from the vascular space into the interstitial space would reduce effective vascular volume, which is expected to increase plasma renin activity; the suppressed plasma renin activity, therefore, is the evidence for primacy of primary salt retention in the pathogenesis of nephrotic edema.

The flaw of this reasoning lies in the faulty assumption that edema due to low oncotic pressure must be accompanied by low effective vascular volume. The truth is that nephrotic edema entirely due to low oncotic pressure would not maintain low effective vascular volume, unless the patient is treated with salt restriction or a diuretic. The compensation mechanism against a low effective vascular volume in such situations would be the infinite gain control mechanism.

Imagine a patient in a third world country develops nephrotic syndrome. The patient is not treated with a diuretic, and he does not know the value of a low-salt diet in treating edema. He continues to ingest a diet that contains the usual amount of salt. Yet almost invariably, his renal salt output returns to the baseline and salt retention stops. Otherwise, the patient will develop relentless sodium retention and progressive edema, and will die in a relatively short period with massive edema. Since a slight reduction in effective vascular volume diminishes renal sodium excretion to virtually zero, restoration of renal sodium excretion to a usual normal value is proof that effective vascular volume has been restored to normal. Plasma renin activity at this point would be normal.

If a patient now develops a renal disease that results in primary renal salt retention, edema will be worse and effective vascular volume will be greater than the usual value, which would cause suppression of plasma renin activity. When the natriuretic effect of the increased effective vascular volume is sufficient to counterbalance the sodium retaining effect of the renal disease, renal sodium output will increase further to achieve a new balance. At this point, edema will not progress any further. The presence of suppressed plasma renin activity in a patient with nephrotic syndrome is a strong indication for the presence of primary renal sodium retention, but it does not prove that low oncotic pressure is not the main cause of edema formation. Indeed, primary renal Na retention alone, e.g., acute glomerulonephritis, rarely causes as severe edema as a non-nephrotic cause of low oncotic pressure, such as severe protein malnutrition.

CLINICAL APPLICATION OF EXTERNAL BALANCE

A serious topic discussed below utilizes the principles of external balance to explain physiological concepts and clinical manifestations of certain disorders of fluid and electrolyte balance.

Determinants of Sodium Delivery to the Cortical Collecting Duct and Renal K Excretion

According to the principles outlined at the beginning of this chapter, in the steady-state, sodium output

is equal to sodium intake, including all salt-retaining and salt-wasting conditions, such as hyperaldosteronism and hypoaldosteronism. One might therefore conclude that sodium delivery to the cortical collecting duct cannot remain chronically abnormal unless intake is altered. However, the principles discussed in earlier sections predict that total sodium output will eventually equal intake; it does not predict that sodium delivery to any particular nephron site cannot remain chronically altered.

In the steady-state, a patient receiving chronic diuretic therapy or one with primary hyperaldosteronism will excrete the same amount of sodium as before the abnormalities developed, if the intake remains the same. In both states, however, a greater amount of sodium would be reabsorbed at the collecting duct because of the increased aldosterone effect, but the amount excreted in the final urine cannot be more or less than the intake. To satisfy both conditions, sodium delivery to the collecting duct at the time of balance restoration must be increased in hyperaldosteronism, and decreased in hypoaldosteronism. Primary hyperaldosteronism will be used as an example to explain this.

The initial abnormality in primary hyperaldosteronism is increased salt reabsorption, mainly at the cortical collecting duct, resulting in reduced salt output. The consequent positive salt balance increases effective vascular volume, which inhibits the proximal tubular salt reabsorption, resulting in increased delivery of salt to the cortical collecting duct. With the increased delivery of salt, the amount of salt that escapes into the urine is more now than at the beginning, but still less than intake because of increased salt reabsorption in the collecting duct. As long as urinary excretion of salt is less than intake, net positive salt retention continues, causing further increase in effective vascular volume. A higher effective vascular volume further inhibits proximal tubular salt reabsorption, causing even greater increase in the distal delivery of salt. The process will continue, with progressive increase in effective vascular volume and further increase in salt excretion. Only when excretion of salt is equal to intake will positive salt balance stop. At equilibrium, salt output equals salt intake, but the quantity of salt delivered to the collecting duct remains increased.

In the case of therapy with a loop diuretic or a thiazide diuretic, initially salt delivery to the collecting duct would be greatly increased; during this period salt balance will be negative. The ensuing volume depletion activates salt-retaining mechanisms at the proximal tubule, and also stimulates aldosterone secretion causing increased reabsorption of salt in the cortical collecting duct. One might predict that in a steady-state, sodium delivery to the collecting duct would be normalized as the two opposing effects cancel out each other's effect. However, as long as the increased aldosterone secretion caused by volume depletion increases reabsorption of Na in the cortical collecting duct, Na delivery to the collecting duct must remain increased, in order to have a normal amount of Na excretion in the final urine. In other words, the combined effect of increased proximal Na reabsorption and decreased Na reabsorption by the diuretics would be chronic increase in Na delivery to the cortical collecting duct. Normal delivery of sodium accompanied by increased reabsorption of sodium at the cortical collecting duct would result in reduced excretion of sodium in the final urine; this is impossible.

For the same reasons, sodium delivery to the cortical collecting duct remains reduced chronically in states of hypoaldosteronism, such as Addison's disease. Because the Na reabsorption at the cortical collecting duct is reduced, the only way to have the same normal amount of Na excretion in the final urine is to have reduced delivery of Na to the collecting duct.

Two most important factors that influence renal K excretion are the amount of Na delivery to the cortical collecting duct and aldosterone concentration. Most clinical states that cause increased renal excretion of K are accompanied by increased Na delivery and increased aldosterone, whereas conditions characterized by reduced renal K excretion are accompanied by reduced Na delivery and a low plasma aldosterone or an impaired aldosterone effect. Renal K excretion is unaffected when these two factors are altered in opposite directions. In a high-salt diet sodium delivery to the cortical collecting duct is increased, but aldosterone secretion is reduced, resulting in a normal K excretion. A salt restriction reduces sodium delivery to the cortical collecting duct, but the aldosterone secretion is increased, resulting in a normal K excretion (Table 10.3).

Enigma of Pendred Syndrome

Pendred syndrome is a genetic disorder characterized by goiter and sensorineural hearing loss, responsible for about 7.5% of congenital hearing loss. The disease is named after Vaughan Pendred, an English physician who first described the condition in 1896.[21] The mechanism of the disease is a defect in an anion exchanger pendrin, which is located in the inner ear, thyroid gland, and the cortical collecting duct. The exchanger, located on the luminal membrane of beta-intercalated cells, appears to play an important role in the reabsorption of chloride, and therefore indirectly of sodium.[22]

Despite the common belief that chloride reabsorption in the collecting tubule duct depends mainly on

TABLE 10.3 Na Delivery to Cortical Collecting Duct (CCD) and Aldosterone Affecting Urine K

Clinical States	Na Delivery to CCD	Aldosterone Effect	Urine K Excretion
Hyperaldosteronism	Increased	Increased	Increased
Diuretics	Increased	Increased	Increased
Hypoaldosteronism	Decreased	Decreased	Decreased
K sparing diuretics	Decreased	Decreased	Decreased
Pendred syndrome	Decreased	Increased	Normal
High-salt diet	Increased	Decreased	Normal
Low-salt diet	Decreased	Increased	Normal

the paracellular chloride channel, supportive evidence is not very strong. For example, in severe volume depletion states, urine chloride concentration is as low as 2 mEq/L.[23] The Nernst Equation would predict that such a low chloride concentration, to be explained entirely by a passive mechanism through the paracellular pathway, would require the transepithelial voltage of over 100 mV. The highest transepithelial voltage observed in states of high aldosterone effect is about 60 mV. It is likely that other mechanisms exist for reabsorption of chloride in the cortical collecting duct, and the most likely one is pendrin-mediated chloride reabsorption.[22] If pendrin were such an important transporter for reabsorption of chloride in the cortical collecting duct, why isn't a pendrin defect associated with any electrolyte abnormality? Indeed, the apparent absence of electrolyte abnormalities is one of the reasons why Pendred syndrome, well-known among specialists of ENT, is not widely appreciated among nephrologists.

The most common and apparent electrolyte abnormality associated with impaired renal salt transport is hypokalemia, but Pendred syndrome is not known to be associated with hypokalemia. The following is the likely scenario. A pendrin defect would reduce the overall reabsorption of NaCl in the cortical collecting duct, and the ensuing volume depletion would stimulate renin and hence aldosterone. However, unlike defects in salt transport caused by impaired salt reabsorption in the distal convoluted tubule (Gitelman's syndrome) or the thick ascending limb of Henle (Bartter's syndrome), both of which are characterized by increased salt delivery to the cortical collecting duct, the delivery of salt to the cortical collecting duct in Pendred syndrome would be reduced. That is because the site of defect in salt transport is the cortical collecting duct itself. According to the principle of external balance, in the long run salt intake must equal salt output, no matter what and where defects in renal salt transport may be. Thus, a patient with Pendred syndrome would be excreting the normal amount of salt in the final urine. The excretion of the normal amount of salt and the reduced salt reabsorption at the cortical collecting duct is possible if the amount delivered to the cortical collecting duct is reduced. The end result is that patients with Pendred syndrome would have hyperaldosteronism, but reduced delivery of salt to the collecting duct. There has been no measurement of plasma aldosterone in patients with Pendred syndrome, but effective vascular volume is likely to be reduced and plasma aldosterone is likely to be increased. As supportive evidence, in a study of 21 patients with Pendred syndrome, not a single subject was shown to have hypertension.[24]

Is it possible that salt reabsorption at the cortical collecting duct is not reduced in Pendred syndrome because of the two opposite influences, a high aldosterone state increasing salt reabsorption and a defective pendrin impairing salt reabsorption? That is unlikely because reduced salt delivery with normal salt reabsorption at the cortical collecting duct would mean reduced salt excretion. Remember that in a steady-state final urine sodium excretion is always normal. Is it possible that salt delivery to the cortical collecting duct is normalized in a steady-state? Again, it is unlikely, because normal salt delivery would mean normal effective vascular volume, and then aldosterone secretion cannot be increased. In the end, in a steady-state in Pendred syndrome, there must be some volume depletion accompanied by hyperaldosteronism. At equilibrium renal K excretion in Pendred syndrome would be normal, because two main regulators of renal K excretion are altered in opposite directions; aldosterone is increased and Na delivery to the cortical collecting duct is reduced. The situation would be analogous to a person on a low-salt diet, in which aldosterone is increased but sodium delivery is reduced (Table 10.3). Thus, the patient with Pendred syndrome would be normotensive (low normal blood pressure) and normokalemic, and have no apparent electrolyte abnormalities.

In a recent case report,[25] a patient with Pendred syndrome treated with a thiazide diuretic developed severe hypokalemia (serum K 2.2 mEq/L) and signs of profound volume depletion. The likely explanation for severe potassium depletion is that the patient has impaired salt transport in both the distal convoluted tubule and collecting duct. Severe renal K-wasting occurred because sodium delivery to the cortical collecting duct was increased by a thiazide diuretic in the setting of high aldosterone. In another report, a patient with Pendred syndrome developed life-threatening

metabolic alkalosis during intercurrent illnesses, indicating the importance in chloride reabsorption.[26]

Hypoxemia is necessary to restore balance between oxygen supply and oxygen demand

While the principle of external balance is most useful in explaining homeostatic mechanisms of fluid and electrolyte balance, the same principle applies to restoration of balances in other homeostatic mechanisms. The following example illustrates the mechanism by which a patient with severe lung disease can maintain the normal supply of oxygen necessary to sustain life.

The basal oxygen consumption of a person with advanced lung disease is no less, perhaps slightly greater because of the increased work of breathing, than that of a healthy individual. This means that the diseased lung somehow takes up a normal amount of oxygen. How does this happen? Here is the explanation. A normal person who has alveolar ventilation of 4 liters a minute needs an uptake of 200 ml of oxygen per minute at the basal state. The oxygen content of one liter of inspired air at an atmospheric pO_2 of 150 mmHg is 200 ml, and the oxygen content the expired air is about 150 ml per liter with the pO_2 at 110 mmHg. With an alveolar−arterial pO_2 gradient of 10 mmHg, the arterial pO_2 would be about 100 mmHg. This means that each liter of ventilated air has resulted in uptake of 50 ml of oxygen or total of 200 ml of oxygen by 4 liters of alveolar ventilation. When alveolar ventilation is reduced to 2 liters per minute, how is it possible to extract the same 200 ml of oxygen? A quick calculation will indicate that, in order to extract the same 200 ml of oxygen, each of 2 liters of alveolar ventilation must result in an uptake of 100 ml of oxygen. Since the inspired air has still the same oxygen content at pO_2 150 mmHg, the expired air must have a pO_2 of 70 mmHg. This requires alveolar pO_2 to decrease to 70 mmHg. Since arterial pO_2 is about 10 mmHg lower, it must decrease to 60 mmHg. In other words, hypoxemia is a necessary condition for restoring oxygen uptake to normal.

How does the body know to reduce the arterial pO_2 precisely to the right level to restore oxygen balance? The body does not know, but the general principle of external balance allows automatic restoration of balance. Let us suppose that alveolar ventilation drops to half that of normal. Initially there will be a discrepancy between the body's demand for oxygen and oxygen supply. The reduced supply in the face of unchanged demand will decrease arterial pO_2. A lower arterial pO_2 means a lower alveolar pO_2, which permits greater uptake of oxygen for a given volume of alveolar ventilation. As long as oxygen uptake is less than oxygen demand, arterial pO_2 will keep decreasing, with further reduction in alveolar pO_2. Only when the alveolar pO_2 decreases sufficiently to allow oxygen uptake to meet oxygen demand, is a new balance achieved between oxygen demand and oxygen uptake.

Will this mechanism of external balance restore oxygen uptake at any severity of lung disease? The answer is no. What would happen if the alveolar ventilation decreased to 1 liter per minute? In order to have an uptake of 200 ml of oxygen by 1 liter of alveolar ventilation, each liter now extracts the entire oxygen content of the inspired air, since the total content of oxygen at pO_2 of 150 mmHg is 200 ml. This would mean that alveolar pO_2 must be 0 mmHg, clearly an impossible situation, since arterial pO2, always lower than alveolar pO2, must be a negative number. Long before the alveolar pO_2 drops to 0 mmHg, the person will die of severe hypoxia.

Mechanism of Volume Expansion in SIADH

Ample evidence exists that patients with SIADH with chronic hyponatremia are volume expanded. Evidence for expanded volume includes low plasma creatinine, low plasma urea, and low plasma uric acid,[27,28] all caused by increased renal clearances. However, persistence of chronic volume expansion in SIADH would seem paradoxical. In the absence of disorders that cause primary renal Na retention, such as renal diseases and primary hyperaldosteronism, would the normal kidney not promptly eliminate the excess Na until the volume is restored to normal?

The explanation for the persistence of volume expansion in SIADH lies in the antinatriuretic effect of hyponatremia.[29,30] The sequence of events is as follows. Initially, water retention causes hyponatremia and volume expansion. Volume expansion causes sodium diuresis, resulting in further reduction in serum sodium. But as serum sodium declines, the antinatriuretic effect of hyponatremia opposes the natriuretic effect of volume expansion. When these two opposing effects are equal, renal Na excretion returns to the baseline value, and a new balance is established, with renal Na excretion equaling salt intake. In other words, when renal Na excretion returns to the baseline, the effective vascular volume must be expanded.

Mechanism of Volume Depletion in Chronic Hypernatremia

In the presence of normal renal function, chronic hypernatremia is always accompanied by reduced effective vascular volume, and the degree of reduction in effective vascular volume is proportionate to the level of serum sodium.[31,32] Exceptions are chronic hypernatremia in renal failure or hypernatremia that develops as a result of chronic administration of

a large amount of sodium. Even in the latter condition, the effective vascular volume would be lower with high serum sodium than with normal serum sodium for the same amount of sodium administered. Although some authors postulate that the effective vascular volume is normal in essential hypernatremia,[31] this rule applies to all hypernatremic states including essential hypernatremia. The following analysis will elaborate on the mechanism.

As hyponatremia is antinatriuretic, hypernatremia is natriuretic.[33,34] For this reason, renal sodium excretion would be increased in normovolemic hypernatremia, as long as the kidney function is normal. Increased renal sodium excretion with the usual intake of sodium would reduce effective vascular volume. Volume depletion would reduce renal sodium excretion and oppose the natriuretic effect of hypernatremia. As long as renal sodium excretion exceeds sodium intake, volume depletion will become progressively greater. Only when volume depletion is sufficiently great to exactly oppose the natriuretic effect of hypernatremia, does renal sodium excretion return to the baseline, equaling the intake. At this point, a new sodium balance is struck between sodium intake and output, but at the expense of volume depletion. Since the natriuretic effect of hypernatremia is proportionate to the degree of hypernatremia, the magnitude of volume depletion needed to counterbalance the natriuretic effect of hypernatremia must also be proportionately great, to match the degree of hypernatremia when the new sodium balance is achieved. In other words, the more severe the hypernatremia, the greater is the volume depletion in a steady-state.

It has been suggested that patients with essential hypernatremia are euvolemic, because hypernatremia in this condition is a result of the resetting of the osmostat.[31] Resetting means that the osmostat is regulated normally, but at higher than usual serum sodium concentrations. More recent evidence indicates that essential hypernatremia is caused by defects in the osmoreceptors, not the resetting.[35] However, regardless of its pathogenetic mechanism, chronic volume depletion is inevitable in essential hypernatremia if renal function is normal. Mild volume depletion can escape detection even by careful physical examination. For example, a small amount of a diuretic, e.g., 50 mg hydrochlorothiazide, can reduce effective vascular volume sufficiently for the kidney to sense a reduction in volume, and thereby reduce clearances of urea, creatinine, and uric acid. Yet a careful physical examination by an astute physician will not detect signs of dehydration without the help of laboratory tests, e.g., a higher serum urate. Indeed, it has been shown that most patients with essential hypernatremia have laboratory evidence of volume depletion when the data are carefully analyzed.[32]

EXTERNAL BALANCE OF PROTONS

Determination of external balance of most univalent ions such as sodium, potassium, and chloride is straightforward; intestinal absorption is complete and they are eventually eliminated from the body since none is metabolized. Balance of polyvalent inorganic ions such as calcium, magnesium and phosphate is more complicated, because of incomplete intestinal absorption. External balance of acids and bases is even more complicated than that of polyvalent ions, because of uncertainties in their intestinal absorption and variations in their metabolism after absorption.

In the steady-state, hydrogen ions enter the body through ingestion of acid or are created endogenously through metabolism. The pH of food offers little guidance to its character as a donor of acid or alkali. Most fruit juices have low pH because of the organic acids in them, but overall they are contributors of alkali, because organic acid is metabolized to CO_2, while organic anions are metabolized to bicarbonate. Sulfur-containing amino acids are mostly metabolized to produce sulfuric acid, but not all sulfur is metabolized to sulfuric acid.

Under steady-state conditions, net acid production must equal net acid excretion, and the traditional view of the external balance of acid–base has been as follows. Acids are produced from three main sources: sulfuric acid derived from the metabolism of sulfur-containing amino acids; incompletely metabolized organic acids; and acid (or alkali) from the diet absorbed in the intestine.[36–38] Acids are excreted either in the form of ammonium or titratable acid, while a small amount of alkali is lost in the urine as bicarbonate. Hence, the total acid excretion measured as the sum of urine ammonium and titratable acid minus bicarbonate is called net acid excretion. However, this traditional view of the acid–base balance must be re-evaluated in light of conceptual uncertainties of this approach, and methodological limitations in the measurement of parameters of acid–base balance by conventional techniques.[38] The following discussion will shed some light on these uncertainties and limitations.

MEASUREMENT OF NET ACID EXCRETION

The concept of titratable acid is straightforward. The pH of urine following glomerular ultrafiltration is the same as that of plasma, but decreases progressively with addition of H^+ by tubular secretion. Most of the secreted H^+ is buffered by HCO_3^-, and this represents indirect reabsorption of HCO_3^-. As urine pH falls

further with tubular secretion of H^+, other urinary buffers are titrated to retard a fall in urine pH. Addition of alkali to the urine until its pH is the same as that of the plasma measures the titratable acid. This back-titration of urine releases all the H^+ titrated by non-bicarbonate buffers except those in the form of NH_4^+, which is not titrated because of its high pK (9.2), and therefore is measured separately.

However, the measurement of titratable acid, ammonium, and bicarbonate does not accurately reflect net acid excretion by the kidney, for the following reasons. First, there is a technical problem with the measurement of titratable acid.[39] Addition of alkali to the urine causes partial precipitation of some urine calcium with HPO_4^{2-}. Selective depletion of HPO_4^{2-} causes conversion of $H_2PO_4^-$ to HPO_4^{2-} with liberation of protons, leading to overestimation of titratable acid. Furthermore, titration of urine to the plasma pH results in titration of 1/64th of urinary ammonium (calculated with the pKa of ammonium of 9.2), resulting in further overestimation of titratable acid; this error is usually negligible, but would be substantial when urine contains a large amount of ammonium.

A potentially more serious source of error is the presence of buffers other than ammonium that are not titrated when urine pH is increased to 7.4.[40] The original assumption that ammonium is the only urinary buffer that escapes titration during the measurement of titratable acid has not been fully proven. Normal urine contains various amines such as ethanolamine, phosphoethanolamine, methylamine, and dimethylamine. Urinary excretion of these substances would represent acid excretion, as does the excretion of ammonium. However, titration of urine to pH 7.4 would not detect the presence of such substances. The individual urine concentration of each of these substances appears to be quite low individually, but the amount might be substantial collectively.

SOURCES OF ACID

Sulfuric Acid

The metabolism of sulfur-containing amino acids produces sulfuric acid:

$$RN - S \rightarrow CO_2 + UREA + H_2SO_4.$$

The resulting H_2SO_4 is buffered by the body alkali, mainly HCO_3^-. Previously it was assumed that virtually all urinary sulfates originate from sulfur-containing amino acids. However, this assumption is wrong, since soft drinks regularly contain sulfate as a preservative, and persons consuming large quantities of soft drinks could acquire a substantial amount of sulfate. In one such study, the average amount of urinary sulfate originating from soft drinks was estimated to be 15 mEq/day.[41] Furthermore, the metabolism of sulfur-containing amino acids does not always result in production of sulfuric acid,[42,43] because some of the sulfur is excreted in a neutral form, such as cystine, taurine or sulfate conjugate.[44–46] Each mmol of sulfur metabolized to H_2SO_4 produces 2 mEq of protons in the following reaction:

$$H_2SO_4 \rightarrow SO_4^= + 2H^+$$

On the other hand, the sulfate conjugation reaction consumes a proton; the result is net production of only 1 mEq of proton for each mole of sulfur oxidized when the final product is sulfate conjugate.

$$R - OH + SO_4^= + H^+ \rightarrow R - O - SO_3^-$$

Sulfate conjugation reaction is an important detoxification mechanism, and the reactions are regulated by various enzymes, such as phenol sulfotransferase.[44–46] The rate of sulfate conjugation reaction seems to depend, in part, on the availability of inorganic sulfate. For these reasons, the fraction of sulfur contained in amino acids that is oxidized to sulfuric acid might vary with individuals, and also with the amount of protein intake. In one study, urinary sulfate recovered following ingestion of methionine was shown to be 85–90% of the sulfur content of the ingested amino acid.[43] On the other hand, urinary excretion of sulfate esters is shown to be as much as 17% of total urinary sulfur excretion,[47] and the amount might be higher in certain situations such as renal insufficiency, in which plasma sulfate concentrations are much higher.[48,49] Another common pathway for sulfate conjugation is the formation of sulfated glycosaminoglycans, such as chondroitin sulfate and heparin (Table 10.4).

The sulfur content of proteins of different food sources varies greatly, and depends on the content of methionine and cysteine.[50] For example, the sulfur content of human milk protein is only half of that of most cereal proteins. The sulfur content of beef is less than that of pork or lamb. In general, with the exception of grains, proteins of vegetable origin have lower sulfur content than proteins from animal sources.[50] The rate of excretion of sulfate in patients on CAPD was shown to be much less than in normal subjects,[48] suggesting the possibility that a greater fraction of sulfur is excreted as sulfate conjugate and other organic sulfur compounds.

In conclusion, the proper method for determining the contribution of sulfur-containing amino acids to the endogenous acid production would require the measurement of sulfate, sulfate esters, and neutral

sulfur in the urine. In addition, the dietary intake of sulfate from soft drinks must be known.[41]

Organic Acid

Production of organic acid results in consumption of HCO_3^- in the reaction:

$$RH + HCO_3^- \rightarrow R^- + H_2CO_3$$

If the organic anion is retained in the body, and subsequently metabolized to HCO_3^-, there is no net loss of alkali. When the organic anion is not metabolized, is not metabolizable (e.g., urate) or escapes metabolism because it is excreted in the urine (e.g., citrate), this represents a net loss of alkali. The nature of many of these organic anions excreted in the urine is not known,[51–53] and therefore total organic acid production cannot be determined by measuring individual components. Instead, they are measured collectively by titration of urine. However, the titration method used most widely, the van Slyke and Palmer method,[54] contains many potential sources of error, some of which result in underestimation and some in overestimation.[55,56]

When a metabolizable organic anion cannot be excreted because of renal failure, it is eventually metabolized. Hence, renal function is an important consideration in the overall contribution of organic acids to total acid production. In the absence of renal excretion, only non-metabolizable organic acids would accumulate. It is not known what fraction of organic acids normally excreted in urine is metabolizable. To the extent that metabolizable organic anions are not excreted, patients in renal failure would have reduced net acid production, as shown in patients treated with maintenance hemodialysis.[57] On the other hand, net organic acid production is greatly increased during hemodialysis procedures, as a large quantity of organic anions are lost into the dialysate during dialysis.[57]

Net organic acid production is also regulated by the blood pH.[58–60] The regulation of net production of organic acids occurs in two ways. One way is the regulation of its production, which is pH-dependent; acidic systemic pH decreases production of both ketoacids and lactic acid, while alkaline pH promotes their production.[60] Another mechanism is regulation of their renal excretion. This effect is mediated mainly by the proximal tubular cell pH. An acidic pH of the proximal tubular cell increases reabsorption of organic anions, and thereby reduces urinary excretion, while an alkaline pH has the opposite effect.[58] Usually the proximal cell pH parallels the blood pH, but sometimes the two are dissociated. In proximal (type II) renal tubular acidosis (RTA) and type IV RTA, the systemic pH is low, but the proximal tubular cell pH is not, and hence organic anion excretion remains normal. On the other hand, in K^+ depletion, the tubular cell pH tends to be low (as H^+ enters the cell in exchange for K^+), and therefore organic anion loss is reduced, contributing to the pathogenesis of metabolic alkalosis.

Phosphoric Acid

Phosphate is ingested as inorganic phosphate and organic phosphate. Phosphates in milk and other dairy products are mostly inorganic. Inorganic phosphates in food usually exist at neutral pH, and hence their influence on the acid–base balance depends mainly on the absorption of phosphate relative to its accompanying cation, calcium and magnesium.[61] To the extent that phosphate absorption exceeds calcium absorption, it will add acid to the body.

Organic phosphates are ingested in food as components of intracellular organic compounds. These include creatine phosphate, ATP, ADP, AMP, cyclic AMP, phospholipids in the cell membrane and intracellular organelles, nucleic acids in DNA and RNA, and phosphoproteins. Their eventual fate either as acid or alkali depends on the number of non-metabolizable cations that balance the phosphate anions. If the total number of non-metabolizable cations in mEq is equal to 1.8 times the number of phosphate in mM, the compound is neutral upon complete metabolism. This prediction is based on the fact the average balance of phosphate at pH 7.4 is 1.8. When the number is greater than 1.8 times phosphate, the compound is an alkali, and when it is less than 1.8, it would be an acid. For example, each molecule of ATP has three molecules of phosphate (which has 5.4 negative charge equivalents when metabolized completely) balanced by four cationic charges, two of which are usually provided by magnesium. Hence, metabolic breakdown of each mole of ATP to adenosine and phosphate results in production of 1.4 mEq of acid. Likewise, metabolism of ADP (3 cationic charges against anionic charges of 3.6 P) and cyclic AMP (1 cationic charge against anionic charges of 1.8 P) produce acid, while breakdown of AMP (2 cationic charges against 1.8 P) would produce alkali (Table 10.5).

Conversion of ATP to ADP during exercise therefore represents an acid releasing process, as the net acid value of 1.4 (ATP) is reduced to the net acid value of 0.6 (ADP). Conversely, conversion of ADP to ATP represents an alkali releasing process. On the other

hand, breakdown of creatine-P to creatine and phosphate represents an alkali releasing process by a slight extent, as it consumes 0.2 mEq of proton for each mmol of creatine-P broken down.

It must be realized, however, that these calculations are based on the mean valence of phosphate of 1.8, which is the value at pH of 7.4. The value will change at different pH values. For example, at the usual pH of the cell, 7.1, the mean valence of phosphate is 1.67, and at a pH of 6.8, the mean phosphate valence is 1.5. Thus, at pH 6.8 (the likely muscle cell pH during exercise), metabolism of each mole of ATP would yield 0.5 mole of acid and that of ADP would result in zero acid production; the conversion of one mole of ATP to ADP would produce 0.5 mole of acid.

Metabolism of phospholipids and nucleic acids in DNA and RNA produces acid, whereas metabolism of phosphoproteins and creatine phosphate produces alkali (Table 10.5). The type of phosphate in the diet is a factor determining the magnitude of intestinal absorption. Phosphate present in phytic acid is poorly absorbable, because the human body lacks the enzyme phytase.[62] However, its GI absoption is greatly increased when phytic acid is broken down by bacterial phytase in the colon.

Another way of determining the fate of phosphate as a generator of acid or alkali is to examine the number of ester bonds. Phosphate has a total of three anionic charges when it is fully dissociated. As phosphate forms an ester bond with an organic substance, the number of anionic charges is reduced, and hence the requirement for the number of non-metabolizable cations such as potassium to balance the anion is also reduced. Thus, when phosphate forms two ester bonds (di-ester bonds) it has only one anionic charge remaining to be balanced by a cation. Phosphates in ATP, ADP, nucleic acids in the DNA and RNA, and phospholipids all form di-ester bonds. This explains why metabolism of AMP results in production of alkali, whereas metabolism of cyclic AMP and cyclic GMP (both are di-esters) result in production of acid. In the case of ATP, first two phosphates form di-ester bonds, and the third phosphate has a mono-ester bond. When phosphate contains tri-ester bonds, it has no metabolizable alkali, and its acid content is equal to the molal content of phosphate $\times$ 1.8.

The effect of phosphate in the diet on acid–base balance depends on the extent of GI absorption. The fraction of phosphate absorbed depends greatly on the type of cation that accompanies phosphate. When phosphate is ingested from the usual diet, about 2/3 is absorbed because food contains calcium, and calcium binds phosphate to form brushite ($CaHPO_4$), which is rapidly precipitated and excreted in stools. On the other hand, phosphate ingested as Na or K phosphate is nearly completely absorbed along with sodium and potassium, as long as the amount ingested does not exceed the capacity of the sodium–phosphate transporter.[63–65] When a large amount of sodium phosphate is ingested, the excess amount causes diarrhea. In summary, the contribution of phosphate to net acid production cannot be determined from dietary intake or urinary excretion of phosphate, but is included as part of net GI alkali absorption, which will be discussed separately later in this chapter.

TABLE 10.5 Alkali Value of Phosphate Compounds after Complete Breakdown to Inorganic Phosphate at pH 7.4

ATP^{4-}: 3 P and 4 negative charges: $4 - (3 \times 1.8) = -1.4$ (net acid)
ADP^{3-}: 2 P and 3 negative charges: $3 - (2 \times 1.8) = -0.6$ (net acid)
AMP^{2-}: 1 P and 2 negative charges: $2 - (1 \times 1.8) = 0.2$ (net alkali)
GMP^{2-}: 1 P and 2 negative charges: $2 - (1 \times 1.8) = 0.2$ (net alkali)
Cyclic AMP^{-}: 1 P and 1 negative charge: $1 - (1 \times 1.8) = -0.8$ (net acid)
Cyclic GMP^{-}: 1 P and 1 negative charge: $1 - (1 \times 1.8) = -0.8$ (net acid)
Creatine-P^{2-}: 1 P and 2 negative charges: $2 - (1 \times 1.8) = 0.2$ (net alkali)
DNA: 1 P and 1 negative charge: $1 - (1 \times 1.8) = -0.8$ (net acid).
RNA: 1 P and 1 negative charge: $1 - (1 \times 1.8) = -0.8$ (net acid)

Conversion of Creatine-P to ATP

During anaerobic metabolism, creatine-P is converted to ATP, which results in the generation of one mole of alkali for each mole of such conversion. The actual chemical reaction that occurs can be summarized as follows: creatine-P + ADP + $H^+ \rightarrow$ ATP + creatine. In other words, conversion of creatine-P to creatine with the simultaneous conversion of ADP to ATP results in the consumption of a proton. This reaction can also be summarized this way. Each molecule of creatine-P has two negative charges, each molecule of ADP has three negative charges, but ATP has four negative charges. Hence, one anionic charge must be buffered by the consumption of H^+. In other words, transfer of P from creatine-P to ADP to form ATP is a hydrogen ion-consuming process. If these reactions occurred at pH 6.8, conversion of 1 mmol of ADP to ATP would lead to production of 0.5 mmol of alkali, and the metabolism of creatine-P to creatine and phosphate would result in the additional production of 0.5 mmol of alkali. A hypothesis has been proposed to explain hyperkalemia during vigorous exercise as a response to the initial increase in intracellular pH caused by these reactions. According to this hypothesis, at the start of vigorous muscle exercise, a fall in ATP concentration causes a conversion of creatine-P in the muscle to ATP, and this is accompanied by an

increase in intracellular pH.[66] There are several flaws to this hypothesis, for many reasons.

First, the actual gain in alkali by these reactions is much less, because the overall reaction assumes gain of ATP at the expense of creatine-P. However, if the primary driving force of the reaction is low ATP, there must be net conversion of ATP to ADP, which is an acid-producing process. Second, the authors assumed that creatine-P exists as a trivalent anion, resulting in overestimation of alkali production upon conversion of creatine-P to creatine and phosphate. Finally, the consumption of creatine-P and ADP to produce creatine and ATP during vigorous exercise is not mediated by low ATP, but by low intracellular pH.[67] There is very little change in ATP concentration in the early stages of muscular exercise, but a huge decrease in pH during vigorous exercise. The initial intracellular shift of hydrogen ion during the early stages of exercise may be due to an extracellular shift of K, which in turn is caused by repeated depolarization of muscle cells during exercise. This, indeed, has been the traditional explanation for exercise-induced hyperkalemia.[68]

Amino acids

Proteins are potential sources of acid, based mainly on their sulfur content, which has already been discussed. Acidity or alkalinity of proteins also depends on the relative content of basic and acidic amino acids. Metabolism of cationic amino acids, arginine and lysine, produces acid:

$$\text{Arginine}^{+}\text{Cl}^{-} \rightarrow \text{urea} + CO_2 + \text{HCl}.$$

On the other hand, metabolism of aspartic acid and glutamic acid results in production of alkali:

$$\text{Na}^{+}\text{glutamate}^{-} + H_2CO_3 \rightarrow NaHCO_3 + CO_2 + \text{urea}.$$

However, the net content of acid and base of proteins cannot simply be determined from the total amounts of basic amino acids relative to the total content of acidic amino acids. We can understand this from plasma albumin. The total number of glutamate and aspartate in a molecule of albumin is 99, and the total number of arginine and lysine is 81, and the net excess of acidic amino acid over basic amino acid would be 18. The molecular weight of albumin is 66,5000 Da, and at a plasma concentration of albumin of 4 g/dL, the concentration of albumin in molarity is about 0.6 mmol/L. If each mole contains 18 negative charges, the net negative charge would be 10.8 mmol/L. In addition, albumin also contains 16 histidine molecules, and some of these will be in a cationic form, and therefore net negative charge should be less than 10.8 mmol/L. The actual measured net negative charge of albumin is about 12 mmol/L,[69] and the greater net negative charges may be explained by the reaction of cationic amino acids with various organic compounds. For example, N-acetylation and glycosylation of amino acids would reduce cationic charges and increase net anionic charges. Furthermore, some of the cationic charges of the amino groups of lysine are no longer cationic at pH 7.4.

The imidazole group of histidine is present in either of two forms: neutral or cationic. Metabolism of the cationic histidine results in the production of acid, whereas metabolism of neutral histidine has no effect on acid balance. The ratio of the neutral histidine to cationic histidine depends on the pK of the imidazole group in the molecule, and the pH of the solution in which histidine is dissolved. The pK of histidine varies widely between 5 and 8, depending on the nature of the molecule with which histidine is associated.[70] The pK is 6. 1 in histidine, but carnosine, a dipeptide composed of beta-alanine and histidine, an important intracellular buffer in the muscle of many vertebrates, has a pK of 6.83.[71] When histidine is part of a protein molecule or peptide molecule, its pK depends on the adjacent amino acid. Next to an acidic group, the pK of histidine rises, and next to a basic group, the pK decreases. Each of 16 histidine molecules in albumin has different pK values because of the differing influences of neighboring amino acids.[72]

The histidine content of hemoglobin is particularly high (38 per molecule of hemoglobin), this fact and a very high concentration of hemoglobin (about 7 times that of plasma albumin) explain the excellent buffering capacity of hemoglobin.[73] Oxygenation of hemoglobin at the lung reduces the pK of the imidazole group, i.e., it becomes a stronger acid. The acid reacts with bicarbonate to create more CO_2, which is eliminated by ventilation.

Even in the case of the basic and acidic amino acids, their eventual acidity or alkalinity depends on the nature of the counter-ions balancing the respective amino or carboxyl groups; when these groups are balanced by non-combustible ions such as Na^+, K^+, Cl^- or phosphate, their metabolism results in a net gain of acid or alkali. If the counter-ions are organic ions, the metabolism of the amino acid does not result in a net gain of acid or alkali. In most foods the total number of non-metabolizable cations exceeds that of non-metabolizable anions,[74] and therefore, apart from the contribution of sulfuric acid production, their metabolism would produce alkali.

Organic Acids in Meat

A substantial amount of organic anions, especially lactate, has been found in meat, and it has been

suggested that in the overall calculation of dietary net acid production a role for lactic acid be included.[75] However, most of lactate present in meat is produced after the death of the animal. Initially, lactic acid is formed and reacts with cellular alkali. When meat is digested and absorbed, during the process of lactate metabolism, exactly the same amount of protons is consumed as were released during the production of lactic acid. In the end, the net alkali or acid content of the body is unaffected by the production of lactic acid. By analogy, addition of acetic acid in the form of vinegar to food would produce acetate, but would not alter the net acid or alkali value of the food. As long as the content of non-combustible cations and anions remains the same, the net acid or alkali of meat would not change.

GI ABSORPTION OF ACIDS AND ALKALI

The normal diet contains large quantities of alkali, potential alkali, acids, and potential acids, but their ultimate impact on the body's acid–base balance depends primarily on their absorption. The pattern of absorption depends not only on the nature of the substance, but also on its interaction with other chemicals, both endogenous and exogenous.[76,77] In general, the amount absorbed is nearly equal to the amount ingested, if the substance is soluble and is readily absorbed. The examples include $NaHCO_3$, Na^+ citrate, K^+ citrate, and NH_4Cl. An insoluble substance such as $CaCO_3$ must react with gastric acid or acid in food to become soluble and absorbable. In some cases, only the anionic part is absorbable (e.g., Cl^- in cholestyramine chloride); in other cases, only the cationic part (e.g., Na^+ sodium polystyrene sulfonate) is absorbable. The overall effects of these substances on the body's acid–base balance are complex, and are often unrelated to the acidity or alkalinity of the substance. The following section describes two major categories of chemical substances, and the effects of their ingestion on acid–base balance.

Ingestion of a Poorly- or Non-Absorbable Cation Accompanied by an Absorbable Anion

Intravenous $CaCl_2$ is neutral, but ingested $CaCl_2$ is an acidifying agent. When ingested, virtually all of the Cl^-, but only a fraction of the Ca^{2+}, is absorbed. The excess Ca^{2+} remaining in the gut is excreted in the stool after combining with $CO_3^=$, organic anions or $HPO_4^=$. The type of anionic exchange determines the effect on acid–base balance. Typically, ingested $CaCl_2$ reacts with $NaHCO_3$:

$$CaCl_2 + 2NaHCO_3 \rightarrow 2NaCl + CaCO_3 + H_2CO_3$$

NaCl is absorbed and the insoluble $CaCO_3$ is excreted in the stool, resulting in net loss of $NaHCO_3$. Thus, the net effect of oral ingestion of $CaCl_2$ that results in formation and fecal excretion of $CaCO_3$ is loss of two moles of alkali for each mole of Ca ingested. On the other hand, when $CaCl_2$ reacts with Na_2HPO_4, NaCl is absorbed and $CaHPO_4$ is excreted in the stool:

$$CaCl_2 + Na_2HPO_4 \rightarrow 2NaCl + CaHPO_4$$

The loss of one mole of Na_2HPO_4 changes the ratio of Na_2HPO_4/NaH_2PO_4 from 4:1 to 3:1. In order to re-establish the ratio of Na_2HPO_4/NaH_2PO_4 at 4:1, 0.2 mole of NaH_2PO_4 must be converted to 0.2 mole of Na_2HPO_4, which would release of 0.2 mole of H^+. The new ratio would be 3.2 $(3 + 0.2)/0.8$ $(1 - 0.2)$, the same 4:1 ratio. Thus, the net effect is the gain of 0.2 mole of acid for each mole of $CaCl_2$ ingested. $CaCl_2$, if absorbed, would have no effect on the acid–base balance.

Since $SO_4^=$ is more readily absorbed than Mg^{2+}, the overall effect of $MgSO_4$ ingestion would be similar to that of ingestion of $CaCl_2$. Similarly, $FeSO_4$ could result in a net gain of acid, to the extent that more SO_4^{2-} than Fe^{2+} is absorbed.

When a person ingests salts consisting of a non-absorbable or poorly absorbable cation, accompanied by an absorbable and metabolizable anion, for example, $CaCO_3$, $Al(OH)_3$, Ca acetate, and Ca citrate, the amount of alkali gained depends on the absorption of anions, either with the accompanying cations or in exchange for non-metabolizable anions, such as phosphate. Absorption of $CaCO_3$ is facilitated when it reacts with HCl in the stomach or acid in food, because $CaCO_3$ is poorly soluble. The reaction in the stomach will be:

$$CaCO_3 + 2HCl \rightarrow CaCl_2 + H_2CO_3.$$

The fate of $CaCl_2$ formed will be the same as that of $CaCl_2$ ingested. Absorption of Ca as $CaCO_3$ or $CaCl_2$ represents a gain of alkali. Absorption of $CO_3^=$ in exchange for $HPO_4^=$ also represents a gain of alkali. Loss of $CaCO_3$ in the stool has no effect on the acid–base balance. Ingestion of organic salts of calcium, such as calcium citrate, calcium lactate, calcium gluconate, and calcium acetate also result in a similar gain of alkali. As with calcium carbonate, alkali gain occurs when these organic anions are absorbed either with calcium or in exchange with phosphate. The overall alkalinizing effect of various calcium antacids depends more on the ability of calcium to bind phosphate than on the absorption of calcium, because the amount of Ca^{2+} absorbed is usually much less than

the amount bound to phosphate to be excreted in the stool. The phosphate-binding ability depends in part on availability of soluble calcium.[78] This might explain why the amount of phosphate bound by calcium when calcium is ingested as $CaCl_2$ is comparable to that bound by aluminum ingested as $Al(OH)_3$,[79] whereas calcium carbonate salt removes only half as much phosphate for the same amount of calcium, because of its poor solubility. Despite poor absorption of aluminum, net gain of alkali is greater with $Al(OH)_3$ than with $CaCO_3$, because aluminum is a more effective binder of phosphate than calcium.[80]

Anion exchange resins are other examples of non-reabsorbable cations accompanied by absorbable anions.[79] As with calcium salts, they have either an acidifying or alkalinizing effect, depending on whether the accompanying anion is metabolizable or not. When the counter-ion is non-metabolizable, such as chloride (e.g., cholestyramine), its absorption in exchange for organic anions, carbonate or bicarbonate represent loss of alkali. When chloride is exchanged for phosphate, it represents 0.2 mEq of alkali loss for each mmol of phosphate lost as HPO_4. When the counter-ion is metabolizable (e.g., acetate), a net gain of alkali occurs when the metabolizable anion is absorbed in exchange for chloride or phosphate. An exchange of a metabolizable anion with organic anions, carbonate or bicarbonate is a neutral process (Table 10.6).

