As reported above, studies performed in mice models clearly indicated that the bulk of the renal reabsorption of Pi in adults can be attributed to NaPi-IIa, whereas the contribution of NaPi-IIc is by far quantitatively smaller. However, in 2006 three independent groups reported an unexpected association between mutations on NaPi-IIc with hypophosphatemic rickets with hypercalciuria (HHRH) in humans[21,187,193] (Table 68.1). This association has been strengthened by more recent publications describing additional mutations on NaPi-IIc in patients affected by HHRH. Although mutations on NaPi-IIa were identified in patients with nephrolithiasis and osteoporosis, their implication on the development of hypophosphatemia in humans is controversial.[68,157] A recent report described inactivating mutations of NaPi-IIa in patients with autosomal recessive Fanconi syndrome and hypophosphatemic rickets (ARFS)[148] (Table 68.1).

Mutations of FGF23

In the last years it has become clear that FGF23 and its co-receptor Klotho are major regulators of Pi homeostasis. Mutations in FGF23 were identified as the cause for autosomal dominant hypophosphatemic rickets (ADHR)[7,42,168] (Table 68.1). FGF23 is inactivated by proteolytic cleavage at a conserved site (RXXR). Mutations resulting in ADRH affect the two arginine located within the proteolytic site. Substitution of either arginine prevents the degradation of FGF23, thus resulting in elevated levels of intact FGF23 in plasma, which despite the mutation retains its phosphaturic effect.[190] Transgenic mice expressing proteolytic resistant FGF23, or animals in which the mutated FGF23 was incorporated by injection of naked DNA, recapitulate the phenotype of ADHR.[33,175] These studies showed that the hypophosphatemia is due to hyperphosphaturia caused by FGF23-induced downregulation NaPi-IIa and NaPi-IIc.

Mutations on FGF23 resulting in low circulating levels of the intact protein have been described in patients with familial tumoral calcinosis with hyperphosphatemia (FTC)[41] (Table 68.1). These mutations lead either to intracellular retention or reduced

TABLE 68.1 Genetic Alterations Leading to Imbalance of Pi Homeostasis

Syndrom	Gene	Serum Pi	PTH	1,25(OH)2-VD	FGF23
HHRH	SLC34A3	Low	Low	High	Normal-low
ARFS and HR	SLC34A1	Low	Normal	Low	Normal
Nephrolitiasis osteoporosis	SLC34A1	Low	Normal	High	
ADHR	FGF23 (gain)	Low	Normal	Inappropiately normal	High
FTC	FGF23 (loss)	High	Normal-low	Normal	Low
FTC	Klotho (loss)	High	High	High	High
HRH	Klotho (gain)	Low	High	Normal	High
XLH	PHEX	Low	Normal	Inappropiately normal	High
ARHR	DMP1	Low	Normal	Inappropiately normal	High
TIO		Low			High
FD/MAS	GNAS	Low			High
FTC	GALNT3	High	Low	Inappropiately normal	Low

Mutations on the genes encoding transporters (SLC34A1 and SLC34A3) or regulatory proteins (FGF23, Klotho, PHEX, DMP1, GNAS or GALNT3) have been reported in patients with different hypophosphatemic syndromes. HHRH: hypophosphatemic rickets with hypercalciuria; ARFS and HR: autosomal recessive Fanconi syndrome and hypophosphatemic rickets; ADHR: autosomal dominant hypophosphatemic rickets; FTC: familial tumoral calcinosis with hyperphosphatemia; HRH: hypophosphatemic rickets and hyperparathyroidism; XLH: X-linked hypophosphatemia; ARHR: autosomal recessive hypophosphatemic rickets; TIO: tumor-induced osteomalacia; FD/MAS: fibrous dysplasia/McCune-Albright syndrome.

proteolytic stabilty of FGF23. In agreement with the human data, FGF23 deficient mice have increased expression of NaPi-IIa and severe hyperphosphatemia.[108,128]

Mutations of Klotho

A mutation in Klotho was found in a patient with FCT who presented hyperphosphatemia despite elevated FGF23[136] (Table 68.1). The mutated Klotho is proposed to have a reduced expression at the plasma membrane, thus preventing the FGF23 phosphaturic effect. An interchromosomal translocation resulting in increased levels of Klotho was reported in a patient with hypophosphatemic rickets and hyperparathyroidism[181] (Table 68.1). Surprisingly, FGF23 was also elevated explaining the hypophosphatemic status.

Hypophosphatemic Syndromes Related to Elevated FGF23

Elevated FGF23 has been reported in several other hypophosphatemic syndromes with clinical features similar to those of ADHR, including X-linked hypophosphatemia (XHL), autosomal recessive hypophosphatemic rickets (ARHR), tumor-induced osteomalacia (TIO) and fibrous dysplasia/McCune-Albright syndrome (FD/MAS) (for review see [168]) (Table 68.1). However, the primary cause of all these pathologies affects genes other than FGF23 itself.

XLH, or familial vitamin D resistant rickets, is caused by mutations in the phosphate regulating gene with homology to endopeptidases on the X-chromosome (PHEX).[183] This gene encodes a metalloprotease produced in the bone. The high levels of FGF23 found in patients with XLH,[83] led to the proposal of FGF23 being a substrate of PHEX. Although this direct connection remains controversial, the hypophosphatemia in Phex-deficient mice (Hyp mice)[185] is corrected by ablation of FGF23, supporting the notion that FGF23 acts downstream of PHEX.[108]

ARHR is caused by mutations in the dentin matrix acidic phosphoprotein 1 (DMP1), a protein highly expressed in bone.[186,188] The phenotype of Dmp1-deficient mice is also reverted by ablation of FGF23, suggesting that the hypophosphatemia is attributable to the high circulating FGF23.[158]

TIO, also known as oncogenic osteomalacia, is an acquired hypophosphatemic disorder characterized by tumors. It was recognized early on that these tumors express a factor able to inhibit Pi transport when applied to renal proximal cells in culture and to induce phosphaturia in mice.[189] Indeed, there were these findings what led to the proposal of a circulating factor/s (phosphatonins) controlling renal excretion of Pi. Later on it was found that the concentration of FGF-23 is high in TIO patients and that surgical removal of tumors corrects renal Pi wasting and restores FGF23 levels.[83,129,191] The molecular mechanism underlying

the increased production of FGF23 in these tumors remains unknown. Several other proteins are highly expressed by tumoral tissues, including DMP1, FGF7, sFRP4, and MEPE (for review see [134]).

FD/MAS, are rare diseases that result from activating mutations on the α subunit of stimulatory G-protein (GNAS). Both syndromes can present with hypophosphatemia due to elevated expression of FGF23.

Hyperphosphatemic Syndromes Related to Reduced FGF23

In addition to mutations on FGF23 or Klotho, FTC caused by reduced FGF23 also associates with mutations in GALNT3.[107] GALNT3 is a glycosyl transferase that glycosylates FGF23 within the proteolytic site, rendering it more resistant to the proteolytic processing. Patients with GALNT3 mutations and Galnt3-deficient mice are hyperphosphatemic, had increased FGF23 expression in bone but low circulating levels of intact peptide.[107,180]

Clinical Disturbances of Phosphate Homeostasis

Theresa J. Berndt and Rajiv Kumar

Mayo Clinic, Rochester, Minnesota, USA

THE IMPORTANCE OF PHOSPHORUS IN BIOLOGICAL SYSTEMS

Phosphorus is the sixth most abundant element in the body and is essential for energy-consuming metabolic processes of cells. Approximately 85% of phosphate in the body is present in bones, 14% in cells from soft tissues, and 1% in extracellular fluids.[1] Phosphorus plays an important role in a number of biological processes, and is an exceptionally important component of hy droxyapatite, the major component of bone mineral.[2] In addition, phosphorus is present in nucleic acids, bioactive signaling proteins, phosphorylated enzymes, and cell membranes.[3–6] A prolonged deficiency of phosphorus and inorganic phosphate results in serious biological problems, including bone mineralization resulting in osteomalacia or rickets, abnormal erythrocyte, leukocyte and platelet function, impaired cell membrane integrity that can result in rhabdomyolysis, and impaired cardiac function.[7] Therefore, the maintenance of appropriate phosphorus homeostasis is critical for the well-being of the organism.

THE REGULATION OF PHOSPHATE BALANCE

Phosphorus exists in plasma almost entirely as inorganic phosphate.[1,7,8] The adult animal or human maintains phosphate balance through a series of complex hormonally and locally regulated metabolic adjustments. In states of neutral phosphate balance, net accretion equals net output. The major organs involved in the absorption, excretion, and reabsorption of phosphate are the intestine and the kidney (Fig. 69.1).[9,10] Furthermore, the movement of phosphorus between the extracellular fluid and bone and soft tissue also plays an important role in the maintenance of normal serum phosphate concentrations. A normal diet adequate in phosphorus normally contains $\approx$1500 mg of phosphorus. Approximately 1100 mg of ingested dietary phosphate is absorbed in the proximal intestine, predominantly in the jejunum. About 200 mg of phosphorus is secreted into the intestine via pancreatic and intestinal secretions, giving a net phosphorus absorption of approximately 900 mg/24 hours. Phosphorus that is not absorbed in the intestine or is secreted into the intestinal lumen eventually appears in the feces. Absorbed phosphorus enters the extracellular fluid pool and moves in and out of bone (and to a smaller extent in and out of soft tissues) as needed ($\approx$200 mg). Approximately 900 mg of phosphorus (equivalent to the amount absorbed in the intestine) is excreted in the urine.

A number of hormones such as parathyroid hormone (PTH) and $1\alpha,25(OH)_2D_3$ are involved in the control of phosphorus metabolism.[11] Concentrations of these hormones are regulated by phosphorus in a manner that is conducive to the maintenance of normal phosphate. Other peptide factors and hormones, such as growth hormone and insulin-like growth factor 1, alter phosphorus balance, although their circulating concentrations are not directly controlled by ambient phosphorus concentrations. The "phosphatonins," fibroblast growth factor 23 (FGF-23), and secreted frizzled related protein-4 (sFRP-4) that induce a state of negative phosphate balance directly by inhibiting renal phosphate reabsorption in the proximal tubule and indirectly by inhibiting the synthesis of $1\alpha,25(OH)_2D_3$

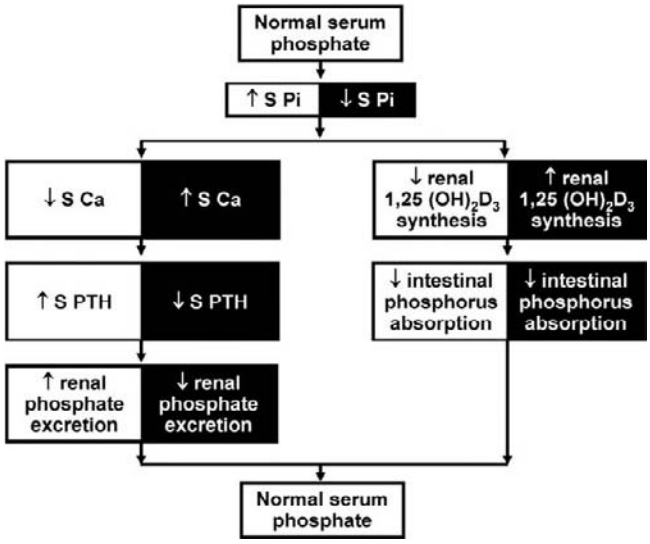

FIGURE 69.2 **Influence of phosphatate (Pi) on parathyroid hormone (PTH) and vitamin D synthesis and activity.** *(From Schiavi SC, Kumar R. The phosphatonin pathway: new insights in phosphate homeostasis. Kidney Int 2004;65:1–14, with permission.)*

and reducing the intestinal absorption of phosphorus, also play a key role in the regulation of phosphate balance.[12–16] Two factors, fibroblast growth factor 7 (FGF-7) and matrix extracellular phosphoglycoprotein (MEPE), have been shown to inhibit phosphate transport in renal epithelial cells in culture and, in the case of matrix extracellular phosphorus glycoprotein, to induce phosphaturia in mice.[17,18] FGF7 and MEPE, however, have not been demonstrated to prevent compensatory increases in serum $1\alpha,25(OH)_2D_3$ concentrations seen in hypophosphatemic states or to directly inhibit 25-hydroxyvitamin D 1α-hydroxylase activity.

Parathyroid hormone, by virtue of its phosphaturic effect in the kidney, decreases overall phosphate retention, whereas $1\alpha,25(OH)_2D_3$ increases phosphate retention by enhancing the efficiency of phosphorus absorption in the intestine and in the kidney.[19–31] It should be noted that parathyroid hormone has two opposing effects. As noted previously, parathyroid hormone increases urinary phosphate excretion. At the same time, it also increases the synthesis of $1\alpha,25(OH)_2D_3$ by stimulating the activity of the 1α-hydroxylase enzyme in the kidney. In turn, $1\alpha,25(OH)_2D_3$ increases the efficiency of phosphorus absorption in the intestine and kidney.[28–30,32–35] The phosphatonins, in contrast, increase renal phosphate excretion and inhibit 25-hydroxyvitamin D 1α-hydroxylase activity, thereby further decreasing the retention of phosphorus.[12,15,36,37]

Figure 69.2 shows the physiological changes known to occur with low or high dietary intakes of phosphate. A decrease in serum phosphate concentrations results in increased ionized calcium concentrations, decreased parathyroid hormone secretion, and a subsequent decrease in renal phosphate excretion. At the same time, by parathyroid hormone-independent mechanisms, there is an increase in renal 25-hydroxyvitamin D 1α-hydroxylase activity, increased $1\alpha,25(OH)_2D_3$ synthesis, and increased phosphorus absorption in the intestine and reabsorption in the kidney.[20–31,35,38] Conversely, with elevated phosphate intake, there are decreased calcium concentrations, increased parathyroid hormone release from the parathyroid gland, and increased renal phosphate excretion. Increased serum phosphate concentrations inhibit renal 25-hydroxyvitamin D 1α-hydroxylase and decrease $1\alpha,25(OH)_2D_3$ synthesis. Reduced $1\alpha,25(OH)_2D_3$ concentrations decrease intestinal phosphorus absorption as well as renal phosphate reabsorption. All of these factors tend to bring serum phosphate concentrations back into the normal range.

THE PHYSIOLOGY OF PHOSPHATE IN THE KIDNEY

In conditions of phosphate deprivation, the kidney rapidly increases tubular phosphate reabsorption and reduces urinary phosphate excretion to negligible levels in order to preserve phosphate balance.[39,40,42–56] In infants and children, phosphate reabsorption is high so as to maintain a positive phosphate balance required for growth.[57–59] Conversely, decreased phosphate reabsorption has been demonstrated in the elderly.[60–63] Phosphate is freely filtered at the glomerulus. Under conditions of normal dietary phosphate intake, and in the presence of intact parathyroid glands, approximately 20% of the filtered phosphate load is excreted.

The other 80% of the filtered load of phosphate is reabsorbed by the renal tubules.

The proximal tubules are the major sites of phosphate reabsorption along the nephron. There is little phosphate reabsorption between the late proximal tubule and the early distal tubule in animals with intact parathyroid glands.[44,64–71] However, in the absence of parathyroid hormone, phosphate is avidly reabsorbed between the late proximal tubule and early distal tubule, reflecting phosphate reabsorption by the proximal straight tubule (Fig. 69.3).[66] Phosphate transport rates are approximately three times higher in the proximal convoluted than in the proximal straight tubules.[72] Renal phosphate handling is characterized by intranephronal heterogeneity, reflecting segmental differences in phosphate handling within an individual nephron as well as internephronal heterogeneity.[44,67,72,73]

The uptake of phosphate is mediated by sodium-phosphate cotransporters that are located at the apical border of proximal tubule cells (NaPi IIa and NaPi IIc).[74–97] The structure and physiology of these phosphate transport molecules have been extensively reviewed, and the reader is directed to other publications in this regard.[82–90] The sodium-phosphate cotransporters are highly homologous and are predicted to have similar structures. Mice with ablation of the NaPi IIa gene exhibit renal phosphate wasting, and it is estimated that the NaPi IIa transporter is responsible for approximately 85% of proximal tubular phosphate transport which contributes to the adaptive increase in tubular phosphate transport in animals fed a low-phosphate diet (Fig. 69.4).[98,99]

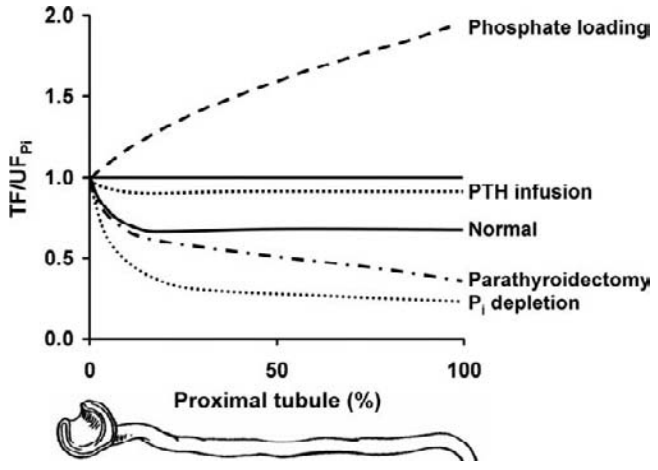

FIGURE 69.3 The generation of tubule fluid/ultrafiltrate phosphate (UFPi) ratios below 1.0 along the proximal convoluted tubule is due to more avid reabsorption of phosphate than isotonic fluid for most circumstances. Diet and parathyroid hormone are the major factors that affect phosphate transport. *(From Berndt T, Knox F. Renal regulation of phosphate excretion. In: Seldin DAG (ed.). The Kidney: Physiology and Pathophysiology. New York: Raven Press, 1992:2511–2532, with permission.)*

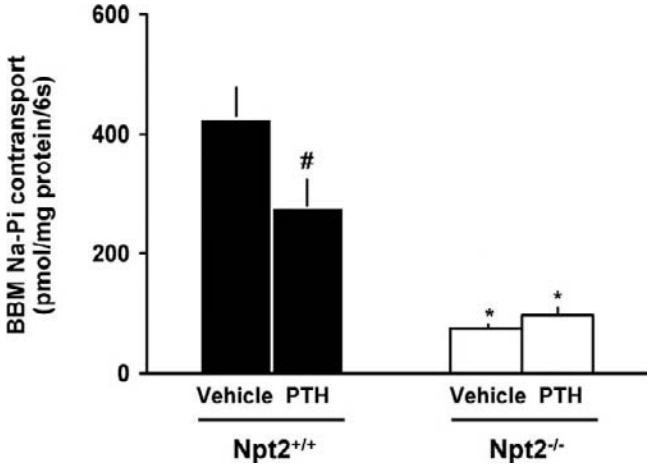

FIGURE 69.4 Effect of parathyroid hormone (PTH) on brush border membrane Na-Pi cotransport in Npt2 +/+ and Npt2 −/− mice. Anesthetized mice were injected with vehicle or PTH (10 μg/100 g BW) and killed 2 hours later. Renal brush border membranes vesicles were prepared from kidney cortex, and transport of Pi was assayed. Effect of PTH in Npt2 + / + mice, $p < 0001$; affect of genotype in PTH-treated mice, $p < 0041$. *(From Zhao N, Tenenhouse HS. Npt2 gene disruption confers resistance to the inhibitory action of parathyroid hormone on renal sodium-phosphate cotransport. Endocrinology 2000;141:2159–2165, with permission).*

FACTORS REGULATING RENAL PHOSPHATE EXCRETION

Dietary Phosphate and Renal Phosphate Reabsorption

The influence of dietary phosphate intake on the urinary excretion of phosphate has been known for many years.[40–56,100] The reabsorption of phosphate is decreased in animals fed a high-phosphate diet, whereas animals with a low intake of phosphate reabsorb almost 100% of the filtered load of phosphate. These changes in phosphate reabsorption are associated with parallel changes in the abundance of NaPi IIa and IIc transporters.[101,102] The dietary intake of phosphate can differ considerably depending on the ingestion of foods containing varying amounts of phosphate.

Although dietary phosphate deprivation results in marked changes in the plasma concentrations of several hormones (Fig. 69.2) that contribute to the increases in phosphate reabsorption, the enhanced tubular reabsorption can also be demonstrated independent of changes in these hormones.[103–106] The mechanism of upregulation of Na/Pi cotransport in OK cells by low-Pi media involves two regulatory mechanisms: an

immediate (early) increase (after two hours) in the expression of Na/Pi cotransporter, independent of mRNA synthesis or stability, and a delayed (late) effect (after 4–6 hours), resulting in an increase in NaPi-4 mRNA abundance (Fig. 69.5).[105,107] Although the changes in phosphate reabsorption in response to a low- or high-phosphate meal are demonstrable within two hours, there are not always concomitant alterations in plasma phosphate concentrations. Thus, the sensing mechanism that initiates the renal adaptations in phosphate reabsorption to the changes in phosphate intake is speculative. The enhanced phosphate reabsorption of short-term phosphate deprivation has been linked to decreased intrarenal synthesis of dopamine and/or stimulation of beta adrenoreceptors, since infusion of dopamine or propranolol restores the phosphaturic response to PTH in short-term (less than three days) phosphate deprivation.[108–110] The concept of central control of phosphate homeostasis was suggested since decreased dietary phosphate intake upregulated the NaPi IIa expression in the brain and increased phosphate intake downregulated the expression of NaPi IIa in the brain.[111] In this study, increasing cerebrospinal fluid phosphate concentrations in the presence of low plasma phosphate concentrations reversed the adaptations to feeding a low-phosphate diet, suggesting that the phosphate concentration in the brain regulates not only central but also renal expression of NaPi IIa transporters. Studies using cultured renal proximal tubular cells provide persuasive evidence of an intrinsic ability of these cultured cells to increase phosphate transport when exposed to a low phosphate concentration in the medium.[103–106] In addition to the factors that play a role in enhancing or decreasing phosphate reabsorption in the proximal nephron in response to changes in dietary phosphate noted previously, it should be remembered that alterations in serum phosphate concentrations also alter $1\alpha,25(OH)_2D_3$ synthesis and serum concentrations.[45,112–115] Infusions of $1\alpha,25(OH)_2D_3$ increase the renal reabsorption phosphate, predominantly in the proximal nephron.[20–27,31] Since the proximal tubule is a major site of phosphate reabsorption, it is the primary site for the tubular adaptation to changes in dietary phosphate intake. The enhanced phosphate reabsorption along the nephron during phosphate deprivation in specific nephron subsegments is dependent on the length and severity of phosphate deprivation.

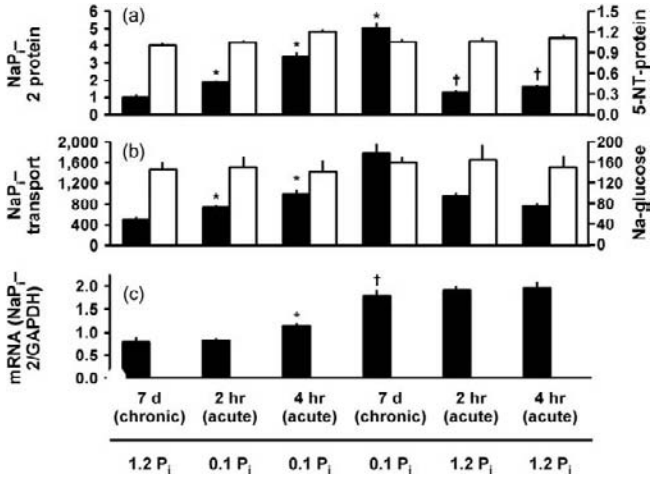

FIGURE 69.5 Pi-deprivation dependent alterations in (A) rat type II transporter (NaPi-2) protein content, (B) rat brush border membrane Na/Pi cotransport activity, and (C) specific rat type II transporter mRNA content (NaPi-2). Rats were fed for 7 days with a diet containing high Pi (1.2 Pi) and were exposed for different time periods to low Pi (0.1 Pi). Rats chronically adapted to low Pi have been re-fed with high Pi for two or four hours. A: Black small square, Na/Pi transport; white square, 5-NT-protein. Renal brush border membrane Na/Pi-cotransport: molecular aspects in PTH-dependent and dietary regulation. Kidney Int 1996;49:1769–1773, with permission.)*

Parathyroid Hormone and Renal Phosphate Reabsorption

Plasma-ionized calcium levels are a critical determinant of PTH secretion. A fall in plasma-ionized calcium increases PTH secretion and an elevation of plasma-ionized calcium above normal levels decreases PTH secretion. Parathyroidectomy decreases renal phosphate excretion and, conversely, injection of PTH increases urinary phosphate excretion.[116–120] Micropuncture studies show that PTH decreases and parathyroidectomy increases phosphate reabsorption along the proximal tubule (Fig. 69.3).[65–69,121] The proximal straight tubule is an important site of PTH modulation of phosphate transport and may be critical in the final regulation of phosphate excretion.[64,70,73,122] Parathyroid hormone maintains phosphate homeostasis as a result of its regulation of the sodium phosphate cotransporters in the kidney. Renal sodium-phosphate cotransporters are reduced in number along the apical borders of proximal tubular cells following the administration of parathyroid hormone 1 through 34 but not by the administration of parathyroid hormone 3 through 34.[94,95] The renal sodium-phosphate cotransporters NaPi IIa have been shown to be internalized and degraded within the lysosomes.[84,89,123,124] Disruption of the NaPi IIa gene in mice resulted in increased excretion of phosphate compared to wildtype mice and a resistance to the phosphaturic response to PTH, although the cyclic adenosine monophosphate

(cAMP) response is normal (Fig. 69.4).[125] Under conditions where the phosphaturic effect of PTH is blunted or absent, such as short-term phosphate deprivation or acute respiratory alkalosis, the inhibitory effect of PTH on phosphate reabsorption by the proximal convoluted tubule remains intact. However, this increased delivery of phosphate is blunted by enhanced reabsorption by the proximal straight tubule.[73,122,70] These studies suggest that the regulation of phosphate reabsorption by PTH in the proximal convoluted and proximal straight tubule subsegments may be mediated by different mechanisms. It should be noted that parathyroid hormone has two opposing effects. As noted previously, parathyroid hormone increases urinary phosphate excretion. At the same time, it also increases the synthesis of $1\alpha,25(OH)_2D_3$ by stimulating the activity of the 25-hydroxyvitamin D_3 1α-hydroxylase enzyme in the kidney.[126–128]

Vitamin D and Renal Phosphate Reabsorption

A complex interrelationship exists between vitamin D and PTH. Both hormones play important roles in calcium and phosphate regulation.[129–134] Decreases in plasma ionized calcium levels increase PTH levels and PTH also stimulates the renal conversion of $25(OH)_2D_3$ to $1,25(OH)_2D_3$ by the 25-hydroxyvitamin D_3 1α-hydroxylase located in the proximal tubule of the kidney.[126–128,135–137] Dietary phosphate deprivation or hypophosphatemia induces 25-hydroxyvitamin D_3 1α-hydroxylase.[34,112–115,138] Mice or rats, but not pigs, fed a low-phosphate diet show a decrease in the activity of the 25-hydroxyvitamin D_3 24-hydroxylase (a renal enzyme involved in the catabolism of $1,25(OH)_2D_3$) compared with rats fed a normal phosphate diet within 24 hours of phosphate restriction.[139–141] Vitamin D modestly decreases renal phosphate excretion, and its primary effect is to enhance phosphate transport in the intestine.[20–27,31] Vitamin D receptor (VDR)-mutant mice exhibit decreased serum phosphate, however, phosphate transport by renal cortical brush border membranes, phosphate excretion or NaPi IIa or NaPi IIc mRNA levels were not different between VDR-null or wildtype mice, while NaPi IIa protein expression and NaPi IIa cotransporter immunoreactive signals were slightly but significantly decreased in the $VDR^{-/-}$ mice compared with the wildtype mice.[102] When VDR knockout mice were fed a low-phosphate diet, serum phosphate concentrations were more markedly decreased in the VDR knockout mice than in the wildtype mice. Other studies performed in vitamin D receptor and 25-hydroxyvitamin D 1α-hydroxylase null mutant mice show that both these knockout mice adapt to phosphate deprivation with increased NaPi IIa protein in a manner similar to that found in wildtype mice.[142] However, when these mice were fed a high-phosphate diet, phosphate excretion was less in the vitamin D receptor and 25-hydroxyvitamin D 1α-hydroxylase null mutant mice compared to the wildtype mice. In vitamin D-deprived rats, NaPi IIa transporter protein and mRNA were reported to be decreased in juxtamedullary but not superficial renal cortical tubules compared with normal rats.[143]

Insulin, Growth Hormone, Insulin-Like Growth Factor, and Renal Phosphate Reabsorption

Insulin decreases plasma phosphate and phosphate excretion in human and animal models.[144–148] This enhanced renal phosphate reabsorption can be demonstrated in the absence of changes in blood glucose, PTH, and phosphate levels or urinary sodium excretion. Initial micropuncture studies by DeFronzo et al.[145] demonstrate enhanced phosphate reabsorption in hyperinsulinemic dogs. Conversely, somatostatin infusion decreases plasma insulin levels and increases phosphate excretion.[149] Growth hormone decreases phosphate excretion and has been postulated to contribute to increased phosphate reabsorption and positive phosphate balance demonstrated in growing animals.[60,61] Administration of a growth hormone antagonist for 4 days to immature rats suppressed growth in these rats and was associated with increased phosphate excretion and a decreased transport capacity for phosphate reabsorption.[150,151] Subsequent studies performed in juvenile rats in which growth hormone was suppressed showed increase phosphate excretion to levels comparable to adult rats as a result of decreased NaPi IIa expression, demonstrating the important role for growth hormone in the enhanced phosphate reabsorption in developing animals.[152] Hammerman et al.[153] demonstrated that growth hormone administration increased phosphate uptake by brush border membrane vesicles prepared from kidneys of adult dogs. These effects of growth hormone on phosphate reabsorption may also be due to insulin-like growth factor-1 (IGF-1).[154–161] Growth hormone stimulates the renal synthesis and release of IGF-1.[154] The addition of IGF-1 to cultured renal opossum kidney cells stimulates sodium-dependent phosphate transport.[157] A selective increase in sodium-dependent phosphate uptake was detectable after 15 minutes and is maximal at five hours. Chronic administration of IGF-1 infused by osmotic mini-pump for six days significantly increased the maximal tubular reabsorption of phosphate in the presence and absence of PTH and enhanced phosphate transport by renal brush border membranes.[158]

Renal Nerves, Catecholamines, Dopamine, and Serotonin

Acute renal denervation increases urinary phosphate excretion independent of parathyroid hormone.[109,162–166] Numerous studies have demonstrated that acute renal denervation or the administration of catecholamines alters phosphate reabsorption.[109,162–175] The increase in urinary phosphate excretion after acute renal denervation could be due to both increased production of dopamine and decreased α- or β-adrenoreceptor activity, since acute renal denervation has been shown to initially increase renal dopamine excretion and almost completely abolish norepinephrine and epinephrine levels in the kidney.[176,177] Epinephrine decreases plasma phosphate, presumably by shifting phosphate from the extracellular into the intracellular space. The hypophosphatemic response to isoproterenol infusion is blocked by propranolol, suggesting involvement of the beta adrenoreceptors. Infusion of isoproterenol markedly enhances renal phosphate reabsorption in normal rats and in hypophosphatemic mice.[173,178] The enhanced phosphate reabsorption and attenuated phosphaturic response to PTH observed in acute respiratory alkalosis and phosphate deprivation is blocked by infusion of propranolol, suggesting a possible role for stimulation of β-adrenoreceptors in these conditions. Stimulation of α-adrenoreceptors by the addition of epinephrine to cultured opossum kidney cells blunts the PTH-induced increase in cAMP levels and the inhibition of phosphate transport.[179] Stimulation of α2-adrenoreceptors *in vivo* has also been demonstrated to attenuate the phosphaturic response to PTH.[109] Dopamine infusion and the infusion of L-DOPA or glupopa, dopamine precursors, increase phosphate excretion in the absence of PTH.[180–182] Dopamine administration has been reported to decrease phosphate transport in cultured opossum kidney cells and rabbit proximal straight tubules.[172,183–188] Studies suggest that dopamine may be a proximal tubular paracrine substance in the regulation of phosphate reabsorption. The enzyme that converts L-DOPA to dopamine is located exclusively in the proximal convoluted and straight tubules, also the primary sites of phosphate reabsorption. Increasing dietary phosphate intake increases urinary dopamine excretion and phosphate excretion.[189] Inhibition of endogenous dopamine synthesis by the administration of carbidopa to rats resulted in decreased dopamine and phosphate excretion, suggesting a role for endogenous dopamine in phosphate regulation.[168,177] A potential paracrine role for dopamine in phosphate regulation was strengthened by studies performed in opossum kidney cells that demonstrated that the addition of dopamine or L-DOPA selectively decreased phosphate uptake (Fig. 69.6). Furthermore, phosphate-replete OK cells produced more dopamine from L-DOPA than phosphate-deprived cells.[185] Administration of dopamine to phosphate-deprived or respiratory alkalotic rats increases phosphate excretion and enhances the phosphaturic response to PTH.[108,109] Subsequent studies in opossum kidney cells performed by several laboratories demonstrated that increasing dopamine synthesis inhibits phosphate transport by multiple mechanisms including activation of DA1 and DA2 receptors.[184,187,188] More recent studies performed using mouse kidney slices, perfused proximal tubules, and opossum kidney cells examined the effect of dopamine on NaPi IIa expression and localization using DA1 and DA2 agonists.[183] In these studies, dopamine induced the internalization of NaPi IIa by activation of luminal DA1 receptors. Renal proximal tubules also synthesize serotonin from 5-hydroxytryptophan by the same enzyme that converts L-DOPA to dopamine. Incubation of opossum kidney cells with either serotonin or 5-hydroxytryptophan enhanced phosphate transport and raises the possibility that serotonin may also be involved in the physiological regulation of renal phosphate transport.[180,186,190,191]

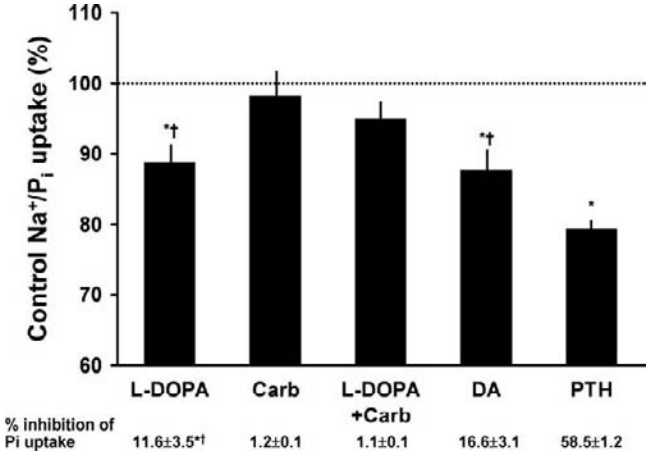

FIGURE 69.6 Effects of incubation either with 250 μM L-DOPA, 250 μM carbidopa (Carb), with combination of both, with exogenous dopamine (DA, 10 μM) or with parathyroid hormone (PTH 2 U/ml) on Na + -Pi cotransport in opossum kidney (OK) cell monolayers. Effects of exogenous and endogenous agents on Na + -Pi cotransport are expressed as % difference (decrease) from basal values denoted by dotted line. *Significant differences ($p < 05$, paired t test) from controls. † Significant difference ($p < 05$) compared with values from PTH. Autocrine/paracrine regulation of renal Na(+)-phosphate cotransport by dopamine. Am J Physiol 1993;264: F618–622, with permission.)*

The Phosphatonins and Renal Phosphate Reabsorption

The term "phosphatonin" was introduced to describe a factor or factors responsible for the inhibition of renal phosphate reabsorption and altered 25-hydroxyvitamin D 1α-vitamin D regulation observed in patients with tumor-induced osteomalacia.[192] Cai et al.[193] described a patient with tumor-induced osteomalacia in whom the biochemical characteristics of hypophosphatemia, renal phosphate wasting and reduced 1α,25(OH)2D disappeared following removal of the tumor. A similar biochemical phenotype exists in patients with X-linked hypophosphatemic rickets (XLH) and the animal model, the Hyp mouse.[194–199] Several investigators have shown the presence of circulating factors in the serum of Hyp mice that inhibit sodium-dependent phosphate transport in the kidney.[200–202] Further studies demonstrated that patients with the disease, autosomal dominant hypophosphatemic rickets (ADHR), had activating mutations within the fibroblast growth factor homolog, fibroblast growth factor 23 (FGF-23).[203] Its persistence in the circulation resulted in the biochemical phenotype of hypophosphatemia, renal phosphate wasting and low 1α,25$(OH)_2$D concentrations.[203,204] Studies using serial analysis of gene expression (SAGE) identified additional genes that were overexpressed in tumors associated with tumor-induced osteomalacia.[205] Some studies have identified several new factors that also play a role in the regulation of phosphorus transport and homeostasis.[12–16,36,206–210] These include the "phosphatonins," FGF-23, and sFRP-4 that induce a state of negative phosphate balance directly by inhibiting renal phosphate reabsorption in the proximal tubule and indirectly by inhibiting the synthesis of 1α,25$(OH)_2D_3$ and reducing the intestinal absorption of phosphorus.[12–16,36,206–210] Two factors, fibroblast growth factor 7 (FGF-7) and MEPE have been shown to inhibit phosphate transport in renal epithelial cells in culture and, in the case of matrix extracellular phosphorus glycoprotein, to induce phosphaturia in mice.[18,211] FGF-7 and MEPE, however, have not been demonstrated to prevent compensatory increases in serum 1α,25$(OH)_2D_3$ concentrations seen in hypophosphatemic states or to directly inhibit 25-hydroxyvitamin D 1α-hydroxylase activity. In contrast, the phosphatonins increase renal phosphate excretion and inhibit 25-hydroxyvitamin D 1α-hydroxylase activity, thereby further decreasing the retention of phosphorus.

Fibroblast Growth Factor-23

As noted previously, FGF-23 was initially postulated to be the factor responsible for autosomal dominant hypophosphatemic rickets.[203] A mutation in the FGF-23 gene resulted in expression of a FGF-23 protein that was resistant to proteolysis and with a prolonged half-life and biopotency.[204,212–216] Recombinant FGF-23 produced hypophosphatemia when administered intraperitoneally to mice.[37] Serum calcium concentrations did not change following the administration of the peptide. When Chinese hamster ovary cells were transfected with an FGF-23 expression plasmid and cells were implanted in nude mice, the animals became hypophosphatemic and the fractional excretion of phosphate was increased within 10 days. Alkaline phosphatase concentrations increased in the serum consistent with changes in bone mineralization. Radiologic evidence of rickets in the long bones and histological evidence of rachitic changes were observed after several weeks. There was a decrease in the amount of messenger RNA for the 25-hydroxyvitamin D 1α-hydroxylase. In support of these studies, Bowe et al. demonstrated that recombinant FGF-23 inhibited sodium-dependent phosphate transport in opossum kidney cells.[206] Furthermore, intravenous infusion of recombinant FGF-23 into mice caused a rapid, dose-dependent increase in the fractional excretion of phosphate with little or no change in sodium excretion (Fig. 69.7).[15] These studies suggest that FGF-23 has direct actions on renal phosphate transport. The role of FGF-23 in modulating plasma phosphate concentrations and 25 hydroxyvitamin D 1α-hydroxylase levels was further supported by the generation of FGF-23 null mutant mice.[217] These mice had reduced growth rate and died 10 to 14 weeks after birth. Serum phosphate concentrations were elevated within 10 days after birth and serum calcium concentrations became moderately elevated 2 weeks after birth. Interestingly, these mice developed increased renal 25-hydroxyvitamin D 1α-hydroxylase messenger RNA levels and associated increases in serum 1α,25$(OH)_2$D concentrations. A moderate increase in serum calcium concentrations was also observed that could be a consequence of the increased 1α,25$(OH)_2$D concentrations and increased intestinal calcium transport. Parathyroid hormone concentrations were diminished in the homozygous mutant mice only at 9 weeks of age. Long bones displayed abnormal mineralization and reduced growth plate. The TmP/GFR was significantly increased in FGF-23 in null mutant animals. Conversely, transgenic mice overexpressing FGF-23 have reduced serum phosphate concentrations, increased phosphate excretion, and reduced renal sodium-phosphate cotransporter, NaPi IIa.[218,219] In addition to changes in phosphate homeostasis, chronic overexpression of FGF-23 has also been linked to disturbances in vitamin D metabolism, calcium homeostasis and increased PTH levels.[212] The exact interaction and the relative contribution of FGF-

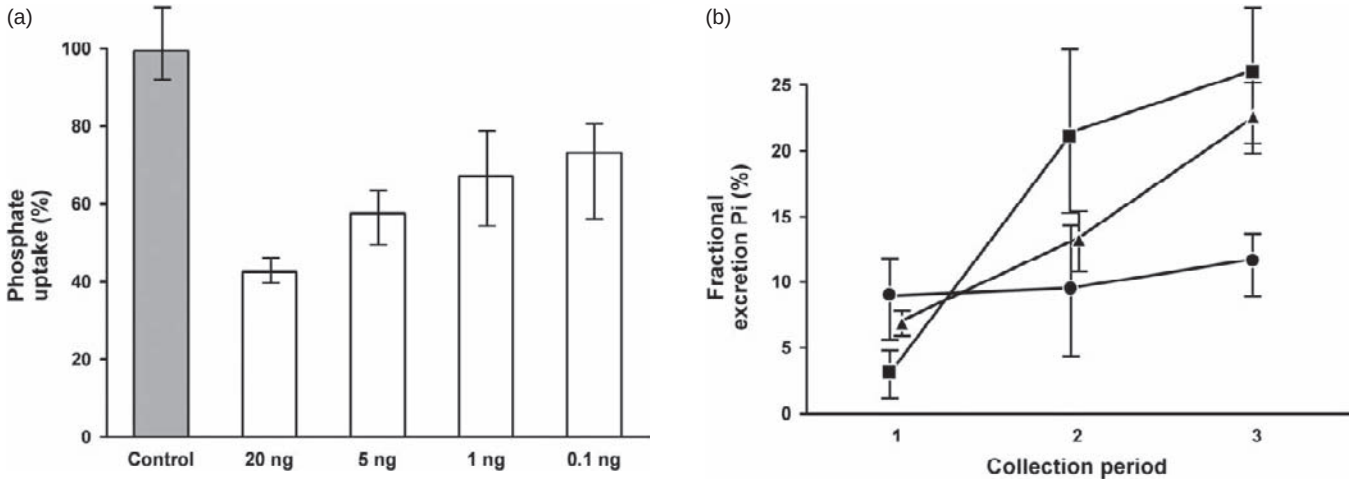

FIGURE 69.7 **Effect of fibroblast growth factor-23 (FGF23) on phosphate transport.** (a) In vitro effects of FGF23 on inorganic phosphorus transport (Pi) in opossum kidney cells. The phosphatonin pathway: new insights in phosphate homeostasis. Kidney Int 2004;65:1–14, with permission.)*

23, PTH, and vitamin D on phosphate homeostasis in these models of chronic FGF-23 excess remains unknown.

The role of FGF-23 in the physiologic regulation of phosphate homeostasis has been addressed by studies to determine the effect of dietary phosphate intake on serum FGF-23 levels. In healthy humans, the effects of phosphate loading and deprivation have shown modest or no changes in circulating FGF-23 concentrations. In one study, an increased phosphate intake slightly increased serum FGF-23.[220] In contrast, other studies in humans did not demonstrate an effect of dietary phosphate intake on serum FGF-23 levels.[221] In rats with renal failure, an increase in dietary phosphate has been shown to increase FGF-23 concentrations in the serum.[222] Future studies are necessary to determine the source of FGF-23 and how its expression is regulated.

The mechanism of action of FGF-23 on phosphate transport is currently unknown. Limited *in vitro* binding studies suggest that FGF23 may bind to FGFR-Fc fusion proteins.[223] Furthermore, tyrosine kinase inhibitors that are known to inhibit signaling through FGFRs block the effect of FGF-23 on sodium-dependent phosphate opossum kidney cells. These results raise the possibility that FGF-23 may signal through one of the known FGFRs.

Secreted Frizzled Related Protein-4

sFRP-4 was among the most consistently overexpressed genes found associated with oncogenic osteomalacia. To assess whether sFRP-4 has phosphatonin activity, it was expressed by recombinant methods in COS or insect cells.[36] Increasing concentrations of the recombinant protein were added to opossum kidney cells to determine whether it inhibits sodium-dependent phosphate transport. We observed that sFRP-4 inhibited sodium-dependent phosphate transport in opossum kidney cells in a dose-dependent manner at concentrations in the pg/ml range. When infused into rats, sFRP-4 increased renal phosphate excretion at 2 and 8 hours following initiation of the sFRP-4 infusion (Fig. 69.8).[36,15] Minimal changes in sodium excretion were seen and calcium excretion did not change. Interestingly, the effects of sFRP-4 were also demonstrated in parathyroidectomized rats, thus demonstrating that parathyroid hormone was not essential for the phosphaturic effect of sFRP-4. During an 8-hour intravenous infusion of sFRP-4, serum phosphate concentrations decreased and phosphate excretion increased. However, no change in 25-hydroxyvitamin D 1α-hydroxylase messenger RNA concentrations was noted in the kidney. The infusion of sFRP-4 was associated with a decrease in β-catenin concentrations in renal cells and an increase in phosphorylated β-catenin, thereby demonstrating that sFRP-4 may act as an antagonist against Wnt molecules in the kidney. Additionally, sFRP-4 was detected in the plasma of healthy subjects and in patients with tumor-induced osteomalacia, although the current assay did not detect elevated levels associated with tumor-induced osteomalacia. Thus, the data published to date suggest that sFRP-4 is a phosphatonin. Details concerning the mechanism by which FRP-4s inhibits renal

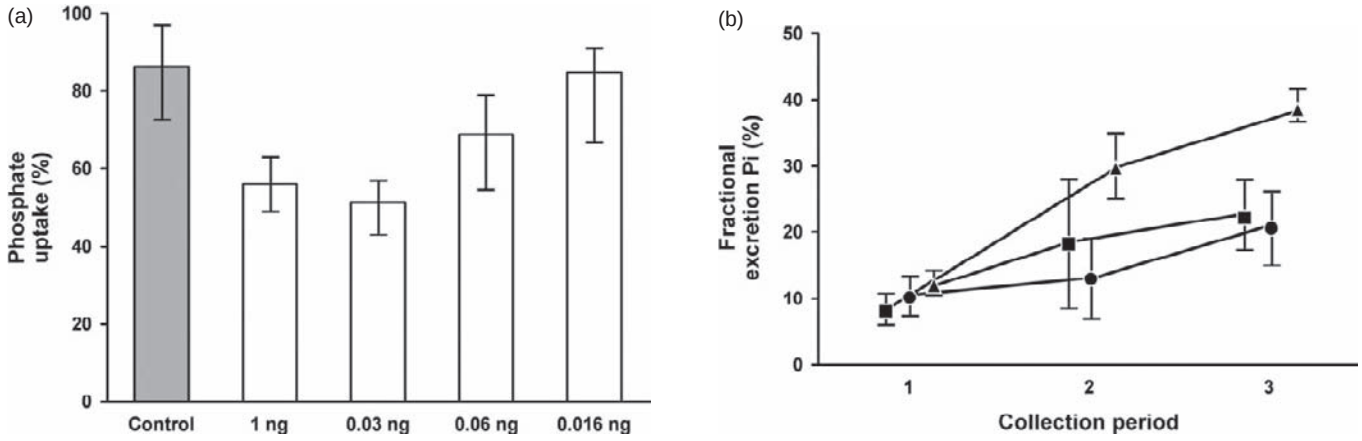

FIGURE 69.8 (a) Effect of frizzled-related protein-4 (FRP4) on phosphate transport. In vitro effects of FRP4 on inorganic phosphorus transport (Pi) in opossum kidney cells. (b) FRP4 effects on the percent fractional Pi excretion. Mice were infused for 2 hours with vehicle (circle), 0.05 μg FRP4/2 hours (square), or 0.5 μg FRP4/2 hours (triangle). *(From Schiavi SC, Kumar R. The phosphatonin pathway: new insights in phosphate homeostasis. Kidney Int 2004;65:1–14, with permission.)*

phosphate reabsorption and its relationship to FGF-23 will need to be elucidated in the future. Studies performed in mice in which the sFRP-1 gene was deleted demonstrate that these mice exhibit enhanced trabecular bone formation in adult mice. In these studies, plasma phosphate concentrations were significantly increased by 29% in male mice at 18 to 20 weeks of age, consistent with the possibility that sFRP proteins modulate renal phosphate reabsorption.[224]

Matrix Extracellular Phosphoglycoprotein

Matrix extracellular phosphoglycoprotein (MEPE) is also among the most abundantly overexpressed mRNA species found in tumors associated with renal phosphate wasting and osteomalacia.[18,205,225] Recently, MEPE has been expressed in insect cells and administered to mice *in vivo*.[18] The protein causes renal phosphate wasting and a reduction in serum phosphate concentrations *in vivo*. Additionally, there is inhibition of sodium-dependent phosphate uptake noted in opossum kidney cells exposed to the protein. MEPE also inhibits bone mineralization *in vitro* and MEPE null mice have increased bone mineralization.[226] This suggests that it may play a role in the pathogenesis of X-linked hypophosphatemic rickets in which there is phosphate wasting and evidence for a mineralization defect that is independent of low phosphate concentrations in the extracellular fluid.[227] Recent evidence suggests that concentrations of this substance are increased in the serum of patients with X-linked hypophosphatemic rickets.[207] It has been suggested that MEPE is a substrate for PHEX[228,229] and that PHEX prevents proteolysis of MEPE and release of a protease-resistant MEPE-ASARM peptide, an inhibitor of mineralization (minhibin). Phex may be acting to interfere with the actions of other enzymes that degrade extracellular matrix proteins. PHEX and MEPE form a nonproteolytic protein interaction via the MEPE carboxy-terminal ASARM motif. The ASARM peptide is believed to inhibit mineralization *in vivo*. The binding of MEPE and ASARM peptide by PHEX may explain why loss of functional osteoblast-expressed PHEX results in defective mineralization in Hyp. MEPE concentrations have been measured in normal humans and concentrations of the protein appear to correlate with bone mineral density and serum phosphate concentrations.[230]

Fibroblast Growth Factor 7

A recent report has shown that FGF-7 is overexpressed in tumors associated with osteomalacia and renal phosphate wasting.[17,211] FGF-7 protein inhibited sodium-dependent phosphate transport in opossum kidney cells. Anti–FGF-7 antibodies attenuated the inhibitory effect of tumor supernatants on sodium-dependent phosphate transport. Only low concentrations of FGF-23 were present in the supernatant medium of tumor cells. At present it is not known if FGF-7 circulates in plasma, whether it alters 25-hydroxyvitamin D 1α-hydroxylase levels or whether it is elevated in the plasma of subjects with tumor induced osteomalacia. Nevertheless, the report does point to the complexity of factors involved in the pathogenesis of tumor induced osteomalacia.

ACUTE AND CHRONIC HYPOPHOSPHATEMIA

Hypophosphatemia is a commonly seen condition in the hospital setting. By definition, this is a decrease in serum phosphate concentrations below those seen in a normal healthy population. Serum phosphate concentrations vary with age, being higher in young individuals than in adults. Table 69.1 shows concentrations of serum phosphorus in males and females of different ages as determined at the Mayo Clinic.

Hypophosphatemia does not necessarily imply an overall deficiency of phosphate, since serum phosphate concentrations can change as a result of redistribution of phosphate from serum and extracellular fluid into bone and soft tissues. When the underlying disorder causing the redistribution resolves, serum phosphate concentrations returned to normal. Hypophosphatemia can be the result of decreased intake or absorption of phosphorus, a redistribution of phosphate from the serum into cells, or decreased renal phosphate reabsorption.[11] Table 69.2 shows the causes and mechanisms of hypophosphatemia. Severe hypophosphatemia, often requiring therapy with phosphate, occurs in the following conditions: acute renal failure (especially when there has been significant tissue damage and necrosis), chronic alcoholism and alcohol withdrawal, dietary deficiency and therapy with phosphate-binding antacids, hyperalimentation, neuroleptic malignant syndrome, recovery from diabetic ketoacidosis, recovery from exhaustive exercise, after kidney transplantation, respiratory alkalosis, severe thermal burns, therapeutic hyperthermia, Reye syndrome, after major surgery, periodic paralysis, acute malaria, drug therapy with ifosamide or cisplatin, acetaminophen intoxication, or cytokine infusions with tumor necrosis factor or interleukin-2.[11]

Hypophosphatemia can cause a variety of clinical disorders. Red cell, leukocyte, and platelet dysfunction has been described.[11] In red cells, hypophosphatemia is associated with a decline in 2,3-diphosphoglycerate and adenosine triphosphate.[11] Structural defects in the red cell resulting in hemolysis have been described.[231,232] In severe hypophosphatemia, leukocyte chemotaxis, phagocytosis, and bactericidal activity are depressed.[233] Platelet dysfunction manifests by thrombocytopenia, an increase in platelet diameter, accelerated platelet disappearance, impaired clot retraction, and hemorrhage into the skin and intestine has been described.[234] Central nervous system dysfunction has been described in patients with severe hypophosphatemia. Patients may manifest irritability, weakness, numbness, paresthesias, confusion, obtundation, seizures and coma.[235] Rhabdomyolysis has been described in severe hypophosphatemia, especially in the context of alcoholism.[236–238] Myofibrillar damage has been observed in severe hypophosphatemia.[239] A reversible cardiomyopathy has been described in experimental animals and patients with severe hypophosphatemia.[11,240] Also, dysfunction can also cause weakness of the diaphragm and has, in some instances, been described to result in respiratory insufficiency.[57,241–250] In some instances, dietary phosphorus deprivation and severe hypophosphatemia have been associated with an osteolytic syndrome.[11] A number of other less well-defined abnormalities have been described in patients with hypophosphatemia, but the precise cause-and-effect relationship remains to be firmly established.[11]

TABLE 69.1 Normal Serum Phosphorus Concentrations in Humans at Mayo Clinic

Males		Females	
Age, y	**Concentration, mg/dl**	**Age, y**	**Concentration, mg/dl**
1–4	4.3–5.4	1–7	4.3–5.4
5–13	3.7–5.4	8–13	4.0–5.2
14–15	3.5–5.3	14–15	3.5–4.9
16–17	3.1–4.7	16–17	3.1–4.7
>18	2.5–4.5	>18	2.5–4.5

Pathophysiology of Hypophosphatemia in Clinical Disorders

An examination of the pathophysiology of hypophosphatemia in various clinical disorders is instructive because it brings to light various mechanisms that are normally involved in the regulation of serum phosphate concentrations. This is particularly the case in the emerging area of inherited rickets and acquired forms of rickets due to tumors. Here, new substances have been isolated and identified that play an important role in the pathophysiology of the syndromes and that might also play an important role in the regulation of phosphate concentrations under normal circumstances.

Respiratory Alkalosis

In the clinical setting, the most common cause of acute hypophosphatemia is respiratory alkalosis (see previous sections), which causes a rapid redistribution of phosphate from the serum into the intracellular space, resulting in a marked decrease in plasma phosphate (Fig. 69.9).[11,251–256] Since respiratory alkalosis decreases the plasma phosphate concentration, it is

TABLE 69.2 Causes of Moderate Hypophosphatemia

Pseudohypophosphatemia	Cellular Uptake Syndromes
Mannitol	Recovery from hypothermia
Bilirubin	Burkitt lymphoma
Acute leukemia	Histiocytic lymphoma
	Acute myelomonocytic leukemia
Decreased dietary intake	Acute myelogenous leukemia
	Chronic myelogenous leukemia in blast crisis
Decreased intestinal absorption	Treatment of pernicious anemia
Vitamin D deficiency	Erythropoietin therapy
Malabsorption	Erythrodermic psoriasis
Steatorrhea	Hungry bone syndrome
Secretory diarrhea	After parathyroidectomy
Vomiting	Acute leukemia
PO43 − binding antacids	
	Increased excretion into the urine
Shift from serum into cells	Hyperparathyroidism
Respiratory alkalosis	Renal tubule defects
Sepsis	Fanconi syndrome
Heat stroke	X-linked hypophosphatemic rickets
Neuroleptic malignant syndrome	Hereditary hypophosphatemic rickets with hypercalciuria
Hepatic coma	Polyostotic fibrous dysplasia
Salicylate poisoning	Neurofibromatosis
Gout	Kidney transplantation
Panic attacks	Oncogenic osteomalacia
Psychiatric depression	Recovery from hemolytic-uremic syndrome
	Aldosteronism
Hormonal effects	Licorice ingestion
Insulin	Volume expansion
Glucagon	Inappropriate secretion of antidiuretic hormone
Epinephrine	Mineralocorticoid administration
Androgens	Corticosteroid therapy
Cortisols	Diuretics
Anovulatory hormones	Aminophylline therapy
Nutrient effects	
Glucose	
Fructose	
Glycerol	
Lactate	
Amino acids	
Xylitol

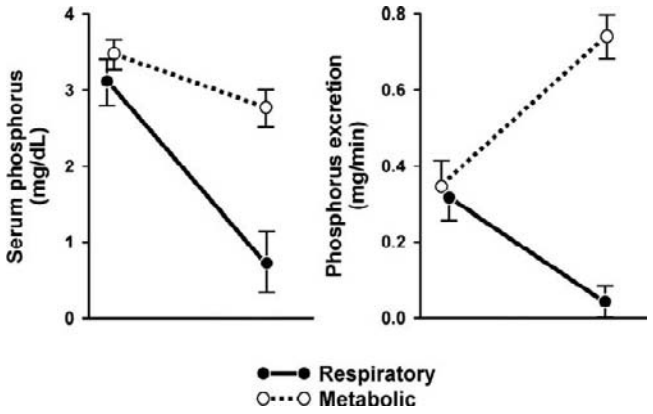

FIGURE 69.9 Respiratory alkalosis may depress serum phosphorus concentration markedly in normal subjects and cause virtual disappearance of phosphorus from urine. Serum phosphorus falls only slightly with the same degree of alkalosis produced by infusion of $NaHCO_3$ and is associated with an increase of phosphaturia. *(From Mostellar ME, Tuttle EP Jr. Effects of alkalosis on plasma concentration and urinary excretion of inorganic phosphate in man. J Clin Invest 1964;43:138–149, with permission.)*

likely that changes in the filtered load of phosphate contribute to the changes in phosphate excretion. However, a direct effect of respiratory alkalosis changes on renal phosphate reabsorption has also been demonstrated in the absence of changes in the filtered load of phosphate.[73,257–259] The effects of acute respiratory alkalosis on plasma phosphate and on phosphate reabsorption are due to the decrease in PCO_2 rather than the concomitant changes in blood pH. The effects of respiratory alkalosis on phosphate homeostasis are mediated, in part, by release of catecholamines.[108,260,261]

Sepsis

Sepsis is associated with hypophosphatemia.[262–268] In septic patients with hypophosphatemia, 80% of these patients had very high levels of tumor necrosis

factor (TNF) and interleukin-6.[263,269,270] Injection of various interleukins and TNFα in experimental animals and in humans decreased plasma phosphate, suggesting a role for inflammatory cytokines in the hypophosphatemic effect of sepsis.[269–275]

Refeeding Syndrome

The earliest descriptions of hypophosphatemia with refeeding were described in starved patients in war time. This syndrome is frequently observed in clinical settings in patients after prolonged fasting, massive weight loss after gastric surgery, chronic alcoholism, chronic malnutrition, oncology patients, and anorexia nervosa.[276–284] Hypophosphatemia is observed after either parenteral or enteral refeeding and is mediated by changes in carbohydrate metabolism, decreased insulin concentrations and increased glucagon levels.

Alcohol Withdrawal

Hypophosphatemia commonly occurs in the context of alcohol withdrawal. It affects approximately 50% of patients with alcoholism, requiring hospitalization.[7,11] The etiology of hypophosphatemia is multifactorial in patients admitted for alcoholism. Poor nutritional intake, magnesium deficiency which can result in hypophosphatemia as a result of renal phosphate wasting[285–289] and alcohol-induced abnormalities in tubular function[290] probably all contribute to the pathogenesis of hypophosphatemia in such patients. Abstinence from alcohol is generally associated with the recovery from hypophosphatemia.

Renal Transplantation

Hypophosphatemia has frequently been reported in transplant patients with concomitant decreased bone mineral density.[291] This hypophosphatemia is the result of decreased renal reabsorption of phosphate and is thought to be due, in part, to elevated PTH levels as a result of prior renal failure and the administration of glucocorticoids. However, some transplant patients exhibit increased phosphate excretion even when kidney function and PTH levels are normal.[292] A recent study examined the mechanism and time course of the post-transplant hypophosphatemia.[293] In this study, early (two weeks to one month) transplantation patients exhibited hypophosphatemia and phosphaturia, compared with control subjects or late (9–12 months) post-transplantation patients. Serum from these patients with hypophosphatemia inhibited phosphate transport by opossum kidney cells, suggesting the presence of a circulating phosphatonin substance.[294] Serum FGF-23 levels are known to be markedly increased in patients with chronic renal failure; however, they are not significantly increased following renal transplantation.[295–297]

Tumor-Induced Osteomalacia

This syndrome is associated with chronic hypophosphatemia and osteomalacia that is corrected following removal of the tumor. Initial experiments performed in patients with tumor-induced osteomalacia (TIO) were the first to describe "phosphatonins" as a circulating factor from the serum of these patients that inhibits phosphate transport in opossum kidney cells.[193] Numerous reports now show that serum FGF-23 is elevated in some, but not all, patients with oncogenic or tumor-induced osteomalacia.[206,296,298–302] Removal of the tumor is generally associated with a reduction in serum FGF-23 concentrations, and there is a temporal association between the reduction in serum FGF-23 concentrations, the increase in serum phosphate concentrations, a decrease in renal phosphate wasting and an increase in serum $1\alpha,25(OH)_2D_3$ concentrations.[296,301,302] In some patients, FGF-23 concentrations are not greatly increased and do not dramatically decrease following tumor removal.[296] The increase in serum FGF-23 concentrations is consistent with the overexpression of messenger RNA and protein for FGF-23 within the tumors themselves. Recently, venous sampling has demonstrated a gradient between FGF-23 concentrations in tumor venous effluent and FGF-23 concentrations in peripheral blood, suggesting that elevations of serum FGF-23 are due to direct secretion from the tumors.[301] As described previously, several phosphatonin molecules, including secreted frizzled related protein-4, MEPE, and fibroblast growth factor-7, have all been isolated from tumors from patients with TIO. Increased serum or renal concentrations of these proteins result in decreased renal phosphate reabsorption which contributes to the subsequent hypophosphatemia and osteomalacia.

Autosomal Dominant Hypophosphatemic Rickets

Autosomal dominant hypophosphatemic rickets (ADHR) is an inherited disorder of phosphate homeostasis characterized by decreased renal phosphate reabsorption and hypophosphatemia linked to chromosome 12p13.[303] These biochemical abnormalities are associated with bone pain, muscle weakness, poor growth, and evidence of rickets and osteomalacia.[304] Individuals with this disease present with renal phosphate wasting and inappropriately normal serum $1\alpha,25(OH)_2D$ concentrations.[304] As noted earlier, mutations in the FGF-23 gene within a pro-convertase processing site were identified as the cause for autosomal dominant hypophosphatemic rickets.[203] These mutations appear to prevent processing of FGF-23 in mice and enhances the *in vivo* biological potency resulting in increased serum concentration of FGF-23, decreased serum phosphate concentrations and low $1\alpha,25(OH)_2D$

concentrations.[212,214] When transgenic mice expressing human FGF-23 were generated, these mice exhibited hypophosphatemic rickets suggesting that increased expression of FGF-23 may play a role in this disease syndrome.[204]

X-Linked Hypophosphatemic Rickets

X-linked hypophosphatemic rickets (XLH) is the most common inherited cause of rickets.[192,305–307] XLH (and murine model of this diseases, Hyp mouse and the Gy mouse) is an inherited X-linked dominant disorder characterized by hypophosphatemia, normocalcemia and an inappropriately low concentration of serum $1\alpha,25(OH)_2D$.[305–309] Many studies have demonstrated that in XLH there is decreased renal phosphate reabsorption.[305–307] This defect in phosphate reabsorption was demonstrated to be due to a humoral factor, since parabiosis performed between a normal and Hyp mouse causes hypophosphatemia in the normal mouse, and this effect is reversible.[200,201] These results are further supported by cross renal transplantation experiments.[202] When a kidney from a Hyp mouse is transplanted into a normal mouse, phosphate wasting is no longer observed. Conversely, transplantation of a kidney from a normal mouse into a Hyp mouse results in phosphate wasting by the normal transplanted kidney. These data are consistent with a circulating hypophosphatemic substance in the circulation of Hyp mice. The addition of Hyp mouse serum to primary renal cells selectively inhibits phosphate uptake, and the Hyp serum inhibits phosphate transport to a greater extent than normal serum, indicating the presence of a factor in Hyp mouse serum that inhibits phosphate uptake.[310] Positional cloning efforts have shown that PHEX (phosphate regulating endopeptidase on the X-chromosome) is the mutant gene responsible for XLH.[311] The same gene is mutated in mice with the Hyp and Gy mutations (in the Gy mouse there is a deletion of the adjacent spermine gene as well).[311–314] Since the mutant gene in this syndrome is a protease, it has been thought that a lack of proteolytic activity results in comparing degradation of a hypophosphatemic substance. With the identification of FGF-23 as a hypophosphatemic peptide responsible for phosphate wasting in patients with autosomal dominant hypophosphatemic rickets, and the elevation of FGF-23 in some patients with tumor-induced osteomalacia, considerable effort has been expended to determine whether FGF-23 concentrations are elevated in patients with XLH and whether FGF-23 is a substrate for PHEX. The evidence for elevated FGF-23 expression in patients with X-linked hypophosphatemic rickets is conflicting. Jonsson and coworkers describe elevated serum FGF-23 concentrations in many subjects,[296] whereas Weber and colleagues reported only modestly increased or normal concentrations of FGF-23.[210] In the Hyp mouse, preliminary reports suggest that FGF-23 serum concentrations are elevated and neutralization of FGF-23 with an antibody ameliorates hypophosphatemia and rickets.[315] These data are consistent with the premise that PHEX processes FGF-23 either directly or indirectly under normal circumstances. The inactivation of FGF-23 by PHEX has been demonstrated by some, but not all investigators.[206,316,317] Inactivation of PHEX, as occurs in individuals with XLH and in Hyp mice, would reduce FGF-23 degradation and cause renal phosphate wasting and hypophosphatemia.

Fibrous Dysplasia/McCune-Albright Syndrome

Fibrous dysplasia is a genetic, noninherited disease caused by somatic activating missense mutations of GNAS1 that affects the skeleton or with endocrine and cutaneous abnormalities, McCune-Albright syndrome.[318–322] Phosphate wasting is observed in approximately 50% of these patients and is associated with defects in bone mineralization.[323–327] Riminucci and coworkers examined the concentrations of FGF-23 in the plasma of patients with fibrous dysplasia, some of whom have hypophosphatemia.[328] These investigators demonstrated that those patients who had low phosphate concentrations had elevated FGF-23 concentrations in the blood, whereas those who had normal phosphate concentrations did not have elevations in FGF-23.

Humoral Hypercalcemia of Malignancy and Hyperparathyroidism

Patients with humoral hypercalcemia of malignancy or primary hyperparathyroidism have elevated serum calcium concentrations, hypophosphatemia, and altered serum $1\alpha,25(OH)D_3$ concentrations. Of note, in patients with primary hyperparathyroidism, $1\alpha,25(OH)D_3$ concentrations are increased. Whereas, in patients with humoral hypercalcemia of malignancy serum, $1\alpha,25(OH)D_3$ concentrations are inappropriately low for the degree of hypophosphatemia that these patients manifest.[329] It is possible that increased circulating FGF-23 could contribute to the hypophosphatemia seen in individuals with these disorders. Recently, serum FGF-23 has been shown to be elevated five- to 10-fold in patients with humoral hypercalcemia of malignancy.[330] Interestingly, the elevations in FGF-23 are not correlated with the concentrations of serum phosphorus. It is possible that a low serum $1\alpha,25(OH)D3$ concentration seen in the patients with humoral hypercalcemia of malignancy could have been due to the increased FGF-23 concentrations. Patients with primary hyperparathyroidism have slightly elevated FGF-23 concentrations that do not change after parathyroidectomy.[331]

ACUTE AND CHRONIC HYPERPHOSPHATEMIA

Hyperphosphatemia occurs in renal failure and tumoral calcinosis. Patients with hyperphosphatemia generally have no symptoms as a result of this disorder. The consequences of hyperphosphatemia include the deposition of calcium in phosphate in soft tissues such as skin, blood vessels, and heart, and the development of secondary hyperparathyroidism as a result of hypocalcemia.

Renal Failure

Hyperphosphatemia and secondary hyperparathyroidism are common complications of chronic renal failure and end-stage renal disease.[11,332,333] The causes of hyperphosphatemia and chronic renal failure are multifactorial. In patients with renal failure, retention of phosphate as a result of reduced glomerular filtration is the primary cause for hyperphosphatemia. While in the early stages of chronic renal failure, an increase in serum phosphate concentrations can be overcome by an increased rate of parathyroid hormone release (which occurs as a result of hypocalcemia and perhaps directly due to the effect of phosphate on the parathyroid gland). As renal failure progresses with further nephron damage, hyperphosphatemia becomes chronic and fixed.[334–344] Parathyroid hormone concentrations remained chronically elevated. At the same time, a reduction in the synthesis of $1\alpha,25(OH)D_3$ occurs as a result of hyperphosphatemia and reduced nephron mass.[11,332,333] This causes a reduction in calcium absorption in the intestine, a negative calcium balance, and further hyperparathyroidism. A reduction in $1\alpha,25(OH)D_3$ concentrations also results in an increase in parathyroid hormone synthesis on account of the absence of inhibition of parathyroid hormone synthesis by $1\alpha,25(OH)D_3$.[11,332,333] Chronically elevated concentrations of parathyroid hormone cause bone disease in these patients.

Tumoral Calcinosis

Tumoral calcinosis is an unusual disorder associated with hyperphosphatemia, elevated $1\alpha,25(OH)_2D_3$ concentrations, and a reduced excretion of phosphorus in the urine. The phenotype seen in this disorder is the opposite of that seen in tumor-induced osteomalacia and in the inherited forms of rickets. It has been speculated that a deficiency of phosphatonin activity could account for this disorder. Two distinct abnormalities have been elucidated in patients with tumoral calcinosis. In some families with tumoral calcinosis, a defect in the activity of an O-linked glycosylating enzyme, GALNT3,[345] has been observed. Interestingly, serum FGF-23 concentrations are high in these patients. It is uncertain from the published report if the serum FGF-23 concentrations were measured using an assay that detects intact FGF-23 or FGF-23 fragments as well as the intact molecule. It is possible that there could be defects in the processing of FGF-23 as a result of a failure in glycosylation of the molecule or as a result of the chronic hyperphosphatemia seen in these patients. Another report suggests that the hyperostosis–hyperphosphatemia syndrome is an allelic disorder similar to tumoral calcinosis.[346] No reports of FGF-23 concentrations in this syndrome are available.

In a second family, mutational analyses identified a homozygous S71G mutation in FGF-23 in the TC patients which was not found in control alleles.[347] These individuals had low normal levels of intact FGF-23. It has been suggested that the mutation stabilizes full-length FGF-23.

In summary, the study of patients with various clinical disorders of phosphate metabolism has yielded rich insights into the handling of phosphate in the kidney and other organs.

Glucose Reabsorption in The Kidney

Charles S. Hummel and Ernest M. Wright

Department of Physiology, The David Geffen School of Medicine at UCLA, Los Angeles, California, USA

OVERVIEW OF GLUCOSE HOMEOSTASIS

Glucose is the major fuel source to the body's tissues, and it comes in various forms in the diet: simple sugar, disaccharides, polysaccharides, and starch. It is utilized in both oxidative and non-oxidative metabolic pathways, it provides a substrate for triglyceride synthesis in adipose tissue, and it is enzymatically polymerized into glycogen for storage in muscle and the liver. Glucose is synthesized endogenously in the liver and kidneys by gluconeogenesis. Its plasma concentration is maintained within narrow limits, 4−10 mM (70−110 mg/dL), with many hormonal influences. Pathological alterations in glucose homeostasis are most often identified with diabetes.

GLUCOSE TRANSPORTERS IN GLUCOSE HOMEOSTASIS

The transport of glucose across biological membranes is a critical step regulating its concentration in plasma. There are two major classes of proteins responsible for glucose transport.

Facilitated GLUcose Transporters (GLUTs) bind to glucose and translocate it across membranes in an energy-independent fashion: they require a glucose concentration gradient to drive net transport; hence they *facilitate* the *diffusion* of glucose. The GLUTs belong to the *SLC2A* gene family, part of the larger Membrane Facilitators Superfamily (MFS).[1] There are currently 14 identified GLUT genes within the human body, for example, the protein coded by the *SLC2A2 gene*, GLUT2, allows glucose to be reabsorbed in the kidney by facilitating diffusion across basolateral membranes, and mutations in this gene are responsible for the Fanconi-Bickel Syndrome (FBS, OMIM 227810).[2]

Sodium-dependent GLucose Transporters (SGLTs) bind Na^+ ions and glucose, transporting them across the membrane in an *energy-dependent* fashion: the Na^+ electrochemical potential gradient, maintained by the Na^+/K^+ ATPase, drives the transport of glucose into cells. This allows non-metabolized glucose analogs to accumulate in tissues in excess of the plasma concentration and so they are crucial for the reabsorption of glucose in the kidneys and the intestinal absorption of dietary glucose. SGLTs belong to the *SLC5A* gene family, part of the Sodium Solute Symporter (SSS) superfamily of proteins.[3,4] Although the amino acid sequences are quite different among members of the SSS family, the atomic structures reveal common features that suggest similar transport mechanisms.[5–7]

As with the GLUTs, SGLT genes are expressed throughout the body.[3,4,8] However, mRNA expression profiles offer only hints of physiological function, and establishing *functional* roles for SGLTs in the body's tissues has proven to be non-trivial.

CELLULAR AND MOLECULAR PHYSIOLOGY OF SGLTS

SGLT1 was the first identified and is the most extensively studied Na^+/D-glucose co-transporter.[4] It was cloned in 1987 by expression cloning,[9] and it is responsible for the intestinal absorption of D-glucose and D-galactose from the diet. Through a combination of biophysics, immunohistochemistry, molecular genetics, and freeze fracture electron microscopy, it was established that either defective translation, post-

translational trafficking, or function of SGLT1 leads to glucose-galactose malabsorption (GGM, OMIM # 182380; online, Mendelian Inheritance in Man, http://www.ncbi.nlm.nih.gov/OMIM). GGM is an extremely rare, autosomal recessive disease, in which patients experience life-threatening osmotic diarrhea starting in the first few days of life. Failure to absorb sugars broken down from the lactose in mother's milk or infant formula leads to profuse, watery diarrhea that abates only when sources of glucose or galactose are eliminated from the diet. As long as GGM is identified and appropriate dietary modifications are made, patients lead relatively normal and healthy lives.[10] Its expression cloning and detailed characterization, in addition to the molecular details of GGM, firmly established hSGLT1 as crucial to glucose and galactose absorption in the gut. On the other hand patients with GGM have only a mild renal glycosuria (see below).

There are four other members of the SLC5A gene family that are capable of transporting glucose, SGLT2, SGLT4, SGLT5 and SGLT6.[11] Human SGLT3, which is expressed in gut neuronal cells, depolarizes the cell upon exposure to glucose, is believed to be a glucose sensor and not a transporter.[12–14] hSGLT6 is a Na^+/myo-inositol co-transporter which also is a low affinity glucose transporter and it is now referred to as hSMIT2.[3,4] hSGLT2 (SLC5A2) is abundantly expressed in the kidney but mRNA is also found in liver, heart, brain and muscle. This is believed to be the transporter responsible for the bulk of glucose reabsorption in kidney and mutations in the gene are associated with renal glucosuria (see below). In addition to D-mannose, hSGLT4 has also been shown to transport D-glucose, fructose, and 1,5-anhydro-D-glucitol.[15] Its mRNA has been detected in small intestine, kidney, liver, lung and brain, where it may be important in maintaining stores of mannose for protein glycosylation. SGLT5, exclusively expressed in the human kidney cortex, is a mannose and fructose sodium cotransporter with a higher affinity and turnover than for glucose.[16] Its cellular location and function within the cortex is as yet unknown.

SGLTS AND RENAL GLUCOSE REABSORPTION

180 g/day of D-glucose is filtered across the glomerulus into the kidney in humans, yet less than <1% of this filtered load ends up in the urine in healthy persons. What is responsible for the efficient reabsorption of glucose, and where is this accomplished within the kidney?

In what has been described as one of the most important contributions to renal physiology,[17] Wearn and Richards developed the free-flow micropuncture technique in 1924.[18] In their first study on frog nephrons, they detected plasma levels of sodium and glucose in the "glomerular urine" but not in the "bladder urine," proving "beyond doubt that the reabsorption of these substances must take place in the renal tubules." By introducing oil blocks and perfusing pipettes in subsequent work, specific tubular regions were quantitatively perturbed and analyzed.[19] With such a novel approach, they showed that nearly all glucose was reabsorbed within the proximal tubule, and this could be blocked by phlorizin.[20]

Micropuncture and single nephron analyses were subsequently adapted for the study of mammalian kidneys, demonstrating that, in rats, glucose reabsorption occurred in the proximal tubule with sensitivity to phlorizin.[21,22] It was previously established that intravenous administration of phlorizin inhibited renal glucose reabsorption in humans by up to 100%.[23]

In 1970, using sensitive fluorometric-enzymatic methods for measuring D-glucose and inulin, as well as Lissamine green for more precisely locating nephron segment puncture sites and tubular transit times, detailed studies of glucose reabsorption could be performed in rat nephrons.[24] These free-flow micropuncture studies demonstrated that ≈98% of D-glucose reabsorption occurred within the PT, and most reabsorption occurred within the first 3 mm from the glomerulus (Figure 70.1); no measurable net glucose reabsorption occurred distal to the PT. A follow-up study showed that glucose competed with [^{3}H]-phlorizin for the same (and at that time) as-yet-unknown "binding site" in isolated brush borders of rat kidney, with reversibility, stereospecificity (D-glucose over L-glucose), and Na^+-dependence.[25] Renal D-glucose reabsorption was attributed to active Na^+/sugar cotransport, similar to and consistent with Crane's hypothesis that Na^+-dependent transport drives intestinal absorption of D-glucose and D-galactose, which he articulated in a groundbreaking 1960 presentation in Prague.[26]

Barfuss and Schafer expanded on these early studies by making quantitative estimates of D-glucose absorption in isolated, perfused segments of early and late PT from rabbit nephrons.[27] They found that in early segments, maximal [^{14}C]-D-glucose absorption (J_{max}) was high, with a relatively low affinity for glucose (K_m ≈ 2 mM). In comparison, later segments showed a 10-fold reduction in J_{max}, with higher affinity for glucose (K_m ≈ 0.4 mM). From this, they concluded there were at least two distinct systems of glucose reabsorption in the proximal tubule. Detailed studies using PT brush border membrane vesicles from human and rabbit kidneys showed more evidence of two transport systems: an early, low affinity (K_m glucose = 6 mM) transporter

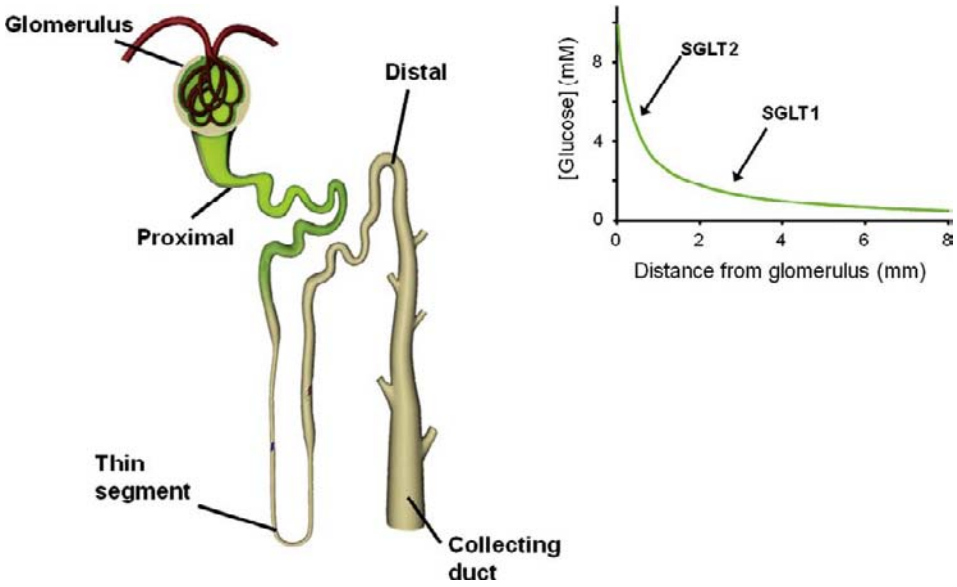

FIGURE 70.1 **Glucose reabsorption in the proximal tubule.** As shown in this simulation of the findings in Frohnert et al. (1970) the reabsorption of the bulk of filtered glucose occurs in the proximal tubule of the kidney. Under normal conditions, some 80% of the tubular glucose is reabsorbed within the first 2 mm of convoluted PT (S1, 2 segment), where SGLT2 is the predominantly expressed isoform. In later portions of PT (S3 segment), SGLT1 is believed to "mop up" the remaining tubular glucose.

with 1:1 Na^+:D-glucose stoichiometry and a later, high affinity (K_m glucose = 0.3 mM) transporter with 2:1 stoichiometry.[28–31]

After the two renal sodium glucose cotransporters were characterized, attention turned to their molecular identification In 1992, low-stringency hybridization screening of human kidney cDNA libraries, using rabbit and human SGLT1 sequences as probes, led to the identification of a clone bearing 59% DNA sequence identity to hSGLT1.[28] When cRNA of the clone was injected into *Xenopus* oocytes, [^{14}C]-α-methyl-D-glucopyranoside (αMDG, a SGLT-specific glucose analog) accumulation was 2- to 3-fold higher than that observed in water-injected oocytes. αMDG transport was Na^+-dependent and phlorizin-sensitive, sugar affinity was low compared to hSGLT1, D-galactose was not a substrate, and Na^+:glucose stoichiometry was 1:1.[32] In the same study, Na^+/glucose co-transport was also reported to be electrogenic and voltage-dependent, although the magnitude of maximal currents observed under voltage-clamp were <1% of those seen in hSGLT1-injected oocytes; but they were 2-fold larger than currents from control (H_2O-injected) oocytes. From this, Kanai and colleagues concluded it was not possible to claim hSGLT2 is a high capacity transporter *per se*, but rather its high level of mRNA in early PT segments—measured by *in situ* hybridization—might correspond to abundant protein expression at the luminal membrane; and hSGLT2 proteins as an *ensemble* might operate with a high capacity for glucose reabsorption. They further suggested that hSGLT1's 2:1 Na^+:glucose coupling, which endows it with greater accumulative power than a transporter with 1:1 stoichiometry, along with its high affinity for glucose, allows it to salvage the remaining tubular glucose in the late PT.

Subsequent studies of rat SGLT2 demonstrated substrate specificity (i.e., lack of D-galactose transport) and an additional estimate of 1:1 Na^+:glucose coupling.[33] *In situ* hybridization and northern blot analyses revealed SGLT2 message predominantly in outer kidney cortex while SGLT1 was found within inner cortical and outer medullary regions. Based on: (1) previous work showing the bulk of glucose reabsorption occurs in the early PT, (2) fluxes in isolated tubules showing evidence of two transport systems, and (3) spatial differences in SGLT1 and 2 mRNA expression, it was concluded that SGLT2 is *the* major Na^+/D-glucose cotransporter in the kidney.

Recently our biophysical characterization of cloned human SGLT1 and SGLT2 expressed in HEK293 cells confirmed and extended the previous oocyte studies:[34] the apparent glucose affinities ($K_{0.5}$) were much more similar than expected, 1.8 and 4.9 mM for SGLT1 and SGLT2; Galactose was a poor substrate for SGLT2 with a $K_{0.5}$ greater than 100 mM; and phlorizin was a more potent blocker of SGLT2 than SGLT1 with a Ki of 11 vs 140 nanomolar. The higher affinity of SGLT2 for phlorizin was mostly due to a slower off rate.

There are several reports on SGLT protein localization within the rat kidney. In the first, SGLT1 and GLUT1 antibodies were tested in various sections—inner medulla, outer medulla-inner segment, outer medulla-outer segment, and cortex. SGLT1 immunoblotting revealed signal in cortical and outer medullary regions, whereas GLUT1 signal was observed in inner and outer medulla but not cortex.[35]

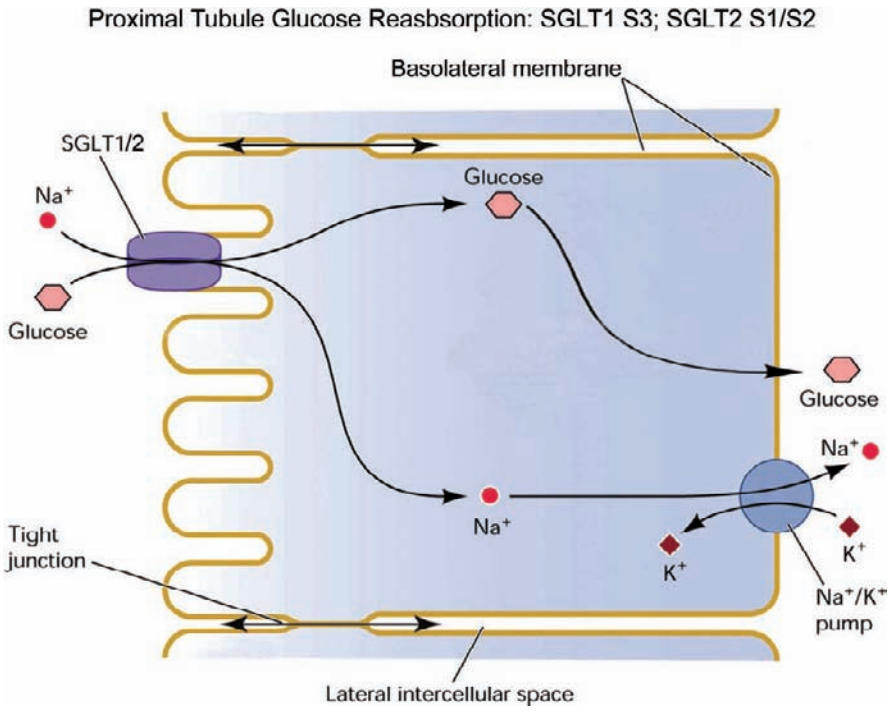

FIGURE 70.2 **Cellular mechanism of SGLTs in glucose reabsorption in the proximal tubule.** A schematic of how SGLT1 and 2 mediate the intestinal absorption, or renal reabsorption, of glucose. The Na^+ electrochemical potential gradient is maintained by the Na^+/K^+ pump, powers glucose accumulation by SGLTs from tubular lumen into cells; glucose subsequently moves down its concentration gradient across the basolateral membrane via GLUT2 (GLUT1 may be involved as well) into the interstitium and then blood. Both SGLT1 and 2 operate in similar fashion at a cellular level, though there are differences in function at the molecular level.

Immuno-fluorescent, -peroxidase, and -gold staining identified SGLT1 signal in all segments—S1, 2, and 3—of PT on apical membrane surfaces, whereas GLUT1 reactivity was observed on basolateral membrane surfaces of S3 PT as well as more inner (outer and inner medullary) regions. A second study examined SGLT1 and GLUT2 distribution;[36] in cortex, SGLT1 (on apical membranes) and GLUT2 (on basolateral membranes) showed co-reactivity in 40% of tubules. Moreover, SGLT1 signal was found in the majority of cortical PTs, based on co-staining with the PT marker, anti-γ-GTP. In a third study SGLT1 was localized on the brush border membrane of the proximal tubule with increasing intensity from the S1 to the S3 segments.[37] There was substantial intracellular staining in the cells of the S1 segment and, surprisingly, there was SGLT-related staining in the apical domains of the macula densa and adjacent cortical parts of the thick ascending limb of Henle. Apart from the fact that different SGLT1 antibodies were used in these studies there is no simple explanation for these subtle differences in SGLT1 distribution. So far there is only one paper reporting on the immunolocation of SGLT2 in the rodent kidney.[38] Here there was specific SGLT2 antibody staining of apical membranes of the early proximal convoluted tubule of the mouse and this was not observed in the $SGLT2^{-/-}$ mice.

Overall, we may conclude that there are two SGLT genes expressed in the kidney, SGLT2 in the brush border membrane of the early proximal tubule and SGLT1 in the brush border membrane of the late proximal tubule. Furthermore the localization of SGLTs to the apical membrane and GLUTs to the basolateral membrane provides plausible cellular mechanisms for glucose reabsorption in kidney (Figure 70.2). However, for human kidney there still are no immunocytochemical studies of SGLT2 and SGLT1 distribution and no physiological studies on isolated tubules.

While the atomic structure of human SGLTs is not yet known, the structure of a bacterial homolog vSGLT with 32% amino acids identity to hSGLT1 has been solved and refined to 2.7 Å (Figure 70.3).[5–7] As expected from biochemical studies the structure contains 14 transmembrane helices, and we also find one galactose molecule bound to the center of the protein occluded from the aqueous solutions on each side of the membrane. The most notable features of the structure are: i) the inverted repeat (TM1−5 and TM6−10) forming the core of the protein. While these repeats can be superimposed there is no amino acid homology between them; ii) there are two discontinuous membrane helices, TM1 and TM6, at the core of the sugar binding sites; and iii) hydrophobic gates occlude the sugar from the external solutions, external gates, M73, Y87 and F424 and the internal gate Y263. The pyranose sugar ring is stacked against the aromatic ring of the inner gate. Molecular dynamic studies show that after

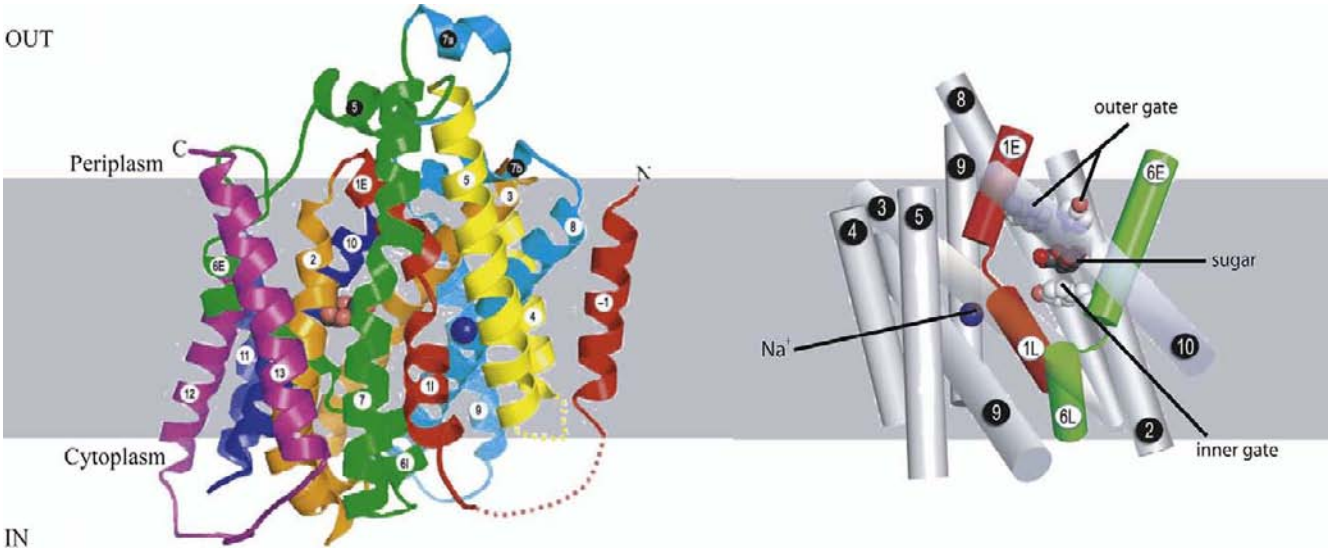

FIGURE 70.3 **The structure of the bacterial SGLT homolog vSGLT.** A side view of the 3-D structure of vSGLT in the membrane. The structure contains 14 transmembrane spanning helices (-1 to 13) with sugar bound in the center occluded from the external solutions. The structure consists of two inverted repeats (TM1-5 and TM6-10) with one TM helix in each repeat containing an unwound region in the middle of the membrane. A simpler model is shown on the right to illustrate the position of the sugar, the outer and internal hydrophobic gates, and the presumed location of the sodium binding site (blue sphere). *(Figure is modified from ref. [5,6,11].) Note: homology models of hSGLT1 show conservation of the sugar and sodium binding sites and the external and internal gates.*[39]

sodium release into the cytoplasm the tyrosine side chain rotates to a different position to allow the release of sugar to the cytoplasm.[7]

The high amino acid identity between vSGLT and hSGLT1, including the conservation of the sugar and sodium coordinating residues and the gates, has facilitated the generation and testing of a hSGLT homology model.[39] Mutation of the glucose binding residues produces profound reductions in the apparent sugar affinity ($K_{0.5}$), e.g. the mutation E102C increases the glucose $K_{0.5}$ from 0.5 to >100 mM. Evidence was also obtained for the opening of the external gates by external sodium, i.e., external methanethiosulfonate reagents and dyes only reached cysteine mutants in the sugar binding site when sodium was present in the external medium, and this access was blocked by sugar and phlorizin. This provides direct evidence that sodium/glucose cotransport is controlled by the coordinated opening and closing of the external and internal gates. Much structural work remains to be done to fully understand the atomic mechanism of transport.

GENETIC ABLATION OF SGLTS

Studies of transgenic mice deficient in SGLT2 ($SGLT2^{-/-}$) and SGLT1 ($SGLT1^{-/-}$) have shed new light on the relative roles of SGLT2 and 1 in renal glucose reabsorption *in vivo*.[38,40–42] In each of the three $SGLT2^{-/-}$ studies, absolute urinary glucose excretion was 60–70% of the filtered load in knock-out ($SGLT2^{-/-}$) mice, compared with 0% in WT mice. This implies that SGLT2 is of major importance in renal glucose reabsorption, but in the absence of functional SGLT2, there is still significant renal glucose reabsorption.

In the first study, detailed micropuncture experiments of cortical (i.e., *superficial*) nephrons were performed.[38] Early proximal convoluted tubular collections demonstrated 80% reabsorption of the filtered glucose load in WT mice, compared with 0% in $SGLT2^{-/-}$ mice. In later PT collections, the fractional reabsorption was 90% in wild type mice and 20% in knock-outs. It was also found that the filtered glucose load was proportional to the rate of excretion in knock-out mice, but independent of the load in WT. A major role for SGLT2 in glucose reabsorption was clearly established by this work; yet there was a significant discrepancy between superficial cortical fluid collections, which suggested SGLT2 is responsible for ≥80% of glucose reabsorption, and whole kidney glucose excretion measurements suggesting SGLT2 was responsible for 60% of glucose reabsorption. The results of this study make clear the importance of considering nephron heterogeneity in defining the role of Na^+/D-glucose co-transporters in renal glucose reabsorption.

A second study looked at mice deficient in SGLT2 and how they handled streptozotocin-induced diabetes.[42] Interestingly, $SGLT2^{-/-}$ mice showed

dramatically increased mortality—70% compared with 10% in wild type—due to sepsis from pyelonephritis. From this work, new questions about the safety of hSGLT2 inhibitors have emerged, which warrant further study.

In a third study, the SGLT2$^{-/-}$ strain used by Vallon et al.[41] was crossed with *db/db*—diabetic, obese, hyperlipidemic—mice. The resulting double transgenics had better glycemic control in both the fed and fasting states, they were less obese, and they displayed improved pancreatic β-cell health—increased cell mass (60%) and reduced cell death—compared with *db/db* mice alone.[41] Also, single transgenic (SGLT2$^{-/-}$) mice fed a high fat diet were protected from developing hyperglycemia, hyperinsulinemia, and glucose intolerance, when compared with their wild-type littermates on the same diet.

Taken together, these studies suggest that SGLT2 plays a significant role in glucose reabsorption, and genetically ablating SGLT2 can result in dramatic improvement of hyperglycemia and associated sequelae in T2DM. Indeed these knock-out studies are consistent with using SGLT2 inhibitors as a viable insulin-independent approach to treating type 2 diabetes mellitus (see below). It is also clear that there are significant compensatory mechanisms of glucose reabsorption in the absence of SGLT2, capable of reabsorbing up to 40% of the filtered load. What are the molecular players behind such compensation? One possibility is that hSGLT1 serves a robust role in the absence of SGLT2.