TABLE 10.6 Effect on Acid–Base Balance of Anion Exchange Resins (AER), Depending on its Accompanying Anion and Type of Anion in the Gut to be Exchanged

- Resin with metabolizable anion, exchanged for non-metabolizable anion: Gain of alkali
- Resin with metabolizable anion, exchanged for metabolizable anion: Neutral
- Resin with non-metabolizable anion, exchanged for metabolizable anion: Gain of Acid
- Resin with non-metabolizable anion, exchange for non-metabolizable anion: Neutral

Ingestion of a Poorly- or Non-Absorbable Anion Accompanied by an Absorbable Cation

An example is ingestion of Na^+ or K^+ phosphate. Intestinal absorption of Na^+ and K^+ is nearly complete as long as the accompanying anion can also be readily absorbed. Absorption of phosphate, on the other hand, is limited for two reasons. First, absorption of phosphate is achieved by sodium–phosphate co-transporters,[63–65] which have a limited capacity. When the intake of phosphate is in excess of the transporter capacity, unabsorbed phosphate is excreted in the stool. This explains why an excessive amount of sodium phosphate causes diarrhea. Second, some of the ingested phosphate can form an insoluble complex with calcium, which is precipitated and excreted in the stool. Na^+ or K^+ will then be balanced by the anion that is left behind, and the precipitated calcium will be absorbed. If the anion that is absorbed with sodium or potassium is an organic anion or carbonate, the result will be net gain of alkali:

$$Na_2HPO_4 + CaCO_3 \rightarrow Na_2CO_3 \text{ (absorbed after conversion to } NaHCO_3) + CaPO_4 \text{ (excreted in stool)}$$

Ingestion of a Cation-Exchange Resin Results in Net Gain of Alkali by a Similar Mechanism

The unabsorbable polyanion in a cation exchange resin is usually sulfonate attached to a polystyrene skeleton balanced by an exchangeable and absorbable cation, e.g., Na^+ in sodium polystyrene sulfonate (Kayexalate). When Na^+ exchanges for K^+, it has no effect on acid–base balance. An exchange of Na^+ for NH_4^+ or H^+ results in gain of alkali. When it exchanges with Ca^{2+}, the net effect is also gain of alkali, because normally the bulk of Ca^{2+} excreted in the stool is insoluble calcium carbonate, which represents loss of alkali.[80,81] When Ca^{2+} in calcium carbonate is exchanged for Na^+ in sodium polystyrene sulfonate (PSS), Na_2CO_3 is formed and then absorbed; at physiological pH, Na_2CO_3 will react with H_2CO_3, and two molecules of $NaHCO_3$ will form, and then be absorbed. This effect is more pronounced when the resin is administered with calcium salts,[80,81] aluminum salts or magnesium salts. Exchange between Na^+ and Al^{3+} or between Na^+ and Mg^{2+} results in formation of NaOH or Na^+ carbonate, which is readily absorbable directly or indirectly.

$$Na_2 - PSS + CaCO_3 \rightarrow Ca - PSS \text{ (excreted in stool)} + Na_2CO_3 \text{ (absorbed after conversion to } NaHCO_3).$$

If sodium polystyrene sulfonate (PSS) is ingested along with $Al(OH)_3$, the following reaction will occur:

$$Na_3 - PSS + Al(OH)_3 \rightarrow Al - PSS \text{ (excreted in stool)} + 3NaOH \text{ (absorbed after conversion to } 3NaHCO_3).$$

Calculation of Net Alkali in a Complex System

Ingestion of, for example, 20 mmol of K^+ citrate, which is completely absorbable and metabolized to $KHCO_3$ in the body, would result in net gain of

20 mEq of alkali. Ingestion of 10 mmol of arginine Cl would result in net gain of 10 mEq of acid. If a food contained both, the net gain of alkali would be 10 mEq. The food contains numerous chemicals, and their absorption depends not only on the type of chemicals ingested, but also on interactions with gastric acid and other chemicals in simultaneously ingested food or drugs. Thus, prediction of the effect of food ingestion on acid–base balance is nearly impossible. Measurements are made, instead, by analyzing net alkali content of food and feces. The difference between these two represents net alkali absorbed.

Net alkali content of food and feces is estimated by the electrolyte balance technique, i.e., the sum of non-combustible cations ($Na^+ + K^+ + Ca^{2+} + Mg^{2+}$) minus the sum of non-combustible anions ($Cl^- + 1.8$ P).[36] The assumption here is that when non-metabolizable cations are accompanied by metabolizable anions, the subsequent absorption and metabolism of their anions would result in gain of alkali, and that ingestion and absorption of non-metabolizable anions accompanied by metabolizable cations would lead to gain of acid. Hence, the difference between the two represents a net gain of alkali or acid. The concentrations of all of the electrolytes are expressed in mEq, except phosphate, which is expressed in mmol and then multiplied by the factor 1.8, the average valence of phosphate at pH 7.4. The pH of food or feces is not a determinant in the calculation of valency of phosphate, since that pH is relevant only in reference to blood pH.

For the calculation of net alkali content of food and feces, the only non-metabolizable ions presumed to be present are Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, and P, because no other ions in food are present in significant amounts. Urinary excretion of sulfate is substantial, but it is assumed to originate almost exclusively from sulfur-containing amino acids, and is measured separately.[43] This assumption does not appear valid any longer, because of ingestion of inorganic sulfates that are contained in substantial amounts in soft drinks. According to one estimate, an average amount of sulfate ingested per day in USA is about 15 mEq/day.[41] Thus, the presence of inorganic sulfate in the diet would lead to the estimation of a falsely increased amount of net GI alkali content. On the other hand, the inclusion of sulfate that originates from inorganic sulfate in soft drinks in the calculation of endogenous acid production would falsely increase its estimation. Thus, these two errors would cancel each other out.

Some organic anions found in food, e.g., tartarate, are poorly metabolized by the human body, and such anions would also result in a falsely increased estimation of net GI alkali absorption. On the other hand, all organic anions excreted in the urine estimated by the titration method are assumed to originate from organic acids produced in the body, and this assumption results in a falsely increased measurement of organic acid generation by the presence of substances such as tartarate in urine. These two errors would cancel each other out. Furthermore, it has been shown that the bulk of ingested tartarate in humans is actually metabolized by colonic bacteria, and only about 14% of ingested tartarate appear in urine unchanged.[82] Choline is an example of an incompletely metabolizable cation, but choline is also mostly metabolized by colonic bacteria.[83]

The measurement of GI absorption of alkali by the analysis of food and feces is difficult and prone to inaccuracies for obvious technical reasons. Measurements can be made only in inpatient settings with controlled diet, and consequently no study has measured net GI absorption of alkali on a normal diet in an outpatient setting. In a simplified technique, net GI absorption of alkali is estimated as urinary non-combustible cations minus urinary non-combustible anions:[84]

$$\text{Net GI Alkali absorption} = \text{Urine}\,(Na^+ + K^+ + Ca^{2+} + Mg^{2+}) - \text{Urine}\,(Cl^- + P \times 1.8).$$

The method is based on the assumption that the difference between the amounts of non-combustible cations and non-combustible anions absorbed from the gut equal the difference between the amounts excreted in the urine under stable conditions. The validity of this assumption is supported by empirical, as well as theoretical, evidence. Theoretically, the amount of non-metabolizable ions absorbed must equal the amount excreted, for the following reasons. The total extracellular content of divalent ions is small (about 45 mEq of Ca^{2+}, 30 mEq of Mg^{2+}, and 30 mEq of P), and their daily net flux with bone is negligible.[38] Hence, the amount of divalent ions excreted in the urine must be quite close to the amount absorbed from the GI tract. For univalent ions, Na^+, K^+, and Cl^-, their GI absorption is nearly complete. Consequently, the amount excreted in the urine would closely reflect the amount absorbed from the GI tract in states of acid–base balance. In a non-steady-state with a net gain of acid by the kidney, there would be excess excretion of Na and K. In a non-steady-state with a net gain of alkali by the kidney, there would be excess excretion of Cl.

Empirically, the measurement of net alkali absorption from the GI tract measured by the analysis of diet and stool showed near perfect correlation with the measurement made by urine electrolytes.[84] The amount

of net alkali absorbed on a usual diet by the latter technique is about 30 mEq/day.[38]

BONE BUFFERING IN METABOLIC ACIDOSIS

Bone Buffering in Chronic Metabolic Acidosis

It was once widely believed that bone was very important in maintaining stable serum HCO_3^- in chronic renal acidosis. Studies have shown that patients with chronic renal acidosis are able to maintain a stable serum HCO_3^-, despite retention of 12–19 mEq of acid daily, with the average duration of acidosis of six years. Because bone is known to have a large alkali reserve, the maintenance of a stable serum HCO_3^- in such settings has been attributed to the sustained release of alkali from bone.[3,4]

However, there has been little direct evidence for substantial bone buffering of acids in chronic acidosis of such long duration. The best evidence against a substantial role of bone in chronic renal acidosis is the lack of significant calciuria.[85] Addition of alkali to the body from Ca^{2+} release by bone occurs only when Ca^{2+} is excreted in urine. Re-deposition of Ca^{2+} salts in tissues or excretion in the stool as alkaline Ca^{2+} salts would reclaim alkali released from bone.[86] If the released calcium is lost in the stool as $CaCO_3$, it would actually result in net loss of alkali. Each mmol of Ca hydroxyapatite releases 10 mmol of Ca and 9.2 mEq of alkali. Loss of 10 mmols of calcium as calcium carbonate excreted in the stool removes 20 mmols of alkali from the body. Hence, the net alkali loss would be 10.8 mmols. If calcium from bone is released as $CaCO_3$, and excreted in the stool as $CaCO_3$, there will be no loss or gain of alkali. Release of calcium from hydroxy apatite with subsequent deposition as hydroxy apatite represents no gain or loss of alkali.

Furthermore, the total amount of alkali reserve in bone is insufficient to account for the buffering of acid for such a protracted period. Assuming total bone content of Ca^{2+} at 60,000 mEq, the total alkali content of bone is estimated to be about 25,000 mEq. At the rate of 19 mEq of acid buffering per day, the bone alkali store would be exhausted in 3.6 years.[38,87]

Bone Buffering in Acute Metabolic Acidosis

It is also widely believed that bone plays an important role in buffering in super-acute acidosis, but the available evidence is not convincing. Fraley and Adler showed that rats and dogs with total thyroparathyroidectomy developed a much more severe metabolic acidosis than those with intact organs.[88] The authors concluded that without intact parathyroid glands, non-extracellular buffers were responsible for titrating only 3 and 22% of the administered acid in rats and dogs, respectively. They concluded that the difference in buffering capacity was due to a difference in bone buffering. Arruda et al. concurred with Fraley and Adler that PTH significantly affected the overall buffering,[89] but the data of Madias et al. did not show any difference in buffering capacity.[90] Buffering of acid by bone could occur in three different ways: (1) release of cations such as Na^+, K^+, Ca^{2+}, and Mg^{2+} accompanied by carbonate, hydroxide or phosphate; (2) exchange of bone carbonate for extracellular phosphate; and (3) deposition of extracellular non-metabolizable anion such as Cl^- along with an H^+.

The third mechanism has not been shown to exist. For the first mechanism to operate, a cation must be released from bone. Mg^{2+} does not participate in acid buffering of bone. Release of bone K^+ cannot play a quantitatively significant role, because the entire bone content of K^+ in adult humans is a mere 20 mEq.[91] Evidence for Na^+ release from bone exists in acute metabolic acidosis, but the magnitude is a not very substantial. Bettice and Gamble showed that the bone content of exchangeable Na^+ decreased by about 5% in 5 hours following acute acid loading in dogs.[92] The bone Na^+ content is about 1200 mEq, and about 40% of this, 480 mEq, is exchangeable. Thus, 5% of 480 mEq represents a mere 24 mEq ($480 \times 0.05 = 24$). In conclusion, it seems highly improbable that bone contributes substantially to the buffering in super-acute metabolic acidosis (acidosis within a few hours).

Release of Ca^{2+} from bone is an important mechanism of bone buffering in acute metabolic acidosis. Urinary excretion of Ca^{2+} can increase by 80 mEq per day. If the entire amount came from Ca^{2+} carbonate, that amount of calcium release would release 80 mEq of alkali. If the same amount of Ca^{2+} originated from hydroxyapatite, alkali released is 36.8 mEq. Increased excretion of Ca^{2+} in metabolic acidosis reaches a maximal value a few days after the start of acid load.[93]

The likely explanation for the appearance of impaired buffering in animals with thyroparathyroidectomy is tissue under-perfusion due to circulatory shock. Since the blood flow to the muscle in humans is only about 700 ml per minute, it is obvious that buffering by skeletal muscle would not be complete in 30 minutes in a resting state. Reduced blood flow by circulatory shock would further delay the buffering by both intra- and extracellular fluid of the muscle, and could have given the impression that cell buffering was virtually absent in this setting.

In conclusion, bone is quantitatively an unimportant source of alkali in chronic metabolic acidosis of several years' duration. In acute acidosis, contribution of bone to acid buffering could be substantial, but its contribution in super-acute acidosis (that of several hours duration) appears negligible.

Renal Cilia Structure, Function, and Physiology

Jay N. Pieczynski and Bradley K. Yoder

Department of Cell Biology, University of Alabama at Birmingham, Birmingham, AL, USA

INTRODUCTION

The first descriptions of the cilium are generally attributed to Leeuwenhoek (as translated in [1]). Cilia were thought to be analogous to the flagellum used by single cell organisms for motility. It soon became obvious that motile cilia also have a function in multiple human tissues; motile cilia found in the respiratory track are involved in clearance of mucus and debris, cerebral spinal fluid movement is assisted by motile cilia on ependymal cells lining the brain ventricles, and flagella function to propel sperm through the reproductive tract for fertilization. In fact, the first human disease associated with cilia dysfunction was Primary Ciliary Dyskinesia ("primary" here referring to the fact that impaired movement of cilia was the cause of the disease (PCD)[2,3]). These patients suffer from chronic rhinitis, bronchiectasis, infertility, and abnormal left–right body axis specification caused by defects in cilia motility.

Most cell types in the mammalian body do not have motile cilia; they possess a single immotile cilium (referred to as the *primary cilium*). The functional importance of the primary cilium remained enigmatic, and the primary cilium was often considered vestigial. It wasn't until the mid-1990s and early 2000s that a number of essential observations were made linking the primary cilium to disease phenotypes, largely through studies in model organisms. One of the initial breakthroughs came from a large-scale insertional mutagenesis project conducted on mice in the laboratory of Dr. Rick Woychik at the Oak Ridge National Laboratories. This screen resulted in the identification of the Oak Ridge Polycystic Kidney (*orpk*) mouse,[4] a genetic model for autosomal recessive polycystic kidney disease (ARPKD, OMIM# 263200). *orpk* mutants have multi-organ defects, including cystic lesions in the kidney, liver, and pancreas, hydrocephalus, anosmia, retinal degeneration, skin and hair abnormalities, brain malformation, and skeletal defects.[5] Many of the phenotypes observed in the *orpk* mutants have also been reported in human disorders caused by mutations in proteins associated with the cilium (Table 11.1). These disorders are collectively referred to as "*ciliopathies*," and the *orpk* mutant mouse has become an important mammalian model system for studying ciliary dysfunction and disease. The transgene insertion in *orpk* mutant mice caused a hypomorphic mutation in a gene called "*Tg737*" that encodes the protein Polaris.[4,6,7] Polaris localizes to the cilium, and in the *orpk* mutants both motile and primary cilia were stunted and malformed, although the function of the protein remained unknown.[8]

Another major advance came from the proteomic analysis of flagella isolated from the green alga *Chlamydomonas reinhardt*.[9] This study identified several components of the intraflagellar transport (IFT) particle that included intraflagellar protein 88 (*Ift88*), the homolog of Polaris in *Chlamydomonas*.[10] IFT is an evolutionarily conserved transport system that mediates bidirectional movement of proteins between the base and tip of the cilia/flagella, and is essential for the construction and maintenance of cilia/flagella (Figure 11.1; Table 11.2; see section "Intraflagellar Transport (IFT) and IFT Motors").[11] In agreement with a role in IFT, further studies in *Caenorhabditis elegans* (*C. elegans*) on OSM-5, the IFT88/Polaris homolog, revealed that mutations disrupting this protein also cause severe defects in cilia assembly.[12]

[a]*Genes are categorized by ciliopathy based on Online Mendelian Inheritance in Man (OMIM, http://www.ncbi.nlm.nih.gov/omim) entries at time of writing.*

Thus, the function IFT88 is highly conserved across diverse species.

One of the most significant breakthroughs connecting cilia dysfunction to human diseases came from studies in *C. elegans* by Barr et al. They conducted a genetic screen to identify genes involved in male mating behavior and uncovered mutations in *lov-1* and *pkd-2*, the homologs of human polycystin-1 (PC-1) and polycystin-2 (PC-2), respectively.[13] Importantly, mutations in these two genes cause human autosomal dominant polycystic kidney disease (ADPKD OMIM# 601313, # 173910); a disorder that affects nearly 1 in 1000 individuals and is a leading cause of end-stage renal disease. In *C. elegans*, both *lov-1* and *pkd-2* proteins localize to the cilium of male sensory neurons.[14] Subsequently, the mammalian proteins were also localized in the cilium of renal epithelium[15,16] leading to a paradigm shift in the understanding of the possible mechanisms involved in human PKD. Multiple cystic kidney disease genes in mice, rats, and humans have now been identified and in nearly every case, the affected proteins encoded by these genes are associated with the cilium (reviewed in [17–20]).

These initial observations in model systems ushered in a renewed interest into the functions and clinical importance of the primary cilium. Even though research into the role of primary cilia has now extended to almost every tissue in the body, the involvement of the cilium in the kidney has garnered particular focus. In part this may reflect the morbidity and mortality associated with PKD, as well as the high incidence of PKD.

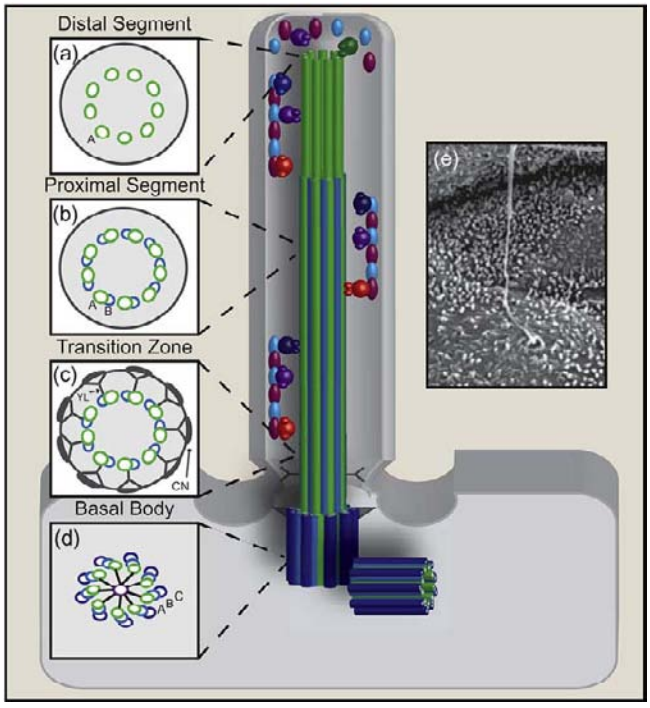

FIGURE 11.1 **Ultrastructure of the primary cilium**. A microtubule-based axoneme nucleates from the basal body and extends the length of the cilium. IFT-A (maroon) and IFT-B (light blue) complexes form IFT-A/B particle trains and travel along the axoneme via IFT with their associated cargoes. Anterograde IFT (left side of axoneme) occurs via Kinesin-2 (dark blue) and Kif-17 (purple) motor proteins. IFT-A/B particle trains are disassembled and reassembled at the ciliary tip. Retrograde IFT (right side of the axomene) removes IFT-A/B particles and associated proteins from the cilium via the cytoplasmic dynein-1 retrograde motor protein (red). Insets (a–d) illustrate cross-sections of ciliary microtubule structure. (a) Distal segment with 9 + 0 "A" axonemal microtuble singlets; (b) Proximal segment with 9 + 0 "A/B" axonemal doublets; (c) transition zone with Y-links (YL) and ciliary necklace (CN) respectively; (d) basal body with "A/B/C" microtubule triplets; (e) scanning electron micrograph of the primary cilium. *(Image adapted from Alvaro, D. et al. CILIA ULTRASTRUCTURE AND COMPONENTS

The primary cilium on renal epithelial cells is a small, membranous, hair-like extension protruding from the surface of the cell into the lumen of the nephron tubule. This simple description, however, disguises the high level of complexity that is necessary for the cilium to function as an intricate signaling and sensory organelle (Figure 11.1). Below the membranous covering of the cilium lies a precisely ordered series of axoneme microtubules. At the base of the cilium, the axoneme microtubules are anchored to the cell and cell membrane by a series of specialized structural components including transition fibers, the transition zone, ciliary necklace, and a modified centriole termed the *basal body*. These structures are further defined below.

Centrosomes and Basal Bodies

Centrosomes are comprised of a pair of centrioles, an older mother centriole and a daughter centriole, surrounded by a proteinaceous matrix. Mother–daughter centrioles are aligned orthogonally, with the mother centriole aligned towards the cell surface. The mother centriole becomes the basal body, which acts as a microtubule-organizing center (MTOC) for axonemal nucleation at the base of the extending cilium. Basal bodies are comprised of a nine-ring helix of triplet microtubules that contain γ-tubulin, in addition to α- and β-tubulins (Figure 11.1d). Axoneme microtubule polymerization is initiated by nucleation of γ-tubulin-containing microtubules of the basal body.

In addition to their microtubule cores, basal bodies are also comprised of numerous associated proteinaceous appendages that facilitate ciliogenesis. Although the basal body appears symmetrical, the distribution of centriolar appendages gives the basal body asymmetry with respect to its proximal–distal axis. The basal foot (also called sub-distal appendages) and the transition fibers (also called distal appendages) extend from the more distal end of the basal body. The formation of transition fibers on the basal body is a distinct process from that of ciliogenesis, yet it has been demonstrated that transition fibers are necessary for cilia to form.[21,22] Transition fibers appear necessary for tethering the basal body to the membrane (see section "Transition Fibers" and [23]), thus establishing the basis for cilia anchorage.

The proteinaceous matrix surrounding the basal body is termed the *pericentriolar material* and contains centriolar components. Although the pericentriolar material does not form the structure of the centriole/basal body, these proteins are necessary for centriolar organization and control of mitosis. Puncta of proteins surrounding centrioles (centriolar satellites) will often be dynamically associated with the centrosome depending on cell cycle stage.[24]

Ciliary Axoneme

The core of both motile and primary cilium is an organized microtubule-based axoneme extending from the basal body. Axonemal microtubules have (+) ends, localized at the ciliary tip, and (−) ends anchored to the basal body. These microtubules serve as tracks for molecular motor protein transport of cargo along the cilium (Table 11.2 and see section "Intraflagellar Transport (IFT) and IFT Motors").

*Mutated in CED.
^Mutated in ATD.

Axonemal microtubules are arranged in a ring of nine doublets (Figure 11.1b). Cryo-electron tomography imaging of cilia axoneme microtubles by Sui and Downing[25] illustrate that each doublet is comprised of a larger A-tubule, and a smaller incomplete B-tubule. Both A and B tubules of the axoneme microtubles are comprised of α- and β-tubulin protofilaments similar to the cytoplasmic microtubules. The axonemal microtubule doublet may either extend the entire length of the cilium or terminate into a mircotubule singlet that continues into the distal cilium (Figure 11.1a). Most motile forms of cilia also contain additional structures used in generating motility. These include a central pair of microtubules, in addition to their nine-ring doublet, radial spokes, inner and outer dynein arms, and nexin links.[26] The incorporation of a central pair of microtubles in motile cilia is referred to as a *9 + 2 arrangement*. However, not all 9 + 2 cilia are motile, as revealed by olfactory sensory neuron cilia. Immotile primary cilia, such as those found in renal epithelia, lack the central microtubule pair and many of the motility components.[27] Lack of a central microtubule pair is referred to as a *9 + 0 axonemal* microtubule arrangement (Figure 11.1).

The Transition Zone

The cilium is not a simple extension of the cell membrane or cytosol, but rather it has a distinct complement of proteins necessary for its construction, signaling, and sensory functions. The specialization is established by structures located at the base of the cilium that function to separate the ciliary compartment from the rest of the cell.

At the proximal end of the cilium nearest the basal body, the cilia membrane is closely associated with the axoneme microtubules. This region is known as the *transition zone*. Ultrastructurally, the transition zone (Figure 11.1c) is comprised of a radial array of Y-shaped links, with the bottom of the "Y" attaching to each axonemal microtubule doublet and top of the "Y" likely forming attachments with the nearby cilia membrane.[28] The molecular composition of the Y-links are unknown, however, centrosomal protein 290 (CEP290)[29] and the protein p210[30] were shown to localize to the distal end of the basal body in the area of the transition zone Y-links in *Chlamydomonas*. The transition zone appears to be an important domain, as many proteins associated with Meckel-Gruber Syndrome (MKS, OMIM# 249000) and Nephronophthisis (NPHP, OMIM# 256100) function as part of genetically and biochemically interacting complexes that also localize in this region.[31,32] In *C. elegans*, mutations disrupting the interactions between the transition zone proteins involved in NPHP and MKS cause the loss of Y-links, detachment of the ciliary membrane from the axoneme, abnormalities in regulating protein entry into the cilium, and defects in cilia positioning, orientation, and assembly.[32] It is not currently known whether the MKS and NPHP proteins are a direct component of the Y-links or whether the loss of the Y-links in *nphp* and *mks* mutants is a secondary consequence.

The Ciliary Necklace

At the position where the Y-links attach to the inside of the ciliary membrane, the outside of the membrane is decorated with electron-dense proteinaceous nodules.[28] These decorations are collectively referred to as the "*ciliary necklace*" (Figure 11.1d; denoted "CN"). When observed by electron microscopy, the ciliary necklace appears to restrict around the axoneme, and somewhat resemble tight junctions in epithelial cells. As such, the ciliary necklace, along with the Y-links, may function as a barrier machinery that is selective for ciliary transmembrane and membrane associated proteins. The composition of the ciliary necklace remains to be defined, and the mechanisms by which this region may function as ciliary barrier is a major focus of ongoing studies.

Transition Fibers

Through electron microscopy studies, it is apparent that there are electron-dense fiber-like structures

extending from the distal end of the basal body that tether the basal body to the base of the ciliary membrane.[23] These structures are known as transition fibers (Figure 11.1). Nine transition zone fibers extend at an angle from the distal tip of the basal body and connect with membrane creating an elaborate pinwheel-like conformation.[23] Space filling models reconstructed from electron micrographs suggest that the space between transition fibers could accommodate particles up to 60 nm,[23] suggesting that this region could act as part of a ciliary gating or barrier mechanism preventing soluble cytosolic protein from entering the cilia. It has therefore been hypothesized that there must be other, active mechanisms for ciliary entry that are localized to this region.[33] Data obtained from studies in *C. elegans* suggest that the transition fibers are docking sites for the IFT particles (see section "Cilia Transport and Trafficking"), and that the transition fibers function in loading and unloading of ciliary cargo onto the IFT particles for transport.[34] Relatively few transition fiber proteins have been identified. One candidate is Cep164, which localizes in the region of the transition fibers and is necessary for ciliogenesis.[21]

Cilia Membrane

The cilium has a distinct composition with regards to both protein and lipid content.[35,36] Identifying the composition of the primary cilia in mammalian cells has been technically challenging, as the surface area of the cilia membrane comprises a small fraction of the total cell membrane. Initial analyses indicate that the cilia membrane contains a high concentration of sterols relative to phosphinostitides when compared to plasma membrane.[37] The high levels of sterols in cilia have led some to speculate that cilia are enriched in lipid rafts, which also have high sterol content. In fact, several ciliary and cystic kidney disease proteins, such as cystin, associate with lipid raft components, and inhibiting this association can impair their transport to the cilium.[38]

Information regarding the protein composition of the cilium has been obtained through proteomic and genetic studies in model systems, as well as comparing the genomes of ciliated and non-ciliated organisms.[39] Although proteomic analysis has been performed on motile cilia and photoreceptor cilia isolated from mammalian cells, currently the most complete information regarding the protein composition of the cilium/flagellum come from *Chlamydomonas*.[40] This is in part due to the ease with which deflagellation can be induced in this organism, allowing for purification and proteomic analyses.

Proteomic data revealed that the cilium contains a large number of transmembrane and membrane associated proteins that in many cases are not found in other regions of the cell. These proteins must be specifically targeted to the cilium (see section "Cilia Transport and Trafficking"). The localization of proteins in the cilia membrane is necessary for normal cilia mediated sensory functions and signaling activities (see section "Cilia Signaling in the Nephron"). This has important implications in common renal disorders, since transmembrane proteins, such as PC-1 and PC-2[15,16] localize in the cilium (see Chapter 81 for a detailed description). Other cystic kidney disease transmembrane proteins found in the cilium include fibrocystin/polyductin, and the Meckel–Gruber syndrome proteins 2[41] and 3[42] (MKS2 and MKS3 respectively) that localize to the transition zone region (see section "Transition Fibers").

CILIA TRANSPORT AND TRAFFICKING

For the cilium to function as a sensory and signaling center, it requires the specific targeting and transport of proteins into and out of the cilium. Although the mechanism of ciliary targeting and protein transport remain poorly understood, great advances have come from seminal studies in model organisms and human ciliopathy patients. We now know many of the core components of the cilia trafficking machinery. Machinery involved in cilia trafficking include the microtubule motor driven intraflagellar transport (IFT) proteins originally defined in *Chlamydomonas*, and the BBSome, a complex of proteins disrupted in Bardet–Biedl syndrome (BBS, OMIM# 209900), that function in cilia membrane protein trafficking and vesicular transport. It has become evident that ciliary trafficking machinery often utilizes canonical endocytic pathways involving the Rab-family of proteins (reviewed in [43]). Understanding how ciliary trafficking falls into conventional trafficking modules is the focus of many ongoing studies.

Intraflagellar Transport (IFT) and IFT Motors

The axoneme provides the cilium structure, and also serves an important role in building the organelle and trafficking proteins through the cilium. Axonemal microtubules are used for trafficking components in both anterograde (toward the cilia tip) and retrograde (toward the basal body) directions in a process known as *intraflagellar transport* (IFT).[11] Coordinated, bidirectional IFT movement is localized between the outer doublet microtubules and the ciliary membrane.

IFT is required to build and maintain the primary cilium through the movement of two interacting

macromolecule complexes, IFT-A and IFT-B (summarized in Table 11.2 and reviewed in [44,45]). IFT-A and IFT-B interact to form a large IFT-A/B particle chain that moves together in both anterograde and retrograde IFT. It has been documented that mutations in IFT complex proteins can cause human ciliopathies. Both Jeune Asphixiating Thoracic Dystrophy (ATD, OMIM# 208500) and Sensenbrenner syndrome (CED, OMIM# 218330) are caused by mutations in IFT genes (Tables 11.1 and 11.2, and see sections "Jeune Asphyxiating Thoracic Dystrophy (ATD)" and "Sensenbrenner Syndrome (Cranionectodermal Dysplasia, CED)." In general, the mutations in IFT proteins identified in human patients are thus far hypomorphic, suggesting that complete loss of IFT function is not viable.

In addition to the proteins that make up IFT complexes A and B proper, there is emerging evidence for IFT associated proteins that are important for ciliary protein trafficking and ciliary function. For example, IFT20 is associated with trafficking of proteins from the Golgi to the cilia base.[46] Also, IFT27 (Rabl4) and IFTA-2 (Rabl5) are both Rab-like proteins that associate with the IFT-A/B complex.[47,48] The function of these proteins is poorly understood; however, in the absence of *Rabl5* in *C. elegans*, cilia regulated signaling pathways are affected even though *Rabl5* is not required for ciliogenesis.[48] Thus, the current hypothesis is that *Rabls5* and other IFT associated proteins may function to connect specific cargo with the IFT complex or in more subtle regulation of cilia signaling and sensory activities.

Specific motor proteins mediate IFT bidirectional movement in the cilium (Table 11.2). Kinesin-2 associates with the IFT-A/B complex to move the IFT particle in the anterograde direction toward the cilia distal segment.[49,50] A second kinesin, Kif17, specifically associates with the IFT-B complex, and appears to function largely in movement of the IFT-A/B particle along the distal segment of the cilium.[51] The retrograde motor, cytoplasmic dynein-2, mediates movement of the IFT-A/B particle with its associated cargo in the retrograde direction toward the basal body.[52] It should be noted that most of the data concerning motor-microtubule specificity is largely based on studies using homologs of cilia motor proteins in *C. elegans* and *Chlamydomonas*.

IFT builds and maintains its primary cilium by shuttling tubulin subunits to the growing (+) end of the axoneme microtubules at the ciliary tip by anterograde IFT, while cilia microtubles are cleared from the cilia by retrograde IFT. This can be demonstrated both *in vivo* and *in vitro*, where mutations in Kinesin-2 proteins (anterograde motor) lead to the absence of cilia,[53,54] while mutations in cytoplasmic dynein-2 (retrograde motor) lead to bulbous, stumpy cilia caused by an accumulation of IFT particles and other ciliary proteins.[52,55–57]

Mechanisms of Cilia Protein Entry

The correct function of the primary cilium is dependent on the localization or enrichment of receptors, channels, and effectors in this specialized compartment. As such, the mechanisms restricting or facilitating protein entry into the cilium remain an area of intense research.

A ciliary barrier or gate, which is likely found at the base of the cilium, could function to restrict entry of non-ciliary proteins and/or impair exit of proteins from the cilium. As indicated above, one of the current models is that the transition zone, transition fibers, and ciliary necklace constitute the barrier machinery (Figure 11.1). Evidence supporting a diffusion barrier at the base of the cilium comes from studies using a glycosylphosphatidylinositol-anchored fluorescent protein that is targeted to the apical plasma membrane.[36] This protein diffuses rapidly across the apical surface, but is restricted from the cilium and a region around the base of the cilium called the *periciliary membrane domain*. Similarly, other membrane proteins localized to the apical plasma membrane are not found in the cilium.

Although there is evidence for a cilia barrier, there are also data indicating that cilia access may in part be determined by protein size and governed by diffusion. GFP is a 27 kDal protein that rapidly equilibrates between the cilium and cytosol. However, larger proteins do not accumulate freely in the cilium, and are dependent on IFT. This has led to the hypothesis that the ciliary barrier may be analogous to nuclear pore complex. Passage through the nuclear pore involves the association of a protein containing a nuclear localization signal (NLS) binding to an importin-family protein for movement into the nucleus catalyzed by Ran GTPase activity. Intriguingly, importin-β2 has been localized to the basal body/transition zone in cultured cells, and knockdown of importin-β2 inhibits cilia localization of retinitis pigmentosa 2.[58] Likewise, Ran is found in the cilium, and experiments using mutated Ran have shown that ciliary entry is mediated through a Ran-GTP gradient.[59] The question remains as to whether there are specific cilia localization signals (CLS) similar to the putative NLS sequence. Indeed, NLS-like sequences have been reported in cilia proteins, such the kinesin KIF17, and disruption of this NLS motif inhibits Kif17 cilia localization.[59] A sequence, V-x-P, necessary for ciliary localization[60] has also been identified in the transmembrane proteins

PC-2 and CNGB1b, and in several G-protein coupled receptors (SSTR3, 5HT6, DRD1, Rhodopsin, and MCHR1); however, the mechanism by which this motif targets these proteins to the cilium is variable, and is most likely protein-specific. Most other cilia transmembrane proteins do not have this signature, indicating there is no universal sequence directing proteins into the cilium.

An alternate hypothesis for ciliary enrichment was proposed by Hu et al. and involves inhibition of lateral diffusion. Ciliary proteins were highly mobile within the cilium, but there was limited exchange between the plasma membrane and the cilium. These data suggest a barrier-impeded diffusion. Hu et al. demonstrated that septin-2 is located around the base of the cilium, and may function as this barrier.[61] Septins were originally identified as a family of guanosine triphosphatases with diffusion barrier function. Knockdown of septin-2 in embryonic fibroblasts and renal epithelium resulted in a marked increase in diffusion and exchange between cell and ciliary membranes, defects in ciliogenesis, and inhibition of cilia dependent signaling (e.g., Sonic Hedgehog (Shh) pathway, see section "Renal Cilia and Hedgehog Signaling").[61] Thus, one possible mechanism is that ciliary transmembrane proteins are continually transported into the cilium and accumulate there as a consequence of slow outward diffusion.

Recently, another model for ciliary membrane protein entry was proposed from the laboratory of Ira Mellman.[62] Francis et al. analyzed gp135/podocalyxin, which is a transmembrane protein localized to the apical surface of renal epithelial cells that is also restricted from the cilium and the periciliary membrane region around the cilia base. gp135 is anchored to the cortical actin cytoskeleton through its PDZ domain. When this motif was disrupted, gp135 was now present ectopically in the cilium. Conversely, proteins that normally enter the cilia could be inhibited from doing so if the gp135 PDZ domain was incorporated into the protein. These data suggested that ciliary exclusion was dependent on attachment of membrane proteins to the cytoskeletal network, rather than the presence of a diffusion barrier. This model is hard to reconcile with the septin-2 data from Hu et al.,[61] the evidence for the BBSome in cilia membrane trafficking of specific GPCRs (see section "Ciliary Targeting and the BBSome" and [60,63,64]), and the presence of multiple membrane proteins that are freely diffusible and have not been detected in the cilium.[36] Further, lipid content in the cilium has been reported to be distinct from that of cell membrane (reviewed in [65]). In the absence of a barrier, one would expect an equilibration between the two compartments.

Vesicular Trafficking of Transmembrane Proteins to the Cilium

Transmembrane proteins destined for the cilia are dependent on the activity of Rab-GTPases. One of the initial Rabs shown to be involved in ciliary targeting was Rab8. Inhibition of Rab8 leads to accumulation of vesicles at the base of the cilium, while Rab8 constitutive activation causes elongated cilia.[66] Rab8 utilizes the ciliary localized exocyst complex and activity from its guanine nucleotide exchange factor (GEF) Rabin8 to dock and fuse vesicles at the cilia base. Although the process of targeting transmembrane proteins to the ciliary base is still being fully deduced, one of the most widely accepted models involves polarized exocytosis through a Rab11-associated trafficking pathway. Through this pathway, transmembrane proteins are shuttled from a Rab11 positive compartment to a Rab8 positive vesicle, dependent on Rab11 activation of Rabin8. Transmembrane proteins in these Rab8 positive vesicles are then transported to the cilia base, and inserted directly into the periciliary membrane domain.[67,68] Importantly, although some vesicular structures have been reported in olfactory and chondrocyte cilia,[69,70] vesicles are not commonly seen in most other cilia or flagella. These data indicate that if polarized exocytosis occurs, the fusion of the vesicles with the cilia membrane likely occurs at the base. In support of this are ultrastructural studies showing numerous vesicles containing putative ciliary-targeted proteins located around the base of cilia and flagella actively fusing with the membrane.[71,72] How these proteins then get across a ciliary barrier, if it exists, is unknown.

It is also possible that the initial targeting of ciliary transmembrane proteins is to the plasma membrane. The ciliary protein would then translocate into the cilium by either lateral diffusion or through an endocytic pathway. This is best understood in the case of Smoothened (Smo), the transmembrane effector protein of the Sonic hedgehog-signaling pathway (Shh). In response to Shh stimulation, Smo translocates from the cell membrane into the cilium. This translocation is not inhibited by expression of a dominant negative form of dynamin,[73] a GTPase required for scission of vesicles during endocytosis in eukaryotic cells. Thus, the data indicate that at least in this case, ciliary targeting is likely mediated through lateral diffusion, and does not require endocytosis of vesicles from the plasma membrane.

Ciliary Targeting and the BBSome

The BBSome is a protein complex involved in trafficking of specific cilia membrane proteins.[64,66]

Mutations affecting this complex of proteins cause Bardet–Biedl Syndrome (BBS). BBS is a rare human ciliopathy characterized by obesity, sensory defects, and cystic kidney disease (see section "Bardet-Biedl Syndrom (BBS)). The assembled BBSome shares structural similarities with the COP/clatherin family of coat proteins, suggesting the BBSome functions as a coat for ciliary cargos. The BBSome coat associates with the GTPase Arl6 (also known as BBS3) when Arl6 is in its GTP–bound, active state. The BBSome/Arl6 complex recognizes the ciliary localization sequence (CLS) in proteins such as SSTR3, and then escorts the protein into the cilium. The BBSome may also function for removal of proteins from the cilium. This is evidenced by the abnormal accumulation of specific transmembrane proteins in the cilium of *bbs* mutant mice.[63]

CILIOGENESIS

Cilia are complex structures that require continual maintenance[74] and must be dissembled and subsequently reassembled at the beginning and end of each cell cycle. The process of building a cilium (ciliogenesis) requires the coordination of centriolar modification/maturation to form a basal body, the motor driven process of IFT to build the cilia axoneme, and carefully timed transcriptional events. These processes are synchronized with cell cycle progression, as cilia are assembled on quiescent cells.[75] Likewise, during mitosis the centrioles must be released from their position below the cilia, and migrate to opposite spindle poles for proper cell division. Ciliogenesis can also be regulated by other factors, such as cell confluence, fluid flow, mechanical stimuli, and injury.[76]

Transcriptional Control of Ciliogenesis

Cilia are extremely dynamic structures that grow and reabsorb depending on physiological conditions. Ciliogenesis is in part regulated through transcriptional control. This is demonstrated in *Chlamydomonas*, where experimentally induced deflagellation results in a large increase in the expression of flagellar genes, including the IFT proteins.[39,40,72,77–79] In addition, in *C. elegans* and mammalian systems, transcription factors of the RFX (regulatory factor X) family have been shown to coordinately control expression of several IFT genes through a motif called the X-box located in their promoters.[80] This process is evolutionarily conserved, and was first reported in *C. elegans.* The RFX transcription factor DAF-19 was needed for expression of several IFT proteins, as well as a few proteins known to be involved in human syndromes with cystic kidney disease phenotypes.[81,82] This includes transition zone proteins such as the NPHP genes *nphp-1* and *nphp-4*, and the MKS genes *mks-1*, *b9d1*(*mksr1*), and *b9d2*(*mksr2*), as well as multiple BBS genes including *bbs-1*, *bbs-2*, *bbs-5*, *bbs-8*, and *bbs-9* (reviewed in [83]).

Cilia and the Cell Cycle

The basal body (see section "Centrosomes and Basal Bodies") is generated from the centrioles that are also components of mitotic machinery. Therefore, cell division, cell differentiation, and ciliogenesis are inherently linked. As cells exit mitosis, ciliogenesis is initiated in the G_1 or G_0 phase of the cell cycle. This can be modeled *in vitro*, as cells will become increasingly ciliated as they reach confluence. Additionally, ciliogenesis can be induced precociously in subconfluent cells when cultured in serum-free medium. These data indicate that cilia formation and mitosis are intertwined, and has led to the proposal that the presence of the cilium may act as a G_0 checkpoint and thus as a tumor suppressor.[84] In addition, rapid or aberrantly dividing cells, such as some tumor cells, frequently do not have a cilium.[85,86] Despite this connection, increased tumor rates are uncommon in human ciliopathy patients or mouse cilia mutants. An exception to this was recently shown in the skin of cilia mutant mouse models in tumors associated with Shh signaling, where cilia have a direct role in pathway regulation.[87]

As cells re-enter the cell cycle, cilia begin to be dismantled. This usually occurs by the G2 phase. Deconstruction of the cilium can occur by either cilia severing or resorbtion.[75] These mechanism(s) regulating deciliation are still poorly understood. Work from *Chlamydomonas* suggests that katanin, a microtubule-severing protein, cleaves microtubules at the junction between the axoneme and the basal body to facilitate cilia release.[88] In *Chlamydomonas*, the kinase activity of Nek8 (NPHP9) is required for deflagellation.[89] In mammalian systems, HEF1 (human enhancer of filamentation 1) in association with Aurora A kinase and the tubule deacetylase (HDAC6) reduce axoneme microtubule stability and induce deciliation.[90]

Cilia Extension

At the initiation of ciliogenesis, the centriole migrates towards the cell surface and proteins required for ciliogenesis, including the IFT proteins, begin to aggregate at a *preciliary patch*. There appear to be at least two mechanisms in which cilia initially form. The first method requires the formation of a ciliary vesicle (CV),[91] a Golgi-derived structure that forms at the distal tip of the mother centriole. As the CV-

mother centriole nears the cell surface, the cilium axoneme extends into the CV. The CV fuses with the plasma membrane, allowing the cilium to extend from the cell surface and emerge into the extracellular space. As a consequence, the basal body and the cilium remain in a small depression in the cell called the *ciliary pocket*.[92,93] The functional importance of the pocket is not certain, but it closely resembles the flagella pocket present in some protists. In these organisms, the pocket serves as a critical sight for vesicular trafficking and endo- and exocytic activity. In the second method, the cell forgoes forming a CV, and the centrosome complex migrates to the cell surface. It is at the cell surface that the mother centriole recruits materials to begin forming the cilia from plasma membrane components.

Post Ciliogenesis Growth Control

Cilia length is an actively controlled process, and is important for normal function (reviewed in [44]). In motile cilia, the increase in cilia length alters beating frequency and pattern, and thus disrupts fluid movement. In primary cilia, it is less clear how changes in length may influence many of the signaling activities. Normal control of cilia length is important, as both excessively short or elongated cilia in the kidney have been shown to cause cysts.[94–97]

Cilia length control is best understood from studies in *Chlamydomonas*, where genetic mutants have been isolated that produce either short or long flagella. Several genes involved in this process have been identified and encode kinases, such as cyclin-dependant kinase,[98] and a mitogen-activated protein kinase (MAPK) member.[99] The homologs for these proteins are present in mammals, suggesting evolutionarily conserved pathways; however, the targets of the kinases are not known.