In awake SGLT1$^{-/-}$ mice the urinary glucose concentration was significantly increased (from ~0 to 20 mM) and the fractional reabsorption was reduced 3% in the absence of any apparent changes in SGLT2 mRNA or protein expression.[40] Micropuncture experiments on the last surface loop of proximal convoluted tubules showed that there was an increase in both the delivery and concentration of glucose in SGLT1$^{-/-}$ mice relative to wild-type mice: from 2 to 4 pmole/min and from 0.4 to 0.8 mM. These studies suggest that SGLT1 in the late proximal tubule does play a role in mopping up the last remaining glucose in the glomerular filtrate. As expected the most obvious phenotype of the SGLT1$^{-/-}$ mice is glucose-galactose-malabsorption, but the surprise is that unlike human GGM this phenotype only develops after weaning.

GENETICS OF RENAL GLYCOSURIA

Familial renal glycosuria (FRG, OMIM # 233100 and 182381) is an autosomal recessive condition characterized by urinary glucose excretion with normal plasma glucose levels, oral glucose tolerance tests, and plasma insulin levels. Patients absorb glucose and galactose normally, and they have no known defects in glucose utilization in tissues.[43] Long before any of the SGLT genes were identified, work was well underway to characterize FRG. In 1969, renal glucose titrations on two families with hereditary renal glycosuria showed that affected individuals typically had a lowered threshold (F_{mingG}) for glycosuria and reduced T_{max} (characteristic of "type A FRG"), and in one instance an exaggerated splay (characteristic of "type B FRG").[44] Importantly, sugar fluxes in jejunal mucosa samples demonstrated no difference in hexose transport between FRG patients and normal controls, i.e. intestinal glucose absorption was unaffected in FRG. There were also hints that inheritance of glycosuria was autosomal recessive, conflicting with the dogma of the time that FRG was inherited in autosomal dominant fashion. Further pedigree and physiological analyses of three generations from a single family established autosomal recessive inheritance as well as an intermediate phenotype of mild glycosuria in heterozygote family members.[45]

In more recent years, given the proposed role for hSGLT2 in renal glucose reabsorption,[32,33] researchers analyzed the gene encoding hSGLT2 (*SLC5A2*) and found it was associated with hereditary glycosuria.[46] Further studies confirmed *SLC5A2*'s involvement in a single individual with glycosuria,[47] and across multiple families, many with consanguineous unions.[48,49] In patients with either homozygous or compound heterozygous SGLT2 mutations, glucose excretion ranged from 15 to 200 g/day; and, consistent with previous hypotheses,[45] heterozygote family members frequently displayed glycosuria of ≤4 g/day. Follow-up studies of patients with combined severe glycosuria and aminoaciduria revealed a novel missense mutation in hSGLT2,[50] and aminoaciduria has been described in another case report of a patient with FRG.[51] The aminoaciduria was not immediately explained and was believed due to the severity of glycosuria rather than an intrinsic defect in amino acid reabsorption.

Analyses of *SLC5A2* mutations in families with FRG have revealed several noteworthy trends. First, most mutations identified in FRG are private: in 23 families with FRG, 21 unique mutations were observed;[49] and in another large analysis, 17 families yielded 20 unique mutations.[48] One mutation, a splice-site mutation ("IVS 7 + 5 g >a"), was observed in nine different families, with index cases showing either homozygosity or compound heterozygosity with this mutation; it was speculated that due to the high prevalence of this mutation, the region encoding the splice-site is a mutational "hot spot." Second, many of the mutations producing pronounced glycosuria (>20 g/d) are predicted to result

in either premature stop codons (by point or frameshift mutations) or deletions/insertions resulting in truncated proteins. There is precedent for this in GGM, where mutations in SGLT1 resulted in proteins which were non-functional or failed to traffic to the plasma membrane.[10]

There is significant heterogeneity in urinary glucose excretion among individuals with FRG. In patients homozygous or compound heterozygous for mutations in *SLC5A2*, excretion ranged from 10 to 200 g/d; some of this may be due to the difference between mutations resulting in partially-functional hSGLT2 protein versus those which produce non-functional or non-trafficked protein. However, in at least one instance, two members of the same family with the same compound heterozygous genotype (R137H, Δ358-8) had remarkably different excretion profiles: 200 g/d for the first index case, and 80 g/day for the second.[49] Such a finding hints at major differences in compensatory mechanisms of renal reabsorption in the setting of partially or completely impaired hSGLT2 function.

In general, FRG patients have no other phenotypic findings other than increased urinary glucose excretion: they do not suffer from hypoglycemia or any other impairment in glucose homeostasis, they do not have alterations in electrolyte excretion or significant changes in volume status, and long-term follow-up of one patient with severe glycosuria showed no alterations in renal function.[52] That said, in one recent study, elevated urinary glucose excretion was linked to mild diuresis in two patients with severe glycosuria: plasma renin activity and serum aldosterone were elevated to 3–4-fold above normal, suggesting volume and/or electrolyte loss accompanies glycosuria.[48] Among the group of mutation analyses and clinical case report data, FRG appears to be linked exclusively to mutations in hSGLT2 further cementing its significant role in glucose reabsorption in the kidney.

A second genetic disorder of renal glucose reabsorption is the rare Fanconi-Bickel Syndrome (FBS) (MIM 227810) linked to mutations in the facilitated glucose transporter 2 (GLUT2).[53] A major part of renal glucose reabsorption—facilitated diffusion of glucose across the basolateral membrane—is impaired (Figure 70.2). Interestingly, GLUT2 does not appear to be essential for intestinal glucose absorption in mice and in FBS patients (see [54]). FBS is described as a glycogen storage disease with hepatic and renal overload. Symptoms include hypoglycemia, hypergalactosemia, failure to thrive, and hypophosphatemic rickets. In addition, patients show generalized aminoaciduria and metabolic acidosis. With frequent carbohydrate feeds, phosphate and bicarbonate supplementation, patients lead relatively normal lives, although they are short in stature.[53,55]

DIABETES MELLITUS: A DISEASE OF HYPERGLYCEMIA

Diabetes mellitus (DM) is by far the most significant disease of disordered glucose homeostasis, in terms of severity, global disease burden, and costs to society. Often referred to as one disease, diabetes comprises a heterogeneous group of disorders, in which plasma glucose levels are elevated both in the fasting and post-prandial state; and it frequently accompanies other metabolic derangements. Type 1 diabetes (T1DM) typically expresses early in life (childhood to early adulthood) and it is caused by the destruction of pancreatic β islet cells leading to an absolute deficiency in insulin secretion. Patients require exogenous insulin to properly handle high post-prandial glucose loads, and they are prone to hypoglycemia and ketoacidosis in the fasting state. Although T1DM is believed to be caused by some combination of infection, autoimmune mechanism, genetics, and environmental factors, no clear etiologic agent has been implicated.[56]

Type 2 diabetes mellitus (T2DM) was historically described as "adult-onset" diabetes mellitus; however this description is no longer relevant as T2DM can affect individuals in early adolescence. This is in part due to the rampant obesity epidemic that has plagued the developed world in recent decades. T2DM is a disease of diminished tissue insulin sensitivity (or diminished β-cell insulin output, i.e., a relative insulin deficiency), and it is linked with obesity, the consumption of foods high in refined sugars and fat, a sedentary lifestyle, and numerous genetic factors.[57,58,59] One in three American adults is projected to have diabetes by 2050,[60] and yet current oral hypoglycemic medications (e.g., biguanides, sulfonylureas, and thiazolidinediones) all have potentially significant side effects and high long-term failure rates.[61] Glycemic control is linked significantly to the incidence of microvascular and macrovascular complications,[62] and thus developing more effective and safer ways to ameliorate fasting and post-prandial hyperglycemia is of critical importance in the treatment of T2DM. One such target with significant interest from the pharmaceutical industry is glucose reabsorption in the kidney by hSGLT2.

BLOCKING RENAL GLUCOSE REABSORPTION AS A TREATMENT FOR DIABETES

Long before the renal SGLTs were identified, the relationship between intravenous phlorizin administration and glycosuria was established. Human studies in the 1930s showed that, at high enough doses, phlorizin

induced renal glucose excretion of ≈100%.[23,63] In the more recent past, phlorizin was shown to diminish hyperglycemia and normalize insulin sensitivity in several diabetic rat models.[64–66] Yet phlorizin was deemed unsuitable as a treatment: it has limited bioavailability due to lactase-hydrolase cleavage in the intestines, and there were concerns it would cause diarrhea by inhibiting hSGLT1.

Based on the promising results from studies of phlorizinized humans and diabetic rodents, while also considering phlorizin's limited oral bioavailability, the Tanabe Seiyaku Company's Discovery Research Laboratory initiated a program to develop renal SGLT inhibitors as antidiabetics.[67] Starting with phlorizin they synthesized the O-glycoside T-1095 (hSGLT1 $IC_{50} = 20\ \mu M$, hSGLT2 $IC_{50} = 2\ \mu M$) and T-1095A (hSGLT1 $IC_{50} = 200$ nM, hSGLT2 $IC_{50} = 50$ nM)[68] (Figure 70.4). T-1095 included a methyl acetate group on carbon 5 of the glucose ring which resulted in enhanced oral bioavailability, and it could be cleaved to its more potent form—T-1095A—in plasma. The relatively low SGLT2:SGLT1 specificity of T-1095A allowed it to inhibit both renal transporters *in vivo*, as does phlorizin. The drug showed efficacy in animal models: diabetic (streptozotocin-induced or C57BL/KsJ-db/db) rats showed dose-dependent reductions in blood glucose. With long term administration, plasma glucose and glycosylated hemoglobin (HbA_{1C}) levels were reduced and glucose tolerance test performance improved.[68] Importantly, the progression of diabetic nephropathy slowed significantly.[69]

In the decade that followed, numerous candidate SGLT2 inhibitors emerged, five are in advanced Phase III clinical trials[70–72] and one, dapagliflozin, has been submitted to FDA and EMA for clinical approval. The discovery and extensive studies of dapagliflozin (Figure 70.4) marked a significant turning point in the development of hSGLT2 inhibitors. Chemists at Bristol-Meyers Squibb started first by reducing the O-glycoside linkage in phlorizin to a C-C bond between sugar and the aglycone's phenyl ring 1; this was designed to prevent enzymatic cleavage by intestinal lactase-hydrolase. Then, through a structure-activity relationship (SAR) optimization scheme they settled on an aglycone notable for a C4 chlorine substitution in ring 1, which was connected to a second ring by a single methylene (-CH2-) linker. The resulting compound (Figure 70.4) showed remarkable potency ($IC_{50} = 1$ nM) and specificity (1200:1) for hSGLT2 over hSGLT1.[73] In rats, a 10 mg/kg-body weight dose of dapagliflozin produced the same 24 hour glycosuric effect (2000 mg glucose excreted per 200 g body weight) as a 300 mg/kg dose of T-1095A.[68,73]

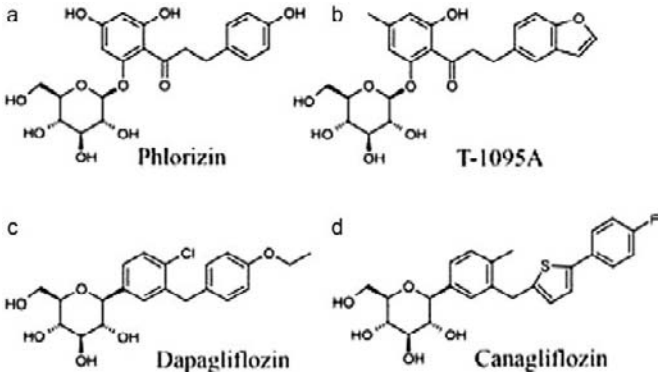

FIGURE 70.4 **Structures of SGLT inhibitors.** (a) Phlorizin is the canonical SGLT inhibitor; (b) T-1095A was the first inhibitor synthesized based on the structure of phlorizin. (c) and (d) Dapagliflozin and Canagliflozin are selective hSGLT2 inhibitors in phase III clinical trials.

Since its discovery, a number of studies have been published on dapagliflozin's performance in animals and humans. It increased urinary glucose excretion in healthy rats and reduced hyperglycemia in diabetic animals;[74] and in diabetic and obese rats it improved glycemic control and pancreatic β-cell morphology and function.[75] In healthy human subjects, dapagliflozin induced dose-dependent urinary glucose excretion of up to 50% of the filtered load.[76] In diabetic patients the results were also impressive: glycemic control improved in patients taking dapagliflozin over a short period,[77] it significantly reduced hyperglycemia and lowered HbA_{1C} in patients with poorly-controlled diabetes.[78] It also worked as part of combination therapies, both with insulin and/or insulin sensitizers[79] and the standard first-line T2DM pharmacotherapy metformin,[80] successfully normalizing markers of diabetic disease extent.

Overall, dapagliflozin has been shown to reduce fasting and post-prandial glucose levels by 20%, lower HbA_{1C} to below 7%, induce weight loss (≈2% of body weight), and it can be administered as *once daily* oral drug therapy. Importantly, every published study to date has demonstrated that dapagliflozin does not cause hypoglycemia—a serious side effect of many anti-diabetes drugs currently in clinical use. It has also shown hints of efficacy in the management of hypertension: it causes mild diuresis and a reduction of ≈5 mm Hg in systolic blood pressure.[80] Side effects reported in greater frequency than in patients receiving placebo were genital infections and symptoms/signs of urinary tract infections.[78–80] This is undoubtedly connected to increased urinary glucose, and it will likely be explored in long-term clinical studies of dapagliflozin (i.e. phase IV clinical trials). At the time of this writing, dapagliflozin was rejected by the FDA owing to concerns about an increase risk of bladder and breast cancer, but it just received (April 2012) a favorable

review from the EMA Committee for Medicinal Products for Human Use. It is anticipated that dapagliflozin (Forxiga) will be the first to market anti-diabetes pharmacotherapy targeting hSGLT2.

Other SGLT2 inhibitors in advanced Phase III trials include empagliflozin[81] and canagliflozin (Figure 70.4). Both are C-aryl glycosides that reduced fasting blood glucose and improved glucose tolerance in high-fat diet fed KK (HF-KK) mice, and it increased urinary glucose excretion in both HF-KK and normal mice and Zucker Diabetic Fatty (ZDF) rats.[82,83] In recently-published phase I clinical studies in healthy human subjects, canagliflozin reduced the renal threshold for urinary glucose excretion (UGE), and single-ascending dose studies demonstrated a maximum 24 hour UGE of 70 g.[84] In addition, normal subjects given $\geq$200 mg doses of canagliflozin before breakfast showed lower plasma glucose levels (10−20%) and reduced insulin secretion ($\leq$50%) compared with persons receiving placebo.

Lexicon has developed a non-specific SGLT inhibitor using L-xylose linked by a C-aryl bond to the aglycone of dapagliflozin, LX4211. This has Ki's of 1.1 nM (hSGLT2) and 36 nM (hSGLT1).[85] LX4211 blocked up to $\approx$50% of glucose reabsorption in diabetic/obese mice.[86] In an early phase 2 clinical trial of 36 diabetic subjects, LX4211 caused urinary glucose excretion of up to 60 g/day, reduced HbA_{1C} by $\approx$0.7% as well as plasma fructosamine, compared with placebo, and lowered fasting (by 50 mg/dL) and post-prandial glucose. Surprisingly, the Lexicon non-specific SGLT inhibitor does not appear to be more effective than the specific SGLT2 inhibitors in blocking renal glucose reabsorption, with a maximum of 50% inhibition.

Although the race is well under way to develop drugs specifically targeting hSGLT2, there are unresolved questions about what role hSGLT2, hSGLT1 and other proteins play in renal glucose reabsorption. Since dapagliflozin, which *in vitro* blocks 100% of D-glucose transport by hSGLT2, inhibits glucose reabsorption *in vivo* by $\leq$50%[76] there may be other significant components involved in renal glucose reabsorption. At the same time, there are lingering questions about precisely *how* inhibitors interact with Na^+/D-glucose cotransporters. For example, little dapagliflozin is detected in the urine,[87,88] suggesting its interaction with the renal hSGLTs may be unique: it is plausible it is an irreversible inhibitor of hSGLT2, it may block glucose transport from the cytoplasmic surface of hSGLT2.

While there have been few mechanistic studies of SGLT2 inhibitors we have characterized the interaction of dapagliflozin and several of its structural homologs with hSGLT1 and hSGLT2.[89] Dapagliflozin and 4-fluoro-4-deoxy-dapagliflozin (F-dapagliflozin) block hSGLT2-mediated αMDG accumulation, as well as D-glucose-coupled Na^+ currents, in cells with high (Ki = 6 nM) potency; furthermore, a D-galactose derivative of dapagliflozin (galacto-dapagliflozin) was also a potent inhibitor (Ki = 25 nM). In comparison, hSGLT1 a 10^2- to 10^5-fold higher concentrations of dapaglifozin and its derivatives was required to block hSGLT1. The SGLT2 and SGLT1 OFF-rates for dapagliflozin and derivatives were compared with those for phlorizin. For hSGLT1, dapagliflozin, F-dapagliflozin, and galacto-dapagliflozin all dissociated very rapidly ($t_{1/2,Off}$ = 1 s); whereas for hSGLT2, dapagliflozin does not readily dissociate, F-dapagliflozin ($t_{1/2,Off}$ = 170 s) dissociated slowly and galacto-dapagliflozin came off rapidly ($t_{1/2,Off}$ = 20 s). These findings indicate that the blockers bind to the external surface of the SGLTs and that the relative potency between SGLT1 and SGLT2 largely depends on the rate of dissociation from the protein. The pharmacokinetics of renal SGLT2 inhibitors leaves many unresolved questions about their mode of action. For example: (1) in the face of high binding to serum proteins, >90%, and the low rate of appearance of the unmodified drugs in the urine, do they inhibit from the tubular lumen as in the case of phlorizin?; (2) what explains the observations that the SGLT drugs only inhibit glucose reabsorption by ~50%, while phlorizin inhibits 100%; and 3) what explains the long lasting effect, in excess of 24 hours, of one oral dose given the high amount of drug metabolism?

CONCLUSIONS

Considerable advances have been made over the past two decades in understanding the physiology of glucose reabsorption by the kidney. It is clear that the SGLTs and GLUTs play central roles in the complete reabsorption of the filtered glucose in the proximal tubule, and mutations in these genes largely account for the glucosuria observed in patients with Familial Renal Glucosuria, Fanconi-Bickel Syndrome, and Glucose-Galactose-Malabsorption. However, questions still remain about possible compensatory changes in mice and men with "ablation" of SGLT2. Contrary to common perceptions, glucose reabsorption from the glomerular filtrate is not essential for life. The clinical studies with the SGLT inhibitors have clearly established that in healthy subjects the loss of 80 grams of glucose to the urine has no remarkable adverse effects and in diabetic patients there is a "normalization" of glucose homeostasis. The added benefit with the use of these drugs in diabetics is the sustained loss in weight, up to 6 kg over three years. While the development of SGLT inhibitors as antidiabetic drugs may or may not

turn out to be a clinical success, this has indeed produced a resurgence in interest in the physiology of glucose handling by the kidney.

Acknowledgments

We are grateful to our past and present colleagues for their contributions to our understanding of the biology SGLTs and to financial support from the National Institutes of Health (DK19567, 0–34; DK0077133, 0–4; and the National Research Service Award DK082153 to CH).

FILTRATION AND REABSORPTION OF AMINO ACIDS AND OLIGOPEPTIDES

Reabsorption of amino acids is a fundamental and evolutionarily well-conserved mechanism that involves active transcellular transport by specialized transporter proteins localizing to both luminal and basolateral tubular epithelial cell membranes. Approximately 50 g (450 mmol) of free amino acids are filtered daily into the primary urine by human kidney glomeruli. By reabsorbing these amino acids, kidney tubules prevent their loss in the urine. In addition, amino acid metabolism by kidney tubules plays an important role in whole body amino acid homeostasis. Di- and tripeptides are also efficiently reabsorbed from the primary urine with uptake, to a large extent, followed by intracellular hydrolysis to free amino acids and subsequent basolateral export.

Depending on the amino acid, plasma concentration of free amino acids and consequently in the ultrafiltrate varies from low μmol/l up to nearly 1 mmol/l (Table 71.1). For most amino acids reabsorption is ~99.5% efficient and therefore the fractional excretion is less than 0.5% of filtered load. In humans, serine, glycine, histidine, and taurine are notable exceptions for which a higher fraction is lost in the urine (Table 71.1). For several amino acids, a variable fractional excretion is observed, for example, tending to increase when the filtered load increases.[1,2] The filtered load also depends on the glomerular fluid filtration rate (GFR), which itself is influenced by factors like circadian rhythm, orthostasis, and extracellular volume. Interestingly, by a mechanism not yet understood, renal plasma flow (RPF) and GFR are increased by a high protein diet or infusion of free amino acids.[3] The involvement of glucagon, NO or tubuloglomerular feedback have been suggested as possible mechanisms.[4,5] As discussed in later sections, differences in the fractional excretion observed for individual amino acids may result from the various selective transporters' (relative) expression levels, kinetics, ion dependence, and axial localization along the nephron.

Evidence that amino acid reabsorption along the nephron is axially heterogeneous was first derived from clinical observations. Specifically, lesions of the early proximal kidney tubule were observed in Fanconi syndrome, a condition characterized by glucosuria, phosphaturia, and aminoaciduria. Since glucose and phosphate were already known to be reabsorbed in proximal tubules, it was inferred that this nephron segment is also the main site of amino acid reabsorption.[6] The hallmark experiments confirming the role of proximal tubules were carried out using micropuncture and microinjection.[7–9] Quantification revealed approximately 80% of filtered amino acids are reabsorbed in the first half of the proximal convoluted tubule (S1 segment) whereas less than 1% remains in the tubular fluid at the end of the straight portion (S3 segment) of the proximal tubule.[10]

Concerning the later tubular segments, it was demonstrated by free flow micropuncture that no additional active amino acid transport takes place along the

loop of Henle.[7] Furthermore, it was shown by microinjection[11] and microinfusion experiments[12,13] that with the exception of taurine, amino acids delivered into the early loops of superficial distal nephrons are recovered quantitatively from the final urine. Taken together, these experiments indicated that there is no significant amino acid reabsorption beyond the proximal tubule. One caveat is that a quantitative difference exists between the amino acid fractional delivery values for superficial nephrons reported above and the urinary amino acid fractional excretion. This difference was suggested to be due to the differential absorptive capacity of superficial and deep nephrons.[14]

FROM "TRANSPORT SYSTEMS" TO TRANSPORTERS

The transport of free amino acids and small peptides was intensively studied during the second half of the last century thanks to the availability of radiolabeled amino acids and sensitive analytical quantification techniques such as paper chromatography and liquid chromatography. Erythrocyte and cell culture models, as well as tissue and organ experimental systems, in particular small intestine and kidney, were used. From the latter epithelial organs, brush border membrane vesicles were produced that allowed measurement of luminal transports in the presence of defined solutes at their trans-side, i.e., inside vesicles. Prior to the molecular identification of transport proteins, the so-called "transport systems" were functionally defined by amino acid selectivity, stereospecificity, ion-(sodium, chloride, potassium), or proton dependence, thermodynamic properties (equilibrative or concentrative) and transport type (co-transport = symport (S), exchange = antiport (A) or facilitated diffusion = uniport (U).[15–17] These "transport systems" were named according to functional properties with letters corresponding to the main/first described amino acid substrate, e.g., system A (L-alanine), N (L-asparagine), L (L-leucine), and ASC (L-alanine, L-serine and L-cysteine). In general, capital letters denoted sodium-dependent (except systems L and T) and lowercase sodium-independent systems (e.g., $b^{0,+}$). The transport of basic or acidic amino acids was identified by a plus or a minus symbol (e.g., system y^+L and X^-_{AG}) and the letter B used for systems with a broad amino acid selectivity (for example B^0, $B^{0,+}$).

A new era started with the molecular identification of transporters, which was made possible by the complementary techniques of DNA cloning and cellular over-expression.[18–22] Currently, about 50 amino acid and peptide transporters have been molecularly described. Researchers identifying new amino acid transporters have generally named them according to the "rules" previously used to describe transport systems[15] on occasion resulting in multiple names for the same transporter. The human genome organization (HUGO) proposed a new classification scheme for the genes of solute carriers (SLC) based on sequence homology.[19] This system is now in use for other

vertebrate species as well. The SLC gene nomenclature is increasingly used also to name the encoded transport proteins (Table 71.2). The molecular identification of transporters has allowed their detailed functional characterization using cellular overexpression systems, in particular *Xenopus laevis* oocytes. Additionally, the availability of cDNA allowed measurement of mRNA expression in tissues, initially by Northern blot analysis, and later by real time quantitative RT-PCR (qPCR) and microarray chips. Furthermore, specific antibodies could be generated and used to localize transport proteins at the tissue, cellular and subcellular levels. Noteworthy, the molecular identification of transporters has resulted in the identification of genetic defects underlying several hereditary amino acid transport-related diseases, in particular causing aminoacidurias (discussed in later sections).

More recently, to address questions about the functional role of amino acid transporters in a physiological context, knockout mice (conventional, tissue-specific and/or conditional) and transgenic mice and rats have been generated. Urine analysis, determination of amino acid fractional excretion, microperfusion, isolated tubule perfusion and other techniques are therefore once again valuable tools for phenotyping genetically-modified animals to increase understanding of the physiological roles of amino acid transporters. In addition, the structure-function relationship of amino acid transporters can be probed using truncated and chimeric constructs, cysteine scanning and so on.[23–25] Specifically questions could be addressed concerning accessibility of residues, substrate and ion binding sites, allosteric binding domains, tertiary and quaternary structure, and protein interactions. Currently, using bacterial homologues of mammalian transporters, the three dimensional structures of GltPh (PDB 1XFH), a homologue of sodium-dependent glutamate transporters (SLC1 family), and of $LeuT_{Aa}$ (PDB 2A65), a homologue of B^0AT1/SLC6A19 (SLC6 family), and PEPT(So) (PDB 2XUT), a homolog of the mammalian peptide transporters (SLC15 family) have been solved[26–28] adding a new level to our understanding of the structure-function relationships of these molecular machines.

FUNCTIONAL SCHEMA OF AMINO ACID REABSORPTION BY PROXIMAL TUBULE EPITHELIAL CELLS

The reabsorption of amino acids by kidney proximal tubules is a transcellular process involving passage across two membranes, namely from the tubular lumen into an epithelial cell, and from the cytoplasm to the extracellular space, for diffusion back into the circulation.

A summary of the current knowledge concerning the arrangement of transporters involved in transepithelial amino acid reabsorption by kidney proximal tubule cells is proposed in the model shown in Figure 71.1 (modified from Verrey et al., 2009).[29] The luminal influx of amino acids is mediated by a set of secondary active transporters driven by the co-transport of Na^+ or H^+ and by one heteromeric amino acid transporter that functions as an antiporter, $(b^{0),+}$AT-rBAT (SLC7A9-SLC3A1).

Transporter selectivity for amino acids overlaps to some extent though generally with different affinities for common substrates. For example, neutral amino acids, which represent > 80% of the free plasma amino acids, are all transported with different apparent affinities and transport rates by the luminal transporter B^0AT1 (SLC6A19) [30–32] (Fig. 71.1). Some amino acids are also transported by the heterodimeric amino acid transporter, $b^{0,+}$-rBAT (SLC7A9–SLC3A1). However, the main function of this exchanger is the import of cationic amino acids and cystine. Furthermore, $b^{0,+}$-rBAT cannot substitute for B^0AT1 since as an obligatory amino acid exchanger (antiporter) it does not contribute to the overall net amino acid import (see sections on specific transporters below).[33–35] The imino and neutral amino acid transporters, SIT1, PAT1 and PAT2 also display overlapping substrate selectivity with B^0AT1. SIT1 (SLC6A20) is an SLC6 family member expressed in the proximal tubule, which in addition to mediating a very efficient L-proline transport, transports other neutral amino acids.[36–38] PAT2 (SLC36A2) and PAT1 (SLC36A1), SLC36 family proton co-transporter(s), also transport L-proline and small neutral amino acids.[39,40] Estimation of the relative contribution of each transporter to the actual transport of a given amino acid is very difficult, since this depends not only on the apparent affinity ($K_{0.5}$) and V_{max} (expression level and transport rate) of each involved transporter and on the amino acid concentration (for the given amino acid), but also on the presence of competing amino acids and compounds. An additional complication is the role of co-transported and/or exchanged substrates, which depending on the transporter are ions, protons, or amino acids. The concentration of co-substrate(s) on both sides of the membrane determines availability and driving force, and thus determines their impact on the amino acid transport rate. Furthermore, in the case of transports driven by an electrical gradient, membrane potential plays an important role.

The majority of the transporters involved in amino acid reabsorption in the kidney are localized along the first two (S1 and S2) proximal tubule segments where

most of the amino acid reabsorption occurs. However, some high affinity luminal co-transporters are localized predominantly in the S3 proximal tubule segment, downstream of lower affinity transporters. This is the case for the high affinity Na^+-Glucose co-transporter SGLT1 (Slc5a1), which is expressed downstream of low affinity SGLT2 (Slc5a2).[45] Additionally, the high affinity oligopetide transporter PEPT2 (Slc15a2) and the high affinity neutral amino acid transporter B^0AT3 (SLCA18) are expressed downstream of PEPT1 (Slc15a1) and B^0AT1 (Slc6a19), respectively.[45,50] This sequential distribution of low and high affinity transporters along the proximal tubule is suggested to optimize recovery from the ultrafiltrate by permitting absorption of residual solutes and of solutes that have diffused back into the tubular fluid via the relatively leaky paracellular pathway. The various secondary active amino acid transporters expressed in the luminal plasma membrane are all described below in short sections.

The basolateral transport of amino acids is not as well understood as the luminal amino acid influx. This is due to several reasons, a trivial one being that

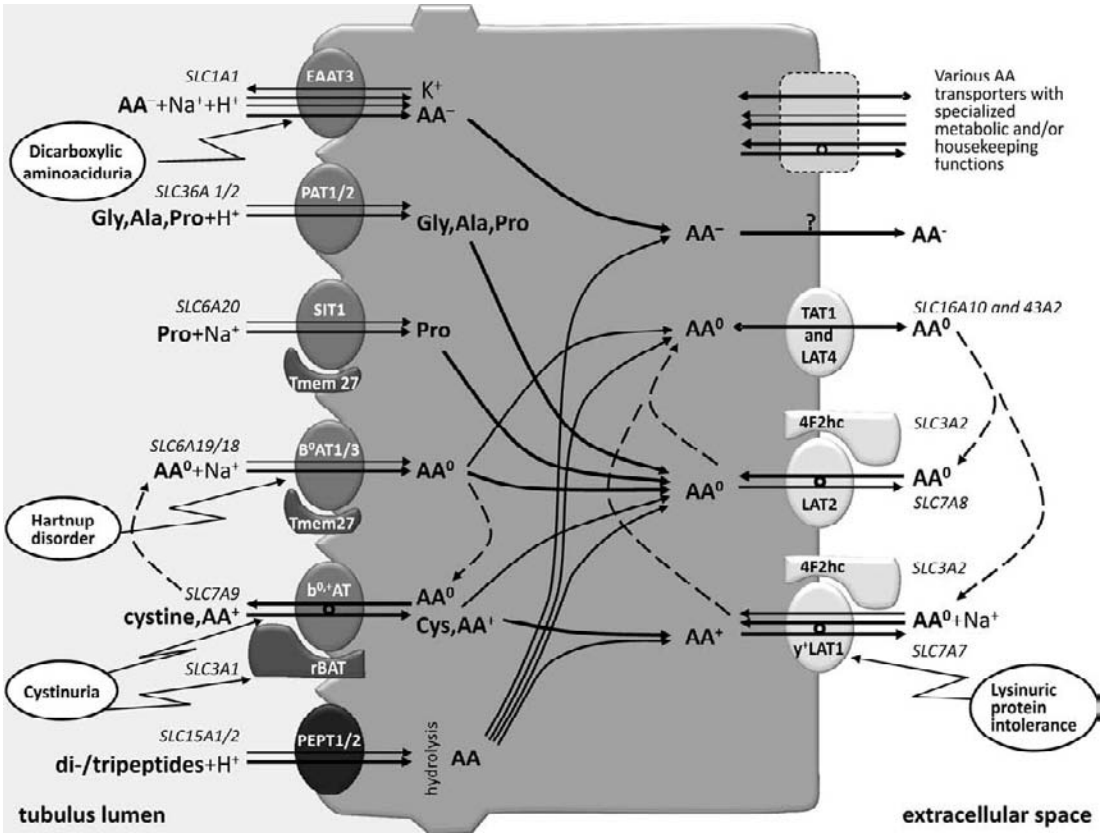

FIGURE 71.1 Cellular model for the reabsorption of amino acids across a proximal kidney tubule cell. Names of the involved transporters and their human gene are indicated. Most of them have been shown to be expressed mainly in the early segments of mouse proximal tubule (S1 and S2), with the exception of SIT1 that is expressed all along the proximal tubule, and of B0AT3 and EAAT3, which are expressed mainly in the later proximal tubule (S2 and S3). AA^0 neutral amino acid, AA^- anionic amino acid, AA^+ cationic amino acid, Tmem27 (collectrin).

measuring efflux is technically more demanding than measuring influx. The central issue is that the role of basolateral amino acid transport is more complex than that of luminal amino acid uptake. Whereas apical transport aims at clearing the filtered amino acids from the urinary fluid, basolateral transport in addition to transporting the cellular amino acid content into the extracelluar space, also maintains a physiological intracellular amino acid concentration. This is a task that basolateral amino acid transporters of tubular cells have in common with those of non-polarized cells. Indeed, intracellular amino acids are required to fulfil cellular housekeeping tasks and as substrates for amino acid metabolism. Therefore, a relatively stable amino acid gradient from the tubular cells towards the extracellular fluid has to be maintained.

Specifically, some amino acids display similar concentrations within and outside of the cells, while others display an asymmetric distribution. This is particularly evident for anionic amino acids that, despite carrying a charge that should drive efflux, are present at higher concentrations in the cytosol than in the extracellular space.[46,47] Likewise, in some cells cationic AAs, whose charge should drive influx, are none-the-less not more concentrated in cytosol than in plasma. Two transporters in amino acid transporting epithelial cells that play important roles in the control of various neutral and cationic amino acid intracellular concentrations are the heterodimeric exchangers (antiporters) LAT2-4F2hc (SLC7A8-SLC3A2, neutral amino acid antiporter) and y^+LAT1-4F2hc (SLC7A7-SLC3A2, antiporter exchanging intracellular cationic amino acids for extracellular neutral amino acids and Na^+). As obligatory exchangers (antiporters), these transporters can only mediate net vectorial transport of those amino acid substrates that are exchanged for co-substrates recycled back through the membrane by unidirectional amino acid efflux pathway(s).[48] To date, two facilitated diffusion pathway transporters (uniporters), which mediate the directional transport of substrates along their concentration gradient, are proposed to fulfil this function in the basolateral membrane of kidney proximal tubule cells. Specifically, we have shown that the aromatic amino acid uniporter TAT1 (Slc16a10) is present

in the proximal kidney tubule basolateral membranes. Using the *Xenopus laevis* oocyte expression system we demonstrated TAT1 is capable of recycling amino acids to drive the efflux of other substrates by the antiporter LAT2-4F2hc.[49] However, the TAT1 knockout mouse does not show the dramatic changes in urinary amino acid concentrations expected if TAT1 alone recycles amino acids activating efflux via the exchangers LAT2-4F2hc and y^+LAT1-4F2hc (unpublished data). Another candidate for the recycling function is LAT4 (SLC43A2), which we have shown also cooperates with LAT2 in the *Xenopus laevis* oocyte expression system.[49] More work is needed to understand the controlled efflux of amino acids through the basolateral membrane of transporting epithelia.

Finally, it can be hypothesized that given the narrow substrate selectivity of the uniporters known to date, some players that drive net transport of neutral, anionic, and imino acids at the basolateral membrane are not, as yet, molecularly identified.

TRANSPORTERS INVOLVED IN THE LUMINAL UPTAKE OF AMINO ACIDS AND OLIGOPEPTIDES

Neutral Amino Acids

B^0AT1 (SLC6A19) is the major neutral amino acid transporter. It is a *symporter* that co-transports Na^+ and a broad range of neutral amino acids (all proteogenic ones) with low affinity (millimolar range).[30,31] Unlike many other members of the SLC6 family, B^0AT1 is not Cl^- dependent, and does not transport biogenic amines nor related osmolites.[50,31] B^0AT1 mRNA was found to be highly expressed in kidney proximal tubule and small intestine. In both mice and humans B^0AT1 is expressed in the brush border membrane of early proximal kidney tubules (S1).[51,42] Another interesting feature of B^0AT1 is its interaction with two tissue specific accessory proteins. In kidney, B^0AT1 interacts with the accessory protein, collectrin (*Tmem27*), and in intestine with the angiotensin converting enzyme 2 (*Ace2*). Tmem27 is a type I transmembrane protein that appears to interact non-covalently with B^0AT1. The collectrin (Tmem27 or *coll*) knockout mouse lacks renal B^0AT1 although intestinal expression is normal. Furthermore, *tmem27* knockout animals display a massive neutral aminoaciduria without glucosuria or phosphaturia pointing to Tmem27 being the specific obligatory subunit of B^0AT1 in the kidney.[52–54] In the intestine, where Tmem27 is not expressed, B^0AT1 interacts with Ace2. The Ace2 knockout mouse, which has normal kidney expression of B^0AT1, lacks intestinal B^0AT1 expression and displays impaired intestinal neutral amino acid transport.[32] The B^0AT1 knockout mouse, which does not express B^0AT1 in either kidney or intestine, has a reduced bodyweight. Consistent with B^0AT1 being the major Na^+-dependent neutral amino acid transporter of small intestine and kidney proximal tubule luminal membranes, brush-border vesicles prepared from both tissue sources lack Na^+-dependent neutral amino acid uptake. Furthermore, they do not show any compensatory increase in peptide transport and have normal expression of both accessory proteins, namely Tmem27 and Ace2.[55]

B^0AT3 is structurally and functionally related to SLC6A19 (B^0AT1). It is highly expressed in apical membranes of kidney proximal tubules with a complementary axial expression vs. B^0AT1, namely with a higher expression in the later S2 and S3 segments. The SLC6A18 gene is localized on chromosome 5p15 in tandem with the SLC6A19 gene and the two protein products share ~50% identity.[42] Functionally, B^0AT3 transports a broad range of neutral amino acids in a Na^+ and Cl^- dependent manner with a substrate specificity similar to B^0AT1, but with higher affinities (micromolar range). As for B^0AT1, B^0AT3 requires the accessory protein Tmem27 for renal expression.[43,44,52] B^0AT3 appears to reabsorb residual tubular amino acids, i.e. amino acids not reabsorbed in early proximal kidney tubule segments by B^0AT1 and/or which have leaked back into the lumen via a paracellular route.[56] Although, in a *slc6a18* knockout mouse model an abnormal excretion of several neutral amino acids (especially glycine) was observed,[43,57] this transporter appears not to play a functional role in humans since a large fraction of the population displays a nonsense single nucleotide polymorphism with no associated phenotype.[58]

Imino and Small Neutral Amino Acids

PAT1 and PAT2 (SLC36A1 and 2) co-transport small neutral amino acids or imino acids with protons. Their functional description was rendered more complicated by the fact that the proton gradient across the luminal membrane of proximal tubule cells depends on the activity of the sodium−proton exchanger NHE3. Therefore, PAT-mediated transport was first erroneously considered to be Na^+-dependent. Both PAT1 and PAT2 mRNAs were detected in kidneys but are mainly expressed in other tissues. PAT1 mRNA was found for instance in small intestine, brain, and colon, while PAT2 in lungs, heart, testis, muscles, and spleen.[39] These two transporters have a similar substrate selectivity that includes L- and D-proline, hydroxyproline, glycine, sarcosine, L, D, and β-alanine, D-serine, D-cysteine, betaine, α-(methylamino)isobutyric acid, and

GABA. Compared with PAT1, PAT2 prefers L- over D-alanine, does not distinguish between L- or D-serine and has a ten-fold lower affinity for GABA.[40] The major functional difference between these two transporters is that PAT1 displays a low affinity for its substrates (millimolar range), whereas PAT2 is a high affinity transporter (micromolar range). The PAT2 protein was shown to localize at the apical membrane of the early proximal tubule portion in human kidney.[59] Although, PAT1 protein has been localized to the brush border membranes of intestinal enterocytes, in mouse kidney proximal tubule cells only a subapical membrane expression has been shown.[44] No report of a knockout mouse model for either PAT1 or PAT2 has been published.

SIT1 (SLC6A20) functions as a symporter, co-transporting with high affinity (micromolar range) L-proline, methylaminoisobutyrate (MeAIB), methyl-proline, or hydroxyproline with Na^+ and Cl^-. Thus, together with PAT2 and possibly PAT1, SIT1 represents the so called "imino system." Unlike PAT1 and -2, SIT1 does not transport glycine or β-alanine.[36,38] The mRNA of SIT1 is highly expressed in small intestine, kidney, lungs, spleen, testis, and brain, and the protein has been shown to localize to the luminal brush border membrane of the entire proximal kidney tubule and of the small intestine.[42] SIT1 has been suggested to interact with the accessory protein Tmem27, since Tmem27 knockout animals showed a much reduced expression of SIT1 in the kidney.[52] Co-expression experiments in *Xenopus* oocytes show that SIT1 can functionally interact with the accessory proteins Tmem27 and Ace2. SIT1 was also shown to co-localize with Ace2 in human small intestine brush border membranes (Vuille-dit-Bille, Camargo and Verrey, unpublished data). As yet, no knockout mouse model for SIT1 (*slc6a20*) has been reported.

Cationic Amino Acids and L-Cystine

rBAT (SLC3A1) and $b^{0,+}$AT (SLC7A9) form together a heterodimeric amino acid transporter (HAT).[60] It is composed of the type II glycoprotein (heavy subunit) rBAT and the catalytic subunit (light subunit) $b^{0,+}$AT, that are covalently linked by a disulfide bridge.[61,62] The light chain, which contains 12 putative transmembrane domains, is the active subunit and confers substrate specificity. Both subunits are primarily expressed in kidney and intestine where they localize to the brush border membrane of proximal tubules or small intestine enterocytes.[62,63] When over-expressed in an epithelial cell model (MDCK cells) rBAT and $b^{0,+}$AT co-localize in the apical membrane, while in the absence of rBAT, $b^{0,+}$AT is retained intracellularly, demonstrating rBAT is essential for cell surface expression of $b^{0,+}$AT.[64,65] The rBAT and $b^{0,+}$AT heterodimer mediates the obligatory exchange of large neutral (notably cystine) against dibasic (arginine, lysine, ornithine) amino acids.[34] Mouse models generated by the ablation of the heavy or light chains excrete higher levels of cystine and dibasic amino acids in the urine.[66–68]

Anionic Amino Acids

EAAC1/EAAT3 (SLC1A1) functions as a high affinity symporter and antiporter. It co-transports L-glutamate, L- or D-aspartate with Na^+ and H^+ from the tubule lumen into the cell in exchange for K^+ that is transported to the outside. The transporter is highly expressed in the later portion of kidney proximal tubules (S2, S3 >S1) and in distal convoluted tubule, the brush border of ileal enterocytes, and in various subpopulations of neurons.[20,69] EAAC1/EAAT3 is the only anionic amino acid transporter thus far detected in the apical membrane of proximal tubule cells. EAAT3 was shown to have an allosteric negative modulator, the glutamate transport associated protein (GTRAP3–18). GTRAP3–18, which interacts with the carboxy-terminal end of the transporter, is a membrane-associated protein expressed in the same tissues as EAAT3 that has been shown to retard the exit of EAAT3 from the endoplasmatic reticulum.[70,71] The ablation of Slc1a1 in a mouse model induced a marked urinary excretion of L-glutamate and aspartate, which was not compensated for by other transporters.[72]

Oligopeptides

PEPT1 and PEPT2 (SLC15A1 and 2) are members of the PEPtide Transporter family. These symporters use the proton gradient as the driving force to transport small peptides derived from protein degradation into the cells. PEPT1 and PEPT2 have a broad selectivity accepting all dipeptides and tripeptides composed of the 20 proteinogenic amino acids. The substrate affinity and localization of the two orthologs diverge; PEPT1 has a low affinity (millimolar range) and is expressed in small intestine, kidney, extra hepatic biliary duct and brain, while PEPT2 has a higher affinity (micromolar range) and is expressed in the kidneys, brain, lungs, eyes, and mammary glands. Both transporters are complementarily expressed on apical proximal tubule membranes. The low affinity PEPT1 is highly expressed in the early segments of the proximal tubule and the high affinity PEPT2 in the more distal portion of the proximal tubule (S3). Importantly, PEPTs

transport a large number of other molecules, in particular drugs from several important classes such as β-lactamate antibiotics (cephalosporins and penicillins). The transport of sartans and ACE inhibitors is still debated.

Knockout mouse models for both transporters have been generated. Both are viable and have a mild phenotype. The clearance of the non-metabolized peptide glycylsarcosine was not different in a PEPT1 knockout mouse compared with wild type animals, while the intestinal absorption of this substrate was drastically reduced. In contrast, glycylsarcosine clearance was twofold higher in PEPT2 knockout mice than in wild type littermates suggesting that the high affinity PEPT2 is responsible for the majority of peptide reabsorption in the kidneys.[73–75]

TRANSPORTERS INVOLVED IN BASOLATERAL EFFLUX OF AMINO ACIDS

Neutral Amino Acids

LAT2 (SLC7A8) and 4F2*hc* (SLC3A2) form a heterodimeric amino acid transporter (HAT) with a broad selectivity for neutral amino acids that functions as an obligatory exchanger. Interestingly its extracellular affinity is quite high (micromolar range) whereas its intracellular affinity for the same substrates is approximately 1000-fold lower.[47] LAT2 is highly expressed in small intestine, kidney, brain, muscles, lungs, bladder, and pancreas.[63,76,77] It localizes to the basolateral membrane of proximal tubule epithelial cells with the highest expression in the early portion (S1). In contrast, the glycoprotein heavy chain subunit 4F2hc, which functions as chaperone assisting in the plasma membrane targeting of LAT2, has a ubiquitous localization. Knockout mice for *Slc7a8* present elevated urinary excretion of glycine, L-serine, L-threonine, L-glutamine, L-leucine, and L-valine. The same amino acids, with the addition of L-lysine, were elevated in the serum of animals. Even though Slc7a8 is highly expressed in the placenta and brain, mice were viable and have only a moderate impairment of movement coordination.[78]

TAT1 (SLC16A10), the T-type aromatic amino acid transporter is by sequence homology a member of the monocarboxylate transporter (MCT) family and functions as a low affinity symmetric uniporter (facilitated diffusion pathway) for aromatic amino acids, L-dopa and iodothyronines.[79,80] TAT1 is highly expressed in the kidneys, small intestine, colon, liver, stomach, heart muscle and testis and localizes to the basolateral membrane of epithelial cells in small intestine and kidney. It is abundant in the early S1 and S2 segments of kidney proximal tubules. The functional interaction of TAT1 and LAT2-4F2 for mediating neutral amino acid efflux is described above in the section on a functional schema of amino acid reabsorption. A TAT1 knockout model has been generated but no functional data has been published yet (F. Verrey, personal communication).

LAT4 (SLC43A2) is a recently identified member of the Slc43 family that is not yet fully characterized. Similar to TAT1, LAT4 functions as a Na^+-independent, facilitative diffusion pathway (uniporter) with narrow substrate selectivity. Branched chain amino acids, L-methionine and phenylalanine are transported with low affinity. It is expressed in kidney, spleen, heart, brain, small intestine, and testis.[81] In situ hybridization data indicates the transporter is expressed in distal nephron segments, namely the distal tubule and collecting duct but our preliminary data indicate that LAT4 mRNA is substantially expressed in proximal tubules (Mariotta, Camargo and Verrey, unpublished data). A LAT4 knockout has been generated but no functional data is yet available (F. Verrey, personal communication).

SNAT3, SN1 (SLC38A3), previously designated as system N, is a sodium dependent glutamine transporter expressed in brain, retina, liver, kidney, pancreas, and adipose tissue. In the kidney, it localizes to the basolateral membrane of later proximal tubules (S3).[82,83] SNAT3/SN1 transports L-glutamine, histidine, L-asparagine and also alanine with low affinity (low millimolar range).[84] The transport is coupled to Na^+ co-transport and proton counter transport. The transport direction has been shown to be reversible.[85] Although extracellular pH influences SNAT3 transport activity, it is primarily the glutamine gradient that determines the direction of transport. The role of SNAT3 in pH control and during metabolic acidosis is discussed below in the section on amino acid metabolism. The SNAT3 knockout in mice is lethal between postnatal days 10 to 14 (C.Wagner, personal communication;[86]).

Cationic Amino Acids

y^+LAT1 (SLC7A7) and 4F2*hc* (SLC3A2) form a heterodimeric amino acid transporter (HAT) that under physiological conditions primarily transports dibasic amino acids out of cells in exchange for the influx of neutral amino acids and Na^+.[87] Under experimental conditions an inverted exchange can be measured revealing a high extracellular affinity for cationic amino acids, similar to the affinity for neutral amino acids. The intracellular affinities are however not

known. The glycoprotein heavy chain subunit 4F2*hc* is ubiquitously expressed, while y^+LAT1 is highly expressed in intestine, kidney, lungs, and leukocytes.[63,87,88] Similar to $b^{0,+}$AT-rBAT, y^+LAT1-4F2*hc* localizes to kidney proximal tubules (S1 >S2 ≫S3) and small intestine enterocytes (jejunal and ileal). However, in contrast to $b^{0,+}$AT-rBAT expression is on the basolateral membranes representing an efflux pathway for cationic amino acids taken up apically by $b^{0,+}$AT-rBAT (see Figure 71.1).[48,63] The 4F2*hc* heavy chain subunit, analogously to rBAT, functions as a chaperone assisting in the plasma membrane sorting of y^+LAT1.[48,87,89] The ablation of the *slc7a7* gene results in intrauterine growth retardation and a low rate survival.[90]

Anionic Amino Acids

AGT1 (SLC7A13) is a member of the heterodimeric amino acid transporter family but its accessory protein (heavy chain), which is neither rBAT nor 4F2hc, remains unknown. The function of AGT1 was tested in *Xenopus* oocytes using fusion proteins with the heavy chains 4F2hc or rBAT. AGT1 fusion proteins were shown to transport L-glutamate and L-aspartate with high affinity (micromolar range) independent of Na^+ and Cl^-. It has not been demonstrated whether it functions like other heterodimeric amino acid transporters as obligatory exchanger. AGT1 appears to be expressed exclusively in the kidney where it localizes to the basolateral membrane of the straight part of the proximal tubules (S3) and also to the distal convoluted tubule. Apparently expression is specifically in tubule segments where the luminal transporter for anionic amino acids EAAT3 is also expressed.[91] This axial localization of basolateral AGT1 suggests its involvement in the transcellular reabsorption of L-glutamate and L-aspartate. If AGT1 functions as obligatory exchanger, a net efflux of these amino acids would imply that substrates that recycle out of the cell via facilitated diffusion pathways must be taken up in exchange. Since AGT1 uptake was only tested at low amino acids concentrations (20 μM), and since competition with 2 mM of some neutral amino acids, e.g. L-cysteine, substantially inhibited the L-aspartate uptake this possibility is not excluded. Additional experiments in an expression system and especially a knockout animal model of *slc7a13* would help in solving this open question.

Amino Acid Transporters in More Distal Segments of the Nephron

Only low amounts of amino acids reach the loop of Henle and the distal nephron segments. As mentioned, beyond the proximal tubule, with the exception of taurine uptake, no substantial amino acid reabsorption was detected by micropuncture and microinjection. Of the amino acid transporters involved in reabsorption described above, only the anionic amino acid transporters EAAT3 (luminal) and AGT1 (basolateral) have been detected in the distal nephron, specifically in the distal convoluted tubule. This suggests that basolateral transporters expressed in later kidney tubule segments primarily fulfill housekeeping functions. Some of these transporters for which localization studies have been performed, are listed below.

Asc-1 (SLC7A10) and 4F2hc (SLC3A2) form a heterodimeric transporter expressed in brain, lung, kidney, and intestine, which functions as antiporter, although possibly not exclusively. Asc1-4F2hc mediates the Na^+-independent transport of small neutral amino acids (Gly, Ala, Ser, Cys, Thr) with high extracellular apparent affinity (micromolar range) and, to some extent, efflux of large neutral amino acids.[92] In kidney, Asc-1 mRNA was shown to be expressed in the loop of Henle, the distal tubule, and the collecting duct. The presence of this transporter in distal nephron segments suggests a role in housekeeping functions rather than for amino acid reabsorption. The *slc7a10* knockout mouse ($asc^{-/-}$) shows a severe brain phenotype with tremor and seizures and early postnatal death. The heterozygous animal was also characterized, and Asc-1 was suggested to be the major D-serine transporter in the brain. The renal function of these knockout animals has not been analyzed.[93,94]

Asc2 (SLC7A12) is a heterodimeric transporter that does not interact with rBAT or 4F2 (Slc3a1 or 2), the accessory proteins (heavy chains) of other Slc7 family members. Asc2 expressed in *Xenopus* oocytes as fusion protein with rBAT and 4F2hc, displayed an amino acid selectivity and affinity similar to Asc1. It was shown to function as a Na^+ and Cl^--independent exchanger. It is expressed in muscles, placenta, spleen, brain, and kidney, where it localizes to the cortical and the outer- and inner medullary collecting ducts. Its subcellular localization has not been conclusively demonstrated,[95] but its axial localization and functional characteristics suggest a housekeeping role.

TauT1 (SLC6A6) is a member of the Na^+-Cl^- neurotransmitter and amino acid transporter family and co-transports taurine, hypotaurine, and β-alanine with high affinity (low micromolar range) together with sodium and chloride.[96] TauT1 is expressed in kidney, intestine, retina, brain, liver, muscles, and placenta. In the kidney, it is expressed in the outer and the inner medulla and the protein was shown to localize apically in the inner medulla collecting duct. Its expression

increases after a salt load, leading to an increased taurine concentration within medullary cells.[97,98] The knockout animals (taut$^{-/-}$) excrete taurine, display hypotaurinemia, but do not show defective antidiuresis upon water deprivation. However, these knockout mice display an impaired ability to lower urine osmolality and to increase urinary water excretion. The latter defect is considered to result from an extrarenal role of taurine transport in the regulation of vasopressin secretion.

Renal Amino Acid Metabolism

The contribution of the kidney to whole body amino acid homeostasis is not only via proximal tubule reabsorption but also due to renal metabolism and interorgan exchange of amino acids and their metabolites.[99] For example, the kidney is the major site for glutamine and proline disposal from arterial blood, and for serine and arginine de novo production and an important source of other amino acids.[100] To illustrate, a 70 kg man produces ~3–4 g serine daily, ~2 g/day arginine, and ~1 g/day tyrosine, as well as lesser amounts (<1 g/day) of threonine, lysine, and leucine.[99] Amino acid supply to the kidney (achieved by reabsorption of amino acids from primary filtrate and the arteriole blood flow) is supplemented by the relatively high renal turnover rate of reabsorbed proteins. Amino acid metabolism in the kidney has local and systemic effects on diverse physiological processes including pH regulation, vasodilation, and urea cycle regulation. Furthermore, renal disease such as acute or chronic renal insufficiency alters kidney protein balance, amino acid metabolism, and nitrogen release thereby contributing to physiological responses throughout the body.[100–102]

Glutamine/Glutamate Renal Transport Metabolism

In the kidney glutamine metabolism contributes to pH regulation through glutamine-glutamate metabolism, ammonia and ammonium formation and excretion, and bicarbonate regeneration.[99] Renal glutamine uptake accounts for ~10–15% of the whole body daily flux (~70 g/day) while urinary excretion accounts for less than 1% of daily renal uptake. Approximately 80% of the taken up glutamine is metabolized by the mitochondrial phosphate-dependent glutaminase in the proximal tubule and a further 10% is metabolized in the distal tubule by γ-glutamyl transferase. Glutaminase activity produces glutamate and ammonia. The majority (70%) of the ammonia is released into the renal vein and the remainder excreted in urine. Urinary glutamate release is considerably less than 1% of renal glutamine uptake. Rather, glutamate is transaminated to alanine and α-ketoglutarate, which can be utilized in the krebs cycle, or further degraded by the glutamate dehydrogenase pathway to ammonia and more α-ketoglutarate. α-Ketoglutarate can also be converted by phosphoenolpyrvate carboxykinase in the gluconeogenic pathway to glucose and two bicarbonate ions. Renal production indeed contributes nearly 25% to the total body gluconeogenesis with 80% of gluconeogesis from glutamine. Ammonia released in the acidotic primary urine is protonated to ammonium helping to increase the H^+ excretion.[83,103] However, unlike the hepatic glutaminase, which is inhibited by low pH and stimulated by ammonia, the renal enzyme is inhibited by both ammonia and glutamate. Since glutamine is rate-limiting for ammonia production and under normal conditions nearly all glutamine is reabsorbed from the urine, to boost ammonia production during metabolic acidosis, glutamine uptake from the blood must increase. Therefore, metabolic acidosis strongly stimulates arterial glutamine uptake and renal metabolism by increasing the expression of basolateral glutamine transporter SNAT3 (SLC38A3) and the activity and expression of glutamine-glutamate pathway enzymes.[104–106]

Arginine, Citrulline and NO

As the primary source of L-arginine (not targeted for immediate urea production) the kidney plays a major role in whole body arginine homeostasis. In addition to protein biosynthesis, arginine is a precursor for creatine, nitric oxide (NO), and (after decarboxylation to agmatine guanidine) other polyamine metabolites. The rate limiting step in L-arginine synthesis is the production of L-citrulline by small intestine metabolism of glutamine.[107] Daily kidneys reabsorb more than 80% or about 1.5 g of L-citrulline from primary urine and release ~2–4 g of L-arginine to the renal vein, of which 5–15% is from de novo synthesis.[108] L-arginine production from L-citrulline is catalyzed by two enzymes. First, argininosuccinate synthetase (ASS) in an ATP consuming step produces adenylocitrulline, which is coupled the amino group of aspartate forming aminosuccinic acid. Subsequent hydrolysis by argininosuccinate lyase (ASL) yields arginine and fumarate. Biosynthetic activity is greatest in proximal tubule S1 cells, and sharply diminishes by the S2 to S3 segments. Citrulline uptake is mediated most likely by B^0AT1 and $b^{0,+}AT$ apically and organic anion transporter OAT1 (SLC22A6) basolaterally.[109,110] In S3 segments protein catabolism produces the arginine derivative asymmetrical dimethylargineine (AMDA), which is

metabolized to L-citrulline by mitochondrial *NG, NG*-dimethylaminohydrogenase, boosting arginine production modestly. The kidney accounts for ~40% of the total body breakdown of AMDA.

Along with de novo L-arginine synthesis, 3.1 g (~8 mmol) of L-arginine are filtered and reabsorbed by human kidneys daily. Proximal tubule cells metabolize ~10% of L-arginine content by three mitochondrial pathways: (1) conversion into guanidinoacetic acid (by cortical arginine:glycine amidinotransferase (GAT)), which is exported into the blood stream for eventual creatine production; (2) hydrolysis by arginase II ((AII) with a complementary distribution to ASS and ASL in PCT) into ornithine and urea; and (3) a low level of decarboxylation by arginine decarboxylase (ADC) to agmatine and CO_2.[107] AII activity increases from the cortex to the inner medulla.[111] Additionally, nitric oxide synthetase (NOS) enzymes metabolize L-arginine to nitric oxide and citrulline—which in the presence of ASS, ASL and aspartate can be recycled to L-arginine.[111] All three isoforms of nitric oxide synthetase, the endothelial, neuronal and inducible (eNOS, nNOS and iNOS respectively) are expressed in various kidney regions and structures, and compete with arginase for L-arginine. Metabolism for creatine production consumes the majority of the L-arginine metabolized in the kidney, while AII, ACD, and NOS enzymes use only a small proportion of renal supplies. Both the subcellular compartmentalization and the heterogeneous distribution in renal cortical vs. medullary zones of L-arginine synthesis and degradation pathways allow kidney to simultaneously contribute to arginine plasma supply, and ornithine, NO, and urea synthesis.[99,101,111]

Aromatic Amino Acids: Phenylalanine and Tyrosine

The kidney accounts for ~40% of the whole body activity of phenylalanine 4-hydroxlase which catalyzes the synthesis of the conditionally essential amino acid L-tyrosine from L-phenylalanine. The total body turnover of L-phenylalanine and L-tyrosine is ~10 g and 7 g per day, respectively. Kidneys, which take up 0.5-1 g L-phenylalanine and release ~1 g per day L-tyrosine, account for ~15% of whole body tyrosine flux.[99] Kidney is a major contributor to the net release of L-tyrosine to the bloodstream, unlike liver, the rate of renal de novo production combined with L-tyrosine release due to protein catabolism (a combined ~7 μmol/min) is greater than disposal rate (~1.8 μmol/min).[112] These rates are altered in patients with chronic kidney disease (CDK) such that tyrosine hydroxylation is decreased. In these patients, L-tyrosine deficiency can develop, emphasizing the importance of renal L-tyrosine synthesis.

Glycine and Serine

In the proximal tubule, 1.5 g of L-glycine are reabsorbed daily and metabolized to L-serine. Glycine decarboylase complex and serine hydroxymethyltransferase catalyze synthesis of one serine, bicarbonate, and ammonia moiety from each two glycine cleaved, accounting for ~30% of renal serine and ~10% of renal ammonia production. The hydrolysis of glutathione by γ-glutamyltranspeptidase in kidney proximal tubule brush border membranes is a further source of glycine. Kidneys also synthesize serine via conversion of L-glutamine, L-glutamate, and L-aspartate to L-serine via the phosphorylated intermediate pathway. Overall, the renal serine production of 3−4 g/day while representing only ~5−7% of total body turnover is equal to the normal daily serine dietary intake.[99]

Protein, Oligopeptide and Glutathione Metabolism

Amino acid supply to the kidney is supplemented by the relatively high renal turnover rate of reabsorbed proteins. Although the gomerular filtration barrier limits the distribution of proteins in the primary filtrate low concentrations are present. Furthermore, in the post absorptive state kidney protein degradation is ~45% greater than synthesis. A number of exopeptidases have been identified in proximal tubule brush border membranes and cytosol. The most abundant is the broad spectrum aminopeptidase N. For dipeptides, in comparison to liver, small intestine (ileum, jujenum) and muscle, kidney exhibits the highest level of hydrolase activity.[113] As much as 10% of all body L-leucine originating from protein degradation comes from the kidneys. In total ~7 g of proteins per day are degraded by the kidneys. Considering kidneys weigh ~1% of total skeletal muscle and <13% of the splanchnic organs, human kidneys contribute disproportionally towards total body protein degradation and synthesis (~10% of the total for each measure).[114] Much of this involves assimilation and/or production of circulating plasma low molecular weight oligopeptides. As an example of the contribution of renal metabolism to oligopeptide metabolism we consider the case of glutathione (glutamyl-cysteine-glycine). Glutathione (GSH) is efficiently taken up by kidney with ~80% plasma GSH absorbed during a single pass. Meanwhile 30% is absorbed from the primary filtrate, the majority (>60%) is absorbed from the plasma by Na^+-dependent and Na^+-independent basolateral

transporter(s). OAT3 (SLC22A6), OAT1 (SLC22A8) and NaC_2 (SLC3A3) all of which are expressed on basolateral membranes have been suggested as candidates.[115] Within cells, DIC (SLC25A10) and OGC (SLC25A11) are responsible for the majority (>80%) of renal mitochondrial GSH transport. On the luminal membrane efflux is carried out by OAT1a1 (SLCo1A1), Mrp2/Abcc2 and Mrp4/Abcc4 transporters.[115] GSH synthesis and degradation pathways are segregated spatially with synthesis occurring in the cytoplasm by sequential glutmate-cysteine ligase and GSH synthetase (ATP-dependent) activities. Whereas in kidney degradation is catalyzed extracellularly by activity of the proximal tubule brush border membrane localized integral membrane proteins, γ-glutamyltransferase (cleaves γ-glutamyl peptide bond between L-glutamyl L-cysteinyl) and dipeptidase (hydrolyzes L-cysteinyl-glycyl peptide bond).[115] Analysis of knockout animals indicates the contribution of PEPT2 reabsorption of gly-cys for renal synthesis of GSH.[116]

AMINOACIDURIAS

Aminoacidurias, which are characterized by the abnormal excretion of specific amino acids in the urine, can be caused by metabolic or transport defects. In contrast to metabolic diseases, in which one or more enzymes involved in the synthesis or catabolism of amino acids is defective, transport disorders result from deficient amino acid transport from the nephron lumen into the proximal tubule epithelial cells or from cells to the extracellular space. Transport diseases are caused by mutations in the genes encoding the membrane proteins responsible for the mostly active transport of amino acids. Clinical consequences of specific aminoacidurias can arise from either a deficiency of particular amino acid(s) (urinary loss), or the precipitation of certain amino acid(s) (e.g. cystine) in the urine. Amino acids deficiencies can also be caused by decreased absorption in the intestine, since many of these transporters are also expressed in the enterocytes of the small intestine and are responsible for substantial amino acid absorption.[117]

The association of a disease with an amino acid transport defect was first suggested a century ago.[118,119] Since then, several diseases due to transport defects have been described. Progress in diagnosing aminoacidurias was greatly facilitated by the advent of reliable and sensitive chromatography methods.[120,121] The molecular characterization of the amino acid transporters has also contributed greatly to advances in genetic diagnoses.[18,55,29] For the purpose of this review the specific aminoacidurias identified so far (see Table 71.3) are classified by the chemical properties of the amino acids abnormally excreted (i.e., neutral, basic (cationic), acidic (anionic), or iminoaciduria).

Basic Aminoacidurias

Cystinuria (OMIM #220100)

Mutations in either interacting subunit gene *SLC3A1* (rBAT) or neutral and basic amino acid transporter encoding gene *SLC7A9* ($b^{0,+}AT$) cause cystinuria.[35,122] Cystinuria, due to mutations in *SLC3A1* (chromosomal locus 2p21), is an autosomal recessive trait with heterozygous parents unaffected. In contrast, mutations in *SLC7A9* (chromosomal locus 19q13.11) lead to a mild to moderately abnormal urinary amino acid pattern in most obligate heterozygotes (e.g., parents) and thus

TABLE 71.3 Aminoacidurias Genetically Elucidated in Human

Aminoaciduria	Gene	Protein	Chromosome	Hallmark (Elevation of Individual AA in Urine)
Cystinuria A	*SLC3A1*	rBAT	2p21	Cystine, Lysine, Arginine, Ornithine
Cystinuria B	*SLC7A9*	$b^{0,+}AT$	19q13.11	Cystine, Lysine, Arginine, Ornithine
Lysinuric protein intolerance	*SLC7A7*	y^+LAT1	14q11.2	Lysine, Arginine, Ornithine
Hartnup disorder	*SLC6A19*	B^0AT1	5p15.33	Neutral amino acids
				Proline
Iminoglycinuria*	*SLC36A2*	PAT2	5q33.1	Hydroxyproline
				Glycine
Dicarboxylic aminoaciduria	*SLC1A1*	EAAT3/EAAC1	9p24	Aspartate
				Glutamate

**Pending independent confirmation.*
According to HUGO (www.genenames.org) and NCBI build 36.

can be seen as an autosomal dominant trait. The initial nomenclature, based on the excretion status of obligate heterozygotes (cystinuria types I, II (non-I), III (non-I)), has been "replaced" by a more meaningful system linked to the genotype.[123] Mutations in *SLC3A1* cause cystinuria type A, mutations in *SLC7A9* cause cystinuria type B, and mutations in both genes ("compound" heterozygotes) cause cystinuria type AB. Disease severity is apparently the same for cystinuria types A and B. The average prevalence is 1 in 7000 births, and to date 133 mutations in *SLC3A1* and 95 mutations in *SLC7A9* have been identified. Reported mutations include nonsense, missense, splicing, frameshift, and large sequence rearrangements.[124]

CLINICAL FINDINGS

Patients with cystinuria often present with nephro- or urolithiasis at almost any age with a clear preference in childhood due to elevated urinary cystine. Kidney stones are radio opaque, although less than calcium containing ones, and easily diagnosed by ultrasound examinations. Stones in the bladder are also often found. The presence of bladderstones in childhood should always prompt consideration of cystinuria. Early diagnosis is important since it allows for the prevention or reduction of kidney stones. Diagnostically, urinary levels of dibasic amino acids L-lysine, L-arginine, and L-ornithine, and most prominently of cystine are elevated (e.g., cystine can be up to 50-times normal). Plasma levels of these amino acids in general are at the lower end of the normal range. Clinical problems arise only from the elevated urinary cystine, which due its low solubility, precipitates within the urinary tract forming cystine stones. Urine microscopy reveals characteristic and pathognomonic hexagonal crystals. The cyanide-nitroprusside urinary test is also used, but is not considered specific.

TREATMENT

Treatment is non-specific and consists mostly of a high fluid intake to keep the urinary cystine below the solubility threshold of about 1000 μmol/l (at pH <7). As cystine solubility increases with pH, alkalization of urine, typically with potassium citrate, can be used. Chelation with D-penicillamine or mercaptopropionylglycine, while highly effective, is rarely used due to serious side effects. Overall, treatment is cumbersome and some patients lose kidney function at some time due to recurrent nephro- and urolithiasis.

Lysinuric Protein Intolerance (OMIM #222700)

Lysinuric protein intolerance (LPI) is caused by mutations in *SLC7A7*, which similar to cystinuria, is a member of the heterodimeric amino acid transporter family (HAT). The mutations causing this autosomal recessive disorder have, in contrast to cystinuria, been identified exclusively in the light subunit *SLC7A7* (chromosomal locus 14q11.2).[125,126] *SLC7A7-SLC3A2* mediates the transport of dibasic amino acids from intracellular to basolateral compartments. The incidence of LPI is very low, but in some populations reaches up to 1:50,000 births. Currently, a total of 50 different LPI causative mutations of *SLC7A7* have been described.[127] Most of the LPI-causative mutations consist of missense, nonsense or small deletions, whereas larger deletions, insertions, or splice-site mutations are less frequent.

CLINICAL FINDINGS

Patients affected by this disorder in general come to medical attention early in life with several significant problems including a failure to thrive and intellectual impairment. Episodes of diarrhea and hyperammonemia coincide with increased protein intake (hence the name). Ammonia typically rises quickly postprandially and may normalize within hours. This makes documentation of hyperammonemia difficult due to timing of blood draw, if not suspected. Apparently, hyperammonemia is caused by an interruption of the urea cycle due to a lack of required intermediates (e.g., ornithine). Patients unfortunately also develop interstitial pneumonia in the form of an alveolar proteinosis, hepatomegaly and liver cirrhosis, severe osteopenia and bone marrow involvement. Renal insufficiency can develop due to glomerulonephritis of suspected immunological etiology. Phenotypic variability and the lack of a specific clinical presentation have caused misdiagnosis variously as disorders of urea cycle, lysosomal storage diseases such as Niemann-Pick type B and Gaucher disease, celiac disease, or autoimmune disorders.[128] Episodes of diarrhea following protein intake can point towards the correct diagnosis.

Elevations of urinary dibasic amino acids, L-lysine, L-arginine, and L-ornithine are diagnostic and more pronounced than in cystinuria; urinary cystine levels in contrast to cystinuria are almost normal (elevated only 2−3 times the norm). In contrast to cystinuria, plasma levels of L-lysine, L-arginine, and L-ornithine tend to be below the norm. Orotic acid and homocitrulline are also elevated and can be of diagnostic value for discrimination from urea cycle defects.

The significance of the clinical picture in LPI can be explained by a more severe loss and reduced intestinal absorption of dibasic amino acids, in comparison to cystinuria, leading to an inefficient urea cycle resulting in hyperammonemia. Obviously, a defect in the basolateral export of dibasic amino acids (as in LPI) has more severe consequences than a defect in the luminal membrane (as in cystinuria). This is attributed to the fact that a large fraction of the nutritional amino acids,

including dibasic amino acids, are (re)absorbed as di- and tripeptides that are then hydrolyzed intracellularly before being transported out of the cell through the basolateral membrane. Some of the unique immunological features of this disease are probably related to the expression profile of *SLC7A7* (y^+LAT1), which is much broader than that of *SLC3A1*/*SLC7A9* (rBAT/$b^{0,+}$AT).[129]

TREATMENT

Treatment is symptomatic and consists of protein restriction, as for other urea cycle disorders, and in this case in supplementation with citrulline. Citrulline is a precursor for both arginine and ornithine, thus can partially restore the defective functions of the urea cycle.

Neutral Aminoacidurias

Hartnup Disorder (OMIM #234500)

Cloning of the human *SLC6A19* gene (chromosomal locus 5p15.33) led to the identification of a deleterious splice site mutation in members of the British Hartnup family, in which the disorder was originally described.[130] Hartnup disorder is an autosomal-recessive disorder with an incidence of 1 to 15,000 live births. In addition to the original Hartnup mutation, 21 further deletions, missense, nonsense and splice site mutations in the *SLC6A19* gene causing the disorder have been identified.[32–133] Mutations in genes encoding the renal and intestinal B^0AT1 accessory proteins, Tmem27 (*tmem27*) and Ace2 (*ace2*) respectively, are not responsible for the disorder. Both tmem27 and ace2 genes are located in the X chromosome, and so far no patients with an X-linked neutral aminoaciduria have been observed.

CLINICAL FINDINGS

First recognized in the 1950s in London/UK as a defect of neutral amino acid transport, Hartnup disorder became an example of how diet can unveil the signs and symptoms of a multifaceted disease. The protein-restricted diet imposed on the population (World War II, and post-war) revealed the defective (re)absorption of amino acids characteristic of Hartnup disorder. The symptoms are variable and patients can present with the pellagra-like signs (including light-sensitive dermatitis), intermittent cerebellar ataxia and psychosis-like symptoms. The variability of the symptoms might be due to the high frequency of compound heterozygosity, and/or to the differential interactions of specific mutations with intestinal and renal accessory proteins, and/or dietary habits.

Diagnostically, elevated urinary neutral amino acids are the first indication of the disorder and are observed in all Hartnup patients. L-glutamine, alanine, tryptophan, tyrosine, serine and the branched chain amino acids can reach values five to ten fold higher than reference. Proline and glycine excretion are not increased. Plasma amino acids levels are usually in the normal range.

The neutral aminoaciduria resulting from Hartnup disorder must be differentiated from a generalized aminoaciduria, which is an obligate diagnostic hallmark of a renal Fanconi syndrome. The most common cause of renal Fanconi syndrome in childhood is cystinosis, a treatable lysosomal storage disorder.

TREATMENT

Currently patients from "protein supersaturated" countries are often recognized only by newborn screening programs, as they are asymptomatic. The question remains whether these patients should or need to be treated. Patients with pellagra-like symptoms are treated with niacin oral replacement, which reverses the clinical features of the disorder. Pellagra and the neurological symptoms are thought to be caused by deficiency of tryptophan, since this is a precursor of niacin and serotonin.

Iminoacidurias

Iminoglycinuria (OMIM #242600)

Mutations in multiple genes have been suggested to be the cause of iminoglycinuria. Identified by sequencing of candidate genes, encoding glycine and imino acid transporters, namely *SLC36A2* (PAT2), *SLC6A20* (SIT1), *SLC6A19* (B^0AT1), and *SLC6A18* (B^0AT3) in patients with glycinuria and iminoglycinuria, a complex combination of mutations and polymorphisms was found and suggested to cause the disorder.[59] However, this hypothesis is controversial. *SLC6A18* (B^0AT3) and *SLC6A19* (B^0AT1) have a broad substrate spectrum. Therefore genetic defects should cause a general neutral aminoaciduria and not solely the abnormal excretion of proline and/or glycine.[32,43,52] The imino transporter SIT1 encoded by the gene *SLC6A20* located at chromosomal locus 3p21.31 is another candidate. However, preliminary genetic studies found no linkage with the region encoding *SLC6A20* (SIT1) (chromosomal locus 3p21.31) and disease,[134] whereas when tested in an exogenous expression system SIT1 mutations (found in iminoglycinuria patients) did decrease transport activity.

Mutations in genes encoding the glycine and L-proline transporters, PAT1 (*SLC36A1*) and 2 (*SLC36A2*), are additional disease candidates. The *SLC36A2* (PAT2) gene seems to be the best candidate while analysis of the *SLC36A1* (PAT1) chromosome

locus (5q33.1) failed to uncover a linkage with the disorder.[134] The incidence of iminoglycinuria is 1:10,000 births.

CLINICAL FINDINGS

Patients with present with elevated urinary levels of glycine, proline, and hydroxyproline. Interestingly, obligate heterozygotes may also display glycinuria.

Patients diagnosed by newborn screening programs should be subsequently confirmed, since iminoglycinuria can occur in normal neonates, presumably reflecting tubular immaturity. Several reports have linked iminoglycinuria with other diseases. However this finding may have been biased due to ascertainment errors resulting from the specific populations screened (e.g., mental health institutions). As for other aminoacidurias, the fractional excretion of all respective amino acids should be analyzed to exclude urinary losses due to elevated plasma levels. Such as occurs in the metabolic disorder hyperprolinemia, in which, due to significantly elevated plasma proline levels, urine findings can mimic iminoglycinuria by exceeding urinary reabsorption capacity.

TREATMENT

At the present time, iminoglycinuria is considered an incidental finding and no treatment is necessary. Whether constant urinary glycine, proline, and hydroxyproline losses have an impact on health is not known.

Acidic Aminoaciduria

Dicarboxylic Aminoaciduria (OMIM 222730)

Dicarboxylic aminoaciduria is an autosomal recessive disorder with an incidence of 1:35,000 births, as estimated from a 25-year screening program in Quebec, Canada.[135] The cause of dicarboxylic aminoaciduria was identified as mutations in the *SLC1A1* gene (chromosomal locus 9p24) encoding the glutamate and aspartate transporter EAAC1/EAAT3.[136–138] In two pedigrees missense and deletion mutations were identified in homozygotes.

CLINICAL FINDINGS

A few patients with an excess urinary excretion of acidic amino acids, i.e., aspartate and glutamate, otherwise lacking clinical symptoms, have been reported.[139,140] The patients with the identified *SLC1A1* mutations presented high urinary glutamate and aspartate and one of them also displayed symptoms of an obsessive compulsive disorder.

PERSPECTIVES

Following the molecular identification of most amino acid transporters, current research aims at understanding their role in mediating and controlling the flux of amino acids between different body compartments, in particular as regards amino acid homeostasis in the extracellular space (milieu intérieur) and their role for the function of organs and cells. A step forward in this direction requires that kinetic, regulatory and expression data of transporters be integrated in the understanding of physiological regulatory networks controlling body and cellular amino acid metabolism. Such integrated analysis of the physiological networks will be necessary to understand the contribution of kidney proximal tubule transport and metabolic functions to body amino acid homeostasis in health and disease. This integrated view shall lead towards a better understanding of the complex pathophysiology and symptoms of genetic diseases such as lysinuric protein intolerance (LPI) and of acquired diseases.

INTRODUCTION

The kidneys efficiently excrete endogenous and exogenous organic anions and cations, including widely used drugs and potentially toxic compounds. At pH 7.4, organic anions carry one or more negative charges, and organic cations one or more positive charges, respectively. Many exogenous organic anions and cations undergo secretion in renal proximal tubules, involving uptake across the basolateral membrane into tubule cells and release across the apical (lumenal, brush-border) membrane into the lumen. For organic anions, uptake from the blood takes place against an opposing inside negative membrane potential whereas, for organic cations, the inside negative electrical potential difference has to be overcome during their release into the lumen. Thus, secretion requires the input of cellular energy. In this chapter, we shall focus on proximal tubular organic anion and organic cation transporters being involved in drug secretion.

ORGANIC ANION TRANSPORT SYSTEMS

Characteristics of Organic Anion Secretion in Proximal Tubules

Initial experiments revealed proximal tubules as the principle site of organic anion secretion in various species (for earlier literature see[1,2]). In most of these studies, *p*-aminohippurate (PAH) served as a model organic anion, and the substrate specificity of the so-called PAH transport system in the basolateral membrane was extensively tested by stop-flow competition experiments with rat kidneys *in situ*. This system preferred amphiphilic compounds carrying one negative charge or two negative charges separated 6–7 Å by a hydrophobic moiety and being able to form multiple hydrogen bridges.[3] The "PAH transport system" turned out to interact with a multitude of chemically unrelated molecules including many drugs.

PAH uptake across the basolateral membrane occurred by an exchange against intracellular α-ketoglutarate.[4,5] Thereby, PAH uptake is a tertiary active process, with the Na^+,K^+-ATPase establishing the extracellular-to-intracellular Na^+ gradient (primary active process), the sodium-dicarboxylate cotransporter utilizing this Na^+ gradient for intracellular α-ketoglutarate enrichment (secondary active process), and the PAH/α-ketoglutarate exchanger using the intracellular-to-extracellular α-ketoglutarate gradient for PAH uptake against the inside negative membrane potential (tertiary active process; see also Figure 72.1). In addition, α-ketoglutarate absorbed from the primary urine or derived from metabolism can drive PAH uptake.[6] The arrangement of three co-operating transporters is conserved among species including man. As opposed, earlier experiments on

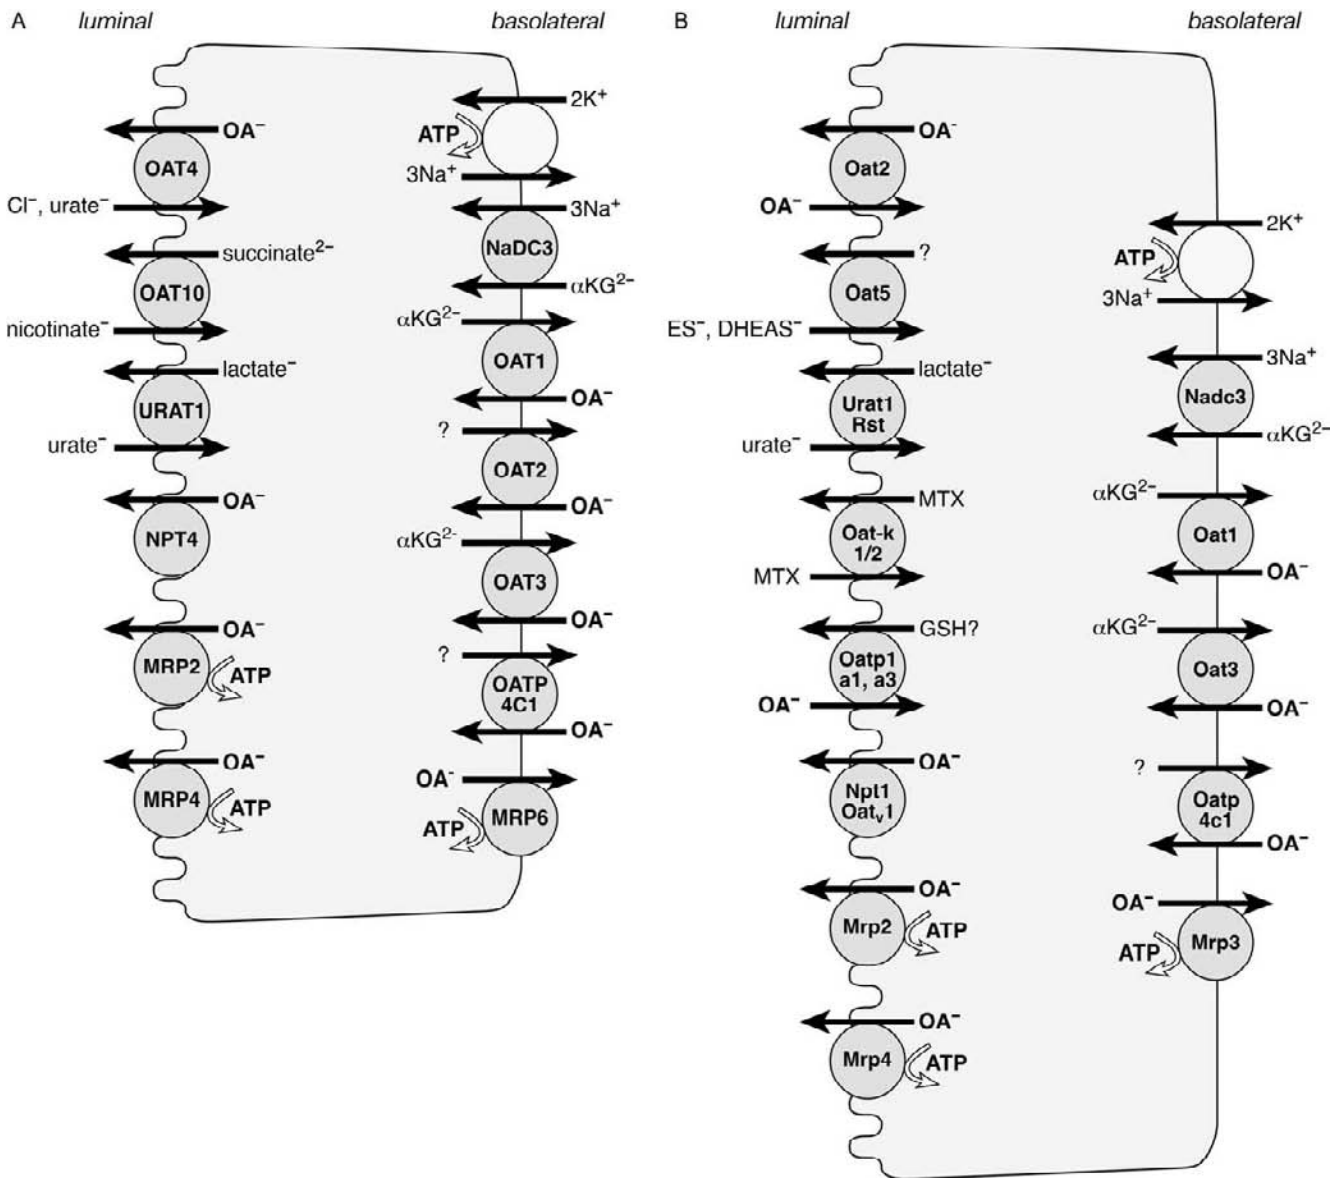

FIGURE 72.1 Organic anion transporters in human (A) and rat (B) renal proximal tubule cells. Lumen (urine) side is left, interstitial (blood) side is right. Transporters are symbolized by circles. Abbreviations: αKG^{2-}, α-ketoglutarate; $DHEAS^-$, dihydroepiandrosterone sulfate; ES^-, estrone-3-sulfate; GSH, glutathione; MTX, methotrexate; OA^-, organic anion.

PAH release across the apical membrane revealed species differences.[1]

With the advent of molecular cloning and heterologous expression techniques, several proximal tubular transporters for organic anions have been characterized. Figure 72.1A shows transporters that are involved in the secretion of anionic drugs and toxins, or are targets of drugs, in the human proximal tubule. These include OAT1, OAT2, OAT3, OATP4C1, and MRP6 in the basolateral cell membrane, and OAT4, OAT10, URAT1, NPT4, MRP2, and MRP4 in the apical membrane. In rodent proximal tubules, Oat1, Oat3, Oatp4c1, and Mrp3 were found in the basolateral membrane, and Oat2, Oat5, Urat1, Oat-K1/2, Oatp1a1, Npt1/Oat_v1, Mrp2, and Mrp4 in the apical membrane (Figure 72.1B). Thereby, both cell sides contain antiporters (OATs/Oats, URAT1/Urat1, OATP4C1/Oatp4c1), ATP-driven systems (MRPs/Mrps) and a voltage-driven system (NPTs/Npts). Taken together, the picture of organic anion transport became more complicated than it was anticipated from earlier *in vivo* and *in vitro* functional studies.

DRUG TRANSPORTERS IN THE BASOLATERAL MEMBRANE OF PROXIMAL TUBULE CELLS

The Organic Anion Transporter 1 (OAT1/Oat1; *SLC22A6/Slc22a6*)

The Organic Anion Transporter 1 (humans, OAT1; other species, Oat1) was cloned from man, monkey, pig (p), rabbit (rb), rat (r), and mouse (m).[7–9] OAT1/Oat1 is the member A6/a6 of family *SLC22/Slc22*, that consist of at least 25 different genes.[10] The gene coding for OAT1 was located to chromosome 11q12.3 paired with that of OAT3.[10,11] OAT1 mRNA is expressed in kidneys, and to a small extent also in brain and other tissues.[12–14] In rats, mRNA expression rose from day 10 after birth and reached a maximum in adult animals[15] whereas, in mice, Oat1 mRNA did not rise before day 25 after birth.[16] Importantly, gender differences were observed in adult rats and mice with higher Oat1 mRNA expression in male animals.[15,16]

Immunohistochemical studies localized OAT1/Oat1 protein to the basolateral membrane of proximal tubules of human, monkey, rat and mouse kidneys.[7–9] In humans, OAT1 was found along the complete proximal tubule whereas rOat1 was highest in the S2 segment. Immunohistochemistry in adult rats revealed more Oat1 protein in male than in female animals.[17,18] Whether gender differences are present in humans is not known (for reviews on gender differences see[8,18]).

The expression of human OAT1 was under positive control of hepatocyte nuclear factors 1α (HNF-1α) and 4α (HNF-4α).[8] An increased expression of rOat1 was found after treatment of kidney slices or proximal tubules with insulin and epidermal growth factor as well as after bile duct ligation in rats whereas, in several other circumstances such as fever, endotoxinemia, renal insufficiency, ischemia-reperfusion, and ureter obstruction, the abundance of rOat1 was—at least transiently—decreased (reviewed in[8,9]). A down-regulation of Oat1 expression most probably decreases the renal excretion of anionic drugs. In this regard, it is interesting that inhibition of COX-2 attenuated the endotoxin-induced down-regulation of rOat1.[19]

Short-term down-regulation involves a protein kinase C (PKC) activity-dependent endocytosis of OAT protein.[20] Thereby, the protein itself is not phosphorylated,[21] but possibly ancillary proteins such as caveolin 2.[22] The appearance of immunoreactive rOat1 in vesicles beneath the basolateral membrane after mercury treatment of rats suggests that endocytosis of Oat1 may occur also *in vivo*.[23]

Several non-synonymous single nucleotide polymorphisms have been described for human OAT1 (summarized in[9,24]). Except for the amino acid change R50H which led to changes in the K_m for adefovir, cidofovir and tenofovir, other amino acid exchanges did not result in altered transport function, at least for the tested substrates.

Following heterologous expression, OAT1/Oat1 proved to be a *p*-aminohippurate (PAH)/α-ketoglutarate antiporter with *in vitro* affinities for PAH between 5 and 50 μM (range, 3.1 to 430 μM[8,25]). A prototypical, though not OAT1-specific inhibitor is probenecid with K_i or IC_{50} values between 1.4 and 18.6 μM.[8,25] Numerous compounds were tested as possible substrates of OAT1/Oat1 either by checking their inhibition of the uptake of labeled PAH (or other labeled or fluorescent substrates), or by direct demonstration of transport of labeled test compounds (results compiled in[7,8,25]). Among endogenous substrates of OAT1/Oat1 are, e.g., medium-chain fatty acids, α-ketoglutarate, cAMP and cGMP, prostaglandins E_2 and $F_{2\alpha}$, urate, and acidic neurotransmitter metabolites. Drugs interacting with OAT1/Oat1 included β-lactam antibiotics, antiviral drugs, non-steroidal anti-inflammatory drugs, diuretics, ACE inhibitors, angiontensin II receptor 1-antagonists, and methotrexate. Furthermore, OAT1/Oat1 interacted with uremic toxins, environmental toxins, and carcinogens. Thus, OAT1/Oat1 covers a wide substrate spectrum, is involved in renal drug handling, and contributes to nephrotoxicity. The interaction of several compounds with the same transporter, OAT1/Oat1, can lead to drug-drug interaction during renal excretion, alter pharmacokinetics and cause potentially serious side effects (for examples see[26,27]).

For mouse Oat1, a quantitative structure-activity relationship was determined.[28] For mono-anions, interaction with mOat1 increased (or K_i decreased) with increasing mass and hydrophobicity, e.g., with the chain length of fatty acids. For di-anions, steric and electrostatic factors became the main determinants of affinity. For transport velocity, other factors seemed important because no correlation was found between V_{max} and K_m or K_i.[28] In general, QSAR on mOat1 was in agreement with earlier data obtained for PAH transport in rat kidney *in situ*.[3] Mutational studies on OAT1/Oat1 were performed to find out residues important for transport function: amino acid residues surrounding the putative substrate binding site of human OAT1 include R466 (transmembrane helix TMH11), K382 (TMH8), Y353, Y354 (both in TMH7), and F374 (TMH8) (summarized in[9]). R466 is also important for the interaction of OAT1 with chloride that increases the V_{max} of the transporter, but has no effect on its affinity towards PAH.[29]

An Oat1 knockout mouse was generated which did not show any gross abnormalities.[30] The clearance of PAH, furosemide, bendroflumethiazide, and a number

of endogenous hydroxyl-substituted short chain fatty acids was decreased.[30,31] Thus, mOat1 contributes to the renal excretion of diuretics and of hitherto unknown endogenous metabolites.

The Organic Anion Transporter 2 (OAT2/Oat2; *SLC22A7/Slc22a7*)

OAT2/Oat2 was cloned from man, rat, and mouse.[7–9] The gene for human OAT2 is located on chromosome 6p21.1.[10] In humans and male rats, the expression of OAT2/Oat2 mRNA was high in liver and low in kidneys. In female rats, Oat2 expression in kidneys exceeded its expression in liver.[13,14] In male mice, message for Oat2 was expressed in kidneys, but hardly in liver whereas, in female mice, message was found both in liver and kidneys. Immunolocalization studies revealed human OAT2 at the basolateral membrane of proximal tubule cells.[32] In rat and mouse kidneys, Oat2 appeared to be present in the apical membrane of proximal tubule cells and exhibited a higher expression in female animals.[33] Thus there are gender and species differences in Oat2 expression.

In liver and kidneys, OAT2/Oat2 expression was under positive control of HNF-1α and HNF-4α.[34,35] In diabetic rats and in cisplatin-treated mice, a decreased renal Oat2 expression was found.[36,37] As regards single nucleotide polymorphisms, three non-synonymous SNPs were reported the functional consequence of which is unknown (see[9]).

Due to conflicting results in the literature,[7,8,25] it is unclear whether OAT2/Oat2 interacts with and is driven by dicarboxylates. High affinities of human and rat OAT2/Oat2 were reported for prostaglandin E_2 and prostaglandin $F_{2\alpha}$. Other endogenous substrates of OAT2 are nucleobases, nucleosides and nucleotides such as adenine, adenosine, GMP, GDP, GTP, cGMP, and cAMP.[38] Urate was transported by OAT2 with an apparent K_m of 1.17 mM, suggesting that OAT2 contributes to proximal tubular urate secretion.[39] Among drugs, some diuretics (hydrochlorothiazide, furosemide), pravastatin, sartanes (losartan and telmisartan), cephalosporins, erythromycin, histamine receptor-2 blockers, NSAIDs, and uricosurics (probenecid, benzbromarone) interacted with OAT2. High affinities were reported for antineoplastic drugs (methotrexate, fluorouracil, taxol).[7,8]

In humans, the basolateral localization of OAT2 would favour a role in organic anion (urate) and drug excretion whereas, in rodents, the apical location of Oat2 is hard to reconcile with secretion. Thus, more information is needed to fully appreciate the function of OAT2/Oat2.