One of the initial functions assigned to primary cilia in the kidney and several other tissues is that of a mechanosensor (see section "Renal Cilia and Mechanosensation"). Thus, cilia length could greatly influence the response or sensitivity of the cell to mechanical stimuli. As in some ciliated protists, mammalian cells are also able to modulate cilia length. Recent studies have revealed that decreased Ca^{2+} or increased levels of cAMP can cause a marked increase in cilia length.[100,101] This length increase is in part dependent on protein kinase A (PKA), and is associated with increased rate of anterograde IFT. Shear stress across the surface of many cell types is able to reduce cilia length. This was also shown to decrease cAMP levels. Importantly, this adaptive response to shear stress was not observed in cells that lack the polycystins.[102] Thus, it has been proposed that dynamic regulation of cilia length is an important regulatory process that controls sensitivity to extracellular stimuli, and that in PKD this has been disconnected.

In addition, cilia length in the kidney, pancreas, and other tissues can be influenced by injury.[103,104] Since renal injury causes rapid cyst formation in the inducible adult cilia mutant mice but not their controls,[105,106] it is tempting to speculate that the cilium may have a function in regulating a pathway involved in a tissue repair process.

Other studies have revealed that cilia length can be influenced by changes in the actin and microtubule cytoskeleton. In a genomic screen for modulators of cilia length, Gleeson and colleagues identified numerous genes required for ciliogenesis, as well as for the maintenance of cilia length.[107] Among these were genes involved in actin dynamics and organization. This included ARP3, a protein necessary for actin polymerization at filament branches, that when knocked-down caused cilia elongation. This effect was further demonstrated using the actin polymerization inhibitor cytochalasin D. These effects on actin are believed to interrupt vesicular docking and stabilization of the pericilary membrane domain at the ciliary base. Further, Sharma et al. demonstrated that actin disruption leads to a concurrent increase in the levels of soluble tubulin that can now be incorporated into the elongating ciliary axoneme. This cilia elongation was inhibited by pretreatment with the microtubule-stabilizing drug paclitaxel.[101] This phenomenon is further supported by data showing that low levels of nocodazole, a microtubule-depolymerizing agent, could recapitulate the effects observed with actin destabilization.

CILIA SIGNALING IN THE NEPHRON

The spectrum of processes regulated by the renal cilium is not fully known. There are a large number of receptors and channels that have now been localized or enriched in the cilium.[15,60,102,108–110] For several of these proteins, their localization in the cilium has great importance to their function. In many cases, loss of ciliary signaling leads to the formation of renal cysts. Therefore, much of our understanding of cilia signaling in the kidney comes from the study of cystic kidney disease models. This section discusses some of the major signaling pathways involved in renal development and physiology in which the cilium is required for efficient signal transduction, and how disruption of these signals results in cyst formation.

Renal Cilia and Mechanosensation

Data indicating that renal cilium function as a mechanosensor came from studies in Ken Spring's laboratory.[111–113] Fluid-flow induced deflection of the cilium causes a transient increase in cytosolic calcium (Figure 11.2). Furthermore, studies by Liu et al.[114] demonstrated that in perfused tubules from the *orpk* mutants, where cilia are severely truncated, this calcium signal is abrogated. The proteins involved in this signal are believed to be polycystin-1 (PC-1) and polycystin-2 (PC-2), both of which localize to the primary cilium. PC-2 is a transient receptor potential (TRP)-like cation channel known to mediate calcium signals. PC-1, which binds to PC-2, is suspected to be a regulator of the channel. Mutations in PC-1 or PC-2 disrupt this calcium signal, even in the presence of a fully formed cilium.[102] This led to a model of cystogenesis where the loss of a cilia-mediated mechanical signal was a driving force responsible for the development of renal cysts.

Recently, data from inducible cilia and *PKD1* mutant mice have raised concern about the cilia mechanosensory model of cyst formation.[106] Disruption of *IFT88* or *PKD1* using conditional alleles and tamoxifen inducible Cre-deletor lines revealed that cilia dysfunction induced prior to postnatal day 12 (P12) caused a rapid onset of the cystic kidney phenotype.[115–117] However, cyst formation is very protracted if induction of cilia loss occurred after P12. It is difficult to reconcile how cyst development could be delayed in the adult induced cilia mutants if cysts arose due simply to the loss of a mechanosensory signal.

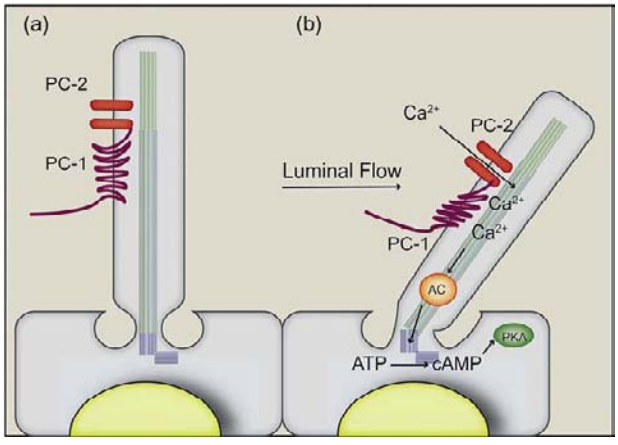

FIGURE 11.2 **Cilia and mechanosensation.** In low flow conditions (a), the TRP-like cation channel, polycystin-2 (PC-2, red) localizes to the cilium and is regulated by polcysitin-1 (PC-1, maroon). Under flow conditions (b), deflection of the primary results in an opening of the PC-2 channel, allowing Ca^{2+} ions to enter the cell, and increasing cytosolic Ca^{2+} levels. As a result of increased Ca^{2+} concentration, adenylyl cyclase (AC, orange) becomes activated, converts free ATP to cAMP, and cAMP activates protein kinase A (PKA) which phosphorylates multiple downstream targets. See color section at the end of the book.

Renal Cilia and Jak/STAT Signaling

The loss of the mechanosensory-based increase in transient cellular Ca^{2+} levels alone is not enough to induce the formation of renal cysts, as revealed by the large delay in cyst formation observed when cilia dysfunction is induced in adult mice. Recently, it has been demonstrated that in addition to regulating PC-2 channel activity, PC-1 also plays a role in transducing a flow-induced signal in the renal cilium through either the Jak/STAT pathway or mTOR signaling (see section "Renal Cilia and mTOR"). PC-1 activates the STAT-family of transcription factors via dual mechanisms (Figure 11.3a,b),[118] depending on the proteolytic processing and nuclear translocation of the PC-1 C-terminal tail (PC-1 CTT).[119,120] In a direct activation pathway, PC-1 resides in the cilium and is able to bind the Jak2 kinase.[118] When luminal flow is lost, Jak2 kinase phosphorylates and activates STAT3, which translocates to the nucleus (Figure 11.3b). Importantly, this process requires the PC-1 CTT to remain membrane-bound to activate STAT3.[118] Also, when fluid flow is lost in the nephron and PC1 is cleaved to release the PC-1 CTT, the PC-1 CTT can bind and activate both P100 and STAT6, which can be found in the cilium or at the basal body (Figure 11.3a).[120] This complex then enters the nucleus to influence gene expression. Alternatively, the PC-1-CTT has been shown to translocate directly into the nucleus, where it enhances the activity of cytokine activated STAT1 and/or STAT3.[118]

The Jak/STAT pathway is canonically described in the human immune response, driving differentiation and proliferation in response to cytokines. So what is the function of the Jak/Stat pathway in the cilium, and how does this relate to cyst growth? Under loss of flow conditions, such as injury, obstruction or cyst formation, the kidney undergoes an inflammatory response, which includes an increase in cytokine levels,[121,122] and infiltration of macrophages.[123–125] The increased cytokine levels trigger the upregulation of the Jak/STAT pathway in the cilium, possibly through association of PC-1 acting as a pseudo-cytokine receptor for Jak2 kinase.[118] This in turn begins the Jak/STAT signaling cascade, where the PC-1 CTT is eventually cleaved and enters the nucleus leading to proliferation. Indeed, high levels of nuclear PC-1 CTT have been observed in the metanephric mesenchyme, developing tubules,[119] and in cyst lining cells[120] where proliferation levels are high.

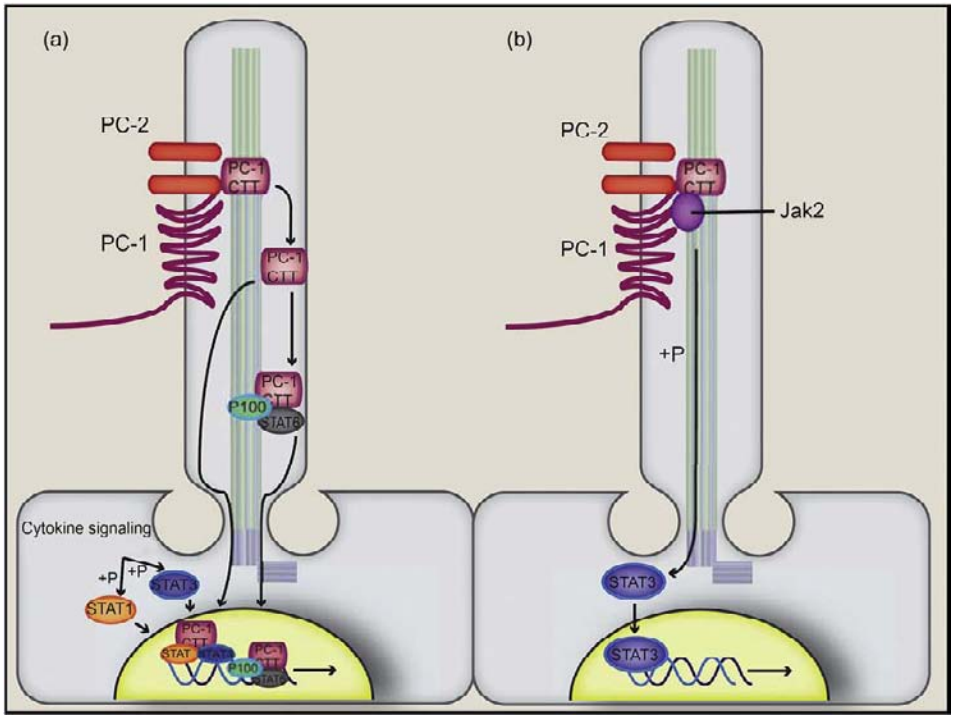

FIGURE 11.3 **Cilia and Jak/STAT signaling.** (a) When luminal flow is lost, the polycystin-1 C-terminal tail (PC-1 CTT, maroon) is cleaved and regulates the nuclear localization and activity of STAT6 (gray) and p100 (green). The PC1-CTT may also translocate into the nucleus to enhance activity of nuclear STAT1 (orange) and STAT3 (blue). (b) Membrane-associated polycystin-1 also directly interacts with Jak2 kinase (purple) to activate STAT3 under low flow conditions. See color section at the end of the book.

Further evidence to support the model of inflammation-based cyst growth has been demonstrated by monitoring macrophage infiltration in renal ischemic injury. The macrophage infiltrate found in ischemic reperfusion injury mice are pro-proliferation instead of pro-inflammatory.[124] Furthermore, Karihaloo and colleagues demonstrated that depleting macrophages in *PKD1* mutant mice lowered cystic growth significantly.[123] Continued work on the contribution of the immune response is needed to fully understand the role of Jak/STAT- and cilia-regulated signaling in the kidney.

Renal Cilia and Non-Canonical Wnt/Planar Cell Polarity (PCP) Signaling

Non-canonical Wnt signaling (Figure 11.4b) is best known for regulating planar cell polarity (PCP). PCP is the ability of cells to position and orient themselves along the plane of the tissue (Figure 11.5). This is accomplished by modulating the cytoskeleton via the Rho-kinase family, positioning of basal bodies, and the asymmetric distribution of proteins to establish cell orientation. Evidence from model organisms demonstrates a role for cilia in controlling the PCP response, most likely due to the close association of the cilium with the basal body and cell cytoskeleton. Morpholino knockdown of cilia or BBS genes in zebrafish give defects in body axis elongation typical of altered convergent extension during gastrulation.[126] Similarly, *bbs* and *ift88* mutant mice have inner ear abnormalities typical of PCP defects.[126,127] Collectively, these findings led to a model where cilia function to modulate the strength and spatial activity of the non-canonical Wnt pathway.

In the developing kidney, PCP likely has a role in controlling orientated cell division, and for convergent extension like movements that occur in the early developing nephron.[128] Therefore, loss of cilia-regulated oriented cell division could cause defects in development of the nephron, and lead to cyst formation. Using mouse and rat models of PKD, Fischer et al. demonstrated that the orientation of the mitotic spindle became randomized in cystic animals, rather than being parallel to the nephron lumen as seen in the control kidneys (Figure 11.5[129]). Similarly, the cystic kidney phenotype observed in conditional cilia mutant mice or mice with mutations in PCP genes, such as the proto-cadherin Fat4, are associated with misorientated cell division.[130–134] The above data suggested that parallel divisions to the long axis of the nephron would drive nephron elongation, whereas division perpendicular to the long axis would result in tubule diameter expansion and eventual cyst development. One proposed model was that cilia function in establishing the position of the mitotic spindle through a mechanical signal, such as fluid flow. Loss of the signal resulting from cilia dysfunction would then alter orientation of cell division and eventually lead to cyst formation.

The connection between changes in orientation of cell division and cyst formation must be considered

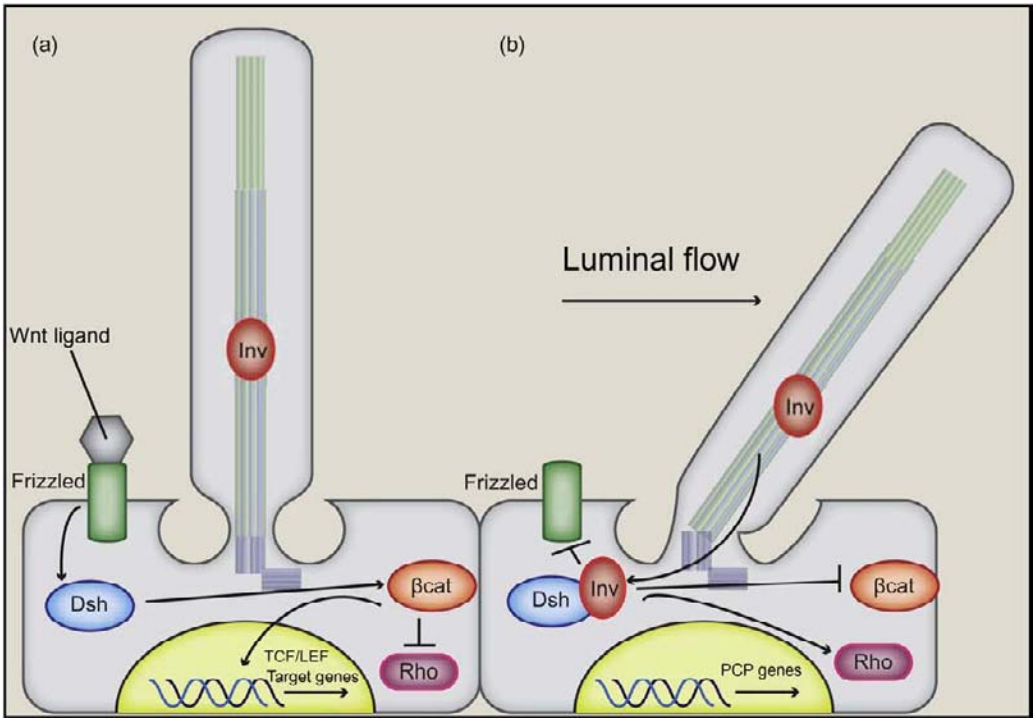

FIGURE 11.4 **Wnt signaling in the cilium.** In the canonical Wnt pathway (a), Wnt ligands (gray) bind the Frizzled receptor (green). Frizzled activates Disheveled (Dsh, blue) which in turn activates β-catenin (βcat, orange). βcat translocates to the nucleus (yellow), resulting in transcription of TCF/LEF target genes. (b) In the presence of fluid flow, cilia bending causes Inversin/NPHP2 (Inv, red) to translocate from the cilium to inhibit Dsh activation of the non-canonical Wnt pathway. Without Dsh activation, βcat is not activated and degraded. Rho-family kinases and PCP genes then become activated. See color section at the end of the book.

in the context of proliferation rate in the developing tubule. As noted in "Renal Cilia and Mechanosensation" there is a dramatic shift in the rate of cyst progression in mouse cilia mutant kidneys after day P12–13.[115–117] Importantly, in mice there is a dramatic drop in proliferation that occurs in a wild-type kidney as part of its maturation process around P12. Thus, it has been proposed that a combination of a highly proliferative environment, along with misoriented cell division that occurs in cilia or PCP mutants, leads to rapid cyst formation. The possible effect of proliferation on cyst initiation and progression was further analyzed using renal injury models. Through either ischemia reperfusion or nephrotoxin induced injury in the adult induced cilia mutants, several groups have shown that insult and subsequent proliferation induced by the repair process reinitiates a program of rapid cyst development, similar to that seen in the young (≤P12) cilia mutants.[105,135,136] This injury model data must be viewed with caution, as the injury also causes significant inflammation, apoptosis, and dedifferentiation of the nephron segments as a part of the repair process. The contribution of these factors to the rate of cyst formation after injury is not known, and could also contribute to cystogenic mechanisms.

The connection between cilia, cyst development, and oriented cell division was recently brought into question as a result of analysis in the *pkhd1* mutants. *PKHD1* mutations in humans cause ARPKD. In the *pkhd1* mouse mutants the orientation of cell division in the nephron was abnormal, yet they do not develop renal cysts.[137] These data indicate that changes in orientation of cell division are not sufficient to cause cystic disease.

Renal Cilia and Canonical Wnt Signaling

In the canonical Wnt pathway, a Wnt ligand binds to and activates a Frizzled-family receptor that stabilizes β-catenin (Figure 11.4a). β-catenin then translocates into the nucleus, where it combines with TCF/LEF to activate transcription of target genes. One of the initial studies establishing a cilia-Wnt connection came from analysis of *nephrocystin-2* (NPHP2, *Inv*) a gene disrupted in human patients with NPHP (see [138] and section "Nephronophthisis (NPHP)"). NPHP2 localizes to cilia and antagonizes Disheveled, a Wnt pathway component regulating β-catenin stability. NPHP2 expression was able to inhibit the ability of Disheveled to activate Wnt signaling. Simmons et al. have demonstrated a link

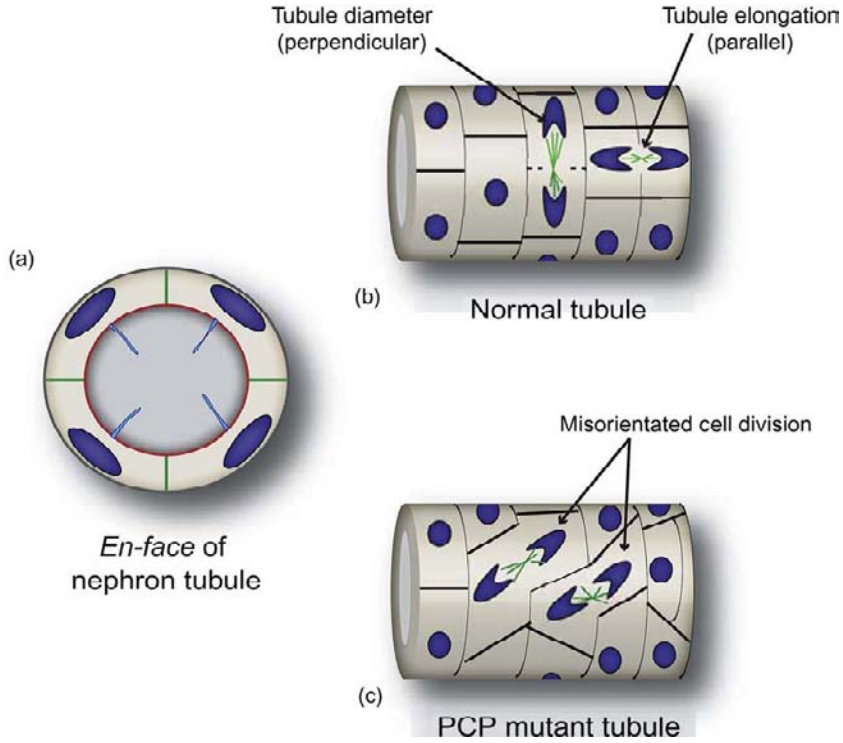

FIGURE 11.5 **Cilia influence planar cell polarity (PCP).** (a) Cilia (light blue) extend from the apical surface (red) into the lumen of the nephron tubule. Under normal conditions (b) cilia may modulate signals controlling cell division, either parallel to the long axis of the tubule to increase tubular length or perpendicular to the long axis of the tubule to increase tubule diameter. In some cilia mutants, a PCP-like pathway is disrupted (c) and cell division becomes random and disorientated with respect to the axis of the tubule. See color section at the end of the book.

between fluid flow through the renal tubules and a switch between canonical and non-canonical Wnt signaling pathways.[139] In this process, NPHP2 modulates the balance between the two different Wnt signaling pathways. Additionally, knockdown studies of the BBS genes lead to an increase in canonical Wnt response, and also inhibited non-canonical Wnts from repressing the canonical response in cultured cells.[140] Furthermore, genetic mutations in the IFT genes *kif3a*, *ift88* or *ahi1*, a cilia gene involved in Joubert Syndrome (JBTS, OMIM# 21330), caused an increase in canonical Wnt activity *in vivo*.[141,142] *Ahi1* mutant mice have vermis-midline fusion defects, and these defects could be partially restored by the canonical Wnt agonist lithium chloride.[142]

In contrast, several studies have argued against any direct role for cilia in Wnt signaling (see [143]). This is supported by the lack of clear canonical phenotypes in most tissues of cilia mutant mice, and in zebrafish maternal zygotic mutants in the *ift88* (*oval*) gene. These studies also analyzed Wnt signaling in mutant fibroblasts, and in direct contrast to the previous data did not find changes in Wnt signaling.[144]

Renal Cilia and mTOR

The renal cilium has also been shown to be a regulator of the mammalian target of Rapamycin (mTOR). mTOR integrates multiple upstream signals to regulate cell processes such as translation, cell growth, proliferation, and protein synthesis. In several of the cystic kidney disease mouse models the mTOR pathway is aberrantly activated.[145–147] Intriguingly, mTOR activation was also shown to be downstream of PC-1 proteolytic processing in the cilium (Figure 11.6a). Dere et al. demonstrated that the C-terminal tail of PC-1 undergoes cleavage in the absence of flow. This regulates the localization of tuberous sclerosis complex 2 (TSC2) to the cell membrane. Importantly, TSC2 is an inhibitor of mTOR, and TSC2 inhibitor activity is controlled by its membrane localization.[148] Therefore, in the absence of PC-1, the PC-1 tail does not undergo processing, which in turn affects the ability of TSC2 membrane association and inhibition of mTOR signaling.

Additional studies indicated that renal cells without a cilium were markedly larger than cells with a cilium when placed in fluid flow conditions. This was also associated with changes in activity of the mTOR pathway. The effect of flow on cell size could be inhibited by treating cells with Rapamycin or inactivating Raptor, a key component of the mTOR pathway.[146] Surprisingly, this fluid flow/cell-size correlation was not dependent on calcium signal mediated by PC-2 or PC-1 cleavage, but rather the tumor suppressor kinase LKB1. LKB1 localizes to the cilium, and has increased activity in response to flow conditions (Figure 11.6b). LKB1 inhibits the mTOR pathway through AMP-

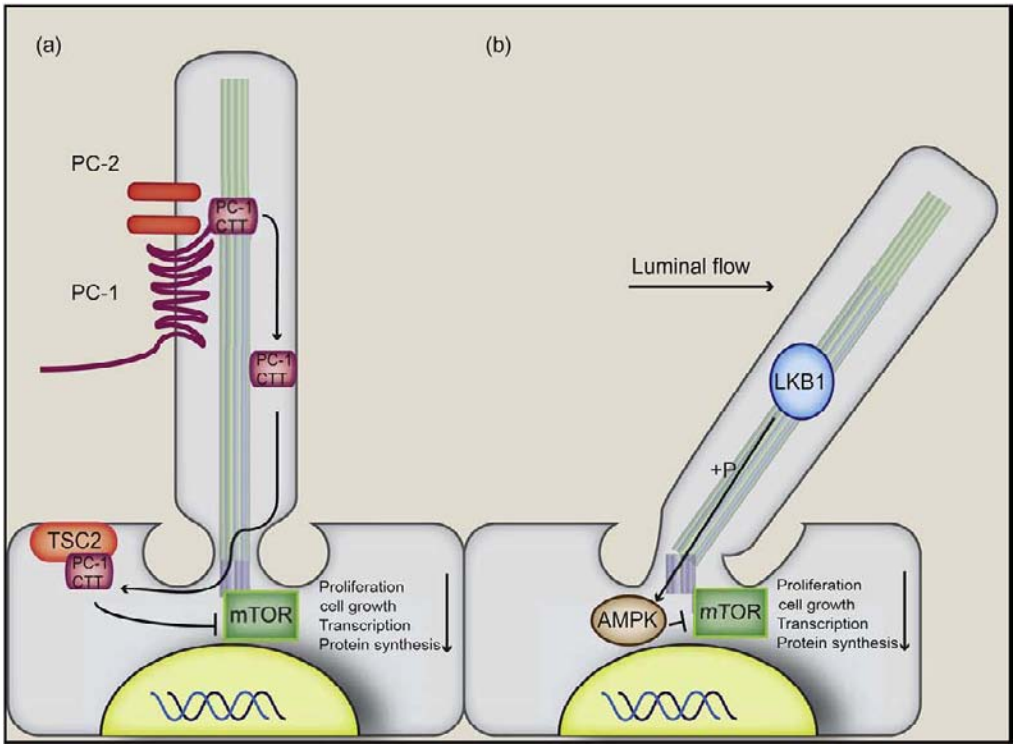

FIGURE 11.6 **Cilia and mTOR signaling under no flow and flow conditions.** Under static conditions (a), TSC2 (orange) is associated with the plasma membrane and functions to inhibit mTOR (green) signaling. The polycystin-1 C-terminal tail (PC-1 CTT, maroon) undergoes proteolytic cleavage by an unknown mechanism. The PC-1 CTT leaves the cilium, binds TSC2, and retains it at the plasma membrane, thus enhancing the ability of TSC2 to inhibit mTOR signaling. Under flow conditions (b), the ciliary kinase LKB1 (blue) phosphorylates and activates AMP-activated protein kinase (AMPK, tan). AMPK in turn phosphorylates and restrains mTOR activity. See color section at the end of the book.

activated protein kinase (AMPK). Thus, the cell size decrease induced by flow appeared to be regulated by cilia deflection that promotes LKB1 activity to phosphorylate AMPK at the basal body to restrain mTOR signaling.

Another connection between mTOR and the renal cilium was reported by Bell et al., using the adult induced cilia mutant mouse model and unilateral nephrectomy.[145] In contrast to the renal damage and the complex repair process that occurs in the ischemia reperfusion/nephrotoxin injury model, unilateral nephrectomy predominantly leads to a hypertrophic signal in the remaining kidney. In control mice, nephrectomy caused normal activation of mTOR, and produced appropriate structural and functional hypertrophy in the absence of cyst formation. In contrast, in cilia mutant mice there was an exaggerated and prolonged activation of mTOR, increased renal hypertrophy, and accelerated cystogenesis.

The increase in mTOR activity reported in multiple cystic kidney diseases, and its disregulation in cilia mutants, suggested that mTOR inhibition was a potential common site for therapeutic intervention. This was demonstrated in several cystic kidney mouse models where Rapamycin treatment was shown to be a potent inhibitor of cyst formation.[149,150] However, initial clinical trials of mTOR inhibitors in human PKD patients have not been overly encouraging (see [149] for a summary of results).

Renal Cilia and Vasopressin Signaling

Vasopressin (ADH) is the major hormone responsible for regulating water homeostasis throughout the body. The vasopressin type-2 receptor (V2R) localizes to the primary renal cilium (Figure 11.7), in addition to its normal basolateral localization in renal collecting duct epithelia. *In vitro* assays confirmed that V2R in the cilium is a functional G-protein coupled receptor (GPCR) activating G_s.[109] The G_s subunit in turn activates adenyl cylclase (AC) in the presence of ADH. AC initiates the conversion of ATP to cAMP, and cAMP ultimately activates protein kinase-A (PKA). PKA is responsible for the phosphorylation of the water channel Aquaporin-2 (AQP2).[151] The phosphorylation of AQP2 by PKA causes trafficking of the AQP2 to the apical (luminal) surface to facilitate water

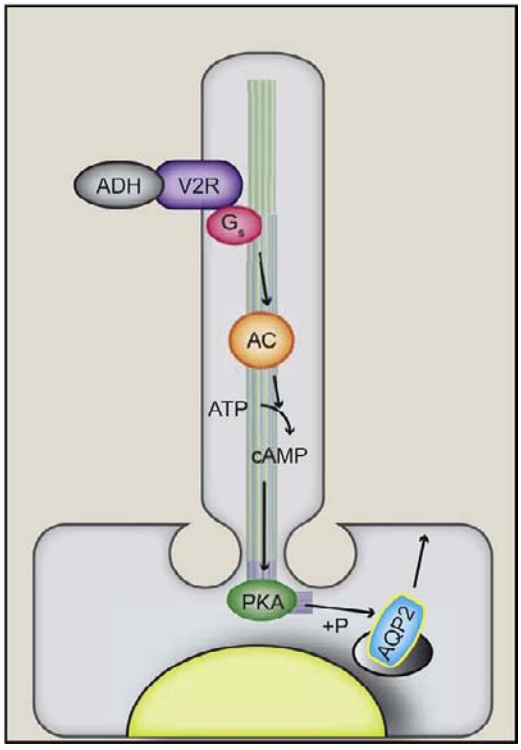

FIGURE 11.7 **Proposed mechanism for the cilium in vasopressin (ADH) signaling.** Luminal ADH signaling is believed to utilize the primary renal cilium. Luminal vasopressin receptor (V2R, purple) localizes to the primary cilium and binds ADH (gray). Binding of ADH triggers the canonical-ADH signaling pathway where G_s activates adenylyl cyclase (AC, orange), causing an increase in cellular cAMP levels. cAMP activates PKA which phosphorylates internalized aquaporin-2 (AQP2, blue), and causes AQP2 trafficking to the apical membrane and water uptake by the renal epithelium.

uptake and ultimately produce more concentrated urine. As a consequence of V2R signaling and corresponding downstream activation of cAMP, *AQP2* gene transcription is increased to further enhance cellular response to dehydration.

Interestingly, mice with cilia dysfunction often have defects in urine concentrating ability that may be associated with altered V2R activity.[152] Also, nearly all cystic kidney mutant mice and human cystic patients have marked elevation of intracellular cAMP levels (reviewed in [153]). The most recent therapeutic strategies have targeted these elevated levels of cAMP using V2R antagonists.[110,154,155] In mouse models, this approach has been remarkably successful in correcting the cystic phenotype,[110] and clinical trials in human patients are currently underway.[156]

Renal Cilia and Hedgehog Signaling

During development, the Hedgehog (Hh) signaling pathway is necessary for the establishment of body pattern, cell and tissue differentiation, proliferation, and growth. Components of the Hh signaling cascade localize to, and function in, the primary cilium (Figure 11.8). Defects in Hh signaling cause severe developmental malformations in many systems, including but not limited to the brain, skeleton, and renal system, and in adults altered Hh signaling contributes to basal cell carcinoma and other tumors. Hh signaling defects have not been directly implicated in the formation of renal cysts, although hydronephrosis and other renal abnormalities are present in mice where Hh signaling is disrupted. Regulation of the Hh pathway is very complex (see [157] for a recent in-depth review). Briefly, in the absence of an Hh ligand, the receptor Patched1 (PTCH1) localizes to the primary cilium. PTCH1 functions to inhibit a second transmembrane protein Smoothened (Smo). Binding of an Hh ligand to PTCH1 in the cilium induces its translocation out of the cilium, while Smo becomes enriched in the ciliary compartment. Additional components of the Hh pathway have also been reported in the cilium, including the Gli transcription factors (Gli1-3), Suppressor of Fussed (SuFu), and the kinesins Kif7/Kif27. When Smo is activated, which appears to require the cilium,[158] it induces the pathway leading to the activation of the Gli proteins. The activated Gli transcription factors enter the nucleus and induce expression of the downstream target genes. In the absence of the Hh ligand, the Gli proteins (Gli3 in particular) are proteolytically processed to a smaller Gli3 repressor (Gli3R) to keep the pathway off. The processing of the Gli proteins into their repressor forms, as well as the initial activating step are both dependent on the presence of the cilium.[159,160] Thus, in the absence of the cilium neither the Gli activator nor repressor proteins are formed, leading to a deregulated pathway.

Multiple Hh signaling components are expressed in the developing and adult kidney. Sonic Hedgehog (Shh) is expressed in the embryonic distal epithelium of the ureter and medulary collecting ducts, and mutations in Shh cause renal aplasia.[161] This in turn influences nephron number[162] and renal patterning[163] during continued development. *Glis2* (NPHP7), a Gli-like protein, transduces an Hh signal in the kidney, and *Glis2* mutant mice have severe renal fibrosis and renal atrophy.[164] Multiple syndromes associated with Hh signaling defects have been identified in humans, and in several cases these syndromes are associated with renal malformation. For example, Pallister–Hall syndrome (PHS) is caused by a mutation in the DNA binding domain of Gli3R, and causes renal dysplasia, hypoplasia, hydroureter, and hydronephrosis (see,[165] and reviewed in [166]). These data suggest an important role for Hh signaling and the primary renal cilium during normal kidney development.

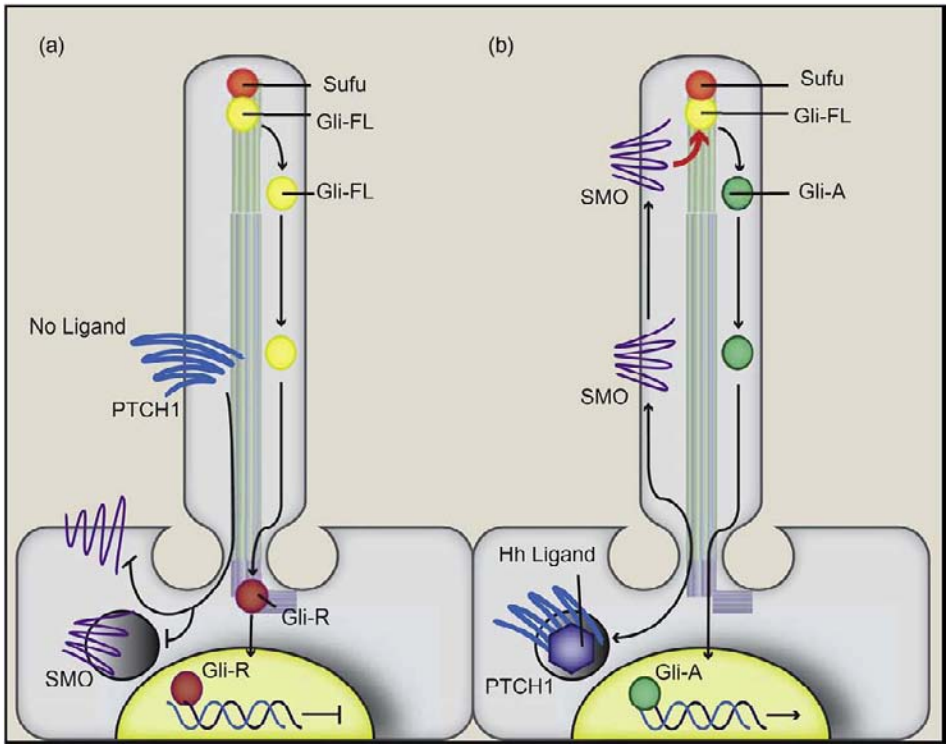

FIGURE 11.8 **Cilia and hedgehog signaling.** In the absence of Hh ligand (a), ciliary Patched-1 (PTCH1, blue) inhibits Smoothened (SMO, purple). Without SMO activation, Supressor of Fused (Sufu, orange) is in association with full-length Gli (Gli-FL, yellow) at the ciliary tip, where SuFu protects Gli-GL from degradation. In an unknown mechanism, Gli-FL is processed to Gli-repressor (Gli-R, red). Gli-R enters the nucleus and silences transcription of Gli-target genes. In the presence of Hh ligand (b), PTCH1 no longer inhibits SMO. PTCH1 translocates from the cilium to the cytosol and SMO enters the cilium. Ciliary SMO activates Gli-FL (red arrow) at the ciliary tip converting Gli-FL to activated Gli (Gli-A, green). Gli-A then translocates out of the cilium and enters the nucleus to transcribe Gli-target genes. See color section at the end of the book.

MODEL SYSTEMS FOR THE STUDY OF CILIOGENESIS AND CILIA DISEASE

Cilia are ancient organelles that have high levels of evolutionary conservation from invertebrates to humans. This high degree of conservation has allowed for the extensive use of model systems to identify molecular mechanisms of ciliogenesis, and has facilitated the analysis of how cilia function as specialized signaling centers. Despite the fact that many of these model systems do not have organs analogous to mammals, they have contributed enormously to the identification of novel ciliopathy genes and the characterization of disease causing alleles. In this section, we discuss some common model systems to study cilia/flagella, and provide a brief description of how these models are contributing to our understanding of cilia function and cystic kidney disease.

Chlamydomonas reinhardtii

Chlamydomonas reinhardtii are single-celled, fresh water, biflagellate alga (Figure 11.9a). One of the most significant contributions to our understanding of cilia biology from *Chlamydomonas* was the initial description of the intraflagellar transport (IFT) system.[11] The ease with which flagella can be isolated from *Chlamydomonas* then led to the isolation of the IFT complex, the identification of individual IFT protein components, and subsequently to the characterization of the entire flagella proteome. Work by Pazour et al. revealed that one of the IFT proteins in *Chlamydomonas* was the homolog of a gene identified in the Oak Ridge Polycystic Kidney (*orpk*) disease mouse model,[10] and is one of the seminal studies establishing the ciliary hypothesis of cystic kidney disease. Importantly, many of the proteins involved in human ciliopathies are present in the proteome of the *Chlamydomonas* flagella. This database of flagella/cilia proteins (http://labs.umassmed.edu/chlamyfp/) continues to be a major resource available to basic and clinical scientists to prioritize candidate genes involved in human disorders thought to be related to ciliary dysfunction.

Caenorhabditis elegans

C. elegans is a transparent soil nematode that provides a powerful genetic model for analysis of the cilium (Figure 11.9b). Unlike mammalian systems, where most cell types contain a cilium, *C. elegans* only have cilia on a subset of sensory neurons. Several of these cilia extend through small pores in the worm cuticle and are exposed to the environment, where they mediate sensory activities involved in chemotaxis and repulsion. These cilia also allow males to locate hermaphrodites and detect the vulva during mating,

and to assess food status and population density. Exposed sensory cilia able absorb fluorescent based dyes and worms with cilia abnormalities are often dye-filling defective (*Dyf*). Thus, *C. elegans* provides easily quantifiable traits to probe behavioral defects and structural phenotypes associated with cilia genes.

Even though *C. elegans* does not have the equivalent of the mammalian kidney, this model system has been responsible for another of the initial breakthroughs connecting cilia to cystic kidney disease. This came from a genetic screen by Barr et al. looking for mutations that cause male mating defects. Two of the mutations identified were in the gene *lov-1* (Location Of Vulva defective) and *pkd*-2, which are the homolog of human PC-1 and PC-2.[13] *lov-1* and *pkd-2* were placed genetically in the same signaling pathway in *C. elegans*, and the localization of these proteins in the cilium was first reported in this model.[14]

Recently the *Dyf* phenotype has been utilized as a means to analyze genetic interactions between mutations in ciliopathy genes associated with cystic kidney phenotypes.[32] Ciliopathies (see "The Human Renal Ciliopathies") such as NPHP, MKS, and BBS are recessive disorders; however, in many human patients mutations are found in only one copy of the gene. This raises questions regarding genetic causality, especially in the case of polymorphisms resulting in missense changes in the protein. This led to the hypothesis that phenotype in ciliopathy patients can be influenced by the overall mutational load in the cilia proteome.[167] *C. elegans* is providing an important system to explore this hypothesis. Single homozygous mutations in any of the known *nphp* or *mks* genes in *C. elegans* does not cause major cilia structural defects and have only minor changes in cilia signaling activity. However, combining mutations between an *nphp* and *mks* genes caused a near complete *Dyf* phenotype. This synthetic *Dyf* phenotype in *nphp;mks* double mutant worms is amiable to chemical mutagenesis screens that will lead to the identification of mutations in genetic loci that interact with either an *nphp* or *mks* mutation (Masyukova and Yoder, in prep).

Another area in which *C. elegans* is providing important insights is in assessing the pathogenic potential of missense mutations that were identified in human ciliopathy patients. This is becoming a major issue as a consequence of NextGen sequencing efforts that have uncovered a large number of missense changes in suspected ciliopathy patients. The contribution of these polymorphisms to disease pathogenesis requires functional assessment. Since *C. elegans* has easily quantifiable phenotypes associated with cilia dysfunction, these phenotypes can be used to assay the pathogenic outcome of these mutations. This has recently been demonstrated for heterozygous missense changes identified in NPHP4 in human NPHP patients.[168] Several of these missense changes altered NPHP4 protein localization/function, enhanced phenotypes in the presence of other ciliopathy gene mutations, and disrupted cilia mediated signaling, and thus are likely to have pathogenic effects.

Danio rerio

Danio rerio, (zebrafish) has become one of the primary vertebrate model systems for analyzing cilia and cilia related diseases (Figure 11.9c). A large number of mutations affecting cilia proteins have now been identified in zebrafish. Unlike *C. elegans* and *Chlamydomonas*, zebrafish contains most of the same basic organ systems as the human body. Thus, these cilia mutants develop many of the same multi-organ phenotypes as observed in human ciliopathy patients, such as hydrocephalus, retinal degeneration, left–right body axis defects, and cystic kidney disease. This is true particularly in the zebrafish kidney, which contains a highly simplified pronephros consisting of a

central glomerulus connected to two pronephric ducts that extend along the body empting through the cloaca. This pronephric tubule consists of epithelial cells with multiple motile cilia and single cilia. The function of these cilia and the consequences of their dysfunction have been well-characterized by Iain Drummond and co-workers.[169] The presence of similar multiciliated cells is not observed in the normal mammalian kidney; however, they have been reported in human diseased kidneys, as well as in distended renal tubules from the *pkhd1*$^{-/-}$ mutant rat.[170] The formation of these motile multiciliated cells in mammals is associated with the induction of the transcription factor FoxJ1 in response to tissue damage.[171]

Zebrafish has become a primary model system for analysis of cilia, in part due to the ease of genetic manipulation and the ability to conduct live, *in vivo* imaging in embryos or high-resolution analysis in fixed tissue. Cilia can easily be visualized with fluorescent tagged proteins using transgenic lines that allow cilia orientation and beat to be evaluated through high-speed video microscopy. Additionally, one of the major uses of the zebrafish model is the ability to conduct morpholino (MO) antisense oligonucleotide knockdown studies utilizing high-throughput approaches. This permits rapid analysis of gene function, and the analysis of the pathogenic effect of missense mutations associated with ciliopathy patients. These studies are done utilizing MO knockdowns to disrupt the function of the endogenous gene, followed by assessing whether expression of the human gene containing the specific missense mutation is able to rescue the ciliary phenotypes. Using these techniques, Nicolas Katsanis and co-workers have demonstrated genetic interactions between ciliopathy genes involved in BBS and assessed mutational load on disease presentation.[172] These studies have also demonstrated a connection between cilia and regulation of canonical and non-canonical Wnt signaling (see sections "Renal Cilia and Jak/STAT Signaling" and "Renal Cilia and Non-Canonical Wnt/Planar Cell Polarity (PCP) Signaling") during convergent extension movements and body axis elongation that may involve the planar cell polarity pathway (reviewed in [173]).

Mus musculus

The mouse (Figure 11.9d) has played a seminal role as the *in vivo* model to assess ciliopathy phenotypes, and was a key factor establishing the initial connection between cilia dysfunction and renal cystic disorders (reviewed in [5]). As described earlier in this chapter, this came from the *orpk* mutant mouse that had a hypmorphic mutation in the *IFT88* gene.[4,174] The *orpk* mouse develops cystic kidney disease, along with other ciliopathy phenotypes including biliary and pancreatic duct cysts, hepatic and pancreatic fibrosis, hydrocephlalus, skeletal patterning and osteogenic abnormalities, retinal degeneration, anosmia, along with skin, hair, and other ectodermal defects.[5] Left–right body axis defects were subsequently observed in mice with null mutations in *IFT88*[6] and *pkd2* mutant mice.[175] The numerous conditional alleles generated in cilia related genes, along with specificity of Cre-deletor lines, are now providing the means to assess cilia function in different developmental stages, specific tissues, and in defined cell types.

THE HUMAN RENAL CILIOPATHIES

The renal ciliopathies are a complex group of oligogenic disorders that now include Polycystic Kidney Disease (PKD, OMIM# 173900, described in Chapter 81), Nephronophthisis (NPHP, OMIM# 256100), Joubert Syndrome (JBTS, OMIM# 21330), Meckel–Gruber Syndrome (MKS, OMIM# 249000), Bardet–Biedl Syndrome (BBS, OMIM# 209900), Alstrom syndrome (ALMS, OMIM# 203800), Orofaciodigital Syndrome Type 1 (OFD1, OMIM# 311200), Jeune Asphyxiating Thoracic Dystrophy (ATD, OMIM# 208500), and Sensenbrenner Syndrome (Cranioectodermal Dysplasia, CED, OMIM# 218330). The phenotypes associated with the ciliopathies can include renal, hepatic, and pancreatic cysts (Figure 11.10a), mental retardation, obesity (Figure 11.10b), neural tube closure and patterning abnormalities, oculomotor apraxia, polydactyly and other skeletal malformations (Figure 11.10c), retinal degeneration, hypotonia, ataxia and cereberellar hypoplasia (Figure 11.10d), hydrocephalus, and cardiovascular defects. Other ciliopathies such as Leber Congenital Amaurosis (LCA, OMIM# 611755) or Senior–Loken syndrome (SLSN, OMIM# 266900), represent variations of the above syndromes (including renal phenotypes) and are not discussed below.

More than 45 human renal ciliopathy disease genes have been identified (Table 11.1); however, in most patients the underlying genetic defect remains unknown. The pace with which ciliopathy mutations are being identified is increasing rapidly due to advances in whole genome sequencing and the availability of cilia/flagella proteome databases. Surprisingly, ciliopathy syndromes share loci (Figure 11.11) despite having very distinct clinical presentations. It is thought that these disorders represent a spectrum of related phenotypes, determined in part by the gene affected and the nature of the mutation. For example, missense mutations may lead to non-lethal ciliopathies, such as NPHP or SLSN, while truncating mutations or null deletions in the same gene cause the lethal MKS. This genotype–phenotype

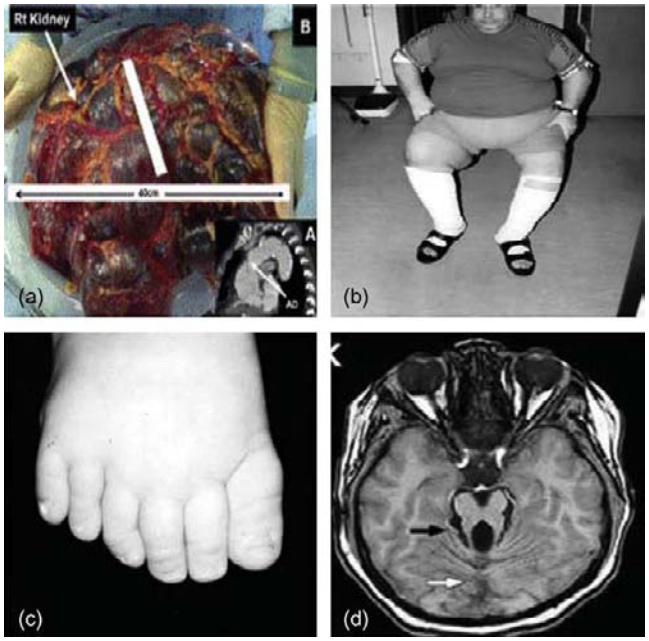

FIGURE 11.10 **Common phenotypes associated with cilia dysfunction.** (a) Cystic kidneys are a common phenotype to many ciliopathies. *(Image adapted from Menon et al. (2011). Ann. Thorac. Surg. Mar; 91 (3), 919–920. With permission.)* (b) Obese BBS patient. *(Image adapted from Iannello et al. (2002). Obes. Rev. May; 3(2), 123–135. Sep; 155(3), 386–392, with permission.)*

correlation, however, has not held up in many ciliopathy patients, leading to the possibility that strong genetic interactions or modifier effects will ultimately determine a phenotype based on the combination of different ciliopathy mutations in the patient's background (reviewed in [167]). The contribution that mutational load has on disease phenotypes will be addressed in the near future through next-generation sequencing of ciliopathy patients, the identification of the full complement of ciliopathy genes, and the generation of informative animal models.

Polycystic Kidney Disease (PKD)

PKD is one of the most common and widely studied ciliopathies. Nearly 1 in 1000 individuals are afflicted with PKD. Most forms of PKD result from mutations in three genes. Autosomal dominant PKD (ADPKD) is caused by mutations in either *PKD1* or *PKD2*, which code for the proteins PC-1 and PC-2 respectively. Autosomal recessive PKD (ARPKD) results from mutations in *PKHD1*, the gene for fibrocystin/polyductin. PC-1, PC-2, and fibrocystin/polyductin localize in the cilium, and have been shown to be involved in the cilia mechanosory signal (see section "Renal Cilia and Mechanosensation").

Nephronophthisis (NPHP)

NPHP is an autosomal recessive cystic kidney disease associated with mutations in at least 13 loci (*NPHP1-12* and *NPHP1L*; Table 11.1 and Figure 11.11). The most frequent mutation occurs in the gene NPHP1 (20%) with mutations in the other known genes (NPHP2-NPHP12, and NPHP1L) accounting for approximately 3% of the cases.[176] In most patients (~70%), the causative mutation is still unknown.

NPHP is the leading cause of heritable end-stage renal failure (ESRF) in children and adolescents, and depending of the genetic mutation,[177] ESRF occurs in infantile, juvenile or adolescent life. All NPHP cases involve renal defects, but approximately 15% of NPHP patients also experience extra-renal phenotypes including mental retardation, retinal degeneration (characterized as SLSN; Figure 11.11), brainstem malformation, situs inversus, cerebellar vermis aplasia (JBTS, see section "Joubert Syndrome (JBTS)"), oculomotor apraxia (Cogan Syndrome), and hepatic and pancreatic fibrosis. Unlike cysts associated with PKD, renal cysts in NPHP patients are located in the corticomedullary junction of the kidney, and the kidney remains normal size or even reduced in size.[178,179]

NPHP proteins localize to the transition zone, centrosome or in some cases cell–cell junctions, where they may have scaffolding functions (reviewed extensively in [20]). Physical interactions link NPHP proteins into functional complexes[31] with several other ciliopathy diseases proteins, such as TCTN1 (Tectonic, see section "Joubert Syndrome (JBTS)"), MKS5, and B9D1 (see section "Meckel-Gruber Syndrome (MKS)"). In general, mutations in NPHP proteins do not cause ciliogenesis defects, and the phenotype in human NPHP patients is thought to be due to abnormal cilia mediated signaling or sensory function. However, stunted cilia were reported in some NPHP shRNA knockdown studies.[180] Also, in *nphp4* mutant mice there is retinal degeneration and male sterility due to photoreceptor cilia defects and loss of sperm flagella, although no cysts are evident in the kidney.[181] Mutations in either *nphp*2 or *nphp3* cause more severe instances of NPHP, often associated with extra-renal developmental phenotypes (situs inversus, cardiac ventricular septal defects), and are involved in modulating Wnt signaling (see sections "Renal Cilia and Jak/STAT Signaling" and "Renal Cilia and Non-Canonical Wnt/Planar Cell Polarity (PCP) Signaling" and [139]). For a comprehensive review of NPHP the reader is referred to Wolf and Hildebrandt.[20]

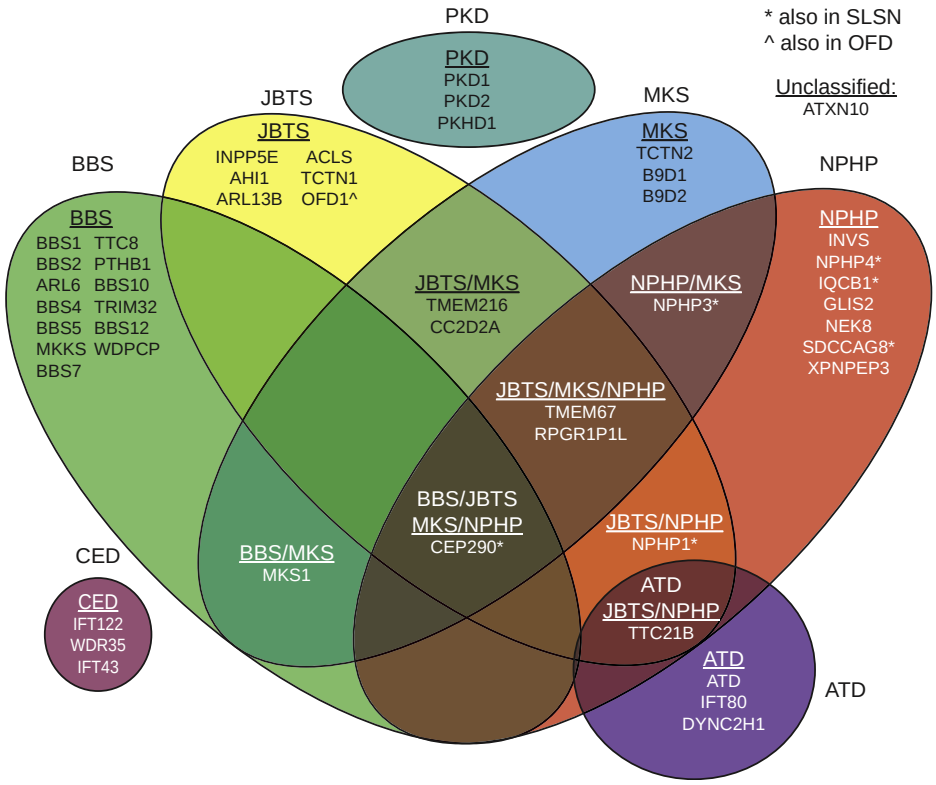

FIGURE 11.11 **Overlapping genes of ciliopathies.** A four-way Venn diagram showing the overlapping causative genes behind renal ciliopathies, creating a spectrum of disease phenotypes that include the kidney but may extend to other organs.

Joubert Syndrome (JBTS)

JBTS is a highly variable disorder with renal phenotypes similar to juvenile NPHP patients (i.e., as small cysts at the cortico-medullary junction and a potential delay in ESRF). Additional phenotypes include vermis hypoplasia, polydactyly, mental retardation, ataxia, retinal degeneration, hypotonia, abnormal breathing pattern, and oculomotor apraxia. The presence of distinct defects in the cerebellar vermis gives JBTS an indicative Molar Tooth Malformation (MTM) that can be clearly distinguished via MRI. There is significant overlap of genetic loci between JBTS patients and those loci associated with other ciliopathies (Table 11.1, Figure 11.11), perhaps explaining why JBTS displays such heterogeneous phenotypes. For this reason, JBTS is often categorized as Joubert Syndrome Related Disorders or JSRD.

There are currently 13 identified JBTS loci (Table 11.1), with *INPP5E* (JBTS1), *AHI1* (JBTS3), *ARL13B* (JBTS8), and *TCTN1* (JBTS13) being identified solely in JBTS. INPP5E is involved in regulating phosphatidyl inostitol signaling,[182] furthering the hypothesis that the primary cilium function as complex signaling centers. Consistent with signaling in cilia, ARL13B (JBTS8) is a Ras-family GTPase localized to the cilia that causes Shh mutant-like phenotypes and lethality when mutated in mice.[183,184] AHI1 interacts with Rab8[185] and with NPHP1,[186] demonstrating a physical linkage between NPHP and JBTS proteins, and possibly explaining the similarity of phenotypes between the syndromes. Likewise, TCTN1 is a transmembrane protein with physical interactions to NPHP and MKS proteins.[31] *TCTN1* mutant mice also have Hh signaling defects[187] consistent with a role for JBTS proteins in cilia signaling.

Meckel–Gruber Syndrome (MKS)

MKS is a prenatal lethal ciliopathy that displays severe developmental defects, including occipital encephalocole, postaxial polydactyly, and cystic kidneys. Other common traits include CNS malformation, underdeveloped genitals, oral/facial abnormalities, and hepatic cysts. There are 10 identified MKS loci that include both cytosolic and tramsmembrane proteins (Table 11.1). A comprehensive review of MKS can be found in .[188]

Many of the known the MKS proteins share similar C2 (MKS5 and MKS6) and B9 (MKS1, B9D1, and B9D2) domains thought to mediate calcium-dependent lipid binding. In *C. elegans*, the B9/C2 domain proteins form a complex (MKS complex) at the transition zone. This complex was shown to genetically interact with several genes encoding NPHP proteins to regulate cilia formation, positioning, and cilia protein composition.[189]

Since these MKS proteins co-localize in the transition zone, it has been hypothesized that they are components of the ciliary necklace and Y-links (see section "The Transition Zone"). MKS2, MKS3, and Tectonic-2 (TCTN2) all contain transmembrane domains, suggesting they may be the anchors that connect the cilia membrane to the microtubule axoneme. This hypothesis is strengthened by data on Cep290 (MKS4) in *Chlamydomonas* showing that it localizes to the Y-links in the transition zone, and that in its absence the Y-links are disrupted.[29]

Bardet–Biedl Syndrome (BBS)

BBS is a ciliopathy with extensive pleiotropy. Phenotypes include hypertension, mental retardation, obesity, retinopathy, hypogonadism, polydactyly, anosmia, and renal malformations. Renal phenotypes of BBS vary, and can include the formation of renal cysts, urine acidification, and reduced filtration rate with difficulties concentrating urine being the most common phenotype.[190,191] Renal mass, localization of cysts, and tubule size can vary widely between BBS patients. It has been demonstrated that ESRD often occurs in BBS patients, and is a significant contributing factor towards mortality. For a comprehensive review of BBS the reader is referred to Zaghloul et al.[192]

BBS has been linked to at least 15 identified genetic loci (Table 11.1). BBS1, BBS2, BBS4, BBS5, BBS7, BBS8, and BBS9 are components of a complex called the BBSome. The BBSome has important functions in regulating cilia membrane composition, possibly as coat proteins on vesicular structures, and for the transport of specific transmembrane proteins into or out of the cilium[64,66] (see section "Ciliary Targeting and the BBSome").

Interestingly, a comparative histological analysis of the renal phenotypes between *bbs2* and *bbs4* null mice showed that although these two genes code for components of the BBSome, they produce different BBS associated renal phenotypes.[193] Differences in renal phenotypes between *bbs2* and *bbs4* mice argue that BBS proteins may have tissue specific functions that contribute to pleiotropy of the disease.[193] Other BBS proteins such as BBS6, BBS10, and BBS12 are not components of the BBSome, and are believed to have chaperone activity facilitating the formation of the BBSome complex.[194] *In vitro* analysis of BBS6, BBS10, and BBS12 knockdown cell lines suggests that these BBS proteins are essential for ciliogenesis, and that dilute urine found in BBS patients could be attributed to the inability to target V2R to the cilium.[152]

Alstrom Syndrome (ALMS)

ALMS is a rare ciliopathy highly related to BBS, with the main distinguishing feature being later onset of symptoms than typically found in BBS patients. There is currently one identified ALMS locus. The majority of mutations in *ALMS1* result in severe truncations of the protein, however the protein still appears to maintain partial function. Interestingly, mutant mouse models of *ALMS* have no cilia structural defects, yet *in vitro* knockdown studies show defects in ciliogenesis.[195]

Orofaciodigital Syndrome Type 1 (OFD1)

OFD1 is a ciliopathy affecting the development of the craniofacial region, central nervous system, and limbs, in the form of postaxial polydactyl. In a few cases of OFD1, patients presented cystic kidneys. The OFD1 protein is expressed in the metanephric mesenchyme during development,[196] and localizes to the basal body[24] where it is required for ciliogenesis.[197] Ablation of the *OFD1* gene in the kidney in mice results in renal cyst formation, and cells lining these cysts fail to form cilia.[147] The cystic phenotype in *OFD1* animals was further associated with an upregulation of the mTOR pathway (see section "Renal Cilia and Canonical Wnt Signaling"), suggesting a mechanism of cyst growth.[147]

Jeune Asphyxiating Thoracic Dystrophy (ATD)

ATD is a ciliopathy classified in the category of autosomal recessive chondrodysplasias. Commonly associated bone defects in ATD include a shortening of long bones, polydactyly, and constriction of the thoracic rib cage. Approximately 30% of documented ATD patients also display renal phenotypes consistent with the loss or dysfunction of cilia.[198] Causative genes of ATD include *IFT80*,[199] *DYNC2H1*,[200] and *TTC21B* (*IFT139*).[201] Importantly, ATD represents one of the first human ciliopathies with identified mutations in IFT genes. These mutations are largely hypomorphic, thus potentially explaining the phenotypic variability found in ATD patients. The identity of genes mutated in ATD suggests that ATD is related to defects in retrograde IFT. Evidence that mutations in *TTC21B* and *DYNC2H1* cause defects in Hh signaling, possibly related to the inability to translocate Hh components (see section "Renal Cilia and Hedgehog Signaling") from the cilia,[57,199,202] are consistent with this hypothesis. Recently, an ATD patient with a *TTC21B* mutation and associated NPHP was uncovered.[201] This study demonstrated genetic interactions between *TTC21B*

and other ciliopathy genes, and further extends the hypothesis of the oligogenic nature of ciliopathies.

Sensenbrenner Syndrome (Cranionectodermal Dysplasia, CED)

CED is a ciliopathy highly related to ATD, with craniosynostosis being the distinguishing feature in CED.[202] Patients may also develop renal phenotypes similar to NPHP. As with ATD, CED represents a ciliopathy with mutations in IFT genes. All currently known CED loci are IFT-A components: *IFT43*,[203] *IFT122*,[204] and *WDR35* (*TULP4*/*IFT121*),[202] and are likely hypomorphic mutations. At the cellular level, CED appears to be correlated with Shh signaling (see section "Renal Cilia and Hedgehog Signaling") defects that arise from improper IFT[203,204] similar to ATD.

CONCLUDING REMARKS

The primary cilium is an evolutionarily conserved organelle, in terms of structure and its capacity to act as a complex signaling and sensory center for the cell. In the past 15–20 years, there have been remarkable advances in our understanding of the role of primary cilium in signaling and development. This is due, in large part, to the multiple model systems available to study the relationship between cilia structure and function. Importantly, since the initial publication of the *orpk* mouse model, the kidney has remained at the forefront of cilia related research. Much of our understanding of cilia biology is due to the use of renal cystic disease models that clearly demonstrate the developmental consequences of cilia dysfunction. Current advances in sequencing, proteomics, microscopy, and molecular genetics will only serve to further our understanding of cilia biology in the kidney and beyond.

TIGHT JUNCTIONS

Structure

General Structure

The tight junction is the most apical component of the junctional complex (Figure 12.1). It is located at the boundary between the apical and lateral membranes, and encircles the cells to form a continuous belt-like attachment. By transmission electron microscopy, it appears morphologically as a series of appositions or "kisses" between the lateral membranes of adjacent cells (Figure 12.2a). The outer leaflet of the lipid bilayers approach each other so closely that they appear to be fused. In the technique of freeze-fracture electron microscopy, the hydrophobic phospholipid interior of the lipid bilayer is cleaved, allowing the tight junctions to be visualized within the plane of the lateral membrane. By this means, tight junctions appear as a series of continuous, anastomosing intramembranous strands on the protoplasmic or P-face, with complementary grooves on the exoplasmic or E-face (Figure 12.5). It is believed that these strands associate in pairs from neighboring cells and obliterate the intercellular space, thus accounting for the kissing points seen by transmission electron microscopy (Figure 12.2b).

Early models of the tight junction posited that it was composed purely of lipid organized into inverted cylindrical micelles, that constituted the tight junction strands.[2,3] There now exist three lines of evidence that refute this. First, tight junction strands were found to be resistant to deoxycholate, an ionic detergent that should solubilize lipids.[4] Second, the lipid model predicts that the outer leaflets of the bilayers of adjacent cells are continuous, yet no transfer of glycolipid or a fluorescent probe could be demonstrated.[5–7] Finally, the discovery of integral membrane proteins within the tight junction now supports a model in which tight junction strands are composed of proteins embedded in the lipid membrane (see below).

Regional Differences in Structure

The structure of the tight junction varies considerably in different regions of the kidney. This is summarized briefly below. For further details, the reader is referred to comprehensive surveys by Orci, Brown, and colleagues.[8,9]

GLOMERULUS

The parietal epithelium of Bowman's capsule is constituted of squamous cells whose extensions overlap obliquely (Figure 12.3). Their tight junctions consist of networks of two to four anastomosing strands with many discontinuities.[10,11] The mature visceral epithelial cell (podocyte) forms a specialized intercellular junction, the slit diaphragm (Chapter 23). Short elements of incomplete tight junctions can sometimes also be seen between the foot processes of adjacent podocytes. True tight junctions do form between immature podocytes in the fetal glomerulus and are of uncertain functional significance.[12,13] These disappear during development, but can reappear during nephrotic states, coincident with effacement of the foot processes and obliteration of the slit pore[14–16] (Figure 12.4).

RENAL TUBULE

Tight junctions are found between the epithelial cells of all tubules, but they vary considerably in their morphology in different tubule segments (Figure 12.5 and Table 12.1). In general, the more proximal segments tend to have simpler junctions, with fewer strands and more discontinuities, correlating with a leaky paracellular pathway, as judged by transepithelial resistance (TER). By contrast, more distal segments tend to have greater numbers of strands, with more continuity and complex anastomosing patterns, loosely correlating with higher TER. Indeed, Claude proposed a model in which TER is dependent primarily on strand number.[17] However, as discussed below, we now know that the TER is also highly dependent on the composition of the tight junction.

Physiological Functions

Gate Function

The gate function refers to the ability to regulate the paracellular permeability. This determines the rate of passive diffusion of extracellular solutes and water between the apical and basolateral aqueous compartments. Early studies, using extracellular macromolecules and lanthanum as electron-dense markers, clearly established the tight junction as the site of the paracellular gate.[1,18,19]

In epithelia that mediate active, uphill transcellular transport, such as the collecting duct of the kidney, this gate must act predominantly as a barrier to prevent backleak of solute gradients that have been generated. To do so, these so-called "tight" epithelia must have very low paracellular permeability and conductance (typical transepithelial resistances (TER) range from 1−2 k′Ω.cm^2 for the renal collecting duct[20] to ~8 k′Ω.cm^2 for amphibian skin[21]).

In contrast, in epithelia that mediate bulk transport of solutes via the paracellular pathway, the gate is predominantly open. For example, in the late proximal tubule of the kidney about one-third of NaCl reabsorption occurs by the paracellular route,[22] and in the thick ascending limb of Henle, Ca^{2+} and Mg^{2+} are exclusively reabsorbed via the paracellular pathway.[23] Characterization of the properties of leaky epithelia have indicated that there must be paracellular aqueous pores.[24,25] Fromter and Diamond were the first to prove that the paracellular leak is physically located at the intercellular junction.[26] Thus, the tight junction is not always a complete barrier, but must also have pores that pass through it.

Fence Function

In epithelia, the lipid and protein components of the plasma membrane are separated into distinct apical and basolateral domains at the tight junction, and this polarity is critical for functions such as vectorial transport. Apical−basolateral polarity is initially established by the Par/aPKC, Crumbs, and Scribble complexes,[27,28] while the tight junction is primarily responsible for maintenance of this polarity. Specifically, the tight junction behaves like a fence, preventing diffusion within the plane of the lipid bilayer. Interestingly, markers that are confined to the exocytoplasmic leaflet cannot pass across the tight junction, but markers that can flip-flop across the bilayer freely diffuse across it,[6,29] suggesting that the fence is located in the exocytoplasmic half of the plasma membrane. Several manipulations can dissociate the barrier and fence functions of the tight junction. Transient ATP depletion[30,31] and depolymerization of the cortical actin network[32] disrupt the paracellular barrier while preserving fence function. This suggests that the fence function of the tight junction is mechanistically independent of its gate function.

Biochemical Composition

The first tight junction-associated protein to be identified was ZO-1, in 1986.[33] Since then, it has become clear that the tight junction is actually a complex of many different proteins. These fall into one of four categories: transmembrane proteins; scaffolding proteins; signaling molecules; and transcriptional regulators. These molecules are associated, through multiple protein−protein interactions, with the scaffolding proteins serving to anchor the complex to the cortical actin cytoskeleton. Table 12.2 lists the known molecules in each category. Here, we focus solely on the transmembrane proteins. These are important because their transmembrane domains traverse the lipid bilayer, while their extracellular domains protrude into the paracellular space. Thus, tight junction membrane proteins are the leading candidates to mediate both gate and fence functions.

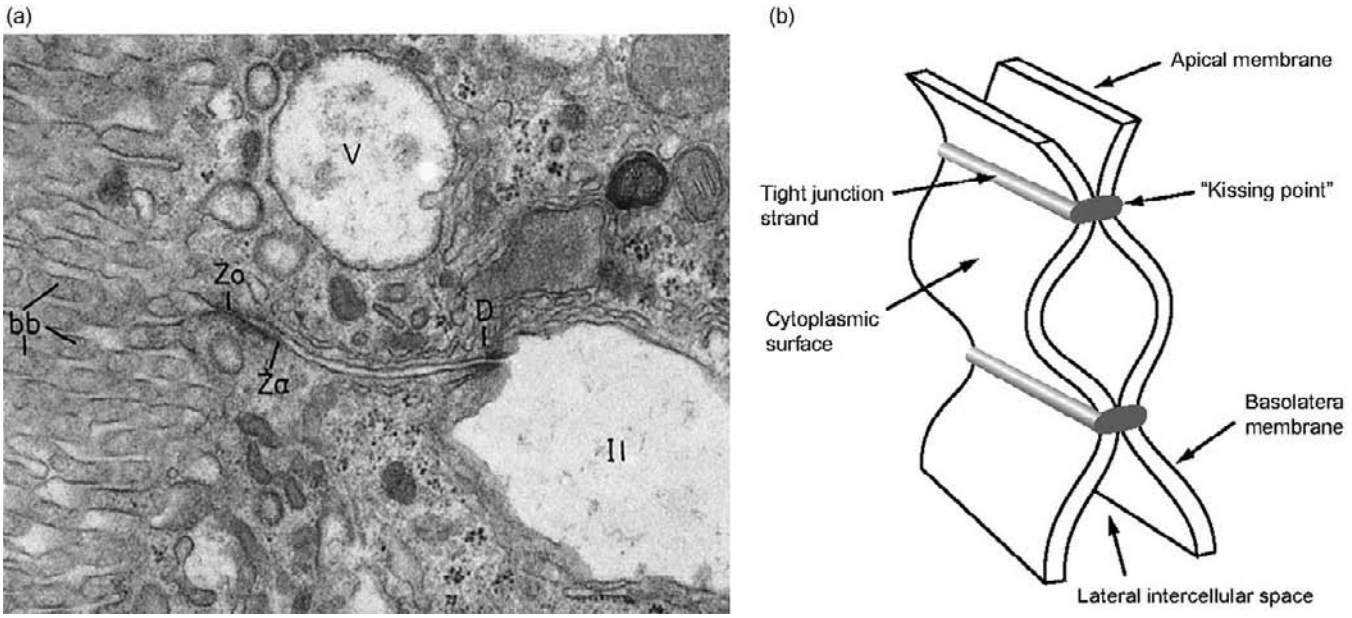

FIGURE 12.2 **Structure of the tight junction.** (a) Transmission electron micrograph of the junctional complex in the epithelium of the rat proximal convoluted tubule (Zo: zonula occludens (tight junction); Za: zonula adherens (adherens junction); D: desmosome; bb: brush border; Il: lateral intercellular space). (b) Three-dimensional depiction of the tight junction. Tight junction strands of neighboring cells associate in a pairwise manner at points where the lateral membranes are closely apposed, obliterating the intercellular space ("kissing points"). *(©The Rockefeller University Press.* The Journal of Cell Biology, *(1963).* ***17****, 375–412.*[1]*)*

(1976).* Cell Tissue Res. ***172****(4), 431–446.*[10]*)*

Occludin

Occludin was the first integral tight junction membrane protein to be identified.[34] It has four transmembrane domains with intracellular N- and C-termini. Occludin is ubiquitously expressed in epithelial cells, localizing predominantly at bicellular junctions (junctions where two cells meet). Its role is poorly understood. Overexpression of a C-terminally truncated occludin protein increases TER, but paradoxically increases mannitol flux, and also disrupts tight junction fence function.[35,36] However, after knockdown or knockout of occludin, cells can still form normally appearing tight junction strands.[37,38] In fibroblasts that do not have tight junctions, occludin cannot reform tight junction networks, but it does co-polymerize into strands with claudin-1.[39] Knockdown of occludin in MDCK cells causes only a slight increase in permeability to small inorganic and organic cations.[38] Interestingly, occludin null mice have assorted unexplained abnormalities, including retarded postnatal growth, male sterility, and chronic inflammation and epithelial hyperplasia in the gastric mucosa.[40] Importantly, though, epithelial barrier function is normal in these mice.[41] Thus, occludin is neither necessary nor sufficient to form tight junction strands and perform barrier, pore or fence functions. However, occludin can incorporate into claudin-based strands, in which case dominant-negative occludin constructs are presumably able to disrupt normal tight junction function.

Tricellulin

Tricellulin is a homolog of occludin that is localized to tricellular junctions (junctions at the confluence of three cells.[42] It is clearly important for barrier function, because knockdown of tricellulin increases paracellular conductance and permeability to uncharged macromolecules,[42] and its overexpression reduces macromolecular permeability.[43] Mutations in tricellulin cause a form of non-syndromic hereditary deafness, indicating that it plays a critical role in inner ear function,[44] but its role in the kidney has not been explored.

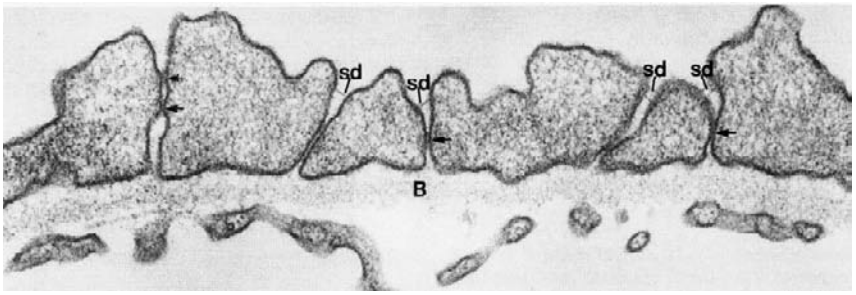

FIGURE 12.4 **Morphologic changes in glomerular podocytes in the puromycin aminonucleoside nephrotic rat kidney.** The membranes of the foot processes appear to come into close apposition or to be fused (arrows), forming tight junction-like structures between neighboring processes. The slit diaphragms (sd), which are normally located above the basement membrane (B), are found above the newly formed junctions between the podocytes (× 74,000). *(Reprinted from* Am. J. Pathol. *(1992),* ***141****, 805–816.*[226] *With permission from the American Society for Investigative Pathology.)*

Claudins

Claudins were discovered by Tsukita and colleagues.[45] They are members of a multigene family of ~20–24 kDa tight junction proteins with four predicted transmembrane segments and two extracellular domains (see refs [46–48] for several recent reviews). When expressed in claudin-deficient cells such as fibroblasts, claudins can form tight junction-like networks of strands, indicating that they polymerize in *cis* (within the same cell membrane), and can mediate intercellular adhesion, indicating the ability to interact in *trans* (across two lateral membranes of adjacent cells).[39,49] Thus, claudins have all the properties expected for a structural component of the paracellular barrier. In 1999, Lifton's group identified the culprit gene mutated in familial hypercalciuric hypomagnesemia, an inherited disorder thought to be due to failure of paracellular reabsorption of divalent cations in the thick ascending limb of the renal tubule. This gene, which was initially named paracellin, turned out to be a claudin (claudin-16),[50] and its involvement in this disease strongly suggested that claudins play a role in regulating paracellular transport. This is now supported by numerous studies demonstrating that overexpressing or ablating expression of various claudin isoforms in cultured cell lines or in mice affects both the degree of paracellular permeability, and its selectivity (reviewed in ref [51]). Moreover, Colegio et al. have convincingly shown that the net charge on residues in the first extracellular domain of claudins determines the charge selectivity of paracellular conductance.[52,53] This suggests fairly strongly that the first extracellular domain of claudins actually forms the lining of the paracellular pore. The permeability properties of different claudin isoforms, as inferred from *in vitro* overexpression and knockdown studies, are summarized in Table 12.3.

FUNCTIONAL DOMAINS OF CLAUDIN

The functions of several of the domains within the claudin protein have been determined (Figure 12.6). The first extracellular loop of claudin forms the lining of the paracellular pore. Chimera studies have shown that exchanging the first extracellular loop between different claudin isoforms confers different pore selectivity characteristics.[53] Furthermore, point mutations that reverse the charge on residues in the first extracellular loop alter the charge selectivity of the paracellular pore, as would be expected if this domain faced the pore lumen.[52] In claudin-2, a cation-selective pore, this loop specifically contains an aspartate residue (Asp-65) that acts as a Na^+-binding site.[54] Several other residues in this domain have also been mapped by cysteine-scanning mutagenesis.[55]

The second extracellular loop of claudin is postulated to participate in *trans*-intermolecular interactions, acting as the adhesion receptor between neighboring cells. This is based on the finding that mutations of selected residues in the second extracellular loop of claudin-5 abolish its ability to concentrate at cell contact sites when expressed in HEK cells.[56]

Claudins all have a long cytoplasmic C-terminal tail that appears to be involved in protein trafficking and degradation. Deletion of this tail in claudin-5 and -6 leads to accumulation of the protein in the cytoplasm.[57,58] This domain also affects protein stability, since swapping it between different claudins confers different protein half-lives.[59] The terminal dipeptide motif in claudins (tyrosine-valine in the majority) binds to PDZ domains on the scaffolding proteins, ZO-1, 2, and 3,[60] and MUPP1.[61,62] However, deletion of this motif does not seem to affect normal trafficking of claudins to the tight junction.[57,63]

The cytoplasmic C-terminal tail in all claudin isoforms also contains multiple potential

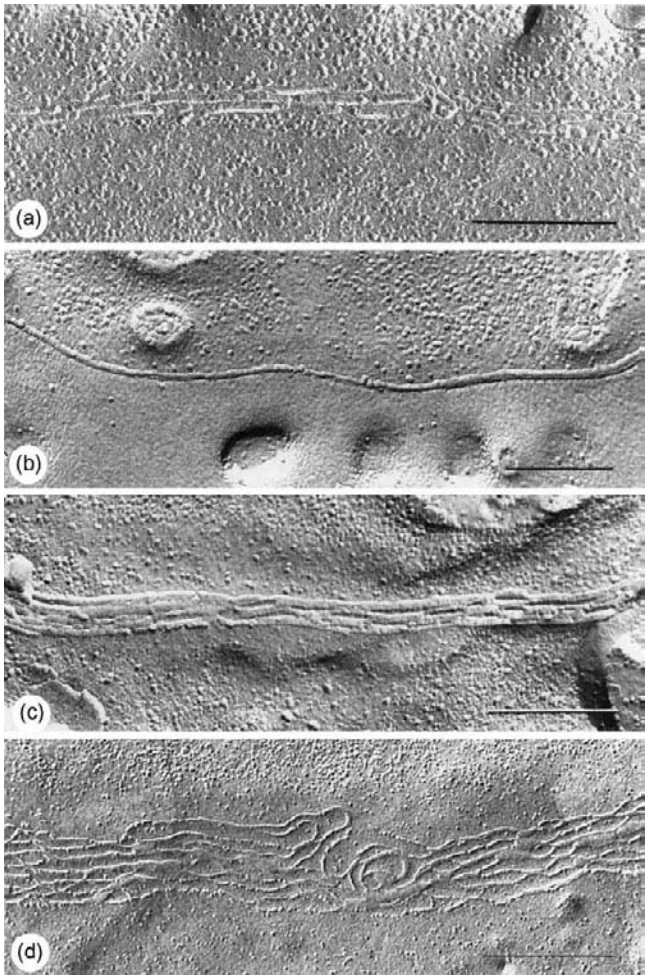

FIGURE 12.5 **Freeze-fracture morphology of tight junctions on the P-faces of four regions of the urinary tubule.** The tight junctions of the proximal convoluted tubule (a) are characterized by fibrils that are often ill-defined and discontinuous. In the ascending thin limb of Henle (b), the tight junctions usually appear as one continuous strand or two closely apposed strands that are covered with fragments of E-face from the adjacent cell, giving the impression of a single, thick strand. In the distal tubule (c), the junctions are composed of several parallel elements. In the collecting duct (d), the tight junctions are the most complex in the entire urinary tubule, and are formed of multiple, branching fibrils (a–c: bar = 0.25 μm; d: bar = 0.5 μm). *(Reproduced with permission from Orci et al. (1981).* Int. Rev. Cytol. *73, 183–242.*[9]*)*

phosphorylation sites for a variety of protein kinases (see ref [64] for a comprehensive review). The most common outcome of phosphorylation by protein kinases in this domain is increased assembly at the tight junction,[65,66] but there are examples of phosphorylation leading to decreased assembly at the tight junction,[67] and also to changes in paracellular permeability.[68–70]

Finally, all claudins have two pairs of conserved cysteines immediately following the second and fourth transmembrane domains. In claudin-14, these have been shown to be palmitoylated, and this seems to be required for efficient localization to the tight junction.[71]

Physiology of the Tight Junction in Different Nephron Segments

Different nephron segments exhibit different tight junction permeability characteristics that are important for their specific function. These paracellular permeability characteristics are likely a function both of the general structure of the tight junction (discussed above), and of the properties of the specific claudin isoforms expressed in that segment. The nephron

TABLE 12.3 Putative Ion Permeability Characteristics of Claudin Isoforms[a]

		Anion barrier	
		Claudin-15	52,88
		Claudin-19[e]	112

[a]*Based on in vitro overexpression or knockdown studies in cultured cell lines. We assume that permeability and selectivity are properties intrinsic to individual claudin isoforms, and ignore the possible confounding effect of heteromeric interactions between isoforms. Claudin-7 is omitted because conflicting data exist suggesting that it is either a Cl-barrier[124,225] or a Na-barrier/Cl-pore.[125]*
[b]*Pore-forming claudins refer to those that predominantly decrease TER or increase solute permeability, while barrier-forming claudins refer to those that predominantly increase TER or decrease solute permeability. The distinction is somewhat arbitrary, since most claudins probably have some finite permeability to most solutes, and the observable phenotype is highly dependent on the properties of the host cell line.[87,222]*
[c]*Acts as a Na barrier in MDCK II cells, but as a Cl pore in LLC-PK1 cells.*
[d]*Net flux studies suggest that claudin-6 and -9 may also act as Cl-barriers.[93]*
[e]*Conflicting data also exists suggesting claudin-19 can act as a Na barrier.[105]*

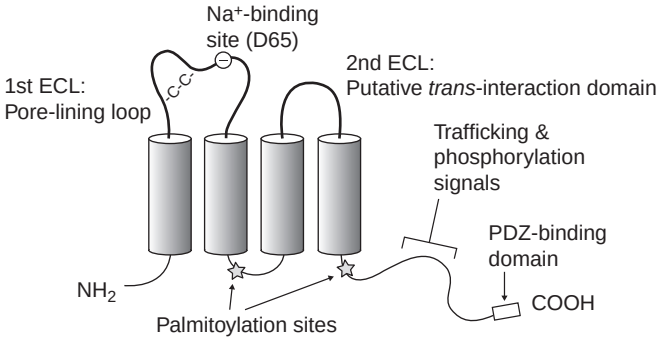

FIGURE 12.6 **Functional domains that have been mapped in claudins.** The Na^+-binding site at D65 has been demonstrated in claudin-2 (ECL: extracellular loop).

segment localization of different claudin isoforms is summarized in Figure 12.7.

Bowman's Capsule

The function of the parietal epithelium of Bowman's capsule is poorly understood, but one might assume that it needs to act primarily as a barrier to contain the glomerular filtrate, and direct flow into the proximal tubule. The tight junction of parietal epithelial squamous cells is unique among cells of the nephron in expressing claudin-1,[72,73] an isoform that has been shown to act as a barrier to ion conductance, and to permeation of 4–40 kDa dextran.[36,74] Claudin-2, a cation- and water-permeable claudin isoform predominantly expressed in the proximal tubule (see below), has also been reported to be expressed in the parietal epithelium.[72,73] However, it is well-known that the parietal epithelium at the urinary pole is constituted of columnar cells that are distinct from the squamous parietal epithelial cells, and morphologically and functionally resemble proximal tubule cells.[75,76] These columnar cells can cover a substantial surface area of Bowman's capsule, for example, one-third of it in male mice, and it is probably just these cells that express claudin-2 (see, for example, Fig. 3A in ref [77]).

Ohse recently showed that the parietal epithelium in mice functions as a barrier to macromolecules, as detected with 3 kDa dextran and 45 kDa ovalbumin as tracers.[78] After experimental induction of glomerulonephritis, this barrier is disrupted and the macromolecule tracers can be observed leaking into the space between the parietal epithelium and the underlying basement membrane of Bowman's capsule, as well as the extraglomerular space.

Proximal Tubule

The primary role of the proximal tubule is bulk reclamation of solutes that evade the glomerular filter, such as Na, K, Ca, Cl, HCO_3, phosphate, glucose, and water. Since the free concentration of these solutes in the glomerular filtrate is similar to that of the peritubular fluid, relatively little energy expenditure should be needed to transport them across the epithelium. To achieve this sort of energy efficiency, the proximal tubule uses a two-step process. In the first step, ATP consumed by the Na-K-ATPase is used to generate a transmembrane Na gradient that drives secondary and tertiary active transcellular reabsorption of Na and other solutes. The stoichiometry of the Na-K-ATPase dictates that the hydrolysis of each ATP molecule in this step should be coupled to the direct transport of three Na ions. In the second step, the transepithelial electrochemical gradients generated by transcellular transport then provide the driving force for passive diffusion of solutes across the paracellular pathway. Measurements of whole kidney oxygen consumption have been used to estimate that five Na ions are transported per ATP molecule,[79,80] demonstrating that paracellular transport greatly enhances the metabolic efficiency of the proximal tubule.

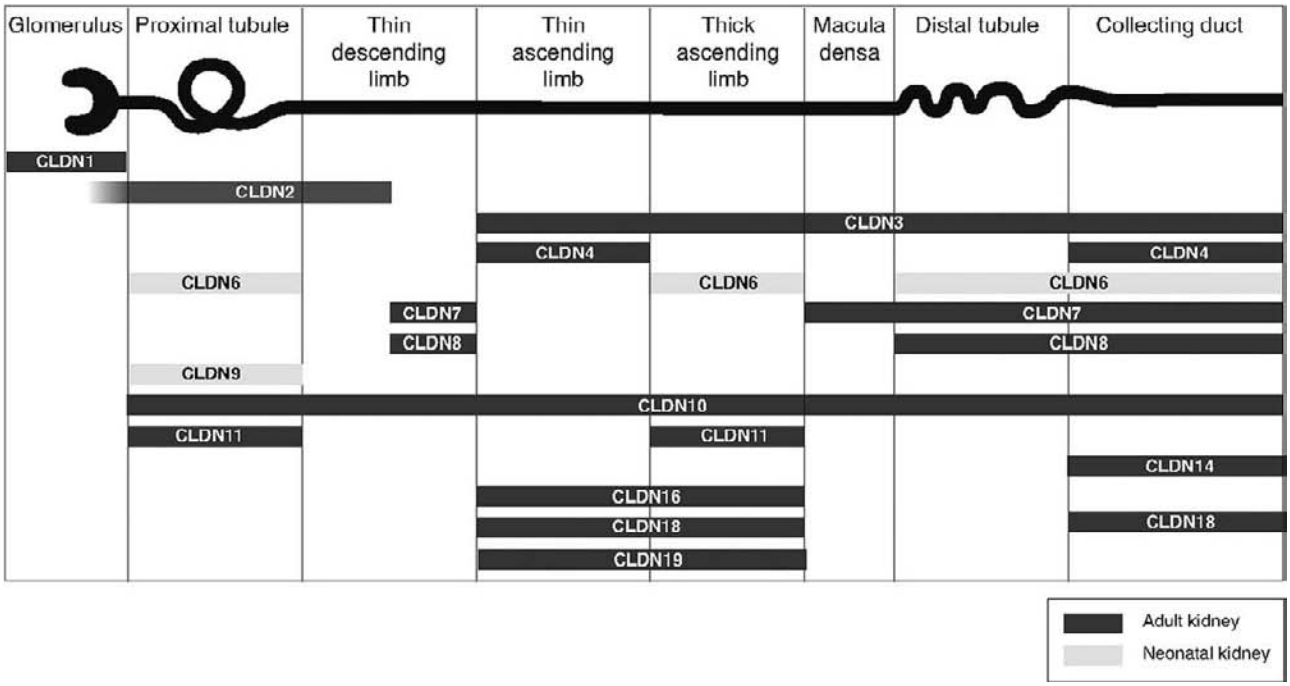

FIGURE 12.7 **Localization of claudin proteins in rodent kidney.** Localization data were collated from the following studies: claudins 1, 3, and 4,[72] claudin-2,[77] claudin-6,[92] claudins 7 and 8,[227] claudin-9,[92] claudin-10,[90] claudin-14,[108] claudin-16,[106] claudin-17,[85] claudin-18,[107] and claudin-19.[105,106] Macula densa claudin expression is from our own unpublished results. Tubule expression of claudins 6 and 9 are only found in neonatal kidney.[92] Localization of claudins in human kidney are essentially identical,[50,228] except that claudin-1 is found in collecting duct and distal tubule, claudin-10 is not found in the distal nephron, and claudin-14 is reportedly in the distal convoluted tubule.[228] Many of these claudins have not been rigorously examined in all nephron segments so the data shown are not comprehensive. Claudins 5 and 15 are confined to endothelial cells of the vasculature and glomeruli,[72] and so are not shown. Claudins 12, 18 and 20–24 have not yet been examined. *(Figure modified from Angelow, S. and Yu, A. S. (2007). Claudins and paracellular transport: an update. Curr. Opin. Nephrol. Hypertens.* ***16****, 459–464. Copyright Lippincott, Williams & Wilkins, 2007.)*

NaCL REABSORPTION

The underlying mechanism for paracellular NaCl reabsorption in the proximal tubule was first proposed by Rector.[22,81] In this model, transcellular Na reabsorption in the early proximal convoluted tubule is coupled primarily to reabsorption of most of the organic solutes and significant amounts of bicarbonate, and followed by isosmotic reabsorption of water. This leads to a luminal fluid that is high in chloride, but low in bicarbonate. The late proximal tubule has a very high passive permeability (presumably due to the paracellular pathway) both to Na and to Cl, but much less so to HCO_3.[82–84] Thus, Cl is reabsorbed paracellularly, driven by its concentration gradient. This in turn generates a lumen-positive electrical potential which then drives concomitant reabsorption of Na.