THE ORGANIC ANION TRANSPORTER 3 (OAT3/Oat3; *SLC22A8/Slc22a8*)

As reviewed in,[7–9] OAT3/Oat3 was cloned from man, monkey, pig, rabbit, rat, and mouse. The gene SLC22A8 is located on chromosome 11q12.3, in direct neighbourhood to the gene of OAT1.[10,11] In all species, the mRNA for OAT3/Oat3 was highest in the kidneys; additional expression was found in brain, liver, skeletal muscle, and adrenals.[12–14] The mRNA levels increased shortly after birth and reached the same levels in mature male and female rats.[15] Based on quantitative mRNA analysis, the expression of OAT3 was threefold higher than that of OAT1, and more than tenfold higher than the expression levels of OAT2 and OAT4.[40] The mRNA levels corresponded to protein expression as tested by Western blotting, indicating that OAT3 is the most abundant OAT isoform in the human kidney.[40]

In immunohistochemistry, OAT3/Oat3 was found at the basolateral membrane of proximal tubules as well as in thick ascending limbs of Henle's loops, connecting tubules and collecting ducts; gender differences were only apparent for rOat3 in proximal tubules with lower expression in female rats (reviewed in[7–9,18]). OAT3/Oat3 was also found in human, rat, and mouse choroid plexus. At this location, OAT3/Oat3 is likely involved in the uptake of organic anions including neurotransmitter metabolites and drugs from the cerebrospinal fluid and their transport into the blood. Indeed, Oat3 knockout mice showed an impaired cerebrospinal fluid-to-blood transport of fluorescent organic anions.[41]

Hepatocyte nuclear factors HNF-1α and HNF-1β induced OAT3 expression and HNF-1α knockouts showed a diminished renal expression of Oat3 (reviewed in[8]). Inhibition of promoter methylation also increased OAT3 expression. As summarized in,[8] OAT3/Oat3 expression is subject to regulation by various factors. Insulin, epidermal growth factor and short term exposure to prostaglandin E_2 increased whereas long term PGE_2 elevation as observed in fever and inflammatory states decreased rOat3. Intracellular cAMP served to increase the OAT3 promoter activity. Several kidney disorders such as ischemia-reperfusion, ureteral obstruction as well as methotrexate and cisplatin treatment decreased rOat3 abundance. Biliary obstruction and 5/6 nephrectomy increased rOat3 protein expression (see[8]).

The existence of several single nucleotide polymorphisms in the promoter and the coding region of human OAT3 have been described (compiled in[9]), including 9 non-synonymous mutations, leading to changes in the amino acid sequence or premature truncation. Three loss-of-function mutations (R149S,

Q239X, I260R) were found in Asian-Americans.[42] The impact of these mutations is unknown.

A widely used test substrate for heterologously expressed OAT3/Oat3 is estrone-3-sulfate with half-maximal transport rates (K_t or K_m) between 2.2 and 21.2 μM.[8] PAH was translocated by OAT3/Oat3, but the affinity was smaller than that of OAT1/Oat1. OAT3/Oat3 is driven by the outwardly directed concentration gradient of α-ketoglutarate. Thus, OAT3/Oat3 is involved in uptake of organic anions from the blood, which fits to its location at the basolateral membrane.

Numerous compounds have been tested as putative substrates of OAT3/Oat3 (results compiled in[7,8,25]). An interaction was demonstrated for endogenous substances such as the second messengers cAMP, cGMP; the vitamin folate; the bile salts cholate and taurocholate; the (sulfated) hormones cortisol, dehydroepiandrosterone sulfate, estrone sulfate; the local hormones prostaglandin E_2 and $F_{2\alpha}$; the purine metabolite urate; and some neurotransmitter metabolites. Highly interesting is the observation that Oat3 knockout mice have a decreased blood pressure.[43] Obviously, intact mOat3 excretes one or more endogenous substances that lower blood pressure. Thymidine could play such a role, because knockout mice had an increased thymidine concentration in blood, and thymidine infusion lowered blood pressure.[43]

Drugs interacting with OAT3/Oat3 comprised ACE inhibitors, angiotensin II receptor blockers, diuretics, statins, antibiotics, antineoplastics, immune suppressants, histamine receptor 2 blockers, and non-steroidal anti-inflammatory drugs.[7,8,25] As compared to OAT1, OAT3/Oat3 has higher affinities for urate, benzylpenicillin, and loop diuretics, suggesting a dominant role in proximal tubular secretion of these compounds. Indeed, Oat3 knockout mice showed a decreased renal excretion of diuretics, benzylpenicillin, quinolones and methotrexate.[31,44]

Chimeras between rat Oat3 and Oat1 revealed that substrate recognition is located in transmembrane helices TMH 6-12, i.e. in the C-terminal part of rOat3. Replacement of the positively charged arginine 454 that is conserved in all OATs, by the acidic amino acid aspartate (R454D) abolished PAH uptake, but did not change the handling of cimetidine.[45] The mutant lysine-370 to alanine (K370A) also was unable to translocate PAH, but still transported cimetidine, indicating that cimetidine interacts with amino acid residues different from those involved in binding and translocation of PAH, and that translocation of PAH requires the presence of cationic amino acid residues in TMH 8 and 11.[45] Aromatic residues in TMH 7 (W334, F335, Y341) and F362 in TMH 8 were found to be important for the translocation of PAH and cimetidine, but not for the transport of estrone sulfate.[46] Whether rOat3 has, as suggested, three parallel transportation paths, one for PAH, one for cimetidine, and one for estrone sulfate, must be clarified in future experiments.

In summary, OAT3/Oat3 has a wider distribution than OAT1/Oat1 along the nephron, operates as an organic anion/α-ketoglutarate exchanger, and handles small and, unlike OAT1/Oat1, also larger and more hydrophobic substrates.

The Organic Anion Transporting Polypeptide 4C1 (OATP4C1/Oatp4c1; *SLCO4C1/Slco4c1*)

OATP4C1 was cloned from human and rat kidneys and in both species, OATP4C1/Oatp4c1 proteins were found in the basolateral membrane of proximal tubule cells.[47] The gene for human OATP4C1 was located on chromosome 5q21.2. In humans, the expression was found in kidneys, liver, and weakly in lungs.[12,13,47] In rats, predominant expression was found in the kidneys and a weaker one in the lungs.[47] Gender differences were not apparent. Thus, OATP4C1 can be regarded as a kidney-specific OATP. Functional tests revealed the transport of the endogenous compounds cAMP, triiodothyronine, thyroxine, but not of cGMP, taurocholate, prostaglandin E_2, estradiol-17β-D-glucuronide, and PAH. Among drugs, digoxin, ouabain, and methotrexate were taken up by OATP4C1.[47,48] It was assumed that the physiological role of OATP4C1/Oatp4c1 is to present thyroid hormones to proximal tubule cells. The extent to which this transporter contributes to the proximal tubular secretion of drugs remains to be determined.

The Multidrug Resistance-Associated Protein 6 (MRP6/Mrp6; *ABCC6/Abcc6*)

MRP6/Mrp6 is a member of the ATP binding cassette (ABC) proteins[49] that is mainly expressed in liver and kidneys.[12,13,26] The murine homologue, mMrp6, showed highest expression in the liver, but was also found in other organs including the skin.[12,49] Within human and mouse kidneys, MRP6/Mrp6 was localized to the basolateral membrane of proximal tubule cells (see[26]). This ATP-driven transporter handled glutathione-conjugates, the endothelin receptor antagonist BQ-123, and conferred low level resistance to epipodophyllotoxins and anthracyclines; probenecid and indomethacin inhibited MRP6.[26,49] Mutations in the second nucleotide binding domain were associated with the connective tissue disease, *Pseudoxanthoma elasticum*, but the exact causal relationship between MRP6 and this disorder is unknown. Given the localization in the basolateral membrane of proximal tubule cells and

the function of an ATP-driven efflux transporter it is unlikely that MRP6 contributes to organic anion secretion.

MRP1 (ABCC1) was found in the basolateral membrane of Henle's loops and collecting ducts, and MRP3 (ABCC3) in distal tubules.[26] In rats, Mrp3 was localized also to the basolateral membrane of proximal tubules. Also these transporters are not likely involved in organic anion secretion but may protect renal tubule cells from cytotoxic compounds.[26]

DRUG TRANSPORTERS IN THE APICAL MEMBRANE OF PROXIMAL TUBULE CELLS

The Organic Anion Transporter 4 (OAT4, *SLC22A11*)

This transporter (reviewed in[7–9]) occurs only in humans. The gene for OAT4 is located on chromosome 11q13, in close neighbourhood to that of URAT1.[10,11] OAT4 expression was highest in the kidneys, lower in placenta, and virtually absent from all other tested organs.[12,14] Immunohistochemical studies revealed the presence of OAT4 in the proximal tubules only where it is located at the apical membrane. Thereby, OAT4 interacts with the scaffolding proteins PDZK1 and NHERF1 through its three C-terminal amino acids.[7] Factors influencing the expression of OAT4 are presently unknown.

Mutational analysis revealed that evolutionary conserved glycine residues at positions 241 and 400 (transmembrane helices 5 and 8, respectively) are functionally important. Replacement of these residues by long aliphatic amino acids abolished transport activity, whereas the glycine-to-alanine mutation (G241A, G400A) reduced transport rates and decreased affinities were observed.[50] Glycine is thought to participate in helix-helix interactions that seem to be important for transport activity of OAT4.

Eight non-synonymous single nucleotide polymorphisms were found, one of which (R48X) is deleterious (reviewed in[9]). The impact of the other amino acid changes on the function of OAT4 is unknown.

Following heterologous expression (for results see[7,8,25]), OAT4 transported estrone-3-sulfate with high affinity (K_t of 1 μM). Other endogenous compounds translocated by OAT4 were urate, the prostaglandins E_2 and $F_{2\alpha}$, and dehydroepiandrosterone sulfate; no inhibition was found with glucuronidated steroids, suggesting that OAT4 only handles sulfated compounds. Cholate, taurocholate, octanoate, and corticosterone inhibited OAT4. Intracellular glutarate *trans*-stimulated estrone-3-sulfate uptake, but did not *cis*-inhibit it when present in the extracellular medium, suggesting different affinities for this dicarboxylate at the inner and outer binding sites.[51] Similar findings for PAH indicate that the internal binding site has a higher affinity to this organic anion than the external binding site. Labeled PAH was not taken up by OAT4, but its efflux was accelerated by estrone-3-sulfate in the medium. It was concluded that OAT may work asymmetrically, taking up estrone-3-sulfate or urate in exchange for intracellular (α-keto)glutarate ("influx mode"). Intracellular organic anions such as PAH are effluxed through OAT4, probably in exchange for external chloride ("efflux mode").[51]

As reviewed in,[7,8,25] OAT4 interacted with β-lactam antibiotics, angiotensin II receptor-1 blockers, methotrexate, diuretics, NSAIDs, and was inhibited by probenecid. The secretion of diuretics such as torasemide can lead to an increased reabsorption of urate due to diuretic/urate antiport at OAT4, explaining the observation that therapy with diuretics can cause hyperuricemia.[52] NPT4 is yet another site for an interaction between diuretics and urate (see later).

Taking together, OAT4 in the apical membrane of proximal tubule cells can contribute to the absorption of estrone sulfate and urate from the primary urine, and to the secretion of anionic drugs. Since OAT4 is not present in rodents it is not possible to learn more about its function from knockout animals.

The Organic Anion Transporter 5 (Oat5, *Slc22a19*)

Oat5 was cloned from rat and mouse in which it was restricted to the kidney and was equally expressed in male and female animals.[53,54] There is no human homologue to Slc22a19.[10] The Oat5 protein was localized to the apical membrane in the late proximal tubule segments. The interaction of Oat5 with dicarboxylates is not yet settled, because conflicting results were reported on the ability of succinate to *trans*-stimulate uptake of estrone-3-sulfate. Endogenous substrates were dehydroepiandrosterone sulfate and estradiol sulfate, but not prostaglandins and urate. A few drugs were tested: furosemide, benzylpenicillin, diclofenac, and ibuprofen inhibited Oat5.[53,54] As long as the driving force for Oat5 is not defined it is not possible to speculate on the role of this transporter in drug secretion or absorption.

The Organic Anion Transporter 10 (OAT10/Oat10; *SLC22A13/Slc22a13*)

OAT10 (previously cloned as orphan transporter ORCTL3) is predominantly expressed in human

kidneys and weakly in brain, heart and colon.[55] The gene is located on chromosome 3p22.2.[10] Western blots showed the rOat10 protein in the apical, but not in the basolateral membrane, and female animals showed a stronger expression of rOat10 than did males.[55] Endogenous substrates of OAT10 were nicotinate, lactate, urate, succinate, and glutathione. Succinate served as counter anion for nicotinate and urate uptake from the lumen. Among the few drugs tested, furosemide, hydrochlorothiazide, sulfinpyrazone, and cyclosporine A inhibited OAT10.[55] It needs to be established whether OAT10 is involved in cyclosporine A-induced nephropathy. The physiological role of OAT10 is probably the uptake of the vitamin nicotinate in small intestine and renal proximal tubule cells.

The Urate Anion Transporter 1 (URAT1/Urat1/Rst; *SLC22A12/Slc22a12*)

URAT1/Urat1/Rst was cloned from human and mouse kidneys (for reviews see[7–9]). The gene for human URAT1 is located on chromosome 11q13.1 adjacent to that of OAT4.[10,11] The highest though not exclusive expression was found in kidneys.[12,14] Human and mouse URAT1/Urat1 were immunolocalized to the apical membrane of proximal tubule cells where they interact with the scaffolding protein PDZK1. Male mice showed a higher expression than female animals, indicating sex differences at least in this species.[18]

Hepatocyte nuclear factor-1α and -1β induced the expression of human and mouse URAT1/Urat1 promoter, and mUrat1 expression was diminished in a HNF-1α knockout mouse. Furthermore, the mUrat1 promoter was found to be hypomethylated, suggesting a tissue-specific epigenetic control (reviewed in[9]).

URAT1 mutations have been linked to familial hypouricemia.[56] Most of the hypouricemic patients in Japan and Korea carry a truncation mutation, W258X. Meanwhile, several more amino acid exchanges have been described (see[9] for a compilation). Some mutations occur also with hyperuricemia and gout, but the molecular mechanism is unknown.[57]

URAT1 expressed in oocytes displayed saturable uptake of urate.[56] Extracellular chloride inhibited, and intracellular chloride *trans*-stimulated urate uptake, indicating that URAT1 can operate as urate/chloride exchanger. Preloading of oocytes with lactate *trans*-stimulated urate uptake, indicating urate/lactate exchange as another transport mode of URAT1.[56] The endogenous compounds L- and D-lactate, acetoacetate, β-hdyroxybutyrate, succinate (but not α-ketoglutarate), and orotate inhibited urate uptake. Exogenous compounds inhibiting URAT1 were the uricosuric drugs probenecid, benzbromarone, losartan; the antiuricosuric drugs pyrazine carboxylate and pyrazine dicarboxylate; the loop diuretics furosemide and bumetanide; the NSAIDs phenylbutazone, salicylate and indomethacin; and the vitamin nicotinate.[56] PAH and estrone sulfate did not affect URAT1.

Also mouse Urat1/Rst transported urate (K_m 1.2 mM) and performed urate/chloride, urate/lactate and urate/pyrazinoate exchange.[58] Uptake of labeled urate was inhibited, when the uricosurics probenecid and benzbromarone, the uremic toxins indoxyl sulfate, indole acetate, hippurate, and a number of acidic neurotransmitter metabolites were present in the medium.[59]

In summary, URAT1/Urat1 is involved in urate absorption from the primary urine. Thereby, urate uptake is driven by exchange against lactate that is transported into the cells by a sodium-lactate symporter in the apical membrane, as has been convincingly demonstrated in a c/ebpδ knockout mouse.[60] This mouse does not express the sodium-coupled lactate transporters Slc5a8 and Slc5a12 in the apical membrane of proximal tubules and excretes lactate and—at unchanged Urat1 expression—urate with the urine. In man, uricosurics inhibit URAT1, and loss-of-function mutations cause an increased urate clearance and a reduction in serum level of urate.

The Voltage-Sensitive Organic Anion Transporter 1 (Oat_v1/Npt1; *Slc17a1*)

Searching for the voltage-driven transporter for PAH and urate in urate-secreting species (rabbits, pigs), Oat_v1 was identified by expression cloning from pig kidneys.[61] The message for $pOat_v1$ was restricted to liver and kidneys. $pOat_v1$ is not a member of the SLC22 family, but showed highest identity to human and rodent NPT1/Npt1 (*SLC17A1*/*Slc17a1*), previously cloned as sodium-dependent phosphate transporters from human, rabbit, and mouse kidneys and located to the apical membrane of the proximal tubule segments S1–S3 (for review see[62]). The human gene for NPT1 was found on chromosome 6p21.3-p23.[62] The expression of mNpt1 was under control of heptatocyte nuclear factor-1α, and HNF-1α knockout mice had greatly diminished proximal tubular Npt1 expression.[63,64] Fasting decreased and streptozotocin-induced diabetes increased renal and hepatic expression of NaPi-1/Npt1 in rats, respectively.[65] Whether gender differences exist is not known.

Human NPT and mouse Npt1/NaPi-1 performed the uptake of radiolabeled organic anions including PAH, urate, estradiol-17β-D-glucuronide, benzylpenicillin, faropenem, and mevalonate.[66–69] Benzylpenicillin, ampicillin, cephalexin, cefazolin,

indomethacin, furosemide, benzoate, lactate, and probenecid inhibited uptake of labeled faropenem by mNpt1.[70] Uptake of labeled PAH by porcine Oat_v1 was inhibited by, e.g., estrone sulfate, penicillin G, salicylate, indomethacin, ibuprofen, diclofenac, furosemide, bumetanide, and probenecid.[61] Organic anion transport was independent of sodium, but was inhibited by increasing chloride concentrations as well as by DIDS and NPPB.[61,66,67,70]

It is likely that organic anion transport through NPT1/Npt1 is electrogenic. Busch et al. observed outward currents upon addition of benzylpenicillin, phenol red and probenecid in *Xenopus laevis* oocytes expressing rbNaPi-1 (Npt1[69]). PAH uptake (K_m 4.4 mM) by $pOat_v1$/pNpt1 was increased at inside positive membrane potentials.[61] More recently, mNpt1 was purified and inserted into proteoliposomes for functional characterization.[68] Both, sodium-dependent phosphate transport and sodium-independent PAH and urate transport were observed, indicating that at least mNpt1 is able to carry out both functions. The affinity of mNpt1 for urate and PAH was similar (K_m 1.1 mM) and uptake was accelerated by a proteoliposome-inside positive membrane potential. Chloride stimulated (whereas it inhibited in other studies) PAH uptake, but was not transported itself. Salicylate, aspirin and acetaminophen, but not other NSAIDs, inhibited PAH and urate transport; radiolabeled aspirin was translocated by reconstituted mNpt1.

The mutation of an arginine residue (R138A) conserved within the SLC17 family abolished transport.[68] A lowered V_{max} was found with the T269I mutation[68] that corresponds to a SNP in human NPT1 gene associated with gout.[71] Taken these data together it is likely that NPT1/Npt1/Oat_v1 is involved in the voltage-driven exit of organic anions including urate, PAH, β-lactam antibiotics, diuretics and some non-steroidal anti-inflammatory drugs.

The Sodium-Phosphate Transporter 4 (NPT4/Npt4; *SLC17A3/Slc17a3*)

Exploring the locus for hereditary hemochromatosis in humans, two genes closely related and juxtapositioned to *SLC17A1* were found on chromosome 6p21.3 and sequenced.[72] One of these genes, *SLC17A3*, was expressed only in liver and kidneys and the gene product was named NPT4. In mice deficient in HNF-1α, the expression of Npt4 in kidneys was reduced, indicating that, like Npt1 (see previous chapter), Npt4 is under control of this hepatic nuclear transcription factor.[63] Npt4 was also isolated from rat kidneys where it was immunolocalized to the apical membrane of proximal tubule cells of the segments S2 and S3; segment S1 following directly the glomerulus did not show any labelling.[73] Human NPT4 was also localized to the apical membrane of proximal tubule cells.[74]

When human NPT4 was expressed in COS cells, a perinuclear localisation was found; the authors speculated that NPT4 is involved in the release of phosphate from the endoplasmic reticulum, and loss of its function should give rise to the glycogen storage disease type 1c.[75] Indeed, a patient with this disease showed a non-synonymous SNP, resulting in a Gly201Arg mutation.[75] The functional consequences of this mutation were, however, not tested.

Single nucleotide polymorphisms of the human *SCL17A3* gene correlated with hyperuricemia.[76] The linkage was not as strong as with SNPs affecting the urate transporter GLUT9 and the breast cancer resistance protein ABCG2[76] and, in later studies, failed to reach statistical significance[77] or were associated with an increase in serum uric acid only in women.[78]

When rat Npt4 was expressed in *Xenopus laevis* oocytes it showed a sodium-dependent phosphate transport.[73] Expression of human NPT4 also in oocytes resulted in the uptake of labelled estrone-3-sulfate, estrone-17β-D-glucuronide, prostaglandin E_2, taurocholate, PAH, bumetanide, and ochratoxin A.[74] Uptake was stimulated by depolarization, and PAH and bumetanide application caused an outward current in voltage-clamped oocytes. PAH uptake was inhibited by the hormones DHEAS, β-estradiol sulfate, estriol, estrone-3-sulfate; the diuretics hydrochlorothiazide, chlorothiazide, trichlormethiazide, bumetanide, furosemide, spironolacton; the NSAIDs diclofenac, ibuprofen and indomethacin; and the common inhibitor probenecid. No interaction with NPT4 was seen for succinate, α-ketoglutarate, lactate, nicotinate, xanthine, and hypoxanthine.

Importantly, labelled urate was transported by NPT4.[74] In Japanese hyperuricemic patients, two mutations (N68H and F304S) were found in NPT4. Expression of these mutants in *Xenopus laevis* oocytes resulted in a decreased urate uptake as compared to oocytes expressing the wildtype NPT4.[74] Thus, it is likely that NPT4 constitutes the voltage-driven exit step for urate secreted into proximal tubules. A decreased function of NPT4 will decrease urate secretion and lead to hyperuricemia.

The Organic Anion Transporting Polypeptides, Subfamily 1A (OATP1A/Oatp1a; *SLCO1A/Slco1a*)

The organic anion transporting polypeptides were grouped into 6 families, OATP1-6.[48,79] The genes (formerly SLC21) have been systematically renamed to

SLCO followed by the number of OATP/Oatp. Human OATP1A2 (SLCO1A2; formerly OATP-A; SLC21A3) was localized to the apical membranes of distal tubules[80] and, hence, is not involved in proximal tubular drug secretion. Of the rat homologues, rOatp1a1 (Slco1a1; formerly Oatp1) and rOatp1a3 (Slco1a3; formerly OAT-K1/K2) have been localized to the apical membrane of proximal tubule cells.[81,82] Oatp1a1 expression in rats and mice was higher in males than in females[83,84] and, in mice, mRNA appeared late in adult animals.[83] Rat Oatp1 transported bile salts, hormones and their conjugates, peptides, drugs, toxins, and even organic cations (reviewed in[48,85,86]). Since it appears that Oatp1 is rather involved in drug uptake across the apical membrane rather than in drug secretion, we do not further consider this transporter in this review.

Oat-K1 and its N-truncated variant Oat-K2 were isolated as rat renal homologues of Oatp1a1 (reviewed in[87]). In the new nomenclature, Oat-K1 was classified as Oatp1a3 (gene Slco1a3; formerly Slc21a4).[79] The message for rOat-K1 was detected exclusively in kidneys and was located to superficial and juxtamedullary proximal straight tubules (S3 segment[82]). Antibodies reacted with a 40 kDa band in rat renal brush-border membranes, indicating the expression of the rOat-K1 protein in the apical membrane.[82] The mRNA for the splice variant rOat-K2 was detected mainly in the S3 segment, but also in proximal convoluted tubules as well as in collecting ducts.[88] When expressed in MDCK cells, rOat-K2 appeared in the apical membrane,[88] suggesting that both transporters are located in the apical membrane.

Rat Oatp1a3/Oat-K1 mediated the sodium-and chloride-independent, bidirectional transport of methotrexate (K_m 2.1 μM) and folate (substrates reviewed in[87]). Further transported substrates were the hormone conjugates dehydroepiandrosterone sulfate, estrone-3-sulfate, estradiol-17β-D-glucuronide; the thyroid hormones triiodothyronine and thyroxin; the bile salt taurocholate; and the mycotoxin ochratoxin A. PAH inhibited methotrexate transport but was not translocated.[89] A series of non-steroidal anti-inflammatory drugs inhibited methotrexate uptake, but were not translocated. Although truncated, rOat-K2 was functional and translocated methotrexate, folate, taurocholate, and prostaglandin E_2. In addition transport of dehydroepiandrosterone sulfate, estrone sulfate, estradiol-17β-D-glucuronide, triiodothyronin, thyroxine, ochratoxin A, and the antiviral drug zidovudine was shown.[87]

Taken together, rat Oatp1a3/Oat-K1 and Oat-K2 interact with endogenous compounds and selected drugs, methotrexate and zidovudine. Oatp3a1/Oat-K1 and K2 were considered important for renal methotrexate secretion.[87,90] The inhibition by NSAIDs could provide an explanation for the toxic accumulation of methotrexate in the body, when co-administered with analgesics.

The Multidrug Resistance Protein 2 (MRP2/Mrp2; *ABCC2/Abcc2*)

The ATP binding cassette (ABC) transporter MRP2/Mrp2 is mainly expressed kidneys, liver, placenta and small intestine (for reviews see[26,49,91,92]). Highest expression was found in human liver and jejunum; in human kidneys, mRNA for MRP2 was moderately expressed as compared to the highly expressed OAT1 and OAT3.[13,93] The human gene, ABCC2, is located on chromosome 10q24.[92,94] In mice, mRNA for Mrp2 was low until day 10 after birth; from day 15 on, the mRNA was higher and did not show statistically significant sex differences in adulthood.[93]

MRP2/Mrp2 is a large protein consisting of 1,545 amino acids arranged in three membrane spanning domains, MSD0, MSD1 and MSD2, with 5, 6, and 6 transmembrane helices (TMH) each, respectively.[49,91] Between MSD1 and MSD2 and carboxyterminal from MSD2 there are two intracellularly located nucleotide binding domains (NBDs). In human MRP2, TMH 6, 9, 16, and 17, and in rMrp2 TMH 11, 14, and 15 are important for function (for literature see[91,95]). In all organs, MRP2 protein was found at the apical membrane. Within human and rat kidneys, MRP2/Mrp2 is located in the proximal tubules in segments S1 to S3 and thus prone to ATP-driven extrusion of its substrates.[96,97]

Several loss-of-function mutations of MRP2 are the cause of the *Dubin-Johnson syndrome* in humans, a rare autosomal-recessive disease with hyperbilirubinemia and deposition of a dark pigment in the liver (for a review of mutations see[95,98]). Mrp2 is absent in two rat strains, the Eisai hyperbilirubinemic rat and the TR$^-$ rat[99,100] that served as models for the Dubin-Johnson syndrome and offered valuable insights into the physiological function of MRP2/Mrp2. More recently, Mrp2 knockout mice were generated which were also hyperbilirubinemic (summarized in[101]). The increased serum levels in bilirubin diglucuronide in MRP2/Mrp2 deficient humans, rats, and mice is due both to an impaired secretion of hepatic bilirubin diglucuronide across the canalicular membrane into the bile and to an increased release of this metabolite through the upregulated Mrp3 and Mrp4 across the sinusoidal membrane into the blood.[101] The functional significance of several other single nucleotide polymorphisms observed in human MRP2 is not yet clear.[98] The SNP 1249G > A that leads to the amino acid exchange

Val417Ile is frequent in Caucasians (22%) and Japanese (13%) and possibly associated with a renal tubulopathy induced by the antiviral drug tenofovir.[102] The SNP -24C > T in the promoter region was found to cause a lower renal MRP2 expression and a decreased excretion of methotrexate.[98,103]

MRP2/Mrp2 is an ATP-driven pump for the endogenous compounds leukotrienes C_4, D_4 and E_4, mono- and bis-glucuronidated bilirubin, estradiol-17β-D-glucuronide, glutathione, glutathione-conjugates, and conjugated bile salts. Exogenous compounds being transported by or interfering with MRP2/Mrp2 include β-lactam antibiotics, statins, NSAIDs, HIV drugs, and a number of anticancer drugs (reviewed in[49,91,92,94,95]). The clinical importance of MRP2 is based on its ability to confer resistance to a number of cytostatic drugs. ln proximal tubules, MRP2/Mrp2 is expected to pump glutathione, glucuronide and sulfate conjugates into the urine, utilizing ATP hydrolysis as energy source. When human MRP2 was expressed in HEK293 cells and inside-out vesicles were prepared from these cells, an ATP-driven uptake of radiolabeled PAH with low affinity was found.[104]

The Multidrug Resistance Protein 4 (MRP4/Mrp4; *ABCC4/Abcc4*)

The mRNA for MRP4/Mrp4 was low in several organs and showed the highest levels in kidneys and prostate.[12,92,93] The human gene for this ABC transporter, *ABCC4*, is located on chromosome 13q32.[94] In mice, the mRNA was present at their birth; at day 15 after birth, a small increase in mRNA levels took place and from day 30 on, expression in female mice exceeded that in male mice considerably, indicating sex differences in adult animals.[93] The female-dominant mMrp4 expression was verified in Western blots.[105] In gonadectomized mice, 5-dehydrotestosterone application decreased mRNA, suggesting that androgens repress the expression of Mrp4.[105] In contrast to mice, rMrp4 showed a male-dominant expression in adult rats.[106] It is unknown whether sex differences exist in human MRP4 expression. In human kidneys, MRP4 was localized to the apical membrane of proximal tubule cells.[107]

Hepatic mMrp4 mRNA expression was regulated through the constitutive androstane receptor (CAR) and the peroxisome proliferator-activated receptor α (PPARα), leading to an increased expression during cholestasis.[108] In mouse kidneys, ischemia-reperfusion injury increased the mRNA, but decreased the Mrp4 protein level, and in rat kidneys, endotoxemia did not change mRNA, but again decreased protein levels, suggesting that a post-translational regulation takes place.[108] Conflicting results have been obtained with Mrp2-deficient TR^- rats with either no change or an increased rMrp4 expresssion; in Mrp2 knockout mice, mMrp4 was upregulated (summarized in[108]).

Several single nucleotide polymorphisms have been reported for the MRP4 gene in Caucasians and Japanese (collected in[98]). Although a number of non-synonymous SNPs lead to amino acid exchanges in conserved regions, no influence on expression and localization of MRP4 was found in liver; functional consequences of these mutations were not studied so far.[98]

MRP4/Mrp4 has only two membrane-spanning domains (MSD1 and MSD2) and lacks MSD0.[49] Thereby, MRP4/Mrp4 is with 1325 amino acids the shortest member of the ABCC family.[108] Morever, MRP4/Mrp4 differs from MRP2/Mrp2 in its ability to transport cyclic nucleotides and nucleoside analogues.[49,108] Cells overexpressing human MRP4 showed a unique resistance to 9-(2-phosphonylmethoxyethyl) adenine (PMEA), 9-(2-phosphonylmethoxyethyl)guanine (PMEG), and azidothymidine (AZT), suggesting that this ATP-driven transporter translocates nucleoside-based antiviral drugs across the cell membrane.[109] Numerous endogenous compounds are substrates of MRP4/Mrp4: cAMP, cGMP, prostaglandins (PGE_1, PGE_2, $PGF_{2\alpha}$), leukotrienes (LTB_4, LTC_4), unconjugated (cholate) and conjugated bile acids, (e.g. taurocholate, glycocholate), conjugated steroids (dehydroepiandrosterone sulfate, estradiol-17βD-glucuronide), folic acid, and glutathione.[94,108] Thereby, cholate, glycocholate, taurocholate, LTB_4 are cotransported with glutathione.[94] In addition, MRP4 turned out as an ATP-driven urate transporter.[110] Since urate transport showed a Hill coefficient of 1.7 it is likely that two molecules of urate may be transported per cycle. Possibly, there are two independent transport sites interacting allosterically.[110] Together with OAT_v1/NPT1 and NPT4, MRP4 is involved in urate secretion in proximal tubules.

Human MRP4 transported a number of drugs including antibiotics (ceftizoxime, cefazolin, cefotaxime, cefmetazole), diuretics (hydrochlorothiazide, furosemide), antihypertensives (enalapril, olmesartan), statins (pravastatin), antivirals (adefovir, tenofovir), and anticancer drugs (methotrexate, topotecan).[94,108] Non-steroidal anti-inflammatory drugs (indomethacin, sulindac), and probenecid inhibited MRP4.[108] The decreased renal excretion of ceftizoxime, adefovir, tenofovir, hydrochlorothiazide, and furosemide in Mrp4 knockout mice proved an important role of Mrp4 in drug secretion.[111–113]

TR^- rats lacking Mrp2 in liver and kidneys, did not show a lower PAH clearance than wildtype rats, suggesting that the contribution of rMrp2 to urinary PAH

excretion is low.[114] Indeed, human MRP4 transported PAH with a K_m of 160 μM, whereas MRP2 exhibited a much lower affinity. ATP-driven PAH transport by MRP4 was sensitive to probenecid, sulfinpyrazone, dipyridamole, and acyclovir. The expression of MRP4 protein (tested by Western blots) was fivefold higher than that of MRP2. Together with the approximately 30 fold higher affinity for PAH, MRP4 should clearly dominate over MRP2 in the efflux of PAH across the apical membrane.[114]

OVERVIEW OF TRANSPORTERS INVOLVED IN TRANSPORT OF SELECTED ANIONIC DRUGS

β-Lactam Antibiotics

Most β-lactam antibiotics are excreted by the kidneys and undergo proximal tubular secretion. Benzylpenicillin (BP in Figure 72.2) is taken up across the basolateral membrane into proximal tubule cells mainly by OAT3, because OAT3 has a higher affinity for this antibiotic than OAT1.[7] Since OAT4, NPT1, and MRP2 interacted with benzylpenicillin, one or more of these transporters may be involved in its exit across the apical membrane.[7,61,67,69,115] However, the quantitative contribution of the apical transporters to overall benzylpenicillin secretion is not clear at present. Most cephalosporines (CS in Figure 72.2) interacted with OAT1 with higher affinity than with OAT3, and OAT2 had a very low affinity, rendering OAT1 the prime candidate for uptake across the basolateral membrane.[7] OAT4 was inhibited by cephalosporines with low affinity, leaving it open whether this transporter contributes much to cephalosporin exit across the apical membrane.[7] A considerably higher affinity for ceftizoxime, cefazolin and cefmetazole strongly suggests that MRP4 is the most important transporter for the release of cephalosporines from tubule cells into the urine.[94,108]

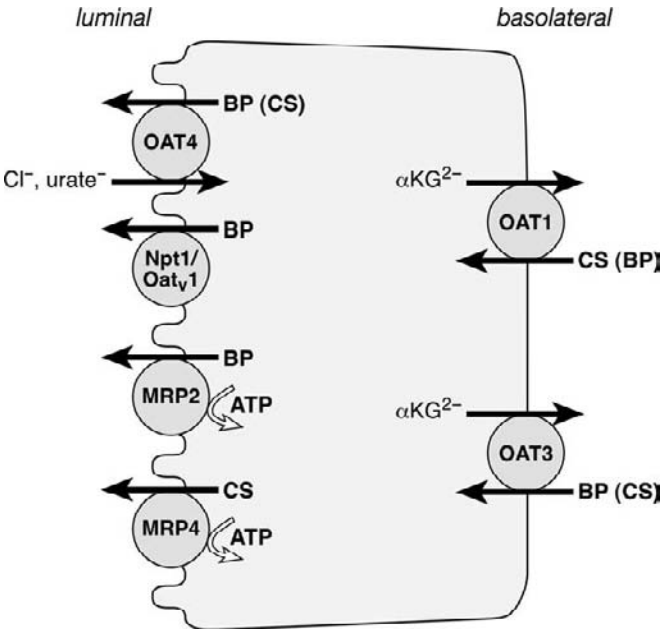

FIGURE 72.2 Proximal tubular secretion of β-lactam antibiotics. The antibiotics are taken up from the bood into the proximal tubule cell by OAT1 and OAT3, both in exchange for intracellular α-ketoglutarate (or another organic anion). Cephalosporines (CS) are preferred by OAT1 whereas benzylpenicillin (BP) shows a higher affinity toward OAT3. At the luminal membrane, OAT4 and MRP2 are involved in benzylpenicillin release, and OAT4 and MRP4 in the release of cephalosporines. In rodents, Npt1/Oat$_v$1 may also export benzylpenicillin.

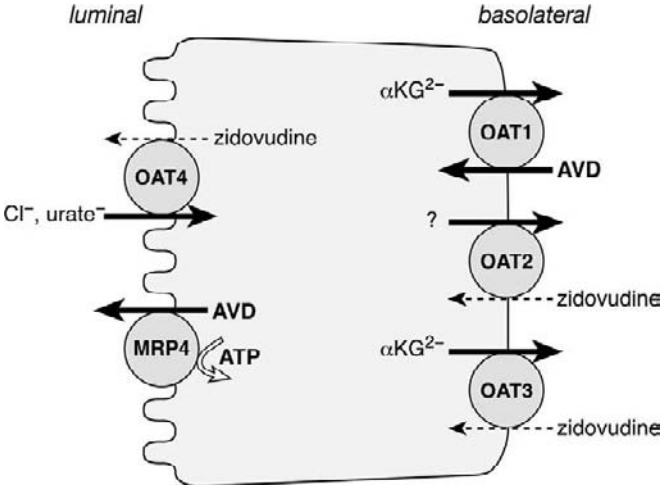

FIGURE 72.3 Proximal tubular secretion of antiviral drugs. OAT1 transports most antiviral drugs (AVD) from the blood into the cell, whereas OAT3 and OAT2 interact only with zidovudine. Once inside the proximal tubule cells, most antiviral drugs leave through MRP4 in the apical membrane. OAT4 may interact with zidovudine.

Antiviral Drugs

Many antiviral drugs (AVD in Figure 72.3) are renally excreted and interact with organic anion transporters, irrespective whether they carry a negative charge, such as adefovir, cidofovir, 9-(-2-phosphonylmethoxyethyl)guanidine (PMEG) and 9-(2-phosphonoethyl) diaminopurine (PMEDAP), or are uncharged, e.g. acyclovir, ganciclovir and zidovudine. Uptake of these drugs across the basolateral membrane is largely mediated by OAT1; only zidovudine was transported also by OAT2 and OAT3[7] (Figure 72.3). Hence, OAT1 is most probably responsible for the dose-limiting, nephrotoxic effects of these compounds. Although OAT4 translocated zidovudine[7] it is more likely that MRP4 is the efflux transporter at the apical membrane, because it afforded a resistance against several antiviral

drugs.[109] In addition, Mrp4 knockout mice accumulated more adefovir and tenofovir in their kidneys and excreted less with the urine.[112]

Non-Steroidal Anti-Inflammatory Drugs (NSAIDs)

Most NSAIDs are preferentially excreted by the liver. However, they interact with renal organic anion transporters, and some of them have been shown to be translocated, i.e., indomethacin by human and rat OAT1/Oat1 and acetylsalicylate and salicylate by rOat1.[7] For all other NSAIDs, an inhibition of OAT1/Oat1 mediated transport was found. In general, the affinity of human OAT1 decreased with increasing hydrophilicity of the NSAIDs.[7] Since labeled acetylsalicylate, indomethacin, and salicylate were transported by rOat2, and salicylate by hOAT3,[7] these transporters may also be involved in uptake of selected NSAIDs from blood into proximal tubule cells. Again, inhibition by various NSAIDs of both transporters were observed.[7]

Interestingly, it has been proposed that NSAIDs should be used to decrease the toxicity of antiviral drugs by drug interaction at OAT1.[116] An interaction at OAT3 was proposed to be involved in the potentially life-threatening accumulation of methotrexate in patients taking NSAIDs (for literature see[117,118]), In this regard, it is important to compare therapeutic plasma levels of NSAIDs with the affinity of OATs. Only the plasma concentrations of salicylate, phenylbutazon, indomethacin, and probenecid are high enough to inhibit OAT3.[119]

NSAIDs were also tested with organic anion transporters present in the apical membrane. OAT4 was inhibited by diclofenac, ibuprofen, ketoprofen, phenylbutazone, but not, or only weakly, by salicylate (see[7]). Oat_v1-mediated transport was inhibited by salicylate, indomethacin, ibuprofen, and diclofenac.[61] The human NPT1 showed a weak transport of labeled indomethacin.[66] Human NPT4 was inhibited by diclofenac, ibuprofen and indomethacin.[74] For rOat-K1, an interaction with indomethacin, ketoprofen, ibuprofen, flufenamate, phenylbutazone, but not of salicylate was reported.[120] Oat-K2, however, did not translocate indomethacin.[88] The competition for Oat-K1 could contribute to the above mentioned methotrexate/NSAID interaction. Several NSAIDs including flurbiprofen, ibuprofen, indomethacin, indoprofen, ketoprofen and diclofenac inhibited MRP4.[121] It is not known, however, whether these compounds inhibit only or are indeed translocated by MRP4. Since methotrexate is translocated by MRP4,[94] inhibition by NSAIDs could contribute to the accumulation of methotrexate in patients treated with analgesics.

In summary, NSAIDs interfere with organic anion transporters in proximal tubule cells. Although renal excretion is not the main route for elimination of most NSAIDs, some of these compounds can inhibit the secretion of other organic anions such as the cytostatic drug methotrexate and cause side effects. On the other hand, NSAIDs may deliberately be used to decrease the nephrotoxicity of, e.g., antiviral drugs during HIV therapy.

Diuretics

Diuretics are secreted in proximal tubules to reach their target salt transporters in the distal tubule from the lumenal side. Among the human basolateral OATs, OAT1 translocated labelled bumetanide and furosemide, OAT2 bumetanide, and OAT3 furosemide; all other diuretics inhibited (see[7] for K_i values). OAT1 possessed a higher affinity for most thiazide diuretics (TZ in Figure 72.4), whereas OAT3 had a higher affinity for loop diuretics (LD in Figure 72.4). Both Oat1 and Oat3 knockout mice showed a decreased renal excretion of furosemide and bendroflumethiazide, strongly suggesting that both transporters are involved in proximal tubular secretion of diuretics.[31]

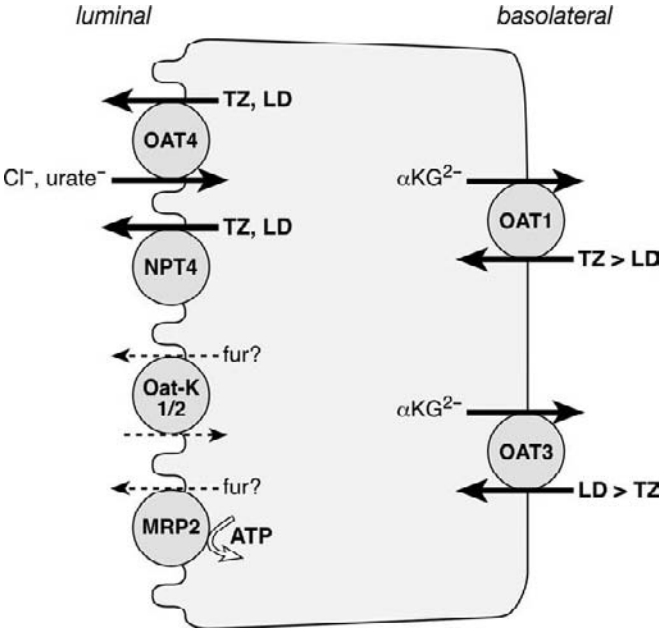

FIGURE 72.4 Transport systems possibly involved in proximal tubular secretion of diuretics. Thiazides (TZ) are preferentially taken up from blood by OAT1 and loop diuretics (LD) by OAT3 in the basolateral membrane. Both classes of diuretics leave the cell across the apical membrane through OAT4, in exchange for urate or chloride ions. NPT4 accomplishes the electrogenic exit of thiazide and loop diuretics. An interaction of furosemide (fur) with OatK-1/2, and MRP2 has been reported but it is not clear whether these transporters are involved in furosemide release.

At the lumenal membrane, it is likely that OAT4 is involved in the efflux of diuretics into the urine. OAT4 transported labeled bumetanide and was inhibited by thiazides and loop diuretics (see[7]). The export of diuretics, e.g., torasemide, in exchange for urate could explain the hyperuricemia observed in antihypertensive monotherapy with diuretics.[52] An interaction of furosemide with rOat-K1[122] and rOat-K2,[88] $pOat_v1$,[61] and hMRP2[115] was reported. However, it is not known whether any of these transporters translocates furosemide and other diuretics across the apical membrane. NPT4, however, is clearly a candidate for the release of diuretics, because thiazides and loop diuretics inhibited NPT4-mediated PAH transport and labelled bumetanide was taken up into NPT4-expressing oocytes.[74] Since extracellular bumetanide induced an outward current it is highly likely that transport is electrogenic. Given the inside negative electrical potential difference across the apical membrane, NPT4, probably acts as an important exit transporter for the negatively charged diuretics.

ORGANIC CATION TRANSPORT SYSTEMS

Characteristics of Organic Cation Transport in Proximal Tubules

In the kidney, organic cations may be ultrafiltrated in the glomeruli and reabsorbed or secreted in renal tubules. Hydrophilic organic cations that do not bind to plasma proteins are readily filtrated and may be reabsorbed in renal tubules. However, most organic cations are not filtrated efficiently because they are relatively hydrophobic and bound to plasma proteins. These organic cations are actively secreted. Reabsorption and secretion of organic cations have been investigated in proximal tubules, distal tubules, and collecting ducts, however, secretion of organic cations in proximal tubules has been studied in most detail.[123] Substrates for organic cation secretion include primary, secondary, tertiary, or quaternary amines that have a positive charge at physiological pH. Organic cations are secreted by a two-step procedure. In the first step, they are taken up across the basolateral membrane by an electrogenic transport system that accepts a variety of structurally different organic cations and uses the electrochemical gradient to accumulate cations intracellularly. The energy provided by the membrane potential is restored by the Na^+,K^+-ATPase. In a second step, organic cations are released across the luminal membrane by a proton/organic cation antiporter that helps to overcome the inside negative membrane potential. This step is energized by an extracellular over intracellular proton concentration difference that is mainly generated by the Na^+/H^+ exchanger. For reabsorption, organic cations are transported across the luminal membrane and leave the cells via a polyspecific transporter in the basolateral membrane. Renal handling of organic cations is dependent on their concentrations in the plasma. For example, in rabbit and dog, choline is secreted at high plasma concentrations, whereas it is reabsorbed at normal plasma concentrations below 25 μM.[124,125]

Figure 72.5 depicts transporters that mediate secretion and reabsorption of organic cations in human renal proximal tubules. The Na^+,K^+-ATPase in the basolateral membrane generates and maintains a high intracellular concentration of potassium, which is the prerequisite for the membrane potential that drives organic cation uptake by the electrogenic organic cation transporters. The extracellular-over-intracellular proton gradient across the luminal membrane generated by the sodium/proton antiporter provides the driving

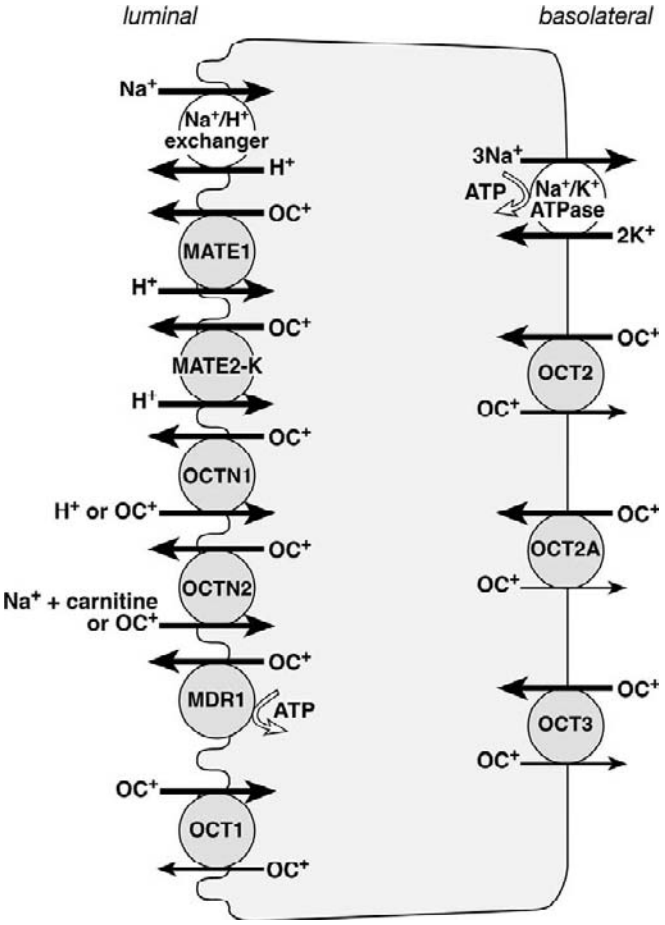

FIGURE 72.5 Transport systems for organic cations in human renal proximal tubule cells. Thick and thin arrows indicate that large and small uptake rates are presumed. OCT2A is a functional active splice variant of OCT2.

force for the proton/organic cation exchangers that mediate the efflux of organic cations into the tubular lumen. Transporters OCT1 (SLC22A1), OCT2 (SLC22A2), OCT3 (SLC22A3), OCTN1 (SLC22A4), and OCTN2 (SLC22A5) belong to the organic cation transporter family *SLC22* which is a member of the major solute facilitator (MFS) superfamily.[125,126] MATE1 (*SLC47A1*) and MATE2-K (*SLC47A2*) are members of the multidrug and toxin extrusion family *SLC47*[123,127] whereas MDR1 (ABCB1) belongs to the ATP-binding cassette transporter family ABC.[128]

Cloning and Functions of OCT1-3/Oct1-3; *SLC22A1-3/Slc22a1-3*

OCT1/Oct1, OCT2/Oct2, and OCT3/Oct3 are electrogenic polyspecific transporters that are expressed in kidney. On the protein level, individual transporter subtypes from different species exhibit cross-species identities of 78 to 95%. Within a given species, the amino acid identities between different subtypes are 67 to 70% between OCT1 and OCT2, 47 to 57% between OCT1 and OCT3, and 49 to 51% between OCT2 and OCT3. In addition to renal excretion and reabsorption, OCT1−3 are critically involved in small intestinal absorption and hepatic excretion of cationic drugs.[123] The OCT-transporters influence the distribution of cationic drugs and endogenous compounds in various tissues, for example in brain and heart.[123,129−131] Species-specific expression and membrane locations of the three OCT subtyes have been observed. In humans, OCT2 is most strongly expressed in kidneys whereas OCT1 and OCT3 are most strongly expressed in liver and adrenal gland, respectively.[123,132]

OCT1/Oct1, OCT2/Oct2, and OCT3/Oct3 have been isolated from rats,[133−135] mice,[136] and humans.[137−139] Oct1 and Oct2 were also cloned from rabbit[140,141] and Oct2 also from pig.[125]

Expression and Main Functions of OCT1/Oct1

In the species tested so far, OCT1/Oct1 is mainly expressed in liver where it is located at the sinusoidal membrane of the hepatocytes.[132,142] In rat, mouse, and rabbit, strong expression of Oct1 was also observed in kidneys whereas relatively small amounts of OCT1 mRNA were detected in human kidney.[123,143] In humans, OCT1 is also expressed in various other organs[123] and in various tumors.[144,145] Using immunohistochemistry, Oct1 protein was localized at the basolateral membranes of S1 and S2 segments of rat proximal tubules,[125] however, in human OCT1 has been recently localized to luminal membranes of proximal and distal tubules.[143] Apical location of OCT1/Oct1 has been also observed in lung bronchial epithelial cells and brain microvessel endothelial cells of rodents and human.[131,146] Human OCT1 transports the endogenous Cyclo(His-Pro) and salsosinol, xenobiotics and drugs ([147] and Table 72.1). Important transported drugs are the antidiabetic metformin; the antineoplastic drugs oxaliplatin, picoplatin and metaiodobenzylguanidine; the antiparasitic drugs furaminidine and pentamidine; and the antiviral drugs acyclovir, ganciclovir, lamuvidine and zalzitabine (Table 72.1). Studies with mice in which either Oct1, Oct2 or Oct3 or Oct1 plus Oct2 were removed indicated the importance of Oct1 and Oct2 for renal secretion of tetraethylammonium (TEA) and of the antidiabetic metformin. In humans with defect mutations in OCT1, increased renal excretion of metformin was observed, suggesting that OCT1 is critically involved in renal reabsorption rather than in excretion of organic cations.[143]

Expression and Main Functions of OCT2/Oct2

In human, rat, mouse, and rabbit, OCT2/Oct2 is most strongly expressed in the kidneys.[123] In addition, OCT2/Oct2 was detected in placenta, thymus, adrenal glands, neurons and microvessel of brain, inner ear, and lung.[123,131,148] In rat and human kidneys, OCT2/Oct2 was localized to the basolateral membrane of proximal tubules.[123] In rat kidneys, where Oct1 is expressed in the S1 and S2 segments, Oct2 was located to the S2 and S3 segments. At variance, in human kidneys, OCT2 is expressed in all three segments of proximal tubules.[123] Uptake measurements of organic cations across the basolateral membrane of isolated proximal tubules from man and rabbit suggest that OCT2/Oct2 is the dominating organic cation transporter in the basolateral membrane of renal proximal tubules in these species.[123] OCT2/Oct2 was localized to apical membranes of the choroid plexus in rat and to apical membranes of bronchial epithelial cells in human and rat.[146,149] Human OCT2 transports various endogenous compounds including choline, the neuromodulators agmatine, Cyclo(His-Pro) and salsolinol, and the neurotransmitters acetylcholine, epinephrine, histamine, norepinephrine and serotonin.[147] Important drugs transported by hOCT2 are the antidiabetic drug metformin; the antineoplastic drugs cisplatin, oxaliplatin, picoplatin, ormaplatin, tetraplatin, transplatin, metaiodobenzylguanidine; the anti-ulcer drugs cimetidine, famotidine, ranitine; the antiviral drugs lamuvidine, zalcitabine; and the anti-parkinson drugs amantadine and memantine (Table 72.1). A pivotal importance of OCT2 for renal secretion of some organic cations in humans can be derived from the finding that the OCT2 substrate cisplatin showed a reduced

nephrotoxicity in patients with a defect mutation of hOCT2.[150]

Expression and Main Functions of OCT3/Oct3

The tissue expression pattern of OCT3/Oct3 is broad.[123,125,147] OCT3/Oct3 is expressed in adrenal gland, uterus, prostate, stomach, liver, placenta, kidneys, heart, small intestine, lung, brain, skin, blood vessels, and thymus. In brain, OCT3/Oct3 is expressed in astrocytes and neurons and is critically involved in central nervous functions.[123,129,130] Human OCT3 has been located to basolateral membranes from placenta epithelium[151] and to luminal membranes of bronchial and intestinal epithelial cells.[123] Like hOCT2, human OCT3 (hOCT3) transports the neuromodulators agmatine, Cyclo(His-Pro) and salsolinol and the neurotransmitters epinephrine, histamine and norepinephrine.[147] hOCT3 transports the anesthetic lidocaine; the antiarrhythmic drug quinidine; the antidiabetic metformin; the antihypotensive drug etilefrine; the antineoplastic drug oxaliplatin; and antiviral drug lamivudine (Table 72.1).

Common Transport Characteristics of OCT1-3/Oct1-3

OCT1-3/Oct1-3 have similar basic functional properties which are species independent as follows.[123] First, they translocate a variety of organic cations with widely differing molecular structures and are inhibited by a large number of additional compounds that are not transported. Substrates and inhibitors of OCTs from human and other species have been compiled in previous reviews.[123,125,147] Second, OCT1-3/Oct1-3 translocate organic cations in an electrogenic manner.[123] Third, OCT1-3 operate independently of Na^+ and Cl^-, and are probably also independent of H^+ gradients.[123,152] Fourth, OCTs/Octs are able to translocate organic cations across the plasma membrane in either direction. In addition to cation influx, cation efflux has been demonstrated for rOCT1, rOCT2, hOCT2, rOCT3, and hOCT3.[123]

For substrates of OCT1-3/Oct1-3 K_m values in the micro- to millimolar range have been determined. Most substrates translocated by OCT1-3/Oct1-3 are organic cations which carry one positive charge or weak bases that are positively charged at physiological pH.[123] Noncharged compounds (for example cimetidine at alkaline pH[153]), organic cations with two positive charges,[154] and the inorganic cation cesium[155] were also transported. Whether OCT1-3/Oct1-3 are also capable to translocate individual organic anions has not been resolved.[156,157] Transported endogenous substrates of human OCTs include the neurotransmitters acetylcholine, dopamine, serotonin, histamine; the neuromodulators Cyclo(His-Pro) and salsolinol[123,158]; and other compounds such as choline, N^1-methylnicotinamide, creatinine, guanidine, and agmatine.[123] Drugs that are transported by human OCTs are indicated in Table 72.1. They include the histamine H_2 receptor antagonists cimetidine and famotidine; the dopamine D2 receptor antagonist pramipexole; the antidiabetic metformin; the anti-arrhythmic drugs quinidine, lidocaine, procainamide, and phenytoin; the anti-parkinson drug memantine and amantadine; the antihypotensive drug etifefrine; and the antineoplastic drugs cisplatin, oxaliplatin and picoplatin. Human OCTs also transport the antiparasitic drugs furamidine and pentamidine and the antiviral drugs acyclovir, ganciclovir, zalcitabine and lamuvidine.[147] Ethidium is an example for a transported toxin.[159] Other organic cations that are transported by human OCTs are tetraethylammonium (TEA), 1-methyl-4-pyridinium (MPP), azidoprocainamide, 4-(4-dimethylamino)styryl-N-methylpyridinium, N-(4,4-azo-n-pentyl)-quinuclidine, tributylammonium azidoprocainamide, and berberine.[123,147] Interestingly, in voltage-clamped oocytes expressing rOct2, it was observed that Cs^+, but not Li^+, Na^+, or K^+, induced inward currents and inhibited rOct2-mediated TEA uptake.[155] This suggested that Cs^{2+} is translocated by rOct2 in addition to organic cations. Table 1 indicates apparent K_m and K_i values of human OCT1, OCT2 and/or OCT3 for drugs. More complete tables of substrates and inhibitors of OCT1, OCT2 and OCT3 of human and other species have been presented in previous reviews.[123,125,147]

Transported substrates of OCTs/Octs exhibit mutual inhibition that can be total at high concentrations of the inhibitory substrates. A variety of cations (for example, tetrapentylammonium, cyanine 863, decynium 22, and disprocynium), noncharged compounds (e.g., corticosterone, deoxycorticosterone, and β-estradiol) and anions (e.g., probenecid and α-ketoglutarate) inhibited OCTs/Octs, but were not transported themselves.[123,147] This indicates that the criteria for selectivity of cation binding to OCTs/Octs and of cation transport are different, implying the limitation of pharmacophore models of OCTs/Octs that were derived from *IC50* values obtained from inhibition experiments.[123]

Ligand Specificities of OCT1-3/Oct1-3

Some substrates and inhibitors have similar affinities for the OCT/Oct subtypes whereas the affinity of several other substrates and inhibitors differs significantly.[123,147] For a given subtype of the OCT/Oct transporters, distinct species differences in affinity for

substrates and inhibitors exist. For example, tetramethylammonium inhibited MPP uptake by OCT1/Oct1 with IC_{50} values (in mM) of 0.9 in rat, 2.0 in mouse, 5.8 in rabbit, and 12.4 in humans.[125] Similarly, corticosterone inhibited MPP uptake by OCT3/Oct3 with IC_{50} values of 4.9 μM in rats versus 0.12 μM in humans.[125] The affinity differences of the OCT/Oct subtypes in individual species can be used to distinguish between cation uptake by the different transporters.[123,125,147] Compounds that interact with two OCT subtypes may be nontransported inhibitors for one subtype and a poorly transported substrate for another. For example, quinine inhibited TEA uptake by rOct1 and rOct2 with IC_{50} values of 4.1 and 23 μM, respectively, and was transported by rOct1, but not by rOct2.[86,160]

Substrate Binding Regions of OCT1-3/Oct1-3

Employing the firstly cloned organic cation transporter from rat (rOct1) as prototype,[133] the outward-open and inward-open substrate binding cleft of this polyspecific transporter has been investigated using site-directed mutagenesis combined with functional characterizations and modeling of tertiary structures.[152,161–165] Conformations of the transporter with the outward-facing and inward-facing substrate binding cleft were modeled and docking of substrates and inhibitors to the clefts was simulated.[165] Functional characterization of the mutants included a comparison of K_m and V_{max} values of different substrates and a comparison of K_i values of substrates and inhibitors. In addition, K_i values of nontransported inhibitors that were either applied to the extracellular or intracellular side of the membrane, were compared.[165,166] Modeling of the tertiary structure of rOct1 was possible since two members of the MFS superfamily, the lactose permease LacY and the glycerol-3-phosphate transporter GlpT from Escherichia coli, had been crystallized and their tertiary structures determined.[167,168] The transporters were crystallized in a conformation with a large inward-open cleft that is formed by eight transmembrane α-helices. The outward-open conformation of rOct1 was modeled by employing a putative rearrangement mechanism for lactose transport by LacY that was proposed on the basis of biochemical data.[152,165,169] Mutagenesis of rOct1 provided evidence for a high quality of the outward-facing and inward-facing structural models. It was shown that mutations of eight amino acids that line the modeled inward-open cleft are involved in substrate recognition and/or translocation (Fig. 72.6). These amino acids are phenylalanine 160 on the predicted second transmembrane α helix (TMH), tryptophan 218, tyrosine 222 and threonine 226 on successive turns of TMH 4, arginine 440, leucine 447, and glutamine 448 in TMH 10, and aspartate 475 in the middle of TMH 11.[161,163,165] Mutations of these amino acids resulted in changed *Km* values for TEA and/or MPP. The selective effect of individual mutants on the K_m value for either TEA or MPP suggests that the binding sites for individual substrates are partially different. Using the nontransported inhibitors corticosterone and tetrabutylammonium (TBuA), the substrate binding region of rOct2 was characterized in its outward-open and inward-facing conformations.[166] The experiments showed that both inhibitors interact from the intracellular as well as from the extracellular side. Interestingly, TBuA had a significantly higher affinity from the outside as compared to the inside, whereas corticosterone had a higher affinity from the inside than from the outside.

Employing a mutant of rOct1 with increased cation induced currents but similar K_m value for TEA and MPP, the effect of point mutations on the inhibition of TEA induced currents by extracellular or intracellular corticosterone was investigated.[165,170] It was observed that mutations of Phe160, Tryp218 and Leu447 changed the affinity for inhibition of cation induced currents by extracellular and intracellular corticosterone whereas replacement of Arg440 by lysine decreased the affinity for inhibition of TEA-induced currents by extracellular corticosterone and reduced the maximal inhibition by extracellular and intracellular corticosterone.[165] Comparing the inhibition of [^{3}H]MPP uptake by extracellular corticosterone in HEK293 cells that were transfected with rOct1 wildtype or rOct1(D475E) it was observed that also this mutation changed the affinity of extracellular and intracellular corticosterone. Importantly Phe160, Tryp218, Arg440, Leu447 and Asp475 are located within the innermost parts of the modeled outward-open and inward-open binding clefts (Figure 72.6).

High-Affinity Binding Sites in OCT1-3/Oct1-3

A comparison of the substrate binding regions in the models of the outward-open and inward-open clefts of rOct1 with sizes of substrates[163] and the partially different amino acids that are relevant for the K_m and/or K_i values of TEA, MPP, corticosterone and/or TBuA suggest that more than one compound can bind at the same time. Using voltage-clamp fluorometry with rOct1 in which phenylalanine 483 in TMH 11 located close to the extracellular surface was replaced by cysteine and labeled with tetramethylrhodamine-6-maleimide (TMRM), high affinity binding sites of organic cations were detected. In oocytes expressing TMRM-labeled rOct1, potential-dependent fluorescence changes were observed which were prevented

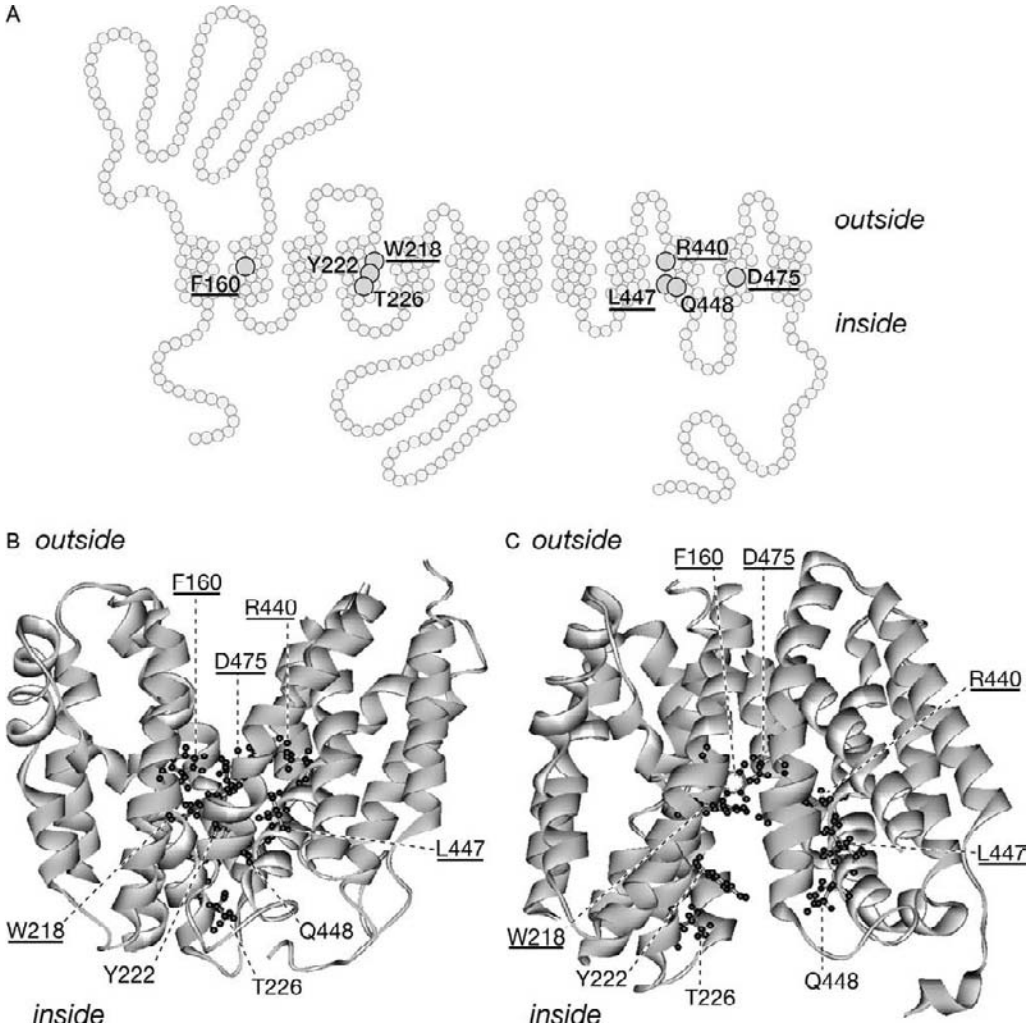

FIGURE 72.6 Structure models of rOct1 with amino acids that are located within the outward-open and inward-open binding clefts. A: Amino-acid sequence and membrane topology model of α-helical transmembrane domains of rOct1. B: Side view of the structural Oct1 model in the outward-facing conformation. A ribbon presentation is shown. **C**: Side view of the inward facing rOct1 model. Mutagenesis experiments showed that the indicated amino acids are critical for affinity and/or selectivity of the substrates TEA and MPP and suggested that extracellular and intracellular corticosterone interacts with the underlined amino acids.

by the substrates TEA, choline and MPP, and by the nontransported inhibitor TBuA. Titrating the substrate effects and the effect of TBuA on fluorescence revealed two affinities of each substrate to rOct1 and three affinities of TBuA to the extracellular side of rOct1. One apparent dissociation constant (K_D) for TBuA (0.3 μM) was similar to the K_i value for inhibition of organic cation transport whereas the other two K_D values (~0.4 nM, ~2 pM) were much lower. These data indicate the existence of two binding sites for the substrates which may be located in the outward-open and/or inward open cleft and three TBuA binding sites in the outward-open cleft. The functional relevance of the high affinity binding sites is not fully understood. So far, for organic cation transport by OCT1-3/Oct1-3 no significant deviation from Michaelis Menten type kinetics has been observed. However, it has been shown that the IC_{50} values determined for the inhibition of organic cation uptake by some drugs were largely different when different substrate concentrations far below the respective K_m value were employed for uptake measurements. For example, for the inhibition of hOCT2 mediated MPP uptake by quinidine IC_{50} values of 446 μM and 13 μM were determined using MPP concentrations of 1 nM or 1 μM for the uptake measurements.[147] High affinity interaction of inhibitors with OCT1-3/Oct1-3 may lead to inhibition of organic cation uptake using low substrate concentrations. For example, the antiviral drug lamivudine inhibited the uptake of 1.3 nM MPP by human OCT1-3 with IC_{50}

values between 8 pM and 20 pM.[171] Thus, high affinity inhibition may be of biomedical importance for drug-drug interaction at OCTs.

Proposed Transport Mechanism of OCT1-3/Oct1-3

Because the OCTs/Octs mediate facilitative diffusion of structurally different compounds and translocate cations in both directions, the question has to be solved whether they are transporters as generally assumed (in which substrate translocation is stoichiometrically linked to structural changes within the protein) or whether they are channels that exhibit short opening times (explaining the relatively low rates of cation translocation) and contain cation-ligand binding sites (explaining the observed saturation at high substrate concentrations). Electrical measurements with Oct2 from rat shed some light on the transport mechanism. In the inside-out configuration, giant patches from oocytes expressing rOct2 clamped to 0 mV yielded K_m values for the efflux of choline and TEA that were similar to the K_m values obtained at the same holding potential for the influx of these substrates into intact oocytes.[172] This suggested symmetric translocation of small cations by rOct2 and is consistent with a symmetric transporter or a channel. Figure 72.7A shows recordings from giant patches with symmetrical choline concentrations and at various membrane potentials. The experiments demonstrated that both inward and outward currents are voltage dependent in a way that is symmetric around the reversal potential. Interestingly, considerably higher currents were observed with 2 mM choline as compared with 10 mM choline on both sides of the membrane. This result would be expected for the simple alternating access model (Fig. 72.7B), but is difficult to reconcile with a channel. The alternating access model predicts electrogenic transport as a result of the sequence of steps (substrate binding to the outside → translocation of the bound substrate to the intracellular side → dissociation of the substrate → reorientation of the empty substrate binding site toward the extracellular side) at low intracellular concentrations of substrate. At high substrate concentrations, this model predicts electroneutral cation exchange, which is not recorded by the electrical measurements. Alternatively, a channel with an inhibitory, low-affinity cation binding site may show a similar decrease of current at high substrate concentrations. Strong evidence in favor of transport was obtained by demonstrating *trans*-stimulation under voltage-clamp conditions. *Trans*-stimulation of MPP uptake by choline into proteoliposomes containing purified rOct1 was observed when the proteoliposomes were clamped to

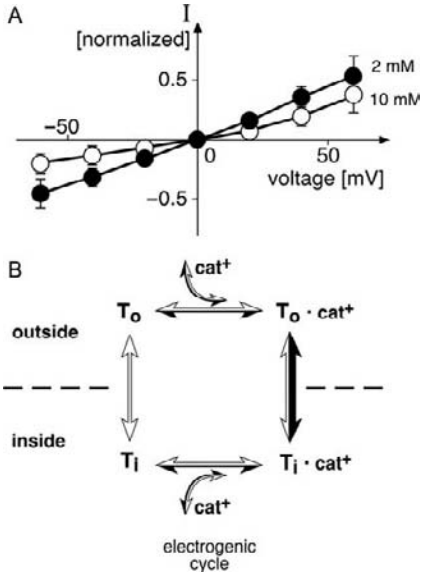

FIGURE 72.7 Characteristics of choline transport by rOct2. A: Current-voltage relation in giant patches of *Xenopus laevis* oocytes expressing rOct2, inside-out configuration with symmetrical choline concentrations of 2 mM or 10 mM; the holding potential between voltage steps was 0 mV. B: Model of a simple transporter, illustrating the individual reaction steps involved in electrogenic cation uniport (closed arrows) and electroneutral cation/cation exchange (open arrows). To and Ti, transporter conformations with the cation-binding site oriented outwardly and inwardly, respectively. Cat^+, monovalent organic cation.

0 mV.[173] *Trans*-stimulation of a transporter is expected if the in-to-out reorientation of the substrate binding site of the loaded carrier occurs more quickly than the reorientation of the empty one (Fig. 72.7B). Finally, a transport mechanism is also supported by the high activation energies which have been determined for rOct2-mediated currents in oocytes observed after addition of tetraethylammonium or cesium to the bath.[155] In oocytes expressing rOct2 clamped to −100 mV, a stoichiometry of 1:1 has been determined for uptake of positive charge and organic cation substrates, demonstrating absence of leakage for inorganic ions under these conditions.[152] In contrast, a surplus of positive charge carried by inorganic ions was translocated together with organic cation substrates at zero membrane potential. Since the potential dependence is consistent with cotranslocation of inorganic ions, but not with leakage, an occluded state during the transport cycle is postulated.

Short-Term Regulations of OCT1-3/Oct1-3

Regulation of transport by OCTs/Octs may influence the excretion of drugs and the exposure of the body to xenobiotics.[123,174] After cloning of OCT1-3/Oct1-3, the

short-term regulation of individual transporters was studied after overexpression of the transporters in epithelial cells. Regulation of human OCT1 (hOCT1), rat Oct1 (rOct1), human OCT2 (hOCT2), and human OCT3 (hOCT3) was investigated in HEK293 cells and CHO cells stably transfected with the individual transporters. The regulation of hOCT1 expressed in HEK293 cells or CHO cells was identical, however, distinct differences in regulation were observed for the three human subtypes and for hOCT1 compared to rOct1. Surprisingly, certain characteristics observed for regulation of 4-[4-(dimethylamino)-styryl]-*N*-methylpyridinium (ASP) transport across the basolateral membrane of human renal proximal tubules were not found for ASP uptake by the individual transporters expressed in HEK293 and CHO cells. This suggests differences between proximal tubular cells and the cell lines used for expression.

Short-term regulation of rOct1 has been investigated in most detail. rOct1-mediated transport of ASP in stably transfected HEK293 cells was stimulated by activators of PKC, PKA, and tyrosine kinase.[174,175] In HEK 293 cells, PKC-dependent stimulation of rOct1 was accompanied by phosphorylation of rOct1. After stimulation of rOct1 by PKC the *IC50* values obtained for inhibition of ASP uptake by TEA, tetrapentylammonium (TPeA), and quinine were decreased by factors of 58, 15, and 2, respectively. Substitution of the individual serine or threonine residues in each of the five putative PKC phosphorylation sites of rOct1 by alanine suppressed the PKC activation. Remarkably, the apparent affinities of TEA, TPeA, and quinine were changed differently in each mutant. After the mutations, no affect of PKC on the apparent affinity of rOct1 for TEA, TPeA, and quinine could be detected.

Taken together, complex, subtype-specific short-term regulations of the organic cation transporters were detected which may involve transporter phosphorylation and binding of regulatory proteins. Thereby functional properties of the transporter and the concentrations of transporters within the plasma membrane may be altered.

Transcriptional Long-Term Regulations of OCT1-3/Oct1-3

The genes encoding human OCT1, OCT2 and OCT3 are located in a cluster on chromosome 6q26−27 together with insulin like growth factor receptor 2 (IGF2R).[125,176] It has been suggested that OCTs and IGF2R are regulated in a coordinated way and that the regulation involves promotor methylation. The promotor of hOCT1 contains two DNA response elements for the hepatocyte nuclear factor-4α (HNF-4α).[177] HNF-4α binds to these response elements and activates transcription of hOCT1. This activation was inhibited by chenodeoxycholic acid via a component (SHP, small heterogenic partner) of the bile-acid inducible transcriptional repressor.[177] Basal transcription of hOCT2 is regulated by upstream stimulating factor 1 (USF1) which binds to a 5E-box regulatory element of hOCT2.[178] Kidney specific expression of hOCT2 versus expression in the liver is regulated by hypomethylation of the promoter including a CpG motif in the E-box.[179] Methylation of the CpG motif prevents binding of USF and down-regulates transcription. In rat kidneys of males expression of rOct2 is higher compared to females. Basolateral uptake of TEA into rat renal proximal tubule cells of male rats was twice as high as in females and correlated with increased levels of rOct2 mRNA and protein.[123] Application of testosterone to female rats resulted in increased expression of rOct2, whereas application of estradiol to male rats decreased the expression of rOct2.[123] Similarly it was shown that levels of Oct2 mRNA in Madin Darby canine kidney (MDCK) cells increased about twofold following exposure to testosterone.[123] Dexamethasone and hydrocortisone had similar effects. In the promotor of rat Oct2 two androgen response elements were identified that are required for the testosterone dependent regulation.[123] The steroid dependent regulation of OCT2/Oct2 is species dependent and may occur on the transcriptional and posttranscriptional level. For example in kidneys of male rabbits the concentration of rbOct2 mRNA was higher compared to female kidneys whereas rbOct2 protein and transport activity in male and female kidneys were similar.[123]

Regulations of OCT1-3/Oct1-3 in Kidney under Pathological Conditions

The expressions of OCTs/Octs in the kidney may be also changed during diseases and after treatments with drugs. For example, in rat renal expression of rOct2 was reduced during chronic renal failure. In 5/6-nephrectomized rats renal clearance of cimetidine was decreased in parallel with the expression of rOct2 protein whereas the expressions of rOct1, rOat1, rOat3, and Na^+,K^+-ATPase were not changed.[123] During diabetes renal expression of OCT1-3/Oct1-3 may be decreased. In rat, streptozotocin induced diabetes was associated with a reduction of renal clearance of N1-methyl-nicotinamide (NMN), basolateral uptake of TEA into renal proximal tubules and renal protein expressions of rOct1, rOct2 and rOct3.[123] During experimental hyperuricemia in rat, renal expression of rOct2 and renal functions were decreased.[123] Rats were made hyperuricemic by feeding with oxonic acid, an inhibitor of uric acid metabolism. After 10 days, plasma uric acid, plasma creatinine, and

blood urea nitrogen levels were significantly increased and TEA uptake in renal slices was decreased. In parallel, renal expression of rOct2 was decreased on mRNA and protein levels whereas expressions of rOct1 and rOct3 remained unchanged. Four days after application of a single dose of cisplatin to mice necrosis of renal proximal tubules and increased blood urea nitrogen levels were observed. In parallel the expression of Oct2 was reduced. The expressions of transporters Oat1, Oat2 and OatpA1 were reduced whereas the expressions of the export transporters Mrp2, Mrp4, Mrp5, Mdr1a, Mdr1b were increased.[37] In rat the renal expression of rOct2 protein was increased after depletion of magnesium.[180] The upregulation may explain why magnesium depletion enhances cisplatin-induced nephrotoxicity.[181]

Expression and Renal Functions of OCTN1/Octn1 (*SLC22A4/Slc22a4*)

OCTN1/Octn1 is another transporter of the *SLC22* family that is expressed in renal proximal tubules. It has been cloned from humans, rats, and mice and has been localized to the brush-border membrane.[182–185] In humans OCTN1 is also expressed in skeletal muscle, trachea, bone marrow, granulocytes, lymphocytes, macrophages and various additional tissues.[123] OCTN1/Octn1 may operate as organic cation/proton exchanger, as organic cation antiporter, as sodium-dependent transporter for zwitterions or as sodium-independent transporter for zwitterions.[123,186] Cations transported by the human transporter (hOCTN1) are TEA, quinidine, pyrilamine and verapamil whereas transported zwitterions are ergothioneine, glycine-betaine, betonicine, stachydrine, gabapentin, and carnitine.[123,186] In patients containing a point mutation in hOCTN1 (Leu503Phe) which leads to a reduced uptake of gabapentin, the excretion of gabapentin in the proximal tubule was decreased.[186] A metabolome analysis of wildtype mice compared with Octn1(-/-) mice indicated a complete deficiency of the naturally occuring antioxidant ergothioneine.[187] OCTN1/Octn1 is critical for ergothioneine absorption in small intestine and for reabsorption of ergothioneine in renal proximal tubules. Mutations in human OCTN1 (hOCTN1) have been associated with rheumatoid arthritis and Crohn's disease.[123] This is supposed to be due to reduced antioxidant effect of ergothioneine because patients with Crohn's disease showed largely reduced blood concentrations of ergothioneine, and Octn1(-/-) mice exhibited greater susceptibility to intestinal inflammation after ischemia.[187] In addition to its role for renal reabsorption or secretion of zwitterions, OCTN1/Octn1 is supposed to contribute to the efflux of organic cations across the luminal membrane of renal proximal tubules.

The proton/organic cation antiporters Mate1 and Mate2-K in the brush-border membrane of renal proximal tubules (Fig. 72.5) are probably the most important extrusion transporters for organic cations,[127] however, OCTN1/Octn1 has a different substrate selectivity and may complement efflux of organic cations.

Expression and Renal Functions of OCTN2/Octn2 (*SLC22A5/Slc22a5*)

OCTN2/Octn2 has been cloned from humans, rats, and mice.[184,188–190] In humans, expression of this transporter has been detected in skeletal muscle, heart, kidney, liver, placenta and many other organs.[123] In kidneys of rats and mice, Octn2 protein was localized to the apical membrane of proximal tubular epithelial cells.[123] Functional characterization revealed that hOCTN2 is a high affinity Na^+-carnitine and Na^+-mildronate cotransporter but can function alternatively as polyspecific and Na^+-independent cation uniporter that translocates for example TEA.[123,191] TEA and L-carnitine interact at the same binding site and/or use the same transport path since carnitine uptake by hOCTN2 was competitively inhibited by TEA, and TEA uptake by hOCTN2 was competitively inhibited by L-carnitine.[123] Na^+-dependent transport of L-carnitine by OCTN2/Octn2 is electrogenic and stereospecific.[123] For human OCTN2, an apparent K_m for L-carnitine of 4 to 5 μM and half-maximal concentrations for Na^+-activation between 2 and 19 mM were determined.[123] hOCTN2 is a polyspecific transporter since Na^+ dependent uptake of L-carnitine by hOCTN2 was inhibited by many organic cations and weak bases (e.g., nicotine, MPP, MPTP, procainamide, quinine, methamphetamine, emetine, clonidine, and cimetidine), zwitterions (e.g. cephaloridine, cefepime, and cefoselis), and noncharged compounds (e.g. corticosterone and aldosterone).[123]

A detailed characterization of the mouse Octn2 (mOctn2) showed that mOctn2 translocates organic cations in either directions across the plasma membrane.[123] L-carnitine uptake was trans-stimulated by intracellular TEA, and TEA efflux was trans-stimulated by extracellular L-carnitine. Studies with juvenile visceral steatosis (jvs) mice that suffer from a homozygous loss-of-function mutation of Octn2 indicated that Octn2 is critically involved in renal excretion of TEA.[123]

Expression, Renal Functions and Regulations of MATE1/Mate1 (*SLC47A1/Slc47a1*)

The *SLC47* family contains two subtypes of H^+-organic cation antiporters called multidrug and toxin extrusion 1 MATE1/Mate1 and kidney specific

MATE2-K/Mate-2K.[127] Human MATE1 was the first cloned and characterized member of the *SLC47* family.[192] Mate1 was also cloned from mouse, rat and rabbit.[127] hMATE1 is strongly expressed in liver, kidney and skeletal muscle, however, the tissue distribution of MATE1 in other species is different.[123] In kidney hMATE1 is located in the brush-border membrane of renal proximal tubules. hMATE1 translocates the model cations TEA, MPP and paraquat as well as fluoroquinolones.[147,193] Transported endogenous compounds are creatinine, estrone sulfate, guanidine and thiamine.[147] hMATE1 transports the antiarrhythmic drugs procainamide and levofloxacin; the antidiabetic drug metformin; the antifungal drug salicylic acid; the antineoplastic drugs cisplatin, oxaliplatin and topotecan; the antimalarial drug quinine; the anti-ulcer drug cimetidine; the antiallergic drug fexofenadine; and the antiviral drugs acyclovir, ganciclovir and tenofovir (Table 72.1). In hMATE1 four glutamate residues within transmembrane domains have been identified that are directly or indirectly involved in binding and/or translocation of TEA and cimetidine.[194] Using double-transfected MDCK cells containing hOCT2 in the basolateral membrane and hMATE1 in the luminal membrane it was shown that the basolateral-to apical transport of metformin as well as intracellular metformin could be inhibited by basolateral application of 1 mM cimetidine.[195] This indicates that both transporters are involved in renal secretion of metformin and may exhibit drug-drug interactions at hMATE1 and hOCT2. Removal of Mate1 in mice (mMate1) proved a potential physiological and pharmacological importance of mMate1 for renal secretion of organic cations.[195] After removal of mMate1 the renal clearance of metformin was reduced by more than 80%. After 5/6 nephrectomy of rats the expression of rMate1 was reduced.[196] Basal transcriptional activity of hMATE1 is regulated by transcription factors Sp1, activating protein-1 and activating protein-2 repressor.[197,198] Recently 10 variants of hMATE1 with reduced expression and/or changed transport function were identified.[199–201]

Expression and Renal Functions of MATE2-K (*SLC47A2*)

MATE2-K was cloned from human (hMATE2-K) and rabbit.[202,203] hMATE-K is predominantly expressed in human kidney. Like hMATE1, hMATE2-K is located in the brush-border membrane of renal proximal tubules and operates as H^+-organic cation antiporter. hMATE2-K transports the endogenous compounds creatinine, estrone sulfate, guanidine, N^1-methylnicotinamide and thiamine.[147] Drugs transported by hMATE2-K are procainamide, verapamil, tetracycline, captopril (antihypertensive), cisplatin, oxaliplatin, topotecan, quinine, cimetidine, acyclovir, ganciclovir and metformin (Table 72.1). For many compounds interacting with hMATE2-K similar affinites have been observed compared to hMATE1. Exceptions are disopyramide, cephradine, desipramine, diltiazem, pramipexole, amantadine, and famotidine (Table 72.1 and[147]). Two variants of hMATE2-K with reduced amounts of transporter protein within the plasma membrane have been identified.[199]

Expression and Renal Functions of MDR1/Mdr1 (ABCB1/Abcb1)

MDR1/Mdr1 or P-glycoprotein is a member of the ATP-binding cassette (ABC) superfamily of transport proteins. It is a polyspecific transporter for hydrophobic solutes including organic cations.[86,123] MDR1/Mdr1 is composed of two homologous halves, each containing six TMHs and an ATP-binding domain. This transporter is infamous for inducing resistance to anticancer drugs in cancer cells; however, it is also found in healthy tissues, including liver, kidney, small intestine, brain and other organs. In kidneys, MDR1/Mdr1 was located to the luminal membrane of proximal tubules in human and mouse.[123] In human kidney, expression of MDR1 was also detected in the mesangium, thick ascending limb of Henle loop, and collecting duct.[123] MDR1/Mdr1 is a primary active transporter that pumps, driven by ATP hydrolysis, compounds of various structures out of cells. Water-soluble substrates are taken up directly from the cytosol, whereas hydrophobic substrates from the cytosol or from the extracellular side partition into the plasma membrane and enter the transporter from the lipid phase.[204] In rat, the involvement of Mdr1 in the renal secretion of digoxin was demonstrated.[123]

Substrates of MDR1/Mdr1 include a large variety of exogenous and endogenous compounds that may be very hydrophobic and may have molecular masses above 1000 Da. The substrates may be amphiphilic or uncharged. They may contain a positive or negative net charge. Human MDR1 transports aldosterone. Drugs that are tranported by human MDR1 are dexamethason and hydrocortisone; the cardiac glycoside digoxin; the antiarrhythmics quinidine, verapamil and propafenone; the antineoplastic compounds colchicine, daunorubicin, doxorubicin, vinblastine, vincristine and topotecan; the antibiotics cefazolin and cefoperazon; the HIV protease inhibitors indinavir, ritonavir and saquinavir; and the immunosuppressant cyclosporine. In addition hMDR1 translocates antihypertensive, anticholinergic, antidepressant, and antihistaminic drugs, antimalaria, antifungal, and antihelminthic agents.[123] For secretion of specific cationic drugs in human

proximal tubules the combined actions of hOCT2 in the basolateral membrane with hMDR1, hMATE-1 and/or hMATE2-K in the brush-border membrane may be required (Fig. 72.5, Table 72.1).

Drug-Drug Interactions at Organic Cation Transporters in Kidney

Drug-drug interactions at organic cation transporters in kidney may influence the excretion of drugs that are secreted in the proximal tubule or the reabsorption of drugs that are ultrafiltrated in the proximal and/or distal tubule. Since significant species differences exist concerning location, selectivity and regulation of the organic cation transporters conclusions about drug-drug interactions in humans should not be drawn from studies in animals. If different drugs are translocated by the same transporter they mutually block their translocation competitively. A nontransported drug may also block binding or translocation of a transported drug. It should be kept in mind that the affinity of nontransported inhibitory drugs to inhibit translocation of different substrates may differ largely at least in case of OCTs/Octs.[147] Drug-drug interactions at individual transporters may be clinically relevant if the respective transporter plays a significant role for the renal excretion or reabsorption of the specific drug and the *in vivo* concentrations of the inhibiting drugs are high enough. Whether transporters are critically involved in renal handling of a specific drug in humans can only be concluded on the basis of studies with patients containing mutated transporters with changed functions. When the critical involvement of a transporter for a specific drug has been determined drug-drug interaction on that transporter may be concluded from clinical studies in which the effects of coapplication of drugs are investigated.

The cytostatic cisplatin is transported by OCT2/Oct2 of human and rodents and it has been shown in rodents that Oct2 is critically involved in renal excretion and nephrotoxicity of cisplatin.[148,205,206] Since the nephrotoxicity of cisplatin was reduced in patients with defect mutations of OCT2, this transporter is also critical for cisplatin nephrotoxicity in humans.[150] In mice, cisplatin nephrotoxicity could be reduced by coapplication of cimetidine suggesting drug-drug interaction of these two substrates at Oct2.[148] Thus cimetidine may be employed to reduce cisplatin nephrotoxicity in humans. Studies in rats also suggest that cisplatin nephrotoxicity in humans can be reduced by coapplication with the antineoplastic drug imatinib which is a high affinity inhibitor of OCTs.[207] Clinical studies suggested interaction of organic cations during renal excretion which may occur at different transporters in the proximal tubule. For example, coapplication of cimetidine which is translocated by hOCT2, hMATE1, hMATE2-K and hMDR1 reduced tubular secretion of metformin which is transported by hOCT1-3, hMATE1 and hMATE2-K,[208] of ranitidine transported by hOCT2,[209] and of procainamide transported by hOCT1, hMATE1 and hMATE2-K.[210]

hOCT2 transports the HIV drug lamuvidine with an apparent K_m value around 1 mM. Lamuvidine inhibited uptake of 12.5 nM MPP 40% with an IC_{50} value of 8 pM.[171] This observation shows that clinically relevant low concentrations of lamuvidine or other cationic drugs may partially inhibit renal secretion of hOCT2 substrates which are present in concentration far below their respective K_m values.

Polymorphisms and Mutations in Organic Cation Transporters

Genetic variants in hOCT, hOCTN and hMATE transporters and hMDR1 may account for interindividual variability of pharmacokinetics of cationic drugs. Geographic, ethnic, and racial differences in the frequency of genetic variants of drug transporters may be reasons for differences in drug response and/or drug toxicity.[147] So far, more than 2000 single-nucleotide polymorphisms (SNPs) for the hOCT, hOCTN and hMATE genes were listed in the databases. Current next-generation sequencing projects aim at the complete sequencing of 1000 human genomes to identify more variants, especially those with low frequencies.[211] Most sequence variants are present in introns and may have no phenotypic consequences. Variants located in the 5′- and 3′-flanking regions may lead to an altered expression level.[132,212] Sequence variants within exons may result in amino acid substitutions. These nonsynonymous or missense variants may affect transport function. The functional effects of missense mutations have to be determined experimentally. They may lead to changed amounts of transport protein in the plasma membrane, to changed regulation, to changed K_m and V_{max} values of transported compounds, and to changes of IC_{50} values of inhibitors. Since the effects on K_m, V_{max} and IC_{50} values may be cation specific, missense mutations may change transporter selectivity. Most non-synonymous variants in human genes encoding OCTs and MATEs that affect function and/or expression have been compiled in a recent review.[147] Some functional relevant missense mutations of hOCTNs have been reported earlier.[123] For recently published functional relevant missense mutations see references.[186,199–201]

It may be very difficult to identify clinical effects of missense mutations. This may be exemplified by the

investigations on effects of hOCT variants on the treatment of the antidiabetic metformin. Metformin is transported by hOCT1, hOCT2 and hOCT3 and variants of hOCT1 and hOCT2 with reduced transport activity for metformin have been identified.[147] A relatively small group of healthy volunteers with defect mutations in hOCT1 showed a blunted reduction of blood glucose after application of metformin.[213] This was explained by reduced uptake of metformin in the liver. At variance no correlation was observed between patients with type 2 diabetes that do not benefit from metformin treatment and patients with hOCT1 variants.[214] Controverse data were also obtained concerning the effects of hOCT2 variants on renal excretion of metformin. In three studies employing 14-26 individuals a decreased renal metformin excretion has been reported in patients with defect mutations in hOCT2.[213,215,216] This observation was not reproduced in a fourth study using 104 patients.[143] This suggests that metformin secretion in the proximal tubule and the role of hOCT2 in this process is not physiologically relevant. Interestingly Tzvetkow and coworkers observed that patients containing hOCT1 variants with reduced transport activity showed an increased renal excretion of metformin.[143] Since hOCT1 was detected in luminal membranes of proximal and distal tubules[143] the authors hypothesized that hOCT1 mediates the first step in the reabsorption of ultrafiltrated metformin and that this reabsorption is physiologically important.

OUTLOOK

After cloning of various polyspecific transporters most systems involved in the secretion and reabsorption of organic anions and cations in human renal proximal tubules have been identified. The relevant modes of operation of these transporters have been defined and admittedly incomplete substrate specificities have been determined. For some transporters the transport mechanism has been tentatively elucidated. Mutagenesis experiments and modeling provided evidence that the OCTs/Octs and, most likely also the other polyspecific transporters contain a large binding region where two or more substrates can bind simultaneously. High and low affinity binding sites were observed which may exhibit mutual allosteric interactions and may inhibit the transport. Most missense mutations in human organic anion and cation transporters leading to functional changes have been identified. Short- and long-term regulations of several transporters have been observed showing that transcription, membrane turnover, substrate selectivity and/or transport activity can be regulated. For short-term regulation some signaling pathways were identified, however, the involved mechanisms are not understood. These observations and species differences concerning substrate selectivities and regulation show that our knowledge derived from individual transporters as well as from knockout mice only provides approximate ideas concerning drug excretion in human proximal tubules *in vivo*. It is a challenge for future investigations to identify the transporters which are critical for secretion and reabsorption of specific drugs in human, to identify the functional consequence of missense mutations, and to determine biomedical relevant drug-drug interactions. These drug-drug interactions may occur at the level of individual transporters (i.e., by competition) or at the cellular level (e.g., by changes of membrane potential). Taken together, we still must follow a long road toward understanding the behavior of drugs in the kidney.

CHAPTER

73

Renal Filtration, Transport, and Metabolism of Albumin and Albuminuria

Erik Ilsø Christensen, Rikke Nielsen and Henrik Birn

Department of Biomedicine, Anatomy, Section of Cell Biology, Aarhus University, Aarhus, Denmark

INTRODUCTION

Albuminuria is one of the oldest yet remains one of the most sensitive and widely used markers of kidney dysfunction. Albumin is the most abundant plasma protein[1] and its urinary excretion is determined by the combined effects of glomerular filtration and renal tubular processing (Fig. 73.1). Dysfunction of both these processes may result in increased excretion of albumin, and glomerular injuries as well as tubular damage have been implicated in the initial events leading to albuminuria. Albuminuria not only indicates acute or chronic renal damage but is also a well established and independent marker of progression in chronic kidney disease (CKD). Interventions aimed at reducing albuminuria have proved effective in ameliorating the continuous loss of renal function in various form of CKD suggesting that albuminuria not only is a marker of kidney disease but in fact involved in the pathophysiology of progression. Experimental evidence points to direct and deleterious effects of albumin on renal tubular cells and identifies a number of downstream mediators initiating inflammation and eventually renal fibrosis.

Gene analyses in human diseases and animal knockout models have identified a number of key molecules regulating glomerular filtration and tubular reabsorption of albumin. In most cases of human disease, however, both the precipitating events and the accelerating mechanisms associated with albuminuria are unknown and may include several, different pathways. The relative importance of the various molecular mechanisms regulating glomerular filtration and tubular handling of albumin remain controversial both in normal physiology and in disease and the evidence for an independent pathogenic role of albumin in the development and progression of renal disease is debated.

This chapter will review the structures controlling glomerular filtration of albumin and discuss the molecular and pathophysiological mechanisms causing changes in glomerular permselectivity. Furthermore, the receptors regulating tubular reuptake of filtered albumin are presented and the possible pathways by which filtered albumin may cause tubular and interstitial damage are discussed in relation to acute and chronic kidney disease.