The claudin isoforms that are known to be expressed in the proximal tubule are claudin-2, -10, and -17.[72,77,85] Claudin-2 behaves *in vitro* as a cation-selective paracellular pore.[54,86–88] Knockout of claudin-2 in mice led to an approximately two-fold reduction in transepithelial conductance, P_{Na}/P_{Cl}, and passive flux of Na, Cl, and water in perfused S2 segments, and an exaggerated natriuretic response to a NaCl challenge.[89] Thus, claudin-2 seems to be the primary route for paracellular Na reabsorption. Claudin-10 exists in two splice variants that differ in their first extracellular domain, and hence charge selectivity.[90] Claudin-10a behaves as a Cl-selective pore, while claudin-10b is Na-selective. The 10a splice variant is uniquely expressed in the kidney, and by *in situ* hybridization appears to be predominantly in the cortex, although tubule localization could not be ascertained. Studies of claudin-17 overexpression in MDCK-C7 cells and knockdown in LLC-PK1 cells indicate that it functions as a Cl pore.[85] Thus, either claudin-10a or -17 could potentially mediate paracellular Cl reabsorption in the proximal tubule.

The neonate proximal tubule has a lower chloride permeability than the adult, which may predispose it to salt-wasting and dehydration.[91] Claudins 6 and 9 are predominantly expressed in the neonatal proximal tubule,[92] but the published functional data are somewhat conflicting as to whether they primarily act as Cl-barriers (which would be consistent with the tubule physiology) or Na-barriers.[93]

WATER REABSORPTION

A substantial amount of water is reabsorbed in the proximal tubule. It is now clear that the majority of water transport is transcellular and mediated by aquaporins. Nevertheless, knockout of AQP1 in mice only reduces proximal tubule water transport by 80%, suggesting that an alternative pathway for water transport exists and is either active under normal conditions or is upregulated to compensate for loss of AQP1.[94] Weinstein has argued that the low reflection coefficient for NaCl ($\sim$0.7)[95] suggests the existence of a paracellular shunt pathway for water.[96] However, Preisig and Berry measured the permeability of the proximal tubule to mannitol and sucrose and, assuming that they were only transported paracellularly, modeled the pore size with the Renkin equation to predict the paracellular water permeability and concluded that it was <2% of transepithelial water permeability.[97] Moreover, Spring measured water flow in the lateral intercellular spaces of MDCK cells (admittedly not necessarily a proximal tubule model cell line) by an optical technique, and concluded that water transport in these cells was entirely transcellular.[98] Thus, the existence of paracellular water reabsorption in the proximal tubule has been quite controversial. Recently, Rosenthal et al. reported that transfection of claudin-2 increases transepithelial osmotic water permeability.[99] Interestingly, they found that when they imposed a transepithelial Na^+ concentration gradient, not only was Na^+ transported vectorially, but water flowed in the same direction, suggesting that Na^+ and water movement are in some way "coupled," and therefore that they probably flow through the same pore.

REABSORPTION OF OTHER CATIONS

A substantial proportion of the filtered load of K, Ca, and Mg are reabsorbed in the proximal tubule, largely by the paracellular pathway. The driving force in each case is probably both an increased concentration of the cation in the lumen due to water reabsorption, and the lumen-positive voltage in the mid-to-late proximal tubule. Claudin-2 is permeable to both K and Ca (Mg has not been tested),[54] and therefore likely mediates their reabsorption by diffusion down their electrochemical gradients.

Thick Ascending Limb of Henle

The thick ascending limb of Henle is a quantitatively important site for paracellular reabsorption of the divalent cations, Ca and Mg.[100] In addition, some of the Na reabsorbed in this nephron segment is also thought to occur paracellularly, thus enhancing the metabolic efficiency of transcellular Na reabsorption, just as in the proximal tubule. The driving force for paracellular reabsorption of each of these cations is a lumen-positive electrical potential difference. This voltage is generated by two distinct and additive mechanisms: (1) transcellular reabsorption of NaCl through the apical Na-K-2Cl co-transporter and basolateral Na-K-ATPase and ClC-K chloride transporter occurs concomitantly with apical recycling of K through the apical K channel, ROMK, giving rise to a net movement of positive charge apically; this generates a 3–9 mV lumen-positive transepithelial potential difference[101]; (2) because the paracellular pathway of the thick ascending limb is highly cation-selective ($P_{Na}/P_{Cl} = 2–6$),[101,102] accumulation of a high concentration of reabsorbed NaCl basolaterally generates a diffusion potential, adding another 10–15 mV to the transepithelial voltage.[103] The paracellular pathway of the thick ascending limb is well adapted for this purpose. It is characterized by a low TER (11–34 $\Omega.cm^2$),[104] high selectivity for Na over Cl, and high permeability to divalent cations.[23]

The thick ascending limb is known to express claudins 3, 10, 11, 14, 16, 18, and 19.[50,72,90,105–108] Claudin-16 (also known as paracellin) and claudin-19 are of particular interest, because mutations in these genes cause familial hypercalciuric hypomagnesemia with nephrocalcinosis (FHHNC), an autosomal recessive disorder characterized by renal Ca and Mg wasting.[50,106] There are two prevailing hypotheses as to the physiological role of claudins 16 and 19. The first hypothesis, initially suggested by Simon et al.,[50] is that they are divalent cation-permeable paracellular pore proteins. In this model, Ca and Mg normally diffuse through these claudins, driven by the lumen-positive potential, but in FHHNC this pathway is abolished. Consistent with this, Ikari et al. found that overexpression of claudin-16 increased Ca permeability, and that this could be competitively inhibited by Mg, while TER was paradoxically increased.[109] Similarly, Kausalya et al. found that claudin-16 increased Mg permeability, but did not affect P_{Na}/P_{Cl}.[110] The second hypothesis is that claudin-16 and -19 together form a pore that is highly selective for Na over Cl, and therefore facilitates the component of the lumen-positive potential generated by the NaCl concentration gradient (component (2) above). In other words, claudin-16 and -19 are involved in creating the driving force for Ca and Mg reabsorption, rather than being part of the permeation pathway. This second hypothesis is supported predominantly by the work of Hou, Goodenough, and colleagues. In their hands, claudin-16 acts like a cation pore that is not selective between monovalent and divalent cations,[111] and claudin-19 acts like an anion barrier.[112] Hou et al. showed that the two isoforms physically interact with each other, and have additive effects to increase P_{Na}/P_{Cl} when co-expressed

together.[112] Indeed, knockdown of both isoforms in mice recapitulated the main features of FHHNC, and was associated with decreased P_{Na}/P_{Cl} as measured in isolated, perfused thick ascending limbs.[107,113]

Claudin-14 appears to act as a negative regulator that binds to claudin-16 to reduce the PNa/PCl of this complex.[108] Importantly, claudin-14 expression is upregulated in response to high extracellular calcium or a high-calcium diet, which stimulate the Ca-sensing receptor in the thick ascending limb and thereby downregulate two micro-RNAs that normally suppress claudin-14 expression. This provides an elegant homeostatic mechanism to increase renal calcium excretion in the setting of calcium excess. The role of the other claudins in this segment is not known at this time.

Aldosterone-Sensitive Distal Nephron

The aldosterone-sensitive distal nephron (ASDN) encompasses the distal convoluted tubule, connecting segment, and collecting duct. This is the last section of the nephron, and is responsible for fine-tuning urinary composition. The remaining excess Na in the tubular fluid has to be reabsorbed here, and K and H^+ secreted. These are active, highly energy-consuming processes, because they need to drive transport uphill against steep electrochemical gradients, utilizing transcellular pathways. Transtubular concentration gradients for Na, K, and H^+ (lumen:blood) of 1:3, 20:1, and 1000:1, respectively, are often achieved by the end of the collecting duct. Thus, the major role of the tight junction in the ASDN is to act as a very tight paracellular cation barrier to prevent dissipation of these transtubular cation gradients. Consistent with this, the ASDN (or at least the collecting duct) expresses five claudins that function primarily as cation barriers: claudins 3, 4, 8, 14, and 18.[114–118] For claudin-8 and -18, the ability to act as a barrier to acid permeation has also been demonstrated.[118,119]

In the connecting segment and collecting duct, Na is reabsorbed primarily electrogenically through epithelial Na channels (ENaC), as distinct from the distal convoluted tubule, which mediates electroneutral, NaCl reabsorption. Thus, Cl in the connecting segment and collecting duct must be reabsorbed either through an independent transcellular pathway (e.g., via the Na-driven Cl-bicarbonate exchanger and pendrin in β-intercalated cells[120,121]) or paracellularly. Consistent with a role in paracellular Cl transport, the cortical collecting duct has been shown to have a substantial paracellular permeability to Cl.[122] A recent study suggests that this paracellular Cl permeability may be mediated by claudin-4 and -8, perhaps interacting with each other to form a heteromeric pore.[123]

Claudin-7 is expressed in the ASDN. When overexpressed in LLC-PK cells, it appeared to reduce Cl permeability (i.e., acted as a Cl barrier).[124] However, knockdown of its expression paradoxically also decreased Cl permeability, suggesting that claudin-7 might normally behave as a Cl pore, and might be responsible for the paracellular Cl conductance in the ASDN.[125] Importantly, mice that had claudin-7 knocked-out by gene targeting exhibited severe renal salt-wasting, hypovolemia, and acute renal failure,[126] which is consistent with a role for claudin-7 in ASDN Cl reabsorption.

REGULATION BY ALDOSTERONE AND WNK KINASES

NaCl reabsorption in the ASDN is stimulated by mineralocorticoids. This is achieved in part by stimulating transcellular Na transport. In addition, aldosterone and other mineralocorticoids regulate paracellular permeability. For example, mineralocorticoids reduce Na permeability in the inner medullary collecting duct.[127–129] This would serve to limit paracellular back-leak of Na, and thereby enhance the efficiency of Na reabsorption. Mineralocorticoids have also been shown to reduce paracellular Cl permeability in the collecting duct,[129,130] but the physiological significance of this is less clear. Interestingly, Le Moellic et al. found that in a rat cortical collecting duct cell line, very brief (<1 hour) aldosterone exposure actually increased paracellular anion permeability.[69] This correlated temporally with phosphorylation of claudin-4 at a threonine residue, although a causal relationship was not established.

NaCl reabsorption in the ASDN is also regulated by WNK1 and WNK4. These are protein kinases that, when mutated, cause pseudohypoaldosteronism, type II (PHAII), a genetic disorder characterized by salt-sensitive hypertension and hyperkalemia.[131] The normal physiological function of the WNKs is quite controversial, but it is clear that PHAII mutations in WNK4 lead to enhanced NaCl reabsorption in the ASDN. This is partly transcellular and mediated by stimulation of the thiazide-sensitive NaCl co-transporter, NCC.[132,133] However, there is also evidence that WNK4 regulates paracellular Cl permeability. WNK4 is localized to the tight junction *in vivo*.[131] When overexpressed in cell lines, WNK4 (particularly the PHAII mutant) stimulates paracellular Cl conductance.[68,70,134] The exact mechanism is unclear. There is evidence both for[68,70] and against[135] direct phosphorylation by WNK4 of several claudin isoforms, including claudins 4 and 7, that are normally expressed in the ASDN.

Tight Junction Dysfunction in Ischemic Acute Kidney Injury

Ischemic injury to the kidney causes reversible disruption of renal tubule epithelial barrier function and

polarity. Renal ischemia or ATP depletion in humans, animal models, and cultured cells cause disruption of the tight junction,[30,136] with internalization of occludin, ZO-1 and -2, and cingulin.[137,138] Similar findings have been demonstrated in renal allografts with post-ischemic injury.[139] One consequence of this is loss of the epithelial barrier and backleak of filtrate into the interstitium,[139,140] which can partly explain the oliguria seen in severe acute kidney injury. Renal ischemia also impairs tight junction fence function, and disrupts epithelial polarity, including mislocalization of the Na-K-ATPase,[141,142] which would be predicted to impair transcellular tubular Na reabsorption. This probably contributes to the inappropriately elevated fractional excretion of Na (F_ENa) commonly observed clinically in ATN, and may also stimulate tubuloglomerular feedback, and thereby contribute to the reduction in GFR.

GAP JUNCTIONS AND CONNEXIN HEMICHANNELS

Structure and Biochemical Composition

Gap junctions are non-selective channels located in the plasma membranes of adjacent cells, and are critical to intercellular communication in most cell types. Functionally, they serve to couple non-excitable cells by allowing the passage of small molecules (less than 1 kDa in size), such as inorganic ions and secondary messengers, between the two cells.[143] Gap junction channels exhibit open and closed configurations, and this gating can be regulated by intracellular molecule concentration, mechanical stress, metabolic inhibition, and transjunctional voltage.[144–146]

Each half of the gap junction, known as a connexon, is composed of six transmembrane proteins from the connexin (Cx) family. There are 21 known human Cx isoforms, all of which present the same topology: intracellular N- and C-termini; four transmembrane domains; two extracellular loops with three cysteine residues; and a single intracellular loop. The N-terminus and position of the cysteine residues are conserved. Variability among the Cx isoforms is found in the intracellular loop and C-terminus. Consequently, these regions appear to be responsible for differences that exist in charge and size discrimination among isoforms.[143] Two styles of nomenclature identifying these isoforms are used. Cxs are most commonly identified by their molecular weight in kiloDaltons (e.g., Cx45), which presents a problem when discussing Cx expression in different species, as molecular weight of the same isoform can vary. Alternatively, Cx isoforms are sorted by class (alpha, beta, gamma), and assigned a number (e.g., Gja1).[147] For simplicity, we will adhere to the first naming convention throughout the chapter.

Connexons may be composed of a single isoform (homomeric) or a mix of Cxs (heteromeric), and their trafficking can occur by two pathways. The first involves formation of the connexon at the endoplasmic reticulum, with trafficking through the Golgi apparatus to the plasma membrane. Alternatively, Cx proteins may bypass the Golgi, and form the hexamer once in the plasma membrane. In either case, the transmembrane domains appear to be involved in the oligomerization process. Within the plasma membrane, connexons tend to group together to form a gap junction plaque. The plaque is a highly dynamic body, with gap junction protein half-life in the order of 2–5 hours. This allows for rapid regulation of the composition of Cxs within the plaque in response to cellular demands.[143] Docking of the connexons in adjacent cells creates the intercellular channel, and connexons of different Cx isoforms can couple to form heterotypic gap junctions. Since different Cx isoforms exhibit variation in terms of gating, regulation, and interaction, the modular and combinatorial nature of gap junctions allows a diversity of function within one type of channel.[148,149]

Beyond the typical intercellular gap junction structure, there is evidence that Cxs can regulate intercellular communication without directly coupling cells. Uncoupled connexons form transmembrane pores known as hemichannels, and these Cx hemichannels serve as a conduit between the intra- and extracellular environments, facilitating the transport of signaling molecules such as ATP.[150,151] They are gated, since a constitutively open channel would be lethal to the cell, and are regulated by the same factors as gap junctions.[146,152] Cx hemichannels are thought to conduct intercellular communication via calcium wave propagation. In this model, mechanical or chemical stimulation triggers the opening of Cx hemichannels in a cell which allows ATP to passively move through the hemichannel into the extracellular environment. The newly released ATP binds to purinergic receptors on local cells, triggering an increase in intracellular calcium levels in these cells, thereby propagating the calcium signal. The functionality of Cx hemichannels, however, remains controversial and it is difficult to prove their existence with certainty.[151]

Gap junctions play a vital role in many cellular processes in nearly every cell type in the body, facilitating normal development, physiology, and apoptosis. Consequently, Cx mutations are associated with pathophysiological conditions including Charcot Marie Tooth disease, congenital deafness, and the skin disease erythrokeratoderma variabilis.[147] Outside of hereditary conditions, complex diseases including diabetes and hypertension have been linked to changes in the expression of Cxs.[153–155]

Renal Localization

Renal intercellular channels were first identified in afferent arteriole vascular smooth muscle cells (VSMC) in the 1970s.[156] Electron microscopy images later provided evidence of gap junction channels in the renal tubules, as well as in the renal vasculature.[157,158] Specification of the Cx isoforms that made up renal gap junctions came later, with mRNA expression studies.[159–164] Localization of Cx proteins in the kidney has been limited by the availability of specific antibodies, and by variation among species. As a result, different studies present divergent results. More recently, the development of Cx knockout and reporter mouse models have provided new insight into the expression of Cxs within the nephron, as well as suggesting their significance in renal physiology.[165–170] Table 12.4 summarizes the renal localization of connexin isoforms.

Vasculature

The renal vasculature expresses Cxs37, 40, 43, and 45, which are found in all vascular systems.[159,166,171,172] Within vessels, gap junction coupling occurs between endothelial cells, between the smooth muscle cells, and at the myoendothelial junctions. Cx expression is best defined in endothelial cells. In rodents, Cx40 is abundantly expressed in the afferent arteriole endothelium, with lower levels of Cx37 and 43 also detected.[159,164,173] In the endothelial cells of the efferent arteriole, Cx37 is expressed in rat, while mice express Cx43.[172,173] Beyond the juxtaglomerular apparatus (JGA), all three isoforms are expressed in the vasa recta and vascular bundles.[173] Cx43 is also expressed in the peritubular capillaries and renal veins.[171,173]

The identity of the vascular smooth muscle Cx(s) is less clear. Cx37 was detected in the VSMCs of murine arcuate and interlobular arteries,[173] but not in rats.[159,174] Likewise, one study found evidence of Cx43 in the preglomular media,[161] but later reports have failed to confirm this.[159,164,174] Cx45, which is commonly expressed in smooth muscle cells in other vascular systems,[175] appears to exhibit the same characteristic localization in the kidney. Several studies have shown Cx45 expression in VSMCs of the interlobular, afferent, and efferent arterioles, both by immunohistochemistry and reporter gene mouse methods.[166,171,176] A lack of Cx40 expression in renal VSMCs has been shown in all studies.[159,164,173]

Glomerulus and Juxtaglomerular Apparatus

Both the glomerulus and juxtaglomerular apparatus (JGA) express gap junction proteins abundantly. Podocytes, endothelial cells, mesangial cells, and the renin-producing JG cells are all characterized by gap

TABLE 12.4 Summary of the Localization of Connexin Isoforms in the Kidney

Cx	Renal Localization	Cell Type	Species
26	Proximal tubule*	Epithelial	Mouse
30	Distal nephron	Epithelial	Rat
	Cortical CD, CNT	Intercalated	Mouse, rabbit, rat
30.3	ATL	Epithelial	Mouse, rabbit, rat
	Cortical CD	Intercalated	Mouse, rabbit, rat
32	Proximal tubule*	Epithelial	Mouse
37	Arcuate artery; IA*	VSMC	Mouse
	RA; AA, EA	Endothelial	Mouse, rat
	Vasa recta	Pericytes	Rat
	Vascular bundles	Endothelial	Mouse
	JGA*	Granular, mesangial	Mouse, rat
	Proximal tubule, TAL, DCT	Epithelial	Mouse, rat
	CNT, CD	Principal > Intercalated	Mouse, rat
40	RA; Arcuate artery; IA; AA	Endothelial	Mouse, rat
	Vasa recta	Endothelial	Rat

ATL: Ascending thin limb of the loop of Henle; AA: afferent arteriole; CD: Collecting duct; CNT: connecting tubule; DCT: Distal convoluted tubule; EA: efferent arteriole; IA: interlobular artery. JGA: juxtaglomerular apparatus; RA: renal artery; TAL: thick ascending limb of the loop of Henle; VSMC: vascular smooth muscle cell.

junction coupling. In addition, the different cell types that constitute the JGA appear to be interconnected by gap junctions. The macula densa cells, however, are exclusive of gap junctions.[157,177] Again, Cx isoform localization has been primarily determined by antibody-based localization techniques, and as a result many studies present differing data. In podocytes, Cx43 is primarily expressed, although Cx45 has been detected in these cells as well.[178] Glomerular endothelial cells showed expression of Cx40 in one study,[164] but another report was unable to reproduce this finding.[173] Cx40 is, however, prominently expressed in the intra- and extraglomerular mesangium, as well as the renin-producing JG cells.[159,171–173] Cx37 follows a similar, if weaker, pattern of expression as Cx40. Expression in the intraglomerular mesangium is limited to the vascular pole, and lower levels of Cx37 staining are found in the extraglomerular mesangium and JG cells.[172,173] The glomerulus also appears to be positive for Cx45, and studies using reporter gene mouse models indicated Cx45 expression was localized to the mesangial cells. These studies also showed Cx45-positive cells expressing renin, leading to the conclusion that the JG cells express Cx45 alongside Cx40.[166] This study conflicts with antibody-based approaches, where Cx45 labeling is only evident in JG cells during embryogenesis.[171] Finally, the endothelial cells of the afferent and efferent arterioles closest to the glomerulus lack any Cx protein expression or structural evidence of gap junction coupling.[164]

Tubules

Despite the recognition of gap junction channels in the proximal tubules,[179] attempts to localize Cx isoforms along the nephron present a complex picture, with different techniques and species again producing varying expression patterns. In the proximal tubules, Cxs26, 37, and 43 have been detected in epithelial cells; however, proximal tubule Cx expression appears weak at best.[180,181] The distal tubules present much stronger levels of gap junction protein expression, but lack any signs of gap junction coupling by freeze-fracture microscopy.[182] While no Cx isoforms have been found in the descending limb of the loop of Henle, the ascending portion expresses Cxs30 and 30.3 in the apical membrane of the thin limb, and Cx37 in the basolateral membrane of the thick limb.[170,180,183] Continuing the pattern seen in Henle's loop Cx30, 30.3, and 37 are expressed along the connecting segment and collecting duct, and are similarly localized to the apical or basolateral membranes. Both Cx30 and Cx30.3 were detected in the intercalated, but not the principal, cells of connecting segment and cortical collecting duct.[170,180,183] The absence of gap junction coupling between epithelial cells, as well as their subcellular localization to apical or basolateral membranes, suggests these Cx proteins may form hemichannels in this region of the nephron. This hypothesis appears to be supported by a study of primary proximal tubular cells that expressed Cx43 and demonstrated hemichannel activity.[182]

Physiological Function in the Kidney

As is the case with the localization of renal connexins, the physiological significance of gap junction proteins in the kidney is still emerging, and current research does not always present a consistent story. To study the functional roles of gap junction proteins in the kidney, both specific methods and non-specific inhibitors are used. In the latter category are chemical gap junction uncouplers and blockers, such as heptanol and carbenoxolone, that inhibit channel activity without regard to their component proteins.[184–186] More specific approaches focus on the Cx isoforms involved, and include the use of knockout mice and gap mimetic peptides.[187–190] These peptides mimic the extracellular loop sequence of Cx isoforms and block gap junction channels through an unknown mechanism.

Vascular Conduction and Myoendothelial Communication

One key area where gap junction coupling influences renal vascular physiology is in the propagation of a vasomotor response, either dilatory or constrictive, along vessels in response to local stimulation. In rat preglomerular arteries and vasa recta, vascular conducted responses are inhibited by the gap junction uncouplers carbenoxolone and 18α-glycyrrhetinic acid.[185,186] Interestingly, vasodilation and vasoconstriction responses appear to involve gap junctions via independent mechanisms. Studies with Cx40 knockout mice and Cx40 mimetic peptides both demonstrated an inhibitory effect of Cx40 loss on vasodilation in mesenteric arteries.[188,190] Conversely, Cx37, but not Cx40, knockout mice have reduced vasoconstriction responses.[190]

Vasomotor stimulation may also spread between the endothelium and the smooth muscle cells of renal vessels via myoendothelial gap junctions. Vasodilation of smooth muscle occurs in response to the hyperpolarization of endothelial cells, and this response can be inhibited by non-specific gap junction blockers in rabbit renal arteries.[184] A similar effect was observed with Cx40 and Cx43 mimetic peptides; however, the inhibition appears to be dependent on the agonist used.[187,189]

Tubuloglomerular Feedback and Renin Secretion

The JGA regulates renal hemodynamics through the mechanism of tubuloglomerular feedback (TGF),

whereby variations in tubular fluid flow and composition in the cortical thick ascending limb are detected by the macula densa cells, and trigger changes in afferent arteriole diameter and renin secretion in response (see also Chapter 24). The TGF mechanism involves a calcium wave (Figure 12.8) which propagates through the JGA.[191] The regulation of calcium signaling by Cxs is well-established in other systems,[143] and given the extensive gap junction coupling in the JGA it appears that this calcium wave is similarly controlled. The gap junction uncoupler 18α-glycyrrhetinic acid and heptanol inhibit the spread of calcium in the JGA in response to an increase in flow.[191] Two possible pathways explain how gap junction proteins coordinate calcium signaling in the JGA. Calcium may spread in coupled cells directly via intercellular gap junction communication. Alternatively, the calcium wave may propagate indirectly via purinergic signaling. In this model, increased intracellular calcium triggers the opening of Cx hemichannels and the release of ATP/UTP to the extracellular environment, which subsequently binds purinergic receptors on neighboring cells, increasing intracellular $[Ca^{2+}]$.[192] Several observations point to the latter mechanism. Removal of direct contact between cells did not inhibit calcium signaling, and stimulation of cells led to the release of ATP, as measured by a biosensor cell technique. The use of purinergic receptor blockers and ATP scavengers also inhibited the JGA calcium wave.[191,193] Both Cx40 and Cx45 appear to function in the JGA calcium wave. Cx40 siRNA reduced calcium signaling in glomerular endothelial cells, while VSMCs isolated from a conditional Cx45 knockout mouse model or treated with a Cx45 gap mimetic peptide showed reduced propagation speed.[166,193]

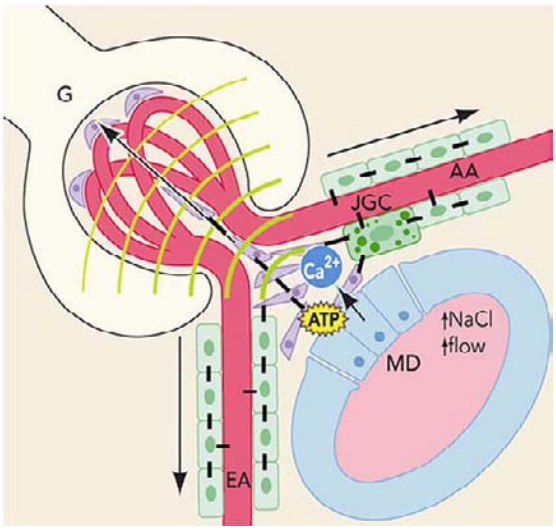

FIGURE 12.8 **Role of gap junctions in the juxtaglomerular apparatus.** Components of the TGF calcium wave include ATP release from macula densa (MD) cells in response to elevations in tubular NaCl and/or flow rate, and paracrine, purinergic calcium signaling. Extracellular ATP-induced elevations in mesangial, vascular smooth muscle (VSMC), and renin-producing juxtaglomerular cell (JGC) $[Ca^{2+}]_i$ are then propagated via gap junctions to distant cells of the afferent arteriole (AA), efferent arteriole (EA), and glomerulus (G) away from the MD region, causing cell contractions. All cell types of the JGA are abundant in gap junctions (−), except for the cells of the MD. Vascular endothelial cells in the AA, EA, and G are also connected with each other and JGCs and VSMCs via gap junctions, and are involved in the calcium wave of TGF. *(Figure modified from Peti-Peterdi, J., Toma, I., Sipos, A. and Vargas, S. L. (2009). Multiphoton imaging of renal regulatory mechanisms. Physiology (Bethesda)* ***24****, 88–96. Copyright American Physiological Society.)*

Renin secretion regulation and control of systemic blood pressure also require gap junction protein expression. Cx40 knockout mice have high blood pressure and high plasma renin, due primarily to the lack of negative feedback control of renin secretion by blood pressure and angiotensin II. Regulation of renin by beta adrenergic receptor stimulation and dietary salt is not affected.[194,195] These mice also show aberrant expression of renin in the preglomerular interstitium, extraglomerular mesangium, and glomerular tuft, while the afferent arteriole VSMCs are entirely devoid of renin. Cx45-deficient mice, which lack Cx45 in afferent and efferent VSMCs, renin-producing granular cells, and mesangium have a similar phenotype as the Cx40 knockout mouse.[166] Replacement of Cx40 by Cx45 (Cx40KI45) results in a reduction of blood pressure and the return of renin regulation. Normal renin cell recruitment in response to a low-salt diet is not restored.[176] These results indicate that cell−cell communication via Cx channels is critical to renin secretion, and that specifically Cx40 is required for renin expression. Cx37 knockout mice have normal renin regulation, while Cx43 knockout models are lethal. Replacement of Cx43 by Cx32 (Cx43KI32) resulted in reduced plasma renin content, loss of renin regulation, and *de novo* renin expression in endothelial cells.[196] An endothelial-specific Cx43 knockout model, however, does not show any changes to renin secretion.[197]

Tubule Function

The role of Cxs in tubular function remains largely unclear despite the expression of Cx proteins along the nephron and gap junction coupling in the proximal tubules. The expression of Cxs 30 and 37 is regulated by dietary salt, with high salt increasing Cx30 expression at the apical membrane of medullary collecting ducts, and low salt increasing cortical expression of Cx37, presumably along basolateral membranes.[180,183] It is hypothesized that Cx hemichannels regulate epithelial transport along the nephron via purinergic signaling (Figure 12.9). Activation of P2 purinergic receptors in the nephron is known to regulate renal transporters, modulating sodium, potassium, and

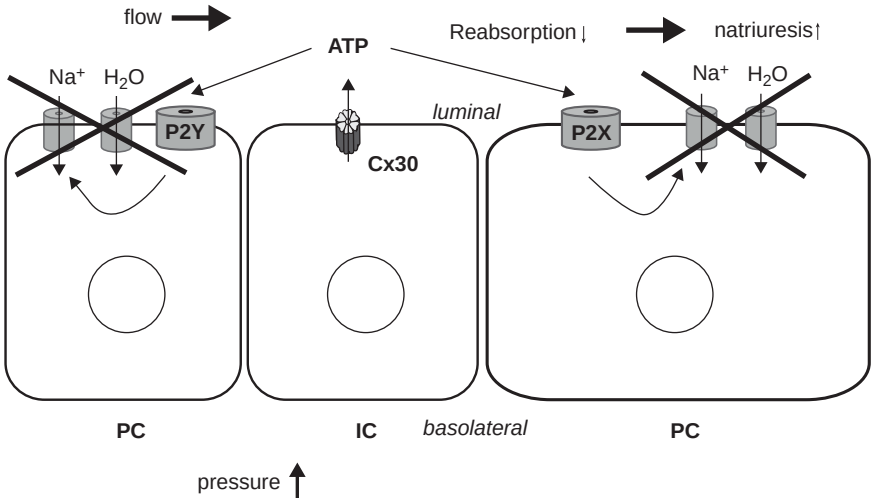

FIGURE 12.9 **Schematic illustration of mechanically induced, Cx30 hemichannel-mediated ATP release into the tubular lumen in the cortical collecting duct (CCD), and its paracrine effects on salt and water reabsorption, natriuresis, and diuresis.** Increases in intra-renal pressure and/or tubular flow rate that accompany blood pressure elevations result in the opening of Cx30 hemichannels at the luminal membrane of CCD intercalated cells (IC), and the release of ATP. Stimulation of luminal purinergic receptors (mainly P_2Y_2) in adjacent principal cells (PC) results in the inhibition of salt and water reabsorption, and increased natriuresis and diuresis. This inhibitory mechanism is absent in $Cx30^{-/-}$ mice, resulting in a salt retention phenotype. *(Reproduced with permission from Sipos et al. (2009). J. Am. Soc. Nephrol. **20**(8), 1724–1732.[10])*

water reabsorption.[198–200] The close proximity of ectonucleotidases and purinergic receptors in the tubular lumen implies local release of ATP.[199,201] Supporting this hypothesis is recent data which shows that Cx30 knockout mice have an impaired pressure natriuresis response, and that at the cellular level, isolated cortical collecting ducts from these mice release less ATP in response to stimulation than their wild-type counterparts. Based on these findings, the study presented a model suggesting a mechanism by which Cx30 plays a role in pressure natriuresis. Increased pressure/flow in the collecting ducts induces the opening of Cx30 hemichannels, allowing ATP to enter the local extracellular environment and bind local P2 receptors. Activation of these receptors inhibits salt and water reabsorption, resulting in homeostasis.[167]

Roles in Renal Pathology

In the kidney, the role that Cxs plays in pathology is relatively unknown and mostly hypothetical. Human mutations in gap junction genes are linked to a variety of diseases, with altered expression of Cxs leading to the pathophysiology observed. Moreover, primary diseases can result in changes to the levels and localization of gap junction proteins. Global genetic knockouts of several Cx genes are embryonically lethal, indicating their importance during development.[147] Despite the widespread expression of gap junctions in the kidney, mutations in Cx genes have only minor effects on renal organogenesis.[202] As described above, Cx40 knockout mice show defects in JGA renin localization, but this is only apparent after birth.[168]

In adult mutant mice, the predominantly observed renal pathology is hypertension. Genetic loss of Cx40 or Cx45 in the kidney leads to high blood pressure in mice, as does the use of gap mimetic peptides in rats.[166,172,194,195] Knockin mice in which the coding region of Cx43 is replaced by that of Cx32 (Cx43KI32) have a protective phenotype, failing to develop renin-dependent hypertension in response to clipping one renal artery (two-kidney, one-clip model).[196] As detailed in the previous section, it appears that the effect on systemic blood pressure is due to the loss of gap junction communication, preventing renin–angiotensin system signaling. There is no known effect of primary hypertension on renal Cx expression in rats or mice. In humans, a variant in the Cx40 promoter that results in lower gene activity is associated with increased risk of high blood pressure, but it is unclear what mechanism drives this correlation.[203]

An increase in vascular intercellular communication and changes in renal Cx expression are also associated with diabetes.[204,205] In diabetic mice, endothelial cells express Cx40 in place of Cx37, and Cx43 is expressed in renin-producing cells *de novo*. The link between Cx expression and diabetes appears to be the nitric oxide (NO) pathway. Diabetes is associated with increased NO availability, and when diabetes was induced in endothelial nitric oxide synthase (eNOS) knockout mice, no changes in Cx expression were observed. Overexpression of eNOS caused changes in renal Cx expression which mimic the pattern seen in diabetes.[173]

ADHERENS JUNCTIONS AND DESMOSOMES

The adherens junction and desmosome are considered together here, because they share a similar function—to maintain the physical association between cells—and similar arrangements of their molecular components. These junctions are found in all epithelia, and there is little about them that is unique to the kidney, so we summarize here the general features of adherens junctions and desmosomes, and refer the reader to several recent reviews for more in-depth discussions.[206,207]

Structure and Localization of the Adherens Junction

The adherens junction in epithelia spans the lateral plasma membranes of adjacent cells at a distance of 10–20 nm, and forms a continuous belt around the circumference of each cell (the "zonula adherens")[206] (Figure 12.2a). The calcium-dependent component is formed by a classical (Type I) cadherin (such as E-cadherin or N-cadherin), a transmembrane protein whose extracellular domain undergoes homophilic adhesion in the presence of calcium, and whose cytoplasmic domain binds to p120-catenin and either β- or γ-catenin (plakoglobin) (Figure 12.10a). These catenins in turn associate with a number of other cytosolic proteins (e.g., α-catenin), some of which are responsible for anchoring the adherens junction to the actin cytoskeleton. In addition, there is a calcium-independent component to the adherens junction, which is formed by members of the nectin family of transmembrane proteins. Nectins, like cadherins, interact via their extracellular domains, although preferentially in a heterotypic manner. Their cytoplasmic terminal has a PDZ-binding motif that associates with afadin (AF6), which can either bind actin directly or indirectly via α-catenin and its partners.

As alluded to in the introduction to this chapter, the mature glomerular slit diaphragm expresses several adherens junction proteins,[208] including P-cadherin, FAT,[209] α-, β-, and γ-catenin, and so it has been proposed to represent a modified adherens junction.[208] In the adult renal tubule, there is differential localization of classical cadherins. The proximal tubule predominantly expresses N-cadherin; the thick ascending limb, distal tubule, and collecting duct predominantly express E-cadherin; and Bowman's capsule and the thin limbs of Henle express both isoforms.[210–212] However, the functional significance of this is unknown. In contrast, the cytoplasmic catenins are ubiquitously expressed in all tubule segments.[213]

Structure and Localization of Desmosomes

Desmosomes are specialized anchoring junctions that serve as tethers for cytoplasmic intermediate filaments.[207] While they are particularly important for maintaining the integrity of tissues subject to mechanical stress, such as the epidermis and myocardium, they are also present in all epithelia and are thought to play roles in tissue morphogenesis. Desmosomes appear as

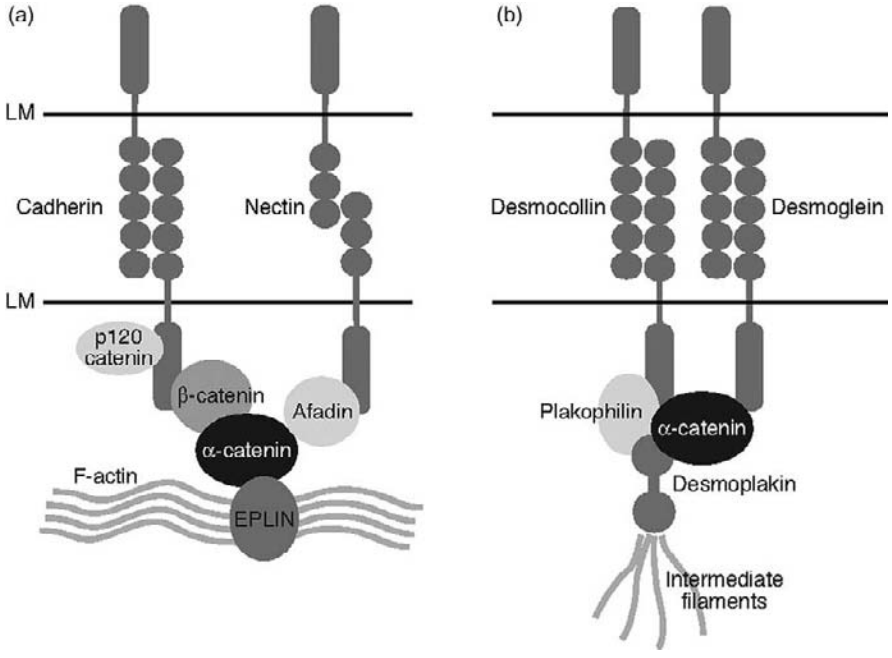

FIGURE 12.10 **Molecular components of the adherens junction (a) and desmosome (b).** LM: lateral plasma membrane.

pairs of dense, disc-shaped plaques on opposing lateral membranes of adjacent cells (Figure 12.2a). The desmosomal cadherins, desmoglein and desmocollin, mediate cell–cell adhesion via their extracellular domains (Figure 12.10b). The armadillo proteins, plakoglobin/γ-catenin, and plakophilin act as adaptor proteins that link the cytoplasmic domain of the desmosomal cadherins to desmoplakin, which in turn links the desmosomal plaque to the intermediate filament cytoskeleton.

In mice, desmoplakin and plakoglobin are expressed at highest levels in the distal tubule, connecting tubule, and collecting duct,[211] whereas in humans, plakoglobin, like other catenins, is expressed along the entire nephron.[213]

Adherens and Desmosomal Junctions in Kidney Disease

In ischemic acute kidney injury, as discussed earlier, there is disruption of the tight junction. This is also associated with degradation of E-cadherin, and dissolution of the adherens junction complex.[139,214] Polycystin-1, the product of the gene PKD1 that is mutated in autosomal dominant polycystic kidney disease (ADPKD), is localized to adherens junctions and desmosomes in renal epithelia, and participates in cell–cell adhesion.[215] In ADPKD, both adherens and desmosomal junctions are abnormal in morphology.[216] Most of the cysts are of distal tubule origin, yet they lack E-cadherin at the adherens junction, and N-cadherin is expressed in its place.[217]

CHAPTER

13

Principles of Cell Signaling

Lloyd Cantley

Yale University School of Medicine, New Haven, CT, USA

INTRODUCTION

The successful transition from single cells to complex multicellular organisms has required the development of mechanisms for cells to communicate with each other, so as to act in concert during processes such as nutrient acquisition, motility, and defense. The most fundamental of these are cell–cell junctions that serve as structural organizers, but also provide information that individual cells can utilize to orient themselves in relation to the remainder of the organism. In larger species that contain multiple organs and cell types, the need to communicate information over long distances has led to the development of diffusible factors that are secreted by one cell and travel to distant cells. These factors can be delivered locally, via the circulation (e.g., hormones and cytokines) or via the nervous system (e.g., neurotransmitters), and are recognized by the appropriate cell surface receptor on the recipient cell. The complex nature of the numerous signals presented to the cell at any given point in time has led to the development of an intricate array of receptor-activated intracellular second messengers that, by undergoing a coordinated series of interactions and enzymatic alterations, can transduce the information presented on the cell surface to effector molecules that mediate the appropriate cellular response.

The kidney serves to protect the internal milieu of higher organisms from perturbations due to the accumulation of metabolic products, as well as those resulting from fluctuations in the intake or loss of water and various salts. To regulate this intricate function, the body must continuously monitor the composition and quantity of the extracellular fluid, and then signal the nephron to appropriately regulate glomerular filtration and tubular cell function in response to changes in these parameters. Regulation of these exquisitely precise events requires that the cells of the kidney are able to respond to signals emanating from distant sites, and then efficiently communicate in an intercellular and intracellular manner to coordinate the response. This chapter will provide an overview of several of the most common receptors and intracellular second messenger pathways that are utilized in this process.

CELL SURFACE RECEPTORS

In the best studied pathway of cell signaling, a first messenger is secreted by one group of cells and travels either to distant cells (endocrine factors) or to local cells (autocrine or paracrine factors), where it binds to a specific receptor. The first messengers in these classic pathways are generally either proteins (growth factors, cytokines), catecholamines (epinephrine, dopamine) or steroids (mineralocorticoids, sex hormones), although receptors have been identified for multiple circulating factors including lipids (e.g., lysophosphatidic acid), ions (e.g., calcium), eicosanoids (e.g., prostaglandin E_2), sugars (e.g., glucose), nucleosides (e.g., ATP), and gases (e.g., nitric oxide). Most of these receptors are located on the cell surface and have an extracellular region (domain) that recognizes and binds to the specific ligand. This ligand-binding domain is connected via one or more transmembrane segments to the intracellular (cytosolic) domain that undergoes a change in conformation or activity in response to ligand binding, and thus initiates the activation and/or modification of intracellular second messengers. In contrast to these cell surface receptors, steroid receptors, which are discussed later in this chapter, are typically located in the cytoplasm. The lipophilic steroid ligands are capable of crossing the cell membrane and binding the receptor, which then initiates signaling events by translocating into the nucleus where the ligand–receptor complex can regulate gene transcription.

Based on their structure, the type of ligand that they bind, and the principle second messengers that are activated, classical cell surface receptors can be grouped into G-protein coupled receptors, receptor tyrosine kinases (RTKs), serine/threonine kinase receptors, and receptor-like phosphatases. However, it has become increasingly clear that other surface proteins serve as signaling initiators to transduce information about the environment surrounding the cell. Thus, cell−cell and cell−matrix adhesion molecules initiate signaling cascades that regulate cell shape, differentiation, proliferation, and survival. The following section will provide a brief overview of these various signaling initiators, focused on those presently considered to be important in regulating normal renal development and maintaining adult kidney homeostasis.

G-Protein Coupled Receptors

The receptor sub-type that is responsible for mediating the signaling responses of the greatest number of ligands in the kidney is probably the G-protein-coupled receptor (GPCR). GPCRs make up the largest family of cell surface receptors, with over 800 members predicted from the sequence of the human genome (reviewed in [1]) (Figure 13.1). GPCRs are transmembrane proteins with their amino terminus on the cell exterior, seven transmembrane α helical segments, and the carboxyl terminus in the cell interior. This arrangement results in three extracellular loops and three intracellular loops joining the transmembrane segments. They bind to extracellular ligands such as epinephrine, dopamine, angiotensin II, adenosine, vasopressin, calcium, and parathyroid hormone, and mediate their intracellular actions.

The extracellular loops serve as the primary binding site for the specific GPCR ligand, with the amino terminus also contributing to the binding site for some ligands. The intracellular loops, most critically the 5−6 loop, serve as the binding site for the principal GPCR intracellular effectors, the heterotrimeric G-proteins. These small GDP/GTP-binding protein complexes are made up of α-, β-, and γ-subunits, with the α-subunit serving as the GDP/GTP-binding site, and the βγ-subunits acting both as regulators of α-subunit localization, and independently as intracellular signaling effectors. The existence of multiple different α-, β-, and γ-subunits allows for hundreds of potential combinations of heterotrimeric G-proteins, and thus imparts specificity of response to the individual GPCR and its ligand.

In the absence of receptor activation, the α-subunit is bound to GDP, and associates with the βγ-subunits at the membrane. However, following ligand binding to the extracellular surface of the GPCR, a conformational change of the receptor results in disassociation of GDP, and binding of GTP to the α-subunit. The binding of GTP stimulates disassociation of the α-subunit from the βγ-subunits and the receptor. The GTP-loaded α-subunit can then associate with its intermediary effectors (such as adenylyl cyclase and phospholipase), while the βγ-subunits can associate with and regulate independent effectors, such as ion channels and the β adrenergic receptor kinase (βARK) (reviewed in [2,3]).

The protein products of the 16 mammalian genes encoding Gα-subunits have been grouped into four classes, the $G_{s\alpha}$ (stimulatory for adenylyl cyclase), $G_{i\alpha}$ (inhibitory for adenylyl cyclase), $G_{q/11\alpha}$ (regulators of phospholipase Cβ (PLCβ)), and $G_{12\alpha}$ (regulators of RhoGEF). Binding of the appropriate GTP-loaded Gα-subunit to its primary effector results in the

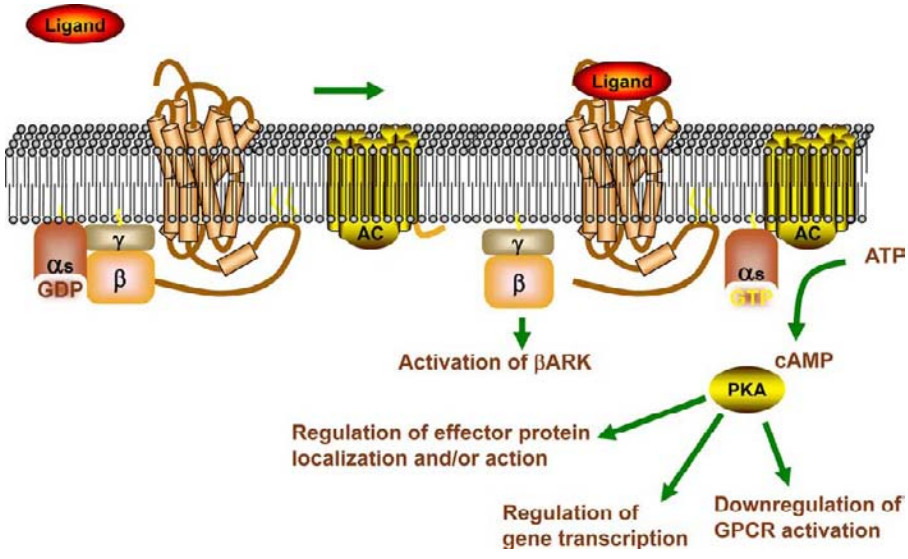

FIGURE 13.1 GPCR signaling through adenylate cyclase. Binding of the extracellular ligand to the GPCR results in the exchange of GTP for GDP on Gα, and its disassociation from the αβγ heterotrimer. βγ can then associate with and activate downstream effectors such as the β-adregeneric receptor kinase (BARK), while the GTP-loaded α-subunit can bind and regulate effectors including adenylate cyclase (AC). In the example shown, Gsα activates AC to convert ATP to cAMP, and thus stimulates downstream PKA signaling.

activation or inhibition of effector function; for example, adenylyl cyclase catalyzes the cyclation of ATP to form 3′,5′-cyclic AMP (cAMP), an intracellular second messenger that can bind and activate downstream signaling proteins such as protein kinase A (PKA). This reaction is activated by GTP-$G_{s\alpha}$ binding to adenylyl cyclase and inhibited by GTP-$G_{i\alpha}$ binding. In addition, $\beta\gamma$ binding to adenylyl cyclase can augment its activation by GTP-$G_{s\alpha}$.

An important concept in all forms of signal transduction is the ability of the cell to carefully control the location, amplitude, and duration of the signal. Signal amplification is the process whereby the cell can regulate the amplitude of the signal. For example, a single GPCR can generate between tens and hundreds of GTP-coupled Gα-subunits, which can subsequently bind to and activate similar numbers of adenylyl cyclase enzymes, which in turn generate multiple copies of cAMP. The number and availability of the intracellular effector enzymes and substrates thus determines the level of signal amplification following the activation of relatively few receptors on the cell surface.

Just as important as signal amplification is the ability of the cell to downregulate the signaling pathway once the desired response has been initiated. For GPCRs, this occurs in several ways. First, the α-subunit is itself a GTPase, meaning that it hydrolyzes GTP to form GDP and inorganic phosphate. This hydrolysis occurs spontaneously following GTP binding to Gα, but can be augmented by the association of specific RGS proteins (regulators of G-protein signaling) with the GDP/Gα complex, as this interaction stabilizes the inactivated state. Once the Gα-subunit is in the GDP-bound state, it can associate again with the $\beta\gamma$-subunit to regenerate the inactive heterotrimeric G-protein.

In addition, many GPCRs are themselves inactivated by a process called homologous desensitization. As has been noted above, the $\beta\gamma$-subunits can associate with the cytosolic protein βARK. βARK, also known as GRK2, is a member of the G-protein-coupled receptor kinases (GRKs) that, following association with $G_{\beta\gamma}$, phosphorylate the intracellular loops and/or C terminus of ligand-associated GPCRs on serine and/or threonine residues. This phosphorylation results in the association of β-arrestin with the receptor, mediating the uncoupling of the ligand−receptor complex from the heterotrimeric G-proteins, and thus diminishing its activity. Binding of β-arrestin has also been shown to target the receptor−ligand complexes to clathrin-coated pits on the cell surface, followed by internalization and either lysosomal degradation or recycling of the inactivated receptor to the cell surface.[4]

The downstream GPCR effector adenylyl cyclase is also subject to phosphorylation-dependent inhibition. As noted above, activated adenylyl cyclase catalyzes the formation of cAMP, which in turn associates with and activates PKA. This enzyme, an intracellular serine/threonine kinase, has multiple phosphorylation substrates within the cell. Phosphorylation of these substrates can regulate their activity, cellular localization, and/or their interaction with other proteins. One phosphorylation substrate is adenylyl cyclase itself, resulting in inhibition of cAMP production. A second substrate is the GPCR. In a process known as heterologous desensitization, activation of PKA by a non-GPCR signal can result in phosphorylation of the GPCR and subsequent inhibition of ligand-mediated GPCR activation.[5]

Receptors for Dopamine and AVP are GPCRs that Regulate Adenylyl Cyclase

A prototypic family of GPCRs in the kidney is the dopamine receptors. There are five dopamine receptors presently described (D_1−D_5), and they are further sub-classified into D_1-like (D_1 and D_5) or D_2-like (D_2−D_4). The D_1-like receptors are associated with $G_{s\alpha}$, and therefore activate adenylyl cyclase, whereas the D_2-like receptors inhibit adenylyl cyclase activity (reviewed in [6,7]). In the kidney, D_1-like and D_2-like receptors are expressed throughout the tubules. The net effect of activating these receptors is the induction of a salt and water diuresis, although by different mechanisms in the different tubular segments. Dopamine-mediated activation of D_1 receptors in the proximal tubule results in activation of adenylyl cyclase, leading to cAMP-dependent inhibition of the activity of NHE-3, NaPi-2, and the Na,K-ATPase, thus inhibiting proximal sodium reabsorption. In contrast, activation of the D_2-like receptor D_4 in the cortical collecting duct leads to a water diuresis by preventing vasopressin-stimulated adenylyl cyclase activation. Dopamine receptors also mediate renal vasodilation, and appear to regulate renin secretion. Due to these effects, defects in dopamine receptor function in mice are associated with salt retention, vasoconstriction, and increased blood pressure.[8−10]

Arginine vasopressin (AVP, also known as antidiuretic hormone (ADH)) binds to three GPCRs, the $G_{q/11\alpha}$-linked V1a and V1b receptors, and the $G_{s\alpha}$-linked V2 receptor. V1 receptors are located on several cell types, including smooth muscle cells of blood vessels, where they mediate the vasoconstrictive ("pressor") response of vasopressin, while V2 receptors are located on epithelial cells in the collecting duct and mediate water reabsorption. Binding of vasopressin to the V2 receptor stimulates adenylyl cyclase-mediated cAMP production, which in turn causes insertion of vesicles containing the water channel aquaporin-2 into the apical membrane of collecting

duct cells. By inhibiting adenylyl cyclase activation in these cells, dopamine can partially counteract this water-reabsorptive effect of vasopressin.

GPCRs Can also Signal through Phospholipase C and MAPK

An example of a GPCR that is coupled to PLCβ signaling is the type 1 receptor for angiotensin II ($AT_{1A}R$). Angiotensin II is the eight amino acid peptide product of the angiotensin converting enzyme (ACE)-mediated cleavage of angiotensin I. Angiotensin II is capable of binding to and activating two distinct G-protein coupled receptors, the type 1 receptor (AT_1R) and the type 2 receptor (AT_2R). The predominant actions of angiotensin in the kidney and adrenal gland are mediated by the AT_1R, including vasoconstriction, smooth muscle hypertrophy, sodium retention, and aldosterone secretion. Most data presently support the idea that the AT_2R receptor acts as an antagonist to AT_1R signaling,[11] although exactly how the AT_2R signals has been much less apparent. The topology of the AT_2R is consistent with a seven transmembrane G-protein coupled receptor, yet it has been controversial as to whether AT_2R in fact signals via traditional G-proteins. There have been several reports that AT_2R can signal via $G_{i\alpha}$, although this has not been universally accepted (reviewed in [12]). Other groups have suggested that AT_2R signaling is pertussis-toxin insensitive (i.e., not dependent on $G_{i\alpha}$), and is instead mediated by production of cyclic GMP.[13] It remains unclear whether the generation of cGMP is a direct result of AT_2R activation or is mediated in an autocrine/paracrine fashion by AT_2R-stimulated bradykinin production.[14]

The AT_1R is in the $G_{q/11\alpha}$ family of GPCRs, meaning that binding of angiotensin II to the receptor stimulates GTP-loading of $G_{q\alpha}$ which in turn associates with and activates phospholipase Cβ (PLCβ) (Figure 13.2). The active form of PLCβ mediates the hydrolysis of phosphotidylinositol 4,5 bisphosphate ($PI_{4,5}P_2$) in the membrane to produce diacylglycerol (DAG) and inositol trisphosphate (IP_3). IP_3 is hydrophilic and enters the cytoplasm where it activates the IP_3 receptor on the surface of the endoplasmic reticulum, thereby stimulating calcium release from internal stores. The simultaneous production of DAG at the membrane, and local release of stored calcium, leads to the recruitment and activation of the classic, calcium-dependent protein kinases C (PKCs). Activation of PKC appears to be required for angiotensin II-mediated renal efferent arteriole vasoconstriction,[15] Na,K-ATPase recruitment to the membrane in proximal tubule cells (resulting in increased proximal sodium reabsorption),[16,17] and stimulation of aldosterone secretion by adrenal zona glomerulosa cells.[18]

In addition to activation of PLCβ, a second signaling pathway that is activated by the AT_1R is the mitogen activated protein kinase (MAPK) pathway. As mentioned earlier, phosphorylation of GPCRs by βARK results in the recruitment of β-arrestin to the receptor complex, and subsequent receptor internalization. β-arrestin has been found to act as a binding scaffold for the core components of the MAPK pathway, including Raf, MEK, and ERK (see "Intracellular Signaling Pathways," below; reviewed in [19]), resulting in the activation of this pathway that mediates cell growth and proliferation.[20–22] This scaffolding function of β-arrestin appears to be both cell type and receptor specific, and can mediate activation of additional intracellular signaling pathways, including the phosphoinositide 3-kinase (PI 3-K) pathway that will be discussed later in this chapter.[23] Activation of these signaling pathways appears to play an important role during kidney development, since newborn mice null for the type I angiotensin receptor or in which angiotensin signaling has been inhibited, have significant renal developmental abnormalities, including renal arterial hypertrophy and papillary atrophy.[24,25]

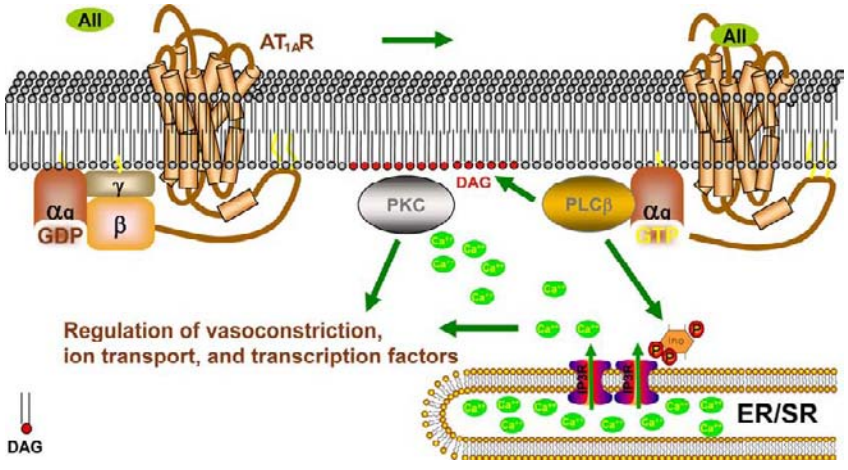

FIGURE 13.2 **Signaling by the angiotensin II (AII) receptor.** Binding of AII results in GTP-loading of the associated Gqα-subunit of the αβγ heterotrimer, which in turn activates phospholipase C β (PLCβ). Activated PLCβ stimulates the hydrolysis of $PI_{4,5}P_2$ in the membrane to form IP3 and diacylglycerol (DAG). IP3 can then bind to its receptor on the endoplasmic or sarcoplasmic reticulum, activating calcium release. The increase in cytosolic calcium can stimulate multiple cellular responses, including activation of PKC (which associates with DAG at the membrane), influx of extracellular calcium via channels at the cell surface, and contraction via actin–myosin coupling.

A second means by which GPCRs can activate MAPK signaling was discovered when the levels of β-arrestin were depleted using RNA interference (RNAi). Under these conditions, angiotensin II was still able to activate MAPK, although to a lesser degree. These experiments uncovered a β-arrestin-independent pathway of angiotensin II-dependent MAPK stimulation that occurs via activation of a second cell surface receptor, a process known as receptor transactivation. As noted above, stimulation of $G_{q\alpha}$ by the $AT_{1A}R$ leads to activation of PKC. PKC, in addition to regulating processes such as ion transport, can activate a cell surface protein called heparin-binding epidermal growth factor (HB-EGF). HB-EGF is one of the ligands for a separate cell surface receptor, the epidermal growth factor receptor (EGFR), and binding of HB-EGF to the EGFR results in the stimulation of multiple signaling events, including MAPK activation (see "Intracellular Signaling Pathways").[18]

Localization and Timing of Pathway Activation Promotes Diverse Cell type Specific Responses

These two independent pathways for activating MAPK signaling provide an example of how scaffolding proteins can compartmentalize signaling within the cell. The β-arrestin-mediated ERK activation is sustained for several hours and occurs in the cytoplasm, whereas the $G_{q\alpha}$/PKC-dependent ERK activation appears to be more transient and primarily within the nucleus. This ability to localize activated ERK in different cellular compartments allows the cell to differentially regulate specific effector proteins, and thus direct distinct cellular outcomes. In the heart, for example, AT_1R-mediated $G_{q\alpha}$/PKC-dependent transactivation of the EGFR, and ultimately MAPK nuclear signaling, is believed to at least partially mediate angiotensin-stimulated cardiac hypertrophy.[26,27]

Many GPCRs can activate multiple Gα-subunits, depending on cellular location and availability. For example, the parathyroid hormone (PTH) receptor can potentially activate $G_{s\alpha}$ (thus activating adenylate cyclase and PKA), $G_{q\alpha}$ (activating PLCβ and PKC), and G_i (inhibiting adenylate cyclase). PTH is an 84 amino acid peptide hormone secreted by the parathyroid gland that acts on bone to increase calcium and phosphate release into the circulation, as well as on the proximal and distal tubules of the kidney to inhibit phosphate reabsorption and stimulate calcium reabsorption, respectively. PTH is proteolytically processed to generate multiple fragments which can bind to and activate the PTH receptor, a class B GPCR (defined by the six conserved cysteine residues that form disulfide bonds in the large extracellular amino terminal domain).[28] Expression of a mutant form of the receptor that selectively fails to activate $G_{q\alpha}$-dependent PLCβ signaling in mice results in abnormalities in bone ossification without a change in serum calcium.[29] The normal serum calcium in these animals suggests that renal tubular calcium handling in these mice is dependent on $G_{s\alpha}$- or G_i-regulated adenylate cyclase signaling, while bone ossification appears to require $G_{q\alpha}$-PLCβ signaling. In support of this hypothesis, complete loss of PTH receptor signaling results in hypocalcemia in addition to bone abnormalities.[30,31] In humans, this is recapitulated by an autosomal recessive mutation in the receptor in patients with Blomstrand chondrodysplasia, a lethal disorder characterized by excessive bone maturation and mineralization.[32]

As noted previously, receptor internalization mediated by β-arrestin is frequently a means by which GPCR are uncoupled from their ligands and signaling is downregulated. For example, PTH related protein (PTHrP) can bind and activate the PTH receptor, leading to GTP-loading of $G_{s\alpha}$ and a transient increase in cAMP followed by receptor desensitization. In contrast, PTH receptor ligands such as PTH_{1-34} (the first 34 amino acids of PTH) can induce a more sustained increase in adenylyl cyclase activation and cAMP levels, leading to systemic responses such as increased vitamin D hydroxylation and higher serum calcium levels. Investigation into the mechanism of this difference has demonstrated that binding of PTH_{1-34} to the PTH receptor leads to internalization of the active receptor−ligand complex in endosomes that also contain adenylyl cyclase, leading to sustained signaling from this intracellular site.[33] These structures, referred to as signaling endosomes, have been shown to mediate signaling via multiple receptor types in addition to GPCR, and to regulate complex cellular responses such as migration, differentiation, and asymmetric division.[34,35]

Kinase Receptors

A second class of transmembrane receptors is the kinase receptors. These proteins typically contain an extracellular ligand-binding domain at the amino terminus, a single membrane-spanning domain, and an intracellular carboxy terminus that includes the kinase domain. In most cases, binding of the ligand to the receptor results in homodimerization of two receptor molecules, bringing the intracellular kinase domains into close proximity where they phosphorylate substrate residues on the adjacent receptor. This phosphorylation step generates binding sites for the recruitment of intracellular signaling molecules, as well as further activating the kinase domain so that non-receptor substrates recruited to the complex can also be phosphorylated.

Tyrosine Kinase Receptors

The largest class of kinase receptors is the tyrosine kinase receptors, also known as receptor tyrosine kinases (RTKs) (Figure 13.3). These molecules frequently serve as receptors for extracellular growth factors, circulating proteins that stimulate cell growth and division. Examples of ligand–receptor combinations in this family include epidermal growth factor (EGF) and its receptors ErbB1 (or EGFR) and ErbB2; platelet-derived growth factor (PDGF) and the PDGF receptor; insulin and the insulin receptor; and vascular endothelial growth factor and its major receptors VEGFR1 and VEGFR2 (also called Flt1 and Flk1).

Once the growth factor has bound to and activated the receptor, newly phosphorylated tyrosine residues on the intracellular carboxy terminus of the receptor serve as binding sites for cytosolic or membrane-associated proteins that contain phosphotyrosine-binding domains. The best characterized of these domains are the src-homology 2 (SH2) domains that share characteristic features first described in the phosphotyrosine-binding region of the cytosolic tyrosine kinase Src. SH2 domains are approximately 100 amino acids in length, and provide specificity of interaction in two ways. First, the interaction of the binding pocket of the SH2 domain and the tyrosine residue is only stabilized when the tyrosine residue is phosphorylated. Second, the amino acids immediately flanking the phosphorylated tyrosine residue determine which SH2 domain interaction is preferred. For example, the SH2 domain on the p85 adaptor protein, α-subunit of the lipid enzyme phosphoinositide 3-kinase (PI 3-K, see "Intracellular Signaling Pathways," below), strongly prefers to bind to phosphotyrosine with a methionine residue at the +3 position.[36]

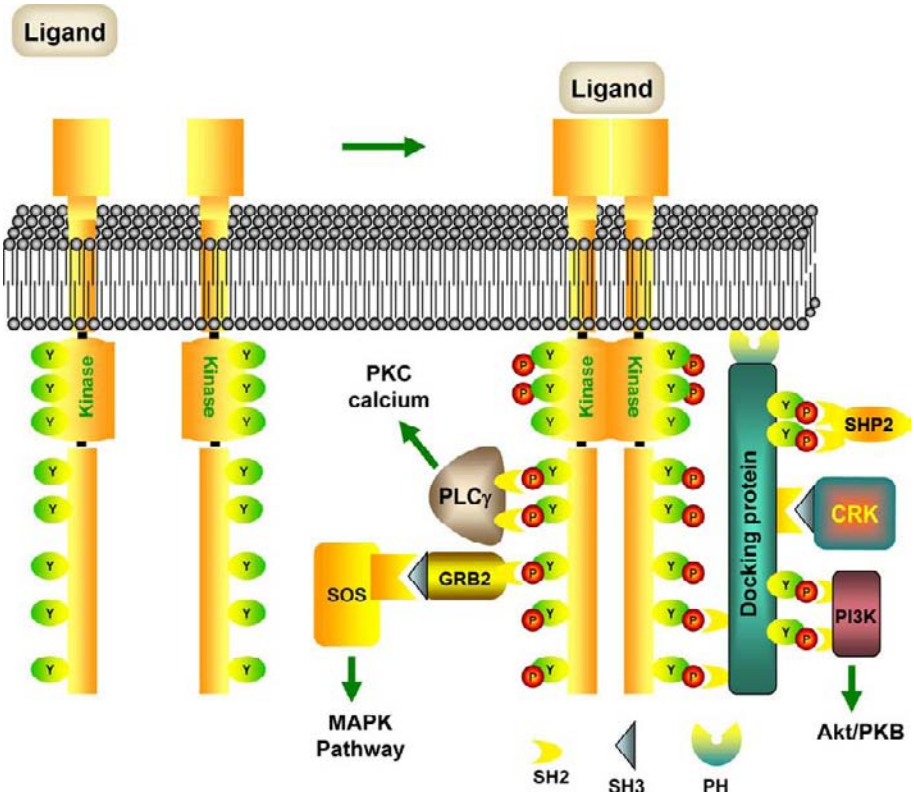

FIGURE 13.3 **Schematic view of a receptor tyrosine kinase (RTK).** In the inactive state, the receptor is primarily in the monomeric form. Following binding of the extracellular ligand, the receptor dimerizes, bringing the kinase domains in close proximity where they cross-phosphorylate each other. This enhances the kinase activity and leads to phosphorylation of tyrosine residues outside of the kinase domain, which in turn become binding sites for proteins that contain SH2 domains. In this manner, downstream signaling pathways can be regulated by recruitment to the receptor. This recruitment can occur via direct association of the effector protein with the receptor (as is the case for phospholipase Cγ (PLCγ)), via association with small adaptor proteins such as Grb2 (as is the case for the guanine exchange factor Sos) or via association with a larger docking protein such as Gab1 or Nck that mediates the association of multiple proteins with the receptor (as can be seen with the phosphoinositide 3-kinase (PI 3K) or the tyrosine phosphatase SHP2). Some docking proteins are additionally stabilized at the membrane via lipid binding domains, such as the pleckstrin homology (PH) domain on Gab1. In addition to SH2 domain interactions, multiple other protein–protein interactions occur and regulate the recruitment of proteins into the complex, including interactions between SH3 domains and proline-rich regions in interacting partners. In this manner, multiple signaling effectors are brought into close proximity where they can interact with each other, be phosphorylated or dephosphorylated (thereby altering their activity or interacting partners) or regulate processes at the cell membrane.

Thus, receptors containing the sequence pTyr-X-X-Met (where X can be almost any amino acid) specifically recruit and activate the PI 3-K.

In the kidney, tyrosine kinase receptors have been implicated in controlling development, mediating hypertrophy, regulating the balance between repair and fibrosis after injury, and promoting the growth of renal carcinomas. During development, glial derived neurotrophic factor (Gdnf) is made by the embryonic metanephric mesenchyme and activates the c-Ret tyrosine kinase receptor that is expressed on the epithelial cells of the adjacent Wolffian duct. The activation of Ret is somewhat unusual, since Gdnf does not directly bind to Ret, but rather binds to a third membrane protein, Gfrα, that mediates dimerization of Ret in response to association with Gdnf (reviewed in [37]). Activation of Ret in this manner results in the activation of multiple intracellular signaling pathways, including the Erk-MAPK pathway, the PI 3-K pathway, members of the Src family of non-receptor tyrosine kinases, and phospholipase Cγ (PLCγ). Activation of the MAPK and Src pathways (see "Intracellular Signaling Pathways") have been found to be critical for the outgrowth and branching of the ureteric bud from the Wolffian duct, the first step in the formation of the metanephric kidney.[38]

Signaling by several other tyrosine kinase receptors has been implicated in kidney development, including the fibroblast growth factor (FGF) receptors, hepatocyte growth factor receptor (Met), and the epidermal growth factor receptor.[39,40] FGF signaling is a complex process that includes 18 known ligands and 4 distinct tyrosine kinase receptors (FGFR1-4) (reviewed in [41]). Like many receptor ligands, FGFs are secreted glycoproteins that are concentrated in proximity to their cell surface receptor by binding to heparan sulfate proteoglycans on the cell and/or nearby matrix components. The interaction between FGFs and their receptors can be further regulated by cell- or tissue-specific expression of FGF co-receptors such as Klotho.[42] Intracellular signaling by the FGFR is regulated in part by the cytosolic adaptor protein FGFR substrate 2 (FRS2), which is phosphorylated by the FGFR kinase domain, leading to the recruitment and activation of downstream MAPK and PI 3-K signaling. In the developing kidney, FGF7 and FGF10, signaling via the IIIb isoform of FGFR2,[43] have been shown to be critical for normal branching and extension of the collecting system,[44] while FGF8 appears to be required for nephrogenesis by the adjacent metanephric mesenchyme.[45]

Many growth factor receptors are expressed in the mature kidney, and are believed to be critical for maintenance of normal tubule architecture and for regulating the cellular response to injury. Renal tubular epithelial cells express EGF receptors as well as Met, the receptor for hepatocyte growth factor (HGF). These tyrosine kinase receptors directly bind their respective ligands via their extracellular amino terminal domains, followed by homodimerization and activation of intracellular signaling. A major mediator of the intracellular signaling mediated by EGF and HGF is the Gab1 docking protein, which functions in a manner similar to that of FRS2 for the FGFR.[46] Recruitment of Gab1 to Met or the EGFR results in its phosphorylation on multiple tyrosine residues and subsequent association with p85, PLCγ, Grb2, a second adaptor protein known as Crk, and the protein tyrosine phosphatase SHP2.[47] Following acute kidney injury, the level of HGF increases in the kidney, resulting in activation of Met, mediating MAPK, PI 3-K, and PLC signaling.[48,49] These pathways in turn are believed to be important for inhibition of apoptosis (the PI 3-K pathway), and stimulation of cell migration and proliferation during the repair process (PI 3-K, MAPK, and PLC pathways).[50–52]

Serine-Threonine Kinase Receptors

A second group of transmembrane kinase receptors are the serine-threonine kinase receptors. Like the non-receptor kinases PKA and PKC, these receptors catalyze the phosphorylation of serine or threonine residues in their substrate molecules. Perhaps the best studied of these receptors in the kidney is the receptor for transforming growth factor β (TGFβ), a member of the TGFβ superfamily of secreted factors that also includes the bone morphogenic proteins (BMPs) and activin.[53] TGFβ-like proteins signal into the cell via a heterotetrameric complex comprised of two subclasses of serine-threonine kinase receptors, the type I receptor and the type II receptor.[54] Like the tyrosine kinase receptors, these proteins have an extracellular ligand recognition domain, a single transmembrane spanning domain, and an intracellular kinase domain. The different TGFβ-like ligands utilize distinct type I and II receptor combinations. For example, TGFβ1-3 signals via the combination of the type II receptor TβR-II and the type I receptors activin receptor-like kinase 1 (ALK-1) or ALK-5,[55,56] while BMPs signal through the type II receptors ActR-II or BMPR-II and the type I receptors ALK-2, ALK-3 or ALK-6.[57]

TGFβ receptor signaling begins when the ligand binds to the extracellular domain of its cognate type II receptor (Figure 13.4). The kinase domain of type II receptors is constitutively active, and binding to the extracellular ligand results in the recruitment of the appropriate type I receptor to the complex, where it is phosphorylated and activated by the type II receptor. In this manner, the TGFβ1-dependent association of ALK-5 with TβR-II allows the constitutively active TβR-II to phosphorylate ALK-5 and activate its intracellular

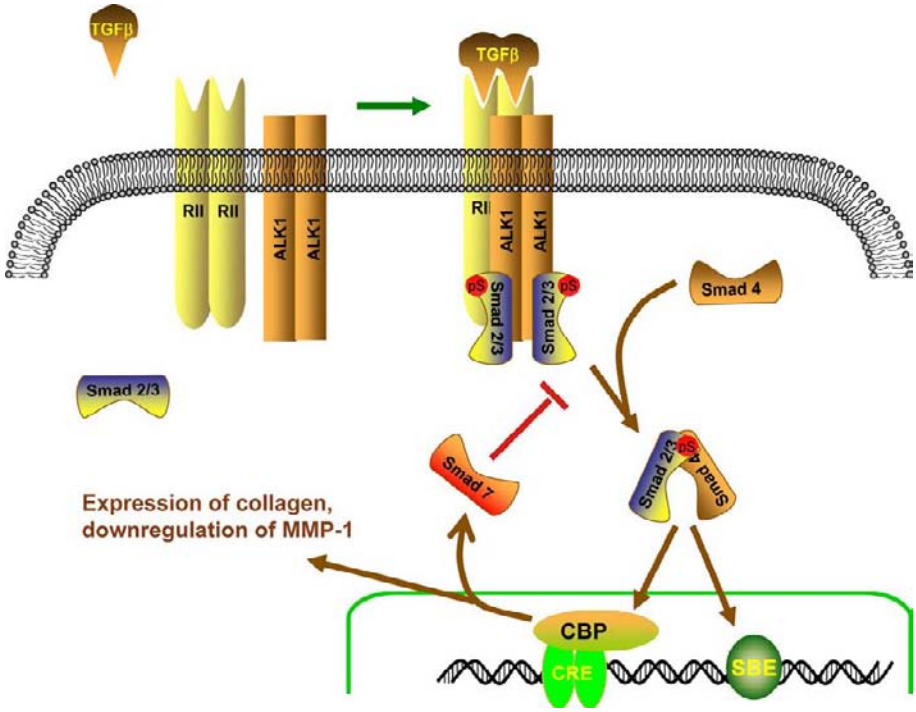

FIGURE 13.4 **Signaling by the TGFβ family of serine-threonine kinase receptors.** Binding of the TGF ligand to the constitutively active type II receptor results in association of RII with the appropriate type I receptor (in this case ALK-1), which is phosphorylated and activated. The activated type I receptor can then phosphorylate the appropriate Smad protein, which then disassociates from the receptor complex, associates with Smad 4, and translocates into the nucleus. In the nucleus the Smad complex can regulate RNA transcription by binding directly to the appropriate DNA Smad-binding elements (SBE) or by binding to and regulating transcriptional regulators such as the cAMP response element (CRE) binding protein (CBP). One of the DNA targets induced by Smad activation is the inhibitory Smad, Smad7. Increased expression of Smad7 inhibits further TβR signaling, providing negative feedback to prevent sustained activation of the pathway.

serine-threonine kinase domain. The specificity of signaling by TGFβ family members is further regulated by the presence in many cells of the accessory receptors betaglycan and endoglin. These transmembrane proteins lack intracellular kinase domains, and appear to regulate the affinity of TGFβ proteins for the various type II receptors, as well as modifying intracellular signaling by the ligand–receptor complex.[58,59]

As opposed to tyrosine kinase receptors that signal primarily via recruitment of SH2 domain containing proteins to activate pathways such as MAPK and PI 3-K, TGFβ receptors signal primarily via a distinct signaling pathway, the Smad proteins. Smads are small cytoplasmic proteins that contain a DNA-binding domain and a TβR-I/Smad4-interacting domain. Based on their structure and function, Smads have been divided into three groups, the receptor activated Smads (Smad1, 2, 3, 5, 8), a regulatory Smad (Smad4), and the inhibitory Smads (Smad6, 7). Upon activation of TβR-I, the appropriate receptor activated Smads (e.g., Smad2 and 3 for ALK-5) are phosphorylated on regulatory serine residues in the TβR-I/Smad4 interacting domain, resulting in their disassociation from the receptor and association with Smad4. This Smad2–Smad4 complex then translocates to the nucleus, where the Smad DNA-binding domain can mediate direct association with Smad-binding elements (SBE) in the DNA of the promotor region of target genes, as well as association with other transcriptional regulators.

One of the transcriptional targets that is regulated by Smad2–4 signaling is another member of the Smad family, Smad7. Smad7 is an inhibitory Smad that can bind to TβR-I, and prevent Smad2 or Smad3 from associating and being activated. In this manner, TGFβ stimulation of Smad7 transcription provides a negative feedback loop that acts to prevent sustained Smad2 and Smad3 activation by the TGFβ receptor.[60]

TGFβ Signaling in the Kidney

Studies in mice that have undergone genetic inactivation of various TGFβ family members demonstrate that Bmp2 and Bmp4 have important roles in normal kidney development (reviewed in [57]). In the mouse embryo, Bmp4 is expressed in the metanephric mesenchyme surrounding the Wolffian duct and adjacent to the ureteric bud (the epithelial structure that will branch to form the entire collecting system of the kidney), while Bmp2 is expressed in the condensing mesenchyme at the tips of the ureteric bud (the region that will differentiate into the glomerulus and proximal portions of the nephron through the connecting segment). The Bmp receptors Alk3 and Alk6 are expressed on the invading urteric bud itself.[61] While complete loss of Bmp2 or Bmp4 results in embryonic lethality prior to kidney development,[62] mice that are heterozygous for loss of Bmp4 expression exhibit multiple defects in the collecting system of the kidney, including doubling of the collecting system, hydroureter, and dysplastic kidneys,[61] and Bmp2 heterozygotes demonstrate exaggerated uretic bud branching.[63]

Thus, it appears that Bmps normally act to inhibit ureteric bud outgrowth and branching during development.

In addition to their role in kidney development, TGFβ proteins have been shown to play a major role in regulating fibrotic responses of the adult kidney by both increasing new matrix deposition and inhibiting matrix degradation.[53,64] *In vitro* studies have shown that TGFβ-dependent Smad3–Smad4 nuclear signaling can induce the expression of multiple collagen isoforms, along with their cellular binding partner β1 integrin,[65–67] and activated Smad3 has been found to mediate decreased transcription of the gene for matrix metalloproteinase-1 (*MMP-1*)[68]. In support of an important role for the TGFβ-Smad signaling pathway in the development and progression of renal fibrosis *in vivo*, genetic overexpression of TGFβ in the rat has been shown to induce glomerulosclerosis due to increased extracellular matrix deposition,[69] while mice lacking Smad3 demonstrate less fibrosis following ureteral obstruction.[70]

Receptor-Like Phosphatases

Much attention has been focused in the field of signal transduction on the role of substrate phosphorylation by receptor kinases in regulating protein–protein interactions or altering the activity of effector proteins. However, a second class of proteins, the phosphatases, is emerging as equally important signaling regulators in determining cellular responses. Similar to kinases, phosphatases can be grouped into transmembrane receptor-like phosphatases and intracellular (cytosolic) phosphatases (to be discussed below). The receptor-like phosphatases that have been identified to date are protein tyrosine phosphatases (PTPs) with an extracellular domain, single transmembrane spanning segment, and intracellular phosphatase domain.

The first receptor-like PTP to be cloned and sequenced was the neutrophil antigen CD45. This protein was found to be necessary for both T-cell development and T-cell activation following engagement of the T-cell receptor (reviewed in [71]). Although there has been no activating ligand identified for CD45, binding to extracellular galectin-1 inhibits CD45 phosphatase activity, resulting in T-cell death.[72] Several intracellular substrates for CD45 have been identified, including members of the Src and JAK kinase families. One critical substrate of CD45 in T-cell signaling is the cytosolic tyrosine kinase Lck[73](Figure 13.5). Lck, like the related tyrosine kinase Src, is normally maintained in the inactive state by the association of phosphotyrosine 505 near the carboxy terminus with its own SH2 domain closer to the amino terminus of the protein.[74] This interaction results in folding of Lck, and thereby prevents the intervening tyrosine kinase domain from recognizing or phosphorylating its substrates. Dephosphorylation of phosphotyrosine 505 by CD45 following antigen presentation by a nearby dendritic cell allows Lck to unfold, and activates the kinase domain.[75] The resultant phosphorylation of the ζ-chain of the T-cell receptor by activated Lck is necessary for recruitment of a second cytosolic tyrosine kinase, ZAP70, to the complex, and subsequent T-cell activation.[76] The administration of monoclonal antibodies that prevent activation of CD45 has been shown to markedly diminish the occurrence of acute rejection in a rodent model of kidney transplantation.[77]

In contrast to CD45, the receptor-like protein tyrosine phosphatase PTPζ/β is expressed on epithelial cells, and has been found to bind to several putative extracellular ligands, including contactin, neural cell adhesion molecule (NCAM), and pleiotrophin.[78,79] Rather than activating PTPζ/β, as is typical of most ligand–receptor interactions, the association of pleiotrophin with PTPζ/β inhibits the phosphatase activity of PTPζ/β.[80] In the kidney, pleiotrophin has been shown to markedly increase branching by the explanted ureteric bud, and thus is believed to play a significant role in determining the number of nephrons that form during kidney development.[81] One substrate for PTPζ/β is the cytosolic protein Git1,[82] a multifunctional adaptor protein that can regulate the signaling pathways that control actin cytoskeletal rearrangement.[83] Dephosphorylation of Git1 by PTPζ/β is therefore proposed to play an important role in the regulation of cell adhesion and migration, as well as cytosolic vesicle trafficking.[84]

Receptors Activated by Proteolytic Cleavage

The previously described receptors bind to their respective ligands and then signal into the cell via activation of substrate protein phosphorylation or dephosphorylation, thus regulating cytosolic signaling pathways that in turn mediate the activation or inhibition of downstream effectors. In contrast, cleavage-activated receptors such as Notch signal directly to the nucleus to regulate gene transcriptional events. Notch is a cell surface protein that contains an extracellular ligand-binding domain, a single transmembrane spanning segment, and an intracellular domain capable of binding and activating nuclear transcriptional factors (reviewed in [85]). The classic Notch ligands, Jagged and Delta, are also transmembrane proteins that contain extracellular EGF-like repeats and a unique domain for binding Notch. When Jagged on one cell engages Notch on an adjacent cell, a cleavage

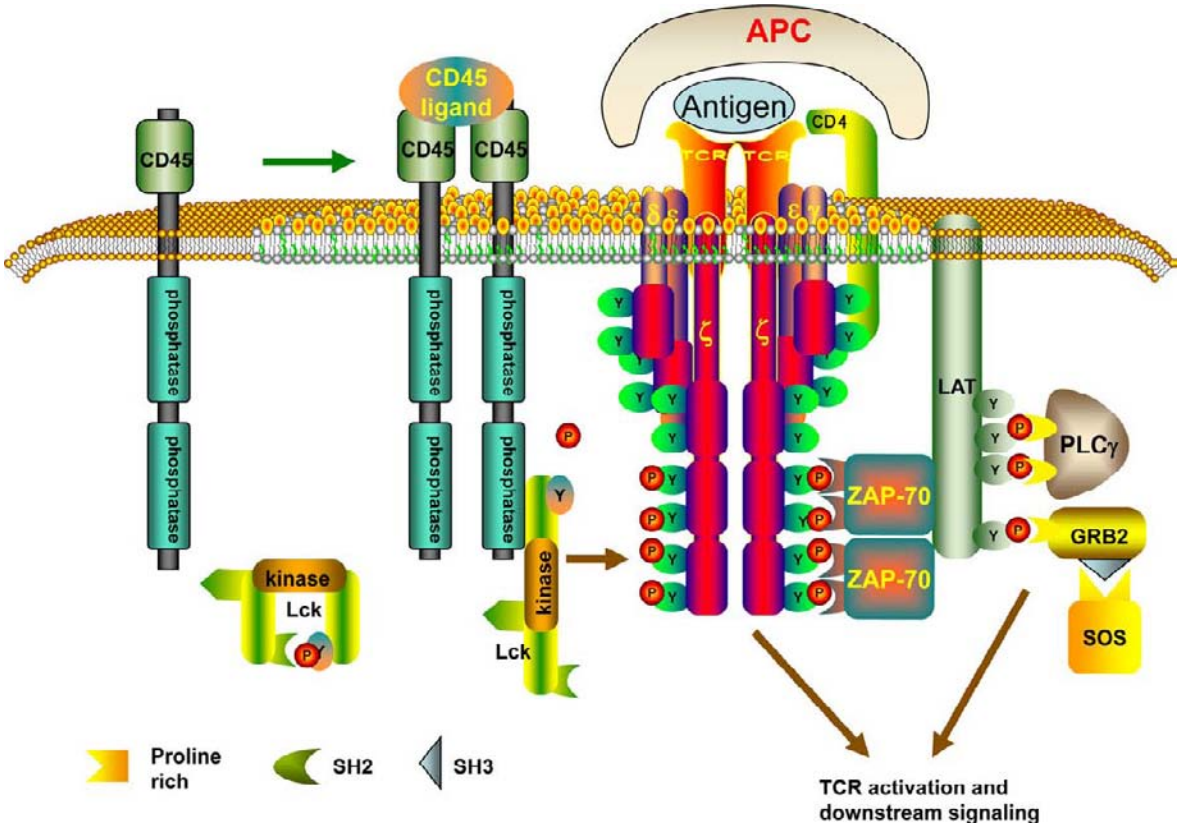

FIGURE 13.5 **Signaling by the CD45 receptor phosphatase.** CD45 is a single membrane spanning receptor phosphatase that is activated by an unknown extracellular ligand. Ligand binding activates the intracellular phosphatase domains, possibly by clustering of the receptors, which dephosphorylate the carboxy terminal tyrosine residue on the cytosolic non-receptor tyrosine kinase Lck. This allows a conformational change in Lck that exposes the kinase domain and facilitates phosphorylation of the ζ chain of the multimeric T-cell receptor. In conjunction with antigen presentation by an antigen presenting cell (APC) to the extracellular domain of the TCR, Lck phosphorylation of the TCR results in recruitment of a second tyrosine kinase, Zap70, to the complex via binding of the Zap70 SH2 domains to the phosphorylated receptor. Zap70 recruitment and activation are required for normal TCR activation, and for phosphorylation of the adaptor protein, Linker for Activation of T cells (LAT). LAT in turn serves as the site for recruitment of multiple signaling pathways involved in the T-cell immune response, including PLCγ (for activation of PKC and calcium signaling) and Grb2-Sos (for MAPK signaling).

site is exposed on the extracellular side of Notch near the membrane, and Notch is cleaved by a member of the A Disintegrin And Metalloproteinase (ADAM) family of proteases.[86] The remaining transmembrane/intracellular portion of Notch then becomes a target for further cleavage by presenilin (a member of the γ-secretase complex) at a conserved site in the intramembranous domain of Notch.[87] Cumulatively, this process is termed regulated intramembranous proteolysis (RIP) (Figure 13.6).