ALBUMIN

Albumin is an anionic, flexible, heart-shaped, 585-amino acid, single polypeptide chain with a MW ~67 kDa present in plasma at a normal concentration of 35–50 mg/ml. While it is not essential to life, a number of important and very diverse functions have been ascribed to this protein including the maintenance of the oncotic pressure and blood volume, acid/base buffer functions, antioxidant functions, and the transport of a number of different substances including fatty acids, bilirubin, ions such as Ca^{2+} and Mg^{2+}, drugs, hormones, and lipophilic as well as hydrophilic vitamins, e.g., vitamin A, riboflavin, vitamin B6, ascorbic acid, and folate.[1] Albumin undergoes posttranslational modification including glycation, acetylation, methylation, carbamylation and phosphorylation.[2] Albumin is almost exclusively synthesized in the liver at a rate of 10–15 g per day in a healthy person and its normal half life is estimated to 19 days representing the balance between synthesis, transcapillary escape, and catabolism predominantly within muscle, liver and

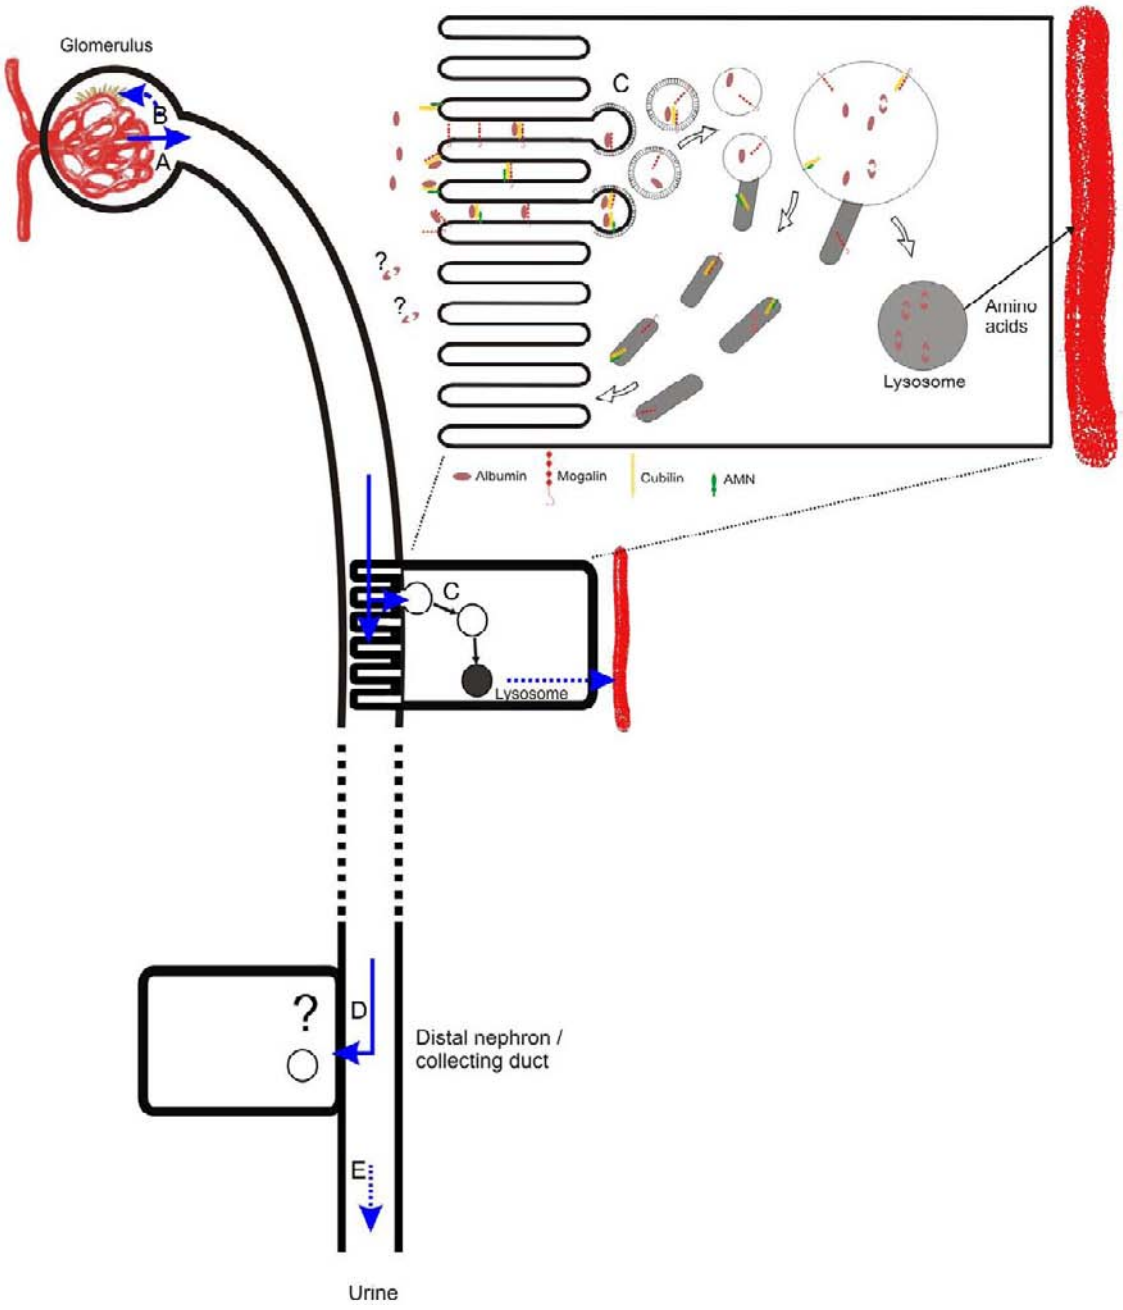

FIGURE 73.1 Renal albumin handling. Plasma albumin is filtered in the glomeruli (A). Filtered albumin may be taken up by podocytes (B) possibly by a megalin mediated process. It is not clear whether albumin is taken up from the subepithelial space or from the urinary space, or both. Filtered albumin is reabsorbed in the proximal tubule by megalin and cubilin/AMN mediated endocytosis (C). Albumin is degraded within the lysosomal compartment and amino acids are released at the basolateral cell surface. Under proteinuric conditions, albumin, not reabsorbed by the proximal tubule, may be taken up by more distal nephron segments or collecting ducts (D) by an unknown mechanism (see also figure 74.6). Depending on the balance between glomerular filtration of albumin and the tubular reabsorptive and degradative capacity, albumin and albumin fragments may be excreted in the urine (E). Urinary albumin fragments have been identified, however, the origin and significance of these remain unclear.

kidney.[1] In kidney diseases such as nephrotic syndrome and end stage renal disease, including well managed patients on peritoneal dialysis, albumin synthesis appears to be increased compensating for increased losses.[1] Normally the albumin gene is silent in the kidney, however, it has recently been shown that the gene is activated in cases of acute kidney failure leading to the renal synthesis of albumin.[3] The local production of albumin is associated with albuminuria, however, the extent to which local synthesis of albumin

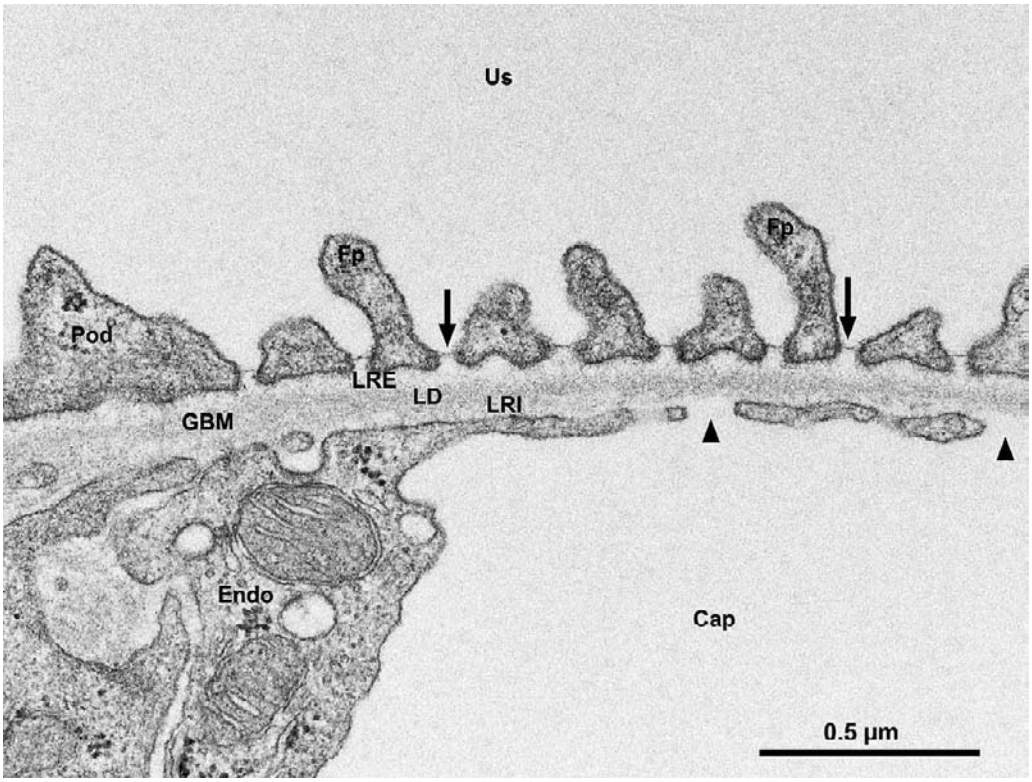

FIGURE 73.2 Electron micrograph of the glomerular filtration barrier. Filtration takes place from the glomerular capillaries (Cap) through the pores (arrowheads) of the endothelial cells (Endo), the glomerular basement membrane (GBM) consisting of the three layers, lamina rara interna (LRI), lamina densa (LD) and lamina rara externa (LRE) and finally through the filtration slit membrane (arrows) between the foot processes (Fp) of the podocytes (Pod) into the urinary space (Us).

contributes to the urinary excretion of albumin is not known.

GLOMERULAR FILTRATION

Glomerular Filtration Barrier

The glomerular filtration barrier is structurally composed of three layers, the capillary endothelial cells, the glomerular basement membrane (GBM) and the podocyte filtration slit membrane (Fig. 73.2). The barrier is freely permeable to water, solutes and small molecules however, increasing size of macromolecules causes increasing restriction to filtration as do negative charge.[4]

The fenestrated endothelium (Fig. 73.2) is unusual since the fenestrae generally are not closed by diaphragms, except as demonstrated in rat where the capillaries which are direct tributaries to the efferent arteriole do indeed have diaphragms closing the fenestrae.[5] The pores in the endothelium appear not to be fully open holes. By special fixation procedures it has been demonstrated that the pores are filled with glycoproteins forming "sieve plugs"[6,7] probably contributing to the endothelial part of the filtration barrier.[8] The endothelial cells have a thick glycocalyx and an even thicker endothelial cell surface coat,[9] which are believed by many authors to contribute significantly to the charge selectivity of the barrier[10] (for a recent review see Haraldsson et al.[4]).

The basement membrane, which in man is about 300 nm thick, consists of three layers, a lamina densa, located between a lamina rara interna facing the endothelial cell and a lamina rara externa, facing the podocyte (Fig. 73.2). In the 1970s the GBM was considered the major contributor to the charge selectivity of the filtration barrier[11–14] (see also Kanwar et al.[15] for references). *In vitro* studies, however, on isolated GBM[16] showed no charge selectivity and removal of charged components of the GBM in mouse knock out studies in general did not change charge selectivity, for discussions see.[15,17] A large variety of both genetic[18] and acquired, albuminuric diseases affect the GBM, e.g., Alport syndrome and diabetes mellitus (see also later).

The third component of the barrier, the podocyte filtration slit membrane (Fig. 73.2), has attracted great interest as a key part of the filtration barrier, especially since the findings that, for example, gene defects of

nephrin (*NPHS1*) induce the congenital nephrotic syndrome of the Finnish type[19] and gene defects of podocin (NPHS2) induce nephrotic syndrome of the non-Finnish type.[20] The porous structure of the filtration slit membrane was first described by Rodewald and Karnowsky[21] measuring the dimensions of the pores to be 4×14 nm. In a recent publication[22] the mean radius of the observed irregular circular or elipsoid pores were measured to be 12.1 nm. In proteinuric rats additional large pores were observed[22] and suggested to contribute to the increased filtration of protein/albumin in pathologic conditions, a finding which awaits confirmation.

An elegant model for the charge restriction has recently been put forward, based on micropuncture experiments in glomeruli of *Necturus maculosus*.[23,24] The authors identified a filtration dependant negative electrical charge in the Bowman's space compared to the capillary lumen, a charge that would allow negatively charged proteins like albumin to be electrophoresed back to the blood and the opposite for positively charged proteins.

There is no doubt that all three structural components of the glomerular filter are necessary for maintaining the barrier, illustrated by the observations that damage to any part eventually leads to albuminuria, that the GBM is synthesized from both the epithelial- and endothelial cells and that vascular endothelial growth factor (VEGF)-A produced by the podocytes influences development and maintenance of the endothelial cells which possesses receptors for VEGF-A, VEGFR-1 and 2.[25]

Glomerular Filtration of Albumin

The amount of albumin normally filtered in the glomeruli has been estimated using various techniques, including micropuncture of rats and dogs, estimating the concentration of albumin in the ultrafiltrate between 1 and 50 μg/ml.[26] This corresponds to a filtered load of albumin between 170 mg and 9 g per 24 h in normal humans. Inhibition of tubular albumin uptake in humans by lysine suggested filtration of at least 281 μg/min, corresponding to ~400 mg/24 h.[27] Similar studies in lysine treated rats resulted in the excretion of 2.5 mg to 25 mg/24 h[28,29] corresponding to 0.7−7 g/24 h in humans. In rat the filtration fraction of albumin was estimated to 0.0006 by micropuncture studies[30] in good agreement with the results mentioned above. This figure was, however, challenged by Comper and colleagues[31−33] who estimated the filtration fraction by two-photon microscopy to be 0.034. As calculated by Gekle[34] this implies a filtration of 225 g/24 h of albumin in humans and the results were immediately questioned by several groups.[34−37] Subsequently, three studies[38−40] have seriously questioned the technical approach applied by Russo et al. Thus, the notion of normal glomerular filtration of such large amounts of albumin remains highly controversial. For an excellent review comparing glomerular permselectivity of ficoll, dextran and globular proteins, see Venturoli and Rippe.[41]

Albumin Uptake in Glomerular Cells

Albumin uptake has been demonstrated *in vivo* in podocytes from human, rat and mouse and *in vitro* in mouse and human podocytes.[42] Accumulation of endocytosed protein in podocytes is also indicated by podocyte vacuolization in proteinuric patients[43] and experimentally, endocytic uptake of tracer proteins in podocytes have been demonstrated *in vivo*.[44,45] The albumin binding receptor megalin (see below) has been identified in rat podocytes[46] and very recently also on human podocytes[47] providing a mechanism for the endocytic uptake of albumin and other proteins. It has been proposed that unless removed, filtered proteins would clog the glomerular filter due to the podocyte slit membrane.[48,49] Such a theoretical clogging of the slit diaphragm may be attenuated by megalin mediated, podocyte endocytosis of trapped protein, including albumin. It should be emphasized that the endocytic uptake of albumin in the podocytes is minimal compared to the subsequent uptake in the proximal tubule (see below).

Tubular Albumin Uptake

Endocytosis of Albumin in the Renal Proximal Tubule

Proximal tubule uptake of albumin by endocytosis was described almost 45 years ago.[50,51] The identification of the receptors megalin, cubilin and amnionless (AMN)[52−54] and subsequent studies of these receptors have now firmly established them as an endocytic complex responsible for the reabsorption of filtered albumin. Megalin has been identfied as an albumin binding protein involved in albumin reabsorption in the proximal tubule *in vivo*.[55] This was later confirmed by the presence of albuminuria in megalin knockout mice[56,57] and in Donnai Barrow patients having mutations in *LRP2* encoding megalin (personal observations). Direct binding of albumin to cubilin was demonstrated estimating a Kd of 0.6 μM[56] and the physiological importance was established by the presence of albuminuria in cubilin knockout mice[58] and in patients with cubilin defects causing Imerslund-Gräsbeck's syndrome/megaloblastic anemia 1,[59] which is an autosomal recessive vitamin B_{12} deficiency disorder caused by malfunction of either cubilin or AMN. AMN has not been shown to

have a direct receptor function, but is a chaperone for cubilin (see later) and lack of AMN has been associated with albuminuria both in humans and in animal models.[56] A recent study further supports the role of cubilin in albumin reabsorption by showing that the SNP I2984V in cubilin is associated with microalbuminuria in the general population.[60]

Renal Expression, Structure and Sorting of Megalin, Cubilin and AMN

Megalin is heavily expressed in the renal proximal tubule brush border, the endocytic compartments, and membrane recycling system.[53,61–63] Megalin is also detectable in lysosomes in small quantities, but after endocytosis the majority of megalin is recycled to the apical membrane via dense apical tubules.[64] Cubilin co-localizes with megalin in the renal proximal tubule[54,65,66] and AMN co-localizes with cubilin.[67] In rats and humans additional expression of megalin in the podocytes has been identified.[46,47] For more information of the expression of the receptors in other epithelia see.[68,69]

Megalin (Fig. 73.3) was identified nearly 30 years ago[46,53] as a large glycosylated protein (600 kDa) belonging to the low density lipoprotein (LDL) receptor family.[70–72] Megalin is a multiligand receptor with four binding clusters in the extracellular domain.[70,72] The binding clusters each contain 7 to 11 complement-type repeats. Structural studies of the LDL receptor and the twelfth repeat in megalin have revealed that each consists of approximately 40 amino acids with 6 cysteines forming 3 disulfide bridges and a C-terminal calcium cage.[73–76] Separation of the binding clusters is obtained by 16 growth factor repeats separated by 8 YWTD spacer regions, which are involved in pH dependent release of ligands.[77] Finally the extracellular domain contains one epidermal growth factor-like repeat which is situated next to the membrane spanning area. The four binding clusters are responsible for the binding of albumin;[55,78] one of the more than 50 ligands which so far has been reported for megalin.[69]

The receptor spans the membrane once and is equipped with a short intracellular tail (209 amino acids) which contains 2 endocytic motifs (NPXY) driving clustering into coated pits and a NPXY-like motif (NQNY) involved in apical sorting of the receptor.[79] Apical sorting is also dependent on the receptor associated protein (RAP),[80] acting as a chaperone[81] and phosphorylation of a PPSP motif in the cytoplasmic tail.[82]

Cubilin (Fig. 73.3) is identical to the intestinal intrinsic factor-B12 receptor[66,83] and is a 460 kDa, peripheral membrane protein. Its structure is dominated by 27 ekstracellular CUB domains (complement c1r/C1s, Uegf (epidermal growth factor-related sea urchin protein)) and bone morphogenic protein 1.[84,85] The CUB domains are involved in ligand binding, but despite the numerous domains only around 15 ligands have been identified[69] including albumin.[56,78] The N-terminus cubilin contains 8 epidermal growth factor (EGF) repeats and a 110 amino acid stretch.[84,85] No transmembrane domain has been identified and sorting

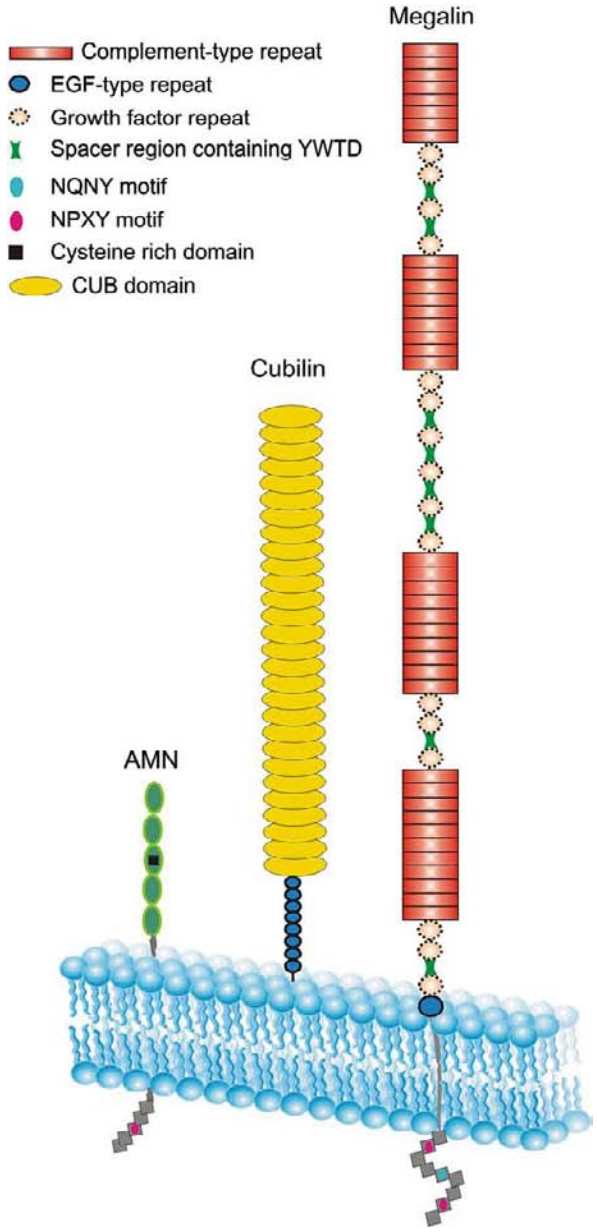

FIGURE 73.3 Schematic illustration of megalin, cubilin and amnionless (AMN). The three receptors co-operate in the proximal tubular uptake of filtered albumin. Cubilin binds albumin, but is dependent on complex formation with megalin and/or AMN to sustain endocytosis. Megalin and AMN contain NPXY motifs necessary for recruitment of the endocytic machinery and initiation of endocytosis. AMN is furthermore involved in translocation of cubilin from the RER to the plasma membrane. *Figure modified from.*[69]

and anchorage of cubilin to the membrane is accomplished through physical interaction with AMN and megalin.[86,67,85] *In vitro* studies showed that sorting relies on interaction of the EGF domains in cubilin with AMN.[87,67] This cooperation between cubilin and AMN is supported by intracellular retention of cubilin in dogs suffering from AMN mutations causing Imerslund-Gräsbeck's syndrome[56,88] and in AMN deficient mice.[89] The apical plasma membrane localization of AMN is in the same manner dependent on intact cubilin as AMN is retained intracellularly both in cubilin deficient mice and in humans with no cubilin expression.[58,90]

Cubilin also associates with megalin through CUB domain 12−17 and 22−27 as well as through the N-terminus[85,86,91] and megalin appears to be important for the stability of cubilin in the membrane as suggested by decreased levels of cubilin in *in vitro* studies and in rabbits producing megalin antibodies[86] as well as by immunocytochemistry in megalin knockout mice.[58,56]

AMN (Fig. 73.3) has a molecular weight ranging from 38−50 kDa[92] and was initially recognized as being involved in normal development of the middle portion of the primitive streak in mice. Mice which lack AMN fail to develop amnion. It has a cytoplasmic tail with the endocytic motif NPXY, a transmembrane domain and N-terminal extracellular domain encompassing approximately 70 amino acids with a cysteine rich region as the only characteristic domain.[52] It should be noted that the above described interdependence of the receptors for normal sorting complicates the endocytic analysis of each receptor separately.

Endocytosis of Albumin Receptors

Endocytosis of megalin is driven by endocytic motifs in the cytoplasmic tail (see above) that mediate the assembly of clathrin and adaptor proteins such as AP-2, Dab2 and ARH.[93,94,95] The significance of Dab2 to the endocytosis of megalin is supported by mutual dependence of megalin and Dab2 for normal localization[96] and the mild, but significant proteinuria observed in Dab2 knockout mice.[97] Dab2 further associates megalin with nonmuscle myosin heavy chain IIA and actin,[98] whereas the adaptor protein GAIP interacting protein C-terminus (GIPC) attaches myosin VI to the complex.[99,100] These interactions are suggested to be important for the post endocytic transport of the complex corroborated by the albuminuria observed in GIPC- and myosin VI knockout mice.[101,100]

Interaction of megalin and cubilin together with their strict co-localization in the proximal tubule suggests that megalin mediates the internalization of cubilin and its ligands.[85] Several *in vitro* studies strengthened this concept such as decreased cubilin endocytosis in megalin compromised cells.[102,103] AMN holds a NPXY motif and it is apparent that in cell cultures lacking megalin, cubilin can work in conjunction with AMN.[67] *In vivo* in the kidney, however, this cooperation is not able to sustain normal endocytosis.[58] The concept of megalin being the motor for albumin endocytosis is supported by a recent study showing that an SNP in the megalin binding area of cubilin is associated with microalbuminuria in the normal population and in diabetics.[60] It has been shown recently, by analysis of the crystal structure of cubilin, that changes in a residue that does not directly interact with intrinsic factor B12 result in Imerslund-Gräsbeck's disease. Thus, a SNP in the megalin binding region might similarily interfere with cubilin association to megalin hindering endocytosis of cubilin-bound albumin.[104]

Regulation of Albumin Receptors

It has generally been assumed that under normal physiological conditions proximal tubule endocytic uptake of albumin is a constitutive process determined only by the receptor expression.[56] Little is known, however, about the regulation of receptor expression in normal physiology. Studies in disease and transgene mice have suggested, that megalin expression may be under influence of the renin-angiotensin system. Angiotensin II decreases megalin expression in a long term proteinuric mouse model induced by renin overexpression.[105] Furthermore, angiotensin II has recently been shown to stimulate trafficking of several sodium transporters and megalin into microvilli.[106] However, in this latter study no apparent decrease in megalin levels was observed. An intrarenal proximal tubular renin-angiotensin system has been suggested[107] and the molecular actions of this system are complex. The role of these components in the direct or indirect regulation of megalin is at present very difficult to deduce. Furthermore, an additional link between angiotensin II and megalin expression has evolved. Transforming growth factor (TGF)-β reduces megalin expression *in vitro*[108] and in a proteinuric hypertensive mouse model the action of TGF-β has been shown to be modulated by angiotensin II receptor antagonists at doses that do not decrease aterial blood pressure. This is believed to be mediated by reestablishment of the equilibrium between TGF-β and bone morphogenic protein 7 (BMP7)/BMP7-inhibitors.[105] Thus, treatment with angiotensin II antagonists might elevate megalin expression through a decrease in BMP7-inhibitors resulting in BMP7 mediated inhibiton of TGF-β. Obviously the effect of angiotensin II on glomerular function in addition to the proposed effect on tubular megalin expression may contribute to the changes in urinary albumin excretion observed with

modulation of this system. In a recently published study it is shown that megalin contains 3 PPAR (peroxisome proliferator-activated receptors) response elements in its promotor region and that megalin expression increases in response to PPAR ligands in mouse kidneys[109] suggesting a direct regulation of megalin expression by PPAR. The physiological significance of this regulation remains to be established, however, PPAR agonists have in a number of studies been shown to be renoprotective in diabetic patients including an amelioration of albuminuria.[110]

RENAL TUBULAR ALBUMIN METABOLISM

Lysosomal Degradation of Albumin

Following proximal tubule endocytic uptake, albumin accumulates within the lysosomal compartment[111,51] where it is degraded.[112] In rats, albumin is reabsorbed within all three segments of the proximal tubule, however, catabolism appears to be slower in the S3 segment.[113] This process is dependent on ATP-mediated acidification of the lysosomal compartment.[114,115] Interference with lysosomal function from increased filtration of albumin has been suggested by experimental induction of albuminuria. This resulted in functional and structural changes in lysosomes[116] and increased activity of lysosomal enzymes such as cathepsin[117] suggesting that albumin overload changes the protein catabolic function of the proximal tubule cell.

It is generally believed that albumin is fully degraded within the lysosomal compartment and that amino acids are returned to the circulation through a basolateral exit mechanism.[118–120] Based on the identification of albumin fragments in normal human and animal urine it has been proposed that albumin fragments resulting from the proximal tubule degradation of proteins are normally excreted at the luminal cell surface.[121–124] Most of these fragments are suggested to be very small with MW <500 Da[125] and apparently undetectable by conventional immune or dye-based assays, however, may be detected either by size exclusion chromatography of injected and processed labeled albumin[126,122] or by the Biuret protein assay.[127] Although cells grown *in vitro* may secrete fragments[126] so far no direct evidence for the tubular generation and luminal secretion of albumin fragments *in vivo* has been published. *In vitro* microperfusion of proximal tubules suggested peritubular, but not luminal release of degradation products[120] and knockout of megalin and cubilin in mice did not change the excretion of urinary albumin fragments showing that receptor mediated endocytosis is not involved in the generation of these.[128] Furthermore, other studies have not confirmed the presence of significant amount of albumin fragments in the urine.[129,130] Thus, the amount, origin and pathophysiologic implication of potential urinary albumin fragments remain to be established.

Transtubular Recovery of Albumin

In addition to the well established endocytic pathway for albumin uptake, the existence of a high capacity pathway for the transtubular transport of very large amounts of intact albumin has been suggested.[131] Such a pathway would be essential for the recovery of $\sim$225 g/24 h of albumin suggested to be filtered in the human kidney if, as proposed by Comper and colleagues, the filtration fraction for albumin is much higher than previously believed.[132]

The transtubular recovery of intact albumin was proposed after the identification of a small, second peak of labeled albumin appearing in the renal vein following bolus injection of labeled albumin into the isolated perfused kidney.[133] Later studies by electron microscopy of endogenous and fluorescent labeled albumin injected into normal rats showing albumin labeled vesicles in the basolateral aspect of the proximal tubule cell and apparent fusion with the basolateral membrane[132,33] were interpreted as evidence of vesicular transcytosis. So far there has been no published, direct evidence for a specific, high capacity, transcellular transport of albumin. In fact, when a high capacity, low affinity mechanism for albumin uptake was identified using isolated, perfused proximal tubules only negligible transtubular transport was found and the uptake was believed to represent nonspecific, fluid phase endocytosis.[120]

The proposed high capacity, transtubular albumin retrieval pathway does not involve megalin and cubilin as demonstrated by the fact that inactivation of these receptors in mice leads to albuminuria in the order of 20–40 μg/h[58,56] which is much less than the proposed amount of transcellular albumin transport. Furthermore, inactivation of megalin and cubilin leads to total abolishment of the normal tubular vesicular labeling (Fig. 73.4)[58,56] disputing the existence of an alternative and significant pathway of vesicular albumin uptake.

It has been hypothesized that the transcellular transport of intact albumin may involve the major histocompatibility complex-related Fc receptor (FcRn). FcRn is responsible for the transcytosis of proteins such as IgG across the placental barrier[134] and possibly podocytes.[135] It has been identified in the luminal part of the kidney proximal tubule cells[136] and binds albumin.[137] FcRn knockout mice are hypoalbuminemic and the half live of circulating albumin is reduced.[138] When kidneys from

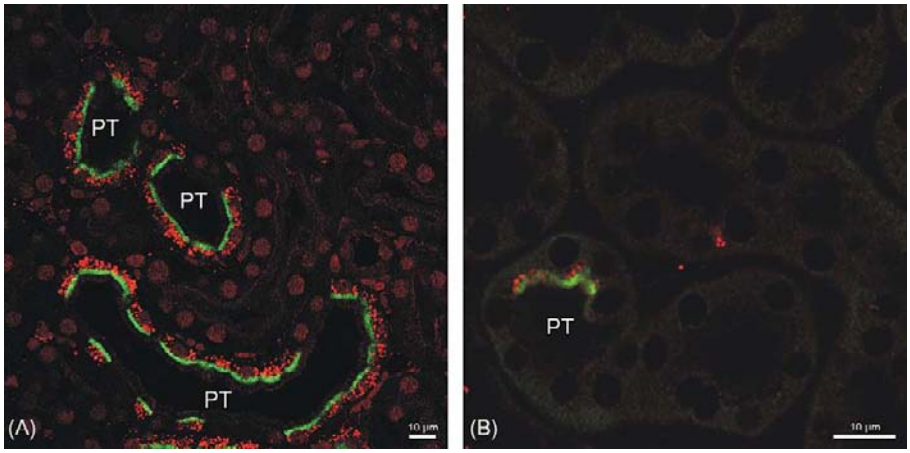

FIGURE 73.4 Immunohistochemical analysis of albumin reabsorption in a mosaic megalin- and a mosaic cubilin knockout mouse showing that both receptors are required for albumin endocytosis. Several proximal tubules (PT) from these mice contain both receptor deficient - and wildtype proximal tubule cells. A. Representative micrograph of a megalin knockout mouse with wildtype cells containing megalin (green) dispersed among megalin deficient cells. All cells contain cubilin (not labeled). Albumin (red) is almost exclusively detected in megalin containing cells indicating that cubilin is unable to sustain endocytosis of albumin without megalin. B. Representative micrograph of a cubilin knockout mouse with wildtype cells containing cubilin (green) dispersed among cubilin deficient cells. All cells contain megalin (not labeled). Albumin (red) is almost exclusively detected in cubilin containing cells suggesting that cubilin is the receptor responsible for binding albumin. See color plate section at the back of the book.

FcRn deficient mice are transplanted into wild type mice the mice become hypoalbuminemic.[139] Although this points to a role for the FcRn in albumin metabolism, no information on the absolute albumin excretion rate in the urine of these mice was given. Furthermore, when FcRn is expressed in Madin-Darby canine kidney (MDCK) cells transcytosis of IgG but not albumin was observed.[140] Finally, albumin binds FcRn preferable at pH 6.5[137] suggesting that the affinity for albumin at the luminal membranes of the proximal tubule is low. In conclusion, although the possibility of transtubular transport of intact albumin cannot be excluded the evidence for the transport of large amount of albumin so far has been indirect. The implication of the FcRn as an additional albumin receptor within the proximal tubule is intriguing, however, needs confirmation.

Albumin Induced Renal Tubular and Interstitial Damage

The concept of proteinuria-induced renal tubular and interstitial damage has been propagated as a major factor causing the progressive loss of renal function in CKD.[141] Albuminuria has been shown to be a major risk-factor for the progression of renal disease and the protective effect of anti-proteinuric treatment has been shown to be correlated to the reduction in proteinuria.[142] Experimental studies have demonstrated the ability of albumin, or albumin bound substances, to induce phenotypic changes in tubular cells and animal models have demonstrated albumin overload induced tubular and interstitial damage (Fig. 73.5).[143,144] In a model based on the amphibian kidney in which some nephrons open into the peritoneal cavity and therefore are selectively exposed to serum or albumin when this is injected intraperitoneally, fibrosis was observed around the exposed tubules.[145,146] Most of the evidence for the direct effects of albumin on renal tubular cells originates from *in vitro* studies in which various renal cell lines are exposed to albumin or derivatives and it is not clear whether the tubular effects of albumin involve the megalin/cubilin receptor complex and whether it is dependent on endocytosis. In fact, studies in analbuminemic rats suggested that albumin itself was not important for the progression of proteinuric, renal disease.[147] Interestingly albumin at low or moderate concentrations may promote *in vitro* cell growth[148,149] possibly by a phosphatidylinositide 3-kinase dependent pathway[150] whereas high concentrations of albumin activates pathways that induce apoptosis, endoplasmic reticulum (ER)-stress, cytokine production and phenotypic changes. Ultimately these changes can cause cell death, local inflammation and fibrosis. Although it is important to recognize that the phenotype of renal cell lines in culture, in particular immortalized cell lines, may not resemble the *in vivo* phenotype, similar changes have been observed in experimental models and human diseases characterized by albuminuria as discussed below.

Apoptosis

Tubular cell apoptosis and atrophy is a marked feature of both acute and chronic, proteinuric renal disease.[151,152] Albumin induces proximal tubule cell apoptosis *in vitro*.[151,153,154] The mechanism by which

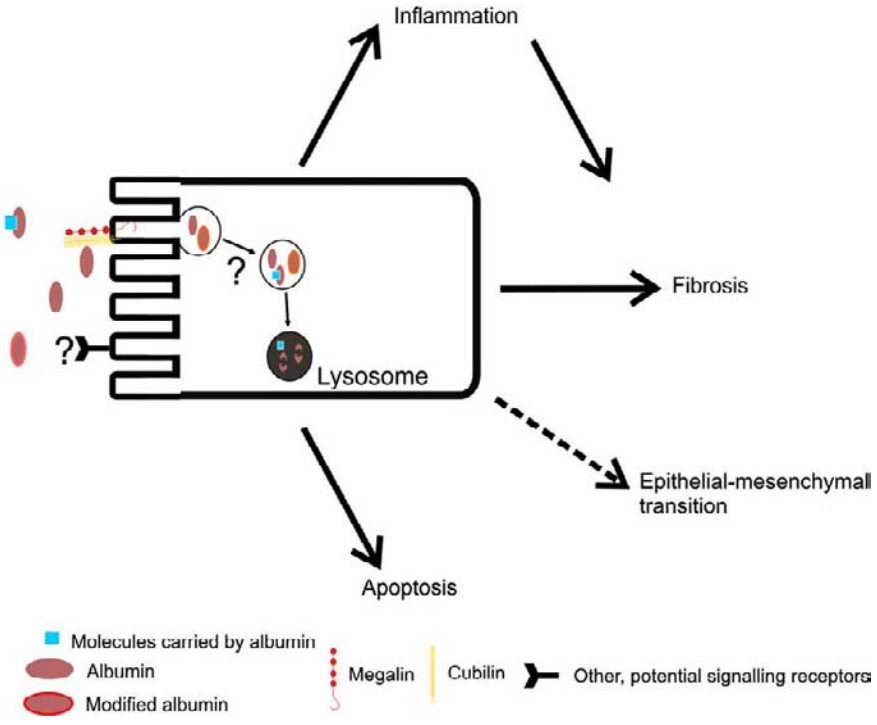

FIGURE 73.5 Effects of albumin on tubular cells. Filtered albumin, whether native or modified, as well as albumin bound substance may affect tubular function and phenotype. Albumin in vitro activates various signaling pathways initiating inflammation fibrosis, apoptosis, and possibly EMT (see text for details). The exact role of the balance between the many pathways in normal physiology is not established, however, experimental studies associated with increased filtration of albumin have demonstrated activation of both apoptosis, inflammation and fibrosis suggesting these mechanism to be involved in the development and progression of renal insufficiency. It is not fully established to which extent all or some of these pathways are dependent on albumin binding to the megalin/cubilin-receptor complex, on endocytosis, and/or on the activation of other potential signaling receptors.

filtered albumin activate downstream mediators of apoptosis is not fully elucidated. Based on *in vitro* studies several pathways have been implicated including both the extrinsic and intrinsic apoptotic pathways. Inactivation of protein kinase C (PKC)-δ both *in vitro* and *in vivo* inhibited albumin and proteinuria induced apoptosis suggesting this acts as an upstream mediator of apoptosis by the intrinsic pathway.[153] Alternatively albumin may induce apoptosis by the stimulation of transmembrane Fas receptor expression that eventually leads to the activation of caspase 8.[155,151] The mechanism by which albumin may induce Fas-receptor expression is not established. Albumin may, by an as yet unknown mechanism, activate mitogen-activated protein kinases ERK1/2 and cause degradation of nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibitor, alpha (IκBα) which then activates activator protein (AP-1) and nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), and increases clusterin production. AP-1 stimulates apoptosis whereas NF-κB stimulates inflammation and blocks apoptosis through Bcl. NF-κB dominates initially, however, later clusterin prevents continued NF-κB activation allowing AP-1 and apoptosis to predominate.[154] This complex hypothesis implies a shift in the balance between albumin-induced proinflammatory and proapoptotic pathways which still needs to be established *in vivo*. Other studies have suggested that megalin may associate with protein kinase B (PKB) facilitating the translocation of PKB to the plasma membrane important for its activation by phosphorylation. Both this association as well as the phosphorylation of PKB appear to be inhibited by exposure to albumin. When LL-CPK1 cells are exposed to high concentrations of albumin the amount of both megalin and PKB at the plasmamembrane is reduced. PKB is important for the phosphorylation of Bcl-2-antagonist of cell death protein (Bad) inhibiting the proapoptotic effect of Bad. Thus, albumin induced and megalin dependent decreases in PKB-activation removes the inhibition on the proapoptotic effect of Bad.[148] The possible interaction between these various pathways inducing apoptosis remains unresolved.

ER-Stress

The ER is the site for folding, glycosylation and degradation of newly synthesized proteins involving ER-resident enzymes and chaperones. In ER-stress the demand for protein folding is increased or the process is disrupted leading to an increase in misfolded proteins within the ER.[156] ER-stress induces a physiological response increasing the expression of ER-chaperones as part of the unfolded protein response (UPR). UPR increases the capacity to handle unfolded proteins and slows the transcription of new proteins, however, it may also lead to apoptosis. Increased expression UPR-proteins have been shown both in glomerular and tubular cells in different experimental models of proteinuric kidney disease[156] and markers of ER-stress have been identified in tubular epithelial cells

of human biopsies of various kidney diseases.[157,152] Increased expression of proteins involved in UPR have also been identified in tubular cells exposed to albumin *in vitro* and this has been associated with apoptosis mediated via C/EBP homologous protein (CHOP)[158,152] suggesting another pathway for albumin induced apoptosis. The ER-stress response is believed to allow cells to recover after injury and to be protective against additional damage, however, if prolonged it causes apoptosis.[156] It is not clear how exposure to albumin induces ER-stress and whether this requires accumulation of the protein within the tubular cell.

Interstitial Inflammation and Fibrosis

In vitro studies using proximal tubule cells have shown that albumin exposure induces the expression of a number of inflammatory and fibrogenic mediators, including cytokines such as regulated on activation normal T cell expressed and secreted (RANTES),[159,160] monocyte chemotactic protein (MCP)-1,[161] fractalkine[162] and tumor necrosis factors (TNF)- α,[163] as well as endothelin,[164,165] TGF-β[164] and collagen,[166] and may induce changes in tubular cell expression of surface integrins.[167] These data suggest that albumin and/or bound ligands initiate a series of events that eventually lead to interstitial fibrosis. The exact cascade has not been established, however, proposed intracellular signalling cascades include the activation of NF-κB[168–172] as well as signal transducer and activator of transcription (STAT)[173] factors, possibly through formation of reactive oxygen species,[169,173] a process that may also depend on protein kinase C.[169] There is some evidence to suggest that the process involves the initial endocytic uptake of albumin as renal cell lines with low endocytic activity do not respond to albumin by activation of intracellular pathways and collagen synthesis.[166] Interestingly, differential effects have been observed depending on post-translational modifications of albumin.[146,174] Two studies have evaluated the effect of proteinuria secondary to glomerular damage in megalin deficient mice in which albumin reabsorption is abrogated.[175,176] In one study crescentic glomerulonephritis was induced by injection of anti-glomerular basement membrane serum into conditional megalin knockout mice revealing ~70% deficiency of megalin in proximal tubule cells. Eighteen days after the induction of glomerulonephritis no difference in tubular degeneration or interstitial fibrosis was observed between megalin deficient mice and controls. However, an upregulation of proinflammatory and profibrotic mediators such as inter-cellular adhesion molecule (ICAM)-1, vascular cell adhesion protein (VCAM)-1, and TGF-β was most pronounced in megalin positive tubular cells. In contrast, an increase in apoptosis markers was more pronounced in megalin deficient proximal tubule profiles.[176] In another study heavy proteinuria was induced by injection of an immunotoxin in sensitive mice expressing human CD25 in podocytes.[175] These mice were combined with conditional megalin knockout mice revealing ~60% deficiency of megalin in proximal tubule cells. Ten days after the induction of proteinuria a higher expression of heme-oxygenase-1 and MCP-1 was identified in megalin expressing tubular cells associated with increased apoptosis.[175] None of these studies examined the isolated effect of albumin on proximal tubule cells nor did they assess any megalin independent effects of albumin which itself was blunted by a residual megalin expression of 30–40%. Furthermore, the studies examined the effect of deficient tubular protein uptake less than three weeks after the induction of proteinuria suggesting that they are not optimal models of CKD. Thus, further studies are needed to examine to effect of targeted disruption of the tubular, albumin receptors in animal models of kidney disease allowing for longer follow up.

Epithelial-Mesenchymal Transition (EMT)

The transition of differentiated tubular cells into myofibroblast-like cells producing α-smooth muscle actin and interstitial matrix components leading to progressive fibrosis has been implicated in the progression of kidney fibrosis.[177] Several mediators have been implicated in this process and recently *in vitro* studies have suggested that albumin may induce EMT possibly through activation of the mTOR pathway.[178] Whether this occur *in vivo* following renal injury and whether EMT is in fact induced by protein overload is still controversial.[179]

Effect of Albumin Distal to the Proximal Tubule

There is some suggestion of distal tubular injury associated with albuminuria,[180] however, whether this is a primary or secondary event has not been established. It has been suggested that the filtration of albumin in excess of the capacity for proximal tubule reabsorption, thus leading to the exposure of distal tubule cells to filtered albumin may cause distal tubular cell damage. Apoptosis as well as the increased expression of TGF-β and its receptor have been induced by albumin *in vitro* in renal cells assumed to have a more distal phenotype such as MDCK cells.[181,151,182] *In vitro* these cells were able to endocytose albumin by a clathrin-mediated pathway. How-ever, although endocytic uptake of proteins has been demonstrated in distal tubular/collecting duct cells[183–185] the mechanism of distal tubular endocytosis

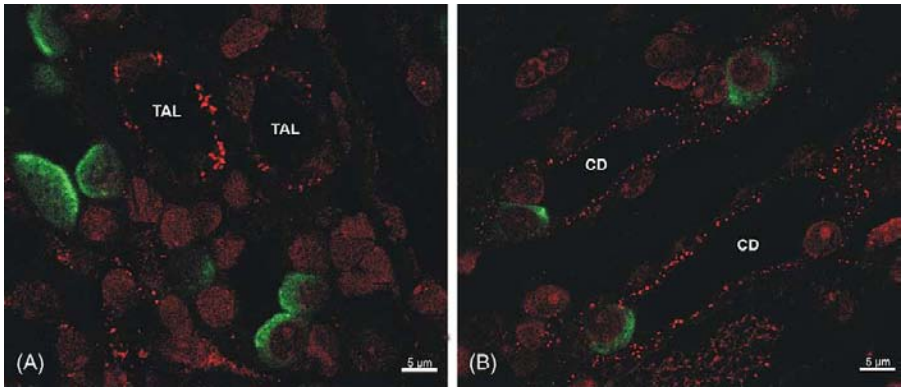

FIGURE 73.6 Immunohistochemical investigation of albumin uptake in renal medulla of a megalin knockout mouse showing that when proximal tubular uptake is disrupted, albumin can be detected in more distal part of the nephron as well as in collecting ducts. A. Micrograph of distal tubule segments (thick ascending limbs, TAL) with visible albumin vesicles (red), next to collecting ducts with intercalated cells positive for H^+-ATP'ase (green). B. Micrograph of collecting duct principal cells positive for albumin (red) and intercalated cell H^+-ATP'ase (green).

in vivo is unresolved[111,186,187] as they do not express megalin or cubilin.[68] See also Figures 73.1 and 73.6 for collecting duct and distal tubular uptake of endogenous albumin in megalin KO mice. Thus, MDCK cells may not be an optimal cell type for the study of the effect of albumin on distal tubule function.

MECHANISMS OF ALBUMINURIA IN DISEASE

Albuminuria denotes the excretion of abnormal and elevated amounts of albumin in the urine. Traditionally albuminuria in the low range of 30 to 300 mg per 24 h has been defined as microalbuminuria although it is unlikely that the 300 mg/24 h limit reflects any abrupt change in pathogenesis. The natural history of albuminuria most likely constitutes a continuum, often fluctuating, as the urinary excretion of albumin, even in healthy people, is determined by a number of factors of which some are not directly related to disease pathology, such as sex, age and physical activity.

Nephrotic syndrome is characterized by the excretion of more than 3 g of albumin/24 h and associated with hypoalbuminemia, hyperlipidemia and edema. Usually this is considered to be due to increased glomerular leak of albumin. Most cases of nephrotic syndrome appear to be acquired, immunemediated diseases, however, within recent years a number of nephrotic conditions have been recognized as the result of single gene defects in podocyte proteins involved in maintenance of the slit diaphragm. Thus, these inherited conditions appear to be the result of changes in the glomerular filtration barrier.[188] In parallel, single gene diseases comprising tubular albuminuria have been shown to be associated with dysfunction of megalin, cubilin and/or AMN (Table 73.1). These include diseases characterized by mutations in the receptor genes, e.g., Donnai Barrow's syndrome (megalin)[189] and Imerslund-Gräsbeck's syndrome (cubilin or AMN).[90] Patients with Imerslund-Gräsbeck's disease have proteinuria in the range of 0.4–1.5 g/24 h[190] reflecting the quantitative significance of cubilin for the tubular reabsorption of filtered albumin. Dent's disease[191] caused by mutations in the gene encoding for the ClC-5[192,193] manifests in decreased levels of megalin and cubilin as demonstrated in a mouse model of Dent's disease[194,195] and in a patient with Dent's disease.[196] Similar mechanisms may be associated with inherited or acquired forms of Fanconi syndrome revealing a protein excretion pattern very similar to that observed in megalin deficient mice.[57]

Clearly most human conditions with albuminuria are not associated with well defined, single gene mutations explaining the phenotype of glomerular or tubular albuminuria. In addition, albuminuria may also be associated with more widespread changes in vascular and organ function as indicated by its association with mortality and cardiovascular disease in large populations. Most primary renal diseases with significant albuminuria are associated with structural changes in the glomeruli signifying that changes in glomerular function are the major contributor to the albuminuria, however, this does not exclude that tubular dysfunction may also be present. In some cases of systemic diseases, such as hypertension and diabetes, tubular dysfunction has been implicated in the early events leading to low grade albumuria as discussed below.

Hypertension and Cardiovascular Disease

Microalbuminuria is an established marker of risk in cardiovascular disease and hypertension.[197] It is traditionally believed that this is due to changes in vascular

TABLE 73.1 Inherited, Single-gene Mutation Diseases with Tubular Albuminuria and Corresponding animal Models

Gene (protein) Affected	Disease	Phenotype	Animal Models
LRP2 (Megalin)	Donnai-Barrow's syndrome[189]	Albuminuria and tubular proteinuria. Cognitive impairment. Hypertelorism, Myopia, Iris coloboma, Sensorineural hearing loss, Agenesis of corpus callosum,	LRP2 gene knock out mice[208] Conditional LRP2 gene knock out mice[209] RAP knockout mice[210]
CUBN (Cubilin)	Hereditary megaloblastic anaemia 1. (Imerslund-Gräsbeck's syndrome)[211]	Albuminuria and tubular proteinuria. Selective intestinal vitamin cobalamin malabsorption. Anemia	Conditional CUBN gene knock out mice[58]
AMN (amnionless)	Hereditary megaloblastic anaemia 1. (Imerslund-Gräsbeck's syndrome)[211]	Similar to above	Inherited selective cobalamin malabsorption in dogs[212]
ClCN5 (chloride channel 5)	Dents disease[191]	Albuminuria and tubular proteinuria. hypercalciuria, nephrolithiasis, nephrocalcinosis. polyuria. Renal failure. Rickets, osteomalacia.	ClCN5 gene knock out mice[195,213]
OCRL (a type II phosphatidylinositol bisphosphate 5-phosphatase)	Lowe syndrome[214]	Albuminuria and tubular proteinuria. Aminoaciduria, hypercalciuria, nephrocalcinosis. polyuria. Renal failure. Cataracts, glaucoma. Mental retardation, reduced muscle tone,	OCRL and Inpp5b gene knock out mice transfected with the human type II phosphoinositide 5-phosphatase encoded by INPP5B[215]
CTNS (cystinosin)	Cystinosis [216]	Fanconi syndrome with tubular proteinuria. Renal failure. Failure to thrive, vomiting, constipation, polyuria, dehydration, rickets. Photophobia, blepharospasm, visual impairment	C57BL/6 CTNS gene knock out mice[217]

and endothelial function.[198] The risk of developing overt kidney disease associated with isolated microalbuminuria is very small.[199] Recently, a single nucleotide polymorphism in the cubilin gene has been associated with microalbuminuria in large populations independent of diabetes and hypertension[60] suggesting that microalbuminuria may in part be a result of differences in receptor function and tubular reabsorptive capacity. Also, experimental observations suggest that tubular dysfunction may contribute to the albuminuria observed in spontaneous hypertensive rats.[200,201] These studies evaluated tubular function indirectly and showed that tubular lysosomal degradation is impaired in hypertension and may be restored by inhibition of the renin angiotensin system. Clearly it is difficult to compare early changes in human hypertensive disease with animal models in particular since long standing, uncontrolled hypertension is known to be associated with renal disease and proteinuria. Thus, the degree of tubular dysfunction in cardiovascular disease with albuminuria remains to be established.

Diabetes

Microalbuminuria in diabetes is associated with increased risk of developing diabetic nephropathy. GBM changes have been identified in diabetes and microalbuminuria but the findings overlap with changes in nonalbuminuric patients.[202] Several studies in humans have suggested that tubular dysfunction in diabetic patients with microalbuminuria may precede increased albumin excretion[124,203] and similar findings have been observed both in animal models[32,204] and *in vitro*.[205] The molecular changes underlying tubular dysfunction have not been clarified but may involve changes in megalin/cubilin mediated uptake.[206,204] Downregulation of megalin has been observed in albuminuric, diabetic rats.[204,207] Increased urinary shedding of megalin and cubilin has been described in microalbuminuric type I diabetic patients.[206] In animal models inhibition of the renin angiotensin system has been shown to improve tubular function[201,207] indicating that regulation of megalin may be affected in diabetic albuminuria and thus providing another potential target for this group of drugs in addition to the effect on blood pressure and glomerular hemodynamics. Interestingly, a single nucleotide polymorphism in the cubilin gene was associated with a small, but significant risk of persistent microalbuminuria in diabetics, but not with severe nephropathy.[60] Thus, while tubular albumin absorption may play a role for the development of microalbuminuria, its role in the development of overt nephropathy is unclear.

In conclusion, the contribution of proximal tubule dysfunction to the albuminuria observed in most proteinuric, human diseases of glomerular or systemic origin is a matter of controversy and still needs to be resolved. Whether tubular dysfunction is a secondary effect simply reflecting the underlying disease, a consequence of albuminuria and/or whether this is part of the pathogenesis and may contribute to the progression also remains to be established. Progress in this area requires introduction of clinical assays to specifically evaluate this aspect of proximal tubule function which will permit the development of specific interventions aimed at restoring tubular function as well.

Physiologic Principles in the Clinical Evaluation of Electrolyte, Water, and Acid–Base Disorders

Daniel Batlle, Sheldon Chen and Syed K. Haque

The Feinberg School of Medicine, Northwestern University, Chicago, Illinois, USA

The kidneys play a fundamental role in the regulation of water and electrolyte excretion as well as in the maintenance of acid base balance. Water and electrolyte homeostasis is accomplished almost exclusively through changes in the volume and composition of urine. Routes of external loss other than from the kidneys play a limited role in regulation, even though they may display some response to the needs of the organism.[1–4] Intake of the various electrolytes and of water can vary extremely widely and almost independently of each other. Balance (used as a synonym for external balance) is the difference between intake and excretion by all routes.[4] Internal balance, on the other hand, means the rate of transfer of a substance between the intra- and extracellular fluids, a concept that has proven especially useful with regard to potassium homeostasis. In this chapter, we will limit the discussion to external balance as we review the physiology underlying the clinical approach to the evaluation of water and electrolyte excretion by the kidneys. No attempt will be made to discuss in-depth specific regulatory mechanisms that are outlined in detail in other chapters. The objective of this chapter is to summarize the rationale and physiologic principles behind the use of urinary indices and clinical tools available in the evaluation of normal and pathophysiologic states related to sodium, water, potassium, and acid–base disturbances.

CONCEPT OF EXTERNAL BALANCE AND STEADY-STATE

The kidney varies the rate of excretion of various solutes to match the input from dietary intake and endogenous production. "Zero balance" or "in balance" both refer to a state in which input equals output.[4,5] Commonly the unit of time is a 24-hour day, and the rate of excretion can only be applied with reasonable certainty to substances that are not metabolized.[4] The term "steady-state" is used to mean a dynamic equilibrium, with the implication that input and output are occurring but are equal.[4] Thus, steady-state, when used with regard to body electrolyte homeostasis refers to zero balance. Humans in a steady-state excrete absorbed ions as well as the metabolic products from their diet.[4] Endogenous production of a substance does not preclude the use of the balance concept. Rather, this production is considered to be a component of intake. For example, water is produced continuously by the metabolism of foodstuffs; this production of water contributes an additional approximate 0.3 L/day to the intake of water from other sources.[4]

The term "steady-state" should not be used to refer to a condition in which both input and output are constant but different. In this case, the body composition is changing progressively, and this clearly represents an unsteady-state.[4] The change in the rate of excretion in

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00074-4

response to a deficit or a surplus of an electrolyte may occur promptly or require a lag period. To reach a steady-state, a variable amount of time is needed for each ion. For example, a water load is excreted within hours, whereas a potassium-deficient diet requires a few days for the renal conservation of potassium to be completed. A low-sodium diet leads to a transient negative sodium balance where sodium excretion exceeds sodium intake in the initial adaptation period (Fig. 74.1).[6] This negative sodium balance reduces extracellular fluid volume (ECFV), which then activates the sodium-conserving mechanisms of the kidney. A high-sodium diet, by transiently resulting in sodium retention, expands ECFV and thereby elicits a signal that deactivates the mechanisms that promote tubular reabsorption of sodium. In both situations, a new steady-state is ultimately reached in which sodium intake and output is equivalent.[5,6] To evaluate the composition of urine in patients, one should first consider their diet. A corollary of this is that there are no "normal" values for the composition of urine, only "expected" ones depending on dietary intake and other stimuli. Because dietary intake fluctuates so greatly (for example, normal dietary intake of sodium may vary from 20 mEq/day to 500 mEq/day), urinary net excretion of sodium varies to match sodium intake. Also, the dietary intake of sodium can be extrapolated from the urine composition of sodium, provided that the patient is in a steady-state. For instance, when a subject is in a steady-state, the finding of 500 mEq of sodium in the urine implies that the subject must have consumed about 500 mEq of sodium in the diet. Likewise, the finding of 20 mEq of sodium in the urine reflects dietary intake of only 20 mEq of sodium. This information is very useful for instance when assessing adherence to dietary instructions in subjects with essential hypertension.

Salt balance is achieved through the integrated action of several factors that regulate sodium reabsorption by the renal tubules.[6] Under normal circumstances, sodium reabsorption by the kidney is determined by the status of the effective arterial blood volume (EABV).[1,7–9] When the EABV decreases, the kidney reabsorbs sodium and chloride, thereby protecting the EABV from contracting further. When the EABV increases, tubular reabsorption decreases, resulting in increased renal salt excretion.[10] Thus, in healthy individuals, sodium balance is directly related to effective arterial blood volume.

When a healthy individual is placed on a low-salt diet, renal NaCl excretion exceeds dietary intake during the initial three to five days (Figure 74.1).[6] The time required to achieve low urine Na^+ and Cl^- varies very little from individual to individual. Age, however, influences this time period, with older individuals taking a longer time to achieve sodium balance.[5] The essential feature of renal salt wasting is ongoing natriuresis, despite a contraction in ECFV to below the lower limit of normal in a normal individual on a salt-free diet. This is clinically evident by an exaggerated decline in blood pressure, sometimes to overtly hypotensive levels or at least manifested by postural hypotension. This fall in blood pressure when coupled with a rise in heart rate upon standing up is a good clinical sign of volume depletion.

In subjects with sodium-retaining states, urinary sodium excretion is usually low but at times it may exceed 200 mEq under certain pathological conditions. For instance, an edematous patient on rigid salt restriction may excrete more than 200 mEq of sodium, but this does not necessarily constitute salt wasting. In this instance, the kidney may be excreting sodium above intake because the mobilization of edema and release of sodium into the circulation.

Now let us consider the situation of a subject who develops acute diarrhea, becomes volume-depleted and maintains an intake of sodium in the normal/high range (250 mEq/day). This subject will avidly reabsorb sodium, reflecting a decrease in EABV despite the high-salt intake and the urinary sodium will be much less than the intake. For instance, urinary sodium could be as low as 10 to 20 mEq a day. This subject is not in a steady-state because of volume depletion from the diarrhea, which provides a potent stimulus for sodium retention. In this case, the extent of sodium excretion does not reflect sodium intake. Accordingly, one should examine the composition of the urine in light of the clinical condition of the subject and the prevailing stimuli.

The concept of the steady-state and appropriate renal response also applies to the excretion of water and solutes other than sodium. For instance, a urinary excretion of 60 mmol of potassium per day may be appropriate for subjects consuming a diet containing 60 mEq of K^+, but would be actually clear evidence potassium wasting in a hypokalemic patient on such diet. Here the hypokalemic stimulus, in someone with normal kidney function, leads to renal retention of potassium as a result of both enhanced reabsorption and decreased potassium secretion.

URINARY CONSTITUENTS AS CLINICAL INDICES: GENERAL CONSIDERATIONS

Urine collected over 24 hours to determine the daily solute excretion is the conventional approach to evaluate external balance of a given solute that is primarily excreted by the kidneys. To the extent that ions such as Na^+ and K^+ are largely excreted by the kidneys one can estimate dietary intake in the steady-state and the

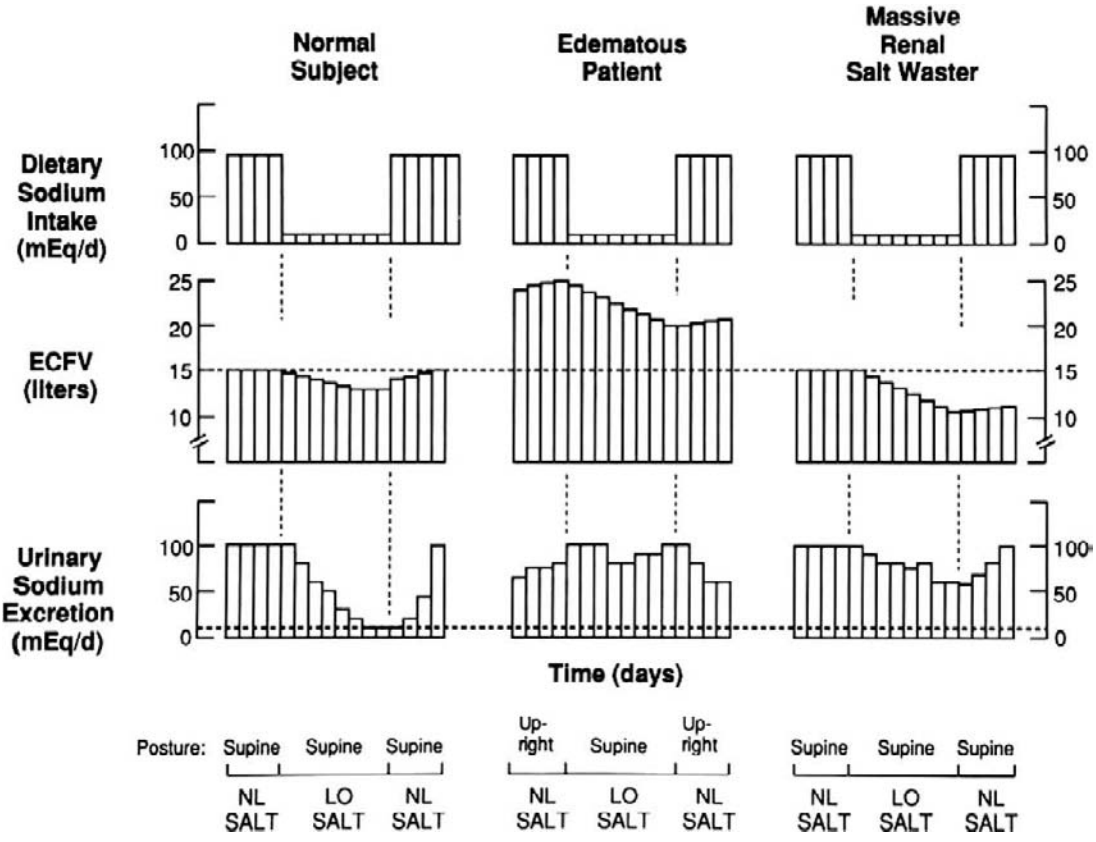

FIGURE 74.1 In the normal subject, a low-salt diet results in a reduction of extracellular fluid volume (ECFV) (middle panel) from a normal value of 15 to about 13 L. At that point, intake (upper panel) and urinary excretion (lower panel) are equal. The subject is in balance. (Horizontal dotted lines represent the basal levels of ECFV (middle panel) and dietary sodium during severe sodium restriction (lower panel).) In the edematous patient, a low-salt diet results in a reduction in ECFV from 25 to 20 L from an initial value of 25 L. Nevertheless, ECFV is still above the normal range and natriuresis continues (lower panel). The patient is in negative sodium balance but is not salt wasting; that is, ECFV remains over expanded. In renal salt wastage, a low-salt diet results in a 5-liter reduction in ECFV with persistent negative sodium balance. This constitutes salt wastage. *(From Toto R, Seldin DW. Salt wastage. In: Seldin DW, Giebisch G, eds. The Kidney: Physiology and Pathophysiology. New York: Raven Press; 1992:2143–63, with permission.)*

kidney response to physiologic and pathophysiologic conditions by measuring the urinary concentrations and calculating the excretion rates when urine volume per unit time is known. In most clinical situations, a random "spot" urine collection is sufficient for the initial evaluation of a patient's condition.[3] Aside from being more convenient and rapid, the spot urine has the advantage that the stimulus is known at the time the urine is collected, and therefore the expected renal response can be predicted. For instance, prior to vigorous volume replacement it is useful to know how the kidneys are responding in terms of avid sodium retention or not.

Since errors are frequent when trying to collect urine accurately, urine creatinine should always be part of the measurement as a way to verify the completeness of the 24-hour collection. The urine creatinine assessment takes advantage of the fact that the kidneys excrete creatinine at a relatively fixed rate depending on the person's muscle mass, a gauge of the daily creatinine input. While excretion of creatinine for an individual is relatively constant over a 24-hour period, provided that the serum creatinine is stable, it might vary depending upon protein intake. Muscular individuals and exercise, both increase creatinine excretion.[11] For clinical purposes, it is generally accepted that a 24-hour urine collection is complete when the total urine creatinine is 20–25 mg per kg body mass for men and 15–20 mg per kg body mass for women.

Urinary Sodium and Chloride as Indices of Volume Status

The medical history and physical examination is always the first step in assessing arterial blood volume at the bedside. The clinical evaluation should be supplemented by the measurement of urine sodium and chloride in spot urine. The kidney has the extraordinary ability to elaborate virtually salt-free urine in the setting of dietary salt deprivation or when extra-renal losses of sodium are sufficient to decrease the EABV.[6] Under

normal circumstances, the kidney excretes sodium and chloride in the urine in an amount equivalent to the dietary intake. As discussed earlier, the kidney modulates sodium excretion and reabsorption in accordance with the status of the EABV.[8,12] When the EABV decreases, the kidney reabsorbs sodium and chloride, thereby protecting the EABV from shrinking further. On the other hand, when the EABV expands, tubular reabsorption of sodium and chloride decreases, resulting in greater urinary excretion of these ions.[5]

In analyzing renal sodium excretion, the existing volume status must always be taken into account, as noted in the earlier discussion regarding renal NaCl excretion in individuals in various clinical settings who were placed on low-salt diets. Further urinary chloride should be concurrently measured with urinary sodium. In volume-depleted states, the simultaneous measurement of urine sodium and chloride provides complementary information regarding the underlying cause, particularly when acid–base status is also altered such as in vomiting or diarrhea.

In states of volume depletion, the urine concentrations of sodium and chloride are both usually below 15 mEq/L, and in volume-replete conditions, they are well above 20 mEq/L (usually above 40 mEq/l). As summarized in Table 74.1, four patterns of urinary sodium and chloride can be encountered.

(1) Low levels of urinary sodium and chloride. This reflects low intake of salt or extrarenal salt losses. This can also be seen after cessation of diuretics when the volume deficit still persists.[13]

(2) Low urinary chloride with normal/high urinary sodium. In a setting of low EABV, this pattern suggests that another anion is present in the urine, usually HCO_3^-, as in the setting of recent vomiting (see following paragraphs). This can also occur in the syndrome of congenital chloridorrhea, which is a syndrome of severe diarrhea, hypokalemia, and often metabolic alkalosis that is caused by a defect in the ileal and colonic chloride–bicarbonate exchange transporter that normally mediates active chloride absorption.[14] In this syndrome, there is appropriate renal response to volume depletion with virtually absent urine chloride, but urinary sodium is elevated because of the high filtered load of bicarbonate which obligates sodium excretion.

(3) Low urinary sodium with normal/high urinary chloride. In a patient with low EABV, as seen in the setting of diarrhea or laxative abuse, this pattern suggests that another cation is being excreted, most often ammonium and rarely potassium.

(4) High excretion of urinary sodium and chloride. In a setting of low EABV, this pattern suggests ongoing diuretic use (both thiazide and loop diuretic) or an intrinsic tubular defect as in Bartter's or Gitelman's syndromes. This pattern is also consistent with salt wastage of any cause with post-obstructive diuresis being a classic example.

TABLE 74.1 Patterns of Urinary Sodium and Chloride in Various Conditions

a. Low urinary sodium and chloride	Salt restriction
	Extrarenal salt losses
	Previous use of diuretics
	Vomiting (maintenance phase)
b. Low urinary chloride but "normal/high" sodium	Vomiting with metabolic alkalosis (generation phase)
	Congenital chloridorrhea
c. Low urinary sodium but "normal/high" chloride	Diarrhea with volume depletion but metabolic acidosis
d. High urinary sodium and chloride	Loop and thiazide Diuretics
	Bartter's and Gitelman's syndromes
	Salt-wasting as seen in postobstructive diuresis and some types of chronic interstitial nephritis

Urinary chloride concentration under physiologic conditions, like urinary sodium, reflects the chloride intake. While urinary sodium and chloride change in the same direction under most circumstances, they may occasionally dissociate (Table 74.1). The most notable situation is patients with vomiting and metabolic alkalosis with volume contraction. In this setting, urinary chloride concentration is low, reflecting the salt-retaining state induced by volume depletion. When the patient is actively vomiting, the increase in plasma bicarbonate and thus filtered bicarbonate might exceed the reabsorptive capacity of the tubules, resulting in bicarbonate excretion. Therefore, bicarbonate is rejected in the proximal tubules and this obligates the excretion of sodium resulting in a sodium bicarbonate diuresis. In this situation, chloride is retained appropriately, reflecting volume contraction. Thus, in a patient with active vomiting, the urine sodium may be high, while chloride concentration is invariably low (Table 74.1).

In the maintenance phase of metabolic alkalosis, however, the ECFV depletion persists even if vomiting has ceased, leading to secondary hyperaldosteronism and sodium retention. Therefore urinary sodium, as well as urinary chloride concentration, can be low after protracted vomiting or nasogastric suction. Similarly, diuretic-induced metabolic alkalosis results in increased urinary concentrations of both sodium and chloride during the generation phase of the metabolic alkalosis when the nephron is under the effects of the

diuretic (Table 74.1). When the diuretic is discontinued, the metabolic alkalosis can be maintained by preexisting volume depletion, decreased glomerular filtration rate (GFR), and secondary hyperaldosteronism, and urinary sodium is usually low. The urinary concentration of chloride, likewise, is appropriately low (< 15 mEq/L), reflecting the persistence of volume depletion and indeed, the administration of saline to restore the volume status to normal results in correction of the metabolic alkalosis.

Under conditions of metabolic acidosis other than the type resulting from renal tubular acidosis, the presence of large amounts of ammonium in the urine obligates the loss of an anion (chloride) resulting in a higher than expected urinary concentration of chloride.[15] The urinary concentration of sodium, however, in this situation will be appropriately low reflecting the intravascular volume depletion.[16,17] This pattern is typically seen in metabolic acidosis caused by diarrhea.[15,18]

In patients with metabolic alkalosis due to Bartter's or Gitelman's syndromes, urinary chloride and sodium concentrations are elevated due to a tubular defect in reabsorption.[19] When these patients become volume-depleted, renal conservation of salt is clearly suboptimal as manifested by relatively high level of urine sodium and chloride.

Spot Urine vs Timed Urine Collections

The 24 hour urine collection remains the proper way to evaluate solute excretion. One can use urine creatinine in a spot urine sample to calculate the urinary sodium/creatinine ratio as a way to estimate 24-hour urinary sodium excretion much in the same way that the urinary albumin/creatinine ratio is used to estimate 24-hour albumin excretion rate. The good linear relationship between the urine sodium/urine creatinine ratio has moreover been used to develop formulas to generate values of 24-hour sodium excretion based on the spot sodium/creatinine ratio. Kawasaki et al.[20] proposed the formula:

$$\text{24-Hour Urinary Sodium (mEq/day)} = 16.3 \times \sqrt{X_{Na}}$$

$$\text{Where } X_{Na} = (\text{Spot } U_{Na}/\text{Spot } U_{Cr}) \times \text{predicted 24 h urinary Cr excretion}$$

$$\text{Predicted 24 h urinary Cr excretion (Male)} = -12.63 \times \text{Age} + 15.12 \times \text{Weight} + 7.39 \times \text{Height} - 79.90 \text{ (mg/day)}$$

$$\text{Predicted 24 h urinary Cr excretion (Female)} = -4.72 \times \text{Age} + 8.58 \times \text{Weight} + 5.09 \times \text{Height} - 74.50 \text{ (mg/day)}$$

Linear correlation between formula-estimated and actual 24-hour urinary sodium was 0.53.[20] Others have reported a similar correlation (r = 0.55).[21]

Interestingly, a strong linear correlation between spot urine Sodium/Creatinine ratio and 24-hour Sodium excretion has been reported when evening spot samples were used but not when morning or random urine samples were used (see Table 74.2 and Figure 74.2).[22] The linear correlation was even better when the evening spot urine Sodium/Creatinine ratio was adjusted for 24-hour creatinine excretion.[22]

It should also be noted that there is a diurnal variation in the excretion of water and electrolytes. A larger amount of the potassium excreted daily occurs close to noon while the rate of excretion of sodium is lowest overnight.[23,24] Ideally, this diurnal variation should be taken into account when interpreting urine tests, but in practice this is rarely done. There is limited information addressing the possible shortcomings of not taking into account the diurnal variation in the interpretation of electrolyte disorders at the bedside using spot urine samples. As noted above, a recent study suggests that spot urine sodium/creatinine ratio when taken in the evening correlates better with 24-Hour Sodium excretion than when taken in the morning.[22] For practical purposes, however, a spot urine sample for electrolytes can be ordered any time of the day when the purpose is to assess a pathophysiologic situation such as volume depletion or renal failure.

Fractional Excretion of Sodium

The fractional excretion of sodium (FE_{Na}) reflects the percent of filtered sodium that is excreted in the urine. The filtered sodium load can be determined from the product of the Glomerular Filtration Rate (GFR) and the Plasma Sodium (P_{Na}). Sodium excretion is equal to the product of the urine sodium (U_{Na}) and the urine

TABLE 74.2 Correlations between Spot Urine Sodium/Creatinine Ratio and 24-Hour Sodium Excretion

Correlation of 24-Hours Sodium Excretion with:	Spot Sodium/Creatinine Ratio: (correlation coefficients)	Predicted 24-Hours Sodium Excretion: (correlation coefficients)
Random Urine Sample	− 0.01	0.17
Morning Urine Sample	0.14	0.31
Evening Urine Sample	0.67	0.86

flow rate (V). Since GFR is often not available, the FE_{Na} can be derived as follows:

$$FE_{Na}(\%) = (U_{Na} \times V/GFR \times P_{Na}) \times 100 \quad (74.1)$$

Since $GFR = U_{Cr} \times V/P_{Cr}$, the equation for FE_{Na} (%) becomes:

$$FE_{Na}(\%) = ((U_{Na} \times V)/(U_{Cr} \times V/P_{Cr}) \times P_{Na}) \times 100 \quad (74.2)$$

Because V cancels out, it follows that:

$$FE_{Na}(\%) = (U_{Na} \times P_{Cr})/(U_{Cr} \times P_{Na}) \times 100 \quad (74.3)$$

FE_{Na} is usually used to distinguish prerenal disease from acute tubular necrosis (ATN), the two most common causes of acute renal failure.[8,12] In prerenal disease, the reabsorption of almost all of the filtered sodium represents an appropriate response to decreased renal perfusion. When GFR decreases due to renal vasoconstriction with intact tubular function, the FENa is low, usually less than 1%.[25] In ATN, there is an associated tubular dysfunction, with an inability to conserve sodium and thus, the FE_{Na} is high, usually more than 2%. A value between 1 and 2% may be seen with a prerenal disorder or ATN, but typically it is below 1% in prerenal disorders.[26] However, FE_{Na} can be low (<1%) in patients with ischemic ATN, if they are evaluated early in the course, as they make the transition from prerenal disease to postischemic ATN, or if they remain ischemic with established ATN.[16] A low FE_{Na} is appropriate in this setting due to continued renal ischemia and can be achieved because

tubular function is relatively intact early in the course of ATN.[27,28] A clinical setting in which ATN is frequently associated with decreased FE_{Na} is the acute renal failure associated with contrast nephropathy.[29–31] Occasionally, it is also observed in sepsis,[32] myoglobinuria,[33] obstructive uropathy,[34] acute glomerulonephritis,[16,17] and renal allograft rejection.[17] In patients with chronic renal failure, renal vasoconstriction may not be associated with a FE_{Na} less than 1% due to chronic adaptation to an increased single-nephron GFR. Here, there is an adaptive decrease in tubular reabsorption in order to maintain sodium balance, thus making the interpretation of FE_{Na} difficult.[25] One mathematical consideration also complicates the interpretation of FE_{Na}. As the renal failure progresses, the urinary creatinine in the denominator decreases, making the FE_{Na} increase on that basis alone. Thus, a patient can be prerenal, but if the reduction in GFR is severe enough, the FE_{Na} can sometimes be pushed well above 1%. The pre-renal state can still be correctly diagnosed, however, by the gold standard test of seeing if the renal failure reverses with volume repletion. Due to the limitations of using FE_{Na}, the need arises for other indices that could help to clinically distinguish between ATN and pre-renal diseases (see following sections). This is not to say that the other indices are better but provide additional information that may help to assess the overall picture. Table 74.3 provides a summary of the expected values in the differential diagnosis of prerenal vs. acute renal failure.

TABLE 74.3 Urine Indices Used in the Differential Diagnosis of Prerenal and Ischemic Intrinsic Renal Azotemia

Diagnostic Index	Prerenal Azotemia	Ischemic Intrinsic Azotemia
Fractional excretion of Na^+ (%)	<1%	>1%
Urinary Na^+ concentration (mEq/L)	<10	>20
Urinary creatinine/plasma creatinine ratio	>40	<20
Urinary urea nitrogen/plasma urea nitrogen ratio	>8	<3
Urine specific gravity	>1.018	<1.012
Urine osmolality (mOsm/kg H_2O)	>500	<250
Plasma BUN/creatinine ratio	>20	<10–15
Renal failure index, (UNa/(Ucr/Pcr))	<1	>1
Urine sediment	Hyaline casts	Muddy brown granular casts

Fractional Excretion of Urea

Urine sodium and chloride concentrations are difficult to interpret with concurrent diuretic therapy.[35] The ensuing rise in urinary sodium and chloride likewise will raise the FE_{Na} and FE_{Cl} (fractional excretion of chloride) even in patients with pre-renal disease and oliguria. The coexistence of a pre-renal state and natriuretic agents (diuretics) clearly alters the interpretation of FE_{Na} such that despite volume depletion sodium excretion is increased during ongoing use of diuretics.[35] In volume depletion and pre-renal azotemia due to vomiting or nasogastric suction, the ensuing metabolic alkalosis causes bicarbonaturia which increases urinary sodium and hence FE_{Na} at high levels.[36,37] Given the limitations of using FE_{Na}, the need arose for a better marker for differentiating pre-renal conditions from ATN. This has led to the use of the fractional excretion of urea (FE_{Urea}).[37–39]

The FE_{Urea} is calculated using the formula used to calculate the fractional excretion of other electrolytes:

$$FE_{Urea} = (U_{ur} \times P_{cr})/(P_{ur} \times U_{cr}) \times 100 \qquad (74.4)$$

The FE_{Urea} is 50 to 65% in healthy subjects and usually below 35% in pre-renal disease.[39] To distinguish pre-renal states from ATN, the use of FE_{Urea} was evaluated by Carvounis et al.[36] The study consisted of three groups; the first group had 50 patients with pre-renal disease, the second group had 27 patients with prerenal disease who had been given diuretics, and the third group had 25 patients with established ATN. The FE_{Na} was characteristically low (<1%) in the pre-renal group but was substantially higher than 1% in the prerenal group on diuretics and in the ATN group.[36] In contrast, the FE_{Urea} was similar in both the prerenal groups (27.9 and 24.5% in groups 1 and 2, respectively) and significantly different from the ATN group (58.6%, $p < 0001$). While 92% of patients in group 1 had a FE_{Na} <1%, only 48% of patients in group 2 had a low FE_{Na}. By contrast, 89% of patients who were prerenal and on diuretic therapy had a FE_{Urea} below 35%. In the prerenal cases (groups 1 and 2), FE_{Urea} had the best sensitivity and specificity (90 and 96%, respectively), and the best positive and negative predictive values (99 and 75%, respectively). These data suggest that when FE_{Urea} of less than 35% is found, 99% of such cases will be prerenal, including prerenal states with diuretic use.[36]

The clearance of urea reflected by the FE_{Urea} is affected by decreased renal perfusion as seen in prerenal states. In evaluating the relationship of urine volume to urea excretion in humans using diuretic agents, it was found that the percent of filtered urea excreted increased with proximal diuretics (mannitol and acetazolamide) but not with distal agents (mercaptomerin and ethacrynic acid).[36,39,40] This is consistent with the

notion that urea is not reabsorbed significantly in the distal nephron. As most of the diuretics in clinical use work beyond the proximal tubule, FE_{Urea} should not be affected by their use. This is unlike FE_{Na}, which is increased by all forms of diuretics.[36,37,40]

There are situations, however, where FE_{Urea} may not predict the ongoing prerenal status. Such settings should be kept in mind when FE_{Urea} is used. For instance, in states of osmotic diuresis, and with the administration of acetazolamide and mannitol, the proximal tubular absorption of salt and water is reduced, and thus an increased FE_{Urea} is to be expected even in the presence of renal hypoperfusion.[36,40] In other studies, the utility of FE_{Urea} has been questioned.[41,42] It is reasonable, however, to use fractional urea excretion in conjunction with other urinary indices such as FE_{Na} to gain a more complete picture than with either one alone in situations where the clinical picture is not straightforward.

Fractional Excretion of Lithium

Markers of proximal fluid reabsorption can be used to assess proximal tubular sodium reabsorption.[41] Such a marker should be freely filtered at the glomerulus, should be reabsorbed in the same fashion as sodium and water in the proximal tubule, should not be reabsorbed beyond the proximal tubule, should not be secreted, and its plasma levels should not fluctuate significantly in response to hormones and changes in ECFV. Lithium fits this profile with the exception that it is reabsorbed in the loop of Henle as well as in the proximal tubule.

To assess proximal fluid reabsorption, the fractional clearance of endogenous or exogenous lithium can be utilized.[42] The endogenous lithium clearance, despite its clear advantages over the exogenous method, would require very sensitive assays to measure trace amounts of lithium present in the serum and is difficult to use. Thus, it is necessary to give lithium either acutely or for several days prior to measuring lithium clearance or its fractional clearance. The fractional excretion of lithium (FE_{Li}) is approximately 20% in healthy controls and below 10% in prerenal disease regardless of diuretic therapy.[42] In ATN, FE_{Li} is typically higher than 25%.[42]

FE_{Li} is probably a more sensitive index than FE_{Na} in differentiating prerenal states from ATN, especially in patients receiving concomitant diuretics.[41,42] The use of lithium, however, has its own disadvantages. Its use is limited by the necessity of administering exogenous lithium, by the expertise needed to detect lithium levels in urine and by the acute changes in tubular electrolyte handling induced by lithium loading.[42,43] Moreover, concern about the value of fractional Lithium excretion as a marker of proximal tubular fluid delivery has been raised because studies suggesting reabsorption of lithium in the thick ascending limb of the loop of Henle, which could be inhibited by loop diuretics.[44,45] For clinical purposes, lithium clearance is not used but it offers valuable information in clinical physiology studies aimed at assessing segmental sodium handling throughout the nephron. It should be noted, however, that initial studies showed that lithium was reabsorbed almost entirely in the proximal tubule in a fashion similar to that of sodium,[44] thus making lithium the marker of choice for determining proximal reabsorption. However, further studies uncovered a number of problems with using lithium clearance for assessing proximal reabsorption.[46–50] First, lithium undergoes significant reabsorption in the loop of Henle, and to a lesser extent in the distal tubule and collecting duct.[41,44] Amiloride can be used to block the reabsorption of lithium in the distal tubule and collecting duct especially when on a Na restricted diet.[51,52] A second problem with the use of lithium is that in the presence of mineralocorticoid-induced volume expansion and with the administration of inhibitors of prostaglandin synthesis, lithium reabsorption in Henle's loop is increased.[53,54] In the aggregate, lithium clearance is the best available method to assess the delivery of sodium and water out of the proximal tubule, and is reasonably accurate in the steady-state. In states of volume and hormonal perturbations, however, lithium clearance is much less reliable.

Fractional Excretion of Uric acid has also been used, but has been found to be no better or inferior to Fe_{Na} and FE_{Li}.[42,45] A summary of specificity and sensitivity of these various indices in the detection of prerenal vs acute renal failure is provided in Table 74.4.

EVALUATION OF DISORDERS OF WATER EXCRETION

The two variables governing water excretion include the magnitude of interstitial osmolality and the vasopressin-regulated, aquaporin-2 (AQP2)–dependent water transport in the collecting ducts. The interstitial osmolality increases whenever there is an increase in either sodium or urea concentration in the medullary interstitium and this provides the driving force for water absorption from the collecting duct for any given level of arginine vasopressin (AVP).[10] For example, increased protein intake results in higher urea levels, which then enhances the ability of the kidney to concentrate the urine.[55,56]

AVP regulates water permeability by principal cells in the collecting tubule by activating basolateral V2 receptors and this result in the insertion of AQP2 water channels into the apical surface of the cells, which

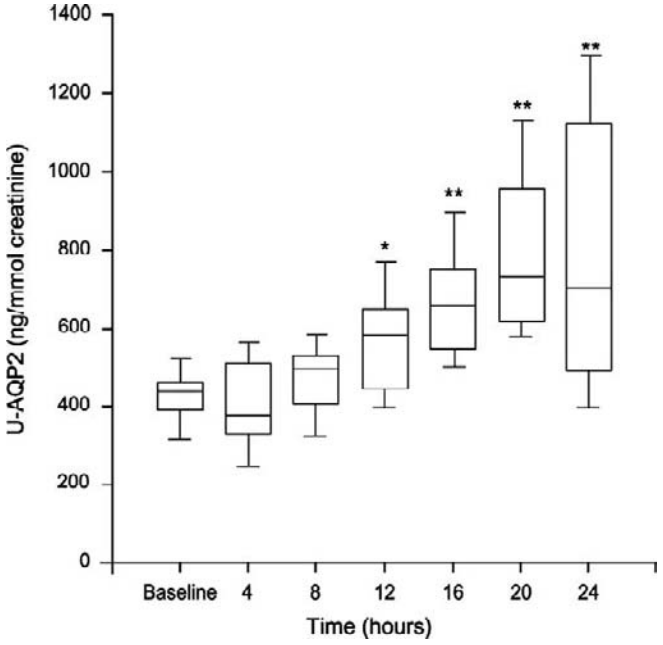

FIGURE 74.3 Urinary (u) aquaporin-2 (AQP2) excretion during 24 hours of water deprivation in 15 healthy subjects. Baseline, 24-hour collection before the experiment; 4 hours, 1200; 8 hours, 1600; 12 hours, 2000; 16 hours, 2400; 20 hours, 0400, 24 hours, 0800 the next morning. Results are medians with 25th, 75th, 10th, and 90th percentiles. $*p < 01$ and $**p < 001$, significant deviation from baseline. *(From Pedersen RH, Bentzen H, Bech JN, Pedersen EB. Effect of water deprivation and hypertonic saline infusion on urinary AQP2 excretion in healthy humans. Am J Physiol Renal Physiol 2001;280:F860–F867, with permission.)*

results in an increase in water permeability.[10,57] Synthesized AVP is released in response to two stimuli: an increase in plasma osmolality and changes in blood volume and pressure.[28] AVP-mediated increases in total AQP2 expression contribute to the long-term regulation of urinary concentration. AVP also increases water reabsorption by the kidney by increasing the expression and activity of the Na^+-K^+-$2Cl^-$ cotransporter and the urea transporter.[58,59] AVP-mediated regulation of AQP2 activity and expression provides by far the main mechanism for regulation of collecting duct water permeability.[60] AVP binding to the V_2 receptor activates a G-protein that increases adenylyl cyclase activity and cyclic adenosine monophosphate (cAMP) function. cAMP-activated protein kinase A then phosphorylates AQP2 and targets it to the apical surface of principal cells, which immediately increases water transport.[57,60]

Measurements of AQP2 protein in the urine correlate with AVP levels, during water deprivation and after AVP administration (Fig. 74.3).[61,62] The critical role of AQP2 in the regulation of water excretion is now widely accepted, but at the clinical level, there is no need currently for measurements of AQP2 in the urine. For practical purposes, the clinical assessment of normal and abnormal handling of water by the kidneys starts with the measurement of plasma and urine osmolality (U_{Osm}).

Plasma and Urine Osmolality

Plasma osmolality is tightly maintained within normal range (275–290 mOsmol/Kg). A 1% increase in plasma osmolality above 280 mOsm/kg triggers corrective response in the form of stimulation of the thirst center and activation of osmoreceptors resulting in the release of AVP.[63] On the other hand, urine osmolality varies greatly, depending on water intake, and therefore should be interpreted in conjunction with measurements of plasma sodium or osmolality. In healthy adults, the urinary osmolality can vary from a minimum of about 50 to a maximum of about 1200 mOsm/kg H_2O. It is to be noted that the concentrating ability tends to fall with age, and the maximum U_{Osm} in an elderly patient may be only 600 to 700 mOsm/kg H_2O.

The urine flow rate is directly proportional to the number of osmoles excreted, and is inversely proportional to the urine osmolality, as expressed below:

$$\text{Urine flow rate (or volume)} = \text{Number of osmoles per day/urine osmolality} \quad (74.5)$$

Several examples of this relationship are shown in Table 75.5. This table shows the urine volume needed to excrete a given amount of solute, at various levels of urine osmolality. In disorders in which the rate of AVP secretion is very low, and essentially constant, for example, in a patient with central diabetes insipidus (DI), the maximum U_{Osm} may be only 100 mOsm/kg H_2O. In this patient, the daily urine volume would be

12 L if 1200 mOsm of solute are to be excreted, as in a typical Western diet that generates a daily solute load of about 900 to 1200 mOsm. Dietary proteins and NaCl are the precursors of most of the urinary osmoles. In patients on a low-solute diet (0.6 g/kg body weight of protein and 10 mg/kg body weight of sodium), the total solute load may be as low as 300 mOsm. In such cases, only 3 L of urine are required to excrete the solute load, if the U_{Osm} is 100 mOsm/kg H_2O (Table 74.5).

In a healthy subject on a diet that generates 1200 mOsm of solutes, about half of the urine osmoles consists of urea. Because the concentration of urea in the luminal fluid is roughly equal to that in the papillary interstitial component,[64,65] urea will not cause water movement across the luminal membrane in the inner medulla. This renders urea an ineffective osmole. Thus, some authors believe that it is more correct to say that the urine flow rate is proportional to the number of nonurea osmoles (electrolytes, predominantly sodium and chloride in healthy subjects, and ammonium and β-hydroxybutyric acid during prolonged fasting) and to their concentrations in the medullary interstitial compartment.[64,65] Accordingly, the effective osmoles in the urine of a healthy subject on a typical Western diet would be half the total solute load, or about 600 mOsm.[13] The formula given above can therefore be modified as follows:

$$\text{Urine flow rate} = \text{Number of ''effective'' urine osmoles per day} / \text{''effective'' urine osmolality} \quad (74.6)$$

An important caveat to the generalization that urea is an ineffective osmole exists when an electrolyte-poor urine is excreted. In this case, the concentration of urea in the urine is more than that in the papillary interstitial compartment.[65] In this setting, urea becomes an effective osmole and the increase in osmolality from the increase in urea reflects renal water conservation. The rationale for this change in permeability for urea is the fact that the chief goal of the urinary concentrating process is to ensure that a decrease in urine output ensues when ADH acts.[3] For this to occur, effective osmoles must be excreted with water. These effective osmoles, usually NaCl, are replaced by urea when the content of electrolytes in urine is low.[64] This latter situation may apply, for instance, to sodium-retaining states, such as congestive heart failure, where sodium and chloride are avidly reabsorbed in the proximal tubule and therefore, the excretion in the urine is low.

TABLE 74.5 Relationship Between UOsm and Urine Volume

UOsm	Urine Volume (L) if 1200 mOsm of Solutes are to be Excreted	Urine Volume (L) if 300 mOsm of Solutes are to be Excreted
100	12	3
300	4	1
600	2	0.5
1200	1	0.25

A complete analysis of water handling by the kidneys requires the calculation of free water excretion and electrolyte-free water excretion.[66] These calculations offer information about the quantity of water absorbed or excreted by the kidney, information that is not provided by measuring only U_{Osm}.[66] The calculation of electrolyte-free water excretion further dissects out the effect of free water excretion that is independent of urea, and helps predict the trend of plasma sodium.

Free Water Clearance and Electrolyte-Free Water Clearance

The excretion of free water relative to the extent of water intake can be estimated by the free water clearance (FWC), which equals the volume of urinary water (over a period of time) that exceeds the virtual volume that would be required to excrete the solute load in an iso-osmolar fashion. Thus, the FWC reflects the amount of pure water excreted.[66–68] This concept is illustrated in the following example. A patient collects 4 L of urine with a urine osmolarity of 70 mOsm/L. A concurrently measured serum osmolarity is 280 mOsm/L, four times as concentrated as the urine. If the urinary solutes excreted (70 mOsm/L × 4L) were dissolved in just one-fourth of the actual volume of urine, then the urine osmolarity would match the serum osmolarity of 280 mOsm/L. The other 3 L would be pure water to make up the remainder of the 4 L total volume. Hence, the FWC is as follows:

$$\text{FWC} = \text{Actual urine volume (V)} - \text{Iso-osmolar urine volume } (V_{iso}) \quad (74.7)$$

In mathematical terms, the virtual volume of iso-osmolar urine can be calculated by determining how dilute or concentrated the urine is compared with the serum:

$$\text{Volume of iso-osmolar urine } (V_{iso}) = V \times (U_{Osm}/S_{Osm}) \quad (74.8)$$

Where V = urinary volume, U_{Osm} = urine osmolarity, and S_{Osm} = serum osmolarity.

After calculating the iso-osmolar volume (1 L in the example above), the remainder of the total urine

volume should be composed of osmole-free water. This is quantified as FWC in the following equation:

$$\begin{aligned} \text{FWC} &= \text{Actual urine volume (V)} \\ &\quad - \text{Iso-osmolar urine volume } (V_{iso}) \\ &= V - \{V \times (U_{Osm}/S_{Osm})\} \end{aligned} \tag{74.9}$$

This can be rearranged to:

$$= V \times \{(1 - U_{Osm}/S_{Osm})\} \tag{74.10}$$

Lastly, clearance is always expressed in terms of volume per unit of time; in the example above, the FWC is 3 L/24 hours. The time term may be introduced by dividing the FWC by the time over which the urine was collected, or $V \times \{(1 - U_{Osm}/S_{Osm})\}$/time. This becomes the general formula for the FWC (or CH_2O):

$$CH_2O = V \times \{(1 - U_{Osm}/S_{Osm})\}/\text{time} \tag{74.11}$$

Where CH_2O = free water clearance, V = volume of urine, U_{Osm} = urine osmolarity, and S_{Osm} = serum osmolarity.

All osmoles, however, are not equally active. Some osmotically active particles, such as urea, freely cross the cell membrane and therefore do not influence water movement between the extracellular and intracellular compartments.[64] Of these, the predominant species are sodium (especially in the extracellular fluid), potassium (especially in the intracellular fluid), chloride, bicarbonate, and glucose. For simplicity, the cationic particles may be summed and used as a surrogate for the overall tonicity. To reformulate the FWC based on tonicity, the osmoles in the equation above should be replaced by their equivalent tonically active cations. Thus, the ratio of U_{Osm}/S_{Osm} becomes $(U_{Na} + U_K)/S_{Na}$, where U_{Na} and U_K are the urinary sodium and potassium concentrations and S_{Na} is the serum sodium concentration. Serum potassium is usually ignored because it represents an insignificant fraction of the total serum cationic tonicity, but urine potassium must be taken into account because it often constitutes a sizeable portion of the total urinary cationic tonicity. Thus, the FWC equation becomes:

$$C^eH_2O = V \times (1 - (U_{Na} + U_K)/S_{Na}\}/\text{time} \tag{74.12}$$

This equation is also known as the electrolyte-free water clearance (abbreviated C^eH_2O) because it includes only the major electrolytes that contribute to the overall tonicity.