This final cleavage event releases the cytosolic domain of Notch (called the Notch intracellular domain (NICD)) that translocates to the nucleus where it can directly bind and regulate transcription factors. In mammals, Notch controls transcriptional regulation by interacting with the DNA-binding protein CSL (also called RBP-J), which in turn regulates transcriptional expression of members of the Hairy and Enhancer of Split (HES), and Hairy-Related Transcription factor (HRT) family of transcription factors. These nuclear proteins control the expression of genes that are critical for regulating normal development.

In the kidney, activation of Notch signaling has been implicated in the specification of the proximal tubule and glomerular podocytes during development.[88,89] The cleaved form of Notch is present in the developing S-shaped body that ultimately differentiates into the nephron, and inhibition of γ-secretase in organ culture leads to the loss of the proximal nephron, even though the distal nephron still develops and fuses to the collecting duct.[90] Genetic interruption of Notch expression has revealed that nuclear signaling by Notch2, rather than Notch1, is required for this proximal specification.[91] In the mature kidney, Notch expression is normally downregulated. However, in disease states such as diabetic nephropathy, re-expression of Notch can activate the transcription of cell cycle genes, leading to increased cell proliferation and ultimately exaggerated fibrosis.[92]

More recently, it has become clear that receptor activation by regulated cleavage plays a role in

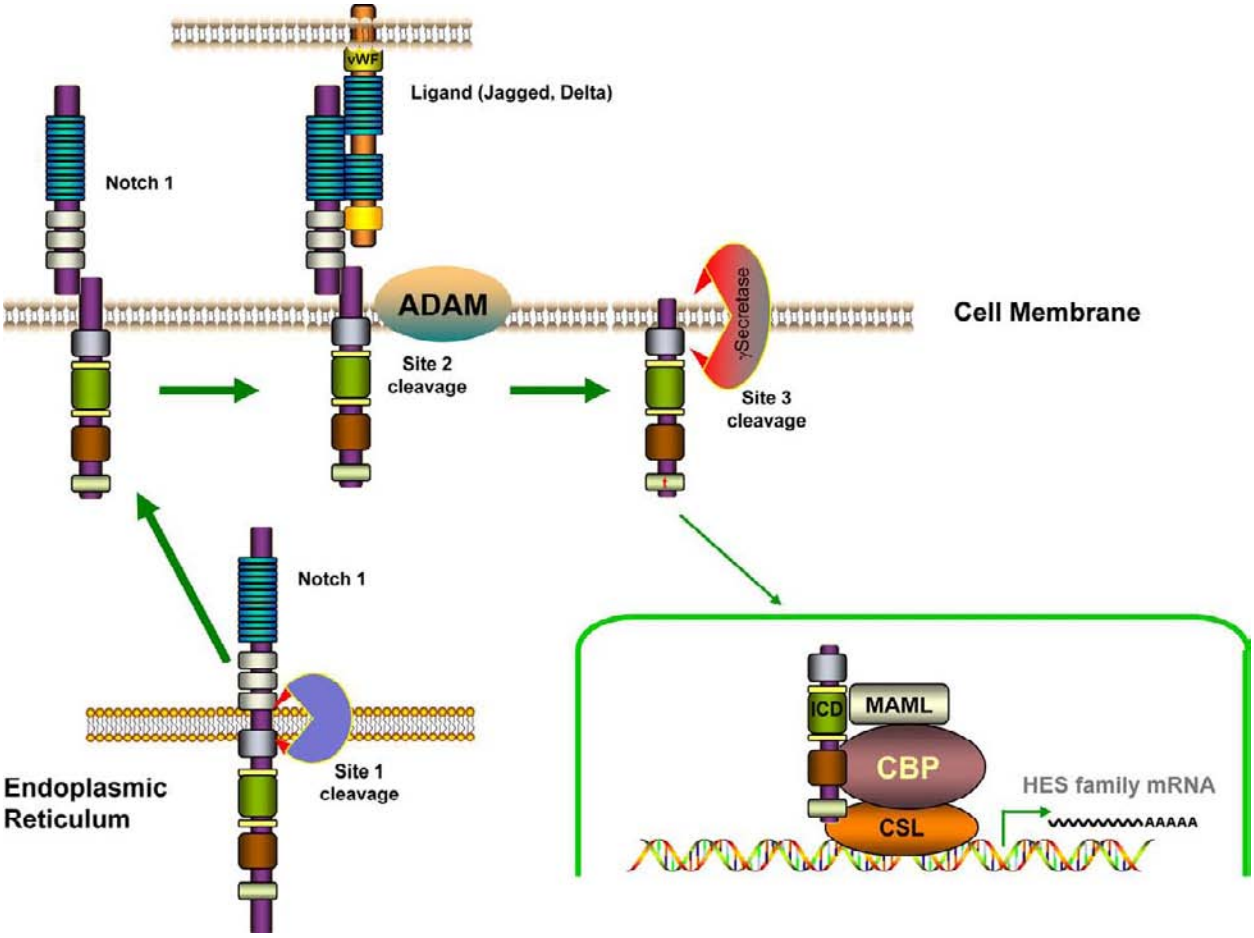

FIGURE 13.6 **Notch signaling as an example of regulated intramembranous proteolysis (RIP).** It is believed that Notch is proteolytically processed in the ER (site 1 cleavage), and expressed on the cell surface as a disulfide-linked dimer of the extracellular domain and the transmembrane-intracellular domain. Binding of the extracellular domain to a Notch ligand (such as Jagged-1) on an adjacent cell exposes a juxtamembrane cleavage site (site 2) for a member of the ADAM family of extracellular proteases. This second cleavage allows the γ-secretase complex (containing presenilin) to cleave the remaining carboxy-terminus at a site within the membrane (site 3 cleavage), releasing the intracellular domain (ICD) which translocates to the nucleus. In the nucleus, the ICD of Notch can bind to members of the CSL family of transcriptional repressors, and in the presence of CSL-binding protein (CBP) and mastermind like protein-1 (MAML), activate transcription of the HES family of genes.

signaling by other cell surface proteins. For example, the γ-secretase complex has been shown to cleave the EGF tyrosine kinase receptor ErbB4 and the adherens junction protein E-cadherin.[93] In the case of ErbB4, this cleavage event is required for the normal proapoptotic effects of receptor activation, arguing that some cell outcomes previously ascribed to activation of tyrosine kinase cascades may in fact be due to receptor cleavage, and subsequent direct regulation of nuclear transcriptional events.[94] While the nuclear targets of some of these cleaved receptors remain to be determined, the likely importance of this pathway in normal cell signaling is emphasized by the finding that the HGF receptor c-Met undergoes a similar cleavage event that regulates cell survival signaling.[95]

Recently recognized targets of regulated intramembrane proteolysis in the kidney include the proximal tubule scavenger receptor megalin, as well as polycystin-1. In the proximal tubule, megalin can undergo ligand-dependent γ-secretase mediated cleavage,[96] leading to release of the megalin intracellular domain that in turn downregulates mRNA expression for both megalin itself and the Na^+/H^+ exchanger 3 (NHE3).[97] Polycystin-1, the protein product of the PKD1 gene that is defective in the majority of patients with autosomal dominant polycystic kidney disease (ADPKD), has also been shown to undergo RIP, releasing an intracellular carboxy-terminal tail (CTT) that is believed to traffic to the nucleus, where it can regulate gene expression.[98,99] γ-Secretase-mediated cleavage of polycystin-1 to generate the CTT appears to be dependent on the presence of polycystin-2, as well as mechanical stimuli such as those that might occur with urinary flow.[100]

Receptors that Signal Cell Location

One of the most important roles of cell signaling is to organize when a given cell should undergo differentiation toward a highly specialized function (such as the increase in sodium transporters in the brush border of a proximal tubule cell in response to angiotensin II signals mediated by volume depletion[101]) or should revert to more basic processes such as cell division and migration (e.g., during development of the embryonic kidney or recovery of the adult kidney from acute kidney injury). While these widely divergent responses are primarily mediated by receptor–ligand interactions such as those mentioned above, cells also have surface proteins that provide important clues regarding cell location and density, and thus establish their level of differentiation, polarity, and responsiveness to outside signals.

Cell–Matrix Interactions can Signal Cell Location

The cells of the nephron reside on a complex basement membrane that provides specific clues regarding cell location. In the glomerulus this structure is highly specialized to not only support epithelial cell attachment (the podocyte), but also endothelial cell attachment, and to serve as a significant component of the glomerular filtration barrier. The basement membrane of the kidney has been shown to be composed of multiple matrix proteins, including collagen, laminin, perlecan, nidogen, nephronectin, and entactin. The specific isoforms and relative contributions of these proteins vary during the course of renal development, as well as along the length of the adult nephron (reviewed in [102]). These matrix proteins interact with members of a large family of specific cell surface receptors, the heterodimeric α/β integrins.

In the kidney, $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_6\beta_4$, $\alpha_8\beta_1$, and $\alpha_V\beta_3$ have been found to be highly expressed in developing and/or adult renal tubular cells (reviewed in [103]). The binding of the heterodimeric integrin complex to its matrix ligand in the basement membrane ($\alpha_1\beta_1$ integrin and type IV collagen, for example) results in clustering of the integrins on the basal surface of the cell at contact sites known as focal contacts or adhesions, and the concomitant accumulation of a large group of intracellular signaling proteins at these sites known as the focal adhesion complex. This complex typically includes the focal adhesion scaffolding proteins paxillin and HEF1, the non-receptor kinases Src, PI 3-K, integrin-linked kinase (ILK) and focal adhesion kinase (FAK), the small G-protein regulated signaling proteins PIX and PAK, and actin-binding proteins such as vinculin, talin, and actopaxin (reviewed in [104,105]). Signaling through this complex can occur in a traditional "outside-in" manner, in which integrin binding to matrix results in formation and activation of the signaling complex or in an "inside-out" manner, in which signals from other sites, such as activated growth factor receptors, can regulate the affinity of the integrin complex for its matrix ligand, for example during growth factor-stimulated cell adhesion and/or migration.

Signals emanating from focal adhesions provide critical clues regarding cell location, establishment of cell polarity, regulation of cell proliferation, and determination of cell differentiation. The recruitment of actin-binding proteins into the focal adhesion complex provides important clues for cell polarity, while the regulation of small G-proteins such as Rac and Cdc42 is critical for regulating cell differentiation and directed migration.[106] Focal adhesion signaling through Src, FAK, and the P I3-K are required to normally activate the ERK MAPK pathway in response to proliferative growth factor stimuli, and thus promote entry into the cell cycle and subsequent cell proliferation.[107] In the event that cell–matrix adhesion is lost, such as can occur in proximal tubule cells following ischemic renal injury, growth factor signaling is muted, the cells enter cell cycle arrest and eventually undergo anoikis (programmed cell death induced by cell detachment) due to activation of the JNK MAPK pathway (see "Intracellular Signaling Pathways").[108]

The importance of providing the right matrix environment for normal kidney development and function has been demonstrated in mice lacking specific matrix proteins and/or integrin receptors. For example, failure to express laminin-10 results in severe abnormalities in glomerular development, as does loss of expression of the laminin-10 receptor $\alpha_3\beta_1$ integrin,[109,110] while loss of β1 integrin severely impairs branching of the ureteric bud.[111] In contrast, mice lacking integrin α_1 expression demonstrate normal kidney development,[112] but have increased fibrosis after glomerular injury, due to an increase in reactive oxygen species (ROS) generation[113] (Figure 13.7).

Cell–Cell Interactions such as Adherens Junctions and Gap Junctions can Signal Cell Density and allow Cells to act in Concert

A second means by which cells obtain clues about their immediate environment is via cell–cell interactions. Of the many types of cell–cell interactions, at least three, adherens junctions, tight junctions, and the gap junctions, play important roles in cell signaling. Adherens junctions form at the lateral border of adjacent cells due to the intercellular interactions of cadherins, a family of cell type specific transmembrane proteins (reviewed in [114]). There are multiple cadherin family members, including the classic epithelial cell member E-cadherin, the endothelial cell cadherin VE-cadherin, and the renal tubule associated cadherin Ksp-cadherin.[115] The extracellular portion of cadherins

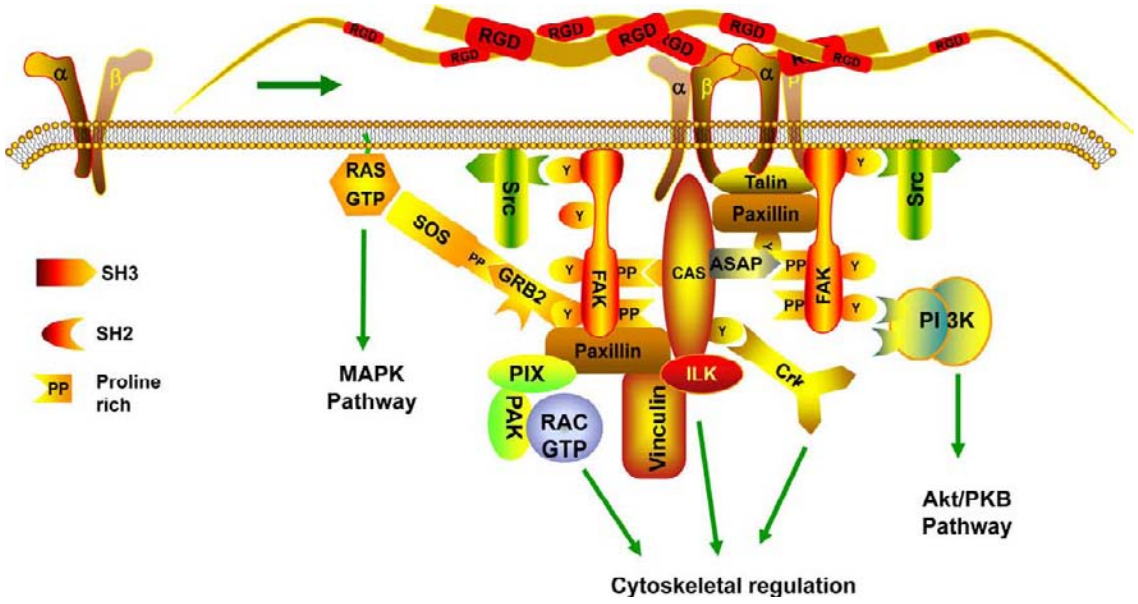

FIGURE 13.7 **Integrin signaling at the cell–matrix interface.** The αβ integrin heterodimers on the cell surface bind to specific sequences in the subcellular matrix (RGD domains in collagen for example), triggering a conformational change in the integrin, and the subsequent recruitment of a large number of cytosolic and membrane-associated proteins (the focal adhesion complex). These proteins include the adaptor and scaffolding proteins p130Cas, Paxillin, Crk, and Grb2. These adaptor proteins in turn mediate the interaction of large numbers of signaling proteins, including tyrosine kinases such as Src, which can phosphorylate and activate other proteins in the complex (including the EGF receptor), and FAK, which activates turnover of the focal adhesion so that cells can migrate. The formation of this complex also activates cell survival and proliferation signals, including the PI 3-kinase and MAPK pathways, and regulators of the actin cytoskeleton such as vinculin, talin, integrin-linked kinase (ILK), and Rac.

contains five repeat sequences (known as EC repeats), that can interact in a homophilic, calcium-dependent manner with the EC repeats present on cadherins in adjacent cells. This interaction is important for providing cell sorting signals during tissue development.[116]

The intracellular domain of the cadherins associates with a group of cytoplasmic proteins known as the catenins. One of these proteins, β-catenin, has a dual role in the cell. It directly binds to cadherins, and thus participates in the formation of cell–cell junctions, but it can also disassociate from adherens junctions and translocate to the nucleus, where it regulates signaling events involved in cell differentiation and proliferation. Originally it was believed that the direct interaction of cadherins with β-catenin created a stable binding site for the actin-binding protein α-catenin, thus generating a static site for lateral attachment of the actin cytoskeleton. However, more recent studies have demonstrated that this protein complex is a dynamic structure that can support actin filament rearrangement during the movement of cells, while maintaining cell–cell junctional integrity.[117]

β-Catenin Signaling can Regulate Cell Differentiation and Proliferation

As noted, β-catenin can leave the adherens junction and enter the nucleus, where it acts as a transcriptional regulator by binding to the TCF/Lef transcriptional complex.[118] Genes that are induced downstream of β-catenin typically lead to increased cell proliferation and regulation of differentiation, events that are important during normal development, but that are typically downregulated in the adult.[119] This transcriptional activity of β-catenin is tightly regulated by controlling the free cytosolic pool of β-catenin that is available for translocation into the nucleus. In the adult renal tubule, the extensive array of intercellular adherens junctions that forms in the confluent monolayer of epithelial cells results in sequestration of the majority of β-catenin with cadherin. To further ensure that free β-catenin levels remain low in the cytosol, a serine-threonine kinase, glycogen synthase kinase-3β (GSK-3β), phosphorylates cytosolic β-catenin and targets it for degradation by the proteosomal pathway.[120] GSK-3β is associated with the adenomatous polyposis coli (APC) protein, and mutations in this complex that prevent β-catenin phosphorylation and degradation lead to increased nuclear β-catenin signaling, cell proliferation, and subsequent tumor formation.[121]

During organ development, and following some types of organ injury, β-catenin nuclear signaling is activated by destabilization of adherens junctions (thereby releasing β-catenin into the cytoplasm) and coincident inhibition of GSK-3β kinase activity.

The classic developmental regulator that has been found to activate β-catenin signaling in this manner is the growth factor Wnt and its receptor Frizzled (Fz)[122] (Figure 13.8). Frizzled is a member of the GPCR family of seven membrane spanning cell surface receptors, and has been proposed to signal, at least in part, by activation of heterotrimeric G-proteins.[123] However, in the canonical Wnt signaling pathway, binding of Wnt to Fz leads to the GSK-3β-dependent phosphorylation of a second membrane spanning protein, the Low-density lipoprotein Receptor-related Proteins 5 and/or 6 (LRP5/6), which in turn mediate the recruitment/activation of the cytosolic protein dishevelled (Dsh).[124] This complex appears to inhibit GSK-3β-dependent phosphorylation of β-catenin and other substrates in the cytosol by sequestering GSK-3β into multivesicular endosomes, thus preventing β-catenin degradation.[125,126]

During kidney development, Wnt4 and Wnt9b, acting at least in part via activation of β-catenin, have been shown to be required for both maintenance of the nephron progenitor pool and normal differentiation of these progenitor cells to form the nephron, suggesting that careful titration of the level of activation of canonical Wnt signaling is critical during mesenchymal-to-epithelial differentiation.[127–129] In addition, multiple Wnts are upregulated following kidney injury, where they appear to play a role in normal repair, as well as in the promotion of fibrosis.[130,131]

Podocyte Slit Diaphragms are Highly Specialized Tight Junctions that Signal to the Cytoskeleton

Tight junctions are cell–cell junctions that are typically located at the interface of the apical and basolateral membranes of epithelial cells, where they serve to regulate the composition of the fluid that moves between cells into the interstitial space. In glomerular podocytes, tight junctions have evolved into elaborate structures that support the extensive interdigitation of adjacent cells along the glomerular basement membrane, and thus constitute a critical component of the glomerular filtration barrier. These cell–cell junctions are termed slit diaphragms, and form when Ig-like domains in the extracellular portion of the transmembrane proteins nephrin and Neph1 form homotypic and heterotypic interactions with nephrin/Neph1 molecules in the adjacent podocyte.[132] Dynamic regulation of these interactions is critical for maintaining the integrity of the slit diaphragm, which is achieved by signaling from the slit diaphragm to the actin cytoskeleton (reviewed in [133,134]). This signaling involves phosphorylation of the intracellular domain of nephrin by the Src-family kinase Fyn, followed by recruitment of a signaling complex including the adaptor proteins Nck1/2, Grb2, and p85, which in turn mediate recruitment/activation of cytoskeletal regulatory proteins including WASP, Pak, and Rac that regulate actin polymerization/depolymerization in the foot process. Mutations that alter nephrin/NEPH interactions lead to disruption of this intracellular signaling complex, destabilization of the actin cytoskeleton and foot process retraction/fusion.

Gap Junctions Promote Rapid Signaling Between Groups of Cells

A second type of cell–cell interaction that is important for cell signaling is the gap junction. These junctions are formed by the alignment of hemichannels on the lateral borders of two adjacent cells to establish a direct cytoplasmic link between the cells, thus allowing the rapid movement of small molecules and electrical charge through multiple cells within a specified region of the organ.[135] Gap junctions are primarily composed of a family of proteins known as connexins, and have traditionally been studied for their ability to rapidly transmit contraction signals through muscles. Investigation of gap junction function within the kidney has demonstrated that mesangial cells contain large numbers of gap junctions comprised of connexin 43 (Cx43), and that these are critical for mediating intercellular calcium-dependent coordinated mesangial contraction.[136] In addition, tubular epithelial cells maintain intercellular gap junctions that can be regulated by growth factors, as well as by ischemic injury,[137,138] although the precise role of these channels in normal tubule function is presently not well-understood.

The Cilia as a Signaling Structure

Many cells of the body, including renal epithelial cells, have a surface structure known as the primary cilium. Cilia are elongated membrane protrusions that surround a central core of microtubules arising from a microtubule organizing center known as the basal body (reviewed in [139,140]). Cells that express cilia with a microtubular arrangement of 9 + 2 (9 microtubule doublets arranged in a cylinder around a core of 2 microtubule singlets), such as those lining the trachea, are motile and can act to facilitate directional movement of fluid (reviewed in [141]). In other cells, such as those lining the renal tubules, cilia have a 9 + 0 arrangement, are non-motile, and were previously believed to be rudimentary structures. However, the finding that genetic mutations that interrupt cilia formation can result in cystic kidney diseases in rodents,[142,143] along with the recent discovery that the two predominant gene products known to cause human autosomal dominant polycystic kidney disease, polycystin-1 (Pc-1) and polycystin-2 (Pc-2), localize to cilia, has resulted in intense investigations into the role of non-motile cilia as renal epithelial mechanosensors.[143,144]

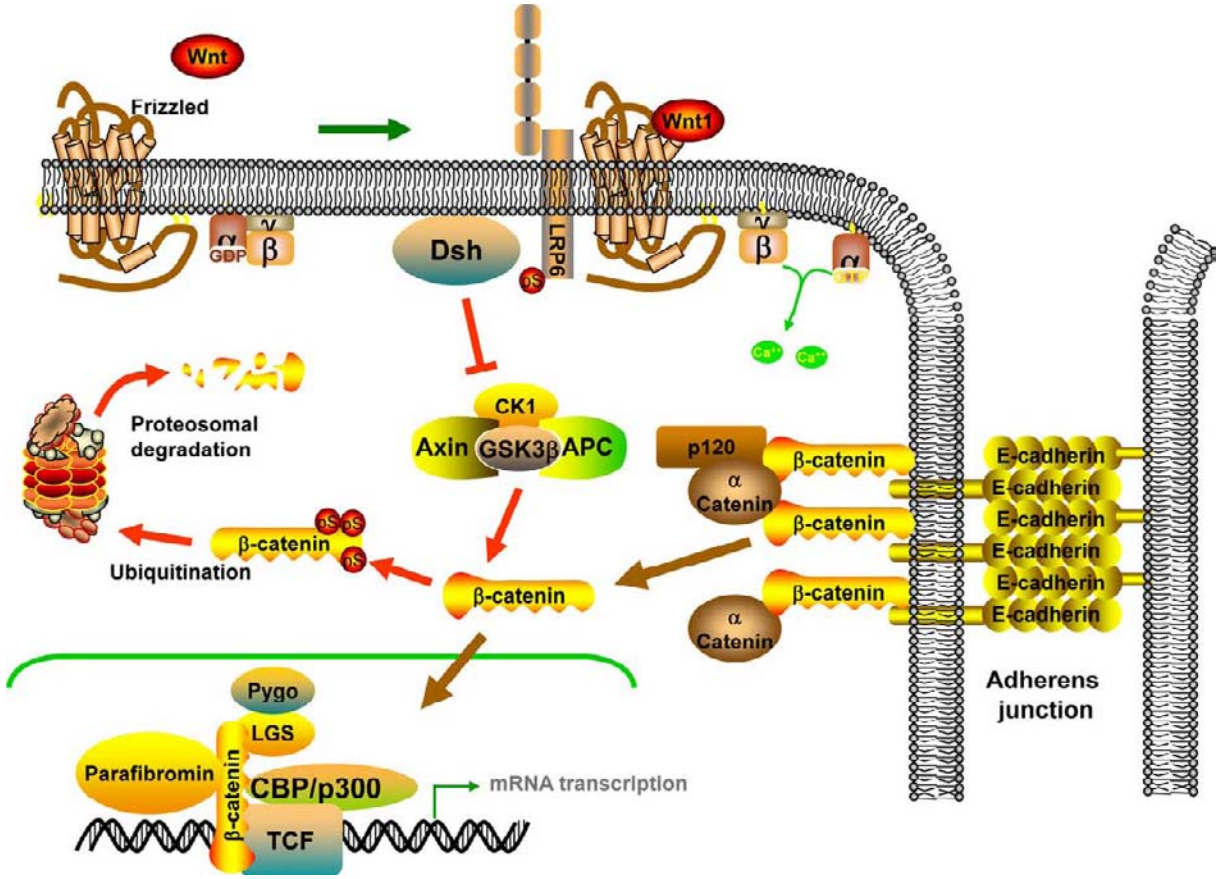

FIGURE 13.8 **Wnt/β-catenin signaling.** Formation of stable cell−cell adherens junctions in mature epithelia occurs due to the lateral interactions of cadherins on adjacent cells. This results in the formation of an intracellular complex of proteins comprised of β-catenin, α-catenin, and p120. α-Catenin can interact with the actin cytoskeleton and the adherens junction complex in a dynamic manner, and thus serve as a nidus for actin cytoskeletal arrangement along the lateral border of the cell. β-catenin can either be sequestered in the adherens junction or released into the cytosol where it is capable of translocating to the nucleus and activating the transcription of multiple genes involved in cell proliferation and dedifferentiation. In mature, non-proliferating cells, free cytosolic β-catenin is rapidly degraded, because phosphorylation by GSK-3β targets β-catenin for ubiquitination and degradation in the proteosome. GSK-3β is found in a complex that includes the regulatory/targeting proteins axin and APC. The kinase activity of GSK-3β can be inhibited following activation of several growth factor receptors. In the best studied pathway, stimulation of the Wnt receptor Frizzled leads to phosphorylation of the membrane spanning protein Lrp6, which in turn activates the Dishevelled (Dsh)-dependent sequestration and inhibition of GSK-3β. The resultant increase in free cytosolic β-catenin leads to its nuclear translocation, where it serves as a scaffold for the association of a complex of proteins that bind and activate RNA polymerase II, leading to gene transcription. There is data supporting a second signaling pathway downstream of Frizzled in which GTP-loading of the Gαi-subunit of the heterotrimeric G-protein results in release of the βγ-subunit, which in turn activates phosphoinositide hydrolysis and downstream calcium release.

These studies have demonstrated that Pc-2 acts as a cation channel, and that regulation of this channel activity can be mediated by its interaction with Pc-1.[145−147] *In vitro* studies have demonstrated that Pc-1 and Pc-2 co-localize on the primary cilium of the apical cell membrane in renal epithelial cells, and that physiological levels of fluid shear stress, such as that created by urine flow in the renal tubule, may be sufficient to stimulate cilia-dependent Pc-1/Pc-2-mediated calcium signaling.[143,148,149] It is presently hypothesized that failure of this signaling pathway can result in abnormalities in both the rate and organization of cell proliferation, and thus can lead to cyst formation.[150]

INTRACELLULAR SIGNALING PATHWAYS

As is clear from the preceding section, activation of cell surface receptors results in the regulation of multiple intracellular signaling pathways. Although numerous studies from the past decade have emphasized the vast amount of cross-talk between the proteins involved in these pathways, it remains useful to identify core signaling cascades that can transduce signals from the receptor to effector proteins that mediate specific cellular responses. Several of these signaling cascades, including the heterotrimeric G-protein-adenylate cyclase-cAMP-PKA pathway, the TGFβ-Smad pathway,

and the Wnt-Fz-Dsh-Gsk3β-β-catenin pathways, have been described in some detail in the section "Cell Surface Receptors." This section will focus on several other signaling cascades that are believed to be fundamental regulators of cell survival and function in the kidney, including the PLC-Ca-PKC pathway, the MAPK pathway, and the PI 3-kinase pathway.

The Phospholipase C Pathway Regulates Intracellular Calcium Release and Activates PKC Signaling

Phospholipase C (PLC) is an enzyme that catalyzes the hydrolysis of the membrane lipid phosphoinositide 4,5 bisphosphate ($PI_{4,5}P_2$) to generate diacylglycerol (DAG) in the membrane and release inositol trisphosphate (IP_3) into the cytoplasm (reviewed in [151]). DAG provides a binding site to recruit protein kinase C (PKC) to the membrane, while IP_3 binds to its receptor on the endoplasmic reticulum that mediates the intracellular release of stored calcium. Thus, activation of PLC regulates both PKC-dependent and calcium-dependent intracellular signaling.

In mammals, there are four known families of phospholipases C, PLCβ, PLCγ, PLCδ, and PLCε. While all four groups share the catalytic X and Y lipase domains, the regulatory domains are widely divergent, allowing activation by distinct upstream receptors. For example, PLCβ is activated following stimulation of certain GPCRs, because it has a carboxy terminal domain that recognizes and binds GTP-loaded $G_{q\alpha}$, as well as the free βγ heterodimer[152,153] (see section "G-protein coupled receptors"). Activation of PLCδ and PLCε are less well-understood, although each appears to be mediated by interaction with small GTP-binding proteins. PLCδ can be activated by associating with the GTPase Ral, whereas PLCε has a Ras-binding domain and can be activated by associating with GTP-loaded Ras.[154–157]

In contrast, PLCγ family members lack the Gα- and βγ-binding regions, but instead encode two SH2 domains and one SH3 domain that mediate their recruitment and activation by receptor tyrosine kinases (RTKs) such as the PDGF receptor, vascular endothelial growth factor (VEGF) receptor, and HGF receptor.[158] Interestingly, PLCγ can also be phosphorylated and activated by non-receptor protein tyrosine kinases, such as Src family members. In this manner, PLCγ can be secondarily activated in immune cells downstream of T-cell receptor activation (see Figure 13.5), as well as following activation of certain GPCRs, such as the angiotensin II receptor.[159]

For PLC to hydrolyze $PI_{4,5}P_2$, it must be recruited to the membrane. Members of both the PLCβ and PLCγ families have pleckstrin homology (PH) domains at their amino termini that promote membrane association by binding to select membrane phospholipids, such as $PI_{4,5}P_2$ and $PI_{3,4,5}P_3$.[160] PLCβ family members are further stabilized at the membrane because their PH domain can also interact with the membrane bound βγ G-protein heterodimer, while the SH2 domains of PLCγ proteins enhance membrane association by mediating recruitment to cell surface receptors. In this manner, PLC is recruited to specific sites at the membrane in the vicinity of the activating receptor, allowing the cell to selectively upregulate DAG and IP_3 production in that area.

PLC-dependent generation of DAG provides a membrane binding site for recruitment and activation of several members of the protein kinase C (PKC) family of non-receptor serine-threonine kinases (Figure 13.9). PKCs are a large group of proteins that are subdivided into the conventional PKCs, novel PKCs, and atypical PKCs. The conventional PKCs (PKCα, PKCβ, PKCγ) are activated in a calcium-dependent fashion following recruitment to the cell membrane by binding to DAG and phospholipids such as phosphatidylserine (PS). The novel PKCs (PKCδ, PKCε, PKCη, and PKCθ) are also recruited to the membrane by binding to DAG and membrane phospholipids, but do not require calcium for activation. The atypical PKCs (PKCλ, PKCζ, PKCμ, and PKCι) lack both the DAG and calcium binding sites, and instead appear to be associated with the membrane and activated solely via their association with membrane phospholipids (reviewed in [161]). In addition to PS, it has been found that the 3-phosphorylated lipid products of the PI 3-K (such as $PI_{3,4}P_2$ and $PI_{3,4,5}P_3$) can bind and activate both novel and atypical PKCs.[162]

Once activated, PKCs have multiple potential phosphorylation targets in the cell. The determination of which targets are phosphorylated is dependent on cell type, the isoform of PKC that is activated, and targeting proteins that specify subcellular localization of the activated PKC. Proteins that are not phosphorylation substrates of PKC, but serve only to target specific PKCs to select sites in the cell, are collectively termed RACKs (receptors of activated C kinase). For example, the cell polarity proteins Par3 and Par6 associate with atypical PKCs, such as PKCζ, and specifically target them to epithelial tight junctions on renal tubular cells.[163] In this location, PKCζ has been shown to regulate both tight junction assembly and disassembly, although the exact phosphorylation targets of PKCζ have yet to be identified.[164,165]

Recent studies have demonstrated that PKC localization to the basolateral membrane can regulate Na,K-ATPase activity in the renal tubule as well. Several phosphorylation sites for classical PKCs (such as PKCα) have been identified in the amino terminus of the Na,K-ATPase α-subunit, and phosphorylation of

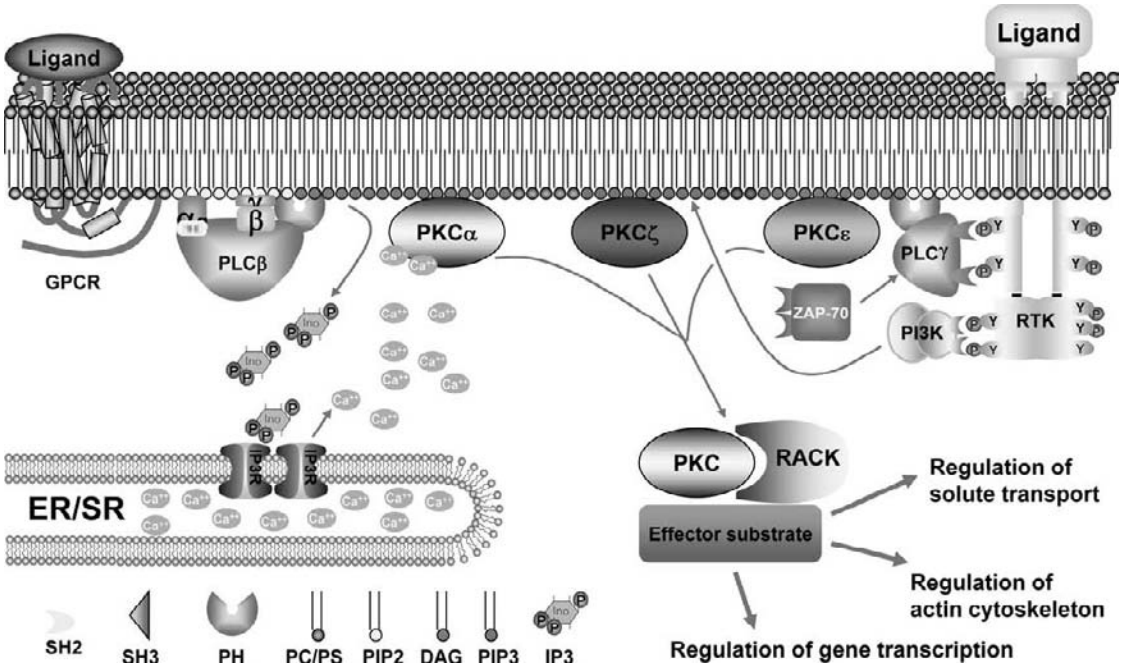

FIGURE 13.9 **Phospholipase C-protein kinase C signaling.** Activation of GPCRs coupled to Gαq can recruit PLCβ to the membrane and activate its phospholipase activity via interactions with the GTP-loaded α-subunit, as well as the free βγ-subunit. PLCγ is classically activated via binding of its SH2 domains to phosphotyrosine residues on RTKs, although PLCγ can also be activated by the non-receptor tyrosine kinase Zap-70. Both PLCβ and PLCγ are stabilized at the membrane via their lipid-binding PH domain, where they hydrolyze PI4,5P2 (PIP2) to generate DAG and IP3. DAG serves as a binding site at the membrane for both conventional PKCs (such as PKCα) and novel PKCs (such as PKCε). While novel PKCs are activated as a consequence of this membrane recruitment, conventional PKCs also require calcium-binding for full activation. This calcium signal comes from IP3-mediated calcium release from intracellular stores. A third family of PKCs, the atypical PKCs such as PKCζ, lack the DAG-binding domain, and are recruited to the membrane and activated by binding to phosphatidyl serine (PS) as well as the lipid product of the PI3K, $PI_{3,4,5}P_3$ (PIP3). Specificity of signaling for this diverse family of serine-threonine kinases is provided by association with receptors of activated C kinase (RACKs) which target the activated PKC isoform to the correct effector protein (such as the α-subunit of the Na,K-ATPase in renal tubular cells).

these sites appears to increase cellular sodium pump activity by increasing membrane localization of the enzyme.[166,167] Interestingly, activation of PKC downstream of the D_1-type dopamine receptors appears to have the opposite effect, inhibiting sodium pump activity as part of the overall effect of the D_1 receptor in inhibiting tubular sodium reabsorption.[168] Exploration of this response has demonstrated that novel PKCs such as PKCθ and PKCε are likely to mediate this Na,K-ATPase inhibitory effect.[169] It is unknown whether these PKCs phosphorylate different sites on the sodium pump than PKCα or act indirectly via phosphorylation of intermediate proteins such as the sodium hydrogen regulatory factor Nherf-1.[170]

Another group of PKC regulatory targets are transcription factors. PKC isoforms such as PKCδ, PKCε, and PKCθ have been found to regulate the activity of multiple transcription factors, including NF-κB (involved in immune and inflammatory responses), signal transducers and activators of transcription (STATs, regulators of inflammatory responses, cell proliferation, and differentiation), and Jun N-terminal kinase (JNK, involved in cell stress response and survival) (reviewed in [171]). By acting upstream of JNK as well as the Raf-MEK-ERK pathway (see below), PKC isoforms can cooperate to mediate increased activity of the immediate early response genes Jun and Fos.[172]

An interesting example of convergence of PKC with other signaling pathways is seen during the activation of T-cells. The rise in intracellular calcium following T-cell stimulation results in the activation of calmodulin and binding of the calcium−calmodulin complex to the non-receptor serine-threonine phosphatase calcineurin (also known as protein phosphatase 2B or PP2B). Activated calcineurin dephosphorylates and activates the nuclear translocation of another protein, nuclear factor of activated T-cells or NFAT (reviewed in [173,174]). While originally described in T-cells, NFATs are expressed in multiple cell types and control the expression of genes such as Il-2, GM-CSF, interferon-γ, TNFα, and Cox2 that regulate processes as diverse as T- and B-cell proliferation in response to antigen stimulation, cardiac myocyte differentiation and hypertrophy, and sodium channel expression (reviewed in [175,176]).

However, the DNA-binding sites of many of these gene targets contain nearby AP-1 promoter sites, and are only upregulated in an efficient manner following the concerted actions of NFAT and the AP-1 binding elements Jun and Fos. Thus, concerted activation of PKC (to activate Jun and Fos) and calcineurin (to activate NFAT) leads to maximal gene expression and cellular response. The importance of calcineurin in mediating immune cell activation has led to the extensive use of calcineurin inhibitors, such as cyclosporine and tacrolimus, for the prevention of transplant rejection.

The Mitogen Activated Protein Kinase (MAPK) Pathway Regulates Cell Survival, Proliferation, and Morphology

The MAPK pathway provides an excellent example of the way in which different extracellular signals can converge on the regulation of a single intracellular signaling pathway, and demonstrates how targeting of that pathway to specific sites in the cell via scaffolding proteins can determine which effector proteins are regulated, and what cell responses are affected. As the name implies, this protein cascade was originally identified based on its activation downstream of pro-proliferative growth factors such as insulin and EGF.[177] In the classic MAPK cascade, binding of the growth factor to its receptor tyrosine kinase (RTK) initiates a series of protein−protein interactions that ultimately result in activation of the cytosolic serine-threonine kinase ERK, which can phosphorylate and regulate diverse effector substrates including transcription factors in the nucleus, focal adhesion proteins at the cell surface, and contractile proteins in the cytosol.[178−180]

The core proteins of this classic MAPK cascade are three kinases, Raf, MEK, and ERK. Raf-1 (also called MEK kinase (MEKK) or MAPK kinase kinase (MAPKKK)) is a serine-threonine kinase that phosphorylates and activates two closely related MEK isoforms, MEK1 and 2. MEK1/2 are dual specificity (tyrosine as well as serine/threonine) kinases that phosphorylate ERK1 and 2 on a highly conserved amino acid motif, Thr-Glu-Tyr, contained in the activation loop of the protein.[181] The efficient activation of ERK in this cascade requires that the three proteins (Raf, MEK, and ERK) are brought into close proximity on a single scaffolding protein. Present studies indicate that several different proteins can serve this scaffolding function, including β-arrestin, IQGAP, kinase suppressor of Ras (KSR), and paxillin.[20,182−184] The location of the scaffolding protein and the regulation of Raf/MEK/ERK association determines which effector proteins are likely to be regulated (reviewed in [185]).

The core module of Raf, MEK, and ERK can be activated following binding of receptor tyrosine kinases to their extracellular ligands. The initial step in RTK-mediated MAPK activation is the recruitment of the GRB2 adaptor protein to the tyrosine phosphorylated receptor. GRB2 is a small molecule that is composed of one SH2 domain and two SH3 domains.[186] As noted previously, proteins containing SH2 domains interact with other proteins that contain phosphorylated tyrosine residues flanked by the appropriate amino acids. The GRB2 SH2 domain preferentially binds to phosphotyrosine residues with an asparagine at the +2 position, such as tyrosine 1096 in the activated c-Ret receptor (pYANW) or tyrosine 1356 in activated c-Met (pYVNV). In contrast, SH3 domains typically mediate constitutive association with short proline-rich sequences in target proteins. The guanine nucleotide exchange factor (GEF) Sos contains such a sequence, and associates with the GRB2 SH3 domain in a constitutive fashion. Sos acts as a GEF for the membrane-associated small GTP-binding protein Ras.[187]

Ras is structurally similar to the α-subunit of the αβγ heterotrimer that associates with GPCRs. However, Ras is activated by non-GPCR GEFs such as Sos and, in the GTP-bound state, associates with and activates Raf rather than adenylyl cylase. This activation step appears to involve the Ras-dependent dephosphorylation of Raf by PP2A, a non-receptor protein phosphatase.[188] Thus, RTK activation results in recruitment of the GRB2-Sos complex to the membrane where it mediates GTP-loading of Ras, and activation of the Raf-MEK-ERK signaling pathway (Figure 13.10).