The most noteworthy term in the electrolyte-free water clearance is the ratio of the urinary electrolyte solutes to the main serum electrolyte solute (sodium). It makes intuitive sense that if the urinary electrolyte concentrations are low compared with those of the serum electrolytes, a fair amount of free water is being excreted, consistent with the formula. On the other hand, if the urinary electrolyte concentrations are relatively high and their sum approaches the value of the serum electrolyte concentration, then the term $1 - (U_{Na} + U_K)/S_{Na}$ will have a low value, indicating a reduced electrolyte-free water clearance. A third scenario is also possible in that the sum total of the urinary electrolytes could exceed the serum electrolytes, yielding an electrolyte-free water clearance that is negative. This equates with the reabsorption of water, and in an individual with hyponatremia, predicts further lowering of plasma sodium unless a therapeutic intervention takes place (see following sections).[66]

Volume Status in the Evaluation of Hyponatremia

The evaluation of hyponatremia is often based on volume status as a way to determine the "appropriateness" of AVP secretion.[10,37] Classification of a patient's volume status as hypovolemic, euvolemic, or hypervolemic based on physical examination findings helps to identify the cause of the hyponatremia and to plan its treatment.[66] The recent introduction of vasopressin V_2 antagonists for the treatment of hyponatremia is based on this classification.[66,69]

The principles underlying the evaluation of alterations in water balance are based on: (1) elucidation of factors involved in the generation and maintenance of osmotic pressure, which is exerted by solutes present in the medullary interstitium, i.e., the driving force and (2) assessment of AVP-regulated water permeability of the apical surface of collecting duct principal cells.[28,55,70] Impaired free water excretion may be attributed to changes in one or both of these two variables.[10] In addition, the delivery of fluid to the diluting segments plays a critical role. A decrease in GFR decreases the delivery of both NaCl and water to the ascending limb causing impaired dilution.[28] For instance, in hypothyroidism, hyponatremia results, at least in part, from a decreased GFR and decreased delivery of NaCl and water to the distal tubule. Thiazide diuretics can also cause hyponatremia via a decreased GFR (in addition to other important mechanisms discussed below) if volume contraction is severe. The associated enhancement in proximal fluid reabsorption further limits the delivery of NaCl and water to the diluting segments.

Diuretics are commonly associated with hyponatremia, and the offending agents are almost always thiazides.[10] Thiazide diuretics contribute to impaired water excretion through various mechanisms, including decreased delivery of filtrate to the diluting sites caused by impaired dilution of luminal fluid in the early distal tubule as a result of inhibition of the electroneutral NaCl cotransporter leading to generation of hypertonic urine.[71] Thiazides may also directly

increase the water permeability of inner medullary collecting duct tubules.[72] Increased water intake generally contributes to thiazide-induced hyponatremia.[73]

Any condition that causes an increase in AVP will result in decreased free water excretion. A decrease in intravascular volume is a potent physiologic stimulus for the release of AVP. Intravascular volume depletion may result from true volume depletion seen in conditions like vomiting, diarrhea, blood loss, or a salt-wasting syndrome, or from hypervolemic conditions associated with decreased effective circulating volume (e.g., congestive heart failure, cirrhosis, or nephrotic syndrome). Hyponatremia is often seen in these conditions.[28,74,75] Patients with cirrhosis or congestive heart failure also have a reduced ability to excrete the water load due, in part, to a blunted decrease in urinary AQP2 and AVP levels.[75]

Impaired free water excretion, due to high circulating AVP is usually exacerbated by increased proximal tubular reabsorption of sodium and water and reduced GFR. This results in a decrease in distal delivery of fluid.[74] AVP is usually not measured in the clinical setting but one can assume that levels of this hormone are increased whenever the urine is concentrated.[10] Some studies estimate that as many as 10 to 20% of patients diagnosed with syndrome of inappropriate antidiuretic hormone (SIADH) have AVP levels at the lower limit of detection by radioimmunoassay.[76] It has been suggested that non-AVP ligands (e.g., oxytocin, nitric oxide, and atrial natriuretic peptide (ANP)) may activate AQP2, causing water retention.[10,70,77,78]

The possibility that ANP release may promote AQP2 channel activity could explain, in part, the mechanism underlying hyponatremia associated with some kinds of neurosurgical disease[79] such as in cerebral salt wasting, a syndrome where hyponatremia develops in the setting of cerebral disease or trauma.[80] In contrast to SIADH, cerebral salt wasting is typically characterized by volume depletion. The primary defect here is sodium wasting, which then results in volume-induced stimulation of AVP release. Cerebral salt wasting is associated with increased circulating atrial and brain natriuretic peptides that increase the GFR and decrease proximal sodium reabsorption causing natriuresis and volume depletion.[80,81]

Electrolyte-Free Water Clearance in the Assessment of Hyponatremia

The following example illustrates the use of the electrolyte-free water clearance in a hypothetical patient with hyponatremia before and after treatment with a vasopressin V_2 antagonist (Table 74.6).[66]

TABLE 74.6 Changes in Serum and Urinary Parameters Before and After Therapy with a V2 Antagonist in a Hypothetical Patient

	SNa, mEq/L	SOsm, mOsm/L	UNa, mEq/L	UK, mEq/L	UOsm, mOsm/L	Urine volume, ml
Pretreatment	126	262	100	60	600	1400
Post-treatment	134	280	80	40	400	2000

The electrolyte-free water clearance (C^eH_2O) for this patient before the administration of a vasopressin antagonist is:

$$\begin{aligned} C^eH_2O &= V \times \{1 - (U_{Na} + U_K)/S_{Na}\}/\text{time} \\ &= 1400 \times \{1 - (100 + 60)/126\}/24 \text{ hours} \\ &= -378 \text{ ml/24 hours} \end{aligned} \quad (74.13)$$

The free water clearance according to the classical formula is:

$$\begin{aligned} CH_2O &= V \times \{(1 - U_{Osm}/S_{Osm})\}/\text{time} \\ &= 1400 \times \{(1 - 600/262)\}/24 \text{ hours} \\ &= -1806 \text{ ml/24 hours} \end{aligned} \quad (74.14)$$

The electrolyte-free water clearance and free water clearance after treatment are as follows:

$$\begin{aligned} C^eH_2O &= V \times \{1 - (U_{Na} + U_K)/S_{Na}\}/\text{time} \\ &= 2000 \times \{1 - (80 + 40)/134\}/24 \text{ hours} \\ &= +209 \text{ ml/24 hours} \end{aligned} \quad (74.15)$$

and

$$\begin{aligned} CH_2O &= V \times \{(1 - U_{Osm}/S_{Osm})\}/\text{time} \\ &= 2000 \times \{(1 - 400/280)\}/24 \text{ hours} \\ &= -857 \text{ ml/24 hours} \end{aligned} \quad (74.16)$$

Practically speaking, the negative electrolyte-free water clearance pretreatment, which is indicative of renal water retention, predicts that the hyponatremia will worsen unless something is done therapeutically and should alert the clinician to the need for more aggressive treatment. For hyponatremia to improve, water excretion must be increased or sodium needs to be gained in excess of water by the administration of hypertonic saline. The latter, however, is not indicated in asymptomatic subjects with moderate hyponatremia.

The principles discussed in the preceding paragraphs are a guide to the rational treatment of hyponatremia, but the urgency and modality of treatment are determined by the presence and severity of symptoms.[66] Once the electrolyte-free water clearance becomes positive, in the case illustrated by the

aquaretic action of a V_2 antagonist, the correction of hyponatremia can potentially occur.[66] As long as the electrolyte-free water clearance is positive, hyponatremia will improve according to the principle of the steady-state unless the patient's water intake exceeds the water output, C^eH_2O plus insensible and stool losses. Water restriction still is needed but, as the positive electrolyte-free water clearance becomes larger in magnitude, the water restriction can be relaxed. Because the administration of V_2 antagonists "vaptans" increases plasma sodium and thus, it may also increase thirst, one should be cautious not to prescribe too strict a water restriction while using these agents.[66] In fact, while using these agents water restriction should be avoided once the positive free water clearance is established and plasma sodium has increased to a safe range.

The electrolyte-free water clearance and the free water clearance usually agree (qualitatively) in their assessment of the renal capacity to excrete water, but as the example in Table 74.6 shows, the free water clearance can sometimes be deceiving.[66] Before treatment, both the electrolyte-free and free water clearances were negative and predicted exacerbation of hyponatremia, but after treatment with a V_2 antagonist, the electrolyte-free water clearance (C^eH_2O) became positive whereas the FWC remained negative. The FWC stayed negative in value because the U_{Osm} remained greater than the S_{Osm}, likely as a result of the urine urea nitrogen (UUN), which keeps the urine osmolarity at a relatively high level.[66] UUN represents a "liability" for the use of FWC as a tool to interpret renal water handling during hyponatremia because urea is freely permeable across membranes and typically does not affect water movement. The persistence of a negative value for FWC might lead some to believe that water is still being reabsorbed, when in fact the kidneys are excreting free water, as indicated by the positive electrolyte-free water clearance (and supported by the FWC becoming less negative). Thus, to be meaningful, the FWC must be followed longitudinally; any single value in time could be misleading.[66] In contrast, the electrolyte-free water clearance gives a more accurate clinical picture, as it is not affected by the problem of urea being an ineffective osmole. We advocate the use of electrolyte-free water clearance over regular FWC as it helps in assessing whether the kidneys are avidly retaining water and whether hyponatremia is likely to worsen or improve. It also aids in the prescription of an appropriate degree of water restriction and other interventions to treat hyponatremia.[66]

C^eH_2O can be simplified through the use of the urine/plasma electrolyte ratio.[82] When the ratio ($U_{Na} + U_K/S_{Na}$) is below 1.0, C^eH_2O has to be positive, therefore reflecting that electrolyte−free water is being excreted (see Table 74.7). When the ratio is even lower (i.e., <0.5), significant amounts of electrolyte-free water are being excreted.[82] In contrast, no electrolyte-free water is being excreted when the ratio is equal to 1.0 or higher (Table 74.7).

TABLE 74.7 Approach to Raising Plasma Tonicity by Water Restriction

Urine/Plasma Electrolyte Ratio	Insensible H_2O Losses	Expected Net H_2O Loss[a]	Recommended H_2O Consumption
≥1.0	800 mL	−800 mL	0 mL
0.5−1.0	800 mL	−800 to −1300 mL	up to 500 mL
≤0.5	800 mL	−1300 to −1800 mL	up to 1 L

[a]*These estimates are based on a U/P ratio, a simplified formulation of CeH2O. They also assume that urine sodium and potassium losses are replaced, that a patient has an average body surface area of 1.73 m2 and eats a normal diet, and calculate for the period during which the next 1 L of urine is excreted.*

Physiologic Principles Guiding Assessment of Polyuric Syndromes

Polyuria is arbitrarily defined as a urine volume of more than 3 L/day in adults and 2 L/m2 in children. Comparing the urine volume in an individual to the average values in a group of subjects, however, is not as physiologically relevant as the urine volume expected for a given stimulus.[83] An individual on a typical diet has an osmole excretion rate of 900 to 1200 mOsm/day. In contrast, the osmole excretion rate in an individual on a low-protein, low-salt diet would be much lower, say 300 mOsm/day. If this individual were capable of maximal urinary concentrating capacity, the U_{Osm} will be 1200 mOsm/kg H_2O, and this subject's expected minimum urine volume would be 0.25 L/day. If this subject has impaired urinary concentrating ability (e.g., a maximal U_{Osm} of about 600 mOsm/kg H_2O) then the minimum urine volume would be 0.5 L/day. This is more than the expected minimum and thus would indicate polyuria due to impaired renal concentrating ability. This example illustrates the inappropriateness of applying data gathered from one population (subjects consuming their usual diet), in defining a condition such as polyuria, to a population with a much lower osmole excretion rate (subjects consuming a low-protein and low-salt diet).[83,84]

Polyuria may be due to a primary surplus of free water (water diuresis) or to the presence of excess osmoles in the urine (osmotic diuresis).[13] To

differentiate the various causes of polyuria, one needs information on urine electrolytes and osmolality. Plasma osmolality should be measured and also calculated from plasma sodium, plasma glucose, and plasma urea. Urine osmolality helps differentiate a water diuresis from an osmotic diuresis. In water diuresis, there is a large volume of dilute urine, with the urine osmolality usually below 250 mOsm/kg H_2O. If the U_{Osm} is more than 300 mOsm/kg H_2O in a polyuric subject, an osmotic diuresis is to be suspected.[13] Further, total solute excretion (calculated on a 24-hour urine collection from the product of the urine osmolarity and the urine output) is normal with a water diuresis (600–900 mOsm/day) but markedly increased (usually more than 1200 mOsm/day) with an osmotic diuresis. In osmotic diuresis, decreased solute reabsorption is the primary abnormality. Glucosuria, high-protein feedings (in which urea acts as the osmotic agent), volume expansion due to saline loading, or impaired sodium reabsorption following the release of bilateral urinary tract obstruction[85–87] are typical examples.

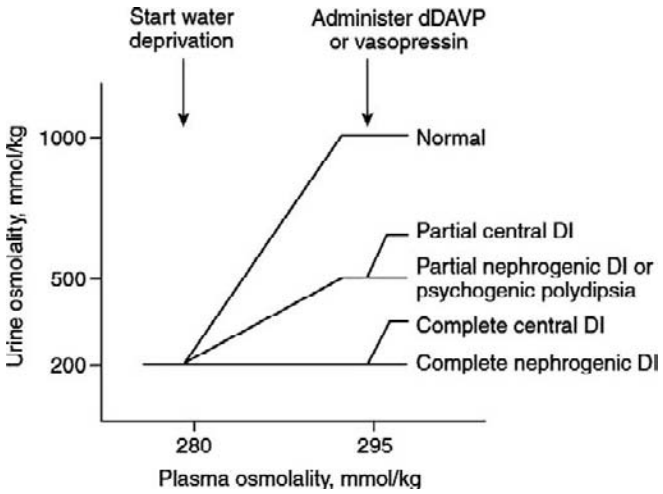

FIGURE 74.4 The diagram shows the typical response after water deprivation in healthy individuals, in patients with complete or partial central diabetes insipidus (DI), in patients with complete or partial nephrogenic DI, and in patients with primary or psychogenic polydipsia. The 200 mmol/kg straight line is for schematic representation because patients with full phenotype (central or nephrogenic DI) have a urine osmolality less than 100 mmol/kg. *(From Sands JM, Bichet DG. Nephrogenic diabetes insipidus. Ann Intern Med 2006;144:186–194, with permission.)*

Direct and Indirect Tests to Evaluate Concentrating Capacity

The three major causes of water diuresis are primary (or psychogenic) polydipsia, central diabetes insipidus (CDI), and nephrogenic diabetes insipidus (NDI). Each of these three disorders is associated with an increase in water output and the excretion of relatively dilute urine. In these cases, urine osmolality can decrease to less than 100 mOsm/kg.[88] With primary polydipsia, the polyuria is an appropriate response to enhanced water intake; in comparison, the water loss is inappropriate with either form of DI. The three disorders can be distinguished from one another by examining the urine osmolality in response to exogenous AVP and to water deprivation (Fig. 74.4).[84,89,90] The fluid deprivation tests provide a standardized approach to interpret urine osmolality, when plasma osmolality is not already elevated. It must be appreciated that there is no need to perform a water restriction test, and, in fact, it is contraindicated clinically when plasma osmolality is above normal.

The first step is to examine plasma sodium. In the polydipsic patient, the plasma sodium is usually in the low range of normal, typically around 135 mmol/L as a result of excessive drinking.[91] On the other hand, in patients with DI, the plasma sodium is in the high-normal range (usually more than 140 mmol/L).[92] A plasma sodium of more than 150 mmol/L is usually not seen in compensated DI, because the initial water loss stimulates the thirst mechanism, thus increasing water intake. In cases where the patients are obtunded or suffering from rare central nervous system (CNS) disorders, where the thirst center is also affected, the patient may have hypo- or adipsia, and thereby develop hypernatremia.

Patients with DI have roughly intact thirst mechanisms and usually do not present with hyperosmolality, but rather, they present with normal plasma osmolality and serum sodium and symptoms of polyuria and polydipsia. In these cases, it is most appropriate to perform a fluid deprivation test.

The water deprivation test can be carried out as an indirect test or by measuring plasma AVP after fluid deprivation.[83] The indirect test has been successfully used in various protocols to make an appropriate diagnosis in most cases (Fig. 74.4).[90] It generally yields interpretable results by the end of the test and does not require sensitive assays for the often unavailable measurement of plasma AVP levels, which are the basis of the direct test.[63] The patient is asked to stop drinking about 12 hours before the test, usually after dinner, and the urine osmolality and volume are measured the following morning. To distinguish central DI from nephrogenic DI, the response to administered AVP (2 to 5 units subcutaneously) or, preferably, the AVP receptor (V_2) agonist desmopressin (DDAVP, 1–2 μg subcutaneously or intravenously) should be assessed. For this, urine osmolality and volume are measured in the two to four hours following AVP administration.

Three different patterns can be observed with the indirect test (fluid deprivation followed by AVP administration):

(1) The urine osmolality does not increase after fluid deprivation (Fig. 74.4).[63,90] This is expected in both complete central and nephrogenic DI despite a modest increase in plasma osmolality caused by the fluid restriction. These two types of DI can be distinguished by administering exogenous AVP. In complete central DI, there is a striking increase in U_{Osm}, between 100 and 800%, with a concomitant fall in urine output.[63,83,93] In complete nephrogenic DI, by contrast, there is an absent response to exogenous AVP (less than 10% increase in U_{Osm}), indicative of total renal resistance to AVP.

(2) The urine osmolality increases after fluid deprivation but only marginally (i.e., less than 50%) (Fig. 74.4).[90] This can be seen in partial nephrogenic DI and in partial central DI. Patients with partial central DI usually achieve a U_{Osm} of 300 mOsm/kg H_2O or higher after AVP administration, while patients with nephrogenic DI typically have a persistently low urine osmolality that rises, but remains well below 300 mOsm/kg H_2O, after exogenous AVP administration.[63,83]

(3) The urine osmolality increases more than 50% after fluid deprivation, usually to above 500 mOsm/kg H_2O (Fig. 74.4).[90] This is observed in primary polydipsia. In this setting, there is no further response to exogenous AVP since endogenous release is intact (provided the patient had been compliant with fluid restriction). It is to be noted that these patients do not reach a normal U_{Osm} of 800 mOsm/kg or more. This is due to impairment of the maximum urinary concentrating ability, resulting from a partial washout of the medullary interstitial gradient, and possibly from downregulation of ADH release and/or renal action during prior protracted water drinking.[94]

Difficulties in interpreting the response to exogenous AVP also can arise in central DI. The water diuresis that occurs in all of these disorders washes out the medullary concentration gradient.[9,84,91,95] In addition, there is a down regulation of kidney AQP2 water channels.[96,97] Thus, the initial increases in urine osmolality in response to administered AVP or dDAVP are not as robust as would be expected.[95] For this reason, plasma AVP levels should be measured to aid in this distinction; hyperosmolar patients with nephrogenic DI will have clearly elevated AVP levels while those with central DI will have undetectable levels (complete central DI) or relatively low AVP levels (partial central DI) relative to the high plasma osmolality.[83]

The measurement of AVP after fluid deprivation has been shown to provide a definite diagnosis in most cases of polyuria and polydipsia, provided the final level of plasma osmolality is above 295 mOsm/kg H2O or the final serum sodium is more than 145 mmol/L.[83] The magnitude of the AVP response to osmotic stimuli is not appreciably diminished by pre-existing chronic overhydration or dehydration.[98] Hence, the relationship of plasma AVP to plasma osmolality is usually within or above normal limits in nephrogenic DI and primary polydipsia. In most cases, nephrogenic DI and primary polydipsia can then be distinguished by measuring urine osmolality before and after the dehydration test and relating these values to the concurrent plasma AVP concentrations. Given the proven usefulness of both the indirect and the direct approaches, a combined fluid deprivation test that synthesizes the crucial aspects of both tests can easily be performed, and in many cases will allow interpretation of both the plasma AVP levels and the response to an AVP challenge. By combining the fluid deprivation test with plasma AVP determinations, greater than 95% of all cases of polyuria and polydipsia can be diagnosed accurately.[83,89]

An unusual situation that mimics central DI is a rare syndrome unique to pregnancy that has been ascribed to increased vasopressinase activity.[99–103] In this situation, the levels of AVP are low because of increased degradation and not a result of lack of production. Since vasopressinase does not degrade synthetic dDAVP, treatment with this analogue is effective. The diagnosis can be made by finding detectable levels of endogenous AVP, which is unlike in severe central DI, and by the increase in urine osmolality seen after exogenous AVP administration or dDAVP, which resembles central DI. These features would not be conclusive if it were not for the clinical setting and the prompt resolution of the symptoms after childbirth.[102–104]

The interpretation of therapeutic responses in the syndromes of DI is best assessed in terms of urine volume in the new steady-state. The clinical response is apparent from the ability to excrete the same daily solute load in a smaller volume of urine.[52] For instance, studies in patients with polyuria due to long-term use of lithium revealed a significant improvement in the urine volume after administration of amiloride (Fig. 74.5).[52] In this study, after weeks on amiloride, urine output decreased, on average, from 4.7 L to about 3.1 L. It should be noted that this has measurable clinical benefit, in terms of decreasing urinary frequency, both at daytime and nighttime. This clinical benefit cannot be assessed by the simple measurement of maximal U_{Osm}, which provides only a qualitative assessment of the renal concentrating ability.

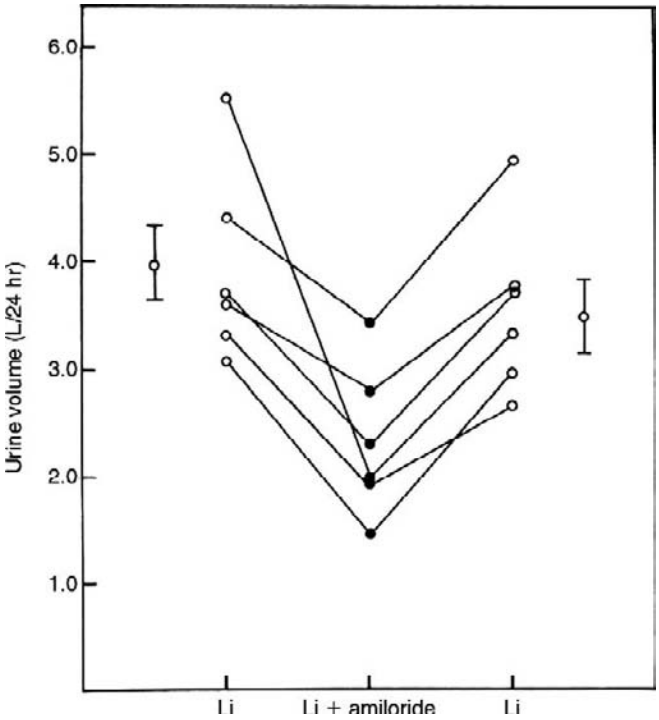

FIGURE 74.5 Twenty-four-hour urine volume in six patients (patients 1, 2, 4, 6, 7, and 9), before, during, and after amiloride administration (20 mg daily). Li, lithium. *(From Batlle DC, von Riotte AB, Gaviria M, Grupp M. Amelioration of polyuria by amiloride in patients receiving long-term lithium therapy. N Engl J Med 1985;312:408–14. EVALUATION OF POTASSIUM DISORDERS

In the steady-state, urinary potassium excretion varies in proportion to dietary intake (median dietary intake is 56 to 84 mEq/day).[105–107] The correlation between dietary potassium intake and urinary potassium content is high ($r = 0.82$).[87] About 90% of ingested potassium is excreted in the urine,[108] with renal excretion varying from10 mEq/day under conditions of potassium deprivation to 700 mEq/day under conditions of potassium loading. Less than 15% of ingested potassium is excreted in the stool (5–15 mEq/day) and a small amount is lost through sweat. It is of interest to note that our modern diet (e.g., saturated fats, oils, cereal grain) is relatively potassium-poor when compared to the potassium-rich diet of our Paleolithic ancestors (e.g., fruits, leafy greens).[109] A list of potassium rich foods is given in Table 74.8.

Approximately 80 to 90% of the filtered potassium is reabsorbed in the proximal tubule and the loop of Henle.[105–107] Of this, approximately 65% is reabsorbed in the proximal tubule and 25% in thick ascending limb of loop of Henle.[98] Potassium is secreted by the principal cells in the cortical collecting tubule via a specific channel called renal outer medullary potassium channel or ROMK.[105,106] In the cortical and outer medullary collecting tubules, the intercalated cells can reabsorb potassium, and thereby counteract the potassium secretion by the principal cells.[110] This process is mediated by an active H^+/K^+-ATPase pump in the luminal membrane, which results in both H^+ secretion and potassium reabsorption.[111,112] The activity of this pump is increased with potassium depletion[111,112] and is reduced with potassium loading.[111]

Tubule flow rate and luminal sodium concentration may independently affect potassium secretion.[113–116] A flow-dependent fall of lumen potassium concentration when delivery of fluid to the distal tubule is increased favors the chemical gradient for potassium secretion.[107,117–119] The relationship between potassium secretion and flow or sodium concentration is initially very steep and then potassium secretion tends to plateau.[107,118,120] While flow rate and sodium concentration may be shown to have independent effects on potassium secretion experimentally, they are usually interdependent on each other. In fact, the increase in distal potassium secretion with increasing flow rate largely depends on the associated increase in sodium concentration in the lumen of the distal tubule which, when reabsorbed via the sodium channel (ENaC), creates a favorable voltage for potassium secretion.[107]

Chronic adaptations take place with either potassium deprivation, surplus, or changes in sodium delivery that involve amplification of both potassium retaining mechanisms (i.e., kaliferic effect) and potassium excretory mechanisms (i.e., kaliuretic effect).[121] When potassium intake is increased, the ability to excrete potassium is greatly enhanced. This adaptive response is evident within one day of increasing potassium intake and persists for one to two days following return to baseline levels of potassium intake. High potassium intake inhibits salt and water reabsorption by the proximal convoluted tubule and/or the thick ascending limb, which results in an increase in sodium delivery and flow rate to distal nephron potassium secretory sites. High potassium intake also stimulates aldosterone which further enhances potassium secretion.[107] Potassium deprivation on the other hand leads to suppression of potassium secretion and enhancement of active tubular potassium absorption, partly as a result of suppression of aldosterone levels due to low serum potassium concentration and also by inhibition of potassium secretion by a decrease in ROMK channel activity in the CCD.[122,123]

TABLE 74.8 High Potassium Foods

Highest (>1000 mg/100 g): (About 1% K+, 10 mEq = 750 gm)	Very High (>500 mg/100 g): (About 0.5% K+, 10 mEq = 750 gm)	High Content (>250 mg/100 g): (About 0.25% K+, 10 mEq = 750 gm)		
Dried figs	Dried Fruits (Dates, Prunes)	**Vegetables**	**Fruits**	**Meats**
Molasses	Nuts	Spinach	Banana	Veal and Beef
Seaweed	Avocados	Tomatoes	Cantaloupe	Pork
	Bran Cereals	Broccoli	Orange	Lamb
	Wheat Germ	Winter Squash	Kiwi	
	Lima Beans	Beets		
		Carrots		
		Cauliflower		
		Potatoes		

The suppression of the normally operating kaliuretic mechanisms, while critical to the adaptation to potassium deprivation, is never sufficient to obliterate potassium secretion completely. This explains why, in humans subjected to dietary potassium deprivation with intake of less than 1 mEq/day, urinary potassium excretion declines but never actually matches intake.[124–126] This decrease in potassium excretion is gradual and reaches a maximum level in five to seven days (Fig. 74.6).[124] While on a high salt intake the initial decline in potassium excretion is blunted (Fig. 74.6). This suggests that the reduction in potassium excretion is not due to increased reabsorption but rather to decrease in potassium secretion which is, in part, sodium dependent.

With potassium restriction, there is a concomitant increase in free water clearance and enhanced diluting capacity consistent with enhancement of the Na^+-K^+-$2Cl^-$ cotransporter activity in the thick ascending loop of Henle, a mechanism that may play an important role in the renal adaptation required for potassium conservation.[127] Potassium secretion in the CCD, however, may not cease completely even with profound degrees of potassium depletion.[128] The adaptation to potassium deprivation is less efficient in terms of renal potassium retention when sodium intake is concurrently increased (Fig. 74.6).[124] This suggests that kaliuresis cannot be turned down quickly if sodium delivery is increased because high intake of sodium favors potassium secretion in the cortical collecting tubule.

Renal potassium wastage is almost always due to enhancement of kaliuretic mechanisms rather than to failure of kaliferic mechanisms.[121] For instance, when mineralocorticoid activity is maintained at a constant level through exogenous administration, in the face of potassium deprivation, a negative potassium balance is seen.[129] Often, several kaliuretic mechanisms may be operating simultaneously (increased distal sodium delivery, increased aldosterone), serving to accentuate the kaliuresis.[121]

Clinical Evaluation of Renal Potassium Handling

The kidney maintains potassium balance primarily by varying the secretion of potassium into the lumen of the distal tubule, according to physiologic needs. Hyperkalemia of renal origin always arises from impaired potassium secretion.[108] The assessment of potassium handling is relatively straightforward since all the potassium that appears in the urine originates from its secretion and this process is restricted to the late distal tubule and CCD, the major site of regulation of potassium secretion.

Many factors influence potassium secretion in the CCD including plasma potassium concentration, dietary potassium intake, flow rate, sodium delivery, transepithelial potential difference, adrenal hormones, and acid–base status.[23] For practical purposes, however, net secretion of potassium in the CCD is critically dependent on and can be best conceptualized and clinically assessed through the interplay of two of these factors: sodium delivery/transport and the level of mineralocorticoid activity.

The interplay between mineralocorticoid activity (aldosterone) and sodium delivery/transport is such that they often, under physiologic conditions, go in opposite directions such that potassium secretion is maintained more or less constant. For instance, when sodium is restricted in the diet, aldosterone goes up

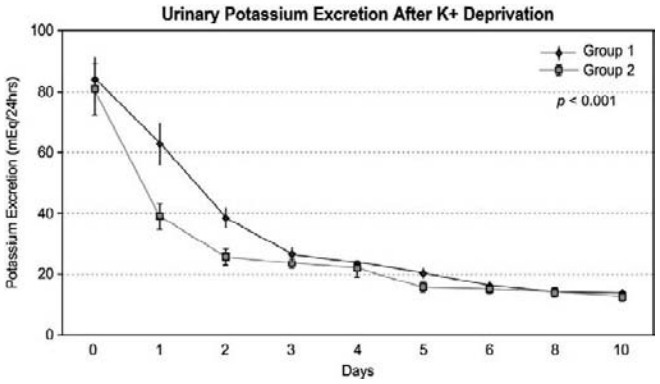

FIGURE 74.6 Urinary potassium excretion (24 hour) in normal volunteers placed on a zero-potassium diet. The upper line (group 1) shows individuals on a high-sodium diet whereas the lower tracing (group 2) depicts individuals on a normal-sodium diet. The initial adaptation to potassium deprivation in the diet is less effective in individuals on a high sodium diet. *(From Cremer EJ, Giricz K, Nakamoto L, Patel S, Schlueter W, Rosa R, Kelani T, Batlle D. Potassium Deprivation in Normal Human Subjects; Impact on Potassium, Sodium, and Acid-Base Balance in Normal Human Subjects. American Society of Nephrology 36th Annual Meeting and Scientific Exposition, 2003, with permission.)*

but sodium delivery goes down and potassium secretion does not change appreciably. Conversely, when sodium is high in the diet, aldosterone is suppressed and sodium delivery increases, resulting in attenuated change in potassium secretion. When both go in the same direction, there are profound changes in potassium secretion, as seen for instance in the syndrome of primary hyperaldosteronism. In this situation, sodium delivery is high and aldosterone is also elevated, resulting in profound potassium wastage and hypokalemia.

The generation of a lumen-negative voltage in the CCD requires an "electrogenic" reabsorption of sodium. The reabsorption of sodium occurs at a faster rate than the reabsorption of its accompanying anion, usually chloride, thereby creating an electric driving force (a "lumen-negative" voltage).[130] Reabsorption of sodium in the CCD occurs by its ion-specific channel (ENaC) in the apical membrane of principal cells. Delivery of sodium to the CCD does not seem to be rate limiting for the secretion of potassium unless when urinary sodium is very low. In other words, provided that urinary sodium is above a critical level of about 20 mEq/L, potassium secretion proceeds provided that there is mineralocorticoid activity. A clinical situation where this is most apparent is chronic liver disease with secondary hyperaldosteronism. In these patients, urinary potassium is very high despite the low urinary sodium.[131]

Potassium channels are not usually rate limiting for the net secretion of potassium.[129] In keeping with this notion, hyperkalemia has not been described as a result of defects in the potassium channel (ROMK). By contrast, interference with the sodium channel often curtails potassium secretion, leading to hyperkalemia. Drugs such as the potassium-sparing diuretics amiloride and triamterene, as well as the antibiotics trimethoprim and pentamidine in their cationic form, block ENaC and hence decrease the lumen-negative driving force for the net secretion of potassium in the CCD.[132,133] These drugs are most effective when urinary sodium is low as they are competitive blockers for sodium uptake. Accordingly, the use of these agents causes hyperkalemia when salt intake is restricted, but is relatively ineffective when salt intake is generous. Conversely, hypokalemia develops when the sodium channel is overactive as seen in Liddle's syndrome, which results from activating mutations in the β or γ subunits of ENaC.[134,135]

Urinary Indices in the Evaluation of Hypokalemia and Hyperkalemia

Urine K^+ Excretion and Spot Urine K^+

Urinary potassium excretion over 24 hours should be sufficient to assess whether the kidney is responding appropriately to the prevailing level of plasma potassium and dietary K^+ intake. If potassium intake is increased slowly, healthy subjects can excrete more than 400 mEq of potassium per day (8 to 10 times normal intake) without a substantial elevation in the plasma potassium concentration.[105–107] Thus, a finding of chronic hyperkalemia invariably reflects the existence of a defect in urinary potassium excretion, since normal renal function would otherwise result in the rapid excretion of the excess potassium.

With potassium depletion of three to five days' duration, 24-hour urinary potassium excretion falls to 10 to 20 mEq/day but never goes below this level (Fig. 74.6).[121,124–126] Thus, in hypokalemia, an appropriately low urinary potassium excretion suggests extrarenal losses (usually from the gastrointestinal tract) or the remote use of diuretics (if the collection has been obtained after the diuretic effect has worn off). In comparison, the excretion of more than 20 mEq of potassium per day indicates a component of renal potassium wasting that is likely the result of inappropriate potassium secretion.

Using a determination of potassium in spot urine may be misleading if urine flow is not taken into account.[13,136] For instance, urinary potassium concentration of 15 mEq/L may be inappropriately high for an individual with hypokalemia who has more than 2 L of urine a day. One can circumvent this by measuring the urine potassium/creatinine ratio or the urine

potassium/osmolality ratio.[13] Measurement of urinary creatinine concentration concurrent with urinary potassium concentration can provide a better measure of actual potassium excretion rate. A potassium-to-creatinine ratio greater than 20 mEq/g has been suggested to indicate the presence of renal potassium wasting.[130]

Similar to the use of spot urine sodium/urine creatinine ratio to estimate 24-H urinary sodium, spot urine potassium/ urine creatinine ratio has also been used to develop formulas to generate values of 24-hour potassium excretion. Kawasaki et al.[20] proposed the formula:

$$\text{24-hour urinary potassium (mEq/day)} = 7.2 \times \sqrt{X_K}$$

where $X_K = (\text{Spot } U_K/\text{Spot } U_{Cr}) \times$ predicted 24 urinary Cr excretion

$$\begin{aligned}&\text{predicted 24 h urinary Cr excretion (Male)}\\ &= -12.63 \times \text{Age} + 15.12 \times \text{Weight} + 7.39 \times \text{Height} - 79.90 \text{ (mg/day)}\\ &\text{predicted 24 h urinary Cr excretion (Female)}\\ &= -4.72 \times \text{Age} + 8.58 \times \text{Weight} + 5.09 \times \text{Height} - 74.50 \text{ (mg/day)}\end{aligned}$$

Linear correlation between formula-estimated and actual 24-hour urinary potassium was 0.44.[20] Thus, the estimation is not precise but maybe of some use in epidemiologic studies where potassium excretion and intake is being estimated using this formula when 24 h potassium excretion is not available.

Fractional Potassium Excretion (FE_K) and Transtubular Potassium Gradient (TTKG)

The fractional excretion of potassium (FE_K) reflects the amount of potassium excreted in relation to the amount of potassium filtered:

$$FE_K\,(\%) = U_K \times V/GFR \times P_K \times 100 \qquad (74.17)$$

When GFR is not available, FE_K can be calculated by the formula that uses plasma and urine creatinine:

$$FE_K\,(\%) = (U_K \times P_{cr})/(P_K \times U_{cr}) \times 100 \qquad (74.18)$$

The FE_K is useful in the evaluation of hyperkalemic syndromes occurring in the setting of chronic kidney disease (CKD). It has the advantage that it takes into account the prevailing GFR, which is usually reduced in patients with chronic hyperkalemia.[137,138]

Often renal hyperkalemia is due to selective aldosterone deficiency or tubular defects in potassium secretion associated with some causes of CKD.[139] In such patients, GFR is usually decreased but higher than 25 ml/min, a level not low enough to account for hyperkalemia. Fractional potassium excretion in these hyperkalemic patients is lower than that of subjects without hyperkalemia and comparable GFR (Fig. 74.7).[137] In the setting of reduced GFR, fractional potassium excretion is useful as it reveals reduced potassium secretion relative to GFR while absolute potassium excretion may be the same as that of normokalemic patients with comparable GFR. Since plasma potassium is elevated, however, absolute potassium excretion relative to the filtered load of potassium is inappropriately low. The following example illustrates this. A patient with a GFR of 25 ml/min has plasma potassium of 6.0 mEq/L and a urinary potassium excretion of 60 mEq/day (Table 74.9). The excretion of potassium may be the same as that of a healthy individual with a GFR of 100 ml/min but plasma potassium of 4.0 mEq/L. Clearly, the excretion in the hyperkalemic patient is low relative to the elevated plasma K^+ and the fractional K^+ excretion does not reflect this because the widely different GFR. Accordingly one needs to compare the FE_K to an individual with a similarly reduced GFR but without hyperkalemia. In this example the hyperkalemic patient has a fractional excretion of 40% which is much lower than that of the normokalemic patient with the same GFR (Table 74.9 and Fig. 74.7).[137]

In the evaluation of hypokalemia, the fractional potassium excretion offers little advantage to simply

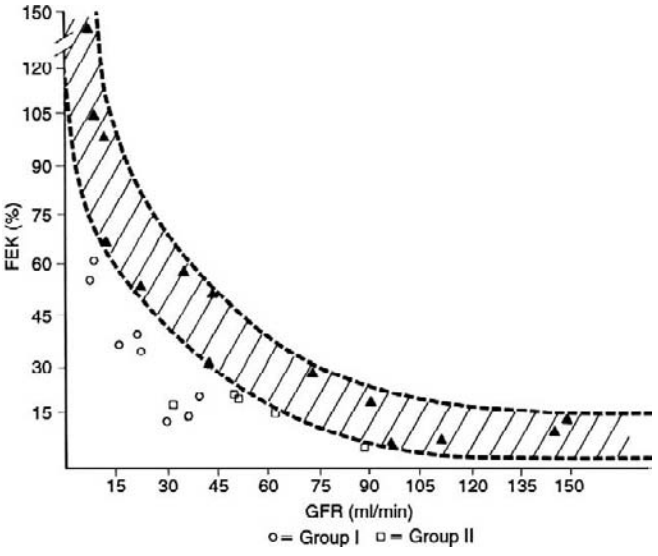

FIGURE 74.7 Relation of fractional excretion of potassium (FEK) to glomerular filtration rate (GFR) under baseline conditions. The area inside the broken lines depicts the normal adaptive increase in FEK observed with a chronic reduction in GFR. Each patient (*open symbols*) had baseline FEK lower than that expected for the corresponding GFR. Open circles denote patients with hyperkalemic distal renal tubular acidosis; open squares represent patients with hyperkalemic metabolic acidosis due to selective aldosterone deficiency. *(From Batlle D, Arruda JAL, Kurtzman NA. Hyperkalemic distal renal tubular acidosis associated with obstructive uropathy. N Engl J Med 1981;304:373–80. TABLE 74.9 Comparison of FE_K with Varying GFR

GFR	Plasma K^+	UK × V	FEK
100	4.0	60	15
25	6.0	60	40
25	4.0	60	60

FEK, fractional excretion of potassium; GFR, glomerular filtration rate.

measuring urinary potassium excretion. A FE_K less than 6% is consistent with appropriate potassium conservation as determined from an analysis of potassium excretion by healthy subjects subjected to dietary potassium deprivation.[125,140,141]

To assess the potassium secretory process in the CCD, the use of the transtubular potassium gradient (TTKG) was introduced.[142] This index is conceptually attractive as it focuses on CCD events where the secretion of potassium is regulated. The first step in the use of this test is to reach an approximation of the K^+ in the lumen of the terminal CCD. This is done by correcting the urinary potassium concentration for the amount of water reabsorbed in the MCD as reflected by dividing urinary potassium concentration by the urine-to-plasma osmolality ratio:

$$K^+CCD = K^+urine/(urine\ osmolality/plasma\ osmolality) \quad (74.19)$$

The TTKG can then be calculated by dividing the K^+CCD by the plasma K^+ as follows:

$$TTKG = \{K^+urine/(urine\ osmolality/plasma\ osmolality)\}/K^+plasma \quad (74.20)$$

The TTKG therefore reflects the driving chemical force for net potassium secretion in the CCD. The validity of this index relies on several assumptions. First, by correcting for water reabsorption in the MCD, it is assumed that most osmoles delivered to the MCD are not reabsorbed in the MCD (i.e., the urine must be at least iso-osmolar with plasma).[142] This assumption is valid except in states of contracted EABV.[3] A second assumption is that potassium is not secreted or reabsorbed in the MCD.[3] This assumption, however, may not be valid in conditions of extreme potassium depletion where net reabsorption of potassium in the MCD can occur and also in conditions of supraphysiologic potassium intake, where potassium secretion in the MCD is seen.[3] A third limitation with the use of the TTKG is that at very high flow rates, the TTKG, if examined in isolation, may falsely underestimate potassium secretion due to lack of equilibration in the cortical distal nephron.[13] With these caveats in mind, the TTKG is a valid clinical tool to assess the driving force for net potassium secretion in the CCD.

Rather than focus on a range of normal values for TTKG, it is more useful clinically to evaluate TTKG in terms of expected values.[136,137,139,142] A large deviation from expected values implies that there is a renal impairment in potassium homeostasis due to either an intrinsic renal defect or because of a normal renal response to an inappropriate stimulus for potassium excretion (e.g., hyperaldosteronism in the presence of hypokalemia).[136] In a study by Ethier et al., expected values for TTKG were derived under stimuli known to modulate potassium excretion, i.e., potassium deprivation, high mineralocorticoid activity and acute potassium loading.[142] On the basis of this study, it was concluded that the value for TTKG should be close to 1.0 in individuals on a low-potassium diet for at least 3 days and that the value for TTKG during hyperkalemia with normal adrenal and renal function should be 10 or higher.[142] Failure to note this high a level with hyperkalemia would imply an intrinsic renal defect or lack of stimulation of potassium secretion (e.g., low aldosterone activity).[130] In a more recent study of hypokalemic patients, TTKG was higher in patients with mineralocorticoid excess (13.3 ± 4.4) and diuretic usage (8.6 ± 1.3) and lower in those with diarrhea (1.6 ± 0.3) than in normal controls, reflecting renal potassium conservation.[136] Another use for TTKG is to follow the renal response to therapy for a potassium disturbance. If a patient with hyperkalemia due to hyporeninemic hypoaldosteronism is to be treated, the TTKG that is initially low (or, at least, inappropriately so) should increase with the administration of fludrocortisones.[143] While the TTKG is an appropriate tool to conceptualize the renal site responsible for hyperkalemia, at the practical level, one can assume that hyperkalemia results from decreased CCD potassium secretion any time that urinary potassium excretion is low in the face of a high level of plasma potassium.

Clinical Approach to Potassium Disorders

In most cases of hypokalemia, the diagnosis is apparent from the clinical history, physical examination and review of medications, such as with diarrhea, vomiting and diuretic use.[136] The physical examination should focus on evidence of volume depletion and the presence or absence of hypertension. A search for possible medications that can alter extrerenal

potassium handling is always in order.[144] Analysis of acid–base status can also be helpful in determining the etiology of hypokalemia. Hypokalemia due to vomiting and nasogastric suction can be associated with metabolic alkalosis. In contrast, diarrhea-related hypokalemia is usually associated with metabolic acidosis. Hypokalemia associated with moderate metabolic alkalosis secondary to diuretic use is common, with volume depletion and secondary hyperaldosteronism playing important roles in the development of hypokalemia.

Determining the cause of hypokalemia can sometimes be challenging, especially in patients who surreptitiously use laxatives or diuretics, as this is often denied by these patients. Laxative abuse is usually associated with metabolic acidosis. Surreptitious vomiting, as in bulimia, and illicit use of diuretics may be seen in weight-conscious individuals. Patients with hypertension and otherwise unexplained hypokalemia should be suspected of having primary hyperaldosteronism. Bartter's and Gitelmann's syndrome are characterized by severe hypokalemia and metabolic alkalosis, which usually manifests in childhood. In these patients, blood pressure is usually low or normal, and hyperreninemia and hyperaldosteronism are present. Renal magnesium wasting results in hypomagnesemia and hypercalciuria is also seen. In Gitelman's syndrome, hypokalemia is usually milder, but hypomagnesemia is more severe and there is no hypercalciuria. Hypomagnesemia induces renal potassium wasting by poorly defined mechanisms, thus magnesium should be measured in all patients with unexplained hypokalemia.[130,145] The hypocalciuria characteristic of Gitelman Syndrome has never been fully explained. An increase in the transepithelial voltage along the thick ascending limb has recently been proposed as the primary stimulus for increased paracellular calcium reabsorption along this segment.[146–148]

With renal potassium losses, reversing the factors promoting kaliuresis is necessary to correct the hypokalaemia (e.g., high-salt intake in a patient receiving diuretics). The use of potassium-sparing drugs such as amiloride or triamterene may be helpful until the potassium deficiency is ultimately amenable to cure (e.g., an adrenal adenoma causing primary hyperaldosteronism).[121] These drugs may also be used as chronic therapy when a surgical cure is not possible (e.g., bilateral adrenal hyperplasia) or in Liddle's syndrome.

The mere finding of chronic hyperkalemia suggests impaired potassium secretion since with normal renal function, an increased potassium burden would lead to rapid excretion of the excess potassium.[108] The urine potassium concentration will be low in the setting of chronic hyperkalemia, as in the syndrome of hyporeninemic hypoaldosteronism, and with drugs that block sodium channels (e.g., trimethoprim and amiloride).[132] The syndrome of hyporeninemic hypoaldosteronism is an important cause of hyperkalemia in patients with a mild to moderate reduction in GFR. As discussed previously, in the setting of CKD, renal potassium secretion is best assessed using the fractional potassium excretion (Fig. 74.7).[137] In patients with chronic hyperkalemia, FE_K is lower than that of normokalemic patients with similar reductions in GFR (Table 74.9 and Fig. 74.7). This is evidence that potassium secretion is impaired in hyperkalemic patients for any given level of GFR.

Acidosis is known to inhibit renal potassium secretion.[149] Renal potassium excretion is inversely related to ammonium excretion, such that potassium excretion is depressed when ammonium excretion is enhanced as in states of metabolic acidosis.[150] In the classic form of RTA, however, renal potassium excretion is increased, leading to severe hypokalemia despite of acidosis. Clearly then, the driving force for hypokalemia in distal RTA cannot be systemic acidosis which would be expected to decrease potassium secretion. The reason for hypokalemia in the classic form of distal RTA remains to be elucidated.[151] The hypokalemia in distal RTA could be readily explained by a permeability defect causing passive potassium secretion, as occurs with amphotericin B administration.[151,152] A permeability defect as a mechanism of distal RTA, however, seems unique to amphotericin B, so alternative explanations are required to explain the potassium wastage mechanism.[151,153]

Enhanced potassium secretion may be driven by secondary hyperaldosteronism which may be a feature of distal RTA.[154,155] Aldosterone oversecretion could be expected due to sodium wastage which has been documented in some patients with distal RTA.[154,155] This may be a reasonable explanation; however, it is unclear why some patients present with striking hypokalemia while others do not. One attractive mechanism that may explain the hypokalemia is the existence of a defect in the renal H^+/K^+-ATPase pump.[156] Renal potassium excretion is determined not only by active potassium secretion localized largely to the distal tubule and cortical collecting tubule, but also by active potassium absorption localized, at least in part, to the outer medullary collecting tubule.[157,158] If the H^+/K^+-ATPase pump in the collecting tubule were defective in distal RTA, one could explain both hypokalemia and metabolic acidosis.

A strong argument against the H^+/K^+-ATPase theory, however, is the finding that severe hypokalemia occurs in all hereditary types of RTA regardless of the molecular defect involved.[151] Hypokalemia is seen in patients in whom the defect is due to a mutation

of the H^+-ATPase, the AE1 (electroneutral anion exchanger) and the carbonic anhydrase-2 genes.[188–193] This suggests that the mechanism of enhanced potassium secretion is not related to a primary H^+/K^+-ATPase defect.[151] Perhaps a concomitant amplification of secretory mechanisms that involve either the potassium channel, ROMK, or the sodium channel, ENaC, is involved in all types of hypokalemic distal RTA.[151]

EVALUATION OF METABOLIC ACIDOSIS

Metabolic acidosis is a process whereby an excess nonvolatile acid load is placed on the body due to excess acid generation or diminished acid removal by normal homeostatic mechanisms.[159,160] Analysis of acid–base disorders begins with the clinical history and assessment of plasma chloride and plasma bicarbonate. The presence or absence of hyperchloremia is a useful clue in the evaluation of metabolic acidosis.[18] When plasma chloride increases out of proportion to sodium (proportional changes in chloride and sodium can be seen with dehydration), either a chronic respiratory alkalosis or a hyperchloremic metabolic acidosis must be present. A blood gas is usually needed to distinguish with certainty between a metabolic acidosis and a chronic respiratory alkalosis. The type of metabolic acidosis present can be initially approached by assessing whether plasma anion gap (AG) is normal or elevated.

Plasma Anion Gap

The anion gap in plasma is used to differentiate hyperchloremic metabolic acidosis (normal AG) from high AG metabolic acidosis.[161] In a pure hyperchloremic metabolic acidosis, there is an increase in plasma chloride equivalent to the fall in plasma bicarbonate, so that the sum of these two anions remains unchanged. The calculation of the plasma anion gap is part of the diagnostic approach as it allows one to classify the disorders into categories of normal anion gap or elevated anion gap. Although these categories can overlap the classification is nevertheless very useful to clinicians.[160] The plasma anion gap in pure hyperchloremic metabolic acidosis is not increased, and may even be slightly reduced due to buffering of protons by proteins. In hyperchloremic metabolic acidosis, hyperchloremia ensues due to enhanced renal chloride retention.[18]

A clinical setting in which the AG may be misleadingly low is hypoalbuminemic states.[162–164] Albumin is negatively charged and makes up a significant portion of unmeasured anions.[165] Therefore, hypoalbuminemia will lead to an underestimation of the size of the AG and potentially to a failure to recognize a clinically important high AG metabolic acidosis. To circumvent this issue, the effect of serum albumin on the plasma AG must be taken into account in the analysis of acid–base disturbances. Figge et al. derived a formula for the plasma AG that takes into account serum albumin, which is based on a mathematical model that has been verified by experiments *in vitro*.[162] This formula is as follows:

$$\text{Albumin-corrected AG} = \text{AG} + 2.5 \times (4.4 - \text{albumin in g/dl}) \tag{74.21}$$

In other words, for each 1-g/dl decrease in serum albumin below 4.4 g/dl, the observed AG underestimates the actual concentration of unmeasured anions by 2.5 mEq/L.[162] This estimation has been shown to correlate more or less with other formulas that take into account the effect of plasma albumin on the anion gap.[165] An alternative is just to accept that hypoalbuminemia leads to a low anion gap and to use this "baseline" anion gap as the basis for comparison with the current anion gap in an acid–base disorder. For example, if a patient with nephrotic syndrome chronically has an albumin of 2.5 g/dl and thus the anion gap is typically around 7, then a current anion gap of 12, though seemingly normal, would constitute an elevated anion gap of 5 units for this patient and should trigger a search for the cause.

A low plasma AG is seen in certain IgG myelomas in which the cationic nature of the paraprotein causes a rise in chloride anions in order to balance the protein's cationic charge.[166] In contrast, the plasma anion gap is normal or even increased in multiple myeloma associated with IgA and IgG paraproteins.[166] IgG paraproteins have isoelectric points that are higher than physiologic pH and are positively charged. The converse takes place with IgA paraproteins, which have isoelectric points below physiologic pH. They behave like anions and when present in large concentrations, the anion gap should increase. In IgA myeloma, however, the AG is usually normal as a result of co-existing hypoalbuminemia, which may reduce an otherwise elevated AG to a normal level. Thus, the interpretation of the plasma AG requires a careful review of all the possible variables that may affect it.

An additional limitation with the use of plasma AG occurs in the detection of mixed metabolic acid–base disturbances.[163] Traditionally, the relationship between changes in the concentration of unmeasured anions (ΔAG) and change in serum bicarbonate concentration (ΔHCO_3^-) helps uncover the presence of a mixed acid–base disorder (typically a high AG metabolic acidosis accompanied by either a metabolic alkalosis or a normal AG metabolic acidosis). Deviation from the presumed 1:1 ratio in this relationship ($\Delta AG/\Delta HCO_3^-$)

that is present in a high AG metabolic acidosis has been used to diagnose these complex acid–base disturbances.[163] When the ΔHCO_3^- (using a mean normal value for bicarbonate of 24 mEq/L) exceeds the ΔAG, a normal AG metabolic acidosis co-exists. Conversely, when the ΔAG exceeds the ΔHCO_3^-, a metabolic alkalosis is present in addition to the high AG metabolic acidosis. Several studies, however, have indicated that there is variability in this ratio, such that a deviation from a 1:1 ratio may not necessarily indicate the presence of a coexisting normal AG acidosis or metabolic alkalosis. This is due to the fact that this 1:1 ratio may be transient and/or depend on the type of metabolic acidosis present.[163,167–171] Studies involving ketoacidosis or lactic acidosis, as well as rarer causes of organic acid accumulation such as toluene poisoning, showed that ratios either greater than 1 or less than 0.8 (the latter being less common) were observed in the absence of an apparent co-existing metabolic alkalosis or normal AG acidosis.[167,168,172–177] This underscores the importance of considering patient history, physical examination, or other laboratory data in accurately defining an acid–base disorder.[163] Nonetheless, the plasma AG, with all the previously mentioned caveats, provides a convenient "starting point" in the evaluation of metabolic acidosis and helps to monitor over time the changes in unmeasured anions such as lactate during therapy for metabolic acidosis in the acute setting.

Urinary Indices in the Evaluation of Metabolic Acidosis

Various urinary indices, including pH and urinary concentrations of sodium, potassium, chloride, and bicarbonate, as well as assessment of the response to provocative tests, can be used, in most cases, to accurately delineate the cause of a metabolic acidosis and its mechanism. Except in patients abusing laxatives, who often deny the practice vehemently, diarrhea as a cause of hyperchloremic metabolic acidosis is evident from the patient's history.

In patients with diarrhea, such as a patient with severe cholera, the acidosis is often more severe than that accounted for by the bicarbonate loss in the stool.[178] The actual bicarbonate concentration of the stools underestimates bicarbonate loss because of the presence in the intestine of organic acids from bacterial products. Titration of intestinal bicarbonate by these acids lowers the final bicarbonate concentration in the stool, resulting in an underestimation of the net alkali loss. Even taking this into consideration, the measured plasma bicarbonate concentration is often much lower than expected from bicarbonate losses due to co-existing lactic acidemia or renal failure, which are common complications of severe cholera.[178]

In addition, volume contraction from diarrhea may be severe enough to inhibit maximal renal tubular acidification. Euvolemic individuals subjected to a chronic acid challenge can increase acid excretion to as much as 200 mEq/day with only a small decrease in plasma bicarbonate. Although studies on renal acid excretion in cholera patients are not available, it seems reasonable to expect that it may not increase maximally, due to the limitation of impaired sodium delivery. This can be inferred from studies of metabolic acidosis in individuals abusing laxatives.[18,179]

Volume depletion in laxative abusers may be unrecognized because these patients have developed compensatory mechanisms and are not overtly hypotensive.[18,179] These patients often come to medical attention due to hypokalemia of unknown etiology. With laxative abuse, hypokalemia is more often seen than hyperchloremic metabolic acidosis and can be severe due to concomitant diuretic abuse and self-induced vomiting. Aldosterone likewise promotes renal potassium loss in these patients. This latter effect may be attenuated despite hyperaldosteronism if distal sodium delivery is impaired from sodium depletion. Urinary sodium availability also affects the ability to lower urine pH.[179] In salt-retaining states with urine sodium below 25 mmol/L, urine pH cannot be maximally lowered (Fig. 74.8).[15] Here, urine pH is a misleading index of distal acidification in that the "intrinsic" renal capacity for distal H^+ secretion is normal once sodium delivery is increased.[15,179] A clue to the diagnosis of laxative abuse is the virtual absence of urinary sodium, which may be less than 1 mEq/day. This, in turn, impairs maximal distal acidification in response to acidemia. When sodium excretion is increased through salt replacement, urine pH falls maximally and acid excretion increases with improvement in the metabolic acidosis (Fig. 74.9).[179]

Whenever a hyperchloremic metabolic acidosis is present without any obvious cause (e.g., diarrhea) and with a relatively normal GFR, distal renal tubular acidosis (RTA) should be suspected. With appropriate suspicion, the diagnosis can usually be confirmed by the findings of an inappropriately low rate of acid excretion and an inappropriately high urine pH.[180] The urine pH is typically inappropriately high in the classic form of RTA (distal or type I RTA) and low in type IV distal RTA (i.e., selective aldosterone deficiency).[138]

Urine Anion Gap

In the presence of metabolic acidosis, ammonium is the most important component of acid excretion. Urinary ammonium (NH_4^+) is usually not measured in the clinical laboratories but can be inferred by

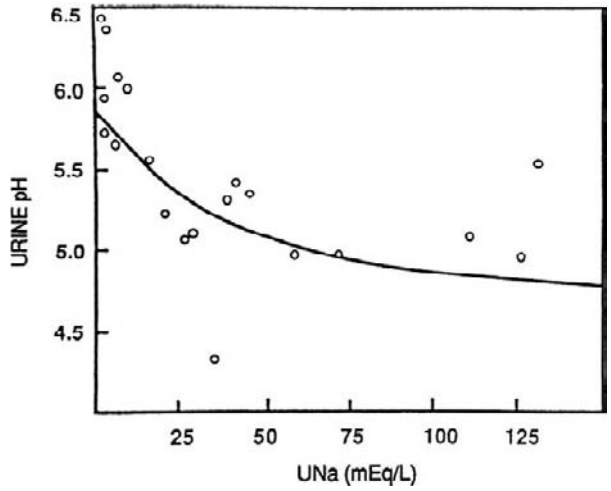

FIGURE 74.8 Urinary pH in relation to urinary sodium concentration in eight patients with diarrhea. Urinary sodium (UNa) was increased by administration of furosemide or sodium chloride. The relation between urinary pH (y-axis) and urinary sodium (x-axis) could be expressed as a curvilinear line, according to the following equation: $y = -0.16 \ln(x) + 5.8$ ($r = 0.75$, $p < .001$). *(From Batlle DC, Hizon M, Cohen E, Gutterman C, Gupta R. The use of the urinary anion gap in the diagnosis of hyperchloremic metabolic acidosis. N Engl J Med 1988;318:594–99. Reprinted with permission of Massachusetts Medical Society, © 1988 Massachusetts Medical Society. All rights reserved.)*

calculating the urine anion gap in patients with a hyperchloremic metabolic acidosis.[15] The principle is similar to that of the plasma anion gap, namely the sum of all anions must equal the sum of all cations. Thus,

$$\{Cl^-\} + \{HCO_3^-\} + \{\text{unmeasured anions}\} = \{Na^+\} + \{K^+\} + \{\text{unmeasured cations}\} \quad (74.22)$$

The unmeasured anions include sulfate, phosphate, and organic anions. Cations not routinely measured include NH_4^+, Ca^{2+}, and Mg^{2+}. NH_4^+ is by far the predominant species in the setting of metabolic acidosis and its excretion can be indirectly estimated through the urinary anion gap (Fig. 74.10).[15] The urine anion gap is calculated from the urine electrolytes by the formula:

$$\text{Urine anion gap} = \{Na^+\} + \{K^+\} - \{Cl^-\} \quad \text{if urine pH is} < 6.5 \text{ or} \quad (74.23)$$

$$\text{Urine anion gap} = \{Na^+\} + \{K^+\} - (\{Cl^-\} + \{HCO_3^-\}) \quad \text{if urine pH is} > 6.5 \quad (74.24)$$

Thus, the urine anion gap provides information regarding the renal response to systemic acidosis.[15,180,181] The urine anion gap will be low (usually a negative value) if there is a decrease in unmeasured anions or an increase in unmeasured cations (e.g., NH_4^+). The urine anion gap will be increased (usually a positive value) if there is an increase in unmeasured anions or a decrease in unmeasured cations (e.g., NH_4^+). Because the concentrations of unmeasured anions in the urine do not change considerably and because NH_4^+ is the major unmeasured cation in the presence of metabolic acidosis, the urine anion gap in this setting provides a rough estimate of urine NH_4^+. It should be noted that the utility of the urine anion gap is limited to the evaluation of metabolic acidosis.[15] In the absence of metabolic acidosis the main determinants of the urine anion gap is the composition of the ingested electrolytes. The urine anion gap can be decreased in diarrhea associated metabolic acidosis, whereas it is typically increased in all syndromes associated with renal tubular acidosis.[15]

Patients with a distal acidification defect (e.g., distal RTA) typically have a positive urine anion gap because of low NH_4^+ excretion, whereas in diarrheal states associated with metabolic acidosis, the urine anion gap is negative, reflecting the fact that NH_4^+ excretion is appropriately increased.[15] Information regarding NH_4^+ excretion from subjects with proximal RTA is limited. The excretion rates of NH_4^+ may not be reduced as compared to those of control subjects.[182–184] For instance, in a study by Brenes et al., the response to a 3-day acid loading test with NH_4Cl was evaluated in eight patients with isolated proximal RTA and in 10 healthy control subjects.[185] In the basal state, all subjects with proximal RTA had rates of NH_4^+ excretion similar to those of the control subjects, suggesting a normal pattern of ammonium renal handling. On the third day of acid loading, however, their NH_4^+ excretion rates were significantly lower than those of controls, demonstrating impairment in maximal urinary NH_4^+ excretion.[185,186] Given this latter finding, it is likely that the urinary anion gap in proximal RTA may not be as negative as in normal people with metabolic acidosis. Although reduced, however, the amount of urinary ammonium may still be sufficient to result in a negative urine anion gap (Table 74.11). Since these previous studies did not provide information on urinary anion gap in proximal RTA, additional data on this parameter are needed from such patients. In distal RTA, the urine anion gap is consistently positive without exception.[15]

Another clinical setting in which the urinary anion gap is useful is with chronic respiratory alkalosis. As with hyperchloremic metabolic acidosis, chronic respiratory alkalosis presents with hyperchloremia and hypobicarbonatemia.[131] Because of these latter findings, a diagnosis of chronic metabolic acidosis is often mistakenly made particularly when blood pH and blood pCO_2 are not available. In reality, many of

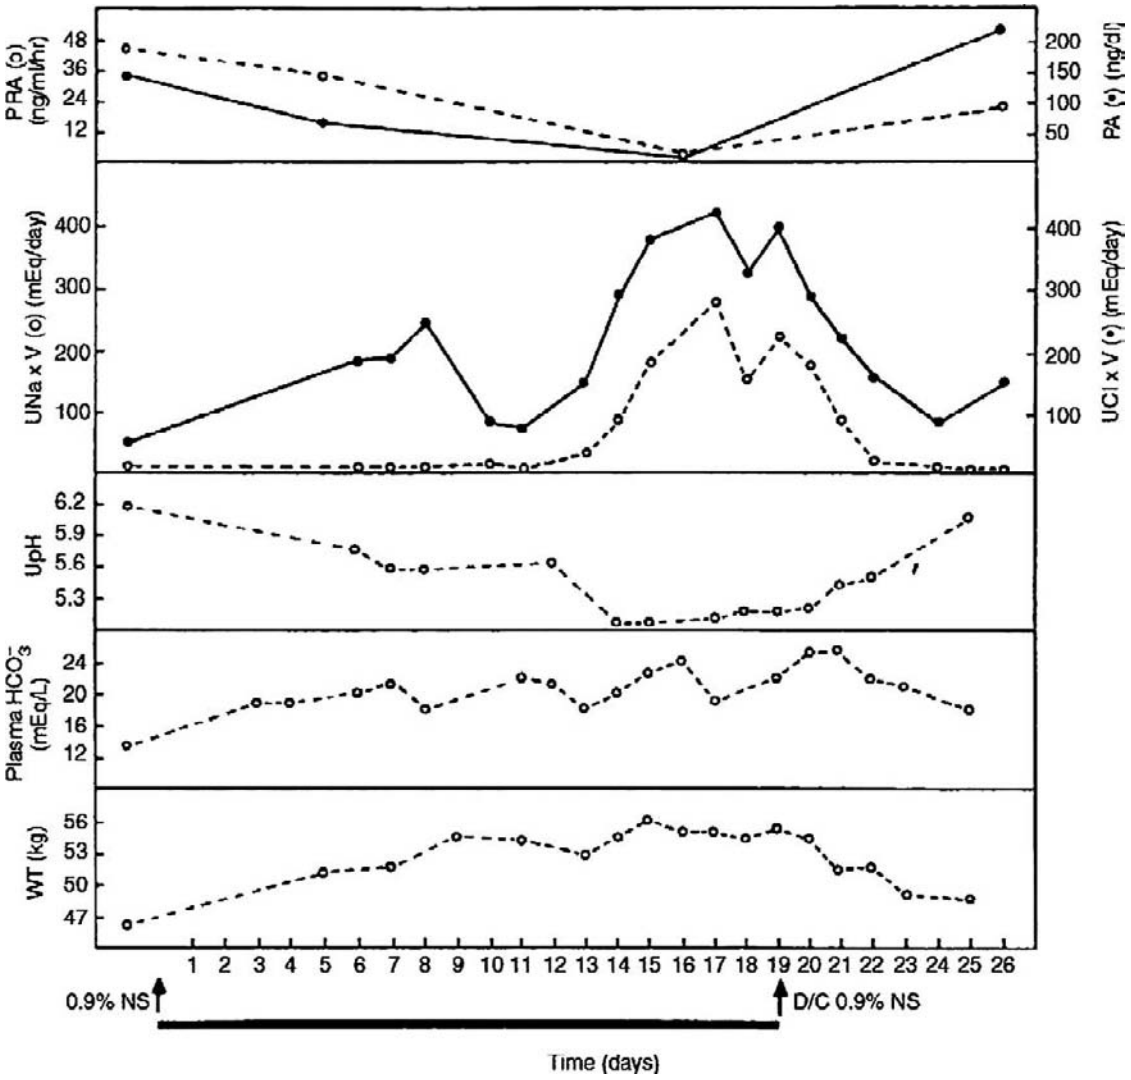

FIGURE 74.9 Effect of daily intravenous saline infusion (0.9% NaCl) on plasma renin activity (PRA), sodium and chloride excretion, urine pH, plasma bicarbonate, and total body weight in a patient who continued to abuse laxatives throughout the observation period. Note the reversible improvement in plasma bicarbonate and the fall in urine pH that occurred during saline administration. *(From Batlle D, von Riotte A, Schlueter W. Urinary sodium in the evaluation of hyperchloremic metabolic acidosis. N Engl J Med 1987;316:140–4. Reprinted with permission of Massachusetts Medical Society, © 1987 Massachusetts Medical Society. All rights reserved.)*

these patients have a chronic respiratory alkalosis but this is not appreciated unless a blood gas is done. The urine anion gap helps to distinguish between a chronic respiratory alkalosis and a chronic metabolic acidosis. A positive urine anion gap in the presence of hyperchloremia and hypobicarbonatemia should suggest a chronic respiratory alkalosis or a renal tubular acidosis (Table 74.10). Because renal tubular acidosis is relatively rare and chronic respiratory alkalosis is frequent in hospitalized patients, we think the urine anion gap is extremely helpful to separate metabolic acidosis from respiratory alkalosis. In chronic respiratory alkalosis, the urine anion gap is positive owing to suppressed ammonium excretion, which serves as an adaptive response to chronic alkalemia. Conversely, the urine anion gap is expected to be decreased (negative) in situations of chronic respiratory acidosis where the formation and excretion of ammonium is increased. Other causes where urine anion gap is increased or decreased are listed in Table 74.11. The acidosis associated with chronic renal failure (or advanced CKD) is largely due to the decrease in ammonium excretion. Normally, an acid load results in a several-fold increase in ammonia excretion with a more modest increase in titratable acid excretion. By contrast, in advanced CKD, despite the prevailing systemic acidosis, there is a failure to increase ammonia

excretion to the levels found in normal subjects with acidosis.[187] Even when factored for GFR, ammonium excretion in patients with advanced CKD fails to increase appropriately.[186,187] Accordingly, the urine anion gap is expected to be increased (positive) with advanced CKD despite the presence of metabolic acidosis (see Table 74.11).

Although, in a qualitative sense, the urinary anion gap roughly reflects urinary ammonium excretion in the setting of hyperchloremic metabolic acidosis, it is not a precise diagnostic index and does have limitations.[15] The urine anion gap is influenced by changes in other unmeasured cations (e.g., calcium and possibly magnesium, the excretion of which are increased during acidosis) or unmeasured anions, or both. For example, the urine anion gap may be decreased (i.e., negative) if the urine contained large amounts of unusual cations such as lithium. Conversely, the gap may be increased (i.e., positive) if the urine contained certain anionic antibiotics such as carbenicillin. In ketoacidosis, the gap is likely to be increased due to the presence of large amounts of ketone anions, despite a high excretion of ammonium.[15,188] In this setting, the urine anion gap would greatly underestimate ammonium excretion. Type of diet and circadian influences can also affect anion excretion and thus influence the urine anion gap.[189] Despite these limitations, the urine anion gap is a useful bedside index of ammonium excretion in a patient with hyperchloremic metabolic acidosis as it helps distinguish metabolic acidosis due to reduced ammonium excretion (i.e., distal RTA) from the acidosis that is due to gastrointestinal bicarbonate losses.

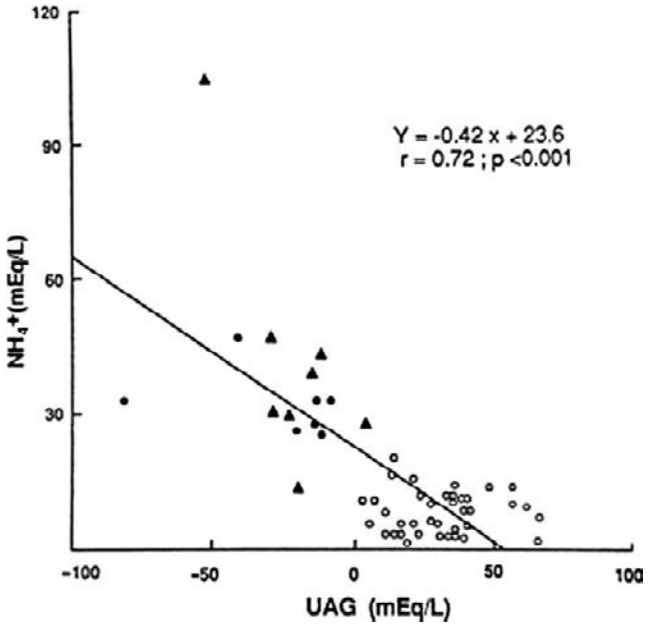

FIGURE 74.10 Urinary ammonium (NH4+) in relation to the urinary anion gap (UAG). Thirty-eight patients with altered distal urinary acidification are represented by open circles; seven normal subjects receiving ammonium chloride, closed circles; and eight patients with hyperchloremic metabolic acidosis associated with diarrhea, triangles. *(From Batlle DC, Hizon M, Cohen E, Gutterman C, Gupta R. The use of the urinary anion gap in the diagnosis of hyperchloremic metabolic acidosis. N Engl J Med 1988;318:594–9. Reprinted with permission of Massachusetts Medical Society, © 1988 Massachusetts Medical Society. All rights reserved.)*

Urine Osmolar Gap

The urine osmolar gap is another method that can be used to indirectly estimate NH_4^+ excretion.[3] The rationale here is that urinary cations (mainly sodium, potassium, and NH_4^+) must be accompanied by an

TABLE 74.11 Conditions where Urinary Anion Gap is Predictably Altered:

1- Increased (Positive) Urine Anion Gap (0 - +50 mEq/l):
• Distal renal tubular acidosis (all types). • Advanced CKD (GFR <20 ml/min). • Chronic respiratory alkalosis. • Vomiting.
2- Decreased (Negative) Urine Anion Gap (0 - − 50 mEq/l):
• Chronic metabolic acidosis from diarrhea. • Proximal renal tubular acidosis. • Chronic respiratory acidosis. • Recovery phase from chronic respiratory alkalosis. • Recovery phase from diabetic Ketoacidosis.

TABLE 74.10 Urine Anion Gap in Various Conditions

	Plasma HCO_3^-	Plasma Chloride	Ammonium	Urine Anion Gap
Metabolic acidosis (diarrhea)	Low	High	High	Negative (0 to −50)
Chronic respiratory alkalosis	Low	High	Low	Positive (0 to +50)
Metabolic acidosis (distal RTA)	Low	High	Low	Positive (0 to +50)
Metabolic acidosis (proximal RTA)	Low	High	Normal or reduced	Unknown*

**Data are limited with respect to use of urine anion gap in proximal RTA. It is possible that the urine anion gap is negative in this setting, reflecting a relatively high rate of ammonium excretion.*
RTA, renal tubular acidosis.

equal number of anions and that the major contributors to urine osmolality are glucose and urea.[3] If all urine components are expressed in mmol/L, the calculated urine osmolality (excluding the portion contributed by NH_4^+ and its anions), is as follows:

$$\text{Calculated urine osmolality} = 2 \times (\text{sodium} + \text{potassium}) + \text{urea} + \text{glucose}$$

The urine osmolar gap is the difference between the calculated and measured urine osmolalities and is assumed to consist of NH_4^+ and its anions. Therefore, urine NH_4^+ concentration is assumed to be equal to half of the urine osmolar gap. One limitation to this estimate is seen with the wide range in the concentration of divalent urine anions, especially sulfate, and of unmeasured urine cations other than NH_4^+ which can be present in variable amounts (e.g., lithium, magnesium, or calcium).[164] Moreover, information on urea and glucose concentrations in urine is usually not available in the usual clinical setting. Thus, it is much easier to use the urine anion gap than the urine osmolar gap to estimate urine NH_4^+.

Minimal Urine pH and Maximal Acid Excretion During Metabolic Acidosis

In addition to measuring urine electrolytes and calculating the urine anion gap, urine pH should be measured to assess the ability of the collecting duct to acidify the urine.[180] Urine pH can be measured during spontaneous metabolic acidosis or after administration of an acidifying salt. It can also be measured following the infusion of sodium sulfate or after giving furosemide. In the presence of systemic acidosis, urine pH should be below 5.5; this would be consistent with appropriate urinary acidification and, thus, exclude distal RTA. The finding of a urinary pH above 5.5 in the setting of systemic acidosis is usually diagnostic of distal RTA, as long as distal Na^+ delivery is adequate. It is important to keep in mind, however, that some patients with RTA have urine pH values below 5.5 during acidosis and still have impaired distal acidification. Many of these patients have hyperkalemia and/or aldosterone deficiency and some have defects in NH_4^+ excretion.[18,138]

Urine pH should be measured in a freshly voided sample in the morning and ideally collected under mineral oil. The presence of mineral oil, however, is not critical, which is contrary to what is traditionally recommended. To rule out a distal acidification defect, inducing only a mild degree of metabolic acidosis is sufficient (i.e., plasma HCO_3^- between 20 and 22 mEq/L). Because the body's homeostatic mechanisms are so efficient, serum HCO_3^- and blood pH can be maintained within the normal range despite ongoing acid challenges such as excessive meat ingestion.[159,190] Unfortunately, there is little information about urinary acidification under these conditions, but it is reasonable to assume that it is appropriately stimulated in terms of enhanced acid excretion. Chronic metabolic acidosis results in decreased citrate excretion.[191,192] A low level of citrate excretion may be a clue to the presence of subclinical or eubicarbonatemic metabolic acidosis.

In normal subjects urine pH is approximately 6.0 for the majority of measurements performed during a 24-hour period.[193] This implies that the urine contains little HCO_3^- and would seem to contradict the view that the kidney maintains acid–base balance in the face of an alkali load by markedly increasing the excretion of HCO_3^-. The traditional formula for net acid excretion is as follows:

$$\text{Net acid excretion} = U_{NH_4^+} + U_{\text{Titratedacid}} - U_{HCO_3^-} \quad (74.26)$$

If bicarbonaturia were the main route for elimination of an alkali load, the expected higher urine pH would, in turn, increase the risk for calcium phosphate stones. Rather than increasing bicarbonaturia, dietary alkali is converted initially to HCO_3^- in the liver and is then titrated through the production of organic acids. Excreting the daily dietary alkali load in the form of organic anions, including citrate, that can be metabolized to HCO_3^- helps to maintain urine pH close to 6.0. In describing the kidney's role in acid–base balance, it is therefore necessary to include the portion of daily dietary alkali load that is excreted in the form of organic anions that can be metabolized to HCO_3^- in the formula for net acid excretion as potential HCO_3^-.[195] A formula for net acid excretion that would take this into account is as follows:

$$\text{Revised net acid excretion} = U_{NH_4^+} + U_{\text{Titratedacid}} - U_{HCO_3^-} - U_{\text{Potential}HCO_3^-}$$

Ammonium Chloride Loading Test

If systemic acidosis is not present, the acidifying agent ammonium chloride can be given orally in a dose of 0.1 g/kg of body weight daily for three to five days or as a single dose of the same cumulative amount.[180] Urine is then collected hourly from two to eight hours. In our experience, the three-day test gives more reliable results and is preferable as it allows time for a maximal increase in NH_4^+ excretion. In healthy subjects, urine pH falls below 5.5 (usually below 5.0) by the first day and continues to remain low.[185] By the third day, ammonium excretion increases at least three- to five-fold. An alternative acidifying agent is calcium chloride (2 mEq/kg of body weight orally), which

TABLE 74.12 Laboratory Workup for Patients Suspected of Having Distal RTA

Tests	Comments
Urine pH	Freshly voided urine collected in mineral oil
	Knowledge of acid–base status needed
	Knowledge of urine $\{Na^+\}$ needed because urine pH does not fall maximally when urine $\{Na^+\}$ <20 mEq/L
	If urine pH <6.3, urine contains little HCO_3^- and proximal RTA unlikely
	If urine pH <5.5, the classic forms of distal RTA can be excluded but not other types such as type IV RTA and some rate-dependent defects
Urine Na^+, K^+, Cl^-	Calculate urine anion gap.[a] Negative value suggests that NH_4^+ excretion is not reduced and tends to rule out distal RTA[b]
Net acid excretion[b]	Calculated as (NH_4^+ excretion + titratable acidity) − HCO_3^- excretion
Other provocative tests[c]	Urine pCO_2 after bicarbonate loading
	Urine pH and acid excretion after furosemide or Na_2SO_4 administration
	Urine pH and urine K^+ excretion after amiloride

RTA, renal tubular acidosis.

gives results similar to ammonium chloride. It can be used in patients who cannot tolerate ammonium chloride due to nausea and vomiting or in patients with liver disease in whom ammonium chloride is contraindicated.[18,196] A suggested laboratory workup of a patient suspected of having distal RTA is summarized in Table 74.12.[180]

Provocative Tests of Distal Acidification

These tests involve the use of sodium sulfate or a loop diuretic to assess Na^+-dependent acidification and can provide additional useful mechanistic information.[137,197,198] By increasing distal sodium delivery, these agents enhance the negative transepithelial potential in the collecting duct and thus stimulate both H^+ and K^+ secretion. A reduction in urine pH accompanied by an increase in potassium excretion following the administration of sodium sulfate indicates a normal response to this enhanced electronegative potential[139,180,197] Fig. 74.11).

Normal subjects can lower urine pH maximally, in the absence of systemic acidosis, provided that distal sodium delivery is increased acutely and while collecting tubule sodium reabsorption is stimulated.[197,199–201] The latter requirement can be achieved by either administration of mineralocorticoid or by placing the subject on a low-sodium diet (i.e., 20 mEq daily) for three days, which stimulates aldosterone release. Aldosterone, in turn, enhances distal sodium reabsorption. The sodium sulfate infusion test can therefore be performed following the administration of fludrocortisone (1 mg orally over the 12 hours preceding the sodium sulfate infusion) or after a low salt diet.[197,202]

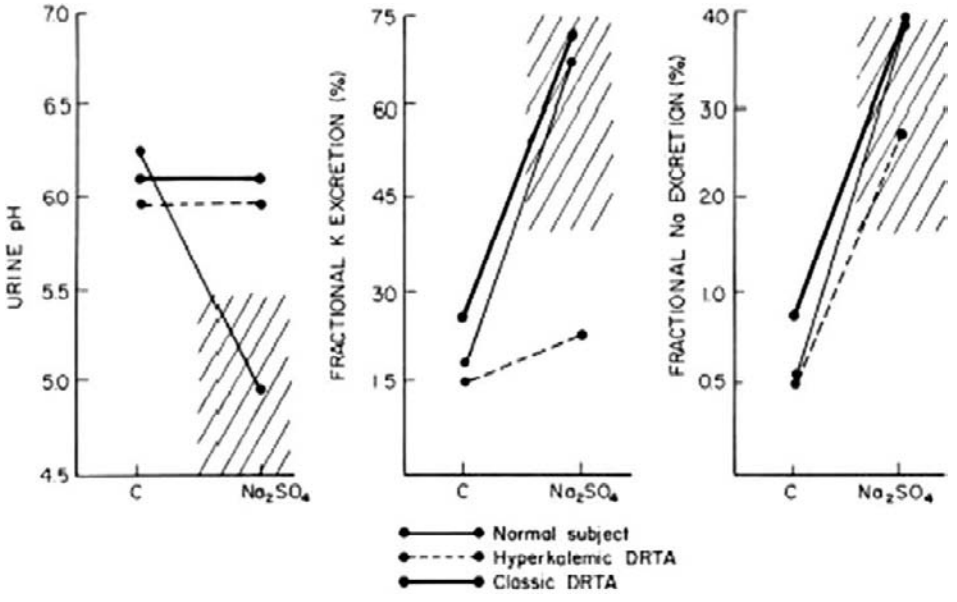

FIGURE 74.11 Response to Na2SO4 in a normal subject, a patient with classic DRTA and a patient with hyperkalemic DRTA. Observe that Na2SO4 fails to lower urine pH and to increase FEK in the patient with hyperkalemic DRTA. In contrast, the patient with classic DRTA increases FEK but cannot lower urine pH normally indicating the presence of an isolated defect for H+ secretion. *(From Batlle, DC. Hyperkalemic hyperchloremic metabolic acidosis associated with selective aldosterone deficiency and distal renal tubular acidosis. Semin Nephrol 1981;1:260–74, with permission.)*

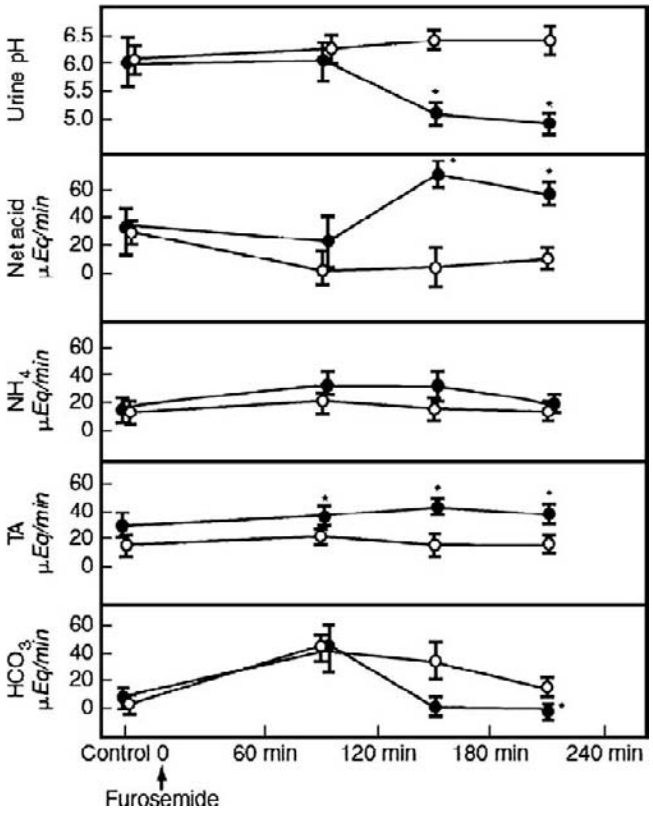

FIGURE 74.12 The effect of furosemide (•) and furosemide + amiloride (o) on urinary acidification in normal subjects. Please note that the lowering effect of furosemide is prevented when amiloride is given concurrently indicating that the effect takes place in the cortical collecting tubule. The asterisk denotes a significant difference between the two experimental conditions. *(From Batlle, DC. Segmental characterization of defects in collecting tubule acidification. Kidney Int 1986; 30:546–54, with permission.)*

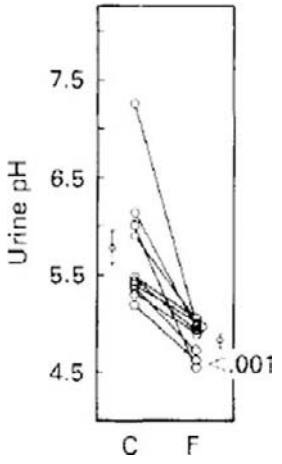

FIGURE 74.13 The effect of Furosemide (F) on urine pH, titratable acid (TA), ammoniurn (NH4), and net acid excretion in ten normal subjects. The data shown in this figure were obtained when urine pH after furosemide was the lowest. C denotes data obtained immediately before furosemide administration. *(From Batlle, DC. Segmental characterization of defects in collecting tubule acidification. Kidney Int 1986; 30:546–54, with permission.)*

When properly performed, the sodium sulfate test results in a fall in urine pH to below 5.5 (usually below 5.0), whether or not systemic acidosis exists. Some subjects may exhibit a late response, so urine collections should continue for two to three hours after the infusion is discontinued. Patients with chronic renal insufficiency also respond normally to sodium sulfate.[202] The increase in acid excretion following sodium sulfate infusion is mainly in the form of NH_4^+. The kaliuretic response that is seen with sodium sulfate administration is also useful in assessing distal potassium secretory capacity (Figure 74.11). Patients with hyperkalemic distal RTA do not increase potassium excretion normally whereas patients with classic distal RTA increase it markedly[137,139,197,199] (Fig. 74.11).

Loop diuretics increase sodium delivery to the collecting duct by blocking NaCl reabsorption in the loop of Henle. Part of the delivered sodium to the distal nephron is reabsorbed in the cortical collecting tubule, which then creates a favorable transepithelial voltage gradient for H^+ and K^+ secretion.[197–199] This interpretation is supported by the finding that the fall in urine pH and the increase in potassium excretion caused by furosemide are obliterated by amiloride (Fig. 74.12).[197,198] Amiloride also mitigates the kaliuretic effect of furosemide. The difference in potassium excretion that is seen, at comparable urine flow rates, when furosemide is given alone and when combined with amiloride demonstrates the significant contribution of the amiloride-sensitive (i.e., Na^+-dependent) component of distal K^+ secretion.[197,198]

The furosemide test is performed by first collecting a urine sample and then giving 40 to 80 mg of furosemide orally.[197] Measurements of urine pH two to four hours following furosemide should give a urine pH below 5.5.[197,198] The test was performed initially without the administration of mineralocorticoid or prior salt restriction to enhance sodium avidity.[197] All subjects responded consistently by lowering urine pH below 5.5 without any prior intervention to enhance avidity for distal sodium reabsorption (Fig. 74.13). More recent studies have used the furosemide test following the administration of mineralocorticoid.[203] While this ensures that distal sodium reabsorption is stimulated we think the furosemide test is reliable even without preexisting minderalocorticoid administration.[197,198] Furosemide when given intravenously[204] or bumetanide administration orally[198] have also been shown to lower urine pH consistently.

The amiloride test is performed by giving 20 mg of amiloride orally following a baseline urine collection

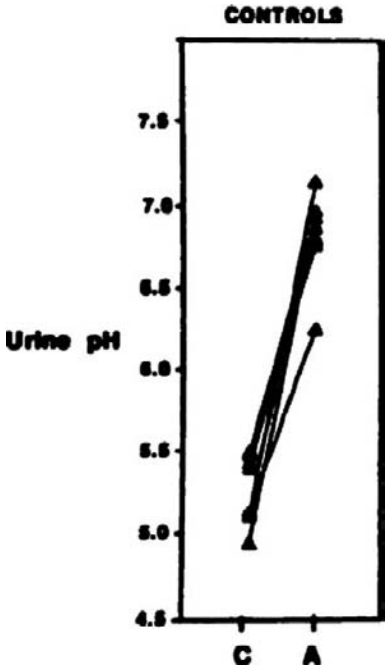

FIGURE 74.14 Effect of amiloride on urine pH in Controls. *(From Schlueter W, Keilani T, Hizon M, Kaplan B, Batlle DC. On the mechanism of impaired distal acidification in hyperkalemic renal tubular acidosis: evaluation with amiloride and bumetanide. J Am Soc Nephrol. 1992 Oct;3 (4):953–64.)*

with hourly urine collections for measurement of pH and electrolyte excretion.[198] Amiloride at low doses blocks apical sodium channels in the cortical collecting duct.[198] Administration of amiloride predictably results in an increase in urine pH and a decrease in urine potassium excretion in normal individuals (Figure 74.14).[198] In patients with a complete voltage-dependent defect, amiloride should not result in a normal increase in urine pH or a further decrease in potassium excretion. A normal response to amiloride (i.e., an increase in urine pH and a decrease in potassium secretion) implies that voltage-dependent H^+ and K^+ secretion is essentially intact.[198] By exclusion then a defect other than a voltage-dependant defect is more likely. It should be noted that for practical purposes, however, the amiloride test is not needed since the presence of hyperkalaemia , in the absence of aldosterone deficiency, suggest a voltage-dependant type of distal RTA.[137]

Another tool to evaluate distal H^+ ion secretion is the assessment of urine PCO_2 in a highly alkaline urine.[205–210] Sodium bicarbonate is given usually intravenously to increase urine bicarbonate concentration to a very high values (urine pH approximately 7.8).[209] This results in a rise in urine PCO_2 to values considerably higher than that prevailing in the blood as a result, at least in part, of H^+ ion secretion in the collecting tubule.[206–210] Normal subjects achieve values of urine PCO_2 higher than 80 mmHg whereas patients with defects in distal acidification fail to increase urine PCO_2 which usually is less than 60 mm of Hg.[209] This test, although cumbersome to execute, is a sensitive test of maximal capacity for collecting tubule H^+ ion secretion. A subnormal rise in urine PCO_2, for example, occurs in patients with incomplete distal RTA.[209]

CHAPTER

75

Biomarkers for Assessment of Renal Function During Acute Kidney Injury

Prasad Devarajan

Nephrology and Hypertension, Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, Cincinnati, Ohio, USA

BIOMARKERS OF ACUTE KIDNEY INJURY—AN UN-MET NEED

The incidence of acute kidney injury (AKI) is rising globally, and so are the associated morbidity and mortality rates. AKI afflicts 5–7% of all hospitalized patients. In critically ill patients, the overall prevalence of severe AKI requiring renal replacement therapy (RRT) is about 6%, with a mortality rate of 60%.[1] Mortality and morbidity from AKI has not substantially improved in the past few decades despite technological advances in supportive care. AKI is largely asymptomatic, and establishing the diagnosis currently hinges on functional biomarkers such as serial serum creatinine measurements. Unfortunately, serum creatinine is a delayed and unreliable indicator of AKI for a variety of reasons.[2] First, normal serum creatinine is influenced by several non-renal factors such as age, gender, muscle mass, muscle metabolism, medications, hydration status, nutrition status, and tubular secretion. Second, a number of acute and chronic kidney conditions can exist with no increase in serum creatinine due to the concept of renal reserve—it is estimated that greater than 50% of kidney function must be lost before serum creatinine rises. Third, serum creatinine concentrations do not reflect the true decrease in glomerular filtration rate in the acute setting, since several hours to days must elapse before a new equilibrium between the presumably steady state of creatinine production and the decreased excretion of creatinine is established. Fourth, serum creatinine production is diminished in critical illnesses such as sepsis, and measured serum creatinine is often further reduced by hemodilution resulting from standard goal-directed fluid therapies. Fifth, an increase in serum creatinine represents a late indication of a functional change in glomerular filtration rate, which lags behind important structural changes that occur in the kidney during the early damage stage of AKI. The delay in AKI diagnosis imposed by our dependence on serum creatinine changes is a problem, since animal studies have identified several interventions that can prevent and/or treat AKI if instituted early in the disease course, well before the serum creatinine begins to rise.[3] The lack of early biomarkers has hitherto hampered our ability to translate these promising therapies to human AKI. Also lacking are reliable methods to assess efficacy of preventive or therapeutic interventions, and early predictive biomarkers of drug toxicity.

DESIRABLE CHARACTERISTICS OF AKI BIOMARKERS

First, with respect to assay characteristics, AKI biomarkers should be non-invasive and easy to perform at the bedside or in a standard clinical laboratory, using easily accessible samples such as blood or urine, with quick turn-around times. The majority of AKI biomarkers described thus far have been measured in the urine. Urinary diagnostics have several advantages, including the non-invasive nature of sample collection,

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00075-6

the reduced number of interfering proteins, and the potential for the development of patient self-testing kits. However, disadvantages also exist, including the lack of sample from patients with severe oliguria, and potential changes in urinary biomarker concentration induced by hydration status and diuretic therapy. Plasma-based diagnostics have revolutionized many facets of medicine, as exemplified by the use of troponins for the early diagnosis of acute myocardial infarction. On the other hand, plasma biomarkers may be confounded by extra-renal sources as well as by subclinical changes in renal elimination. Thus, in the case of AKI, it is ideal to develop both urinary and plasma biomarkers.

Second, with respect to diagnostic properties, AKI biomarkers should be sensitive to facilitate early detection, with a wide dynamic range that allow for risk stratification. They should also be highly specific for AKI, enable the identification of AKI sub-types and differentiate AKI from chronic kidney disease (CKD). Ideally, biomarkers are also needed to identify the primary location of injury (proximal tubule, distal tubule, interstitium, or vasculature), and discern AKI etiologies (ischemia, toxins, sepsis, or a combination).

Third, with respect to prognostic abilities, AKI biomarkers should allow for risk stratification (duration and severity of AKI), prediction of hard clinical outcomes (need for renal replacement therapy, length of hospital stay, mortality) and monitoring the response to AKI interventions. Biomarkers associated with clear biologic plausibility and known pathophysiologic mechanisms in AKI are most likely to satisfy the desired diagnostic and prognostic characteristics.

Given the limitations of serum creatinine, the search for improved biomarkers of AKI is of intense contemporary interest. During the past decade, an improved understanding of the early pathophysiologic response of the kidney to stress has uncovered a number of genes and proteins that are rapidly induced in the kidney.[3] They have been implicated in the regulation of novel pathways and mechanisms that modulate the kidney injury. Serendipitously, some of these kidney proteins are also detected in the urine and/or plasma, and are emerging as early non-invasive biomarkers of AKI and its clinical outcomes. Table 75.1 lists the desirable characteristics of AKI biomarkers in general, and illustrates the current status of the four most promising novel AKI biomarkers whose bench-to-bedside translation is chronicled in this chapter. Table 75.2 summarizes the biological characteristics of these and other proposed AKI biomarkers. Since NGAL represents the most extensively studied of the novel biomarkers, it will be the primary focus of this chapter.

TABLE 75.1 Desirable Characteristics of Acute Kidney Injury Biomarkers

Property	NGAL	KIM-1	IL-18	L-FABP
Noninvasive (measured in urine or blood)	Yes	Yes	Yes	Yes
Rapid, standardized clinical platforms available	Yes	Yes	No	No
Sensitive to establish an early diagnosis of AKI	Yes	Yes	Yes	Yes
Results available while damage is limitable	Yes	Yes	Yes	Yes
High gradient to allow severity prediction	Yes	Yes	Yes	Yes
Specific to intrinsic AKI (versus pre-renal AKI)	Yes	Unknown	Unknown	Unknown
Discerns AKI from chronic kidney disease	No	No	No	No
Predicts hard clinical outcomes	Yes	Yes	Yes	Yes
Predicts response to therapies	Yes	Unknown	Unknown	Unknown
Associated with a known mechanism	Yes	Yes	Yes	Yes

AKI: acute kidney injury; NGAL: neutrophil gelatinase-associated lipocalin; KIM-1: kidney injury molecule-1; IL-18: interleukin 18; L-FABP: liver type fatty acid binding protein.

NEUTROPHIL GELATINASE-ASSOCIATED LIPOCALIN (NGAL) AS AN AKI BIOMARKER

NGAL Physiology and Pathophysiology

Human NGAL was originally identified as a novel protein isolated from secondary granules of human neutrophils, and subsequently shown to be a 25-kDa protein covalently bound to neutrophil gelatinase. Mature peripheral neutrophils lack NGAL mRNA expression, and NGAL protein is synthesized at the early myelocyte stage of granulopoiesis during formation of secondary granules. NGAL mRNA is normally expressed in a variety of adult human tissues, including bone marrow, prostate, salivary gland, stomach, colon, trachea, lung, liver, and kidney.[2] Several of these tissues are prone to exposure to microorganisms, and constitutively express NGAL protein at low levels. The promoter region of the NGAL gene contains binding sites for a number of transcription factors, including NF-κB. This could explain the constitutive as well as inducible expression of NGAL in several of the non-hematopoietic tissues. Like other lipocalins, NGAL forms a barrel-shaped tertiary structure with a

TABLE 75.2 Biological Characteristics of Promising Acute Kidney Injury Biomarkers

Biomarker	Sample	Origin	Biological Function
NGAL	Urine	Distal tubule, collecting duct	Regulates iron trafficking, promotes tubule cell survival and proliferation, limits tubule cell apoptosis
NGAL	Blood	Liver, lung, neutrophils	Acute phase reactant, marker of organ cross-talk following acute kidney injury
KIM-1	Urine	Proximal tubule	Promotes epithelial regeneration, regulates tubule cell apoptosis
IL-18	Urine	Proximal tubule	Initiates and promotes tubule cell apoptosis and necrosis
L-FABP	Urine	Proximal tubule	Endogenous antioxidant, suppresses tubulointerstitial damage
NAG	Urine	Proximal tubule	Marker of proximal tubule lysosomal enzyme release as a result of damage to proximal tubule
β2-MG	Urine	Systemic and Proximal tubule	Marker of altered glomerular permeability and/or decreased proximal tubular reabsorption due to damage
Albumin	Urine	Systemic and Proximal Tubule	Marker of altered glomerular permeability and/or decreased proximal tubular reabsorption due to damage

NGAL: neutrophil gelatinase-associated lipocalin; KIM-1: kidney injury molecule-1; IL-18: interleukin 18; L-FABP: liver type fatty acid binding protein; NAG: n-acetyl glucosaminidase; β2-MG; beta2-microglobulin.

hydrophobic calyx that binds small lipophilic molecules. The major ligands for NGAL are siderophores, small iron-binding molecules. Teleologically, NGAL comprises a critical component of innate immunity to bacterial infection. Siderophores are synthesized by bacteria to scavenge iron from the surroundings, and use specific transporters to recover the siderophore-iron complex, ensuring their iron supply. The siderophore-chelating property of NGAL therefore renders it as a bacteriostatic agent. Experimental evidence for this role is derived from mice genetically modified to lack the NGAL gene, which renders them more susceptible to Gram-negative bacterial infections and death from sepsis.

On the other hand, siderophores produced by eukaryotes participate in NGAL-mediated iron shuttling that is critical to various cellular responses such as proliferation and differentiation. This property provides a molecular mechanism for the documented role of NGAL in enhancing the epithelial phenotype. During kidney development, NGAL promotes epithelial differentiation of the mesenchymal progenitors, leading to the generation of glomeruli, proximal tubules, Henle's loop, and distal tubules. However, NGAL expression is also markedly induced in injured epithelial cells, including the kidney, colon, liver and lung. This is likely mediated via NF-κB, which is known to be rapidly activated in epithelial cells after acute injuries, and plays a central role in controlling cell survival and proliferation. In the context of an injured mature organ such as the kidney, the biological role of NGAL induction is one of marked preservation of function, attenuation of apoptosis, and an enhanced proliferative response.[4,5] This protective effect is dependent on the chelation of toxic iron from extracellular environments, and the regulated delivery of siderophore and iron to intracellular sites. Not surprisingly, gene expression studies in AKI have demonstrated a rapid and massive upregulation of NGAL mRNA in the distal nephron segments—specifically in the thick ascending limb of Henle's loop and the collecting ducts. The resultant synthesis of NGAL protein in the distal nephron and secretion into the urine comprises the major fraction of urinary NGAL. Although plasma NGAL is freely filtered by the glomerulus, it is largely reabsorbed in the proximal tubules. Thus, any urinary excretion of NGAL is likely only when a kidney disease precludes proximal tubular NGAL reabsorption, and/or induces distal tubular *de novo* NGAL synthesis. With respect to plasma NGAL, the kidney itself does not appear to be a major source. NGAL protein released into the circulation from distant organs such as the liver and lung constitute a distinct systemic pool. Additional contributions to the systemic pool may derive from activated neutrophils, macrophages, and other immune cells. Furthermore, any decrease in GFR would decrease the renal clearance of NGAL, with subsequent accumulation in the systemic circulation in patients with CKD.

Preclinical transcriptome profiling studies identified *Ngal* (also known as lipocalin 2 or *lcn2*) to be one of the most upregulated genes in the kidney very early after acute injury in animal models.[6] Downstream proteomic analyses also revealed NGAL to be one of the most highly induced proteins in the kidney after ischemic or nephrotoxic AKI in animal models.[7,8] The serendipitous finding that NGAL protein was easily detected in the urine soon after AKI in animal studies has inspired a number of translational human studies, and NGAL has emerged as an excellent biomarker in the urine and plasma for early diagnosis, therapeutic monitoring, and prediction of prognosis in common clinical AKI scenarios. The deployment of standardized clinical platforms for the rapid and accurate measurement of NGAL in urine and plasma has further facilitated the

widespread use and validation of NGAL as a biomarker.

NGAL for the Prediction of AKI and its Severity

In a cross-sectional study of adults with established AKI (doubling of serum creatinine) from varying etiologies, a marked increase in urine and serum NGAL was documented by Western blotting when compared to normal controls.[5] Urine and serum NGAL levels correlated with serum creatinine, and kidney biopsies in subjects with AKI showed intense accumulation of immunoreactive NGAL in cortical tubules, confirming NGAL as a sensitive index of established AKI in humans. An explosion of subsequent studies has now implicated NGAL as an early diagnostic biomarker for AKI in several common clinical situations.

Operations involving cardiopulmonary bypass comprise the most frequent major surgical procedure performed in hospitals worldwide. Even a minor degree of post-operative AKI as manifest by only a 0.2−0.3 mg/dl rise in serum creatinine from baseline (which occurs in up to 30% of cardiac surgeries) is associated with a significant increase in mortality and other adverse outcomes. The pathogenesis of cardiac surgery-associated AKI includes ischemia-reperfusion injury, exogenous toxins (contrast media, non-steroidal anti-inflammatory drugs), endogenous toxins (iron released from hemolysis), and inflammation and oxidative stress (from contact with bypass circuit, surgical trauma, and intra-renal inflammatory responses). The predictive value of NGAL has been most extensively studied in this setting (Table 75.3). In single center prospective studies of children who underwent elective cardiac surgery, AKI (defined as a 50% increase in serum creatinine) occurred one to three days after surgery.[9−15] In contrast, NGAL measurements by ELISA revealed a 10-fold or more increase in the urine and plasma, within two to six hours of the surgery in those who subsequently developed AKI. Both urine and plasma NGAL were excellent independent predictors of AKI, with an area under the receiver-operating characteristic curve (AUC-ROC) of >0.9 for the two to six hour urine and plasma NGAL measurements. A recent prospective multicenter study of children undergoing cardiac surgery has confirmed the early peak (within six hours of initiating cardiopulmonary bypass) of urine and plasma NGAL associated with higher odds of developing AKI,[16] but the diagnostic accuracy by AUC-ROC analysis was lower (0.71). These findings have also been confirmed in several prospective single center studies of adults who developed AKI after cardiac surgery, in whom urinary and/or plasma NGAL was significantly elevated by one to six hours after the operation.[17−31] The AUC-ROCs for the prediction of AKI have ranged widely from 0.61 to 0.96. A prospective multicenter study of adults undergoing cardiac surgery has confirmed the early peak of urine and plasma NGAL associated with higher odds of developing AKI,[16] but the diagnostic accuracy by AUC-ROC analysis was only 0.67 to 0.70.[32] The somewhat inferior performance in adult populations may be reflective of confounding variables such as older age groups, pre-existing kidney disease, prolonged bypass times, chronic illness, and diabetes. The predictive performance of NGAL also depends on the definition of AKI employed, as well as on the severity of AKI.[22−24] For example, the predictive value of plasma NGAL post cardiac surgery was higher for more severe AKI (increase in serum creatinine >50%; mean AUC-ROC 0.79) compared to less severe AKI (increase in serum creatinine >25%; mean AUC-ROC 0.65). Similarly, the discriminatory ability of NGAL for AKI increased with increasing severity as classified by RIFLE criteria. Thus, the AUC-ROC improved progressively for discrimination of R (0.72), I (0.79) and F (0.80) category of AKI. Furthermore, the predictive power of urinary NGAL for AKI after cardiac surgery varied with baseline renal function, with optimal discriminatory performance in patients with normal preoperative renal function.[33] Despite these numerous potential variables, a meta-analysis of published studies in all patients after cardiac surgery revealed an overall AUC-ROC of 0.78 for prediction of AKI, when NGAL was measured within 6 hours of initiation of cardiopulmonary bypass and AKI was defined as a >50% increase in serum creatinine.[34] A current analysis of 25 published studies strongly supports the use of NGAL for AKI prediction after cardiac surgery, with an overall sensitivity of 71%, specificity of 78%, and an average AUC of 0.80 (Table 75.3).

AKI is a frequent complication in critically ill patients, and results in a 40−60% mortality rate. This patient population is extremely heterogeneous, and the etiology and timing of AKI is often unclear. Etiologies include sepsis, nephrotoxins, hypotension, kidney ischemia, mechanical ventilation, and multi-organ disease. Even in such heterogeneous settings, urine and plasma NGAL measurements have been shown to represent early biomarkers of AKI (Table 75.4). Initial studies in the pediatric intensive care setting demonstrated that NGAL predicted AKI about two days prior to the rise in serum creatinine, with high sensitivity and AUC-ROCs of 0.68−0.78.[35,36] Several studies have also examined plasma and urine NGAL levels in critically ill adult populations.[37−47] Urine NGAL obtained on admission predicted subsequent AKI in multi-trauma patients with an outstanding AUC-ROC of

0.98.[39] However, in more mixed populations of all critical care admissions, the performance of urine NGAL on admission was more variable, with an AUC-ROC ranging from 0.71 to 0.89 (Table 75.4). In studies of adult intensive care patients, plasma NGAL concentrations on admission constituted a very good to outstanding biomarker for development of AKI within the next two days, with AUC-ROC ranges of 0.79–0.92.[44–47] In the closely related setting of the emergency department, where again the causes of AKI are myriad and timing of the initial insult uncertain, a single measurement of urine NGAL at the time of initial presentation predicted AKI with an outstanding AUC-ROC of 0.95 in a single center study of adult patients.[48] This has now been confirmed in children,[49] as well as in a large multicenter prospective study of adults presenting to the emergency department,[50] in which urine NGAL was predictive of subsequent AKI with an excellent AUC of 0.81. However, it should be noted that patients with septic AKI display the highest concentrations of both plasma and urine NGAL when compared to those with non-septic AKI,[51] a confounding factor that may add to the heterogeneity of the results in the critical care setting. In addition, the predictive power of urinary NGAL for AKI in the critically ill was optimal in patients with normal preoperative renal function.[42] A meta-analysis revealed an overall AUC-ROC of 0.73 for prediction of AKI, when NGAL

AKI: acute kidney injury; NR: not reported.

was measured within six hours of clinical contact with critically ill subjects and AKI was defined as a >50% increase in serum creatinine.[34] A current analysis of 18 published studies strongly supports the use of NGAL for AKI prediction in the critically ill population, with an overall sensitivity of 77%, specificity of 81%, and an average AUC of 0.83 (Table 75.4).

AKI due to ischemia-reperfusion occurs to some extent almost invariably in deceased donor renal allografts, and even in some live donor transplants, often resulting in varying degrees of early renal dysfunction. AKI leading to delayed graft function (DGF) complicates 4–10% of live donor and 5–50% of deceased donor kidney transplants. In addition to the well-known complications of AKI and dialysis, DGF predisposes the graft to both acute and chronic rejection, is an independent risk factor for suboptimal graft function at one year post transplant, and increases the risk of chronic allograft nephropathy and graft loss. NGAL has been evaluated as a promising biomarker of AKI and DGF (defined as dialysis requirement within the first post-operative week) in patients undergoing kidney transplantation. Protocol biopsies of kidneys obtained one hour after vascular anastomosis revealed a significant correlation between NGAL staining intensity in the allograft and the subsequent development of delayed graft function.[52] In a prospective multicenter study of children and adults, urine NGAL levels in samples collected on the day of transplant identified those who subsequently developed DGF (which typically occurred two to four days later), with an AUC-ROC of 0.9.[53] This has now been confirmed in a larger multi-center cohort, in which urine NGAL measured within six hours of kidney transplantation predicted subsequent DGF with an AUC-ROC of 0.81.[54] In the largest study reported to date, in 176 recipients of deceased donor grafts, 70 developed DGF. Urinary NGAL levels obtained on the first day after kidney transplant predicted prolonged DGF with an AUC-ROC of 0.75.[55]

Several investigators have examined the role of NGAL as a predictive biomarker of AKI following contrast administration.[56–59] In a prospective study of children undergoing elective cardiac catheterization with contrast administration, both urine and plasma NGAL predicted contrast-induced

AKI: acute kidney injury; NR: not reported; values for NGAL are in ng/ml.

nephropathy (defined as a 50% increase in serum creatinine from baseline) within two hours after contrast administration, with an AUC-ROC of 0.91−0.92.[56] In several studies of adults administered contrast, an early rise in both urine (four hours) and plasma (two hours) NGAL were documented, in comparison with a much later increase in plasma cystatin C levels (8−24 hours after contrast administration), providing further support for NGAL as an early biomarker of contrast nephropathy.[57−59] A meta-analysis revealed an overall AUC-ROC of 0.894 for prediction of AKI, when NGAL was measured within six hours after contrast administration and AKI was defined as a >25% increase in serum creatinine.[34]

Many reports have now demonstrated that early NGAL measurements are predictive of AKI severity, as classified by the standardized RIFLE criteria.[60] The average concentrations of early NGAL measurements correlate with rising RIFLE stage reached, as shown in Table 75.5. These findings support the use of early NGAL measurements for AKI risk prediction and stratification, and hence as a useful tool for triaging of patient care.

NGAL for the Differential Diagnosis of AKI

In the setting of acute illness, up to 60% of patients may have already sustained AKI on presentation, and up to 30% already display an increase in serum creatinine concentrations on initial presentation.[48] Differentiating between volume-responsive prerenal azotemia, intrinsic AKI, and CKD is critical for appropriate triaging and medical management. Recent evidence suggests that NGAL measurements can serve this purpose. In three published studies of urinary measurements done at the time of presentation to the emergency department, NGAL levels were only mildly elevated in patients with prerenal azotemia or CKD, but markedly elevated in those subsequently adjudicated to have intrinsic AKI, with an overall AUC-ROC for intrinsic AKI prediction of 0.86 (Table 75.6).

NGAL for the Prognosis of AKI

A number of studies have demonstrated the utility of early NGAL measurements for predicting the severity and clinical outcomes of AKI. In children undergoing cardiac surgery, early post-operative plasma NGAL levels correlated with duration and severity of AKI, length of hospital stay, and mortality.[12] In a similar cohort, early urine NGAL levels correlated with duration and severity of AKI, length of hospital stay, dialysis requirement, and death.[13] In a multicenter study of children with diarrhea-associated hemolytic uremic syndrome, urine NGAL obtained early during the hospitalization predicted the severity of AKI and dialysis requirement with high sensitivity.[61] Early urine NGAL levels were also predictive of duration of

AKI (AUC 0.79) in a heterogeneous cohort of critically ill pediatric subjects.[35]

In adults undergoing cardiopulmonary bypass, those who subsequently required renal replacement therapy were found to have the highest urine NGAL values soon after surgery.[17–28] Similar results were documented in the adult critical care setting.[38–42] Collectively, a meta-analysis of the published studies revealed an overall AUC-ROC of 0.78 for prediction of subsequent dialysis requirement, when NGAL was measured within six hours of clinical contact.[34] Furthermore, a number of studies conducted in the cardiac surgery and critical care populations have identified early NGAL measurements as a very good mortality marker, with an overall AUC-ROC of 0.71 in these heterogeneous populations.[34] There is now evidence for the utility of subsequent NGAL measurements in critically ill adults with established AKI. Serum NGAL measured at the inception of renal replacement therapy was shown to be an independent predictor of 28-day mortality, with an AUC of 0.74.[62] Representative publications reporting the adjusted odds ratios for adverse outcomes related to elevated NGAL levels early in the course of critical illnesses are shown in Table 75.7.

Limitations of NGAL as an AKI Biomarker

Published studies to date indicate that NGAL represents a novel predictive biomarker for AKI and its outcomes. However, NGAL appears to be most sensitive and specific in homogeneous patient populations with temporally predictable forms of AKI. Meta-analyses have also identified age as an effective modifier of NGAL's performance as an AKI biomarker,[34] with better predictive ability in children (overall AUC-ROC 0.93) than in adults (AUC-ROC 0.78). Plasma NGAL measurements may be influenced by a number of coexisting variables such as chronic kidney disease (CKD), chronic hypertension, systemic infections, inflammatory conditions, anemia, hypoxia, and malignancies.[2] In the CKD population, both plasma and urine NGAL levels are elevated, and this correlates with the severity of renal impairment. However, it should be noted that the increase in NGAL in these situations is generally

much less than those typically encountered in AKI. Urine NGAL has also been shown to represent an early biomarker for the degree of chronic injury in patients with IgA nephropathy and lupus nephritis, and may be increased in urinary tract infections.[2] However, the levels of urine NGAL in these situations are significantly blunted compared to that typically measured in AKI.

KIDNEY INJURY MOLECULE-1 (KIM-1) AS AN AKI BIOMARKER

Preclinical subtractive hybridization screens identified kidney injury molecule 1 (*Kim-1*) as a gene that is markedly up-regulated in ischemic rat kidneys.[64] Downstream proteomic studies have also shown KIM-1 to be one of the most highly induced proteins in the kidney after AKI in animal models.[65,66] KIM-1 is a transmembrane protein that is not expressed in normal kidney but is specifically upregulated in dedifferentiated proximal tubule cells after ischemic or nephrotoxic AKI. It has been identified as a phosphatidylserine receptor that transforms epithelial cells into phagocytes by recognizing cell surface-specific epitopes expressed by apoptotic tubular epithelia.[67] A proteolytically processed extracellular domain of KIM-1 is detectable in the urine soon after AKI. KIM-1 represents a promising biomarker for the early diagnosis of AKI and its clinical outcomes.[65,66] The recent availability of a rapid urine dipstick test for KIM-1 will facilitate its further evaluation in preclinical and clinical studies.[68]

In hospitalized patients with established AKI, urinary KIM-1 levels predicted adverse clinical outcomes such as dialysis requirement and mortality (69). In children undergoing CPB who developed AKI one to three days post surgery, urine KIM-1 concentrations were significantly increased within 12 hours.[15,25] The AUC for AKI prediction at 12 hours was 0.83. In a cross-sectional study of critically ill adults with AKI, KIM-1 levels were markedly elevated when compared to healthy controls, yielding an AUC-ROC of 0.95.[37] Age-adjusted levels of urinary KIM-1 were significantly higher in patients who died or required dialysis.[37] KIM-1 is also an excellent marker of nephrotoxicity in preclinical studies.[70] Several prospective studies examining KIM-1 as a biomarker of AKI are underway. The current status of KIM-1 as an AKI biomarker is illustrated in Tables 75.8 and 75.9. Urinary KIM-1 is also increased in a number of chronic kidney diseases, and is an independent predictor of chronic graft loss in renal transplant recipients.[71]

TABLE 75.8 Novel Urinary Biomarkers for the Early Diagnosis of Aki

Biomarker	Cardiopulmonary Bypass (CPB)	Contrast Nephropathy	Kidney Transplant (Tx)	ICU or Emergency Room
NGAL	2 hr post CPB 2 days pre AKI	2 hr post contrast 1–2 days pre AKI	6 hr post Tx 2–3 days pre DGF	On admission 2 days pre AKI
IL-18	6 hr post CPB 1–2 days pre AKI	Not increased	6 hr post Tx 2–3 days pre DGF	2 days pre AKI
L-FABP	6 hr post CPB 1–2 days pre AKI	Not tested	Not tested	2 days pre AKI
KIM-1	12 hr post CPB 1–2 days pre AKI	Not tested	Not tested	Not tested

NGAL, neutrophil gelatinase-associated lipocalin. IL-18, interleukin 18. L-FABP, liver-type fatty acid binding protein. KIM-1, kidney injury molecule 1. AKI, defined as a 50% or greater increase in serum creatinine from baseline. DGF, defined as dialysis requirement within the first week after transplant. Times shown are the earliest time points when the biomarker becomes significantly increased from baseline.

TABLE 75.9 Novel Urinary Biomarkers for the Prediction of Aki Outcomes

Biomarker Name	Cardiopulmonary Bypass (CPB)	Kidney Transplant	ICU or Emergency Room
NGAL	Predicts AKI duration, severity, dialysis, death	Predicts AKI duration	Predicts AKI duration, severity, and dialysis
IL-18	Predicts AKI duration, severity, dialysis, death	Predicts AKI duration	Predicts death
L-FABP	Not tested	Not tested	Predicts AKI severity, dialysis, and death
KIM-1	Not tested	Predicts long term graft loss	Not tested

NGAL, neutrophil gelatinase-associated lipocalin. IL-18, interleukin 18. L-FABP, liver-type fatty acid binding protein. KIM-1, kidney injury molecule 1. AKI, defined as a 50% or greater increase in serum creatinine from baseline.

LIVER-TYPE FATTY ACID BINDING PROTEIN (L-FABP) AS AN AKI BIOMARKER

L-FABP is a protein expressed in the proximal tubule of the kidney. Increased expression and urinary excretion have been described in animal models of AKI.[72–74] Although its precise function is unknown, L-FABP in the kidney has been postulated to represent an endogenous antioxidant capable of suppressing tubule-interstitial damage.

In children undergoing CPB who subsequently developed AKI, urine L-FABP concentrations were significantly increased within four to six hours of the surgery.[11,15] The early urinary L-FABP level was an independent risk factor for the development of AKI, with an AUC of 0.81. In hospitalized patients with established AKI, the AUC of urinary L-FABP for prediction of AKI was 0.93.[75] Urinary L-FABP levels in this cohort were significantly higher in patients with poor outcome, defined as the requirement for renal replacement therapy or the composite end point of death or renal replacement therapy. In patients with septic shock and AKI, urinary L-FABP measured at admission was significantly higher in the non-survivors than in the survivors, with an AUC for mortality prediction of 0.99.[76] Thus, emerging data point to L-FABP as a promising urinary biomarker of AKI and its outcomes (Tables 75.8 and 75.9). However, the urinary excretion of L-FABP is also increased in the setting of CKD.[77] Standardized clinical platforms for the measurement of urinary L-FABP are not currently available.

INTERLEUKIN-18 (IL-18) AS AN AKI BIOMARKER

IL-18 is a pro-inflammatory cytokine and a known mediator of inflammation that is induced in the proximal tubule, and activated by caspase-1.[78] It is a pro-apoptotic molecule that has the potential of worsening the functional consequences of AKI. While very small amounts are present in the normal urine, its concentration is dramatically increased soon after AKI in animal and human models.

In a cross-sectional study, urine IL-18 levels were markedly elevated in patients with established AKI, but not in subjects with urinary tract infection, chronic kidney disease, nephrotic syndrome, or prerenal azotemia.[79] Urinary IL-18 was significantly upregulated prior to the increase in serum creatinine in patients with acute respiratory distress syndrome who develop AKI.[80] On multivariate analysis, urine IL-18 levels predicted the development of AKI 24 hours before the rise in serum creatinine, with an AUC of 0.73. In children undergoing CPB who developed AKI, urinary IL-18 levels increased around six hours and peaked at over 25-fold at 12 hours post CPB. The six hour IL-18 measurement predicted subsequent AKI with an AUC of 0.75-0.84.[10,15] In kidney transplantation, urine IL-18 is an excellent predictive biomarker for DGF, with AUCs in the 0.8–0.9 range.[53,54] Urine IL-18 measurements also represent early biomarkers of AKI in the pediatric intensive care setting, being able to predict this complication about two days prior to the rise in serum creatinine.[81] Early urine IL-18 measurements correlated with the severity of AKI as well as mortality. In two recent prospective multicenter studies in children[16] and adults[32] undergoing cardiac surgery, IL-18 have emerged as an excellent predictor of AKI severity as well as poor clinical outcomes (including longer length of hospitalization, and increased risk for dialysis and death. Overall, IL-18 appears to be more specific to ischemic AKI, and largely unaffected by chronic kidney disease or urinary tract infections. However, IL-18 measurements may also be influenced by a number of coexisting variables, such as endotoxemia, immunologic injury and cisplatin toxicity. Furthermore, plasma IL-18 levels are known to be increased in various pathophysiologic states, such as inflammatory arthritis, inflammatory bowel disease, and systemic lupus erythematosus. The current status of IL-18 as an AKI biomarker is illustrated in Tables 75.8 and 75.9. Standardized platforms for the clinical measurement of urinary IL-18 remain to be developed and validated.

AKI BIOMARKER COMBINATIONS

From the above, it is apparent that there is no single perfect AKI biomarker. A combination of biomarkers may be necessary to provide the best diagnostic and prognostic information in a context-specific manner. Recent studies have explored this possibility. In a large prospective multicenter study of a panel of nine biomarkers to predict clinical outcomes in 971 emergency department patients with suspected sepsis, plasma NGAL emerged as the strongest predictor of shock and death.[82] In a secondary analysis of this cohort, an elevated plasma NGAL level at the time of presentation to the emergency department predicted severe AKI with an AUC of 0.82.[47] In a study examining biomarkers for the prediction of AKI following elective cardiac surgery, urinary NGAL concentrations measured at the time of admission to the ICU predicted the subsequent development of AKI with an AUC of 0.77, and outperformed other biomarkers including α1-microglobulin

and cystatin C.[29] In a similar analysis of multiple urinary biomarkers following cardiac surgery, the six-hour post-operative NGAL best predicted severe AKI with an AUC of 0.88.[28]

Serial measurements of multiple urinary biomarkers after pediatric cardiac surgery have revealed a sequential pattern for the appearance of AKI biomarkers,[15] with NGAL and L-FABP being the earliest responders (with two to four hours after initiation of cardiopulmonary bypass) and KIM-1 and IL-18 representing the intermediate responders (increased 6–12 hours after surgery). The importance of determining the temporal sequence of the biomarkers is underscored by the fact that the course of experimental AKI proceeds in four phases: initiation, extension, maintenance, and recovery.[3] The initiation phase is the period during which initial exposure to the ischemic insult occurs, intracellular ATP depletion is profound, and generation of reactive oxygen molecules and labile iron is initiated. Vasodilator, ATP-donor, anti-oxidant, and iron chelation therapies may be especially effective during this phase, and the appearance of the earliest non-invasive biomarkers such as NGAL may be used to trigger such therapies. Prolongation of ischemia followed by reperfusion ushers in the extension phase. Tubules undergo reperfusion-mediated cell death, and the injured endothelial and epithelial cells amplify the inflammatory cascades. This phase probably represents a window of opportunity for early diagnosis with intermediate biomarkers such as L-FABP and IL-18, and active therapeutic intervention with anti-apoptotic and anti-inflammatory strategies. During the maintenance phase, both cell injury and regeneration occur simultaneously. Measures such as growth factors and stem cells that accelerate the endogenous regeneration processes, initiated by later biomarkers with high specificity such as KIM-1, may be most effective during this phase. Current multicenter studies of multiple biomarkers will help determine which combinations best predict AKI and its outcomes in a context-dependent manner. In this rapidly evolving area of study, ongoing functional genomic and proteomic analyses may also reveal additional biomarkers that further advance this field in the near future.[83]

LIMITATIONS OF EXISTING STUDIES EXAMINING AKI BIOMARKERS

Despite the optimism in the field, there are important limitations that exist in the published AKI biomarker literature that must be acknowledged. First, majority of studies reported were from single centers that enrolled small numbers of subjects. Validation of the published results in additional large multicenter studies will be essential. Second, most studies reported to date did not include patients with CKD. This is problematic, not only because it excludes a large proportion of subjects who frequently develop AKI in clinical practice, but also because CKD in itself can result in increased concentrations of AKI biomarkers, thereby representing a confounding variable. Third, only a few studies have investigated biomarkers for the prediction of AKI severity, morbidity, and mortality.

Finally, and perhaps most importantly, the definition of AKI in the published studies was based largely on elevations in serum creatinine, which raises the conundrum of using a flawed outcome variable to analyze the performance of a novel assay. This definition of AKI sets up the biomarker assay for lack of accuracy due to either false positives (true tubular injury but no significant change in serum creatinine) or false negatives (absence of true tubular injury, but elevations in serum creatinine due to pre-renal causes or any of a number of confounding variables that plague this measurement). It will be crucial in future studies to understand the clinical outcomes of subjects who may be prone to AKI and are "biomarker-positive" but "creatinine-negative." Indeed, a recent multicenter pooled analysis of published data on 2322 critically ill children and adults revealed the surprising finding that approximately 20% of patients display early elevations in NGAL concentrations but never develop increases in serum creatinine.[84] Importantly, this sub-group of "NGAL-positive creatinine-negative" subjects encountered a substantial increase in adverse clinical outcomes, including mortality, dialysis requirement, ICU stay, and overall hospital stay. Thus, early NGAL measurements can identify patients with sub-clinical AKI who have an increased risk of adverse outcomes, even in the absence of diagnostic increases in serum creatinine. It is likely that the other structural AKI biomarkers discussed herein will provide similar diagnostic and prognostic stratification, independent of functional markers such as serum creatinine. Since the gold standard for true AKI (tissue biopsy) is highly unlikely to be feasible, it is vital that large enough future studies demonstrate (a) the association between biomarkers and hard outcomes such as dialysis, cardiovascular events, and death, independent of serum creatinine, and (b) that randomization to a treatment for AKI based on high biomarker levels results in an improvement in kidney function and reduction of clinical outcomes. These should be the next challenges to overcome, in order to firmly establish the clinical utility of AKI biomarkers, and to dramatically improve the outcome of AKI.

CLINICAL OVERVIEW

Classifications and Definitions

Acute Kidney Injury (AKI) is a heterogenous syndrome defined by a rapid decline in glomerular filtration rate (GFR) which may lead to accumulation of metabolic waste products and disturbances in fluid, electrolyte and acid-base handling.[1] In the last few years, the previous terminology of Acute Renal Failure (ARF) has largely been abandoned and the new term AKI has been widely adopted in the medical literature. In this chapter, the term AKI will be used to describe the entire spectrum of disorders that share the same physiologic characteristics but may be pathophysiologically distinct.

In 2002, based on the recommendations of the Acute Dialysis Quality Initiatives (ADQI) the staging of AKI was proposed. The RIFLE classification of AKI is divided into three levels of renal dysfunction namely, "*r*isk", "*i*njury" and "*f*ailure" based on either GFR or urine output criteria whichever is more severe. The GFR criteria assesses renal dysfunction by using either changes in serum creatinine or the percentage decline in GFR from baseline GFR. The parameters used have a high sensitivity, are prognostic based on severity of stage, but represent a retrospective analysis.[2,3] Two other very important clinical outcomes are also incorporated into the RIFLE criteria: "*l*oss" of kidney function as defined by persistent AKI with the need for renal replacement therapy (RRT) for more than four weeks, and "*e*nd" stage kidney disease, defined as the need for RRT for greater than three months. These parameters are more strict and therefore have a higher specificity.[2]

Recently, the Acute Kidney Injury Network (AKIN) proposed a modification of the RIFLE criteria with the addition of a $>=$ 0.3 mg/dl increase in serum creatinine to the criteria that define Risk. Because of the linear relationship between GFR and 1/serum creatinine, it should be kept in mind that a small rise in serum creatinine, in the normal or near normal values, corresponds to relatively large decline in GFR. For example, in a steady state, a serum creatinine of 0.8 mg/dl in a young 50 kg female corresponds to a GFR of approximately 100 ml/min, while a serum creatinine of 1.6 mg/dl would reflect in a GFR of 50 ml/min, a decline of nearly 50% in GFR. In the non-steady state of AKI, the serum creatinine value should be considered very carefully, as this is not an equilibrium state. Thus an overestimation of the GFR is made if standard steady state calculations are made using formulas such as Cockroft-Gault or MDRD if the serum creatinine is rising. Hence during the evolution of acute renal dysfunction, serum creatinine underestimates the degree of renal dysfunction, and conversely it underestimates the degree of renal recovery as function recovers. Having said that, the change from baseline and perhaps the rate of rise of creatinine are still potentially useful in the clinical evaluation of GFR decline. Even creatinine clearance (when collection is accurate) suffers from the same limitation as mentioned above, and causes an overestimation of GFR. Determining an accurate GFR in clinical settings is rarely accomplished and perhaps more important would be the determination of whether the GFR is improving or not. Hence one should always remember that to detect AKI, it is *essential to assess the change in creatinine*, and that *across all patients, a single creatinine valuenever corresponds to a given GFR*.[4]

TABLE 76.1 RIFLE and Acute Kidney Injury Network (AKIN) Definition and Staging of Acute Kidney Injury

RIFLE	AKIN
Definition	
An increase in serum creatinine of >50% developing over < 7 days; or a urine output of <0.5 ml/kg/hr for > 6 hours	An increase in serum creatinine of > 0.3 mg/dl or >50% developing over < 48 hours; or a urine output of <0.5 ml/kg/hr for > 6 hours

Staging Criteria				
RIFLE Stage	**Increase in Serum Creatinine**	**Urine Output Criteria**	**Increase in Serum Creatinine**	**AKIN Stage**
Risk	≥ 50%	<0.5 ml/kg/hr for > 6 hours	≥ 0.3 mg/dl; or ≥ 50%	Stage 1
Injury	≥ 100%	<0.5 ml/kg/hr for > 12 hours	≥ 100%	Stage 2
Failure	≥ 200%	<0.5 ml/kg/hr for > 24 hours or anuria for > 12 hours	≥ 200%	Stage 3
Loss	Need for renal replacement therapy for > 4 weeks			
End-stage	Need for renal replacement therapy for > 3 months			

The production rate and volume of distribution of creatinine also affect the plasma creatinine value, while other factors such as medications (e.g. cimetidine) can inhibit distal tubular creatinine secretion and cause a rise in serum creatinine without being secondary to AKI. Abnormalities in liver function, decreased muscle mass and aging decrease the production of creatinine, whereas fever, immobilization, glucocorticoids or muscle trauma increase its production.

Urine output is sensitive to changes in renal hemodynamics, but extremely insensitive to define or differentiate AKI. Oliguria has been defined as urine output of <400 ml/day or <0.3 ml/kg/hour, and has been found to be associated with a higher mortality as compared to non-oliguric ARF.[5] However, severe AKI can exist in non-oliguric states as well, whereas obstructive causes could present with a fluctuating levels of urine output. The RIFLE criteria does employ urine output as markers of risk, injury or failure, though concordance between serum creatinine and urine output criteria has not been established, even with regards to mortality risk.

Acute Kidney Injury: Incidence and Risk Factors

Incidence

The exact incidence of AKI has varied in the past due to the absence, until recently, of a standard definition. It has been estimated that 3% to 20%[6,7] of hospitalized patients and 25% to 67% of ICU patients develop AKI,[8,9] with 5 to 6% of the ICU population requiring renal replacement therapy after developing AKI.[5,10–13] Studies have indicated that there is an increasing incidence of AKI over the last twenty years. Amongst all Medicare patients, Eggers et al. noted that after adjusting for sex, age and ethnicity, AKI rates increased 10% per year from 14 cases per year in 1992 to 36 cases per year in 2001.[14] The CDC noted >20 fold increase in the incidence of AKI for patients hospitalized between 1980–2005 using ICD-9 codes.[14a]

In another multinational, multicenter observational study of 29,269 critically ill patients, 5.7% developed severe AKI and 4.3% received renal replacement therapy.[15] Although there is less confusion with regard to rates of AKI requiring renal replacement therapy, reported rates still vary due to differences in characteristics of patient populations and variability in criteria for the initiation of renal replacement therapy. Population based studies have shown a rate of 2147 cases of AKI per million population.[13]

Risk Factors

An extremely important aspect in trying to prevent AKI is to identify high risk populations and clinical conditions, or high risk situations and procedures to devise strategies to minimize the incidence and impact of AKI. Numerous risk factors have been identifiedin different population groups, some of which are discussed here (Table 76.2). Most studies have found age to be an independent risk factor for the development of AKI. In 2009 the URSDS, reported incidence rates of AKI in the US using three different datasets from 1995 to 2007[15a] and found the largest increase in AKI incidence was seen among older individuals >85 years age. In a large observational cohort study across five academic centers in the United States, the mean age of patients was 59.5 years. Possible reasons why age

TABLE 76.2 Common Risk Factors for Developing Acute Kidney Injury

Risk Factor
Age
Pre-existing Chronic Kidney Disease
Reduced Effective Arterial Volume
Volume Depletion
Nephrotic Syndrome
Congestive Heart Failure
Cirrhosis
Sepsis
Diabetes Mellitus
Drugs
Non-Steroidal Anti-Inflammatory Drugs
Aminoglycosides
Radio-Contrast Agents
Inflammatory States
Trauma
Burns
Sepsis
Post-Surgical State
Post Solid Organ/Allogenic Bone Marrow Transplant
Mechanical Ventilation

could be an independent risk factor includes decreased residual renal function, presence of comorbidities and increased susceptibility to infections.[16,17] Pre-existing renal insufficiency is a major risk factor for the development of AKI in the non-ICU and ICU setting. Even small decrements in systemic hemodynamics can lead to significant alterations in the renal hemodynamics, due to diminished capacity to auto-regulate the response to a decreased perfusion pressure, leading to a reduction in GFR. Increasing levels of risk are associated with more severe baseline chronic kidney disease (CKD). Compared to patients with baseline eGFR >60 ml/min/1.73 m^2, those with eGFR values of 45–59 ml/min/1.73 m^2 had a nearly 2-fold increased risk of developing dialysis-requiring AKI. This risk increased to more than 40-fold among patients with baseline eGFR values <15 ml/min/1.73 m^2. Underlying diabetes mellitus, hypertension, and the presence of proteinuria were also associated with increased the risk for hospital-acquired AKI.[18] CKD patients are at high risk for development of AKI secondary to radio-contrast agents, aminoglycosides, atheroembolism, and cardiovascular surgery.[19,20]

The presence of exo-and endo-toxins increases the risk for AKI. Antibiotics, non-steroidal anti-inflammatory agents, anesthetic agents, contrast media and diuretics are well defined risk factors for AKI. There is a synergestic increase in nephrotoxicity from such agents when there is renal hypoperfusion for any reason. Severe infections, especially in the setting of a surgical procedure are often associated with AKI. AKI complicating trauma is often multifactorial in origin, resulting from a combination of hypovolemia and myoglobin release from muscle tissue. AKI remains a frequent complication of surgery necessitating cardiopulmonary bypass despite off pump techniques.

Etiology

Frequently the cause for AKI is multifactorial, involving more than one insult. However, traditionally the etiology of AKI has been categorized anatomically into pre-renal, renal and post-renal (Figure 76.1).

Prerenal Acute Kidney Injury

The most common cause of AKI is prerenal azotemia and it accounts for about 40–55% of the cases.[5,10,16] It results from kidney hypoperfusion due to a reduced effective arterial volume (EAV). The effective arterial volme is the volume of blood effectively perfusing organs. Conditions causing hypovolemia resulting in a reduced EAV include hemorrhage (traumatic, gastrointestinal, surgical), GI losses (vomiting, diarrhea, nasogastric suction), kidney losses (over-diuresis, diabetes insipidus) and third spacing (pancreatitis, hypoalbuminemia). In addition cardiogenic shock, septic shock, cirrhosis, nephrotic syndrome and anaphylaxis all are pathophysiologic conditions that decrease effective circulating volume, independent of the volume status, resulting in reduced renal blood flow. Pre-renal AKI reverses rapidly once renal perfusion is restored because the renal parenchyma remains uninjured. However, when hypoperfusion is severe, it may result in ischemia leading to acute tubular necrosis.

Pre-renal azotemia has also been divided into volume responsive and volume non-responsive. In volume responsive pre-renal azotemia correction of the patients volume status results in increased kidney perfusion and resolution of the disorder. In volume non-responsive forms, additional intravenous volume is of no help in restoring kidney perfusion and function. Disease processes such as severe congestive heart failure and sepsis may not respond to intravenous fluids as markedly reduced cardiac output or a reduction in total vascular resistance, respectively, prevent volume mediated improvement in kidney perfusion. Therefore

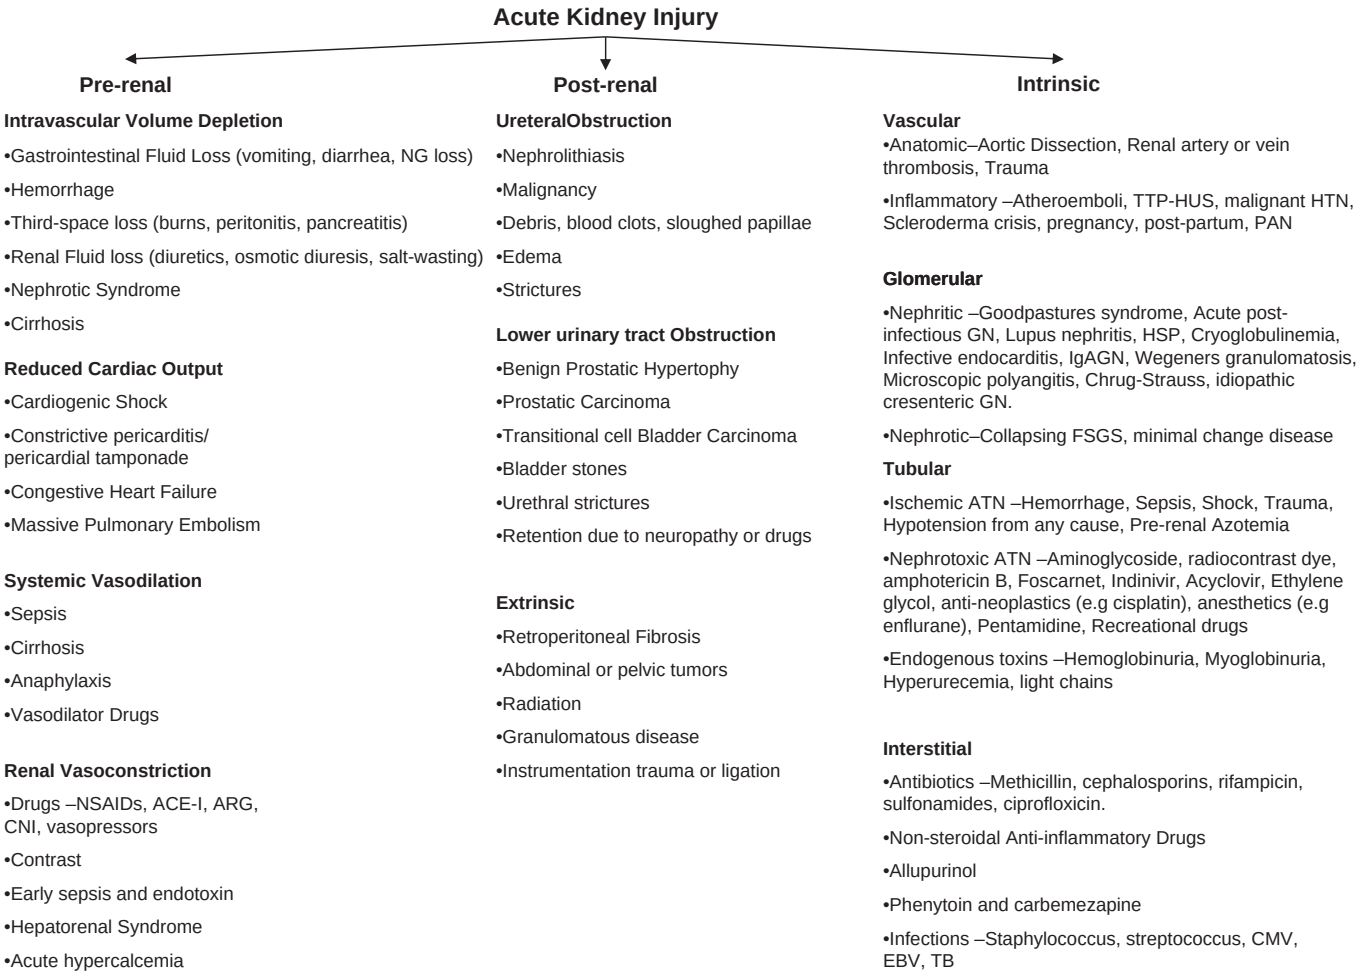

FIGURE 76.1 Etiology of AKI based on anatomical categories (pre/intrinsic/post).

it is essential to understand the mechanism mediating pre-renal azotemia in order to correct it.

Hypovolemia causes a decrease in mean arterial pressure which activates baroreceptors and initiates a cascade of neural and humoral responses. This leads to the activation of sympathetic nervous system that causes increased production of catecholamines especially norepinephrine. The other major consequence is the activation of the renin-angiotgensin-aldosterone (RAAS) system that causes production of angiotensin II (ATII), a very potent vasoconstrictor. There is also an increased release of anti-diuretic hormone (ADH) mediated both by hypovolemia and a rise in extracellular osmolality, that retains water, as well as influencing urea back-diffusion into the papillary interstitium.

In response to volume depletion or states of decreased EAV there is increased intra-renal ATII activity. This increases proximal tubule Na^+ absorption through a complex effect in the glomerulus by preferentially increasing the efferent arterioral resistance. Thus the glomerular hydrostatic pressure is increased and preserves GFR. With severe volume depletion there is greater ATII activity leading to afferent arteriolar constriction, that reduces both renal plasma flow and the filtration fraction.[21] ATII has also been shown to have direct effects on transport in proximal tubule through receptors located in the proximal tubule. It has also been postulated that the proximal tubule can locally produce ATII. Hence under conditions of volume depletion, ATII stimulates a larger fraction of the transport, whereas volume expansion will blunt this response.[22,23]

There is also significantly increased renal sympathetic nerve activity in pre-renal azotemia. Studies have shown that in volume depleted states adrenergic activity independently constricts the afferent arteriole as well as changing the efferent arteriolar resistance through ATII. Renal nerve activity is linked to renin release through β-adrenergic receptors on renin-containing cells while α-a adrenergic influences primarily the vascular resistances within the kidney. In contrast α-2 adrenergic agonists primarily decrease the glomerular ultrafiltration coefficient via ATII. Although vasodilation might be

expected as a result of acute removal of adrenergic activity, a transient increase in ATII is actually seen, along with constancy in GFR and renal blood flow. Even after sub-acute renal denervation renal vascular sensitivity increased to ATII as a result of major up-regulation of ATII receptors. Hence complex effects on the renin-angiotensin activity occur within the kidney secondary to renal adrenergic activity during pre-renal azotemia.[24]

All these systems work together and stimulate vasoconstriction in musculocutaneous and splanchnic circulations, inhibit salt loss through sweat, stimulate thirst and retain salt and water to maintain blood pressure and preserve cardiac and cerebral perfusion. Various compensatory mechanisms preserve glomerular perfusion.[25] Autoregulation is achieved by stretch receptors in afferent arterioles that cause vasodilation in arterioles in response to reduced perfusion pressure. Under physiologic conditions autoregulation works until a mean systemic arterial blood pressure of 75–80 mm Hg. Below this, the glomerular ultrafiltration pressure and GRF decline. Kidney production of prostaglandins, kallikrein and kinins as well as nitric oxide is increased contributing to the vasodilation.[26,27] NSAIDs, by inhibiting prostaglandin production, worsen kidney perfusion in patients with hypoperfusion. Selective efferent arteriolar constriction, which is a result of ATII, helps preserve the intraglomerular pressure andGFR. ACE inhibitors inhibit synthesis of angiotensin II and so disturb this delicate balance in patients with severe reductions in EAV such as severe CHF or bilateral renal artery stenosis and can worsen prerenal azotemia. On the other hand, very high levels of angiotensin II seen in circulatory shock causes constriction of both afferent and efferent arterioles which negates its protective effect.

Although these compensatory mechanisms are protective against acute renal failure, they are overwhelmed in states of severe hypoperfusion. Renovascular disease, hypertensive nephrosclerosis, diabetic nephropathy as well as older age predispose patients to kidney hypoperfusion[28] at lesser degrees of hypotension.

Post-Renal Acute Kidney Injury

Post-renal AKI occurs from either ureteric obstruction or bladder/urethral obstruction. AKI from ureteric obstruction requires that the blockage occur either bilaterally at any level of the ureters, or unilaterally in a patient with a solitary functioning kidney or CKD. Ureteric obstruction can be either intraluminal or external. Bilateral ureteric calculi, blood clots, and sloughed renal papillae can obstruct the lumen, while external compression from tumor or hemorrhage can block the ureters as well. Fibrosis of the ureters intrinsically or of the retroperitoneum can narrow the lumen to the point of complete luminal obstruction. The most common cause for post-renal azotemia is structural or functional obstruction of the bladder neck. Prostatic conditions, therapy with anti-cholinergic agents and a neurogenic bladder can all cause post-renal AKI. Relief of the obstruction usually causes prompt return of GFR if the duration of obstruction has not been excessive. The rate and magnitude of functional recovery is dependent on the extent and duration of the obstruction.[29]

AKI resulting from obstruction usually accounts for less 5% of cases, although in certain settings, e.g., transplant, it can be as high as 6–10%. Clinically the patient can present with pain and oliguria, though these are non-specific. Because of the ease of ultrasonography, its diagnosis is usually straightforward, although a volume depleted patient or a patient with severe reduction in GFR may not show hydronephrosis on radiological assessment. Since initially during the course of the disease GFR is not affected, volume repletion can help with the diagnosis by increasing GFR and urine production into the ureter leading to dilation of the ureter proximal to the obstruction and enhancing ultrasound visualization. Early diagnosis and prompt relief of obstruction remain key goals in preventing long-term parenchymal damage as the shorter the period of obstruction the better the chances for recovery and long-term outcomes. The pathophysiology and treatment of obstructive uropathy are discussed extensively in another chapter.

Intrinsic or Intra-Renal Acute Kidney Injury

It is helpful to divide the causes of intrinsic renal azotemia among categories that delineate the site of the initiating injury. Thus the most useful classification is as follows: (1) Vascular—(a) large renal vessels and (b) renal microvasculature; (2) Glomerular; (3) Tubular and (4) Interstitial. AKI secondary to vasculitides and rapidly progressive glomerulonephritides are discussed elsewhere in the text. Below we shall focus on AKI pathophysiology secondary to tubular and interstitial diseases before going on to discuss ATN in detail.

Interstitial

Acute interstitial nephritis (AIN) represents a frequent cause of acute kidney injury, accounting for 15–27% of renal biopsies performed because of this condition. By and large, drug-induced AIN is currently the commonest etiology of AIN, with antimicrobials and nonsteroidal anti-inflammatory drugs being the most frequent offending agents.[30] Other conditions such as leukemia, lymphoma, sarcoidosis, bacterial infections (e.g., E.coli) and viral infections (e.g., cytomegalovirus) can also cause acute interstitial disease

leading to AKI. The inflammatory cellular infiltrates that characterize AIN, mainly composed of T lymphocytes and macrophages, are a powerful source of cytokines that increase the production of extracellular matrix and the number of interstitial fibroblasts, and induce an amplification process recruiting more inflammatory cells and eosinophils into the interstitium.[31] These are often patchy and present most commonly in the deep cortex and outer medulla and mostly comprised of T-cell and monocytes/macrophages and eosinophils. These infiltrations are always associated with interstitial edema, and sometimes with patchy tubular necrosis that if present is usually in close proximity to areas with extensive inflammatory infiltrates.[32] A few neutrophilic granulocytes may be present as well. The majority of cases of AIN are probably induced by extra-renal antigens being produced by drugs or infectious agents that may be able to induce AIN by: (1) binding to kidney structures, (2) modifying immunogenetics of native renal proteins, (3) mimicking renal antigens, or (4) precipitating as immune-complexes and hence serving as the site of antibody or cellular mediated injury.[33] Medications and specific microbial antigens could elicit an immune reaction after their interstitial deposition (planted antigens). Conversely, tubular cells have the capacity to hydrolyze and process exogenous proteins. In this regard, medications can bind to a normal component of TBM, behaving as a hapten, or can mimic an antigen normally present within the TBM, inducing an immune response directed against this antigen.[34] Immunofluorescence studies in renal biopsies of patients with AIN are generally negative, indicating the absence of antibody-mediated immunity that has a marginal, if any, pathogenic role.[31]

TABLE 76.3 Classification of Various Common Drugs Based on Pathophysiological Categories of AKI

1. **Vasoconstriction/impaired microvasculature hemodynamics (pre-renal)** – NSAID's, ACE-inhibitors,angiotensin receptor blockers, norepinephrine, tacrolimus, cyclosporine,diuretics, cocaine, mitomycin C, estrogen, quinine, interleukin-2, COX-2 inhibitors
2. **Tubular cell toxicity**–Antibiotics – Aminoglycosides, amphotericin B, vancomycin, rifampicin, foscarnet, pentamidine, cephaloridine, cephalothin. Radio-contrast agents, NSAID's, acetaminophen, cyclosporine, cisplatin, mannitol, heavy metals, IVIG, ifosfamide, tenofovir.
3. **Acute Interstitial Nephritis** – Antibiotics – Ampicillin, penicillin G, methicillin, oxacillin, rifampicin, ciprofloxacin, cephalothin, sulfonamides. NSAIDs, aspirin, fenoprofen, naproxen, piroxicam, phenybutazone, radio-contrast agents, thiazinde diuretics, phenytoin, furosemide, allopurinol, cimetidine, omeprazole
4. **Tubular Lumen obstruction** – Sulfonamides, acyclovir, cidofovir, methotrexate, triamterene, methoxyflurane, protease inhibitors, ethylene glycol, indinivir, oral sodium phosphate bowel preparations.
5. **Thrombotic Microangiopathy** – Clopidogrel, cocaine, ticlodipine, cyclosporine, tacrolimus, mitomycin C, oral contraceptives, gemcitibine, bevacizumab.
6. **Osmotic nephrosis** – IVIG, Mannitol, dextrans, hetastarch

Exogenous Nephrotoxins

The kidneys are vulnerable to toxicity as they are the major elimination/metabolizing route of many of these elements and also because epithelial cells reabsorb agents from the interstitium that is exposed to high concentrations of these agents.

RADIOCONTRAST INDUCED NEPHROPATHY (CIN)

CIN is a common complication of radiological or angiographic procedures. The incidence varies from 3–7% in patients without any risk factors, but can be as high as 50% in patients with chronic kidney disease (CKD). Other risk factors include diabetes, intravascular volume depletion, high osmolar contrast, advanced age, proteinuria and anemia.[35,36] The pathophysiology of CIN likely consists of combined hypoxic and toxic renal tubular damage associated with renal endothelial dysfunction and altered microcirculation.[37,38] Initially, radiocontrast injection leads to an abrupt but transient increase in renal plasma flow, GFR and urinary output[39] due to the hyperosmolar radio-contrast agent enhancing solute delivery to the distal nephron and leading to an increased oxygen consumption by enhanced tubular sodium reabsorption. A transient phase vasodilation is followed by a period of sustained vasoconstriction, resulting in hypoxic cell damage mainly to the outer medulla.[40] Renal parenchymal oxygenation decreases especially in the outer medulla as documented in various studies where the cortical PO_2 declined from 40 to 25 mmHg, while the medullary PO_2 fell from 30–26mmHG to 9–15 mmHg.[38,41,42] The renin-angiotensin system is thought to be activated by RC media, while there is also evidence that Ca^{2+} as a second messenger is involved in the renal vasoconstriction.[43] Perturbations in the local vasodilatory system are evident as suggested by aggravation of RCIN in the setting of concomitant NSAID presence, thus highlighting the role of altered renal prostaglandin production in its pathogenesis. Similarly, NO inhibition potentiates the renal damage while L-argninine, a precursor of NO, attenuates the damage implying that a disturbance in NO production likely worsens the decrease in RBF after RC infusion. Increased synthesis and release of endothelin (ET) and adenosine from endothelial cells, combined with suppression of NO production likely results in medullary hypoxia secondary to shunting of blood flow to the cortex. Although experimental animal studies have demonstrated beneficial effects of

using ET-antagonists, their efficacy has not been reproduced in human clinical studies. Video microscopy studies have shown that radiocontrast agents markedly reduced inner medullary papillary blood flow, to the extent of near cessation of RBC movement in papillary vessels, associated with RBC aggregation within the papillary vasa recta.[44] Lastly, mechanical factors such as the viscosity of the radiocontrast agent also plays a role, as the contrast agents increase blood viscosity in the inner medulla which already has hypertonic conditions.[45,46]

Cell-culture studies indicate direct RC media toxicity to proximal tubule cells, which has been observed in human studies where biopsies have shown morphological features of proximal tubular vacuolization, tubular degeneration, and interstitial inflammation and edema. These effects are more pronounced under hypoxic or high-osmolarity conditions. Apoptosis is also induced by RC media in *in vitro* studies.[47] RCIN typically manifests as an acute deline in GFR within 24 to 48 hours after administration with return to baseline by one to two weeks. Urinalysis in these patients can show either findings of pre-renal azotemia with low fractional excretion of sodium, but in severe cases, findings similar to ATN with tubular epithelial cells and coarse granular casts are seen. In human studies, volume expansion is key to prevention but possibly N-acetyl-cysteine or sodium bicarbonate therapy have been shown to be beneficial in reducing RCIN. The reno-protective effects of N-acetlycysteine may be related to improved NO dependent vasodilation and medullary oxygenation in addition to scavenging of free radicals.[37]

ACUTE PHOSPHATE NEPHROPATHY

Oral sodium phosphate containing preparation solutions for colonscopic procedures have recently been identified as a cause for AKI.[48–50] The pathogenesis is related to a transient and significant rise in serum phosphate concentration that occurs simultaneously in the setting of intravascular volume depletion due to the prep agent itself. Intra-tubular precipitation of calcium phosphate salts obstructs the tubular lumen and causes direct tubular damage. Although the complete mechanisms are not fully eludicated, risk factors for acute phosphate nephropathy include pre-existing volume depletion, use of ACE inhibitors and ARBs, CKD, older age, female sex, and higher doses of oral sodium phosphate.[49,50]

Endogenous Nephrotoxins

Myoglobin and hemoglobin are endogenous toxinscommonly associated with ATN. Muscle injury due to insults such as trauma, excessive immobilization, ischemia, inflammatory myopathis, drugs and metabolic disorders, cause the rapid and excessive release of myoglobin.[51] Myoglobin, a 17 kDa hemeproteinis highly filtered by the glomerulus, and enters the proximal tubule epithelial cells through endocytosis and is metabolized. It causes red-brown colored urine with a positive dipstick for heme, but relative absence of red cells. Intravascular hemolysis results in circulating free hemoglobin, which, when it exceeds haptoglobin-binding is filtered, resulting in hemoglobinuria, hemoglobin-cast formation and heme uptake by proximal tubule cells. AKI in rhabdomyolysis is due to a combination of factors including volume depletion, intra-renal vasoconstriction, direct heme-protein mediated cytotoxicity and intraluminal cast formation. The heme center of myoglobin may directly induce lipid peroxidation, generation of isoprostanes and liberation of free iron.[52] Iron is an intermediate accelerator in the generation of free radicals. There is also evidence to suggest increased formation of H_20_2 in rat kidney model of myohemoglobinuria.[53] The subsequent hydroxyl (OH^-) radical plays a vital role in oxidative stress induced AKI through mechanisms discussed in detail later in the chapter. Iron chelators such as deferoxamine and scavengers of reactive oxygen species such as glutathione have been shown to provide protection against myo-hemoglobinuric AKI.[54] Similarly, endothelin antagosists have also been shown to prevent hypofiltration and proteinuria in rats that underwent glycerol induced rhabdomyolysis.[55] These studies implicate the important role of vascular mediators such as endothelin-1, thromboxane A, TNF-α, and F-isoprostance. Others have shown NO supplementation might be beneficial by preventing the heme induced renal vasoconstriction, as heme proteins scavenge nitric oxide.[56,57]

Precipitation of myoglobin with Tamm-Horsfall protein and shed proximal tubule cells leads to cast formation and distal tubular obstruction which is enhanced in acidic urine.[58] In human studies volume expansion and perhaps alkalinaztion of urine to limit cast formation are the preventive measures generally employed as none of the experimental agents used in animal studies have been convincingly beneficial.

Other endogenous nephrotoxins include uric acid and light chains. Excessive light chains, produced in diseases such as multiple myeloma, are filtered, absorbed and then catabolized in proximal tubule cells. The concentration of light chains leaving the proximal portion of the nephron depends on the capacity of the proximal tubule to reabsorb and catabolize them as well as the filtrate concentration. Certain light chains can be directly toxic to the proximal tubules themselves.[59] Light chain-induced cytokine release has been associated with nuclear translocation of NF-κB suggesting that its endocytosis leads to production of

inflammatory cytokines through activation of NF-κB.[60] Once the capacity for proximal tubule uptake is overwhelmed, a light chain load is presented to the distal tubule where upon reaching a critical concentration the light chains aggregate and co-precipitate with Tamm-Horsfall protein and form characteristic light chain casts.[61] Light chains, in the amount seen in plasma cell dyscrasiasts, are also capable of catalyzing the formation of H_2O_2 in cultured HK-2 cells. H_2O_2 stimulates the production of monocytes chemo-attractant protein (MCP-1), a key chemokine involved in monocytes/macrophage recruitment to proximal tubule cells.[62]

Any process reducing GFR such as volume depletion, hypercalcemia or NSAID's will accelerate and aggravate cast formation. It has been proposed that acutely reducing the presented light chain load by plasmapheresis might be beneficial in limiting cast formation and reducing the extent of the AKI in certain select patients.[63] Tumor cell necrosis following chemotherapy can release large amounts of intracellular contents such as uric acid, phosphate and xanthine into the circulation that can potentially lead to AKI. Acute uric acid nephropathy with intratubular crystal obstruction and interstitial nephritis is not seen as commonly as it was in the past mainly due to prophylactic use of allopurinol prior to chemotherapy and or rasburicase to acutely lower the serum uric acid levels.

Other therapeutic agents such as amphotericin B, acyclovir, indinavir, cidofovir, foscarnet, pentamidine, and ifosfamide can all directly cause tubular injury.

MODELS OF ACUTE KIDNEY INJURY

Experimental Models of ARF

Despite a variety of animal and cell culture models of AKI, there remains a need to develop *in vivo* experimental models of ischemic AKI more closely mimicking clinical human AKI for the development of effective therapies.[64,65] Some of the important principles in studying the pathophysiology of AKI in various models include the importance of measuring parameters at multiple appropriate time points and the ability to control physiological functions known to affect kidney function (e.g., temperature, blood pressure, anesthesia, fluid status etc.). A limitation in many experimental models is the lack of co-morbidities such as aged animals, chronic kidney disease, multi-organ failure, pre-existing vascular changes or multiple renal insults, which quite often co-exist in human AKI. We will briefly describe the pros and cons of using these experimental models (Table 76.4).

The warm ischemia-reperfusion renal clamp model is one of the most widely used experimental models in rats and mice because of its simplicity and reproducibility. In rats the inflammatory response, tubular injury and repair, and medullary congestion are similar and probably comparable to human ischemic ATN. However, in human AKI, isolated ischemia is seen rarely seen and neither is there usually complete cessation of blood flow to the kidneys. In this model, important mediators of injury suchreactive oxygen species (ROS) and perioxynitrite species may have a different or delayed role as compared to low oxygen states in hypoperfusion models. Total blood flow cessation also prevents the degradative products of the ischemic kidney from being eliminated. Other factors playing a role in the pathophysiology of AKI such as inflammatory mediators released from gut ischemia, endothelium, smooth vascular muscle cells need to be taken into consideration in any experimental model. Release of bowel proteins into the circulation can act as inflammatory mediators and increase the susceptibility to AKI.[66] The S3 segment of the proximal tubule is almost completely necrosed in such models, a finding not seen very frequently in human ARF. In contrast to animal models, human AKI histological biopsy data are lacking at early time points from the onset of insult.[65] This has made comparison between animal models and human AKI of limited value. Lastly, drug delivery is prevented in total occlusion models, which actually may be of significant value during the peak ischemic insult.

The cold ischemia-warm reperfusion model resembles AKI in human transplants but this model is inadequately studied and difficult experimentally. In the isolated perfused kidney model, the kidney is perfused in *ex vivo* using perfusates either with or without erythrocytes, and employs either ischemic (stopping perfusate) or hypoxic (reduced oxygen tension of erythrocytes) to induce functional impairment. The morphological patterns are different in erythrocyte free and erythrocyte rich perfusates. The latter system is more comparable with what is observed histologically in animal models. Additionally, limitations include exclusion of various inflammatory mediators, neuroendocrine hemodynamic regulation, and systemic cytokine and growth factor interactions known to be present and play a pathophysiologic role in animal models.

Cardiac arrest is a common scenario leading to human ARF. Rabb et al. have described whole body ischemia reperfusion injury model induced by 10 minutes of cardiac arrest, followed by cardiac compression resuscitation, ventilation, epinephrine and fluids, which that lead to a significant rise in SCr and renal tubular injury at 24 hours.[67] One of the unique advantages of this model is the cross talk between vital organs such as the brain, heart, lung and the renal hemodynamics.[68] A hypoperfusion model of AKI using partial aortic clamping was first described by Zager

et al. may be more representative of human AKI reflecting a state of reduced blood flow to the kidney with systolic blood pressure around 20 mm Hg, resulting in reproducible AKI.[69,70] This was also recently adapted and refined in a study where a novel compound, soluble thrombomodulin, was used to minimize ischemic injury in a partial aortic clamp AKI model.[71]

Toxic models of renal failure employ various known toxins, such as radiocontrast, gentamicin, cisplatin, glycerol and pigments including myoglobin and hemoglobin. Septic models to study AKI include cecal ligation and puncture, endotoxin infusion andbacterial infusion into the peritoneal cavity. The endotoxin model which is simple, inexpensive and suitable to study new pharmacological agents, has certain drawbacks as well. There is variability amongst sources and types of lipopolysaccharide (LPS) endotoxin, rate and method of administration, and it is usually of short duration due to the high mortality associated with the doses required to induce AKI. It also tends to be a vasoconstrictive model and does not recapitulate the hemodynamics nor inflammation of human sepsis.[72] In the cecal ligation and puncture model (CLP), there is considerable similarity with sepsis in humans with acute lung injury, metabolic derangement and systemic vasodilation, accompanied by increased cardiac output initally. However there is some variability depending on the mode and size of cecal perforation. Star et al. have developed a new sepsis model keeping under consideration the following facts: (1) animals should received the same supportive therapy that is standard for ICU patients (i.e., fluid resuscitation and antibiotics); (2) age, chronic co-morbid conditions and genetic heterogeneity vary.[73] Complex animal models of human sepsis that introduce these disease-modifying factors are likely more relevant and may be more pharmacologically relevantthan simple animal models.[73] The zebra fish model developed by Bonventre et al. has the advantages of markedly improved accessibility of the kidney, feasibility of knock-down and upregulation of genes and a short phenotypic readout time, while at the same time possessing the complexity of an organism to study renal injury. These properties may make it a useful inexpensive tool to screen therapeutic agents in the future.[74]

Experimental models of hypoxic acute kidney damage differ morphologically in the distribution of tubular cell injury and tubular segment types differ in their capacity to undergo anaerobic metabolism, mount hypoxia-adaptive responses mediated by hypoxia-inducible factors (HIFs).[75] Hence it is important to keep them in mind the potential pitfalls when evaluating experimental studies or therapeutic interventions using these models. The lack of ability to demonstrate effectiveness of an agent in humans which has been shown to be efficacious in animal models, does not necessarily reflect a flaw with the model. Most often, the agent is administered very late in the course of the human disease, and the patient heterogeneity of the population makes it even more difficult to establish true efficacy.[76]

Role of Biomarkers in AKI

Changes in serum creatinine and/or urine output to diagnose AKI[77] may not be able to identify the early stages of intrinsic kidney injury. Early identification and subsequent early pharmacologic intervention may improve outcomes in AKI. In order to facilitate the early diagnosis of intrinsic injury, multiple biomarkers of tubular injury have been evaluated.[78,79] Biomarkers for AKI include N-acetyl-*B*-D-glucosaminidase (NAG), kidney injury molecule 1 (KIM-1), neutrophil gelatinase-associated lipocalin (NGAL) and interlukin 18 (IL-18), among others.[78,79] In addition, serum cystatin C has been proposed as more sensitive and timely than serum creatinine for detecting changes in GFR, and urinary cystatin C has been proposed as a marker of tubular injury.[78,80,81] Although not utilized yet for routine clinical use, these biomarkers have the potential to provide an early diagnosis of intrinsic AKI and the ability to differentiate pre-renal AKI from intrinsic tubular damage, as well as to provide prognostic information of an episode of AKI. One biomarker or a panel of these biomarkers may eventually provide the necessary early diagnosis to allow therapies to limit kidney damage and promote recovery of kidney function. Please refer to Chapter 75 for a detailed explanation on the role of serum and urinary biomarkers in AKI.

PATHOPHYSIOLOGY OF ACUTE KIDNEY INJURY

Morphological Changes of AKI

Acute Tubular Necrosis (ATN) is the most common form of AKI, and this process of renal tubular injury encompasses more than just cell death followed by repair. It is easier to understand the entire spectrum of injury if one looks at the different compartments involved and the phases they go through (Fig. 76.2).

Tubular Epithelial Cell Injury

Although data regarding which nephron segments in humans with ATN are more severely affected is sparse due to lack of biopsies early in the course of ATN, experimental animal models provide sufficient information to help understand and delineate the

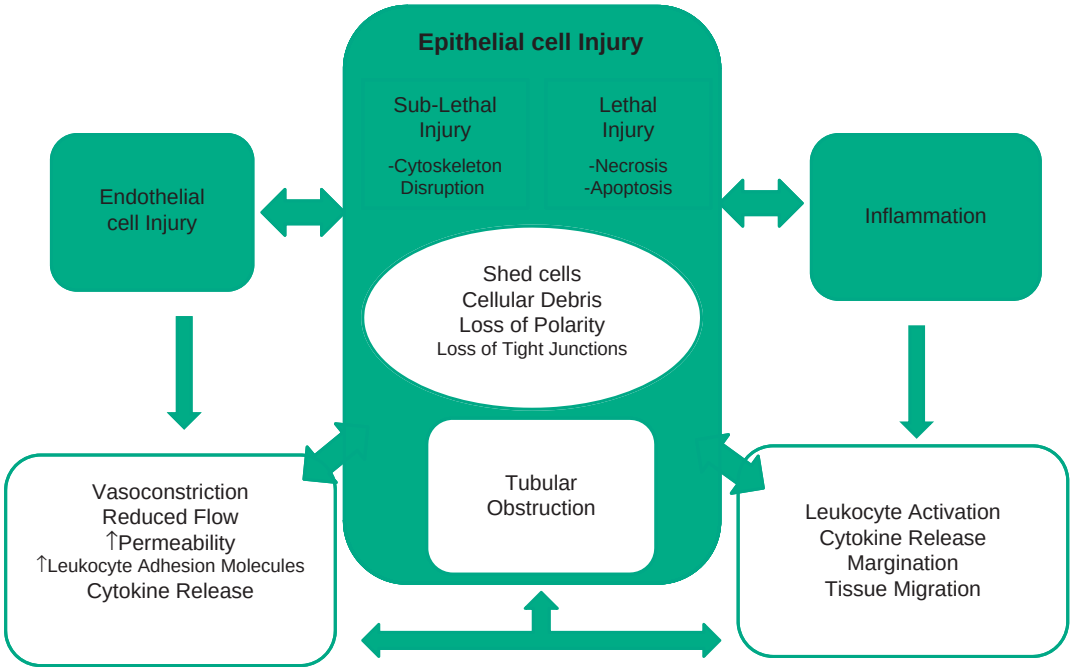

FIGURE 76.2 Overview of pathogenesis in acute kidney injury. The major pathways of impairment of glomerular filtration rate (GFR) in ischemic acute tubular necrosis as a result of vascular and tubular injury (see text for details). *(Source: unpublished figure from Encyclopedia of Intensive Care Medicine. Publisher, Springer. Eds, Vincent, Jean Louise Hall, Jesse B. Ch Epithelial Cell Injury by Asif Sharfuddin and Bruce Molitoris. First Edition due to published March 2012).*

mechanisms of ATN by histological analysis. In ATN the most severe tubular injury takes place within the outer medulla of the kidney, and involves the S3 segment of the proximal tubule (pars recta) and the medullary thick ascending limb (MTAL) of the distal nephron.[82] The S3 segment has limited capacity to undergo anaerobic glycolysis. Secondly, due to its unique primarily venous capillary regional blood flow, there is marked hypoperfusion and congestion in this medullary region post injury that persists even though cortical blood flow may have returned to near normal levels after ischemic injury. Endothelial cell injury and dysfunction are primarily responsible for this phenomenon, known now as the "extension phase" of AKI.[83] The proximal tubule S_1 and S_2 segments are most commonly involved in toxic nephropathy due to their high endocytic rates leading to increased cellular uptake of the toxin.

The apical brush border of proximal tubule cells (PTC) is damaged early resulting in microvilli disruption and detachment from the cell surface forming membrane bound "blebs" released into the tubular lumen. Loss of microvillar surface leads to ineffective enzymatic activity, endocytosis, channel and transporter density resulting in diminished effective transcellular absorption. Patchy detachment and subsequent loss of tubular cells exposing areas of denuded tubular basement and focal areas of proximal tubular dilatation along with the presence of distal tubular casts is also a major pathological findings in ATN.[84] Because the surviving adjacent cells tend to spread out and become flattened, in an attempt to completely or partially cover the denuded epithelium, the appearance is often of a flattened and pauci-cellular epithelium.

Sloughed off tubular cells are also present in the tubular lumen, where they can be overtly necrotic or viable. These cells along with brush border vesicle remnants and cellular debris combine with Tamm-Hosrfall glycoprotein (THP) and form the classical "muddy-brown granular" casts, that have the potential to obstruct the tubular lumen. Cast formation may be potentiated by relative stasis of tubular fluid flow because of the reduction in GFR. On biopsy, these casts may not be captured since they exist within the medulla and actual site of obstruction may be a short segment. However, dilation of tubules proximal due to obstruction is often seen as long as the GFR and regional tubular epithelium are maintained. Eventually decompression of these tubules will occur because of decreased GFR, damage to proximal tubular cells, and persistent reabsorption of tubular fluid in uninjured areas. The injury to the proximal tubule cells in humans is also seen in experimental models of ischemic AKI (Fig. 76.3).

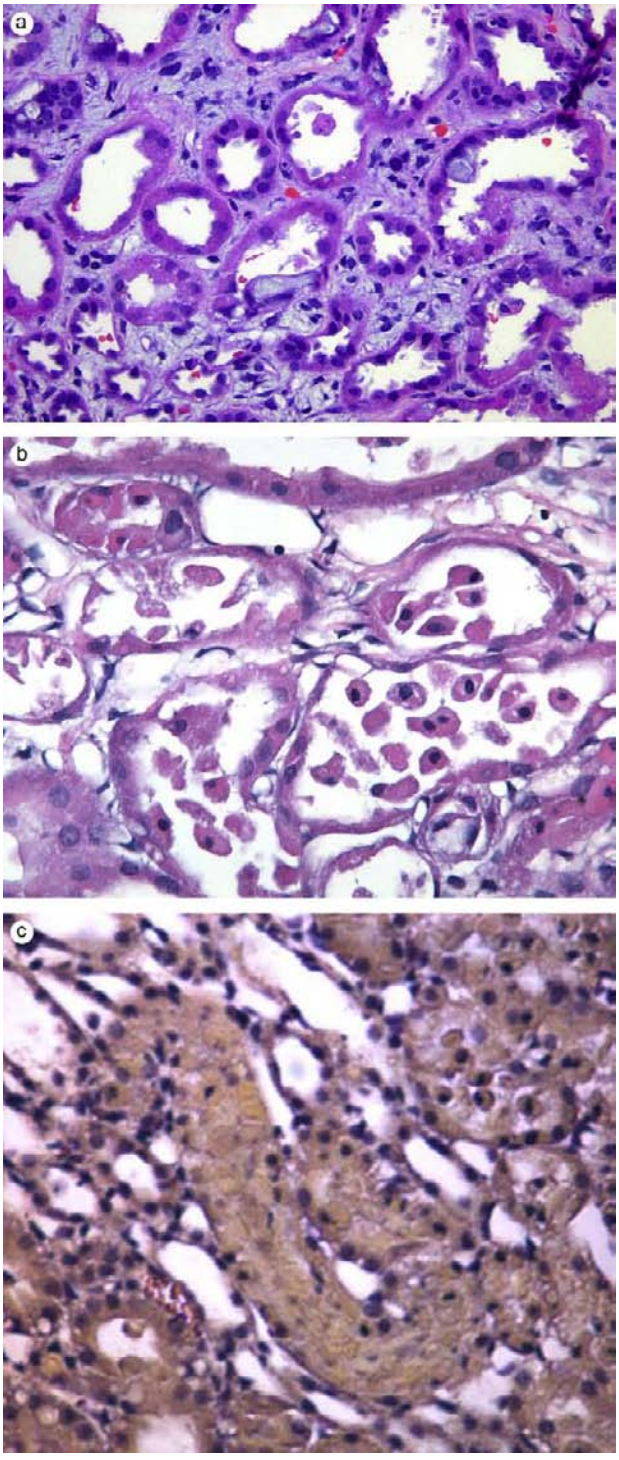

FIGURE 76.3 A. Morphology of acute tubular necrosis in human biopsy specimen. Proximal tubules show loss of brush border, flattening of tubular cells with denuded basement membranes, blebbing of cytoplasm (arrowhead) and vacuolization in a patient with toluene induced acute tubular necrosis. There is also evidence of extensive interstitial edema and expansion with presence of inflammatory cells (arrow). (*Slide courtesy of Dr Carrie Phillips*). B. Morphology of acute tubular necrosis in rat kidney specimen subjected to 60 minutes of hypoperfusion. Areas of detachment of cell and intact cells within the tubular lumen. C. Cellular cast within the tubular lumen. See color plate section at the back of the book.

Apoptotic features are more commonly seen in both proximal and distal tubule cells as compared to necrosis which itself is inconspicuous and restricted to the highly susceptible outer medullary regions. Apart from the proximal tubular cells, the other major epithelial cells of the nephron are those of the medullary thick ascending limb located distally. Apoptotic changes have been detected in human AKI, as shown in distal nephron segments in nephrotoxic acute tubular necrosis. Distal tubular cell apoptosis also occurs in donor biopsies before engraftment, which was predictive of delayed graft function due to acute tubular necrosis.[85] In an *ex vivo* model of hypoxic AKI, inhibition with FG-4497 (specific prolyl-hydroxylase inhibitor which leads to activation of HIF-Aplha) in the isolated perfused kidney led to decreased selective outer medullary distal tubular injury.[86] The course of a tubular cell alterations may take different paths depending on the type and extent of injury as discussed later.

GLOMERULUS

The glomerular tuft collapses in ischemic injury, and some investigators have described the diameter of ischemic endothelial cell fenestrae on average to be larger than that of untreated kidneys.[87] Other human biopsy studies have documented enlargement of juxtaglomerular apparatus during the oligoanuric phase, and thickening and coarsening of foot processes. But these findings have not been confirmed and there still exists a paucity of data on glomerular changes in human ATN in different stages.[87,88] Glomerular epithelial cell injury in ischemic, septic or nephrotoxic injury is not classically seen although some studies have shown thickening and coarsening of foot processes and recently Wagner et al. have shown podocyte specific molecular and cellular changes.[89]

Epithelial Cytoskeletal Abnormalities

Cytoskeletal Alterations

Cellular structure and function are mediated by an interactive and dynamic role of the actin cytoskeleton including but not limited to proximal tubule brush border microvilli structure and function, cell polarity, endocytosis, signal transduction, cell motility, movement of organelles, exocytosis, cellular division and migration, barrier function of the junctional complex, cell-matrix adhesion and signal transduction.[90] Actin is present in globular form (G-actin) that can self-assemble into filamentous (F-actin) to form helical microfilaments. In conjunction with actin-binding proteins, guanosine triphosphatases (GTPases) and adenosine triphophate (ATP), the dynamic process of actin assembly and disassembly is accomplished. The actin

cytoskeleton is present as a layer of microfilaments below the apical plasma membrane, forming the terminal web. The architectural integrity of brush border microvilli is dependent upon extensions of actin filaments from the terminal web to the tip of the individual microvilli.

Under physiologic conditions most actin monomers are ATP-bound, while the bulk of actin found within actin filaments is ADP-bound. The unique binding sites of actin for nucleotides and divalent cations allow conformational changes, apart from its hydrolytic properties that are activated by polymerization. The G-actin ADP complex released on depolymerization (disassembly) undergoes nucleotide exchange with abundant cytosolic ATP, and is then stored as a high energy G-actin ATP intermediate by thymosin-sequestering proteins until needed for polymerization.[91,92] Four groups of actin-binding protein mediate different effects on the actin cytoskeleton including actin sequestering, capping, severing and nucleation. These effects in turn coordinate the continual remodeling of the cytoskeleton and give it the ability to respond to various internal and external stimuli.[93]

Ischemic insults to proximal tubule cells induce a rapid and severe degeneration of the microvillar F-actin core, which in turn mediates the plasma membrane finger-like microvillar structural morphology changes including loss of the apical membrane through blebbing. The degeneration of this F-actin core occurs as a result of ATP depletion leading to depolymerization of microvillar actin. In addition ezrin, an actin binding phosphorylated protein, becomes dephosphorylated during ischemia and the attachment between the microvillar F-actin core and the overlying plasma membrane is lost[94] (Fig. 76.4). The apical membrane is then either exfoliated as "blebs" into the tubule lumen or internalized with the capability of being recycled during cellular recovery. Furthermore, the concentration of F-actin in the cell increases with the formation of large cytosolic aggregates in the perinuclear region and also near the junctional complexes and basolateral membrane. ATP-G-actin levels decrease rapidly during ischemia. Since ADP G-actin cannot be sequestered by thymosin its concentration exceeds a critical threshold resulting in the polymerization in an unregulated fashion.[92]

The actin binding protein family of cofilin, also known as actin depolymerizing factor (ADF), has been shown by Molitoris and colleagues to be a critical mediator in F-actin severing during ischemic injury. In proximal tubule cells (PTC) ADF/cofilin, which when phosphorylated is inactive and does not bind actin, gets rapidly dephosphorylated and therefore activated by renal ischemia. This leads to relocalization from the cytoplasm to the surface membrane, as well as in shed membrane-bound vesicles seen in PTC lumen.[95,96] The mechanism by which disruption of F-actin structure occurs also involves the role of another family of actin

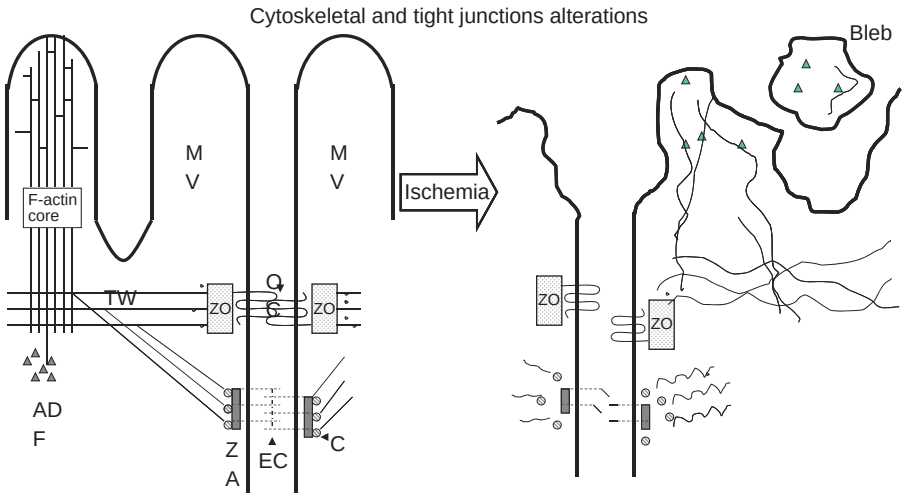

FIGURE 76.4 Cytoskeletal and tight junctions alterations in AKI. Ischemic insult to a proximal tubule cell disrupts actin cytoskeleton and junctional complexes. The orderly arrangement of the actin microfilaments extends from terminal web (TW) into microvilli (MV) as well as interacting with tight junction proteins zonula adherens (ZO), and adherens junction proteins zonula adherens (ZA). Occludin (OC) is transmembrance integral protein of the tight junction forming a multiprotein complex with ZO, controlling paracellular permeability. Severe ATP depletion results in occludin translocating to the cytoplasm, compromising adhesion and permeability. Similarly adherens junction proteins such E-cadherin (EC) and catenins (C) that interact with actin and other junctional components are compromised. ADF or cofilin is activated with ischemia that translocates and gets recruited to apical microvilli and binds to F-actin structures, resulting in severing and depolymerization of F-actin. This leads to subsequent apical membrane disruption and bleb formation.

binding protein called tropomyosin. Under physiologic conditions tropomyosin binds to and stabilizes the F-actin microfilament core in the terminal web, and protects the filaments from ADF/cofilin induced severing and depolymerization. Ashworth et al. have demonstrated that after ischemic injury there is dissociation of tropomyosin from the microfilament core providing access to microfilaments in the terminal web for F-actin binding, severing and depolymerizing actions of ADF/cofilin proteins.[97]

Alterations in the activity of Rho family of GTPases also contributes to changes in actin cytoskeleton associated with ischemia. First, chemical ATP depletion was shown to cause Rho GTPase inactivation.[98] Secondly, GTP depletion during ischemia could also inactivate Rho GTPase function.[99] These two findings, coupled with the finding that cells transfected with a constitutively active form of RhoA during chemical ATP depletion are protected against actin depolymerization, provide evidence of ischemia-induced RhoGTPase inactivation.[100] An additional cytoskeletal component important for cellular polarity and protein trafficking is microtubules. Wald et al. have shown that in reperfused rat proximal tubules non-centrosomal microtubule organizing centers (MTOCs) were fully detached from the cytoskeleton and scattered throughout the cytoplasm at three days after reperfusion when brush borders membranes were mostly reassembled with normal F-actin distribution. At that time microtubules were also fully reassembled but lacked their normal apicobasal orientation, hence demonstrating that the reestablishment of the submembrane F-actin does not seem to be sufficient for a full polarization of the cells.[101] Microtubule formation also occurs by continuous assembly and disassembly of α and β tubulin heterodimer with an intricate polymerization process. Studies indicate that during ischemia α and β tubulin do not participate in microtubule polymerization and their localizations are also different. The fact that GTP levels are depleted by 90% after 30 minutes kidney ischemia in rats supports this assumption of impaired microtubule polymerization.[102]

Epithelial cells are characterized by an asymmetrical distribution of proteins and lipids in the apical and basolateral membrane resulting in surface membrane polarity of these cells. In ischemic ATN this polarity is abolished, but has the potential for re-establishment during recovery. Molitoris et al. have shown evidence to suggest the Na^+K^+-ATPase pump that normally resides in the basolateral membrane of proximal tubule cells, under conditions of chemical anoxia, is redistributed to the apical membrane.[103] This redistribution, which can occur as early as 10 min after ischemia, is another consequence of the disruption of the actin cytoskeleton, which normally maintains the attachment of the Na^+K^+-ATPase to the basolateral membrane.[103–105] Furthermore, both ankyrin and fodrin dissociated from F-actin and each other during ATP depletion.[106] These data were confirmed and indicate wide spread actin cytoskeleton alterations during ATP depletion lead to altered protein-protein interactions.[107] Other nephron segments such as the distal tubule cells, and TAL do not show similar apical redistribution of the Na^+K^+-ATPase. This redistribution results in functional consequences reflected in the loss of unidirectional transport of salt and water across the epithelial cell, resulting in one mechanism of the high fractional excretion of Na^+ seen in patients with ATN (Fig. 76.5).

Junctional Defects and Permeability Alterations

Cell-cell junctional complexes actively participate in the establishment and maintenance of cell polarity, paracellular transport, cytoskeletal interactions, and rearrangements in cellular shape. Ischemia also induces functional changes in the epithelial junctional complexes, which are comprised of at least three structures: adherens junctions (also known as zonula adherens (ZA)), tight junctions (zonula occludens (ZO)) and desmosomes. Tight junctions are located directly apical to the adherens junction, are composed of a growing list of proteins such as occludin, claudin, protein kinase C (PKC), ZO-1 etc., with multiple functions such as adhesion, permeability, structural integrity and paracellular transport of solutes. The actin present in the cortical belt, and in the terminal web, is also linked to the tight junction. Adherens junction, which are located directly below the tight junction, form strong cell–cell adhesion complexes and are composed of proteins such as cadherins and catenins are associated with numerous other junctional and cytoplasmic proteins. They are responsible for adhesion of adjacent cells, regulation of adhesion, and are also linked to the actin cytoskeleton.[108]

In vivo and *in vitro* studies indicate that in early ischemic injury there is an "opening" of the tight junctions as the proteins such as ZO-1 and cingulin become insoluble during ATP depletion, and associate into macromolecular intracellular complexes.[109] This leads to increased permeability of the tight junctions in sublethal injury resulting in back-leakage of glomerular filtrate, which is an important factor in the reduction of GFR as discussed later. If ATP is repleted before lethal injury the permeability defect resolves.[110] PKC signaling regulates both tight junction and adherens junction assembly. Evidence suggest that tight and adherens junction proteins including ZO-1, ZO-2, ZO-3, occludin, vinculin, and p100–p120 are affected by this kinase signaling pathway.[111] It is also likely that disruption of the actin cytoskeleton and reduction in activity of Rho-GTPases also contribute to the changes

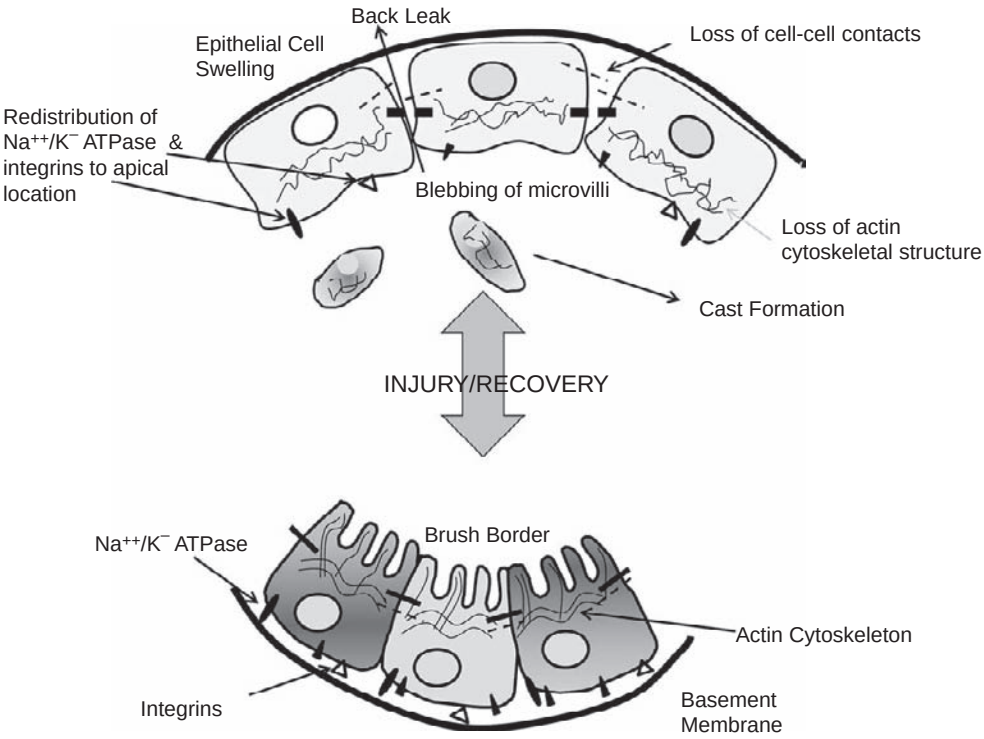

FIGURE 76.5 An overview of sublethal injury to tubular cells. An overview of sublethally injured tubular cells. Na/K/ATPase pumps are normally located at the basolateral membrane. In sublethal ischemia the pumps redistribute to the apical membrane of the proximal tubule. Upon reperfusion, the pumps reverse back to their basolateral location. *(Source: unpublished figure from Encyclopedia of Intensive Care Medicine. Publisher Springer. Eds, Vincent, Jean Louise; Hall, Jesse B. Ch Epithelial Cell Injury by Asif Sharfuddin and Bruce Molitoris. First Edition due to published March 2012.)*

in the tight junction during ischemia.[100] The loss of adherens integrity is in part caused by activation of c-Src which translocates to the adherens junction and tyrosine phosphorylates components such as β-catenin.[112] Nigam et al. have demonstrated the role of tyrosine kinases and phosphatases in the disassociation of adherens junction.[113] The importance of these animal model findings is highlighted by findings in human allografts with ATN where Kwon et al. have shown the same features noted in experimental models of loss of cell polarity and tight junctions.[114]

Epithelial cells also lose their attachment to the underlying extracellular matrix, the mechanism for which has been elucidated as at least being partially due to loss of polarity and redistribution from the basal membrane to the apical membrane of β1-integrins. Integrins are transmembrane proteins normally responsible for the anchoring of epithelial cell to the matrix through actin cytoskeleton and actin-binding proteins.[115] *In vitro* studies of MDCK cells have shown that adherence of these cells to a collagen I substratum is mediated by peripheral actin filaments and adhesion complexes regulated by myosin light chain kinases and adhesion complexes controlled by RhoA.[116] The detachment and loss of tubular cells into the lumen also contributes to the back-leakage of the glomerular filtrate, and at the same time the β1-integrins and E-cadherins might even play a role in mediating the aggregation of these exfoliated cells worsening intraluminal cast formation.

Although the glomerular injury is not as prominent in AKI, Wagner et al. have demonstrated in an *in vivo* rat model that renal ischemia induces podocyte effacement with loss of slit diaphragm and proteinuria owing to rapid loss of interactions between the tight junction proteins Neph1 and ZO-1. Cell culture models using human podocytes further showed that ATP depletion resulted in rapid loss of Neph1 and ZO-1 binding, and redistribution of Neph1 and ZO-1 proteins from the cell membrane to cytoplasm; ATP recovery increased phosphorylation of Neph1 and restored Neph1 and ZO-1 binding and their localization at the cell membrane.[89]

Tubular Obstruction

Tubular obstruction has been noted in ischemic as well as toxic models of injury. Renal tubular epithelial cells can be seen in the urine of patients with AKI,

and can be either alive, apoptotic or necrotic. Micropuncture studies, done over 20 years ago, demonstrated elevation of intratubular pressure early after reperfusion following renal artery occlusion. This is characteristically evident as tubular dilatation, with cast deposition in the distal nephron causing luminal obstruction and back pressure. Although intratubular pressures tend to fall towards normal after 24 hours, the presence of persistent obstruction can be revealed by extracellular volume expansion, which again elevates intratubule pressures. An obstructing cast in the collecting duct could potentially impair the function of multiple nephron units, as many nephrons drain into a single collecting duct.