In addition to this classic model of GRB2-Sos-Ras-dependent MAPK activation mediated by RTKs, several alternative mechanisms of MAPK pathway activation have now been elucidated. For example, as described in the section "G-protein coupled receptors," the recruitment of β-arrestin to activated GPCRs can result in β-arrestin-dependent scaffolding of Raf, MEK, and ERK, and thus can facilitate ERK activation (reviewed in [189]). Another pathway of MAPK activation is that of PKC-mediated Raf activation. As noted previously, PKCs are activated downstream of GPCRs, RTKs, and non-receptor kinases (such as the PI 3-K) by associating with DAG and/or phospholipids at the cell membrane. Once activated, one of the PKC phosphorylation targets is Raf,[190] leading to Raf activation and the downstream activation of MEK and ERK, even in the absence of GTP-loaded Ras.[191]

ERK Activation is Regulated by the Cross-Talk of Multiple Signaling Pathways

Classically, activated ERK has been shown to regulate gene transcription factors involved in promoting cell survival and inducing cell proliferation. Careful

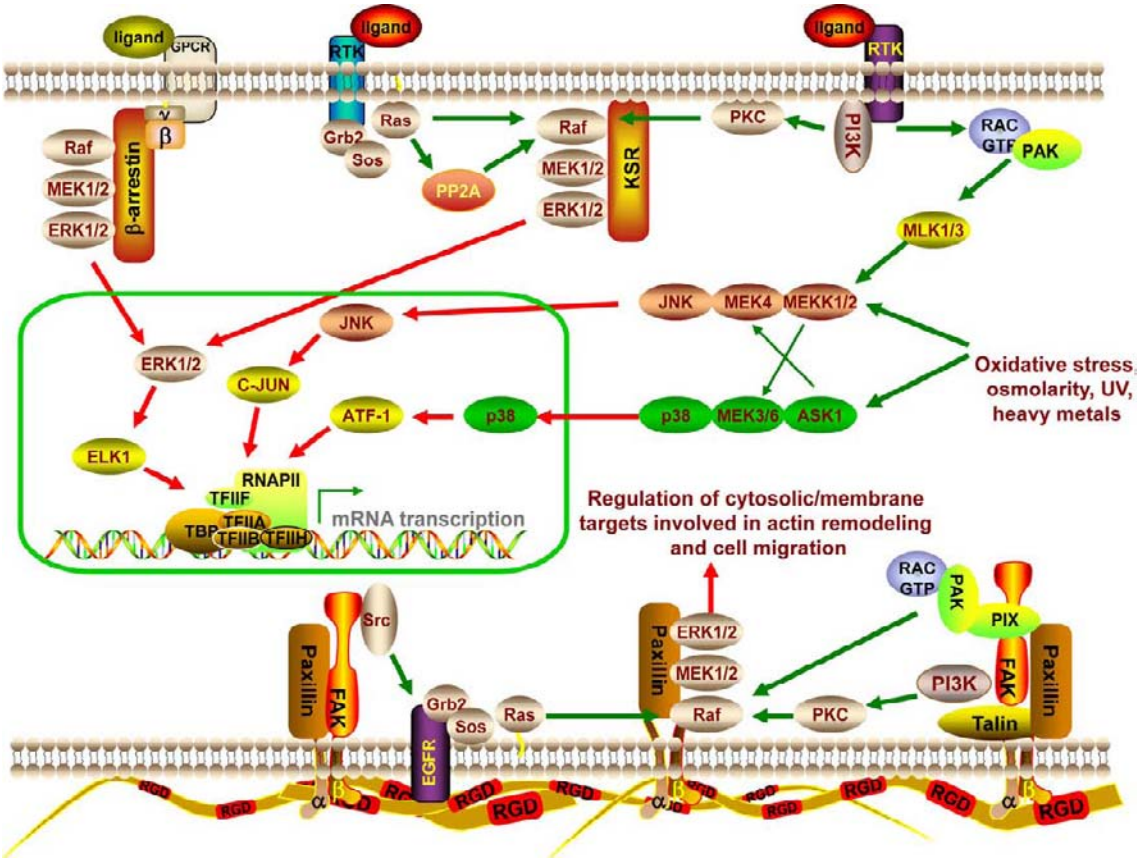

FIGURE 13.10 **MAPK signaling.** The prototypic MAPK pathway involves the growth factor stimulated activation of the small G-protein Ras at the membrane, followed by Ras binding and activation of the serine-threonine kinase Raf (a MAPK kinase kinase or MAPKKK). This process involves dephosphorylation of Raf at an inhibitory site by the serine-threonine phosphatase PP2A. In addition, Raf can be activated by PKC-dependent phosphorylation or by recruitment to the GPCR scaffolding protein β-arrestin. The MAPK pathway can also be activated in a growth factor-independent fashion via focal adhesion signaling when cells attach to the basement membrane. Activation of Raf results in phosphorylation and activation of the downstream kinases MEK and ERK. Depending on the site of ERK activation, it can translocate to the nucleus where it phosphorylates and activates transcription factors such as Elk1 or it can remain in the cytoplasm where it phosphorylates and regulates proteins involved in actin cytoskeletal rearrangement and cell migration, such as Myosin Light Chain Kinase (MLCK) and paxillin. Two other MAPK pathways present in most cells are the stress-activated protein kinases (SAPK) p38 and JNK. Multiple factors have been shown to activate p38 and JNK, including oxidative or osmolar stress, heavy metals, cytokines, and growth factors such as EGF and TGFβ. These stimuli induce the activation of a group of MAPKKKs including apoptosis signal-regulating kinase 1 (ASK1) and MEKK1/2. Activation of the MAPKKK results in phosphorylation of the appropriate dual specificity MAPKK (MEK) such as MEK3, MEK4, and MEK6, which in turn phosphorylate and activate JNK and p38. Small G-proteins such as Rac and Cdc42 can also activate the p38 and JNK pathways via binding and activating intermediate kinases such as the Mixed Lineage Kinase (MLK) family of serine-threonine kinases. There is considerable cross-talk between these pathways, resulting in simultaneous activation of JNK and p38 under many conditions. Like ERK, activated JNK and p38 translocate into the nucleus, where they phosphorylate regulatory transcription factors such as c-Jun, ATF-1, Elk-1, and Sap1. These in turn regulate the RNA polymerase transcription initiation complex to activate the transcription of multiple genes including pro-survival and pro-apoptotic factors, matrix proteins, heat shock factors, etc.

control of these events is fundamental to normal organ physiology, so it is not surprising that ERK activation is regulated by a complex series of signals derived from extracellular stimuli, such as growth factors and cell–matrix interactions. It has long been known that adherent cells, such as endothelial cells and epithelial cells, can proliferate when attached to the proper basement membrane, but undergo anoikis when they lose their attachment. This type of cell death is common in detached tubular epithelial cells following acute renal injury, and it is believed that the loss of anoikis contributes to the metastatic spread of tumor cells.[192–194] As described earlier, the sites of cell attachment to the basement membrane, focal adhesions, provide the nidus for the aggregation of multiple signaling proteins on the cytosolic face of the attachment. Among the many proteins involved in this complex are the MAPK scaffolding protein paxillin, the Rac-activated protein p21 associated kinase (PAK), the EGF receptor, and the non-receptor tyrosine kinases Src and FAK.

Attachment of the cell to a subcellular matrix can activate MAPK signaling, even in the absence of extracellular growth factor or cytokine stimulation. One mechanism for this activation is that attachment-dependent activation of FAK results in the recruitment and activation of the PI 3-kinase, which leads to the local production of $PI_{3,4,5}P_3$. As noted earlier, $PI_{3,4,5}P_3$ binds and activates PKC, which in turn can phosphorylate and activate Raf.[195] Furthermore, the EGF receptor localizes to focal adhesions in adherent cells, and can be phosphorylated and transactivated by the non-receptor tyrosine kinase Src even in the absence of extracellular EGF, thus mediating ERK activation via the classical Grb2-Sos-Ras pathway. In addition to the ability of focal adhesions to directly activate MAPK signaling, these signaling structures are also required for growth factors to efficiently stimulate MAPK signaling.[196] Although the mechanism of this is not entirely understood, recent studies suggest that activation of the focal adhesion associated serine-threonine kinase PAK leads to phosphorylation of Raf that is required for the efficient activation of Raf by GTP-Ras.[197] Thus, focal adhesions serve as sites to directly activate ERK, as well as supporting ERK activation downstream of proliferative stimuli.

ERK Regulates both Nuclear and Cytosolic Protein Actions

Translocation of activated ERK to the nucleus has been found to signal both pro-proliferative and anti-apoptotic responses. In the nucleus, ERK phosphorylates and activates transcription factors such as Elk-1 and RUNX2, which in turn regulate the mRNA expression of the cell cycle proteins cyclin D1 and $p21^{WAF1}$,[198–200] (reviewed in [201]). Furthermore, ERK activation can downregulate the expression of pro-apoptotic proteins such as Bim1, a process that is believed to be critical for ERK-dependent inhibition of anoikis.[202] These effects of ERK depend on both the amplitude and the duration of ERK activation. For example, transient high level ERK activation in renal tubular cells treated with the growth factor HGF results in activation of focal complex signaling and Rac-dependent cell migration, but does not result in significant cell proliferation.[183] In contrast, sustained low level ERK activation appears to be required for cell cycle entry (leading to proliferation) and the anti-apoptotic effects of ERK.[203–205] For this reason, the degree of ERK activation is tightly regulated by a series of phosphorylation and dephosphorylation steps at the level of Raf.[188]

Activation of ERK can also lead to the phosphorylation of substrate proteins in the cytoplasm. ERK has been shown to phosphorylate and activate myosin light chain kinase (MLCK), resulting in stimulation of cell motility.[180] In addition, ERK activation at focal adhesions in renal epithelial cells can mediate phosphorylation of paxillin, and subsequent FAK and PI 3-K activation.[52] This process plays a regulatory role in the local activation of another family of small GTP-binding proteins, Rho, Rac, and Cdc42. These proteins are regulators of actin cytoskeletal remodeling, and by binding to their respective effector proteins (such as the Rho-kinase for Rho), mediate the cytoskeletal changes required for cell spreading, lamellipodia formation, and migration (reviewed in [206]). Besides activation downstream of ERK and the PI 3-K, focal adhesion signaling can also activate Rho family members by stimulating the guanine nucleotide exchange factors Vav and/or PIX (reviewed in [207]). In the kidney, regulated activation of Rac and Rho are fundamental for the morphogenic changes involved in developmental tubulogenesis,[208] and Rho activation appears to be required for angiotensin II-dependent regulation of glomerular arteriolar tone.[209]

In addition to the classic ERK MAPK pathway, two other well-conserved MAPK pathways, the JNK and p38 pathways, have been extensively studied and found to play important roles in regulating cell survival (reviewed in [210,211]). Similar to the ERK pathway, p38 and JNK signaling are mediated by a core complex of three proteins, including a MEK kinase which phosphorylates a MEK family member (MEK3 or 6 in the p38 pathway, MEK4 or 7 in the JNK pathway), which in turn phosphorylates the effector kinase p38 or JNK, respectively. Activated p38 or JNK can then translocate to the nucleus, where they phosphorylate and regulate transcription factors such as ATF-1, ATF-2, c-Jun, and STAT-3.

Activation of the p38 and JNK signaling cascades occurs in response to cell stress signals, including UV irradiation, ischemia, and hypoxia, as well as following cytokine stimulation (IL-1 and TNFα) and certain growth factors (EGF, TGFβ).[212,213] Based on *in vitro* studies demonstrating increased extracellular matrix production following p38 activation, it has been proposed that p38 may play an important role in the development of renal fibrosis following injury (reviewed in [214]). In support of this, *in vivo* studies using p38 inhibitors in rodents have demonstrated that activation of p38 stimulates the progressive renal tubular fibrosis seen in models of chronic ureteral obstruction.[215] Similarly, mice that overexpress TGFβ exhibit p38-dependent glomerular podocyte apoptosis, an early component of the progression to glomerulosclerosis,[213] and p38 activation may be required for the development of proteinuria following acute glomerular injury.[216] Activation of the ERK, p38, and JNK pathways occurs during the oxidative stress of renal ischemia/reperfusion. Under these conditions, JNK activation appears to mediate the tubular cell apoptotic response, while ERK activation can be protective.[217–219]

The Phosphoinositide 3-Kinase Pathway Regulates Diverse Events Including Glucose Metabolism, Cell Migration, Cell Survival, and Proliferation

Another major intracellular signaling pathway is regulated by a lipid kinase known as the phosphoinositide 3-kinase (PI 3-K).[220] This enzyme is composed of two subunits, the p85 adapter protein and the p110 catalytic-subunit. Recruitment of the p85/p110 complex to the membrane occurs when p85 binds via its SH2 domains to tyrosine phosphorylated receptors (such as the PDGF receptor) or docking proteins (such as the EGF receptor associated protein Gab1 or the insulin receptor associated protein IRS-1). The p110 enzymatic-subunit is activated by this translocation and phosphorylates target lipids, such as $PI_{4,5}P_2$ (PIP2), to form the 3-phosphorylated derivative $PI_{3,4,5}P_3$ (PIP3). PIP3 then serves as a membrane-binding site for multiple proteins that contain lipid-binding domains, such as the pleckstrin homology (PH) domain, the PTB domain, and FYVE domains (reviewed in [221]).

As described previously, several PKC family members are recruited to the membrane and activated by binding to PIP3, as are the docking protein DOCK180 and the guanine nucleotide exchange factor Vav.[222,223] However, the best described targets of PIP3 are the PH-domain containing proteins 3-phosphoinositide dependent kinase-1 (PDK1) and its major substrate enzyme Akt (also known as protein kinase B (PKB)). The generation of PIP3 at the membrane results in recruitment and activation of PDK1, which in turn phosphorylates and activates Akt.[224] In addition to Akt, activated PDK1 can phosphorylate and activate IKK, the upstream regulator of NF-κB, as well as the p70 and p90 ribosomal S6 kinases, and several PKC isoforms.[225,226]

Akt is a serine-threonine kinase that regulates multiple intracellular events, including protein ubiquitination/degradation, glucose metabolism, nitric oxide generation, cell survival, and cell proliferation. To regulate these disparate processes, Akt associates with and phosphorylates multiple cytosolic protein targets (reviewed in [227]). One of these targets is the constitutively active cytosolic enzyme glycogen synthase kinase-3β (GSK-3β), described earlier for its role as a regulator of β-catenin ubiquitination and degradation downstream of the Wnt signaling pathway.[228,229] Phosphorylation of serine 9 at the N-terminus of GSK-3β by Akt causes the kinase domain of GSK-3β to recognize this region as a pseudosubstrate, leading to autoinhibition of the GSK-3β kinase activity and an increase in free cytosolic β-catenin levels.[230,231] β-catenin can then translocate into the nucleus, where it regulates the transcriptional expression of genes involved in stimulating cell proliferation and dedifferentiation. In addition to β-catenin, GSK-3β has also been shown to phosphorylate several other cellular substrates that regulate cell proliferation as well as cell survival. For example, GSK-3β can enter the nucleus where it phosphorylates the cell cycle protein cyclin D1, thus targeting it for rapid degradation.[232] In addition, phosphorylation of translation initiation factor eIF2B by GSK-3β inhibits protein translation, leading to initiation of apoptosis and ultimately cell death.[233] Thus, activation of the PI 3-K/Akt pathway by inhibiting GSK-3β results in increased cyclin D1 levels and eIF2B activation, promoting entry into the cell cycle and preventing apoptotis.

Besides these indirect effects of Akt in preventing cell apoptosis, Akt activation directly inhibits apoptotic responses by phosphorylating and inhibiting the pro-apoptotic factors BAD and caspase 9, as well as the forkhead transcription factor FKHRL1.[234] In addition, Akt activation can stimulate protein synthesis and cell growth via its effects on mTOR, the mammalian target of rapamycin (reviewed in [235]). mTOR is a serine-threonine kinase that phosphorylates and activates the ribosomal protein translation initiators S6 kinase and 4EBP, leading to increased protein translation and promoting cell growth and division. Rapamycin, by inhibiting mTOR, prevents protein translation and inhibits cell division, leading to its use to suppress tumor growth, and as an immune suppressant (due to inhibition of T- and B-cell expansion).

The kinase activity of mTOR is activated by binding to the small GTP-binding protein Rheb. Like Ras, Rac, and Gα, Rheb is active when in the GTP-bound state, and inactive when in the GDP-bound state. Conversion of GTP-Rheb to GDP-Rheb is mediated by a GTPase complex made up of two proteins, tuberin and hammartin. The GTPase activity of these proteins, which are mutated in many patients with tuberous sclerosis, is in turn negatively regulated by phosphorylation of tuberin by activated Akt.[236] In this manner, activation of Akt downstream of the PI 3-K results in stabilization of Rheb in the GTP-bound state, thereby activating mTOR and accelerating cell growth and division (Figure 13.11).

In addition to its fundamental role in regulating cell survival and proliferation, another major physiologic process regulated by the PI 3-K/Akt pathway is insulin-dependent glucose metabolism (reviewed in [237]). Binding of insulin to its receptor tyrosine kinase results in the tyrosine phosphorylation of a docking protein, insulin receptor substrate (IRS-1), which in turn activates multiple intracellular signaling pathways including the PI 3-K. Activation of the PI 3-K has been shown to regulate insulin-dependent glucose uptake, glycogen synthesis, and lipolysis. Glucose uptake is

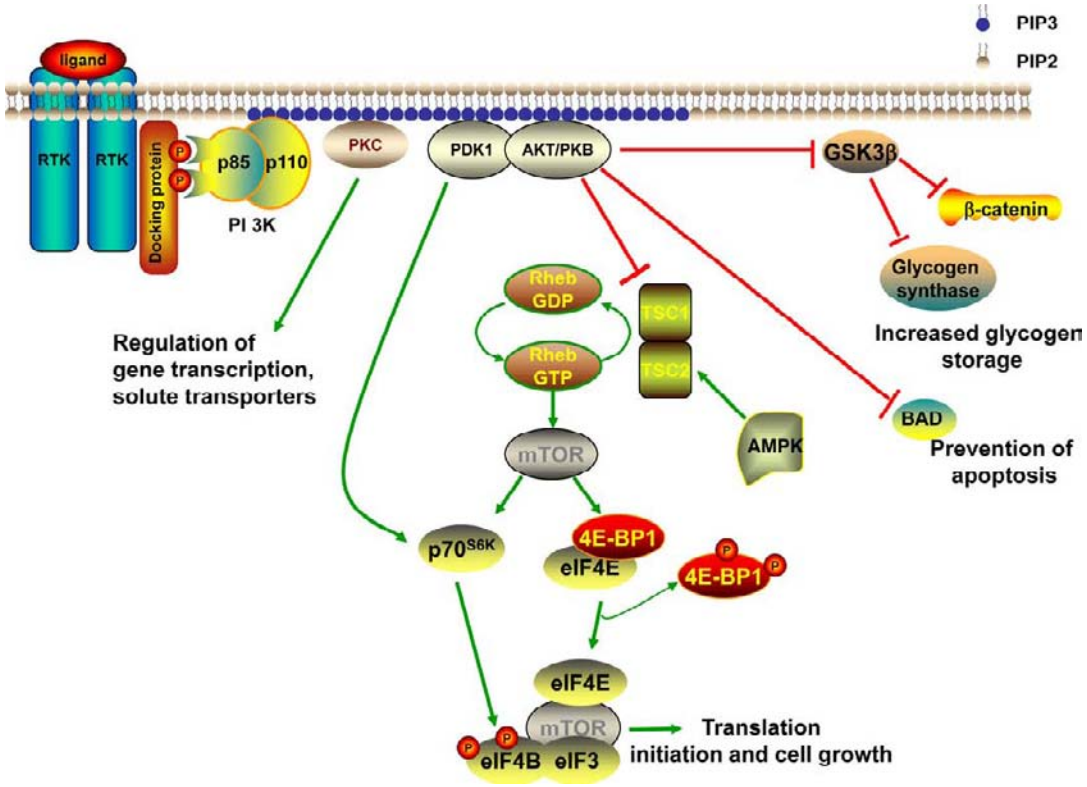

FIGURE 13.11 **Signaling through the PI 3-kinase/Akt pathway.** The activation of growth factor receptors results in the recruitment of the p85/p110 PI 3-kinase heterodimer to the membrane via binding of the SH2 domains of p85 to phosphotyrosine residues on the receptor or an associated docking protein such as IRS-1. Activation of the lipid kinase activity of p110 occurs, resulting in generation of $PI_{3,4,5}P_3$ (PIP3) at the inner leaflet of the membrane. PIP3 serves as a binding site for proteins that contain lipid-binding domains, including several PKC family members, docking proteins, and the serine-threonine kinase phosphoinositide-dependent kinase (PDK1). PDK1 has several targets in the cell, including the protein translation activator p70 S6kinase and the cytosolic serine-threonine kinase protein kinase B (PKB), also known as Akt. Akt phosphorylates multiple substrates in the cell (typically resulting in inhibition of their action) that promote cell growth and survival. Thus, phosphorylation of the tuberosis sclerosis complex (TSC1 and TSC2) inhibits their GTPase activity, leading to accumulation of GTP Rheb and activation of mTOR. mTOR in turn activates p70 S6kinase and phosphorylates 4E-BP, resulting in its disassociation from eukaryotic initiation factor 4E (eIF4E), and cumulatively stimulating increased protein translation. During times of ATP depletion and AMP accumulation, mTOR activity is inhibited by the AMP activated kinase AMPK. AMPK phosphorylates and activates the TSC complex, thus converting GTP Rheb to GDP Rheb and inactivating mTOR. Activated Akt also phosphorylates and inhibits pro-apoptotic factors such as BAD and caspase 9, and inhibits degradation of intracellular proteins, such as glycogen synthase, by phosphorylating and inhibiting GSK-3β.

mediated by the transport protein GLUT4. In the absence of insulin, GLUT4 is located in intracellular vesicles, but fuses with the plasma membrane following insulin stimulation. This translocation of GLUT4-containing vesicles to the membrane is mediated by $PI_{3,4,5}P_3$-dependent activation of both PKCζ and Akt (reviewed in [238]).

Once glucose enters the cell, it is rapidly sequestered by conversion into glycogen via the actions of the enzyme glycogen synthase. In quiescent cells, the constitutively active form of GSK-3β normally phosphorylates glycogen synthase, keeping it in the inactive state. By stimulating the PI 3-kinase, insulin can increase Akt activation, thereby inhibiting GSK-3β activity and increasing glycogen synthase-dependent incorporation of glucose into glycogen.[239]

EXAMPLES OF SIGNALING EFFECTORS IN THE KIDNEY

The extraordinarily complex interactions that initiate, regulate, and terminate intracellular second messenger pathways, such as those described above, ultimately lead to the change in location, function or amount of effector proteins that actually mediate the cellular response to the initial signal. These effector proteins regulate fundamental cellular events such as division, programmed cell death, migration, and differentiation that are required for the development, maintenance, and repair of all tissues. In the kidney, signaling pathways are also critical for the precise regulation of glomerular filtration and for alteration of tubular cell channel function in response to changes in

the internal milieu. While more detailed descriptions of these regulatory events are presented in the appropriate chapters of this book, examples of several specific effector proteins are presented here in order to provide general paradigms of the ways in which signaling pathways can regulate effector protein function in the kidney.

Angiotensin II Signaling in Glomerular Vascular Smooth Muscle

Maintenance of GFR in the face of falling renal perfusion is achieved by the independent regulation of afferent and efferent vascular tone, which is in part determined by the arteriolar smooth muscle response to locally produced angiotensin II. In the efferent arteriole of the glomerulus, stimulation of smooth muscle contraction by angiotensin II requires the coordinated regulation of both myosin light chain kinase (MLCK) and myosin light chain phosphatase (MLCP, reviewed in [240,241]). Activation of the AT1 receptor on the efferent arteriole results in activation of $G_{\alpha q}$ and the downstream second messenger PLCβ. As noted previously, the hydrolysis of PIP2 by PLCβ results in the formation of DAG and the release of IP_3. In smooth muscle cells, IP3 binds to its receptor on the sarcoplasmic reticulum, stimulating intracellular calcium release, which in turn activates calcium entry from outside the cell. The resultant rise in intracellular calcium leads to calmodulin-dependent activation of MLCK, which in turn phosphorylates and activates the regulatory light chain of smooth muscle myosin II, leading to actin−myosin coupling and muscle contraction.

The phosphorylation sites on myosin II are targets for subsequent dephosphorylation by MLCP (also known as myosin phosphatase). In concert with its activation of MLCK, activation of the AT1 receptor stimulates two pathways that lead to inhibition of MLCP (reviewed in [242]). First, the formation of DAG in the membrane, coupled with the rise in intracellular calcium, leads to recruitment and activation of both conventional and novel PKCs. One of the phosphorylation targets of activated PKC in the smooth muscle cell is CPI-17, and in the phosphorylated state CPI-17 associates with and inhibits MLCP via binding to the PP1Cδ catalytic-subunit.

A second group of proteins phosphorylated by PKC are the matrix metalloproteinases.[243] These proteins are involved in cleaving and shedding cell surface proteins, including the cell attached growth factor HB-EGF. Shedding of HB-EGF leads to activation of the EGF receptor, with stimulation of downstream signaling including the PI 3-kinase. This process of GPCR-dependent activation of a nearby growth factor receptor is termed transactivation. In smooth muscle cells, one target of the activated PI 3-kinase is a Rho GEF named leukemia-associated Rho guanine nucleotide exchange factor (LARG).[244] Activation of LARG converts Rho to the GTP-bound state, mediating its association with Rho kinase. This activation of Rho kinase can inhibit MLCP activity, both by direct phosphorylation of MLCP at an inhibitory site, and via phosphorylation of CPI-17 in conjunction with PKC. By simultaneously increasing the phosphorylation of the light chain of myosin II via activation of MLCK and inhibiting its dephosphorylation via inactivation of MLCP, angiotensin II can greatly augment myosin II coupling with actin and subsequent smooth muscle contraction. In addition to stimulating smooth muscle contraction, sustained angiotensin II-dependent increases in intracellular calcium can lead to calmodulin−calcineurin interactions and subsequent activation of NFAT, which in turn activates the transcription of genes involved in promoting muscle cell hypertrophy (reviewed in [245]) (Figure 13.12).

Regulation of Ion Transport Channels

The regulation of GFR by controlling afferent and efferent vascular tone must be coordinated with appropriate changes in solute reabsorption along the nephron. Typically this regulation occurs in one of three ways: regulation of the amount of the transporter in the cell; regulation of the location of the transporter; or regulation of the active state of the transporter at the membrane. In most cases, more than one of these regulatory steps is utilized, allowing both short- and long-term regulation of transporter function.

Sodium Reabsorption in the Collecting Duct can be Regulated by Controlling Cellular Levels of ENaC

The epithelial sodium channel ENaC is expressed on the apical membrane of principal cells of the collecting duct. Regulation of ENaC function is one of the major ways in which the kidney controls the amount of sodium that is excreted in the urine each day. ENaC is comprised of three subunits that are synthesized in the ER and then transported to the Golgi for proteolytic cleavage and activation, followed by trafficking to the apical membrane. ENaC channels present in the membrane can then be internalized where they are either degraded or maintained in a submembranous pool available for rapid recycling back to the membrane. The principal factors that regulate the synthesis, location, and degradation of ENaC are aldosterone and, to a lesser degree, AVP.

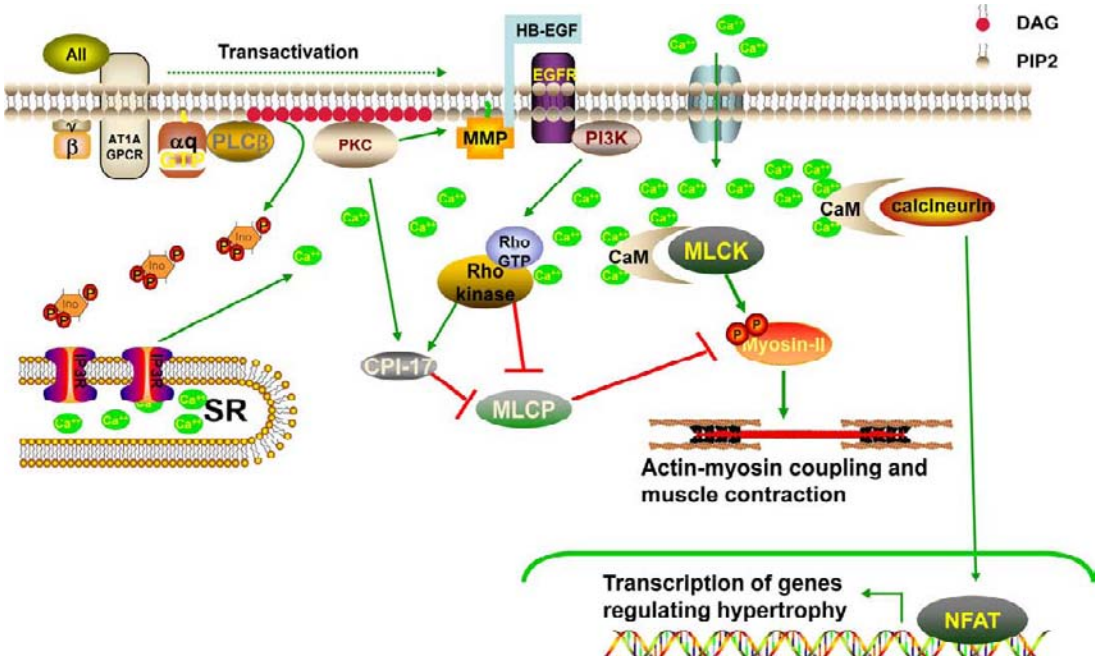

FIGURE 13.12 **Angiotensin II regulation of vascular smooth muscle contraction.** Binding of angiotensin II to the AT1A receptor results in activation of PLCβ, and subsequent generation of IP3 and DAG. DAG production at the membrane can mediate the recruitment and activation of PKC, while IP3 binding to the IP3 receptor in the sarcoplasmic reticulum stimulates calcium release. Angiotensin II may also stimulate extracellular calcium entry via cell surface calcium channels. Binding of the calcium to calmodulin (CaM) results in calmodulin-dependent activation of myosin light chain kinase (MLCK), which phosphorylates myosin II to initiate actin–myosin contraction. Myosin II is dephosphorylated by myosin light chain phosphatase (MLCP) to end the contraction. However, during the period immediately after AT1A stimulation, myosin II phosphorylation is maximized, because MLCP is inhibited by PKC-dependent phosphorylation of the MLCP inhibitory binding protein CPI-17. In addition, GPCR activation can stimulate transactivation of nearby growth factor receptors (such as the EGFR) which in turn can activate the PI 3-K. One mechanism of transactivation is the PKC-dependent activation of matrix metalloproteinases (MMP) which cause shedding of the cell attached protein HB-EGF, which binds and activates the EGFR. The resultant PI 3-K activation mediates GTP loading of the small G-protein Rho, and subsequent activation of Rho kinase. Rho kinase can directly phosphorylate MLCP at an inhibitory site, and can phosphorylate CPI-17 and thus increase its inhibitory effect on MLCP. Sustained contractile stimuli result in the calmodulin-dependent activation of calcineurin. Calcineurin is a phosphatase that binds to and dephosphorylates the nuclear factor of activated T-cells (NFAT), resulting in NFAT-dependent transcriptional regulation of genes involved in smooth muscle cell hypertrophy.

Steroid Hormones such as Aldosterone Bind to Cytoplasmic Receptors and Regulate Nuclear Transcription Events

Aldosterone is a steroid hormone that binds to and activates the mineralocorticoid receptor (MR), which is present in the principal cell, but also in other cell types including intestinal epithelial cells, neuronal cells, and cardiac myocytes. The MR is a member of the steroid/thyroid family of ligand-inducible transcription factors that includes the vitamin D receptor, glucocorticoid receptor, thyroid receptor, and retinoic acid receptor (reviewed in [246]). Unlike the transmembrane receptors discussed in the section "Cell Surface Receptors," these receptors reside in the cytoplasm. The ligand, such as thyroid hormone or aldosterone, can cross the cell membrane, bind the cytosolic receptor, and then translocate as a ligand–receptor complex into the nucleus and bind to specific DNA sequences known as steroid response elements (SRE). In the case of aldosterone, these regulatory sequences are found in the promoter regions of target genes such as *SCNN1A* (the ENaC α-subunit gene) and *SGK-1* (encodes SGK, serum, and glucocorticoid-induced kinase).

In the principal cell, the β- and γ-subunits of ENaC are produced in excess, but do not traffic efficiently to the cell surface until the α-subunit is made (reviewed in [247]). The increase in ENaC α-subunit protein expression that occurs following stimulation with aldosterone leads to ER assembly of αβγ in a complex with the predicted stoichiometry of 2α:β:γ, and its subsequent proteolytic activation in the Golgi. In this manner, aldosterone directly increases the total number of active ENaC transporters available in the cell, leading to an increase in sodium reabsorptive capacity.

A second way in which aldosterone can increase the number of ENaC channels available to reabsorb sodium is by inhibiting ENaC degradation. This is mediated by the transcriptional regulation of SGK expression.[248] SGK is a serine-threonine kinase that phosphorylates and inactivates Nedd4-2, a ubiquitin–protein ligase that can

associate with ENaC and stimulate its internalization and degradation[249] (Figure 13.13). By increasing SGK expression, aldosterone inhibits Nedd4-2-mediated ENaC degradation, and thereby increases the amount of ENaC present on the cell surface. Mutations in ENaC that prevent its association with Nedd4-2 lead to sustained increases in sodium reabsorption due to increased ENaC expression, resulting in the progressive hypertension seen in Liddle's syndrome.[250]

Regulation of Water Reabsorption in the Collecting Duct is Achieved by Trafficking of Aquaporin-2.

The regulation of channel amount by altering rates of synthesis and/or degradation is a relatively slow process that typically takes hours to days to accomplish, and is believed to be most relevant in the adaptive responses to long-standing volume depletion or volume excess. In contrast, regulation of channel location provides a way to rapidly alter channel function in the cell. Aquaporins, transmembrane channels that provide a conduit for water movement across cell membranes, are one of many proteins that can be regulated in this fashion. In the kidney, aquaporin-2 (AQP2) is expressed in cells of the collecting duct, and its ability to mediate water movement is regulated by AVP (reviewed in [251]). In contrast, AQP1 (present in the proximal tubule and thin descending limb[252]) and AQP3 (present on the basolateral side of collecting duct cells[253]) are relatively insensitive to AVP.

In the absence of AVP, AQP2 is present primarily in submembranous vesicles in the collecting duct. Stimulation of V2 receptors by AVP results in the fusion of these vesicles with the apical membrane of the collecting duct cell. Mutations in either the V2

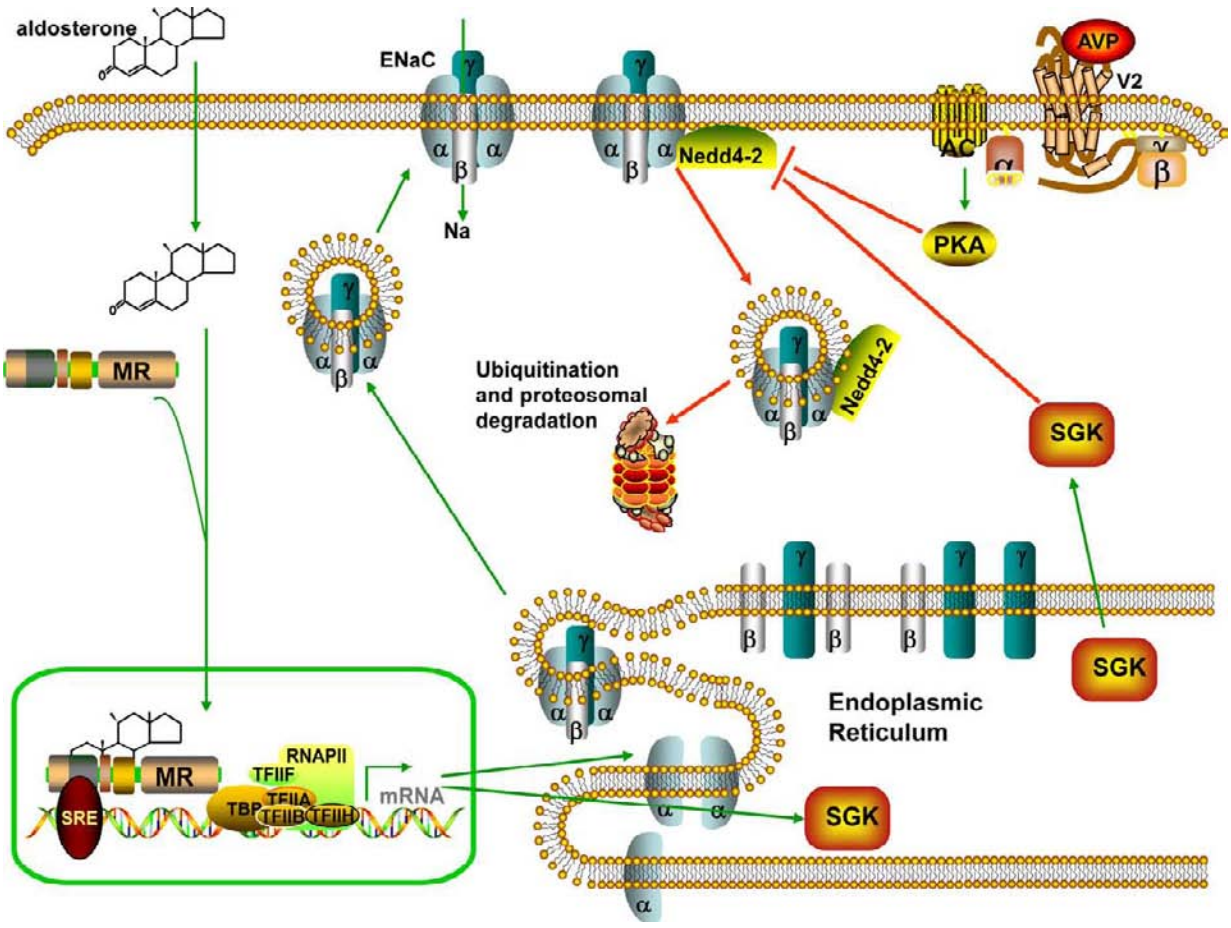

FIGURE 13.13 **Regulation of ENaC.** Aldosterone is a steroid hormone that can cross the cell membrane and bind to the mineralocorticoid receptor (MR) in the cell cytoplasm. The aldosterone–MR complex translocates into the nucleus, where it binds to steroid response elements in genes such as *SCNN1A* encoding the α-subunit of ENaC and *SGK-1* encoding a cytosolic serine threonine kinase. Synthesis of the α-subunit of ENaC promotes formation of the complete ENaC multimer in the ER and its translocation to the cell surface. At the membrane, the ubiquitin ligase Nedd4-2 can bind to ENaC, targeting it for internalization and proteosomal degradation. Nedd4-2 function is inhibited following phosphorylation by SGK, further increasing ENaC expression at the cell membrane, and therefore sodium reabsorptive capacity. Vasopressin (AVP), acting through the V2 GPCR, can also increase collecting duct sodium reabsorption. V2 activation leads to cAMP production and subsequent PKA activation. Like SGK, PKA can phosphorylate and inhibit Nedd4-2.

receptor or AQP2 itself result in nephrogenic diabetes insipidus, due to the failure of the collecting duct to increase water reabsorption in response to AVP. The translocation of AQP2 vesicles to the cell membrane is dependent on AVP-stimulated production of cAMP, and the subsequent activation of PKA. Activated PKA is targeted to AQP2-containing vesicles via association with A kinase anchoring proteins (AKAPs). AKAPs comprise a large family of proteins that localize activated PKA to specific sites within the cell, thus providing specificity and compartmentalization of PKA signaling. AKAP18δ, PKA, and AQP2 can be co-purified from vesicles isolated from the cytosol of inner medullary collecting duct cells, suggesting that this AKAP may be important for facilitating the recruitment of PKA to AQP2-containing vesicles.[254]

Activated PKA directly phosphorylates serine 256 in the carboxy terminus of AQP2, stimulating membrane translocation of the AQP2-containing vesicles.[255] How phosphorylation of serine-256 in AQP2 mediates vesicle fusion with the membrane is not yet fully-understood (reviewed in [256]). Based on present studies, it appears that membrane targeting involves the actin cytoskeletal-dependent association of SNARE proteins (such as syntaxin-3 and -4) on the AQP2-containing vesicles with SNAP23 at the cell membrane.[257,258]

The vesicles that mediate AQP2 translocation to the membrane also carry signals for downregulation of the pathway. Recently it has been found that these vesicles contain cAMP-specific phosphodiesterase-4D (PDE4D), an enzyme that can degrade cAMP, leading to inactivation of PKA.[259] In the presence of the AKAP18δ scaffold, PKA can phosphorylate and activate PDE4D, leading to decreased cAMP, loss of PKA activation, and prevention of AQP2 phosphorylation and translocation. In addition, the serine-threonine phosphatase PP2B is present in these vesicles, and is capable of dephosphorylating AQP2, thereby potentially inhibiting channel translocation.[260]

AQP2 function can be regulated by mechanisms in addition to membrane trafficking. In the setting of continuous stimulation by AVP, total cellular levels of AQP2 message and protein increase, demonstrating that AVP can induce transcription of the AQP2 gene. *In vitro* experiments have suggested that this is due to transcriptional activation of AQP2 mRNA expression via a cyclic AMP response element (CRE) in the AQP2 promotor.[261] Activation of multiple intracellular serine-threonine kinases, including PKA, can stimulate phosphorylation and activation of the CRE-binding protein (CREB), which in turn binds CRE and activates transcription of the appropriate target gene, in this case AQP2. Sustained exposure to hypertonicity can also increase AQP2 mRNA expression in cultured collecting duct cells, independent of AVP-mediated PKA activation.[262]

In addition to its ability to regulate AQP2-mediated water absorption, AVP has been shown to regulate ENaC-mediated salt absorption (see Figure 13.13). Nedd4-2, the ubiquitin ligase that is inactivated by SGK-mediated phosphorylation, can be phosphorylated at the same sites by AVP-activated PKA, leading to inhibition of the Nedd4-2/ENaC association and increased ENaC protein stability.[263] In addition, the cAMP-stimulated activation of PKA by AVP can promote the translocation of ENaC from a pool of internalized channels to the membrane, similar to its effects on AQP2.[264,265] The increase in ENaC surface expression resulting from these signaling events is believed to partially mediate the observed increase in sodium reabsorption following AVP treatment[266] (reviewed in [267]).

Transporters such as ROMK can be Regulated by Changes in their Active State

A third way in which transporters can be regulated is via alteration of the active state of the protein. For membrane channels this typically means a change in the open probability (P_o) of the channel (the time that the channel spends in the open configuration). ROMK (also known as Kir1.1) is an apical membrane potassium channel in thick ascending limb cells and principal cells that is required for potassium recycling in the TAL, and potassium secretion in the collecting duct (reviewed in [268]). One of the major determinants of P_o for ROMK is the concentration of PIP_2 in the membrane in the vicinity of the channel, an effect that appears to be due to an extensive series of interactions between the basic amino acids in the carboxy terminus of ROMK and the negatively charged head groups of the membrane phospholipids (reviewed in [269]). PIP_2 is produced by lipid kinases such as the $PI(4)P_5$ kinase, and degraded by phospholipases such as PLA_2 and PLC (reviewed in [270,271]). Thus, it is speculated that signals that enhance PIP_2 production or inhibit its degradation will increase ROMK activity at the membrane, whereas pathways that reduce PIP_2 levels, such as activation of PKC, will inhibit its activity.

Alterations in the P_o for ROMK have also been found to be due to direct phosphorylation of the channel by PKA (reviewed in [269]). *In vitro* studies have demonstrated three PKA phosphorylation sites in ROMK, and phosphorylation of two of those sites (serine 219 and 313) causes an increase in P_o for the channel, without changing the number of channels at the membrane. As with other PKA effectors, the presence of the appropriate AKAP is required to target activated PKA to ROMK at the membrane. Although the precise mechanism by which PKA phosphorylation regulates P_o in ROMK has yet to be determined, it appears that at least part of the effect is due to an increased affinity of ROMK for PIP_2, thus reducing the concentration of PIP_2 needed to

support the channel in the open state.[272] Based on these studies, it is presently believed that the AVP-stimulated increase in thick ascending limb potassium recycling is due to V2-dependent activation of PKA, and subsequent phosphorylation and activation of ROMK.[273]

Similar to the regulation of aquaporin-2 and ENaC, ROMK can also be regulated by altering channel location or synthesis. Several kinases have been implicated in regulating the trafficking of ROMK, including PKA, SGK, and a recently described kinase WNK (with no K (lysine)). As noted above, there are three PKA phosphorylation sites on ROMK. While two of the sites directly regulate channel open probability, phosphorylation of the third residue (serine 44) increases the number of channels present on the cell membrane. In addition to PKA, SGK can phosphorylate ROMK on serine 44 and increase channel activity in the oocyte expression system.[274] This appears to occur in concert with a scaffolding protein, NHERF2, which increases trafficking of ROMK to the membrane via its interaction with the carboxy terminal PDZ-binding motif.[275] Thus, the increased expression of SGK following aldosterone stimulation can lead to sustained increases in ROMK-dependent potassium excretion via increased numbers of channels on the cell membrane.

Recently, another family of serine/threonine kinases, the WNKs, have been found to play an important role in regulating the activity of diverse ion channels in the kidney (reviewed in [276]). To date there have been four WNK kinases described in humans, all sharing the unusual substitution of a cysteine residue for the more typical lysine in β strand 3 of the kinase domain.[277] Of these four, WNK1, WNK3, and WNK4 have been directly implicated in regulation of tubular ion transport, including the sodium-potassium-chloride co-transporter in the TAL (NKCC2), the sodium-chloride co-transporter in the distal convoluted tubule (NCC), ROMK, EnaC, and the tight junctional proteins claudin1-4 that regulate paracellular chloride flux,([278–280] reviewed in [281]). Mutations of WNK1 and WNK4 have been shown to cause pseudohypoaldosteronism II (PHAII), a syndrome consisting of hypertension with increased sodium reabsorption and hyperkalemia.[282]

The mechanisms by which WNKs regulate ROMK and NCC depend on distinct aspects of WNK function. Mutations in WNK1 and WNK4 that cause PHAII result in decreased ROMK at the membrane, and therefore hyperkalemia due to decreased K secretion.[280,283] It has been shown that ROMK associates with a complex including WNK1, WNK4, and the scaffolding protein intersectin, and that intersectin is required for the endocytosis of ROMK in clathrin-coated vesicles.[284] The formation of this complex is independent of WNK kinase activity, and instead requires the association of proline-rich regions of WNK1 and WNK4 with the SH3 domain of intersectin. Mutations in WNK4 that cause PHAII appear to increase the association of the ROMK−WNK1−WNK4 complex with intersectin, thereby augmenting ROMK internalization and impairing potassium secretion.[285]

WNK kinases regulate sodium uptake by determining both the surface availability and activation state of NCC. This process is complex and not yet fully elucidated, but appears to involve a balance between WNK4-dependent degradation of NCC and WNK1-dependent activation of NCC that is present on the cell surface (reviewed in [276]). In the presence of active WNK4, newly synthesized NCC is targeted via sortilin for lysosomal degradation rather than cell surface expression, thus reducing the pool of NCC available for sodium transport.[286,287] In contrast, WNK1 and WNK3 activate the sodium transport function of NCC that is on the cell surface by phosphorylating the intracellular kinase SPAK, which then phosphorylates and activates NCC. A second phosphorylation target of WNK3 is WNK4 itself, resulting in inhibition of the WNK4-mediated NCC degradation, and thus increasing NCC surface expression. Mutations in WNK4 that cause PHAII result in increased sodium reabsorption at least in part due to increased NCC on the cell surface.[288]