The term "back-leak" generally implies the passive movement of GFR into the interstitium from the tubular lumen, eventually being recirculated to the systemic vasculature through the venous network. Studies have revealed that if radiolabeled compounds are microinjected into renal tubules after ischemic injury, they can be detected in the contra-lateral kidney. Human studies by Myers et al. provided evidence of transtubular leakage of GFR after ischemic renal failure as well as tubular obstruction, leading to a reduction in measured or effective GFR.[117,118] The presence of areas of open PTC tight junction or denuded basement membrane in electron-microscopy biopsy specimens provides a logical morphological explanation of back-leakage. However, understanding the mechanism responsible for tight junction dysfunction or detachment of tubular cells is key to defining the event of cast formation and tubular obstruction. The integrin superfamily of proteins, located on the basal aspect of the cell, is responsible for the complex cell-matrix adhesion events. The β chains coupled with α chains form β1 integrins, which interact with the actin cytoskeleton and actin-binding proteins such as α-actinin, vinculin and talin. The extracellular domain of the β1 integrins attaches to receptors of proteins such as collagen and fibronectin, which are abundant and constitute the tubular basement membrane. The tri-peptide sequence of arginine-glycine-asparagine (abbreviated as RGD), is a well define receptor for β1 integrin on the extracellular matrix. The loss of polarity causes redistribution of β1 integrins, which become expressed in the apical domain of sublethally injured cell. It was hence hypothesized that administraton of an excess of soluble RGD containing molecules would saturate the extracellular binding site of all exposed β1 integrins within the lumen of the nephron, and thus prevent luminal renal tubular cell-cell adhesion, and this prevent intratubular obstruction. Both intravenous and direct intrarenal infusion of RGD peptides resulted in amelioration of ischemic AKI. It is also possible that the detached tubular cells adhere to Tamm-Horsfall protein (THP) in the distal tubule by RGD sequence peptides. By using dual labeled RGD peptide sequences, it was also discovered that RGD peptides also mapped to intimal surface of vessels in ischemic kidneys.[119] Further studies utilizing RGD peptides in ARF could provide key answers to questions of vascular and epithelial injury in ATN. Recent studies also show a role of the sphingosine-1 phosphate receptor (S1PR) in maintaining structural integrity after AKI. Okusa et al. have shown that S1PRs in the proximal tubule are necessary for stress-induced cell survival, and $S1P_1R$ agonists are renoprotective via direct effects on tubular cells.[120]

MICROVASCULAR INSULT IN AKI—FUNCTIONAL BASIS AND MORPHOLOGICAL CHANGES

Microvasculature and Interstitium

A prominent feature of AKI is interstitial edema, which is in part due to altered endothelial permeability,[121] as well as increased tubular pressure, perhaps via backleak through the wall of injured or distended tubular cells. Solez et al. in 1974 demonstrated there was intravascular leukocyte accumulation following ischemic injury, a finding which is still commonly seen in peritubular capillaries, particularly in the ascending vasa recta in the outer and inner medulla. The pathogenesis and significance of this finding is discussed in detailed later. The peritubular capillaries of the corticomedullary junction and outer medulla are most often affected in ischemic human AKI, exhibiting vascular congestion, accumulation of inflammatory cells and either compression or dilatation of vessels.[122] Subtle and few changes may be seen in larger vessels such as arterioles and arteries. The pathologic profile of interlobular and afferent arteriolar vessels in renal artery clamp experiments shows vacuolization in the muscular layer as early as four hours post-ischemic insult, followed by focal necrosis in the smooth muscle.

Medullary Ischemia

Renal Blood flow (RBF) approximates 20−25% of the total cardiac output, and various forces regulate glomerular filtration as a result of autoregulation of renal blood flow. A small fraction of RBF is delivered to the medulla, while the cortex receives the majority. A relatively hypoxic region thus exists in the medulla with partial pressures of oxygen as low as 20−30 mm Hg. In contrast the partial pressure of oxygen in the cortex is about 80−90 mmHg. It has been known for years that restoration of total RBF to near normal, shortly after an ischemic insult does not prevent the extension or

maintainence phase of AKI. Thus a sequence of endothelial and epithelial cell processes is triggered that are independent of re-establishing total RBF.

The principal determinant of the medullary oxygen requirement is the rate of active Na^+ reabsorption along the mTAL. Therefore, not only the reduction of oxygen delivery, but also the increment of oxygen demand can cause an imbalance. Dehydration, volume depletion and renal hypoperfusion are major stimuli of urine concentration through active sodium reabsorption, which may further exacerbate hypoxic tubular damage. By volume repletion and salt loading, this workload is decreased, obviating the need for urine concentration, and hence able to tilt the balance back to match the oxygen supply. The kidney does have its own protective mechanism known as tubuloglomerular feedback (TGF), the stimulus for which appears to be the sodium concentration of the tubular fluid as sensed by the macula densa of the juxtaglomerular apparatus. Increased sodium sensed in this nephron segment, will in turn activate TGF to reduce the GFR, resulting in reduced metabolic demand placed on the tubule, giving the nephron an optimal oxygen supply versus demand balance. Clinically this results in oliguria, which could be termed as an appropriate physiological response to an insult. When this response system is overwhelmed, due to continued insults such as sever hypoxia, or hypoperfusion, this balance is lost, leading to cell death or necrosis.

Although tubular injury is a major mechanism initiating the decrease in GFR with AKI, the concomitant vascular changes are now being recognized as an important pathophysiologic variable. The glomerular capillary hydraulic pressure is maintained by variations in the preglomerular and postglomerular arteriolar resistances. GFR remains relatively constant despite variations in renal perfusion pressure through the process of autoregulation which includes tubuloglomerular feedback (TF) and myogenic alterations of arteriolar tone. Structurally, resting or basal tone is determined by intrinsic smooth muscle tone, and endothelial cells. Endothelial cells can detect changes in shear stress and mediating responses to altered flow. Basal nitric oxide (NO) activity is an important determinant of resting vascular tone. Responses to extrinsic stimuli are used to measure vascular function, also termed as vascular reactivity. These stimuli can be systemically generated, e.g., ANP, catecholamines, angiotensin II, or locally (paracrine), e.g., thromboxane A2, PGH2, endothelin-1 (ET-1), platelet activating factor (PAF), NO, amongst others. The kidney of all organs has the greatest vasoconstrictor sensitivity to ET-1. Characteristics of tubular fluid also modulate autoregulation of GFR to maintain fluid and electrolyte balance.[123]

It is very important to note that abnormalities in RBF in AKI lead to persistent hypoxia in certain areas of the kidney. Severe hypoperfusion of the outer medulla persists long after the insult which initiated ATN has resolved. As cortical blood flow improves after reperfusion and cortical tubule cells demonstrate repair and regeneration.[124] However, the S3 and MTAL segments of the outer medulla experience ongoing ischemia, thought to be due to "shunting" of oxygen between descending and ascending vasa recta, and vascular congestion in the peritubular capillaries. This contributes to ongoing injury to the S3 PTC and mTALC causing the extension phase of ATN.[125] Studies have also emphasized the role of tubular cell swelling as a cause for vascular congestion, as well as a possibility of compression of capillaries by swollen tubules causing mechanical impediment, limiting reperfusion to the cortico-medullary junction of the kidney.[126] Finally, WBC attachment, especially to the outer stripe venous capillaries and RBC rouleaux formation, leads to reduced and even stagnant flow to that area.

Nitric Oxide in ATN

A variety of vasoactive substances are vasconstrictive mediators of the microcirculation and thought to be major determinants of decreased RBF in AKI. Endothelial cell damage contributes to intra-renal vasoconstriction, by an imbalance of vasodilators and vascoconstrictors. The role of NO in the kidney ranges from homeostatic regulation and integration of tubular, vascular and glomerular functions, to integral cellular functions including energy metabolism, cellular respiration, proliferation and transcription. Specifically NO helps regulate local renal circulation, renal afferent and efferent nerve activity and direct fluid and electrolyte reabsorption in tubules. It is produced in both renal and non-renal vasculaturefrom L-arginine by the Nitric Oxide Synthase (NOS) isoforms, of which the three principal forms are neuronal NOS (nNOS), inducible NOS (iNOS) and endothelial NOS (eNOS).[127] Intrarenal NO is responsible for up to one third of the normal renal blood flow and helps maintain the low renal vascular resistance under physiological conditions. NO also plays a key role in regulating perfusion of the renal medulla and local infusion of NOS inhibitors into animals reduces medullary blood flow and promotes salt retention. Conversely L-arginine infusion increases NO levels and enhances medullary blood flow.[128]

During AKI the production of NO increases in tubular cells as a result of cytokine induced increase in expression of iNOS. Studies by Ling et al. have shown that proximal tubule cells isolated from mice with

iNOS deficiency were resistant to damage by hypoxia, while mice lacking eNOS or nNOS were damaged by hypoxia.[129] Inhibition of eNOS is also known to occur as endothelial dysfunction develops. Furthermore high output NO production by iNOS may suppress the activity of eNOS without changing its abundance. Hence in ischemic AKI, *there is an imbalance of eNOS and iNOS*. Goligorsky et al. have proposed that due to a relative decrease in eNOS, secondary to endothelial dysfunction and damage, there is a loss of anti-thrombogenic properties of the endothelium, hence leading to increased susceptibility to microvascular thrombosis.[130] The decrease also leads to enhanced PMN adhesion, and vasoconstriction. On the other hand, the relative increase in iNOS leads to enhanced PMN motility, induction of tubular epithelial cell injury, loss of vasomotor response and suppression of eNOS.[130] Generation of superoxide and NO in ischemia/reperfusion injury results in the formation of peroxynitrite anion ($ONOO^-$). This metabolite is cytotoxic and is capable of causing lipid peroxidation and DNA damage. Effective scavenging of peroxynitrite by ebselen resulted in amelioration of renal dysfunction and a decrease in nitrotyrosine formation.[131] Hence, apart from oxidative stress, there is a role for nitrosative stress in ensuing loss of kidney function (See section on Reactive Oxygen Species). Selective inhibition, depletion or deletion of iNOS have clearly shown reno-protective effects during ischemia.[129,131] This effect is in part due to rescue of tubular cells from injury by iNOS or its reactive oxidized by products. Administration of L-arginine, NO-donor molsidomine, or the eNOS cofactor tetrahydrobiopterin can preserve medullary perfusion and attenuate acute kidney injury (AKI) induced by ischemia/reperfusion (I/R); conversely the administration of Nω-nitro-L-arginine methyl ester, an NO blocker, has been reported to aggravate the course of AKI following I/R injury.

Certain other forms of AKI, such as rhabdomyolysis, also have their own unique effect on NO balance. This is due to the fact that heme proteins are potent scavengers of NO, and hence when there is an excess of heme proteins, the basal vasodilatory effect of NO is abolished. Since NO has an inhibitory effect of endothelin-1 synthesis (ET-1), there is a surge in ET production thus aggravating the vasoconstriction. It should also be emphasized that both myoglobin and free hemoglobin themselves can induce iNOS thus acting as another pathogen in the AKI associated with rhabdomyolysis.

ROLE OF ENDOTHELIN

The role of endothelin-1 (ET-1) in AKI has been extensively studied. Ischemic and toxic injury increase the expression of pro-ET-1 gene, and the release of mature ET-1 from endothelial cells.[132] ET-1 is the one the most potent vasoconstrictor known, and is produced from a precursor of 38−39 amino acids by the enzyme endothelin-converting enzyme in endothelial cells. It has been shown that ET-1 is detectable in the plasma of human and animals and also in a variety of tissues. The kidney is a major site of ET-1 production and its effect. The major actions of ET-1 are: (1) Hemodynamic-renal vasoconstriction and mesangial cell contraction. (2) Transport: low doses cause diuresis and natriuresis. High doses cause profound anti-natriuretic and anti-diuretic effects.[132] (3) Proliferation: mitogenesis and proliferation of mesangial cells through ET-A receptor stimulation.[132] (4) Inflammation: recruitment and activation of leukocytes.[133]

The renal vasconstrictive effects are produced by vascular smooth muscle cell contraction following activation of ET-A receptor causing a flux of intracellular calcium. The end result is reduction in both RBF and GFR. With the development of various specific ET receptor antagonists there is compelling evidence of its role in ARF. Most ET receptor anatagonists are able to ameliorate the renal injury after ischemic and toxic injury. Jerkic et al. demonstrated that administration of bosentan, a dual ET receptor antagonist, in experimental ischemic AKI resulted in decreased tubular cell injury and increased RBF and GFR.[134] Other toxic injury models such as endotoxin, CsA and myoglobinuric-induced renal failure have all shown to be associated with elevated plasma ET levels.

ENDOTHELIAL CELL INJURY IN AKI

It has been known for over thirty years that endothelial cells in the renal vasculature undergo an early swelling during ischemia leading to a narrowing of the lumen.[135] Evidence of endothelial dysfunction also comes from experiments that have found over expression of ICAM-1 by vascular endothelial cells and enhanced expression of the Arg-Gly-Asp (RGD) peptide binding integrins in ischemic AKI**.** Using minimally invasive intravital microscopy of the glomerular and peritubular capillaries, Goligorsky et al. have shown endothelial dysfunction andthe no-reflow phenomenon manifested by reversal, deceleration and cessation of blood flow, occurring in a sporadic fashion in pre- and postglomerular capillaries in post-ischemic kidneys.[136]

The integrity of endothelial barrier is also impaired in AKI as shown by *in vitro* studies demonstrating endothelial cell desquamation and formation of gaps between confluent endothelial cells treated with thrombin, while *in vivo* studies in inflammatory states have

provided direct evidence for increased gaps between endothelial cells with increased permeability.[121] The cytoskeletal structure of endothelial cells includes actin filament bundles that form a supportive ring around the periphery, along with the adhesion complexes that provide the integrity of the endothelial layer. Alteration of the normal actin cytoskeleton of endothelial cells *in vitro* has been demonstrated with ATP depletion as a model of ischemic injury and with H_2O_2 as a model of oxidant-mediated reperfusion injury. ATP depletion has been demonstrated to rapidly and reversibly disrupt the normal cortical and basal F-actin structures in endothelial cells resulting in F-actin aggregation and polymerization. Oxidant-mediated endothelial cell injury also has been demonstrated to disrupt the cortical actin band in cultured endothelial cells.[137] The assembly and disassembly of actin filaments is regulated by a large family of actin binding proteins including actin depolymerizing factor (ADF)/cofilin. With ischemic injury, the normal architecture of the actin cytoskeleton is markedly changed along with endothelial cell swelling, impaired cell-cell and cell-substrate adhesion and loss of tight junction barrier functions. ATP depletion of cultured endothelial cells has been shown to induce dephosphorylation/activation of ADF/cofilin in a direct and concentration-dependant fashion. This results in depolymerized and severed actin filaments, seen as filamentous (F) actin aggregates at the basolateral aspects of the cell[138–140] (Fig. 76.6).

Endothelial Permeability Defects

The endothelial barrier serves to separate the inner space of the blood vessel from the surrounding tissue and to control the exchange of cells and fluids between the two. It is defined by a combination of transcellular and paracellular pathways, the latter being a major contributor to the inflammation-induced barrier dysfunction.

Sutton et al. have studied the role of endothelial cells in acute kidney injury by a series of experiments utilizing florescent dextrans and two-photon intra-vital imaging. The increased microvascular permeability observed in acute kidney injury is likely a combination of numerous factors such as: loss of endothelial monolayer, breakdown of perivascular matrix, alterations of endothelial cell contacts and upregulated leukocyte-endothelial interactions. They have shown that 24h after ischemic injury there was loss of localization in vascular endothelial cadherin immunostaining, suggesting severe alterations in the integrity of the adherens junctions of the renal microvasculature.[121] *In vivo* two-photon imaging demonstrated a loss of capillary barrier function within two hours of reperfusion as evidenced by leakiness of high molecular weight dextrans (300,000 Da) into the interstitial space.

Critical constituents of the perivascular matrix, including collagen IV, are known to be substrates of matrix metalloproteinase (MMP)-2 and MMP-9, which are collectively known as gelatinases. Breakdown of barrier function may also be due to matrix metalloproteinase -2 or -9 activation and this up-regulation is temporally correlated with an increase in microvascular permeability.[83,141] In addition, minocycline, a broad based MMP inhibitor, and the gelatinase specific inhibitor ABT-518 both ameliorated the increase in microvascular permeability in this model. Taken together, many findings indicate that the loss of endothelial cells following ischemic injury is not a major contributor to altered microvascular permeability, although renal microvascular endothelial cells are vulnerable to the initiation of apoptotic mechanisms following ischemic injury that can ultimately impact microvascular density[142] (Fig. 76.8).

ENDOTHELIUM AND COAGULATION ABNORMALITIES IN AKI

Endothelial cells have a central role in coagulation through their interaction with protein C mediated by the endothelial cell protein C receptor (EPCR) and thrombomodulin. Protein C is activated by thrombin-mediated cleavage and the rate of this reaction is augmented 1000-fold when thrombin binds to the endothelial cell-surface receptor thrombomodulin. The activation rate of protein C is further increased by approximately 10-fold when EPCR binds protein C and presents it to the thrombin–thrombomodulin complex. Activated protein C acquires antithrombotic and profibrinolytic properties, and participates in numerous anti-inflammatory and cytoprotective pathways to restore normal homeostasis.[143] Activated protein C is also an agonist of protease activated receptor-1.[144] Animal studies have shown pre-treatment with aPC to be beneficial in ameliorating AKI from ischemic or septic injury in rats by inhibiting leukocyte activation through TNF-α, and not by inhibiting coagulation abnormalities.[145,146] It has also shown that both pre -treatment and post-injury treatment with soluble thrombomodulin attenuates renal injury with minimization of vascular permeabilility defects with improvement in capillary renal blood flow.[71]

Injury to endothelial cells could have a role in chronic disease, Basile et al.[89] documented a significant decrease in the density of blood vessels following acute ischemic injury, which led to the phenomenon of "vascular dropout." This phenomenon was verified by Horbelt et al.[90] who found that vascular density was

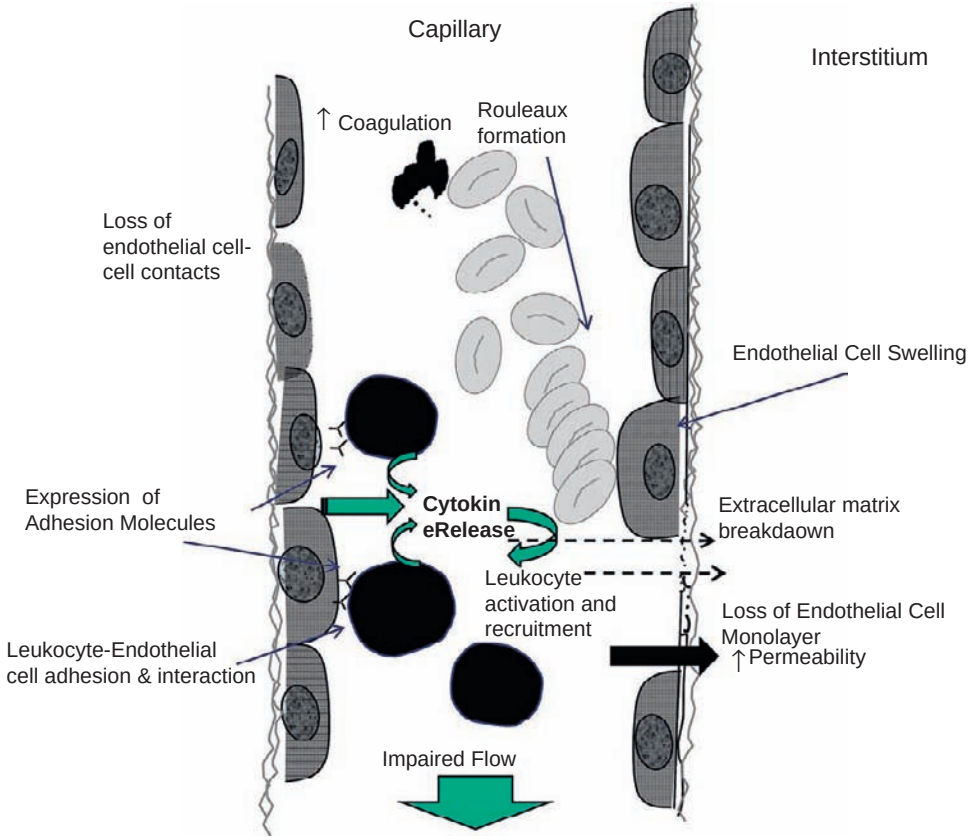

FIGURE 76.6 Endothelial injry in AKI. Key events in endothelial cell activation and injury. Ischemia causes upregulation and expression of genes coding for various cell surface proteins such as E-(endothelial) and P-(platelet) selectin, vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-1 (ICAM-1) and reduced thrombomodulin (TM). Activated leukocytes adhere to endothelial cells through these adhesion molecules. Endothelial injury increases the production of endothelin-1 and decreases endothelial derived NOS (eNOS) which serve to induce vasoconstriction and platelet aggregation. The combination of leukocyte adhesion and activation, platelet aggregation and endothelial injury serves as the platform for vascular congestion of the medullary microvasculature. There are permeability defects between endothelial cells as a result of tight and adherens junctional altrerations. *(Source: unpublished figure from Encyclopedia of Intensive Care Medicine. Publisher Springer. Eds, Vincent, Jean Louise; Hall, Jesse B. Ch Endothelial Cell Injury by Asif Sharfuddin and Bruce Molitoris. First Edition March 2012.)*

reduced by almost 45% at four weeks after an ischemic insult. This observation indicates that, unlike renal epithelial tubular cells, the renal vascular system lacks comparable regenerative potential. Ischemia has been shown to inhibit VEGF, while inducing the VEGF inhibitor ADAM-TS 1.[147] The lack of vascular repair was postulated to be due to the reduction in VEGF expression, as administration of VEGF to postischemic rats preserved microvascular density.[148] Vascular dropout might mediate increases in the expression of hypoxia inducible factor (HIF), increase fibrosis, and alters proper hemodynamics, leading to hypertension. Basile et al. have also shown that the poor regenerative potential of endothelial cells and transformation into fibroblasts is in large part owing to the lack of VEGF expression.[149] This may have a critical role in accelerating progression of CKD following initial recovery from ischemia or reperfusion-induced AKI.[150,151] Vascular dropout could predispose individuals to recurrent ischemic events and AKI.[152]

INFLAMMATION IN ACUTE KIDNEY INJURY

Inflammatory Response, Adhesion Molecules and the Role of Leukocytes

Inflammation and recruitment of leukocytes during epithelial injury are now recognized as major mediators of all phases of endothelial and tubular cell injury. Human AKI/ATN biopsies seldom have accumulated neutrophils, as compared to the abundance in experimental animal ischemic studies.[153,154] Neutrophils likely play a modest role as an effector cell in the initiation and extension phases, while T-cells and B-cells

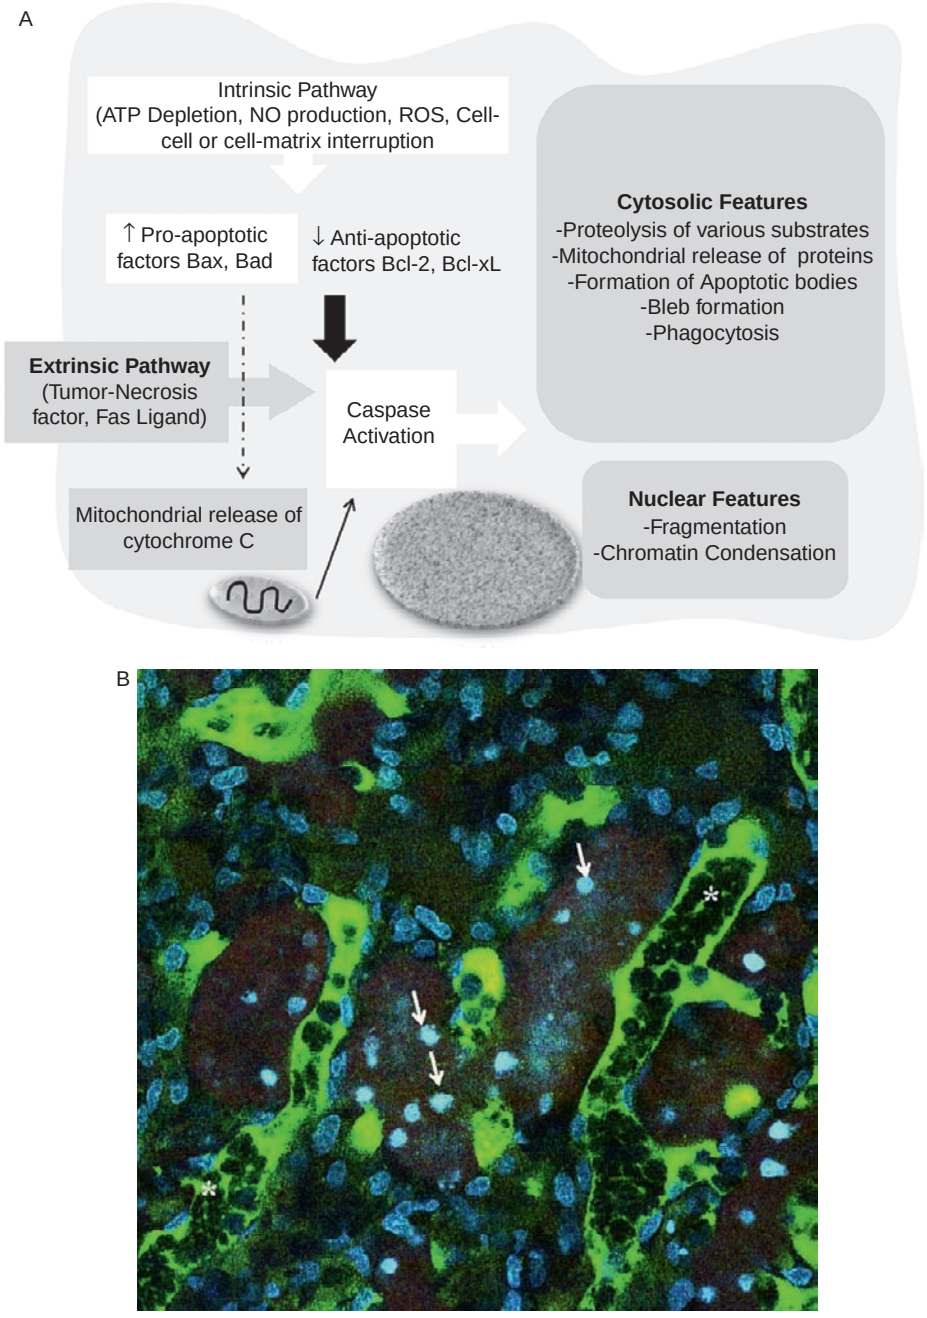

FIGURE 76.7 A. Apoptosis pathways. The cell injury or intrinsic pathway leads to translocation of Bax and other pro-apoptotic proteins from cytosol to the mitochondria, forming pores, causing the release of cytochrome c. Apoptosis-activating factor (APAF) is activated by cytochrome c which binds to and activates procaspase-9. Caspase-3 is activated by activated caspase-9, which along Encyclopedia of Intensive Care Medicine. Publisher Springer. with other downstream caspases induce proteolysis of various cytosolic and nuclear proteins. The death receptor or extrinsic pathway functions primarily by binding of death ligands such as Fas or TNF-α to their cell-surface receptor, resulting in the activation of procaspase-8 to its active form. This occurs through mediation with adaptor proteins such as FADD (Fas ligand associated death domain) and TRADD (TNF-R1 associated death domain). Active caspase-8 activates caspase -3 as well as cleaves proapoptotic protein Bid to its truncated form tBid, that acts visa Bax to induce cytochrome c from the mitochondria. Hence the extrinsic pathway also amplifies the events induced by the intrinsic pathway. *(Source: Adapted from Levine JS, Lieberthal W: Terminal pathways to Cell Death. In Acute Renal Failure: A Companion to Brennor & Rector's The Kidney. 2001, p43; and unpublished figure from Encyclopedia of Intensive Care Medicine. Publisher Springer. Red represents 3KD Texas Red dextran that is filtered and labels the tubular lumens. Note apoptotic nuclei which show intense Hoechst staining along with condensation and fragmentation (arrows). Many of these apoptotic nuclei are shed into the lumens of tubules with compromised urine flow. Also noted is the rouleaux formation and congestion in peritubular capillary with lack of blood flow. *(Source: Courtesy of Pierre Dagher, MD, Division of Nephrology, Indiana University School of Medicine.)*

and macrophages probably have major modulatory roles in the extension and repair phases. A complex series of events involving several classes of adhesion molecules including selectins, mucins, integrins, and the Ig superfamily occurs.

Leukocyte recruitment into most organs occurs in a cascade-like fashion. Adherence to the vascular endothelium is a dynamic multifaceted process involving both the leukocyte as well as the endothelial cell. For the leukocyte to be activated to release cytokines it has to receive signals through chemokines circulating in the bloodstream, or through direct contact with the endothelium. Rolling leukocytes can be activated by chemoattractants such as complement C5a and platelet activating factor. Upon activation, leukocyte integrins change their confirmation and bind to endothelial ligands to promote firm adhesion. For neutrophil recruitment β2-intgerin (CD18) seems to be most important. These interactions with the endothelium are mediated through endothelial adhesion molecules that are upregulated during ischemic conditions.[155]

Initially there is slow neutrophil migration mediated by tethering interactions between selectins and their endothelial cell ligands. Singbartl et al. found that platelet P-selectin and not endothelial P-selectin was the main determinant in neutrophil mediated ischemic renal injury.[155] There is also significant protection from both ischemic injury and mortality by blockade of the shared ligand to all three selectins (E-, P- and L-selectin) which seems to be dependent on the presence of a key fucosyl sugar on the selectin ligand.[156,157] In a CLP model of septic azotemia mice gene-deficient for E-selectin or P-selectin or both were completely protected. Selectin-deficient mice revealed unchanged intraperitoneal leukocyte recruitment but altered cytokine levels when compared to wild-type mice.[158] Therefore, it is possible that selectins exert their effects through modulation of systemic cytokine profiles rather than through engagement in leukocyte-endothelial cell interactions.[159]

After the initial rolling, firm adhesion is imparted by interaction between endothelial cell integrins and intercellular adhesion molecule-1 (ICAM-1). Blockade of integrin CD11/CD18, ICAM-1, or deficiency of ICAM-1, were all found to protect from ischemic renal injury.[160] Treatment of humans with anti-ICAM-1 antibodies however did not reduce the rate of delayed graft function or acute rejection following renal transplantation.[161] Alpha-melanocyte-stimulating hormone (α-MSH), a known inhibitor of interleukin-8 (IL-8) and ICAM-1 induction, initially thought to be protective through these mechanisms, was found to be protective independent of inhibition of neutrophil recruitment.[162]

Biopsies of human AKI have demonstrated lymphocytes in ATN, and only recently has the modulatory role of T-cells in the mediation of ischemic injury been established. Rabb et al. in a series of recent experiments showed that T-cell deficient *nu/nu* mice are protected against ischemic injury, along with attenuation of ICAM-1 expression.[163] An early transient increase in T-cells might explain how T-cells could still have a role without being present in histological analysis. Additional evidence that suggests a role of T-cells is derived from studies where blockade of the CD28-B7 co-stimulatory pathway reduced injury, as well as data from STAT-4 deficient mice, which have impaired Th1 phenotype of T-cells, revealing the deleterious role of Th1 phenotypes.[164] There is also now evidence that B-cell deficient mice are protected from ischemic renal injury, while transfer of serum from wild type to B-cell deficient mice restored injury.[165] Macrophage chemoattractants are up-regulated during ischemia, resulting inmigration of macrophages into the outer medulla of the rat kidney. Data from osteopontin knockout mice revealed there was less macrophage infiltration and less fibrosis, even though the course of renal dysfunction was similar to wild type mice. Okusa et al. have also shown recently that although macrophages are required for the full extent of the ischemic renal injury, activation of their adenosine 2A receptors reduces neutrophil accumulation and provides protection against injury, as seen in experiments with macrophage depleted and adenosine 2A receptors deficient mice. The protective effect of adenosine 2A receptor activation is independent of IL-6 and TGF-β mRNA induction.[166]

Macrophages produce proinflammatory cytokines that can stimulate the activity of other leukocytes. Day et al.[111] showed that depletion of macrophages in the kidney and spleen using liposomal clodronate prior to renal ischemia reperfusion injury prevented AKI, whereas adoptive transfer of macrophages reconstituted AKI. This group also showed that agonists of sphingosine-1-phosphate induced lymphopenia, which had a protective effect.[167] However, studies have also shown a lymphocyte independent role of the sphingosine-1 phosphate receptor (S1PR) in maintaining structural integrity after AKI as S1PRs in the proximal tubule are necessary for stress-induced cell survival, and agonists of this receptor are renoprotective via direct effects on tubular cells.[168] Dendritic cells are also thought to have a role in AKI; Dong et al.[114] demonstrated that after AKI, renal dendritic cells produce the proinflammatory cytokines TNF, IL-6, C-C motif chemokine 2, and C-C motif chemokine 5, and that depletion of dendritic cells prior to ischemia substantially reduced the levels of TNF produced in the kidney.[169]

Cytokines in AKI

There is increased renal expression of many proinflammatory cytokines in response to acute ischemic or toxic injury. These include TNF-α, interferon-γ, granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukins 1,2,18, as well as chemokines such as monocytes chemotactic protein-1 (MCP-1), macrophage inflammatory protein-1 (MIP-1), and RANTES. It is also possible that AKI is associated with up-regulation of IL-10, an anti-inflammatory cytokine supported by studies showing protection against AKI in ischemic and cisplatin models of injury by IL-10 administration.[170]

Recent human data suggest the role of both pro-inflammatory as well as anti-inflammatory cytokines in predicting mortality, with higher IL-6, IL-8 and IL-10 plasma levels in non-survivors amongst critically ill patients with AKI. Interestingly, IL-1 and TNF-α were not predictive.[171] Critically ill patients with AKI also have decreased and impaired monocyte cytokine production and elevated plasma cytokine levels in a pattern that closely resembles critically ill patients without AKI, suggesting the very complex role of these cytokines.[172] It is also important to remember that the maximal capacity to produce cytokines in response to stimulation can have considerable inter-individual variation due to genetic pre-determination for their expression.[173] Single nucleotide polymorphisms (SNPs) within the promoter region of these cytokines genes with stable allelic variants have been identified, and in a recent prospective evaluation of these polymorphisms, Jaber et al. found TNF-α and IL-10 gene polymorphismsrelated to the risk of death among patients with ARF who require dialysis. As the list of these cytokine gene polymorphisms grows it is possible that we may be better able to identify patients at higher risk of organ injury.[174]

AKI IN SEPSIS

Sepsis is a common cause for AKI occurring in up to 50% of septic patients with the incidence increasing depending on the severity of the septic shock syndrome.[175–177] When AKI complicates sepsis the mortality can be as high as 70% as compared to AKI without sepsis with a mortality rate ranging from 20–40%.[177]

By using endotoxinor CLP experimental models of sepsis a better understanding is now possible of the intrinsic and complex processes that take place in sepsis related ARF. The primary pathophysiologic renal response to LPS infusion is an alteration in renal hemodynamics with subsequent microvascular damage and relatively mild tubular injury. However, there is substantial variability in LPS response amongst different species and severe AKI typical of ATN is usually not a feature of this model.

The predominant pathogenetic factor in sepsis mediated AKIis renal vasoconstriction mediated through vasoactive hormones that precedes the advent of systemic vasodilation, hypotension and septic shock. Bacteria or endotoxin can induce NO synthase in the systemic circulation leading to nitric oxide-mediated systemic arterial vasodilation. This results in the sensing by the baroreceptors of an underfilled arterial system leading to the increase in sympathetic outflow with the activation of the renin-angiotensin-aldosterone system (RAAS), and also the release of arginine vasopressin from the central nervous system. The combined effects of increased sympathetic tone and RAAS result in intense vasoconstriction with intact tubular function as demonstrated by increased reabsorption of tubular sodium and water. Rats infused with endotoxin show a FENa of less than 1%, eventually leading to pre-renal azotemia.[72] If this prerenal state is not reversed it leads to progressive decrease in sodium reabsorption resulting in a higher FENa, that may progress to an established ATN. Renal denervation studies of mice afforded protection against the decline in GFR during the initial 16 hours of endotoxemia. It is also seen that plasma concentrations of norepinephrine, epinephrine and renin that activate the RAAS are higher in the LPS mice.[178] Such studies indicate the role of vasoactive hormones and neural mediation in early sepsis related AKI.

Endothelin also seems to be indirectly involved in septic AKI,as demonstrated by numerous studies showing a beneficial effect of using non-specific ET antagonists in renal injury during endotoxic shock.[179] ET can also cause a decrease in plasma volume by increasing the "leakiness" of the capillaries.[180] As earlier discussed in the section on nitric oxide, an imbalance exists between iNOS and eNOS in ischemic AKI and a similar pattern is seen in septic AKI as well. Schrier and colleagues investigated the role of NOS in mice given LPS. Due to the lack of specific eNOS inhibitor, a knockout model of eNOS deficient mice was used and found to exhibit increased RVR and higher susceptibility to endotoxemic AKI than wild-type mice despite a higher MAP.[181] Prior studies have revealed down-regulation of eNOS within the kidney and increased expression of iNOS in the renal cortex occurs during the initial 16 hours after exposure to endotoxin. Endothelial cell damage also occurs during sepsis and is associated with microthrombi formation and increased von Willebrand factor (vWF) levels.[182] eNOS production is impaired leading to further imbalance between these two proteins. In humans the use of a non-specific NOS inhibitor was found to increase

mortality in patients with septic shock further substantiating the presence of local and systemic imbalance, as well as between the two isoforms eNOS and iNOS.[183] However, a selective iNOS inhibitorhas been used in a rat model showing protection, but this approach has not been translated in human studies.

In the systemic vasculature upregulated iNOS mediates the arterial vasodilation with a profound and potent effect, causing resistance of the pressor responseto norepinephrine, and angiotensin II. The vascular smooth muscle cell (VSMC) is another key player in systemic vasodilation, as changes in pH or cellular ATP depletion open the ATP-sensitive potassium channels (K-ATP). This causes hyperpolarization of the cell leading to closure of the voltage gated calcium channels, required for the action of the above mentioned pressor hormones. The receptors for these vasoactive hormones might also be down-regulated because of their high endogenous levels. Clinically this is manifested as a poor response of vasopressors such as norepinephrine to raise blood pressure.[176] Arginine vasopressin, an endogenous vasopressor, may help maintain the blood pressure despite the nonresponsiveness of other vasopressore hormones. Some theories behind this hypothesis include: vasopressin-induced inactivation of K-ATP channels, decrease in synthesis of iNOS, and a synergistic mechanism with norepinephrine and angiotensin II, since these three agents share the same intracellular signaling pathway. In sepsis the sites of major arterial vasodilation, such as the splanchnic bed, muscles and skin, have an abundance of the vasopressin receptor V1a. At the glomerular level, vasopressin causes constriction of the efferent arteriole, as compared with norepinephrine which causes afferent arteriolar vasoconstriction, thus making vasopressin a better agent to increase filtration pressure and consequently GFR. Cytokines such as TNF-α, IL-1β, IL-6, and IL-8 are pro-inflammatory and released in response to infectious stimuli. A wide range of effects are seen when levels of these cytokines are elevated during sepsis. These include increased expression of adhesion molecules, increased production of other pro-inflammatory mediators, and activation of various leukocytes. Infusions with TNF-α and IL-1 have produced a similar sepsis like syndrome in animals. Along the same lines, blocking these pro-inflammatory mediators through antibodies has attenuated the shock like state in animal models. However, SIRS or sepsis is not an isolated proinflammatory state.[184] There is also substantial evidence for the presence of anti-inflammatory cytokines IL-10 and IL-13 as well in patients with septic shock. Thus SIRS or sepsis may be more accurately described as a malignant form on intravascular inflammation rather than a mere overexpression of pro- or anti-inflammatory cytokines. The role of TNF-α in endotoxin AKI has been tested in both humans and animals. It has been suggested that TNF-α can cause vasoconstriction even in the absence of iNOS as indicated by knockout mice studies. It is also known that caspases activate both IL-1β an IL-18, along with the resultant upregulation of adhesion molecules. Caspase-1 knockout mice or non-specific capsase inhibitors protect against endotoxemic AKI.[185]

Other mediators of sepsis include the complement cascade and the metabolites of arachidonic acid (PGE2, PGI2, Thromboxane). Thromboxane (TAX) causes platelet and leukocyte aggregation and vasoconstriction. Platelet activating factor (PAF), released by many cells amplifies cytokine production as well as stimulating leukocyte adhesion to endothelial cells. Complement cascades are activated during sepsis, and C5a, a potent complement component with procoagulant properties has been found to be elevated in rodent models of sepsis. Blocking C5a or its receptor has shown some promise in improving survival with sepsis.[175] In sepsis levels of protein C are decreased, and its conversion to activated protein C is also down-regulated.[186] Anti-thrombin III and tissue factor pathway inhibitor are also dramatically reduced. This leads to a procoagulant state resulting in thrombosis of glomerular capillaries and other intra-renal capillary beds causing persistent renal hypoxia to tubules.[187]

Some of the most recent advances in understanding sepsis have involved determining the pathophysiologic roles of NF-κB and Toll-like receptors (TLR). NF-κB is crucial for the maximal expression of many cytokines involved in the pathogenesis of inflammation. It is an intracellular species, resident in the cytosol as a heterodimer and attached to an inhibitory sub-unit called IκB. Activation of NF-κB occurs through loss of IκB which is phosphorylated by serine kinases through oxidant stress pathway mechanisms. The active heterodimer NF-κB then enters the nucleus after undergoing a conformational change, and binds to various promoter sites on the genome stimulating mRNA synthesis of gene coding for most of the pro-inflammatory cytokines such as TNF-α, IL-1β, IL-2, IFN-β, GM-CSF, adhesion molecules such as endothelial-leukocyte adhesion molecule-1, VCAM-1, immuno-receptors such as tissue factor-1, MHC 1 and 2, T-cell receptor 1 and 2, and others proteins such as COX-2.[188]

Toll-like receptors (TLR) are a family of receptors, involved in the innate immunity, that recognize components of bacteria, viruses, parasites and fungi, and induce pro-inflammatory responses by many cells. Nine murine and ten different TLRs have been cloned in humans, each differing in their specificity for microbial components, e.g., LPS, gram-positive cell wall, bacterial DNA and so on. Extracellular matrix breakdown products such as hyaluronan, heparan sulfate,

fibrinogen, or the fibronectin EDA domain can activate TLR4. TLR4 was identified as the receptor for LPS and requires the presence of an extracellular accessory protein called MD-2. CD14, a cell surface receptor, binds LPS complexed with LPS binding protein and transfers the endotoxin to the TLR4 and MD-2 dimer.[189] Each component of this complex is required for effective LPS-induced signaling. The serine kinase required for NF-κB activation occurs via the TLR4 receptor pathway, hence linking the TLR and the transcription factor in the intracellular signaling mechanism. Tubular epithelial cells are among the non-immune cells that express TLR1, -2, -3, -4, and -6, suggesting these TLR might contribute to the activation of immune responses in tubulointerstitial injury.[190]

Upon stimulation with LPS mouse tubular cells in culture upregulate TLR2, -3, and -4 and secrete CC-chemokines such as CCL2/MCP-1 and CCL5/RANTES. These data suggest that tubular TLR expression might be involved in mediating interstitial leukocyte infiltration and tubular injury during bacterial sepsis.[191] TLR4 deficient mice were found to be completely resistant to endotoxin-induced acute renal failure, which was associated with a lack of a systemic TNF-α response. Cross transplantation studies showed that TLR4-deficient recipients of wild-type kidneys developed minimal LPS-induced acute renal failure, whereas wild-type recipients of a TLR4-deficient kidney had severe acute renal injury after exposure to endotoxin.[192] These data strongly indicate a role for extra-renal TLR4 activation in acute renal failure of sepsis. However, they do not support the hypothesis that renal TLR4 expression (e.g., on tubular epithelial cells) plays a major role in sepsis-induced acute renal failure. In contrast, they rather implicate a systemic response to sepsis, involving TLR4 and TNF-α in the development of acute renal failure during sepsis.[190,192] Necrotic tubular cells release potential TLR ligands such as heat shock proteins (HSP) that could activate other tubular cells or resident immune cells in the kidney. Activation of TLR2 and TLR4 on tubular epithelial cells has been shown to specifically stimulate the NF-κB pathway in response to oxidative stress. Furthermore, TLR2 and TLR4 activation on tubular epithelial cells leads to secretion of CC-chemokines indicating a role for these TLR in the initiation of phagocyte influx and immune activation during acute tubular necrosis. Thus TLR activation may be a link between mechanical, toxic, or ischemic tubular cell injury and the onset of an inflammatory "innate" immune response in the pathogenesis of AKI.[190]

The role of ROS has also been recently investigated as a potential mediator of injury in endotoxin-related ARF. Endotoxemia is known to be associated with the generation of oxygen radicals, which may contribute to the renal injury. Exogenous oxygen-radical scavengers were shown to protect against ARF in normotensive endotoxic mice.[193] Furthermore, the early vasoconstrictor response of ARF in sepsis can be potentiated by oxidant-related endothelial cell damage.

Apoptosis and Necrosis

The fate of the epithelial cell after an injury ultimately depends on the extent of the injury. Cells undergoing sublethal injury remain capable of complete functional and structural recovery if the insult is abolished. Severly injured epithelial cells can also become dedifferentiated, express mesenchymal proteins and ultimately repolarize into functional cells with the epithelial phenotype.[194] Cells that suffer a lethal injury either undergo apoptosis or necrosis leading to cell death. In general, the mechanism of cell death induced by an ischemic or cytotoxic insult is determined by the severity and duration of injury.

Morphologically in necrosis there is swelling of cells and organelles and loss of plasma membrane integrity with rupture of cell. The cytosolic contents escape into the surrounding tissue causing injury and reactive inflammation. These cells usually die in contiguous groups. In contrast, apoptotic cells shrink in size, lose microvilli as "blebbing," but have relatively normal plasma membrane and mitochondrial structure. They lose the cell-cell and cell-matrix adhesion early ending up being exfoliated or phagocytosed as single cells. The nuclei in apoptotic cells have a characteristic appearance of chromatin condensation and nuclear fragmentation, resulting in formation of apoptotic bodies. Finally, the apoptotic cell disintegrates into multiple plasma-membrane bound apoptotic bodies that are rapidly phagocytosed by macrophages and neighboring epithelial cells.[195]

Mechanisms of Cell Necrosis

Severe ATP depletion plays a central role in necrosis after ischemic cell injury. The severity and duration of ischemia dictates the fate of the oxygen deprived cell. Weinberg and colleagues have recently discovered novel mechanisms of mitochondrial injury that are a prominent feature of necrosis. Hypoxic tubule cells in suspension undergo a severe and prolonged abnormality in oxidative phosphorylation due to major changes in the complex I function of the mitochondria. It has also been noted that amelioration of mitochondrial dysfunction by improving the cell energy depleted state, caused by hypoxia, was possible through substrates such as α-ketoglutarate plus malate or succinate and aspartate that can be anaerobically metabolized to produce ATP.[196]

Several studies have suggested a role for increased intracellular calcium in the pathogenesis of ATN. Maintainence of low cytosolic (approx 100 nM range) calcium concentrations is crucial to the normal homeostasis of the cell and its organelles. This gradient between extracellular fluid and cytosol is regulated by a complex system of pumps and electrochemical gradients and requires the integrity of membranes and availability of ATP for pump function. The role of calcium in glomerular hemodynamics is discussed elsewhere in the text, while we discuss its role in tubular cell injury.[197]

Numerous studies have shown that ATP depletion leads to a rise in intracellular calcium through impairment of calcium ATPases while inhibition of Na^+/K^+-ATPase activity potentiates calcium entry into cells via the sodium-calcium exchanger. Increased cytosolic calcium during hypoxia causes mitochondrial injury as well as cytoskeletal alterations. High concentrations of Ca^{2+} may alter the inhibitory actions of villin, an actin-binding protein regulating the capacity to sever F-actin or nucleate G-actin, thus leading to cytoskeletal disruption. However this has not been shown to affect loss of brush-border integrity. In the isolated perfused tubule system, actin cytoskeleton alterations seem to be both calcium-dependent and independent, as lethal membrane injury is not a necessary end result of intracellular calcium changes.[198] It is also possible that the interactions between high intracellular Ca^{2+} and the actin cytoskeleton are dynamic and multiplicative and once either is disrputed it leads to a lethal cycle of events resulting in exacerbating the injury.

Phospholipids in the membrane bilayer are substrates for phospholipases, and help maintain the integrity of the cell and its organelles. Because of this crucial role it has long been postulated that activation of phospholipases may play a role in post-ischemic or nephrotoxic tubule cell injury. Enzymes such as phospholipase A2 (PLA2) and calpain are calcium dependent and are activated during ischemic cellular injury. Activation of PLA2 appears to be an important mechanism of plasma and mitochondrial disruption after ischemia, an observation evident from the fact that there is phospholipid degradation that persists after reperfusion.[199] PLA2 activation results in release of fatty acids and lysophospholipids, both of which have been shown by investigators to cause lipid membrane damage. The effect of PLA2 deficiency on renal cells has not yet been examined. Besides the direct hydrolytic action, and generation of possibly toxic free fatty acids, phospholipases also play additional roles through release of eicosanoids which have a vasoactive and chemokine action. The release of arachidonic acid metabolites results in production of lysophospholipids as well as reactive oxygen species, both of which have been shown to contribute to ischemic and nephrotoxic injury.[200,201]

Calpain, which is a cysteine protease, has increased activity in hypoxic conditions that precedes cell membrane damage leading to a further increase in its activity. The role of calpain as a mediator in ischemic rat proximal cell damage, cyclosporine nephrotoxicity and mercuric chloride induced renal injury is evident as pharmacological inhibition elicits cytoprotection in these models.[202] There is also evidence that calpain mediates increased plasma membrane permeability and hydrolysis of cytoskeleton-associated paxillin, vinculin, and talin during renal cell death.[203] The internalization of Na^+/K^+-ATPase from the membrane and the loss of cell polarity could be mediated through calpain induced cleavage of actin-binding proteins such as spectrin, filamin, ankyrin and α-actinin which has been shown indirectly by the use of calpain inhibitors which improved recovery of active Na^+ transport in rabbit renal proximal tubule cells after hypoxia and reoxygenation.[204] All these data tie together the intricate role calpain plays in the ischemic cell damage. Caspases, as discussed in later sections on apoptosis, might also play a role in necrosis when activated, and could well be involved in the pathway leading to this form of cell death.[205]

DNA fragmentation is detected in the kidney cortex as early as 12h after reperfusion, and approximately 40 double-stranded DNA breaks per cell have been shown to be lethal with ineffective DNA repair beyond these levels. Endonucleases generally cleave double stranded (ds) DNA only at sites unprotected by histones. This is evident as the typical "ladder" pattern generated by gel electropheresis of DNA from apoptotic cells. In necrosis there is also release of lysosomal enzymes and proteases that degrade the histones resulting in accessibility of the endonuclease to the entire segment, resulting in shorter segments. This is evident as the typical "smear" pattern seen in gel electropheresis on necrotic cells[206] (Fig. 76.7).

Apoptotic Mechanisms

Unlike necrosis the fundamental biochemical pathways can be divided into a commitment phase and an execution phase, each controlled by various triggers and factors ultimately deciding the fate of the cell. The morphological changes seen, as described above, are the typical apoptotic bodies. Since histones remain intact in apoptosis the activation of specific caspase-activated deoxyribonuclease (CAD) results in cleavage of the dsDNA only at the linking regions between the nucleosomes.[207] But one has to be careful as this does not necessarily reflect apoptosis only and other studies have shown that apoptosis can occur in the absence of inter-nucleosomal cleavage.[208] Similarly, the laddering

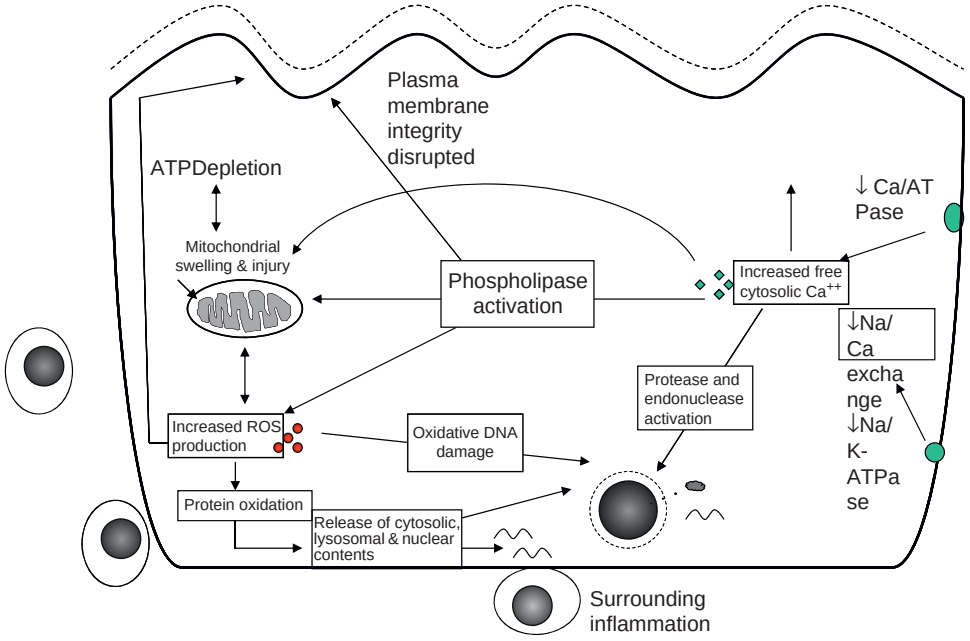

FIGURE 76.8 Pathways of necrosis. Major biochemical pathway of cell necrosis. Severe ATP depletion causes profound mitochondrialinjury which further worsens cellular energy stores and leads to the generation of reactive oxygen species (ROS). Free intracellular calcium levels are increased as a result of decreased pump activity leading to phospholipase activation resulting in disintegration of the plasma membrane as well as further ROS production. High intracellular levels of Ca^{2+}also activate endonucleases damaging DNA, an end-effect which is multifactorial through oxidative damage as well as loss of critical enzymes because of protein oxidation. Cytosolic leaks from the dead cell induce a surrounding inflammatory reaction.

of DNA seen in apoptosis is not specific and can be seen in necrosis or even as an artifact.[209]

Until recently the mode of cell death following ischemia has been related entirely to the severity of ATP depletion. Dagher et al. have shown that ischemia causes depletion of guanosine triphosphate (GTP) as well as ATP in both the ischemic kidney *in vivo* and in cultured renal tubular cells (RTC). They provide seminal evidence that GTP, without substantial ATP depletion, induces apoptosis of RTCs while selective ATP depletion causes necrosis. They also have shown that in animals subjected to acute ischemic renal injury the administration of guanosine maintained renal GTP levels within the normal range without changing the severity of ATP depletion. In addition, guanosine supplementation ameliorated renal dysfunction induced by renal ischemia and appeared to reduce apoptosis of RTCs while having little effect on the amount of necrosis. These studies provide strong evidence that changes in cell GTP as well as ATP stores play an important role in determining the mode of tubular cell death after lethal injury.[210]

CASPASES IN AKI

There is increasing evidence of a role for caspases in hypoxic renal tubular cell injury. Caspases are cysteine proteases that cleave their substrates irreversibly after aspartic acid residues, and can be divided into three major subfamilies. Caspases 1, 4 and 5 do not appear to have any role in apoptosis, rather they have a pro-inflammatory role by activating the cytokines interleukin-1β and interleukin-18. The second group of caspases 3, 6 and 7, are classified as "effector" caspases. Effector caspases are more abundant and catalytically robust than initiator caspases and, by cleaving many cellular proteins, are responsible for the 'execution phase' of apoptosis and for the classic apoptotic phenotype. Caspase 3 activates additional downstream effector caspases. Lastly caspases 2, 8 and 9 are "initiator" caspases and are the first to be activated by pro-apoptotic stimuli. Pro-caspase 8 is activated by interactions between death receptors and their ligands, and pro-caspase 9 by direct injury to cells. Once activated, caspases 8 and 9 both converge on and activate pro-caspase 3, an effector caspase.[185,211]

Caspases are activated by ischemic and cytotoxic insults to cultured RTCsand to the kidney *in vivo*. Furthermore, inhibition of caspases ameliorates ischemia-reperfusion injury in the kidney, and in the heart, brain, liver and gastrointestinal tract. Collectively, these studies provide strong evidence that caspases are important contributors in the pathogenesis of ischemic injury. Conflicting results have been seen when using caspase 1 knockout mice in ischemic renal

injury with two groups reporting less severe injury in caspase 1 -/- mice than in the wild-type controls. This was thought due to a defect in interleukin-18 activation and a consequent reduction in intrarenal inflammation. The other group found no substantive difference in the severity of renal dysfuction or intrarenal inflammation in control and caspase 1 -/- mice following ischemic AKI.[212] Caspase-1 deficient mice were also protected against cisplatin induced renal injury while cold ischemic injury in mice was ameliorated in mice using caspase inhibition.[213,214]

The balance of evidence so far suggests that both groups of caspases are activated by acute renal injury and that both are probably involved in AKI by promoting intrarenal inflammation and by inducing RTC loss by apoptosis.[211] The recent development of potent caspase inhibitors highly specific for the executioner caspases 3 and 7 may provide more effective experimental tools for examining the contribution of RTC apoptosis to the pathogenesis of AKI. Similarly two of the known murine caspases, caspases 11 and 12, are activated only under pathologic conditions of ischemia or stress. Caspase 11 activates caspases 1 and 3 directly inducing both inflammation and apoptosis in an apoptosome-independent manner.[215] The identification of caspases that respond exclusively to pathologic stimuli, however, is of potential therapeutic importance since it suggests the possibility of developing therapeutic interventions that target pathologic cell death without affecting apoptosis.

Caspase inhibition may also protect against lipopolysaccharide—induced AKI—not only by preventing apoptotic cell death but also by inhibiting inflammation. These data raise the possibility that apoptotic kidney cells may actually be a source of this local inflammation, contributing to subsequent non-apoptotic renal injury.[185] Using the cisplatin model of AKI van de Water et al. have shown that α-adducin, a cytoskleletal protein, is a caspase substrate and that it is cleaved by caspase 3 during apoptosis. This is involved in the dismembering of the actin cytoskeleton that is necessary for many of the classic morphological features of apoptosis.[216] Cisplatin has been shown to activate caspases 1, 3, 8 and 9, while caspase inhibition ameliorates cisplatin-induced cell death. Thus, as in ischemic injury, there is evidence that caspase activation is an important contributory factor in the pathogenesis of cisplatin-induced AKI.[217]

MITOCHONDRIA

Apoptosis unlike necrosis is energy requiring and hence a mitochondrial dependent process resulting in release of cytochrome c through mitochondrial pores secondary to ATP depletion and increases in cytosolic Ca^{2+}. Cytochrome c is an essential cofactor for activation of procaspase-9. Molecules such as Bax and Bak are thought to be responsible for the formation of pores.[218] In living cells these changes are prevented by anti-apoptotic members of the Bcl-2 family of proteins. Therefore, the balance between cell survival and apoptosis is determined partly by the relative concentrations of pro-apoptotic and anti-apoptotic Bcl-2 family members. Bcl-2 and Bcl-xL can inhibit the formation of mitochondrial pores and data exist indicating a relative deficiency of Bcl-2 proteins in kidneys subjected to acute injury *in vivo*, while overexpression of Bcl-2 confers resistance of RTC to cisplatin-induced apoptosis.[219] Microinjection of Bcl2_syn into stimulated LLC-PK1 cells significantly reduced the percentage of apoptotic cells detected within four hours, after the treatment. Growth factors might also induce phosphorylation and inactivation of the pro-apoptotic protein Bad and the simultaneous induction of Bcl-xL.[220]

Nuclear Factor κB (NF-κB), an anti-apoptotic transcription factor, is activated by a wide variety of stimuli such as growth factor deprivation, TNF-α, hypoxia, oxidative stress and cisplatin. NF-κB protects against apoptosis through transcriptional induction of anti-apoptotic Bcl-2 family members and through decreased expression of iNOS in tubule cells.[221] The pro-apoptotic transcription factor p53 can be activated by hypoxia, via the hypoxia-inducible transcription factor (HIF-1α), and by other stimuli such as cisplatin, adriamycin, UV light and γ-irradiation.[222] Kelly et al. have demonstrated p53 protein levels increase significantly in both cultured renal tubular cells, as well as *in vivo*, in the medulla 24 h post-ischemia in the renal clamp rat model. This induction was inhibited with the supplementation of guanosine by minimizing cellular GTP depletion. In addition, pfithrin-α, a specific p53 inhibitor prevented apoptosis and protected renal function. The effects of pifithrin-alpha on p53 included inhibition of transcriptional activation of downstream p53 targets, like p21 and Bax, and inhibition of p53 translocation to the mitochondria.[223]

RECEPTOR MEDIATED PATHWAYS

Two receptor classes namely the CD95 (Fas) and the TNF receptor 1 (TNFR-1), when bound to their ligands FasL and TNF-α respectively, lead to activation of caspase 8 and 10 resulting in apoptosis. Tubular cells are normally relatively resistant to FasL and TNF-α induced apoptosis, but when exposed to inflammatory cytokines or to ATP depletion, the expression of Fas/FasLand TNF-α/TNFR-1 is upregulated and the cells become susceptible to Fas and TNF-α mediated apoptosis.[211] So far most of the data are from *in vitro* studies except one study demonstrating that Fas-deficient mice are protected from ischemic AKI.[224]

KINASE MEDIATED PATHWAYS

Several studies now recognize the role of phopatidylinositol 3′ (PI-3) kinase/Akt phosphorylase in the signaling cascade that blocks apoptosis. Akt, a serine/threonine kinase, is activated by PI-3 through phosphorylation, which can bind down stream to the pro-apoptotic Bcl-2 family member Bad and render it dysfunctional. This in turn restores the balance towards greater availability of anti-apoptotic proteins such as Bcl-2 and Bcl-xL. In cisplatin-induced renal tubular injury Shah et al. have shown that suppression of caspase 3 and 9 activation occurs through the PI-3/Akt mediated pathway. Similar results were also obtained in hypoxia-induced RTC's. Akt also induces activation of the pro-survival transcription factor NF-κB.[212,225]

Extracellular signaling kinases (ERK), jun-N-terminal kinase (JNK) and p38 are mitogen activated protein kinases (MAPK), that are responsible with other signal transducing factors for mediating cellular responses involved in apoptosis, survival and cellular repair. Growth factors such as hepatocyte-growth factor (HGF), insulin-like growth factor-1 (IGF-1), epidermal like growth factor (EGF), and vascular endothelial growth factor (VEGF) mediate their actions through ERK1 and ERK2 kinases, which get translocated to the nucleus and activate transcription factors responsible for induction of genes in mitogenic activity. Growth factors also inhibit apoptosis by ERK signaling mediated phosphorylation of the PI-3K, and by effects independent of the PI-3K/Akt pathway. These independent mechanisms include inactivation of Bad, and through activation of the anti-apoptotic transcription factor CREB.[226]

A variety of stimuli of importance in AKI activate JNK, and are well known to promote apoptosis. Bonventre et al. have reported the role of JNK activation after ischemia-reperfusion injury could play a role in the loss of tubular cells.[227] Inhibition of JNK through administration of N-acetly-cysteine points towards a renoprotective mechanism of suppression of this pathway. Another important factor that might decide the fate of the cell depends in part on the relative activation of ERK and inhibition of JNK.[228] Interestingly, increased production of TNF-α by RTCs during ischemia also appears to be mediated by activation of p38.[229] There are also data to suggest that loss of cell-matrix or cell-cell adhesion also leads to apoptosis.

Autophagy, which is the process involved in degradation of a cell's own components through the lysosomal machinery, is now increasingly recognized as perhaps the most frequent cell-death pathway for injured epithelium. Li et al. have demonstrated the important role of autophagy in renal epithelial cells in obstructive uropathy models, while Koesters et al. have shown that transforming growth factor-β expression leads to excessive autophagy in injured tubules.[230,231]

The therapeutic implications of apoptosis in AKI are significant considering the fact that numerous targets are available for modulation. Inhibiting apoptosis seems more of a successful pathway as compared to necrosis where there could be a window of opportunity to tilt the balance towards anti-apoptotic triggers promoting renal cell survival. The initiating caspases are more likely to be effective in preventing cell death than the downstream effector caspases. However, it remains to be seen whether novel therapies can be developed that effectively modulate 'pathologic' apoptosis without interfering with apoptosis required for normal physiologic processes[211] (Fig. 76.8).

Stress Response and the Heat Shock Proteins

A basic cellular defense mechanism against numerous stresses such as fever, trauma or inflammation is the complex heat shock protein (Hsp) system. At baseline in the unstimulated cell they reflect only 2% of the resting cellular protein component. However, they can be induced to up to 20% under conditions of stress. Diverse HSP families of different molecular sizes function as molecular chaperones facilitating the folding of enzymes and other proteins into their functional conformation. After injury, HSPs are believed to facilitate the restoration of normal function by assisting in the refolding of denatured proteins and degradation of irreparably damaged proteins and toxic metabolites, limiting aggregation of damaged peptides and in aiding the appropriate folding of newly synthesized essential polypeptides.[184,232,233] Among the cell-stress pathways activated by renal ischemia the stress proteins Hsp90, Hsp72 and Hsp25 have been studied by several groups of investigators. These proteins are induced after renal I/R injury and their overexpression prior to injury can protect renal epithelia from specific insults and manifestations of *in vitro* injury. Overexpression of Hsp25 has been shown to be protective against actin-based cytoskeleton disruption and some results suggest that 25-kD and 70-kD HSPs induced by ischemic conditioning stabilize the cytoskeletal anchorage of Na^+/K^+ ATPase during repeat renal ischemia.[234,235]

In vivo studies have been subject to greater controversy; initial studies using either an ischemic preconditioning model or cross-tolerance after heat stress induction suggested that heat shock proteins contribute little, if any, protection against ischemic injury in the kidney. However, more recent studies using ischemic or heat preconditioning do suggest a role for either Hsp72 or Hsp25 in protecting against injury from renal ischemia *in vivo*.[232] The apparent conflicting results

from these previous *in vivo* preconditioning studies highlight the potential advantage of studying a model of intrinsic resistance to injury, as recently demonstrated by Basile et al. in the Brown Norway rat, where a preconditioning insult is not required.[236] In the nephrotoxic model recent findings suggest that Hsp72 attenuates cisplatin-nephrotoxicity, and there was evidence of increased Bcl-2/Bax ratio and less apoptosis thus implicating its role in cell death.[237]

Heme Oxygenase

The enzyme heme-oxygenase-1 (HO-1) is responsible for the degradation of heme to bilirubin, carbon monoxide and iron. Its gene is arguably one of the most readily inducible genes responding to numerous stressors including but not limited to hypoxia, hyperthermia, oxidative stress, LPS to name a few. Consequently, induction of HO was described in various forms of AKI including ischemic, endotoxin and nephrotoxic models. A number of studies indicate a protective effect of induction of HO-1 in AKI.[238,239] Prior induction of HO-1 by hemoglobin can reduce endotoxemia-induced renal dysfunction and mortality. Inhibition of HO activity in the intact, disease free kidney reduces medullary blood flow without exerting any effect on cortical blood flow. Overexpression of HO-1 by hemin results in a significant reduction in cisplatin-induced cytotoxicity.[240] TNF-α induced apoptosis in endothelial cells is also attenuated by induction of HO-1. These findings have been supported by studies in which HO-1 deficient mice, in the glycerol-induced AKI model, exhibited marked exacerbation of renal insufficiency and mortality.[241] The protective mechanisms of HO-1 have been extensively studied by Nath et al. who showed over expression of HO-1 in cultured renal epithelial cells induces upregulation of the cell cycle inhibitory protein p21 and confers resistance to apoptosis.[242] Thus the biologic actions HO-1 that appear particularly relevant to AKI include vasodilatory effects, cytoprotective effects, anti-inflammatory actions, anti-apoptotic effects and cellular proliferative effects making it a potentially exploitable expressive enzyme in the prevention and reduction of AKI. Perhaps more importantly it might also benefit in the repair and regeneration of tubular cells.[56,239]

Reactive Oxygen Species and Oxidative Stress

Reactive oxygen species (ROS) have been implicated in the pathogenesis of ischemic and toxic AKI. Three highly reactive ROS, the hydroxyl radical (HO^-), peroxynitrite ($ONOO^-$) and hyperchlorous acid (OCl^-) are discussed here.

The hydroxyl radical (HO^-) is formed from superoxide using the enzyme superoxide dismutase that utilizes ferrous iron as a catalayst. Superoxide is constantly produced by normal cells that are normally protected against the injurous effects of HO^- by numerous scavenging systems. Perioxynitrite ($ONOO^-$), like the HO^- radical, is a potent oxidant formed by the noncatalysed reaction between superoxide and NO. Antioxidants, catalases, and glutathione peroxidases convert the intermediate molecule hydrogen peroxide (H_2O_2) to water. Oxidant stress occurs when there is either a lack of these antioxdants or enzymes or when there is excessive ROS generation.

In ischemic, myoglobinuric or hemoglobinuric renal injury, iron is liberated from storage sites and free iron promotes the generation of HO^-. Other sources of generation include mitochondria where oxygen deprivation leads to "reduction" of the redox state of the electron transport chain, and when reperfusion occurs, free electrons are released capable of increasing superoxide production. A second important source in rats is xanthine oxidase whose production is increased in ischemic and reperfusion and generates superoxide. In the presence of reduced nicotine adenine dinucleotide (NADH) or reduced NAD phosphate (NADPH) the enzymes involved in the metabolism of arachidonic acid produce superoxide. Neutrophils when activated produce superoxide as a result of NADPH oxidase enzyme. Endogenous renal cells, such as tubular epithelial cells, also possess this enzyme which may thus serve as a source of oxidants in ischemia-reperfusion injury. Collectively, an extremely high concentration of ROS can accumulate under pathological conditions overwhelming the scavenging and antioxidant systems as they themselves become suppressed during injury.[243]

ROS damage tissue in a variety of ways. Cells and their organelles—lipids, carbohydrates, proteins, and nucleic acids—can all be affected by ROS. For example, peroxidation of lipids in plasma and intracellular membranes perturbs membrane fluidity, permeability, and ion and solute transport. In response to oxidant stress partially purified membrane fractions from the outer medulla of the kidney display diminished activity, turnover rates, and sulfhydryl content of Na^+K^+-ATPase, accompanied by increased peroxidation of membrane lipid. Cytoskeletal proteins and proteins such as integrins, that facilitate the attachment of cells to the neighboring extracellular matrix, can also be destabilized by ROS. Exposure to hydrogen peroxide rapidly causes single-strand breaks in DNA leading to the activation of the DNA repair enzyme, poly-ADP-ribose polymerase (PARP) resulting in the consumption of NAD* and impaired ATP synthesis. Additionally, hydrogen peroxide compromises

mitochondrial ATP synthesis by inhibiting the ATP-synthetase complex.[243]

Evidence for the role of ROS in AKI comes from both *in vitro* and *in vivo* studies. The generation of ROS during ischemic and postischemic phases is well documented. For example, studies undertaken in renal epithelial cells demonstrate that increased amounts of ROS are generated not only during reoxygenation after hypoxic exposure, but also during the hypoxic phase.[233] Superoxide anion is usually vasoconstrictive-based on its capacity to scavenge nitric oxide, while hydrogen peroxide may exert vasodilatory or vasoconstrictive effects. ROS can also alter the expression or activity of variousvasoactive species, can greatly impair the endothelium, and can profoundly perturb vascular reactivity because of ROS-mediated effects on intracellular calcium handling in smooth muscle cells. ROS can also promote leukocytic adherence to the endothelium. Thus, ROS contribute to many renal vascular and hemodynamic changes observed during the initiation and established phases of ATN: endothelial injury, leukocytic adherence, increased endothelial expression of vasoconstrictive peptides, impaired endothelium-derived vascular relaxation, heightened sensitivity to vasoconstrictors, greater sensitivity to neural stimulation, increased basal vascular tone, and dysfunctional autoregulation.[123]

Oxidative stress can injure plasma and intracellular membranes by activating phospholipases, in particular, phospholipase A_2, present in membrane-bound and cytosolic fractions. ROS can also damage DNA, impair enzymatic processes, and ion pumps, including direct oxidant injury to Na^+/K^+-ATPase and Ca^{2+}-ATPase. That oxidative stress may contribute to inflammatory events in the ischemic kidney is demonstrated by studies of ischemic injury in mice that overexpress oxidant-scavenging genes, such as glutathione peroxidase. Such mice exhibit less ischemic injury to the kidney along with less activation of NF-κB and attenuation in the upregulation of relevant chemokines.[244]

The demonstration in relevant disease models that antioxidant maneuvers exert beneficial effects has stimulated the application of antioxidant therapies to human ATN. Relevant to this is the demonstration that the administration of the thiol-donating antioxidant, N-acetyl-cysteine, reduces the risk of renal insufficiency induced by contrast dye.[245] There have been numerous studies that have illustrated benefits of antioxidants in preventing renal ischemic damage, including superoxide dismutase, catalase, inhibitors of xanthine oxidase, scavengers of HO^- and agents that bind free iron. Unfortunately, the transition from bench research on animals and cells to clinical studies has proven less promising.[246] As gene-deletions and knockout mice models become more available to study the mechanisms of disease, and the effect of therapies, their use in oxidant injury has also been evaluated. Recently it has been shown that PARP ablation preserved ATP levels, renal function, and attenuated the inflammatory response in the setting of IRI in the mouse model.[247]

The capacity of ROS to influence the expression of growth-promoting substances and, in turn, the utilization by growth factors of ROS as signaling species, raises the intriguing possibility that ROS may be also involved in the recovery phase from ATN.[243]

CELLULAR REPAIR, REGENERATION AND RECOVERY

Renal tubular regeneration is one of the most remarkable phenomena in mammalian biology research as it can restore kidney function and structure after ischemic or toxic renal injury. This is clinically evident in the fact that most patients recover from AKI, if the insult is removed within a critical time period, before complete necrosis sets in. Sublethally injured cells initiate the process of repair and regeneration once reperfusion commences. Most sublethally injured cortical PTC cells repair themselves without going through a "dedifferentiated stage." Although exfoliation of cells might not be considered a morphological stage of repair, it is associated with the generation of signals that initiate the process of repair including accumulation of leukocytes, and the integration of growth factors to determine the fate of the epithelial cells. The stage of regeneration in severly injured cells is the "dedifferentiated stage," which is manifested morphologically as the appearance of flattened cells, with a poorly differentiated brush border. In the S3 segment of the proximal tubules, the viable cells exhibit marked increase in proliferation, spreading across the injured denuded basement membrane. Finally, these poorly differentiated cells regain their differentiated character and produce a normal proximal tubule epithelium.

At a cellular and molecular level, recovery from ATN means the re-establishment of the normal cellular architecture and the physiological functions of the renal tubule. This is obviously dependent on cellular ATP repletion once there is adequate oxygen delivery and metabolic substrates.This ATP repletion occurs in a biphasic manner with a rapid initial phase followed by a slow gradual increase to pre-ischemic levels.[248] The reassembly of the cytoskeletal structure occurs with concurrent ATP repletion, restoring the apical microvilli within 24 hours. Na^+/K^+-ATPase is reassociated with basal actin cytoskeleton within 24 hours even though some apical Na^+/K^+/ATPase activity

persists for longer periods of time. The restoration of the lipid polarity lags behind that of the Na^+/K^+-ATPase pump and is complete by 10 days post-ischemia.[249]

Role of Growth Factors

Growth factors have been implicated in the control of both cell differentiation and proliferation.[194] The kidney is a known site of synthesis for several growth factors, including Transforming Growth Factors β (TGF-β), Epidermal Growth factors (EGF), Hepatocyte Growth Factors (HGF), and Insulin-Like Growth Factor I (IGF-1) to name a few. Observations describing changes in the renal expression of these factors after experimentally induced ischemic ARF in rats are abundant, implicating a potential role in the regeneration process. We shall briefly discuss each one and their proposed roles in the process of recovery.

TGF-β

In the later stages of renal repair TGF-ß, a polypeptide growth factor, has the capability to mediate numerous events including as apoptosis, tubulogenesis, cellular hypertrophy and differentiation of regenerating proximal tubule cells. It may also negatively regulate cellular proliferation thereby balancing the activity of pro-mitogenic growth factors. In *in vitro* studies TGF-β stimulates extracellular matrix (ECM) synthesis, cell clustering, tubulogenesis and apoptosis while inhibiting proliferation of renal proximal tubule cells. Within 12 hours of ischemic injury there is enhanced expression of TGF-ß1 mRNA and protein in damaged and regenerating proximal tubules that may remain elevated for up to 14 days post-ischemia. However, overall there is no substantive evidence suggesting that it plays a critical role in the renal tubular repair response as inhibiting TGF-β does not accelerate recovery.[250]

Although fibrosis is generally not evident within the time frame that TGF-β expression returns to baseline values, recent data support the concept that transient TGF-β activity post-ischemia may induce subsequent interstitial fibrosis by promoting the deposition renal fibroblasts. Another important observation is that TGF-β neutralization prevented the loss of renal microvessels and GFR following recovery from AKI.[194,250]

Other Growth Factors

HGF has potent mitogenic activity that is localized in the peritubular endothelial cells. The kidney is both a target and generation site of HGF. Extrarenal and intrarenal HGF mRNA and HGF protein measurements are elevated within six hours of ischemic or toxic ARF, and numerous reports of exogenous administration enhancing recovery of renal function in experimental models are now available.[251] Results from transgenic mice indicate that overexpressing HGF within the proximal tubule cell may ameliorate renal damage induced by ischemia/reperfusion by at least two different processes: enhancement of tubule cell proliferation and protection against cell death.[252]

IGF-1 expression is predominantly located in the medullary collecting duct and to a lesser degree in glomeruli and proximal tubule cells. Like HGF it may be involved in the repair process of the injured kidney. IGF receptors are found throughout the kidney but there are very high concentrations in the basolateral membrane of proximal tubules. Renal artery clamp induced AKI was significantly attenuated by exogenous administration of exogenous IGF-1.[194] IGF administration has also been shown to induce up-regulation of cell-cycle inhibitory protein p21 (discussed later). Human trials using IGF-1 in AKI in the ICU setting or delayed graft function on post-transplant patients have not yet revealed any significant difference versus placebo therapy.[253,254] However, the study in the AKI patients in the ICU setting was started several days after the onset of AKI. This alone could have limited the efficacy of the drug.[254] In the delayed graft function post-transplant study the drug was instituted within five hours of transplant but still lacked any beneficial effect.[253]

Growth Hormone (GH) regulates the expression of IGF-1 and the growth hormone receptor has been found to be down-regulated in experimental ischemic AKI. Exogenous supplementation with high dose GHhowever does not modify the course of experimental ischemic ARF in rats and in human trials critically ill patients recombinant GH was actually found to be associated with higher mortality and morbidity.[255]

EGF is normally produced by the mTAL and distal tubules. The EGF receptor is present in glomeruli, proximal tubule cells, medullary interstitial cells and collecting ducts. It is normally present in the basolateral membrane, but upregulated to the apical membrane during ischemic injury in the proximal tubule cell in rats. Exogenous EGF administration *in vivo* enhances proliferation and or DNA repair, and accelerates recovery of damaged proximal tubules after ischemic or mercuric-chloride-induced damage.[194,256]

VEGF is specific in its action on the endothelial cells and may be involved in neovascularization after injury. It is expressed in glomeruli and collecting duct epithelial cells in adult kidneys while its receptors are in the glomerular endothelium and peritubular capillaries. Recent data suggest that, unlike in other organs, during renal I/R injury VEGF synthesis in kidneys is primarily regulated post-transcriptionally and is interrelated to IL-6 levels.

VEGF treatment ameliorates disease manifestations in several models such as glomerulonephritis, remnant kidney and TMA. However, overall the exact role of VEGF in AKI remains controversial and still needs to be fully evaluated.[257,258]

It is interesting to note that quite a few of the sites of expression of gene involved in the repair and regenerative processes, are localized to the mTAL or peritubular capillarysegments of the nephron. This suggests a possible paracrine signaling mechanism to stimulate regeneration in severely injured cells of the neighboring S3 proximal tubule cells.

Cell-Cycle Regulators

The protein p21 (also known as WAF1, CIP1 or SD11) regulates cell proliferation by inhibiting the cell cycle through the cyclin kinase pathway. It also has been shown to inhibit apoptosis induced by numerous stimuli. Safirstein and colleagues have demonstrated its induction in murine kidneys after ischemia, cisplatin and acute obstruction.[259] By delaying the entry of cells into the cell-cycle, they can reduce cell death from apoptosis or necrosis. In p21 knockout $^{-/-}$ mice subjected to ischemia reperfusion morphologic damage was evident throughout the cortex, where as wild type mice only had damage in the S3 segment of the proximal tubule.[260] As discussed earlier, heme-oxygenase-1 (HO-1) overexpression induces p21 up-regulation. Similarly IGF administration also causes upregulation of p21. Hence all these protective mechanisms are likely linked through delay in cell death by arresting a particular phase of the cell-cycle through p21 protein.[259]

Growth Factor Receptors

To complete the discussion on growth factors the role of their receptors also needs to be considered. A number of studies have shown that the expression of receptors for EGF, HGF, FGF-7 and IGF-1 is enhanced with acute renal injury. For example, histologic analyses show the increase in HGF receptor immunoreactivity is most marked in the most severely damaged nephron segments in the outer medulla. In the injured proximal tubules the receptor is redistributed from an apical location to an intracellular location. The prolonged elevation of this receptor (up to eight days), could mean that even late treatment with exogenous HGF might be beneficial,[261] although there are no data to support this hypothesis.

Acute Kidney Injury

Long-Term Effects and Cross-Talk Amongst Organs

A series of experiments has shown that the post-ischemic kidney has persistent local hypoxia that stimulates pathways leading to progressive interstitial scarring. In post-ischemic animals subjected to bilateral ischemic injury the authors found localization of pimonidazole, which binds to cellular thiols at pO_2 levels of less than 10mmHg, consistently in the outer medullary zone up to five weeks after ischemic insults. In animals undergoing a unilateral nephrectomy followed by ischemic insult this localization was more intense and widely distributed. The rate of interstitial scarring, development of proteinuria and decline in GFR was faster in these animals as compared to those with bilateral injury. Lastly, they found supplementation of L-arginine increased the renal blood flow, reduced hypoxia, and attenuated the secondary manifestations of ischemic damage.[262]

These observations prove that chronic hypoxia does indeed exist long after an ischemic insult and that the hypoxia is more severe in the setting of reduced renal mass resulting in progressive fibrosis that develops following apparent recovery after ischemic injury. Although no study to date has examined the long-term vascular structure and function in ARF among native human kidneys there is evidence from renal allografts, where damage to peritubular capillaries correlates with progressive functional loss.[263] It is possible that loss of peritubular capillary density could contribute to delayed graft function and development of chronic allograft nephropathy. Apart from ischemic injury, numerous factors can cause capillary rarefaction including aging, cyclosporine, angiotensin II, glomerulonephritis and radiation-induced renal injury with altered expression of VEGF.[264] It is also possible that the vascular injury could lead to potential hypertension in the long run as experimental model data suggest reductions in peritubular capillary density are associated with salt-sensitive hypertension, elevated pressure measured at 20 weeks after injury to solitary kidney and greater pressor responsiveness to angiotensin II.[265] Thus it is possible that after recovery from injury a subject could be predisposed toward higher arterial blood pressures with increased Na^+ intake.

CROSS TALK AMONGST ORGANS

AKI is likely a systemic event that can potentially cause alterations in other organs of the body. Kelly et al. have demonstrated the effects of renal ischemia on cardiac tissues.[68] Induction of IL-1, TNF-α, and ICAM-1 mRNA was seen in cardiac tissues as early as six hours post renal ischemic injury, and remained elevated upto 48h post-renal ischemic injury. There was also a significant increase in myeloperoxidase activity in the heart and liver, apart from the kidneys. The increase in cardiac MPO activity could be prevented by administration of anti-ICAM-1 antibody at the time of renal ischemia. At 48 h cardiac function evaluation by

echocardiography also revealed increases in left ventricular end systolic and diastolic diameter and decreased fractional shortening. As little as 15 min of ischemia also resulted in significantly more apoptosis in cardiac tissue.[68] Rabb et al. have shown that renal ischemic injury leads to increase in pulmonary vascular permeability defects which are mediated through macrophages.[266] Furthermore they also showed that in a rat model of bilateral renal ischemic injury or nephrectomy there was down regulation of lung epithelial Na channel, Na^+/K^+-ATPase and aquaporin-5 expression, but not in unilateral ischemic models suggesting the role of uremic toxins in modulating these effects in the lung.[267]

Conversely speaking, other organs also regulate ischemic renal injury. Slutsky et al. have recently demonstrated the role of lung injury in inducing renal damage. They found that in rabbits, injurious lung ventilatory strategies (high tidal volume and low peak end expiratory pressure) alone, were sufficient to induce renal epithelial cell apoptosis. This was further substantiated by the fact that plasma obtained from rabbits that underwent the injurious ventilation strategy induced greater apoptosis in cultured LLC-RK1 cells *in vitro*, suggesting that circulating soluble factors associated with the injurious mechanical ventilation might be involved in this process.[268] Another example of extra-renal organs regulating ischemic acute renal failure is the effect of the brain death on renal transplants. Traumatic brain injury elicits a cytokine and inflammatory response. These cytokines result in renal inflammation in renal transplants from brain dead, but not living donors.[269] The absence of such inflammation may contribute to the success of living unrelated donor renal transplants compared with cadaver transplants that have better immunologic matches.[270]

CLINICAL COURSE & DIAGNOSTIC TESTS IN AKI

Clinical Course

Prerenal azotemia by definition should rapidly reverse upon restoration of renal perfusion. The clinical course of ATN can be divided into four phases: initiation, extension, maintenance, and recovery. During the initiation phase, which can last several hours, the patient is exposed to the insult and parenchymal cell damage is established. Thus the severity of ATN is potentially limitable if this phase can be clinically detected, but unfortunately it is seldom that this duration is long enough or recognized early enough to prevent frank ATN. The recently proposed extension phase by Sutton et al., involves continued hypoxia of the corticomedullary junction secondary to microvascular congestion along with inflammation in this region.[125] As has been described in detail earlier, cellular injury in this region of the outer medulla continues leading to a fall in GFR through continued epithelial cell damage and release of inflammatory cytokines. This phase could represent a window of opportunity to prevent further progression of established ATN.[125] In the maintenance phase of ATN, the GFR remains low and this phase typically lasts between one to two weeks, but can be as long as up to six months. Finally, the recovery phase is heralded by a rise in urine output followed by a decline in serum creatinine. An excessive post-ATN diuresis might result if the recovery of the tubular reabsorptive process lags behind glomerular filtration. The usual diuresis seen after ATN is likely a combination of osmotic diuresis induced by filtration of filtered urea and other solutes, the appropriate excretion of salt and water accumulated during the maintenance phase,[195,271,272] along with a distal concentrating defect that has not yet resolved.

Clinical Features

A detailed history and physical exam is crucial to the diagnosis and management of any form of AKI. Evidence of volume depletion includes symptoms of thirst and dizziness, while physical exam will reveal absolute or orthostatic hypotension, tachycardia, reduced jugular venous distension, dry mucous membranes and decreased skin turgor. Weight loss, increased fluid loss from gastrointestinal, urinary or insensible sources and documentation of hemorrhage all support the evidence of volume depletion as a cause for AKI. One should also carefully review nursing and pharmacy records to identify potential nephrotoxic drugs. Causes of reduced effective arterial blood volume (EABV) such advanced heart failure may reveal their characteristic findings such as elevated jugular venous pressure, bibasilar pulmonary rales or effusions, cardiomegaly, S3 gallop rhythm, liver congestion and peripheral edema. Other patients may demonstrate typical stigmata of chronic liver disease such as ascites, palmar erythema, splenomegaly, jaundice and telangiectasia, serving as important supportive clinical findings for reduced EABV as the cause of AKI. In the ICU setting it is quite often difficult to assess the volume status of a critically ill patient as physical exam is often complicated by edema due to third space losses. In these settings, the use of invasive hemodynamic monitoring using central venous pressure monitoring or Swan-Ganz catheter or both is often quite helpful in determining the EABV in a patient.[273]

Other causes of AKI will have their own diagnostic features in the history and physical exam.

Urinary and Blood Tests

Urinary indices are quick, inexpensive and extremely useful tools to assist in the differential diagnosis of AKI. The fractional excretion of sodium (FENa) is a sensitive index for this purpose and has been substantiated in several reports since it was first reported by Espinel.[274–276] Prerenal azotemia is a state of avid reabsorption of filtered Na^+ and water leading to low urine concentrations of sodium and relatively high urine/plasma (U/P) ratio of osmolality, urea nitrogen, and creatinine resulting generally in a FENa of less than 1%. In contrast, ATN has functional impairment of proximal tubule cells resulting in higher urinary Na^+ concentration, and lower U/P ratios of osmolality, urea nitrogen and creatinine, leading to usually a FENa of >1%. Animal models of AKI that have studied mechanisms of tubular injury, as described earlier in the text, have elucidated the effects of ischemia on the Na^+/K^+-ATPase pumps and co-transporters present in the tubules. However, one should keep in mind that none of them are absolutely specific or sensitive, neither have they altered the management or outcome of ARF. Because the process of AKI is dynamic the timing of urinary testing, effects of diuretics, and the presence of underlying CKD can all alter the mechanisms for Na^+ reabsorption and should be kept in mind when interpreting the results. Similarly, approximately 15% of patients with non-oliguric ischemic or nephrotoxic AKI have a FENa of less than 1% which could represent an early phase or a milder form of injury as has been reported in the course of ARF accompanying rhabdomyolysis, sepsis, radiocontrast nephrotoxicity, ischemia, acute glomerulonephritis, renal allograft rejection, hepatorenal syndrome and NSAID exposure.[277,278] The Na^+ transporting segments in other areas of the nephron, and their function, are probably relatively preserved in such circumstances as compared to the corticomedullary junction and the outer medulla which suffers more localized epithelial cell damage.

A more useful test in settings of chronic kidney disease or in patients who have received a diuretic is measuring the fractional excretion of urea. A low fractional excretion of urea (FE_{UN}) was recently shown to have a high sensitivity (85%), high specificity (92%), and more importantly a high positive predictive value (98%). If a FE_{UN} of 35% or less is found, 98% of such cases will have prerenal azotemia[278] (Table 76.5A and B).

TABLE 76.5A Urine Indices Used in the Differential Diagnosis of Pre-Renal AKI and Acute Tubular Necrosis

Diagnostic Index	Pre-renal AKI	Acute tubular necrosis
Fractional excretion of sodium (%)	<1*	>2*
Urine sodium concentration (meq/L)	<20	>40
Urine creatinine/plasma creatinine ratio	>40	<20
Urine urea nitrogen/plasma urea nitrogen ratio	>8	<3
Urine specific gravity	>1.018	~1.010
Urine osmolality (mOsm/kg H_2O)	>500	~300
Plasma BUN/creatinine ratio	>20	<10–15
Renal failure index, $U_{Na}/(U_{Cr}/P_{Cr})$	<1	>1
Urine sediment	Hyaline casts	Muddy brown granular casts

FE_{Na} may be >1% in prerenal AKI associated with diuretic use and/or the setting of bicarbonaturia or chronic kidney disease; FE_{Na} often <1% in acute tubular necrosis caused by radiocontrast or rhabdomyolysis

Pathophysiologic Basis of Complications of AKI

Hyponatremia and Fluid Overload

Life threatening complications secondary to AKI may arise rapidly in these patients and have to be anticipated to prevent adverse consequences. Careful and frequent monitoring of volume status and electrolytes is essential in deciding the approach to management. Volume overload is a result of salt and water retention and is aggravated by attempts to restore diuresis in oliguric patients as well as obligatory needs such as medications and nutrition.[279] Intravascular volume excess may be particularly dangerous in elderly or heart failure patients. Hyponatremia may be caused by excessive free water ingestion or by the administration of dextrose solutions or hypotonic fluids.

Hyperkalemia

Hyperkaemia is a common and life-threatening complication of AKI, reflecting the decreased GFR, low cortical collecting duct flow rate and decreased distal sodium load. It is compounded by coexisting metabolic acidosis and a hypercatabolic state causing efflux of potassium from the intracellular space. Medications such as ACE-I, NSAID's, digitalis, spirinolactone, beta-blockers and heparin may further aggravate the rise in serum potassium. Electrocardiographic (ECG) abnormalities include peaked, thin, symmetrical T waves which is the earliest change seen, followed by prolongation of PR interval, depressed ST segment and QRS widening. Life-threatening arrhythmias such as ventricular tachycardia, bradycardia, heart block, asystole and ventricular fibrillation may ensue if hyperkalemia is not corrected.[279] In addition, neuromuscular derangements

TABLE 76.5B Urine Sediment in the Differential Diagnosis of Acute Kidney Injury

Normal or few red blood cells or white blood cells
Pre-renal azotemia; Arterial thrombosis or embolism; Pre-glomerular vasculitis
HUS/TTP; Scleroderma crisis
Post-renal AKI
Granular casts
Acute tubular necrosis; Glomerulonephritis or vasculitis ;Interstitial nephritis
Red blood cell casts
Glomerulonephritis or vasculitis; Malignant hypertension
White blood cell casts
Acute interstitial nephritis or exudative glomerulonephritis; pyelonephritis
Marked leukemic or lymphomatous infiltration
Eosinophiliuria (>5%)
Allergic interstitial nephritis (antibiotics >> NSAIDs) ; Atheroembolism
Crystalluria
Acute urate nephropathy ;Calcium oxalate (ethylene glycol intoxication); Acyclovir;
Indinavir
Sulfonamides; Radiocontrast agents
HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura;
NSAID, non-steroidal anti-inflammatory drugs

such as hyporeflexia, flaccid paralysis, weakness and parasthesias may occur and can be life-threatening if they extend to involve the respiratory or phonation muscles. Certain medications such as cisplatin, amphotericin and aminoglycosides may cause transient early hypokalemia reflecting TAL epithelial injury.[280,281]

Hyperurecemia

AKI patients usually develop a mild degree of hyperuricemia (12−15 mg/dl), as the primary route of elimination of uric acid is glomerular filtration and proximal tubule secretion. Higher levels should raise the suspicion for acute urate nephropathy secondary to tumor lysis syndrome or rhabdomyolysis. Sometimes it is possible to differentiate borderline mixed scenarios by measuring urine uric acid/urine creatinine ratio which is typically less than 0.75 in states of impaired excretion and greater than 1.0 in states of increased uric acid production.[282] The fractional excretion of uric acid can also be helpful in differentiation prerenal AKI (less than 10%) and intrinsic ATN (greater than 15%).[283]

Uremia

Due to the inability to excrete nitrogenous waste products, non-oliguric, non-catabolic AKI patients can exhibit a daily rise in serum BUN and creatinine of 10−20 mg/dl and 0.5−1.0 mg.dl, respectively. Oliguric, catabolic patients exhibit comparably larger daily changes in these values. Manifestations of uremia can vary from vague non-specific symptoms such as lethargy, nausea, confusion, anorexia and restless leg syndrome to severe life threatening signs such as seizures, pericarditis, pericardial effusion with tamponade and coma. Other clinical signs include asterexis, myoclonus, stupor, hyperreflexia, focal neurologic deficits and ileus.[284] The severity of the renal injury generally dictates the severity of these complications.

Acidosis

Due to decreased proximal tubule reabsorption of HCO_3 and the inability of the acutely injured kidney to regenerate bicarbonate through ammoniagenesis, there is progressive accumulation of organic acids such as sulfate and phosphate leading to metabolic acidosis. The main systemic features of metabolic acidosis include Kussmaul respiration, nausea, vomiting, fatigue, lethargy, stupor, coma, decreased myocardial contractility, cardiac arrhythmia, resistance to vasopressor drugs, peripheral arterial vasodilation and insulin resistance. Acidosis may be severe when there are concurrent mechanisms of hydrogen ion generation such as lactic acidosis, liver disease or sepsis which will further exacerbate hyperkalemia, hyperphosphatemia and hyperurecemia.

Calcium and Phosphorus

Hypocalcemia is commonly found in AKI secondary to a combination of these processes: (1) decreased synthesis of 1,25-$(OH_2)D_3$; (2) increased serum phosphate caused by skeletal resistance to PTH as well as reduction in GFR; and (3) deposition of calcium in damaged tissues.[285] Clinical manifestations of hypocalcemia are usually not evident and most patients are asymptomatic. However, in certain cases (e.g., pancreatitis and rhadomyolysis) severe symptomatic hypocalcemia with resultant signs and symptoms such as muscle cramps, seizures, confusion, positive Trousseau and Chvostek signs as well as electrocardiographic features of prolonged QT interval and non-specific T wave changes occur. The same processes that lead to hypocalcemia cause hyperphosphatemia which can be exacerbated in conditions such as rhabdomyolysis and tumor lysis syndrome, active tissue necrosis and hemolysis. Acidosis and hypercatabolism can also cause

shifts of phosphorus from the ICF to ECF space further increasing the serum levels. Metastatic deposition of calcium phosphate occurs usually when the calcium x phosphorus product exceeds 70, further lowering calcium levels.[286]

Magnesium

Oliguric AKI patients commonly will have mild asymptomatic Hypermagnesemia due to the decreased excretion of dietary or medication related (antacid, laxative etc.) magnesium. Severe hypermagnesemia (levels >5mg/dl) is rare even in anuric AKI but when present can lead to hypocalcemia. Certain drugs such as aminoglycosides, amphotericin, cyclosporin and cisplatin can cause hypomagnesemia in non-oliguric AKI due to impaired tubular transport of magnesium.[279] Hypokalemia is aggravated by hypomagnesemia and patients can have symptoms of seizures, cardiac arrhythmias, cramps and neuromuscular instability.

Anemia

Anemia is a common occurrence in AKI and occurs rapidly post injury. It is usually multifactorial with ineffective erythropoiesis, inappropriate erythropoietin (Epo) production and hemolysis being the major contributors. It has been consistently noted there is a rapid decline in erythropoietin levels post AKI and that normalization does not take place till weeks after recovery.[287] Tan et al. also found that in experimental AKI a substantial capacity for Epo production is retained but the sensitivity of the Epo response to blood oxygen availability is significantly reduced.[288] A qualitative platelet dysfunction secondary to uremia also exists in AKI that could serve to exacerbate the anemia by potential blood loss.

Nutrition

One of the most frustrating and troublesome complications of AKI is malnutrition as most patients have a net protein breakdown that sometimes exceeds 200mg/day. Some of the reasons why AKI patients end up in a net negative nitrogen balance include a) anorexia secondary to uremia, b) hypercatabolism, c) loss of essential nutrients through dialysis or drainage fluids and lastly d) restriction of adequate protein intake secondary to volume overload or azotemia[279,289] (Fig. 76.9).

PATHOPHYSIOLOGIC BASIS OF THERAPY OF AKI

Preventive Strategies

One of the main principles behind preventive strategies in ARF is avoidance. In any clinical scenario the use of less or non-nephrotoxic agents should be considered an essential option in considering treatment or diagnostic options. Examples include using non-iodinated contrast agents such as gadolinium or carbon dioxide in radiological procedures. Another example would be to consider non-invasive testing of cardiovascular status to better risk-stratify a patient.

The second principle is of prophylaxis. Aside from using clinical scores to predict high risk patients, other measures can be taken to prevent AKI. The single most important preventive therapy that has been shown consistently to minimize and prevent AKI in high risk settings is optimization of intravascular volume status and hemodynamics. Whether it is post-surgical ATN, burns, hypovolemic shock, nephrotoxicity from numerous agents, infections, restoration of volume prevents the development of experimental or human ATN. A prime example of this is in the setting of radiocontrast nephropathy where it has been demonstrated that prophylactic administration of saline before and after the procedure is effective in minimizing AKI.[290] Along the same line, certain other agents, e.g., oral N-acetylcysteine and recently intravenous sodium bicarbonate, have been added in combination with volume repletion and shown to be further protective than hydration alone.[245,291]

Thirdly, it is imperative to accurately and closely monitor for signs of renal dysfunction if nephrotoxins or other insults have occurred. Using adjunctive testing such as drug monitoring or more frequent serial blood and urine testing perhaps can help in diagnosing early subtle changes of ARF.

Role of Ischemic Pre-Conditioning

A significant amount of data now exists to suggest there may be intrinsic mechanisms brought to bear by the kidney when exposed to a toxic or ischemic insult, that protect it against a subsequent exposure to ischemia. Zager and colleagues performed the first experiments evaluating the effects of prior exposure to ischemia on subsequent susceptibility to ischemic injury. This group focused on early time points after an initial ischemic exposure and concluded that the rat is not more susceptible to a second ischemic episode when timed at or near the peak of functional deficit after the first.[292] Park et al. found that in contrast to what normally occurs after 30 min of bilateral ischemia, when a second period of ischemia of 30 or 35 min duration is imposed 8 days later, there is no subsequent increase in blood urea nitrogen or creatinine, no decrease in glomerular filtration rate, or increase in fractional excretion of sodium. A shorter period of prior ischemia (15 min) was partially protective against subsequent ischemic injury 8 days later.[227] Possible mechanisms include upregulation of certain protective

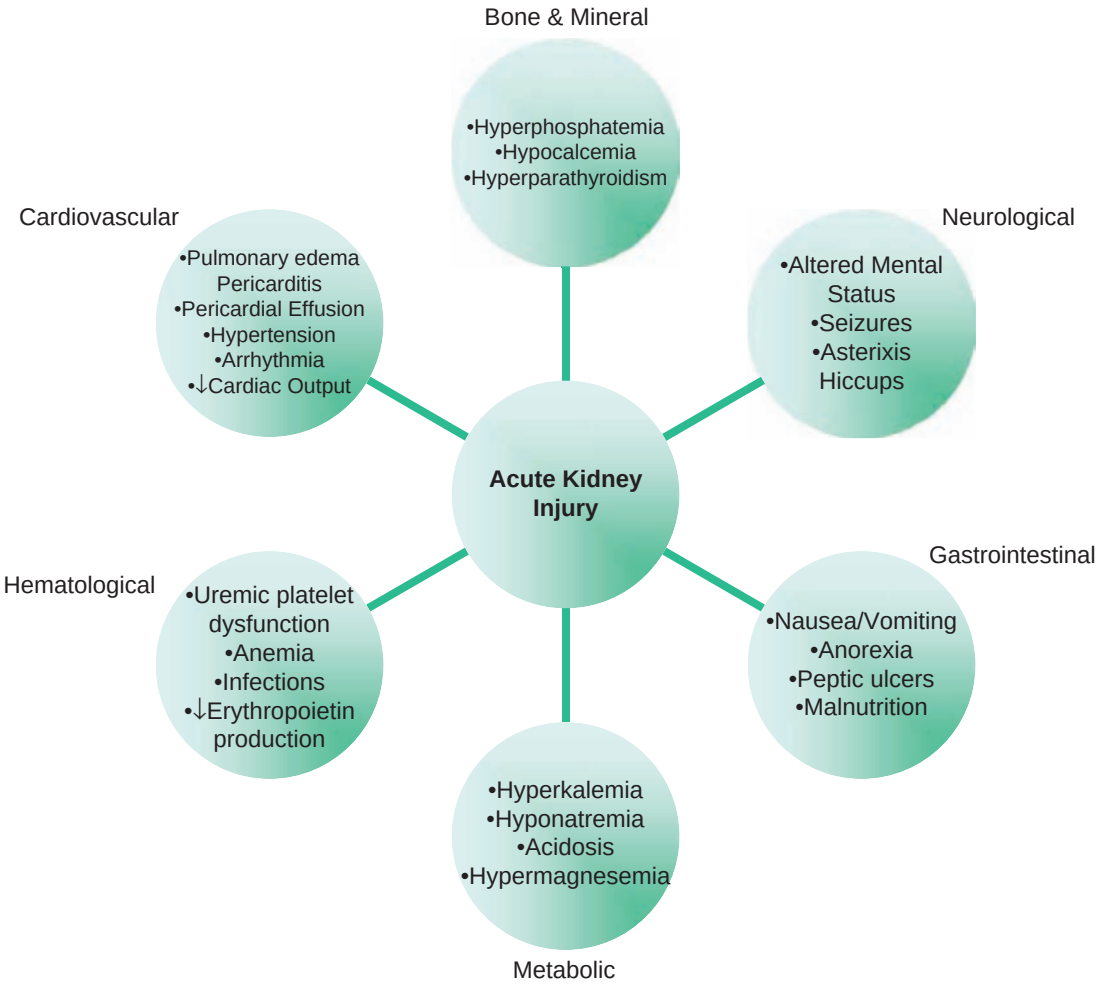

FIGURE 76.9 Common complications of AKI.

proteins such as HSP-25. Post-ischemic HSP-25 levels are much higher in the preconditioned kidney, which may stabilize the actin cytoskeleton post-ischemia and contribute to the alteration in expression of these kinases. There are also data to suggest the protective effect of ischemic preconditioning on ischemia/reperfusion -induced acute renal failure is closely related torenal nitric oxide production following the increase in eNOS expression after the reperfusion and the suppressive effect of ischemic preconditioning on the ischemia/reperfusion-induced renal ET-1 overproduction may be partly involved in the ameliorating effect of ischemic preconditioning.[293] A recent randomized, single-blind, controlled pilot trial of patients undergoing cardiopulmonary bypass-assisted cardiac surgery who received remote ischemic preconditioning by an automated thigh tourniquet of lower extremity ischemia showed an absolute risk reduction of AKI of 0.27 and a significantly reduced relative risk due to preconditioning of 0.43. Hence, remote ischemic preconditioning may prevents acute kidney injury in patients undergoing high risk surgeries.[294] With this understanding, it might be possible to mimic these processes using exogenous influences and hence prevent or alter the course of AKI.

Novel and Potential Therapies

Research in experimental animal models in the last decade has led to the discovery of potentially novel targets for the treatment of AKI. An exhaustive list of agents has been shown to be effective in animal models. We shall discuss a few of the relevant potential therapies that have recently been found to be beneficial.

ERYTHROPOIETIN

Erythropoietin is a glycoprotein hormone that controls the proliferation, differentiation of erythroid progenitor cells, synthesized by fibroblasts that are in direct contact with the capillaries and tubules. Apart

from its role in erythrogenesis, it plays important functions including protection of vascular endothelium from apoptosis and acting as an angiogenic factor. In the kidney, the expression of erythropoietin (Epo) is virtually absent at 24h following ischemic injury. However, erythropoietin receptor expression in the kidney remains well maintained. The role of erythropoietin in cell survival, proliferation, migration and differentiation have been well described recently in various in-vitro models.[295] Thus, its utility as a therapeutic agent in AKI has been under recent investigation. Rabb et al. were the first to show that intravenous administration of Epo in rats rapidly treats anemia associated with AKI as well as significantly improving survival, but they found no effect on renal function as measured by serum creatinine.[296] However, three different authors have shown a beneficial effect of using Epo in the setting of ischemic AKI. Cumulatively, these different studies indicated that pretreatment with Epo decreases ischemia induced renal dysfunction, attenuates mTAL apoptosis, decreases caspase activation and decreases renal leukocyte accumulation.[297–299] There is also evidence to suggest that Epo inhibits the JNK pathway, and induces heat shock protein 70, affording protection against apoptosis.[300,301] Functionally, Epo afforded protection by inhibiting a decline in GFR, prevented reduction of aquaporin 1,2,3 channels, and decreases in Na^+/K^+-ATPase and N^+H^+exchanger 3 pumps.[302] Although the dosing and timing of Epo administration varied amongst these studies there was universal agreement between them showing protective effects in all pre-injury treatment with Epo studies. The effect of using Epo late after ischemic injury has has also been found to be beneficial.[301] Human trials using bio-marker based early intervention strategies however havefound conflicting results of the effect of Epo in reducing the incidence of AKI[303] and its use remains unclear in the setting of AKI.[304] It is possible that it has more benefit in a single injury human scenario such as transplantation where it has shown benefit.[305]

Ichimura et al. demonstrated that injured kidney epithelial cells expressing kidney injury molecule-1 (KIM-1) could assume the attributes of endogenous phagocytes by internalizing apoptotic bodies. KIM-1 was directly responsible for phagocytosis in cultured primary rat tubule epithelial cells, and also in porcine and canine epithelial cell lines. KIM-1 specifically recognized the apoptosis marker phosphatidylserine and oxidized lipoproteins expressed by apoptotic tubular epithelial cells, which led to remodeling and repair of the tubule.[306]

Another protein, the transmembrane glycoprotein NMB (GPNMB), is upregulated 15-fold following ischemic damage in kidney tissue, more than 10-fold in macrophages, and threefold in surviving epithelial cells after injury.[307] Macrophages and epithelial cells expressing GPNMB contained 3 times more apoptotic bodies than cells not expressing GPNMB. Mutation of GPNMB or ablation of inflammatory macrophages prevents normal repair of the kidney. Kidneys from post-ischemic GPNMB-mutant mice exhibited a fivefold increase in apoptotic cellular debris compared with wildtype mice.[307] GPNMB is, therefore, a phagocytic protein that is necessary for recruitment of the autophagy protein LC3 to the phagosome where these proteins are colocalized, and for lysosomal fusion with the phagosome and hence bulk degradation of their content. These studies demonstrate that GPNMB is necessary for crosstalk between the macroautophagy degradation pathway and phagocytosis, and an important component of epithelial repair.[307]

Macrophages also have an important role in repair and recovery. The Wnt pathway ligand Wnt7b is produced by macrophages to stimulate repair and regeneration. When macrophages are ablated from the injured kidney, the canonical Wnt pathway response in kidney epithelial cells is reduced.[308] Furthermore, when Wnt7b is somatically deleted in macrophages, repair of injury is greatly diminished. Injection of the Wnt pathway regulator Dkk2 into accelerates the repair process and indicates a therapeutic option for ischemic AKI. Because Wnt7b is known to stimulate epithelial responses during kidney development, these findings indicate that macrophages are able to rapidly invade an injured tissue and re-establish a developmental program that is beneficial for repair and regeneration.[308]

STEM CELLS

There is emerging data now supporting the role of extra-renal cells in the regenerative process following AKI. Stem cells are undifferentiated cells found in the bone marrow as either hematopoietic stem cells (HSC) or mesenchymal stem cells (MSC). Studies in humans have demonstrated that when female kidneys were transplanted into male recipients who experience post-transplant ATN, Y chromosome-bearing cells were found in the transplanted kidney tubular epithelium.[309] This gives rise to the concept that extra-renal cells participate in the repair or regenerative process post ATN. Igarashi et al. have demonstrated in mice that HSC can differentiate into renal tubular cells after I/R injury.[310] Similar observations were made by Cantley et al. who showed that adult mouse bone marrow stem cells are mobilized by transient ischemia and home specifically to regions of injured tubules,[311] differentiate into renal tubular epithelial cells and appear to constitute the majority of the cells present in the previously necrotic tubules. The loss of stem cells following bone marrow ablation resulted in a greater rise in blood urea

nitrogen after renal ischemia, while stem cell infusion after bone marrow ablation reversed this effect.

The use of pluropotent mesenchymal stem cells (MSC), which can easily be harvested and cultured from bone marrow, in the treatment of ischemic AKI has recently been demonstrated by Westenfelder et al.[312] Animals infused with MSC either immediately or 24 hours after reperfusion had significantly better renal function, lower renal injury and apoptotic scores and higher mitogenic indices than vehicle treated animals. The authors found no or scarce numbers of infused MSC in the renal parenchyma, but did note that the expression of pro-inflammatory genes such as IL-1β, TNF-α, IFN-γ, and iNOS was significantly reduced, while expression of anti-inflammatory gene IL-10 was marked elevated. Expression of known renoprotective growth factors such bFGF, and TGF-α, along with anti-apoptotic protein Bcl-2 were also noted to be enhanced. Hence the authors concluded there was little trans-differentiation of these MSC into tubular or endothelial cells, but rather the action of MSC is probably paracrine in nature. However, another group of investigators have been able to demonstrate the actual presence of green fluorescent protein (GFP) labeled MSC in the tubular epithelial lining as far out as 21 days post glycerol induced ARF in mice.[313] Similarly, Morigi et al. have demonstrated injection of MSC of male bone marrow origin remarkably protected cisplatin-treated syngeneic female mice from renal function impairment and severe tubular injury where these cells localized in the tubular epithelial lining. These data indicate mesenchymal stem cells engrafted in the damaged kidney and differentiated into tubular epithelial cells, thereby restoring renal structure and function.[314]

$CD133^+$ progenitor/stem cells with regenerative potential have also been identified in the human kidney.[315] These cells were able to differentiate into both renal epithelium and endothelium *in vitro*. Mice with glycerol-induced AKI injected with these cells showed improved recovery from tubular damage.[316] MSCs are also present in the kidney and might be derived from the embryonic tissue or bone marrow. Bone-marrow cells can migrate to the kidney and participate in normal tubular epithelial cell turnover and repair after AKI.[317] Lange et al. demonstrated that infusion of MSCs improved recovery of renal function and were predominantly located in glomerular capillaries whereas tubules showed no iron labeling, indicating absent tubular transdifferentiation.[318] Knockdown of VEGF by short interfering RNA reduced effectiveness of MSCs in the treatment of ischemic AKI in a rat model. Animals treated with VEGF-depleted MSCs had reduced microvessel density, indicating that VEGF is an important mediator of the early and late phase of renoprotective action of stem-cell treatment.[319] With the use of genetic fate-mapping techniques and chimeric mice, Humphreys et al. showed that the predominant mechanism of repair following ischemic AKI was regeneration of surviving tubular epithelial cells rather than engraftment of bone marrow stem cells.[320,321] Therefore, the "renotropism" exhibited by progenitor and stem cells could have a huge impact on therapeutic options in the future once their roles are more fully defined.[322]

Hence, although the exact mechanisms of renoprotection using stem cells still remain to be fully elucidated, this is an exciting and active area of research and therapies aimed at enhancing the mobilization, propagation, and/or delivery of bone marrow stem cells to the kidney hold potential as entirely new approaches for the treatment of acute tubular necrosis.

ENDOTHELIAL PROGENITOR CELLS

There is also now emerging evidence of a potential role of using endothelial cells as therapeutic agents. Brodsky and colleagues have shown that rats infused with intact endothelial cells in ischemic AKI have an attenuated renal injury. They were also able to demonstrate actual implantation of the transplanted endothelial cells into the renal microvasculature.[323] They also found that stem cells harvested from a skeletal muscle have a potential to differentiate *ex vivo* into the endothelial lineage and are endowed with the potential to ameliorate acute ischemic renal dysfunction.[324] The concept of restoring vascular supply to damaged or ischemic organs for accelerating their regeneration is well-established.[325] One therapeutic strategy based on this concept is the delivery of angiogenic factors to the site of injury.

Another strategy could be the use of endothelial progenitor cells (EPCs). This heterogeneous group of cells originates from hematopoietic stem cells (HSCs) or their angioblastic subpopulation and MSCs. In the bone marrow, these cells are characterized by surface markers, such as CD34, VEGF-R2 (Flk-1), and an early marker CD133; moreover, circulating EPCs can express markers such as HSC, c-kit and Sca-1. Upon further differentiation, these cells lose CD133 and express VE-cadherin and von Willebrand factor.[326] Data indicate that EPCs are mobilized after acute ischemic injury and are recruited to the kidney, where they can ameliorate AKI through both paracrine effects as well as repair of the injured renal microvasculature.[327] Human HSCs administered systemically 24 h after kidney injury were selectively recruited to injured kidneys of immunodeficient mice and localized prominently in and around the vasculature.[327] This recruitment was associated with repair of the kidney microvasculature and tubule epithelial cells, improved functional recovery, and increased survival. HSCs recruited to the kidney

expressed markers consistent with circulating EPCs and synthesized high levels of proangiogenic cytokines, which promoted proliferation of both endothelial and epithelial cells. Although purified HSPCs acquired endothelial progenitor markers once recruited to the kidney, engraftment of human endothelial cells in the mouse capillary walls was rare, indicating that renal repair mediated by human stem cells is by paracrine mechanisms rather than replacement of vasculature.[112] Targeting the mechanisms to block these dysfunctional intra-cellular processes may be of key therapeutic value in the field on intensive care medicine

CONCLUSION

Major progress has been made in our understanding of molecular and pathophysiological mechanisms of AKI with the literature now rich with fascinating new approaches to treat AKI. We hope that recent advances in proteomics, discovery of newer early biomarkers, improved imaging techniques and sensitive quantitative bioassays will ultimately culminate in better understanding of AKI leading to effective therapies. Clearly, an exciting and dynamic era lies ahead of us in the field.

[3]University of Texas Health Science Center at San Antonio, San Antonio, Texas, USA

The intrinsic ability of the kidney to regulate renal blood flow and glomerular filtration rate (GFR) over a wide range of perfusion pressures has fascinated physiologists for decades. These adaptive responses to physiologic and pathologic alterations in renal perfusion, known collectively as renal autoregulation, serve to maintain renal excretory function in settings of decreased renal blood flow, such as in states of volume depletion, hypotension, or reduced cardiac output. Another important and unique setting of renal hypoperfusion is that of renal arterial occlusive disease due to a fixed stenosis, a situation that typically presents with a chronic, gradual, and eventually critical reduction of perfusion. This physiologic stress depends on renal autoregulation to maintain GFR, but the ongoing global renal hypoperfusion appears to eventually produce chronic ischemic injury to the renal parenchyma through mechanisms that are not clearly understood. This latter prospect is clearly a threat to the viability of the kidney and appears to be an important cause of chronic and often irreversible kidney disease. An understanding of the limits, mechanisms, and the pharmacologic manipulation of renal autoregulation is important in this setting because the disordered physiology is silent. Likewise, an understanding of the pathophysiology of chronic ischemic injury is important in designing effective clinical strategies to treat this disorder.

This chapter will focus on the clinically important issue of atherosclerotic renal artery stenosis (RAS) as a cause of ischemic renal disease, also known as ischemic nephropathy (IN). This disorder is recognized more frequently as a cause of end-stage renal disease. The patient population most likely to benefit from revascularization procedures is, however, not clearly defined. However, recently completed clinical trials, in conjunction with ongoing studies, are likely to bring clarity to this clinical conundrum. This chapter will review the clinical presentations of ischemic renal disease, the modalities available for diagnosis, the pathophysiology of renal hypoperfusion and ischemic renal injury, and provide insights into treatment.

ATHEROSCLEROTIC RENAL ARTERY STENOSIS: A COMMON DISORDER WITH INCREASING CLINICAL RECOGNITION AND PUBLIC HEALTH IMPORTANCE

Over the past few decades, the lesions of renal artery stenosis have been more frequently diagnosed in atherosclerotic patients with hypertension or deteriorating renal function. In addition to an increased awareness of the disorder among clinicians, the proliferation of noninvasive diagnostic techniques such as magnetic resonance angiography, computed tomography (CT) angiography, and duplex sonography has fueled this trend. Among the estimated 60 million Americans with hypertension, the prevalence of significant RAS in this population has been estimated at 2 to 5%. Autopsy series done in the 1960s indicate that RAS is common in the elderly. An autopsy study by Holley et al.[74] demonstrated a 27% prevalence of 50% stenoses in patients with a mean age of 64 years, however, the prevalence increased to 62% in individuals greater than 70 years old. Alternatively, a study by Schwartz and White demonstrated a lower prevalence of stenoses $\geq 50\%$: 5% if younger than 65 years, 18% in 65- to 74-year-olds, and 42% if 75 years and older.[156] Kuroda et al.[92] found atherosclerotic RAS of at least 75% luminal area

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00077-X

narrowing in 10% of autopsies of 60-year-old Japanese individuals with a history of stroke, and a 24% prevalence in individuals with carotid stenosis.[92] Importantly, it is likely that these autopsy series overestimate the rate since Edwards et al. have described a prevalence of 6.8% in a prospective U.S. cohort of adults >65 years old when a liberal Duplex velocity threshold of 1.8 meters/second was used during community screening.[48] In aggregate these studies suggest that renal stenoses are rather common, and that the prevalence rises rather dramatically in the elderly and it is undoubtedly true that many of the "50%" stenoses documented at autopsy were hemodyamically irrelevant. This latter point is of importance as more patients are now identified with non-invasive imaging.

As would be expected given the generally diffuse involvement of atherosclerosis, the prevalence of RAS is high when renal angiography is performed on patients who are undergoing angiography for other indications.[60,145] When performed in the evaluation for aortic disease,[19,175] coronary artery disease,[66,80,145] or peripheral arterial occlusive disease,[117,169] the prevalence has ranged from 11 to 42%. The highest prevalence seems to be in patients with peripheral vascular and aortic disease.

The public health importance of kidney disease due to RAS can be gauged by the number of individuals who progress to end-stage renal disease (ESRD) as a result of this disorder. The true prevalence in this population has been difficult to accurately estimate. It is widely believed that clinical diagnosis of IN is often missed and that many individuals who have been labeled as having hypertensive nephrosclerosis as a primary cause of ESRD may actually have suffered IN. On the other hand, the mere presence of RAS in an individual with chronic kidney disease does not prove IN as its etiology. Using the U.S. Renal Data System database, Fatica et al.[50] reviewed the primary causes of ESRD in patients starting ESRD therapy during 1991 to 1997, and they found that the incidence of renovascular disease as a primary cause of ESRD increased from 1.4% of new ESRD cases to 2.1%. The annualized increase was 12.4% per year. This is a greater rate of increase than for ESRD from diabetes mellitus (8.3% per year) and ESRD overall (5.4% per year).[50]

In a report from England, Scoble and colleagues prospectively performed renal arteriography in all new patients with ESRD during an 18-month period in the late 1980s.[157] Atherosclerotic renal artery disease was ultimately believed to be the cause of ESRD in 6% of all patients and in 14% of patients older than 50 years. Appel and coworkers suggest that renovascular disease accounts for 11% of all patients with ESRD older than 50 years and 20% of ESRD cases among whites older than 50 years.[6] Mailloux et al.[106] performed an analysis of patients entering their ESRD program between 1982 and 1985 for possible ischemic nephropathy and estimated a prevalence of 16%. This represented a significant increase from a prevalence of 8% reported among those who entered their program between 1970 and 1982.[106] This was thought to most likely be a reflection of increased awareness of the disease and the rising age of the dialysis population.

Further supporting the public health importance of IN is the clear evidence that this diagnosis imparts a high mortality risk and that patients with ESRD due to IN do poorly on dialysis. Given the frequent coexistent atherosclerotic coronary artery disease in these patients, cardiovascular deaths are common. In a Swedish study of a cohort of patients with RAS lesions exceeding 50%, Johansson and colleagues found a risk ratio (versus age-matched controls) was 3.3 for overall mortality and 5.7 for cardiovascular mortality.[81] Baboolal et al.[8] published a report in 1998 describing the poor outcome of medically treated patients with severe bilateral RAS: such patients had a crude mortality rate at 60 months of 45%. In an analysis of survival of patients who started dialysis from 1970 to 1985 by Mailloux et al.,[105] patients with renovascular disease as the cause of ESRD had very poor survival, a mean survival of 27-months and a 12% 5-year survival rate.

Over the past few decades intraluminal renal artery revascularization has enjoyed tremendous technologic advances and has become a very commonly performed procedure. This is likely in response to the increased awareness of the diagnosis and in hopes of favorably altering its poor prognosis. Among the estimated two to four million cases of renal artery stenosis in the United States, approximately 7000 such procedures are done annually, at an estimated cost of $1.7 billion per year. It remains unclear if the rate of utilization is appropriate, and some experts have suggested that this rate is far too low while others have suggested that it is far too high. Unfortunately, the current body of literature in this area supports only opinion-based rather than firm evidence-based recommendations. Although there is controversy surrounding the management of this disorder and conflicting recommendations from experts regarding treatment, the prevalence of the disorder mandates that clinicians know how to efficiently diagnose the disorder and be familiar with the current understanding of the pathophysiology and natural history of IN.

CLINICAL PRESENTATIONS OF ISCHEMIC NEPHROPATHY

IN can present as one of several clinical manifestations. Mild to moderate kidney disease in a patient

with known renovascular disease should raise suspicion for the presence of ischemic renal disease. These patients tend to be older, have a shorter duration of hypertension, require more medications for blood pressure (BP) control, show other features of diffuse vascular disease, and have a higher incidence of hypertensive retinopathy and vascular bruits than patients with essential hypertension. These patients may develop a progressive decrease in renal size by sonography along with a rising serum creatinine concentration. Ischemic renal disease should also be considered in any elderly patient who presents with unexplained acute or chronic kidney disease, especially if there is evidence of generalized atherosclerosis, even in the absence of hypertension. Development of hypertension later in life (after age 60) or an abrupt loss of blood pressure control in previously well-controlled essential hypertension, with evidence of a decline in renal function, should also raise the suspicion of this entity. Bilateral renovascular disease may be suspected from the occurrence of acute kidney injury following the initiation or intensification of antihypertensive therapy, especially with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker. Nevertheless, the absence of ARF in this setting does not rule out the possibility of ischemic renal disease.[78] A similar reduction in GFR may occur in the setting of intravascular volume depletion, congestive heart failure (CHF), and use of other antihypertensive agents such as vasodilators. A clinical scenario in which the diagnosis of renal artery disease is often suspected is in patients with poorly controlled hypertension, renal insufficiency, and left ventricular hypertrophy who develop acute pulmonary edema rapidly, so-called "flash pulmonary edema." Finally, unstable angina with poorly controlled hypertension may be a presenting complaint, especially when the degree of coronary stenosis seems proportionally less than the severity of the presentation.[87]

The character of the renal disease is nonspecific, with progressive azotemia with mild-to-moderate proteinuria (rarely nephrotic) and a bland urinary sediment. There have been reports of nephrotic-range proteinuria that has been attributed to the development of focal glomerulosclerosis in the kidney contralateral to a unilateral RAS lesion.[4,13,54,82] Rarely the disease may present with acute oligoanuric kidney disease due to progression from a high-grade, compensated lesion to complete or critical obstruction.[139,146,151]

DIAGNOSIS OF ISCHEMIC NEPHROPATHY

Given the large population of atherosclerotic patients and the nonspecific nature of the presentation, the diagnosis of IN is often considered in an extremely large number of patients. A cost-efficient, effective, and safe diagnostic strategy is desirable to identify these patients with IN. This section addresses various tests available. A recommended strategy for diagnosis is then presented.

There is an extensive body of literature and many reviews on the diagnosis of renovascular hypertension (RVH), but there is a relative dearth of data on the diagnosis of IN. To what degree this literature on RVH can be applied to the setting of IN is not clear. The tests that depend on the presence of a high renin state or high angiotensin II (Ang II) tone would not be expected to extrapolate well to the diagnosis of IN given the differences in pathophysiology of the disorders. However, data derived from the RVH literature on the anatomic diagnosis of RAS are useful. A meta-analysis published in 2001 by Vasbinder et al.[179] evaluated the literature on diagnostic tests for renal artery stenosis in patients suspected of having RVH. These authors constructed receiver-operating characteristic (ROC) curves, and these are shown in Figure 77.1. From this analysis they

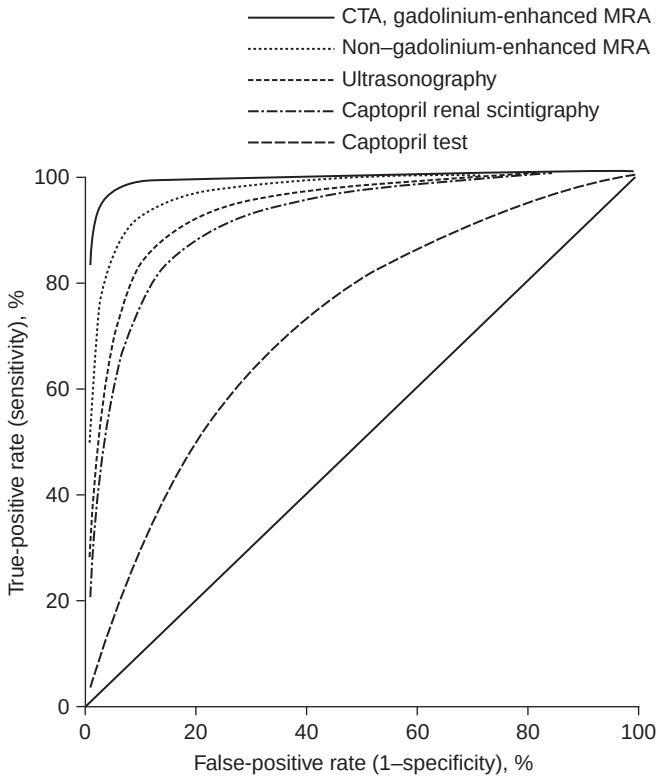

FIGURE 77.1 Summary receiver-operator curves for diagnostic tests in patients suspected of having renovascular hypertension. *(from ref. [179], with permission.)*

concluded that computed tomography angiography (CTA) and gadolinium-enhanced three-dimensional magnetic resonance angiography (MRA) were the most reliable noninvasive tests when compared to the gold standard of renal angiography. The authors also noted that few studies on these tests had been published and recommended further research in this area. In this effort, this same Dutch group later published their results of a prospective study of these two diagnostic modalities compared to intra-arterial DSA in this setting.[180] They found suboptimal diagnostic characteristics of CTA and MRA, with the combined sensitivity and specificity of 64 and 92% for CTA and 62 and 84% for MRA. They concluded that CTA and MRA are not sufficiently sensitive to rule out RAS in hypertensive patients, and they contended that DSA is the diagnostic method of choice.

Angiography

Angiography remains the single most accurate test to diagnose and quantitate renal artery disease. This may be performed with conventional technique but has largely been supplanted by intra-arterial Digital Subtraction Angiography (DSA) technique. Although *intravenous* DSA was once considered as a less invasive alternative to conventional angiography, in that it does not require arterial catheterization, it still requires nephrotoxic radiocontrast which limits its utility in patients with renal insufficiency. In contrast *intra-arterial* DSA can be performed with small volumes of contrast, and it has been reported to have similar sensitivity as conventional angiography.[89] Intra-arterial angiography can be accomplished using carbon dioxide,[67] however, the images are of lesser quality and may create greater uncertainty about lesion severity unless combined with judicious use of iodinated contrast.[103]

Renal angiography during intra-arterial angiography performed for other indications may be a reasonable diagnostic strategy, for example, during evaluation for aortic disease, lower extremity peripheral arterial occlusive disease, or coronary artery disease. When a cardiologist performs a renal angiography during a cardiac catheterization that is done through the femoral approach (pejoratively termed "drive-by" renal angiography), essentially the only incremental risk is that of the minimal volume of contrast needed to visualize the renal arteries. The suprarenal aorta has already been traversed for the coronary study, and therefore the risk for lower extremity and renal embolic sequelae has already been realized. The limitations of noninvasive evaluation for RAS (as discussed previously), the high incidence of incidental RAS in this population,[144] the prolonged phase of silent progression that may result in irreversible renal injury when it finally becomes clinically manifest, and the potential for interrupting the course of IN (to be discussed in the following sections) have been the justification for routinely including this renal artery evaluation during coronary catheterizations done via the femoral approach. Apposing this is the increased contrast exposure resulting from additional angiographic images of the abdominal and scraping of the aorta by the catheters (with an attendant risk of atheroembolization) if selective images of the renal arteries is performed. To balance these risks consensus guidelines were developed and published.[186] The more difficult issue involves the decision of whether to place a renal artery stent during the procedure and this issue requires circumspection, knowledge of the competing risks and benefits of revascularization versus medical management, and informed consent from the patient.

Duplex Ultrasonography

Another anatomic test for RAS that has a role in noninvasive evaluation of RAS is duplex ultrasonography. There are several major advantages of Duplex, namely that it is entirely safe and that the data provides functional information about lesion severity (systolic velocity and turbulence of flow) as well as anatomic information (lesion location). However, as shown in the meta-analysis by Vasbinder, it appears to have inferior diagnostic characteristics compared with MRA and CTA. This technique involves B-mode imaging with a pulsed Doppler beam to measure end-diastolic to peak systolic velocities in the renal artery and aorta. Some centers have reported sensitivity of 92.5 to 98% and specificity of 96 to 98%.[130,143] It is an operator-dependent test, and although diagnostic accuracy is improving, it will require further improvements to become the universal noninvasive test of choice. Obesity, recent food intake, increased bowel gas, and adhesions from prior surgery may limit the quality of images and may hinder diagnostic utility.

Functional Testing for RAS

Given the suboptimal characteristics of these anatomic tests, the functional tests—or "hemodynamic probes" as some authors have called them—may be useful in certain settings. Most rely on the interruption of Ang II–maintained GFR or the lowering of renal perfusion distal to a lesion by inducing controlled

systemic hypotension. Textor et al.[171] have shown that nitroprusside-controlled lowering of arterial blood pressures will decrease GFR in individuals with bilateral RAS, but the logistics preclude using this as a common diagnostic test. Combining the use of captopril with renal scintigraphy, may yield helpful information about blood flow beyond a stenotic lesion in the renal artery. The most commonly used renal scans are the 99mTc-DTPA scan (which estimates GFR) and the 131I-iodohippurate scan (Hippuran) (which estimates renal plasma flow). The 99mTc-mercaptoacetyltriglycine (Mag3) combines the advantages of both of these, and can be used to quantify the relative blood flow to each kidney.[77] However, several studies have demonstrated poor performance of renal scintigraphy for the evaluation of renal artery stenosis.[75,49] In one circumstance, the evaluation of renal function in a patient with an occluded renal artery, scintigraphy may still be useful if it demonstrates significant residual function of the post-occlusion kidney.[44]

Diagnostic Strategies

When one has at least a moderate suspicion of the disease and when a finding of RAS would guide management, many experts feel that an anatomic test for RAS should be pursued. Unless an angiogram is planned for a separate indication (such as to evaluate for coronary artery disease), a noninvasive evaluation is generally a prudent next step. Until recently MRA with gadolinium would be considered, however, in patients with IN and an estimated GFR less than 40 ml/min/1.72m^2 the risk of nephrogenic systemic fibrosis, is prohibitive. If the patient has normal renal function (which is generally not the case when the diagnosis is considered in the evaluation of ischemic nephropathy), CT angiogram is an acceptable alternative. Duplex ultrasonography is a useful alternative since it is entirely non-invasive, safe, and provides information on the functional significance of lesion severity as measured by the flow velocity. If a coronary catheterization or aortic angiography is being done on such a patient, then the angiographer should visualize the renal arteries as part of the study. In selected patients it may be justified to proceed directly to angiography if the pretest suspicion is sufficiently high and the other modalities are contraindicated (MRA or CTA because of contrast concerns) or the images are unlikely to be of diagnostic utility (example: morbid obesity and Duplex ultrasonography). CO_2 may be used as an adjunct to limit the volume of iodinated radiocontrast in individuals at risk for radiocontrast nephropathy.

CLINICAL SIGNIFICANCE OF ATHEROSCLEROTIC RENAL ARTERY STENOSIS

After the diagnosis of a renal artery lesion is secure, the next step is to assess the clinical significance of the lesion in hopes of prospectively identifying patients who will benefit from therapy. In this regard, it is important to have an appreciation of the anatomic natural history, the clinical natural history, and the pathophysiology of the disorder. These issues will be addressed later in the chapter. Several diagnostic tests have been proposed to test the physiologic and clinical significance of a given lesion, and these are reviewed here.

A parameter that may have a role in assessing the clinical significance of a lesion and in guiding the use of invasive revascularization interventions is that of the sonographically measured renal resistance-index value.[140] It has been hypothesized that intrarenal small-vessel disease may limit the benefit of main renal artery revascularization in patients with atherosclerotic RAS, and increased intrarenal renal vascular resistance may be a functional marker of this microvascular disease. The sonographically determined resistance index (RI) is considered a noninvasive measure of intra-renal resistance to blood flow, and it is calculated as follows:

$$\mathrm{RI} = [1 - (\text{end-diastolic velocity}/\text{maximal systolic velocity})] \times 100 \quad (77.1)$$

Radermacher et al.[140] assessed the prognostic value of this parameter among 138 patients who had unilateral or bilateral RAS of at least 50% of the luminal diameter and who underwent angioplasty or surgical revascularization. Their data indicated that a resistive-index value of at least 80 reliably identifies patients in whom angioplasty or surgery will not improve renal function, blood pressure, or kidney survival. Others, such as the group led by Hansen, have demonstrated that a high resistive index was associated with loss of GFR post-revascularization and high long-term mortality, but not with blood pressure response.[39]

Hemodynamic Assessment of RAS

The physiologic tests or "hemodynamic probes" may also have a role in this setting. As will be discussed later in the chapter, GFR is maintained in settings of reduced renal perfusion (such as may be the case with a high-grade RAS lesion) by maintenance of increased efferent arteriolar tone by Ang II. These tests are intended to demonstrate whether there is a drop in GFR distal to a RAS lesion after the pharmacologic interruption with an ACE inhibitor (ACE-I) of Ang

II–maintained efferent arteriolar tone. Safian and Textor suggest using captopril renography with nuclear scans to assess the functional significance of lesions by determining the renal function of the individual kidneys and by determining the dependence of renal function on Ang II.[149] As described above, the practice of using scintigraphy diagnostically though has not been validated. In contrast there is a growing literature about the use of pressure gradients measured during invasive angiography, either at rest or with a pharmacologic agent, to predict outcome of revascularization.[96] These investigators have observed that a higher pressure gradient (>21 mmHg) induced by intra-arterial papaverine was associated with an improvement in blood pressure post-procedure.

Another important issue that must be considered when assessing the clinical significance of an individual lesion is what degree of stenosis is considered hemodynamically significant? The most important consideration is the cross-sectional area through which renal blood flows. Assuming that the stenotic lesion narrows the lumen circumferentially, the luminal can be calculated as the area of a circle by multiplying pi by the square of the radius ($A = \pi r^2$). The severity of stenosis is generally assessed clinically by an estimation of the degree of reduction of luminal diameter (rather than luminal area) on angiographic longitudinal projections. Thus, decreasing a luminal radius or diameter to half would reduce the luminal area to one quarter. A basic understanding of fluid dynamics is also helpful in understanding the flow and pressure effects of the length and degree of stenotic lesions. This rearranged version of Poiseulle's equation shows the relationship of the parameters:

$$P1 - P2 = 8[Q \times n \times 1/\pi \times r^4] \qquad (77.2)$$

where Q = flow, n = viscosity coefficient, r = radius, l = length of narrowing, and P1 − P2 = pressure gradient across the stenosis. Obviously the situation is much more complicated in a physiologic system with distensible blood vessels and with pulsatile, less-than-perfectly laminar flow. Nevertheless, the equation indicates that the radius of the stenosis should be much more hemodynamically important than length of the lesion: a reduction of radius by half would increase the pressure gradient by a factor of 16 while a doubling of the length would increase the gradient by a factor of 2.

With these considerations in mind, it should be noted that autoregulation fails to maintain GFR below SBPs of 75 to 80 mm Hg and that experts have stated that this occurs when reduction of luminal diameter is reduced by 70%. Classic studies on dogs by May et al.[109] in the early 1960s support the contention that the degree of obstruction must exceed 70 to 80% of the cross-sectional luminal area before appreciable pressure gradients develop across a lesion. Using cardiac-gated magnetic resonance cine phase-contrast flow measurements with high temporal resolution in a canine model of renal artery stenosis, Schoenberg and colleagues[153] made more sophisticated descriptions of pulsatile flow profiles and pressure gradients to describe the immediate hemodynamic impact of various degrees of stenosis (as measured by reductions in luminal diameter). As shown in Figure 77.2, the area under the single cardiac-cycle flow-versus-time curve as a measure of mean flow did not substantially decrease until the degree of stenosis reached levels between 70 and 90%. They also showed that trans-stenotic pressure did not significantly

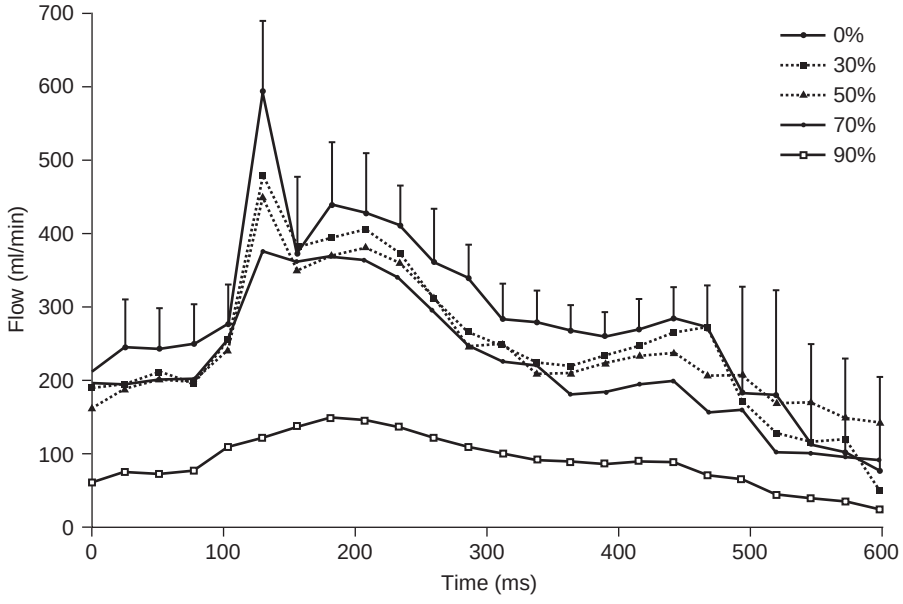

FIGURE 77.2 Hemodynamic changes in the time-resolved flow profiles obtained noninvasively with cardiac-gated magnetic resonance flow measurements. Averaged data of seven dogs are presented. For reasons of clarity, error bars are given only for the normal flow curve (0% stenosis). With increasing degree of stenosis, the early systolic peak declines, followed by a loss of the midsystolic maximum. Whereas the area under curve as a measure of mean flow does not substantially change up to 80% stenosis, the early systolic peak is sensitive to minor stenoses induced in the renal artery. *(from ref. [153], with permission.)*

change until the animal was confronted with similarly high degrees of stenosis. As shown in Fig. 77.2, the only significant flow abnormality observed at lesser degrees of stenosis was a gradual loss of the early systolic peak of flow. The ultimate clinical significance of such subtle flow changes is not known. Raising concern that lesser degrees of obstruction may have a long-term deleterious impact, Myers et al.[123] found that subcritical (< 65%) stenosis is a significant risk factor for progressive chronic kidney disease in hypertensive patients with type 2 diabetes mellitus and azotemia (serum creatinine of at least 1.8 mg/dl), as shown in Figure 77.3. This finding raises the possibility that large-vessel RAS may also be a marker for progressive small vessel disease. As described above the pressure gradient across the stenosis may be predictive of the response to revascularization, although this remains somewhat controversial.[96] A concept that has received little attention is the relationship between intrarenal resistance and translesional pressure gradients. For example, it is possible that translesional gradients are lower when post-lesion intra-renal resistance is high. The drop in pressure sensed by the kidney is likely dependent upon the relative degree of obstruction of the renal artery before the kidney and the amount of intra-renal resistance to flow. Whether these factor(s) are dynamic or static, and their relationship within patients and to the response to revascularization has not been explored experimentally.

Assessment of Kidney Size

The global renal atrophy of IN is an important non-invasive marker of the disorder, and its implications on the reversibility and prognosis of disease may be different than that in other chronic renal diseases, where small kidney size is widely considered a marker of irreversibility. Given the distinct pathophysiology of IN, it is not clear when reduced renal size indicates "death" versus "hibernation" of the kidney. Caps et al.[27] elucidated the incidence of renal atrophy when they followed 204 kidneys in 122 subjects prospectively with serial (every 6 months) duplex scans for a mean of 33 months and observed that the 2-year cumulative incidence of renal atrophy (defined as >1 cm reduction in length) was 5.5, 11.7, and 20.8% when the index scan revealed a normal artery, less than 60% stenosis, and greater than or equal to 60% stenosis, respectively. They also found that systolic blood pressure (SBP) above 180 mm Hg and elevations in creatinine also correlated with atrophy.[27] Greco and Breyer contend in their 1997 review of atherosclerotic renal disease that renal atrophy is reversible, and they cite evidence from studies that indicate good renal functional outcomes following surgical revascularization of small kidneys and that indicate that renal size may increase after revascularization.[60] Tubular atrophy and glomerular collapse, which are generally considered reversible, are often seen in IN, and perhaps this could contribute to renal shrinkage in this setting. Alternatively, glomerular sclerosis and interstitial fibrosis could be present, and this pathology is considered irreversible. A renal biopsy could be used to distinguish between these causes of atrophy and gauge prognosis and guide therapy, but this is rarely done in this setting.

Despite the availability of these various anatomic and hemodynamic tests, the current state of the art in predicting which patients with RAS will benefit from invasive revascularization is inadequate. As will be discussed, the literature on treatment of RAS indicates that a substantial proportion of patients with RAS do not benefit from or are harmed by revascularization procedures. To understand why repairing a stenosis in the renal artery might not work, one must have an appreciation of the pathophysiology of IN.

PATHOPHYSIOLOGY OF RENAL UNDERPERFUSION AND ISCHEMIC NEPHROPATHY

The classic experiments of Goldblatt provide insight into the acute physiologic alterations that result in renovascular hypertension following constriction of the renal artery.[57] Goldblatt produced *in vivo* renal artery stenosis by applying a metal clip to partially occlude the renal artery. In the Goldblatt two-kidney—one clip model of renal artery stenosis, the hypertensive state that results is associated with increased renin levels. However, because of pressure natriuresis in the

nonstenotic kidney, volume status is normal. This situation approximates unilateral stenosis in an individual with two functioning kidneys. In contrast, the one clip-one kidney model is characterized by normal renin levels and hypervolemia. Volume expansion persists due to the absence of a compensatory pressure natriuresis in an unaffected contralateral kidney. Further studies have demonstrated that the renin dependence of the two-kidney−one-clip model is not permanent.[21,137] During the first few months following renal artery constriction, renin levels are high and removal of the clip will reverse the hypertensive state (known as phase I). This evolves to a state in which renin declines, but in which hypertension is still reversible (phase II), and finally to a state in which removal of the clip does not reverse the hypertension (phase III). These experiments, along with many subsequent studies, have made it clear that the pathophysiology of renal artery stenosis is at least partly time-dependent, that RAS may result in irreversible renal damage, and that the anatomic correction of RAS lesions does not necessarily correct the underlying pathophysiology. Understanding why this is the case requires an understanding of the physiology of renal autoregulation, the pathophysiology of prolonged states of renal underperfusion, and the causes of nephropathy in the clinical scenarios of renal ischemia.

ADAPTIVE RESPONSES TO RENAL UNDERPERFUSION

The unique positioning and independent control of resistance vessels proximal and distal to the glomerular capillary loops, the afferent and efferent arterioles, provide the kidney with an effective means of regulating the hydraulic forces driving glomerular filtration. An understanding of the hemodynamic effects of Ang II in renal artery occlusion requires some knowledge of the determinants of GFR. A summary of the interactions between these determinants is shown in the Figure 77.4. The rate of filtrate formation depends on several dynamic variables: systemic blood pressure, plasma flow rate (QA), glomerular hydraulic pressure (PGC), and afferent and efferent arteriolar resistance (RA and RE, respectively). In general, the driving force for filtration is PGC, which is determined by the systemic blood pressure, QA and the relative pre- and postglomerular resistances, RA and RE. For any given pressure gradient across the glomerular capillary wall, the absolute rate of filtrate formation also depends on the ultrafiltration coefficient (Kf), which is the product of the capillary surface area and the intrinsic hydraulic permeability of the capillary wall. As renal perfusion pressure declines, the afferent arteriole dilates and total renal vascular resistance declines. This vasodilation appears to be primarily an intrinsic, myogenic response to the decline in perfusion pressure. In addition to the direct effect of reducing perfusion pressure on the afferent arteriole, a decrease in solute delivery to the macula densa region of the distal tubule elicits vasodilation in the afferent arterioles. This communication between the macula densa cells and the afferent arteriole is termed "tubuloglomerular feedback" (TGF). The exact mechanisms responsible for this action are not completely understood. Potential local mediators include adenosine, thromboxanes, and nitric oxide.[20,152,168]

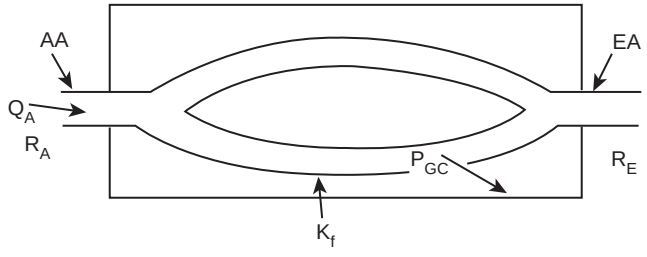

FIGURE 77.4 Determinants of glomerular filtration rate (GFR). AA, afferent arteriole; EA, efferent arteriole; QA, plasma flow rate; PGC, glomerular hydraulic pressure; RA, afferent arteriolar resistance; RE, efferent arteriolar resistance; and Kf, ultrafiltration coefficient.

The most common cause of a reduction in renal artery pressure is low systemic blood pressure. Under circumstances in which systemic blood pressure is reduced, circulating levels of several vasoconstrictive factors, including Ang II, arginine vasopressin (AVP), the sympathetic nervous system, and plasma catecholamines rise, leading to an increase peripheral resistance,. If renal vascular resistance increased in proportion to systemic vascular resistance, renal plasma flow, glomerular capillary pressure, and GFR would fall. However, at least two mechanisms combine to differentially alter the the response of the renal vasculature to a reduction in perfusion pressure and to preserve GFR; increased renal prostaglandin production leading to a reduction in afferent arteriolar resistance and the relative constriction of the efferent arterioles.

Renal prostaglandins are autocoids that are derived from the cyclo-oxygenase (COX) enzyme-catalyzed metabolism of arachadonic acid. Prostaglandins synthesized in the kidney act locally and have minimal systemic effects. They oppose the vasoconstrictive effects of Ang II, AVP, and increased renal nerve activity on the afferent arteriole, resulting in a net reduction in afferent arteriolar resistance in response to decreased renal artery pressure.[3,43] In this regard, prostacyclin and prostaglandin E2 (PGE2) appear to be the

most important renal prostaglandins. The renal prostaglandin system appears to be inactive and insignificant in states of normal renal perfusion, and inhibition of the renal prostaglandin system in health typically has few detectable effects. However, under circumstances in which systemic vascular resistance is increased in order to preserve blood pressure, renal prostaglandin synthesis and release dramatically increase. It is under these circumstances that inhibition of renal prostaglandins would produce deleterious effects on renal perfusion and glomerular filtration. This explains the well-known adverse effect on GFR that has been observed when a nonsteroidal anti-inflammatory drug (NSAID) is administered to patients with conditions that impair renal perfusion such as true volume depletion, effective circulating volume depletion (such as liver failure), and states of low cardiac output (such as CHF).[128,132] Hemodynamically, significant RAS is another condition in which inhibition of prostaglandin synthesis could adversely effect GFR.

The second factor that preserves GFR during reductions in renal artery pressure is preferential constriction of the efferent arterial in response to increased local concentrations of Ang II. The increase in efferent arteriolar resistance is associated with an increase in total renal vascular resistance and a decrease in renal plasma flow; however, because of the downstream location of this resistive force relative to the filtering unit (glomerulus), PGC remains constant tending to maintain GFR. In this manner, the kidney is able to increase the filtration fraction (GFR/renal plasma flow [RPF]) and preserve GFR despite reductions in renal plasma flow, such as occur in states of reduced cardiac output, volume depletion, or renal artery obstruction. There is also evidence that norepinephrine and the renal sympathetic nerves (possibly via Ang II) preferentially constrict the efferent arteriole relative to the afferent arteriole.[14,15,45,47,90]

Given the dependence of P_{GC} and GFR on Ang II during reductions in renal perfusion pressure, it would be expected that pharmacologic interruption of the renin/angiotensin/aldosterone system could have clinically important effects, and this is clearly the case. When ACE-I therapy decreases Ang II production or when angiotensin receptor blockers inhibit Ang II effects in conditions of increased vasoconstrictor tone, efferent resistance may decline leading to clinically important reductions in PGC and GFR. The magnitude of the effect of administration of an ACE-I on GFR depends in large part upon the local Ang II level and on systemic hemodynamics. If ACE-I administration fails to improve systemic hemodynamic parameters such as cardiac output, is associated with a marked decline in systemic blood pressure or is administered in a setting where GFR is markedly dependent on efferent arteriolar constriction, then RE will fall sharply and PGC and GFR will decline. As might be expected, this situation may exist when the blood flow through the renal artery is impaired by a fixed obstruction.

It is important to appreciate that the effects of ACE inhibition in the stenotic or ischemic, underperfused kidney are theoretically different from those in other progressive renal diseases, where renal artery pressure is not is not reduced. In the latter circumstance, glomerular hyperfiltration and glomerular hypertension may contribute to the progressive injury and scarring that leads to loss of function. In that setting, the effect of ACE-I and angiotensin II receptor blocker (ARB) therapy to dilate the efferent arteriole and lower glomerular capillary is beneficial in slowing the rate of progression of chronic diseases such as diabetic renal disease.[2,55,83,101,108,131] The renal protective effects of ACE-I and ARB may also be relevant to the nonstenotic kidney in patients with unilateral ischemic renal disease. ACE-I and ARB therapy may also be useful in reducing the amount of proteinuria in chronic glomerular diseases.[53,68] The chronically ischemic, underperfused kidney distal to an obstructive renal artery lesion, on the other hand, may respond differently to ACE-I therapy if there is dependence on Ang II to maintain a physiologically acceptable GFR.

Pathophysiology of Ischemic Nephropathy

The kidneys receive a blood supply that is three- to fivefold higher than other metabolically active organs such as heart and liver. There appears to be a critical perfusion pressure of about 70 to 80 mm Hg (which generally correlates with a greater than 70% stenosis in a systemically normotensive individual), below which the adaptive physiologic mechanisms described previously are no longer able to sustain GFR. Given that less than 10% of the oxygenated blood flow to the kidney is needed for metabolic requirements of the kidney, it would be expected that reductions in excretory function would occur in an affected kidney well before major ischemic injury develops. The intermediate steps by which this initially reversible decline in GFR then progresses into structural changes in the kidney are not well understood. The pathological changes do not appear to be directly a result of tissue hypoxia, as supported by the following observations: (1) the kidney is endowed with a generous supply of oxygen;[129] (2) as renal artery pressure and GFR decline as a result of decreased perfusion pressure, active transport and solute reabsorption also cease, markedly reducing oxygen utilization by the kidney; (3) measurements of oxygen tension in the renal veins of patients with renal artery stenosis do not demonstrate

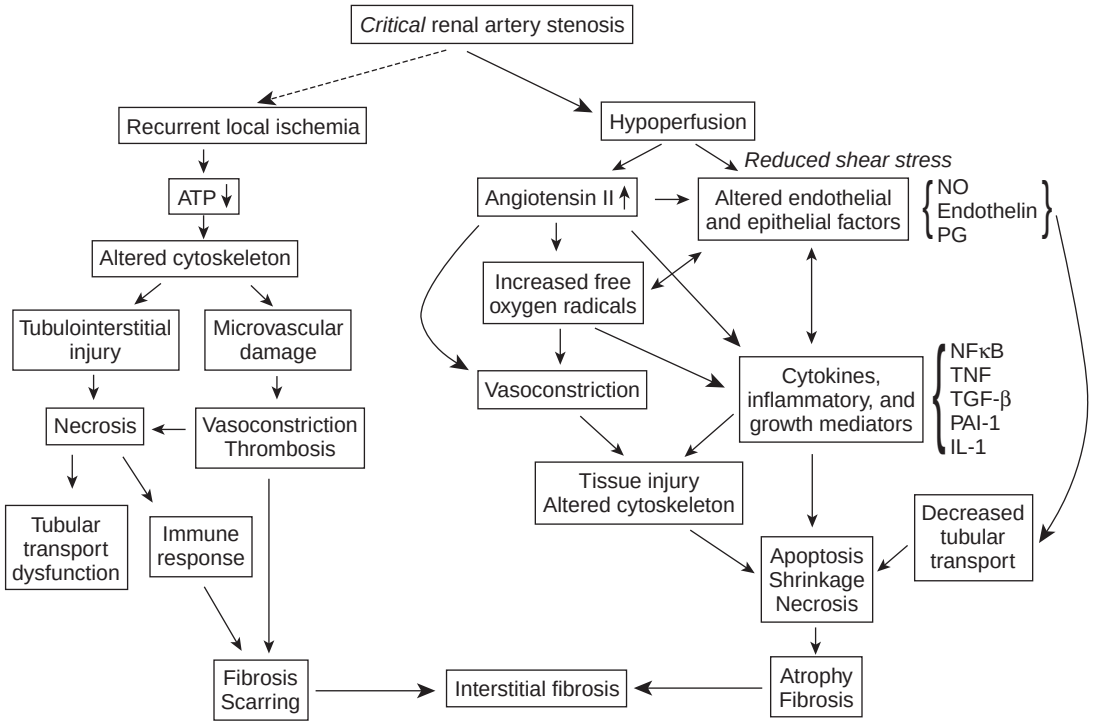

FIGURE 77.5 Summary of proposed interrelated mechanisms by which renal artery stenosis induces kidney injury leading to ischemic nephropathy. *(from 97, with permission.)*

desaturation;[187] (4) there is no augmentation of erythropoietin production from the affected kidney;[187] and (5) IN develops commonly in individuals with atherosclerotic RAS, but rarely develops distal to RAS lesions of similar hemodynamic impact produced by fibromuscular dysplasia (FMD).[97] Based on these observations, it appears that ischemic nephropathy is not simply the result of global hypoxia of the kidney and that other mechanisms are at play.

The precise pathophysiology by which RAS causes IN is not well understood. In addition to or as a result of the ischemia of the kidney, the process probably involves a complex interaction of oxidative, vasoactive, apoptotic, fibrogenic, inflammatory, atheroembolic, and micro-atherosclerotic factors. The relationship and relative importance of these various factors will require further study. An understanding of these mechanisms will be critical in developing optimal treatment strategies and guiding a rational use of medical and invasive interventions. A review by Lerman and Textor[97] addresses in detail the pathophysiology of ischemic nephropathy, and their schematic diagram, shown in Figure 77.5, lists many of these proposed pathways and indicates complex interactions among them. Several of these factors will be addressed in the following sections. The main reason for understanding the IN process in the kidney ipsilateral to renal artery stenosis is that the presence of IN may underlie the failure in renal function and blood pressure to improve after the renal artery obstruction is corrected.

Atherosclerosis

As stated previously, IN develops commonly in individuals with atherosclerotic RAS, but it rarely develops distal to RAS lesions of similar hemodynamic impact produced by FMD.[138] The sparing of patients with FMD, who are generally younger women and otherwise free of atherogenic risk factors, suggest that additional factors related to atherosclerosis [diabetes, hyperlipidemia, platelet activation or atheroembolization] may contribute significantly to kidney injury. Chade et al.[29,30] demonstrated using the porcine model of RAS that hypercholesterolemia superimposed on RAS accelerates the development of fibrosis in the stenotic kidney. Clinically, high resistance to flow in smaller arteries of the kidney (sonographically measured noninvasively by calculating intrarenal resistive index of the segmental arteries) has been shown to be highly predictive of poor renal recovery after successful revascularization,[140] and this may be due to atheromatous intrarenal small vessel disease. Interestingly, in patients with *atherosclerotic* renal disease a combination of vascular sclerosis, interstitial fibrosis, inflammatory cell infiltration, atubular glomeruli, and focal or global glomerulosclerosis is seen when biopsy of the affected kidney is performed.[156] While some of these changes

are seen in animal models of experimentally induced renal stenosis, "this mixture (of changes) cannot be reproduced in animal models.[114]"

Redistribution of Intrarenal Blood Flow

In experimental models of reduced renal artery blood flow, relative blood flow is altered to favor the corticomedullary circulation over more superficial cortical areas.[100] This probably serves to protect the more ischemic medullary parenchyma. The changes in flow distribution are probably mediated by various vasoactive substances such as prostaglandin E2, nitric oxide, urodilatin, endothelin, Ang II, and adenosine. The involvement of this mechanism is supported by findings by Mounier-Vehier et al.,[121] which show that a reduction in ultrasound-measured cortical thickness is an early morphologic marker of atherosclerotic renal disease, one that tends to develop before gross renal length decreases.

Atheroemboli

Histopathologic abnormalities in IN often include evidence of renal cholesterol microembolization, and the cholesterol emboli syndrome can be an obvious complication of angioplasty or surgery. The cholesterol microemboli may lodge in a small artery and impair distal blood flow. The ensuing foreign body reaction causes intimal proliferation, giant cell formation, and further narrowing of the vascular lumen. The microemboli seem to elicit an immune reaction, as hypocomplementemia, eosinophilia, and eosinophiluria are frequently observed with the cholesterol emboli syndrome. Work by Edwards, Hiramoto and others data suggests that a large number of emboli may be released during renal stenting,[46,71] This has led to interest in devices to capture emboli liberated during stenting. As stated above, evidence for spontaneous atheroemboli can be demonstrated with renal biopsy,[156] although the degree to which this contributes to loss of kidney function is not known.

Imbalance of Vasoconstrictors

One of the predominant effects of renal artery stenosis may be activation of the renin-angiotensin-aldosterone axis. The decrease in renal blood flow in animal models of RAS can be blunted by Ang II receptor blockers, suggesting that Ang II plays a role in renal ischemia. On the other hand, effects of Ang II blockade by ACE-Is have also been shown to accentuate the renal atrophic changes in the two-kidney−one-clip model independent of the effects of lowering of systemic blood pressure.[56,172] In addition to Ang II, other potent vasoconstrictors such as thromboxane and endothelin appear to be activated by ischemic insults. The renal vasculature is especially sensitive to the effects of endothelin,[181] which causes afferent and efferent arteriolar vasoconstriction and decreases the filtration coefficient (Kf), producing a net decline in GFR. In experimental models of acute and chronic ischemia (the latter induced by cyclosporine administration), functional and morphologic changes can be blunted by administration of anti-endothelin antibodies.[93] High levels of endothelin have been observed in chronic renal ischemia models as well as in renal hypoperfusion in the setting of hepatorenal syndrome.[120] However, systemic endothelin levels do not appear to be elevated in patients with renovascular disease when compared with patients with essential hypertension,[164] suggesting that if endothelin plays a role in human ischemic renal disease, it must be intrarenal.

Reduced Shear Stress

Under conditions of hypoperfusion, the normal counterbalancing release of vasodilator substances such as prostaglandins and NO may be impaired, thereby accentuating the ischemia.[159,160] One of the reasons for this may be a loss of shear stress due to decreased renal blood flow. Even subtle reductions of perfusion pressure and flow, as demonstrated by Schoenberg (Fig. 77.2),[153] could conceivably initiate injury through this mechanism. It has been shown that shear stress is a major regulatory mechanism for production of nitric oxide.

Oxidative Stress

As discussed previously, hemodynamically significant RAS stimulates the renin-angiotensin system, resulting in increased production of Ang II. It has also been reported that Ang II stimulates the production of reactive oxygen species such as superoxide, probably through the activation of membrane-bound nicotinamide adenine dinucleotide (NADH) or NADPH (nicotinamide adenine dinucleotide phosphate) oxidase.[52,141] The pro-oxidant effects of Ang II may interact with those of coexisting metabolic disorders and hypertension such that a relative increase in reactive oxygen species (especially superoxide) and reduced production of nitric oxide (NO) may be present. This imbalance may promote endothelial dysfunction by a resultant increase in oxidative stress. Lerman et al.[98] demonstrated increased oxidative stress in their pig model of RAS. Higashi et al.[70] demonstrated evidence of excessive oxidative stress in patients with RVH that appeared to reverse after angioplasty and was associated with evidence of endothelial dyfunction that also improved after angioplasty. Minuz et al.[116] showed that oxidative stress, as indicated by measurements of lipid peroxidation products, is increased in patients with renovascular disease and hypertension as compared with patients with essential hypertension.

Furthermore, this appeared to be due to activation of the renin-angiotensin system, and it was associated with an increase in thromboxane A2 biosynthesis, which would be expected to enhance platelet activation. Enhanced platelet aggregation and adhesion could contribute to microvascular renal injury as well as cardiovascular disease associated with this disorder. Additionally, this oxidative stress and reduced NO production may impair endothelium-dependent vasodilation, which may have local and systemic consequences. Locally, the resulting vasoconstriction could increase ischemic tissue injury. Systemically, hypertension could result. Increased free-oxygen radicals could also impact on fibrogenic and inflammatory mediators. Chade et al.[31,32] demonstrated in the porcine model of RAS described previously that chronic blockade of the oxidative stress pathway using antioxidant vitamins improved renal hemodynamics and decreased inflammation and fibrosis in the ischemic kidney.

Fibrogenic Factors

Fibrogenic, trophic, and inflammatory mediators are probably involved in the progression of IN. These may include nuclear factor kappa B (NFκB), tumor necrosis factor (TNF), transforming growth factor beta (TGF-β), interleukin-1 and others. Pathologically, interstitial fibrosis and glomerular sclerosis are often seen in chronically ischemic kidneys. Chade et al.[29,30] demonstrated in pigs increased expression of TGF-β, increased trichrome staining (indicating collagen deposition), as well as more prominent interstitial fibrosis, tubular atrophy, and glomerular sclerosis in kidneys distal to a RAS lesion.

Inflammation

Inflammatory responses to the altered ischemic milieu may also contribute to the renal injury. Histological examination of ischemic kidneys often shows evidence of mononuclear infiltrates, tubulitis, and interstitial fibrosis.[29,174] Immunoglobulin and complement deposition has been noted in the areas of sclerosis in human ischemic kidneys.[189] The inflammatory process is likely initiated by alterations in cellular antigenicity induced by ischemia.[174] Inflammation may then contribute to interstitial fibrosis and atherosclerosis.

Disruption of Cellular Membrane Integrity and Intracellular Milieu

Ischemic injury can result in derangements of cellular membrane pumps responsible for maintenance of the internal milieu. One of the key events in this process may be calcium influx. Anoxic injury results in a rapid increase in cytosolic calcium, which can impair several vital cell functions.[22] This may explain the protective effects of calcium channel blockers in some models of ischemic injury. Mitochondrial calcium uptake impairs oxidative phosphorylation, further reducing cellular adenosine triphosphate (ATP) levels. In the acute kidney injury model, an increase in cytosolic calcium also activates phospholipases and generates toxic oxygen radicals, which can cause further membrane damage.[110,163] Ischemia delays the recovery of adenine nucleotide levels, and leads to depletion of high-energy stores from phosphate bonds in the acute kidney injury model. It has been shown that a decrease in cellular ATP by 50% is associated with severe apical microfilament disruption and cytoplasmic actin polymerization, and these changes can be reversed by increasing the cellular ATP to 70% of control values.[86] Van Why and others have devised an *in vivo* ischemic model, which results in graded ATP depletion. They have shown generation of heat-shock proteins when cellular ATP decreased to 50 to 60% of control values.[178]

Apoptosis

Enhanced renal apoptotic activity is evident within one week of unilateral RAS, but whether there is true cellular reduction or whether it represents a natural compensation for the hyperplastic response after injury is unclear. It appears that enhanced apoptosis is ongoing for several months after an insult, a finding that suggests that apoptosis is necessary for remodeling of tubular structure.[56] Apoptosis occurs primarily in the thick ascending limb after an acute ischemic insult.[155] Tubular atrophy is commonly observed by routine histology and is primarily due to a decrease in cell size. This is accompanied by a decrease in cell organelles and cellular protein content.[24,56] It has been noted that the autophagolysosome activity, which increases degradation of cell organelles, is transiently increased in ischemic kidneys.[24] Apoptosis likely contributes to the global renal atrophy that is observed in IN.

Other Issues Pertinent to the Pathophysiology of IN

The true hemodynamic events in IN likely involve numerous,transient acute reductions superimposed on chronic, progressive and, eventually, a critical reduction in blood flow to the involved kidney.[170] Acute hypoperfusion and chronic, slowly progressive ischemia clearly have different consequences for the kidney. It must be noted that some of the hypotheses discussed above have been derived in large part from data obtained in models of acute ischemic kidney injury or isolated chronic ischemia models that do not adequately incorporate the complex combination of hemodynamic, metabolic, and atherogenic insults that

typically exist in human disease. Lerman et al.[99] developed a swine model of renal artery stenosis, which is induced by the intravascular placement of a local irritant coil in the renal artery, and the gradual and progressive renal artery narrowing in this model resembles human RAS lesion progression and has been useful in elucidating mechanisms of injury. The administration of a high-cholesterol diet has been used to produce an atherogenic milieu in the animals.[29,30] However this model probably does not incorporate repetitive acute ischemic insults, which have been postulated to be important in human IN and appear to provoke delayed, cumulative pro-fibrotic sequelae in the kidney.

Another important issue in the pathophysiology of IN is that renal blood flow may be maintained via collateral arterial supply to a kidney whose flow is impaired by a severely stenotic artery.[60] Presumably, the collateral circulation would be more substantial in settings of a slowly progressive RAS lesion. Collateral arteries may arise from the suprarenal, lumbar, and ureteric vessels. Because of this collateral circulation, renal viability and function may be maintained despite occlusion of the main renal artery.[66] In fact, salvage of renal function by revascularization of dialysis-dependent patients with IN has been associated with the presence of collateral circulation on angiogram.[7,12]

Clinically, it is also important to understand that reductions in systemic blood pressure, even when the reductions are from frankly elevated to normal blood pressures, may further impair perfusion distal to a RAS lesion. When the kidney senses underperfusion, it releases renin thereby activating pressor and sodium-retaining mechanisms (primarily via the renin-angiotensin II–aldosterone system) that induce a state of systemic arterial hypertension in order to restore renal perfusion across the resistance of the stenotic lesion. This process of RAS producing systemic hypertension is known as renovascular hypertension (RVH), and a full discussion of this topic is beyond the scope of this chapter. Due to the risks of uncontrolled hypertension (which is often very severe or malignant in patients with RVH), antihypertensive medications are indicated and generally administered to such patients. Antihypertensive medications are usually effective in achieving a sustained normalization of systemic blood pressures. Interruption of RVH may lower the forward pressure head that pushes blood through the RAS lesion, and consequently worsen the perfusion to the post-stenotic kidney. This perfusion impairment may be severe enough that autoregulation fails to maintain GFR and that ischemic pathologic changes occur. Experimental observations by Michel et al.[115] support this theoretical concern, as they demonstrated much more severe histopathologic changes (glomerular collapse and fibrosis) after 5 weeks of therapy with ACE inhibitor. Discussed below, there is now observational data suggesting a lower rate of dialysis for patients with RAS treated with ACE or ARB, however this may result from better preservation of the contralateral, non-stenotic kidney in patients with unilateral RAS, despite more rapid progression of IN in the post-stenotic kidney.

PATHOLOGY OF THE KIDNEY IN ISCHEMIC NEPHROPATHY

Based on experimental models, biopsy, and autopsy material, several pathological changes of ischemic renal disease have been described.[193] The glomeruli usually are shrunken, with wrinkling of the glomerular tuft and thickening of the Bowman's capsule. Glomerular cysts, which are derived from filtration into an obstructed space due to detachment from the proximal tubule, may be seen. Localized areas of glomerular sclerosis are also common.[111] Renal tubular changes are prominent, showing patchy necrosis and atrophy associated with dimunition in cell size and involution of tubular epithelial cells. Bowman's space may be filled with collagenous material and patchy peritubular inflammatory cell infiltrates are seen. Histological changes of renal atrophy include small glomeruli crowded together among small atrophic tubular cells. Vascular changes due to generalized atherosclerosis as well as preexisting hypertension are also common. These consist of medial thickening of the intrarenal arteries, arteriolar hyalinosis and interlobular fibroelastosis. Evidence of cholesterol embolization is also frequently observed. Electron microscopic examination of the tubular epithelium usually reveals decreased features of differentiation.[24] Proximal tubular cells show loss of brush border, decreased number of mitochondria, and simplification of basement membranes. The antigenic profile of the tubular epithelial cells changes with new expression of keratin and vimentin and changes in surface glycoproteins.[174]

Gross renal atrophy may accompany these histologic findings. Gobe et al.[56] studied the cellular events leading to progressive atrophy in kidneys distal to stenotic

renal arteries. During the initial phase, tubular cell death resulted from necrosis and apoptosis. During the chronic phase (10–28 days), the gross reduction in kidney size continued while cell death resulted from apoptosis alone and the level of mitosis returned to near normal. Following correction of RAS, they observed hypertrophy and hyperplasia, interpreted as evidence of regeneration. Although diminutive renal size is considered to imply irreversibility in other chronic renal diseases, these findings suggest that there might be some recovery of renal function in chronic ischemic kidneys. However, the clinical experience is that renal function does not usually improve following revascularization of small, shrunken kidneys less than 7 cm in length. Histopathologic findings of glomerular collapse and tubular atrophy would imply a better prospect for improvement than glomerular sclerosis and interstitial fibrosis.

NATURAL HISTORY OF ISCHEMIC NEPHROPATHY

It is now well recognized that obstructive lesions of the renal artery may lead to chronic renal insufficiency and end-stage renal disease (ESRD).[158] These occlusive lesions may progress gradually and may erode renal function over time in a process that is initially silent and then later clinically apparent. This disease has variously been termed "ischemic renal disease," "ischemic nephropathy (IN)," "azotemic renovascular disease," or "hypoperfusion injury." IN is not synonymous with renal artery stenosis, and it is only one of the several often-overlapping clinical syndromes that may result from RAS. Others are listed in Table 77.1. Renovascular hypertension is hypertension caused by RAS and does not necessarily involve renal parenchymal damage: not all patients with IN have hypertension.

  - –Kawasaki disease
- –Williams syndrome

It should also be remembered that there are also multiple different disorders that may result in hemodynamically significant obstructive renal artery lesions, and these are listed in Table 77.2. The overwhelming majority of the cases are due to atherosclerotic lesions, and this etiology is the only epidemiologically significant cause of clinically evident IN. Arterial fibrodysplasias (including fibromuscular dysplasia) are the second leading cause of renal arterial occlusive disease; and, although this type of pathology is a potentially correctable cause of secondary hypertension, it very rarely causes ischemic nephropathy. Atherosclerotic lesions typically involve the proximal main renal artery, rarely extending beyond the proximal third of the vessel. In about 75% of cases, significant aortic atherosclerosis is also present. A stenosis of the renal artery due to atherosclerosis may be bilateral in up to 50% of patients.[166] There is a body of literature to support the provocative theory that infectious diseases such as *Chlamydia pneumoniae* infection may contribute to atherosclerotic disease,[5,59,91,122] including that involving the renovascular bed.[176]

To optimally utilize interventions for patients with RAS, it is important to understand the natural history of RAS lesions that are not revascularized. Table 77.3 shows the rates of anatomic lesion progression in various reports in the literature.[60,145] It indicates that progression of the arterial lesion occurs in a substantial percentage, although perhaps a minority, of affected arteries. Depending on the population studied, the length of follow up, the indications for repeated anatomic assessment, and the definition of progression, rates of progression range from 29 to 71% and rates of occlusion range from 3 to 16%. The study by Caps et al.[26] indicated that the risk of progression increases with the degree of occlusion on the index ultrasound: 18% of initially normal renal arteries, 28% of arteries with less than 60 RAS, and 49% of arteries with greater than or equal to 60% RAS demonstrated progression in this prospective study; hypertension (systolic blood pressure >160 mm Hg) and diabetes mellitus also were associated with progression. Importantly, these rates have not been validated in the current era of effective antihypertensive medications, anti-platelet medications, and lipid-lowering medications including statins. As a consequence the rates may over-estimate what is likely to be observed in a compliant, actively managed patient.

Notwithstanding the anatomic progression, an accurate estimate of the much more meaningful outcome of clinically significant chronic kidney disease has been even more elusive. In this regard, the literature is confusing and contradictory. In 1981 Dean et al.[40] reported that 17 (41%) of 41 patients randomly selected for nonoperative management of RAS experienced a

deterioration of renal function or loss of renal size despite acceptable blood pressure control by their unspecified standards. In a prospective cohort study published in 1994, Connolly et al.[35] estimated the 2-year renal survival to be 97% with unilateral disease, 82% with bilateral stenosis, and 45% with unilateral stenosis and contralateral occlusion. Their data confirmed the logical expectation that chronic kidney disease is more likely to develop if RAS lesions affect the whole of the functioning renal mass. In a 1998 article by Baboolal et al.,[8] patients with severe bilateral RAS demonstrated a decrease in the median GFR from 39 ml/min to 31 and 24 ml/min at 24 and 60 months, respectively ($p < .05$). Of the 51 patients who underwent angiography, six patients had reached ESRD over a median period of follow-up of 52 months.[8] Two other reports, however, have suggested a more benign course of incidentally discovered RAS; and their findings can be used to support a conservative approach to management of RAS lesions, at least those found incidentally. In 2001, Leertouwer et al.[95] retrospectively evaluated a cohort of 126 patients with incidental RAS of at least 50% on angiograms done in evaluation for extrarenal arterial occlusive disease and found that during a 10-year follow-up amazingly none had required renal replacement therapy and that serum creatinine values were stable, even with bilateral disease. Chabova et al.[28] followed 68 patients with incidental RAS of at least 70% on angiogram for mean of 39 months and reported in 2000 that only four (5.8%) eventually had renal revascularization and 7.4% developed ESRD, with only one case due to vascular occlusive disease. Thus, while it is reasonable to suspect some progression of atherosclerosis will occur in affected renal arteries over time, it is likely that total occlusion of the renal artery occurs in a minority of patients.

It is also important to understand that the progression of IN is dominated by a phase that is essentially clinically silent. During this stage, the disorder would be obscure were it not for a high clinical index of suspicion, the finding of renal asymmetry on abdominal scanning done for other reasons, or the incidental finding on angiography done for other reasons. As illustrated in a review of the subject by Safian and Textor,[149] when the lesions progress asymmetrically, as is usually the case, the relatively uninvolved kidney may maintain normal serum creatinine through compensatory hypertrophy and hyperfiltration (as well as through increased tubular creatinine secretion). As illustrated in their review article, the serum creatinine level does not increase until the individual's disease progresses to involve the other kidney such that the entire renal mass is then rendered ischemic. Of course, an individual with a solitary functioning kidney or an individual whose contralateral kidney is simultaneously injured during the course of RAS progression (for example, by uncontrolled hypertension or by diabetes), the kidney injury would become manifest sooner in its course. Given that the disorder is generally not sought until a workup for clinically apparent chronic kidney disease is undertaken, the prospects for amelioration of established disease are of critical importance in the deciding on whether to pursue invasive revascularization.

Treatment of Ischemic Nephropathy

The optimal treatment strategy of RAS lesions is not clear. Various algorithms have been proposed,[124,136,137,148,170] and there is much controversy among experts regarding which patients should be managed conservatively and which patients should undergo

invasive interventions. The benefits of revascularization may include stabilization of or improvement in renal function. Even salvage from dialysis has been described in such patients (see subsequent sections). However, these benefits are not universally or predictably realized. Furthermore, the vascular interventions have risk(s), and a substantial proportion of patients who undergo revascularization realize no benefit and/or encounter complications. The ability of clinicians to predict which patients will benefit from revascularization is imperfect. The vagaries of the natural history of medically managed RAS—with some reports suggesting a low risk for progression to ESRD—and the uncertainties of the benefits of invasive interventions have left the indications for revascularization controversial. In addition to understanding the pathophysiology, natural history, and diagnostic tests of IN, it is important to be familiar with the literature on treatment so that clinicians may provide informed opinions to patients.

Before reviewing the current literature, some clarifications are appropriate. The definitions of renal functional improvement, stabilization, and improvement vary widely from study to study. Most reports use static measures of renal function (usually serum creatinine or creatinine clearance measures) at the time of intervention and then at certain times after intervention. Outcomes are categorized based on comparisons of the pre- and postintervention measures of static renal function. However, a more meaningful outcome would involve a comparison of dynamic renal function—that is, the stability or rate of change of renal function as measured by the slope of a plot of renal function versus time—before and after interventions. In 2002, Rundback et al.[147] under the auspices of the American Heart Association, published a consensus scientific statement that proposed guidelines for the reporting of renal artery revascularization in clinical trials, and they recommended incorporating a comparison of slope of GFR versus time before and after the intervention, also known as breakpoint analysis, in the reporting of renal outcomes and in defining benefit and failure of treatments. Figure 77.6 shows examples of situations that would be considered benefit and failure. A stabilization or a slowing of the rate of deterioration of renal function would be considered a benefit using this system, but these situations would be considered "no change" or "worsening" in the static comparison system.

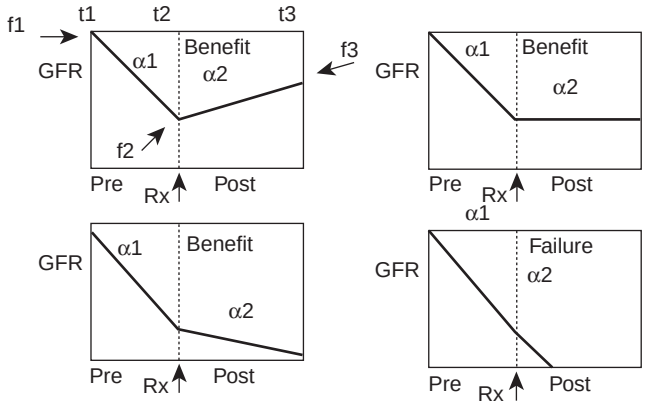

FIGURE 77.6 Breakpoint analysis. α1 indicates slope of GFR before treatment [(f2 − f1)/(t2 − t1)]; α2, slope of GFR after intervention [(f3 − f2)/([t3 − t2)]; Δα, change in slope of GFR after treatment (α2 − α1); f1, value of GFR at a definable time (t1) before intervention; f2, value of GFR at the time of intervention (t2); and f3, value of GFR at a definable follow-up time (t3). *(from ref. 147, with permission.)*

Another important issue to consider when reviewing the literature on RAS is the importance of patient selection for the studies. Important baseline factors include the following: severity of stenosis, degree of threat to renal function imparted by RAS lesions, and severity and acuity of renal dysfunction.

Severity of Stenosis

Stenosis severity can be graded by several measures: minimal luminal diameter, percent stenosis, or by the magnitude of decline in blood pressure measured across the stenosis. Whereas percent stenosis is the most commonly reported measurement, Leesar and others have suggested that minimal luminal diameter and the pressure gradient measured with a pressure sensing 0.014 in guidewire and after a vasodilatory drug are best correlated with clinical outcome.[34,96] Various degrees of stenosis have been used as inclusion criteria in clinical trials and registries, with many studies requiring between 50 and 70% minimal luminal narrowing. The American Heart Association consensus statement on RAS research has recommended that stenosis more than 50% in diameter should be considered the minimum threshold for inclusion in a renal revascularization trial.[147] Given that duplex ultrasound generally categorizes stenoses as greater than 60% diameter stenosis and that it does not have the ability to precisely quantitate the degree of stenosis above this level, this threshold may be used in studies that use this technology. As discussed previously, the hemodynamic consequences of stenotic lesions of less than 70 to 80% are questionable. Only subtle changes in flow patterns have been noted at less critical degrees of narrowing,[153] and these probably have no immediate impact on global oxygenation and no definite effects on renal function.

Degree of Threat to Renal Function Imparted by Renal Artery Stenosis Lesions

Some studies have required that the entire functioning renal mass be threatened by RAS lesions (that is bilateral RAS or unilateral RAS in a solitary functioning kidney), while others have permitted inclusion of

patient with unilateral disease. Obviously there is no risk of symptomatic kidney injury in patients with unilateral disease and a normal non-stenotic kidney. Patients with fibromuscular dysplasia are often included in the studies, however, these patients are also unlikely to develop renal insufficiency as a result of their RAS lesions.

Severity and Acuity of Renal Dysfunction

The degree of renal dysfunction of subjects entering the studies is of critical importance. There may be a "window of opportunity" in which revascularization can produce benefit. In patients with advanced chronic azotemia, renal dysfunction may result from irreversible, intrinsic kidney damage and, therefore not be amenable to treatment by revascularization. Other studies may require that patients have progressive, but not end-stage, renal disease, and such studies would be more likely to show a benefit of interventions if such benefits exist.

Thus, many patients included in these studies (i.e., those with <70% stenosis or those whose whole functioning renal mass was not threatened by RAS lesions or those with nonatherosclerotic RAS) had disease that would not have been expected to cause azotemia. Therefore, one would not expect improvement in renal function in these patients even with successful revascularization, and it could be argued that long-term stability of renal function (and not improvement) would be the desired outcome after revascularization of these patients.

Before proceeding with a discussion of the treatment of ischemic nephropathy, it is worthwhile to briefly address the treatment of renovascular hypertension, as this diagnosis often coexists or is suspected of coexisting in patients with ischemic nephropathy. Separate from the decision whether to offer revascularization with the intention to produce improvement or stabilization of renal function, one must consider whether revascularization should be offered to patients with RAS for the purpose of lowering blood pressures or curing hypertension. Historically, control of blood pressure in RVH had been the major impetus for the development of renal revascularization techniques. However, the accrual over the years of a highly effective armamentarium of antihypertensive drugs that are now capable of inhibiting many blood pressure regulatory pathways has rendered this indication substantially less important. These authors feel that revascularization for the purpose of curing or improving control of hypertension is infrequently indicated in patients with *atherosclerotic* RAS. In such patients, revascularization rarely produces a cure, with studies suggesting cure rates of well less than 10%[17,177,25] which stands in contrast to the treatment of fibromuscular dysplasia where hypertension cure is commonplace.[162] Modern randomized controlled trials indicate that percutaneous transluminal renal artery angioplasty (PTRA) of atherosclerotic RAS is not substantially better in treating hypertension than is medical management in patients with atherosclerotic RAS.[135,177,183] Given the significant risks of the surgical and endovascular procedures, we do not believe that revascularization is indicated in most such patients. Perhaps it could be offered to patients with extremely resistant or severe hypertension, or in those in whom medical therapy is not well tolerated, however even in these settings superiority of medical therapy is not established.

Another group of patients with RVH to whom revascularization should be considered (separate from the indication of treating RVH or IN) includes those who present with heart failure, or "flash pulmonary edema." The latter syndrome has been described in the literature, and it is likely due to labile hypertension, diastolic left ventricular (LV) dysfunction due to chronic hypertension, and sodium retention caused by RAS-induced activation of renin-angiotensin system and renal dysfunction.[133] It is generally accompanied by severely elevated BP (mean SBP of 200 mm Hg in one series). Several retrospective observational studies have suggested that correcting RAS is associated with improvement.[16,42,58,113,134] In a report from Bloch et al.,[16] 17 of 22 patients with bilateral RAS and recurrent pulmonary edema had no further episodes after successful stent placement in one or both renal arteries. The five patients who developed recurrent episodes after stenting were found to have had stent thrombosis or restenosis. However, the use of ACE inhibitors was substantially greater after in these patients after revascularization, and this may also have contributed to the reduced incidence of symptomatic CHF. Currently this represents the only Class I indication for renal artery revascularization in the current AHA guidelines for Peripheral Arterial Disease, although the basis for this recommendation is retrospective observational data and expert consensus that in aggregate is described as level "B" evidence.[72] In fact, there are no randomized controlled trials demonstrating better outcomes in patients with RAS and symptomatic CHF that were revascularized as compared to those treated medically.

MEDICAL MANAGEMENT

As discussed in the section on natural history of IN, the efficacy of medical therapy is not clear. Clearly, anti-atherosclerotic therapies are indicated, such as lipid-lowering therapies, antiplatelet medications, treatment of hyperglycemia, and treatment of

hypertension. The optimal blood pressure in these patients is not known. The low goal of ≤130/80 mmHg that is generally recommended for patients with renal insufficiency may not be optimal for patients with RAS, who may require higher systemic blood pressures to maintain adequate blood flow across a stenosis. Additionally, as discussed previously, ACE-Is and ARBs carry the additional concern that interruption of the ANG II–maintained efferent arteriolar vasoconstriction may cause reductions in glomerular pressure and renal excretory function and as such carry a "black box warning" in their FDA approval. However, recent data suggests that these agents are reasonably safe and more importantly improve outcome. Specifically, observational data from the Province of Ontario analyzed by Hackam et al suggests that treatment of RAS with ACE/ARB is associated with lower CV event rates (10 vs 13%) and need for dialysis (1.5 vs. 2.5%) at the expense of an increased risk of acute kidney injury hospitalizations (1.2 vs. 0.6%).[61] In parallel the use of statins appears to be associated with improved survival, restenosis-free survival after stent revascularization, and lessened lesion progression.[9,33,36,160,161]

Surgical Treatment

It has been shown by many groups that RAS can be successfully revascularized surgically and that renal function may improve or stabilize in some subjects after the intervention. Novick et al.[126] reported on 51 patients with differing anatomies who underwent revascularization procedures. Success was achieved for a wide spectrum of anatomic possibilities, including patients with chronic bilateral arterial occlusion (but good distal runoff), patients with arterial stenosis in a solitary functioning kidney, patients with bilateral high-grade stenosis, and patients with unilateral high-grade disease or occlusion in an atrophic kidney. Overall, improvement occurred in nearly two thirds of patients in the short follow-up period of the study. No control group was included.

Dean et al.[40] reported similar success in a surgical revascularization study. In this study, the authors noted that a renal biopsy to determine kidney viability was usually not helpful and that larger poorly functioning kidneys had the worst prognosis. Successfully revascularized patients with bilateral occlusive disease and moderate azotemia or a serum creatinine above 3.0 mg/dl had the largest fall in serum creatinine after the operation. These results suggest that even patients with advanced disease may benefit from the surgical revascularization. Patent distal vessels without evidence of stenosis are predictive of a good outcome. Successful operative outcomes have also been reported in the circumstance of the totally occluded renal artery with renal parenchyma supplied by collaterals. In a larger series of surgical revascularization from the Cleveland Clinic, Novick et al.[126] reported in 1987 that of the 161 patients, who underwent the procedure, 89% showed improvement or stabilization in renal function and 11 % had progression of chronic kidney disease. As expected, the longer the kidney is occluded, the worse the postoperative function; however, salvage of function after 4 months of renal artery occlusion has been reported. A common limitation of the surgical literature is a lack of a corresponding control group that is treated medically. As a consequence it is oftentimes difficult to understand the absolute or relative

TABLE 77.4 Renal Outcome of Surgical Revascularization in Ischemic Renal Disease

advantage and to what degree patient selection plays in the outcomes.

Table 77.4 summarizes the renal outcomes of several of the surgical series that have been reported.[60,145] With the advent of endovascular revascularization techniques, there have been fewer publications on surgical revascularization. These studies are generally reports on the outcomes in different groups, and these are not randomized, controlled trials. Inherent in these studies is some bias in that groups with greater expertise in the procedure are usually the ones reporting results. In contrast, groups with poor outcome probably are less likely to publish results. Therefore, it is not clear that such results are widely achievable. Furthermore, the risk of major vascular surgery in elderly patients with widespread atherosclerosis is a major consideration. It has been generally reported that the major complication rate is 8 to 11% and that the mortality rate is 2 to 8%.[149] These facts have been highlighted in a recent review of a large and contemporary US database of hospital discharge data demonstrating a 10% in-hospital mortality.[118] A follow-up report from this group reanalyzed the dataset to address the effect of hospital volume on outcome. Only a very marginal effect was seen: high-risk patients did no better or worse at high volume centers whereas low risk patients apparently benefited by treatment in a high volume center.[119]

There is a body of literature that reports some dialysis-dependent patients with RAS may benefit from surgical revascularization. Four series from different institutions[7,12,64,85] included 35 patients on maintenance dialysis (including one patient who had been on maintenance dialysis for 13 months) and have demonstrated effective partial recovery of renal function after surgical revascularization, and all patients were able to discontinue dialysis, although the duration of follow-up in these studies is generally short. Serum creatinine levels of some patients returned to normal. Normal renal size, collateral blood flow,[41] nearly normal histology on biopsy, and a rapid pre-ESRD loss of renal function were associated with salvage. In general however, surgical revascularization has been supplanted by percutaneous methods such as angioplasty for FMD and stenting for atherosclerosis, given the prohibitive mortality associated with surgical revascularization.

Renal Artery Angioplasty

Percutaneous transluminal renal angioplasty (PTRA) is a less invasive alternative to surgical revascularization whose utility has largely been relegated to treatment of fibromuscular dysplasia, supplanted by stenting for the treatment of atherosclerotic renal stenoses. There is only one head-to-head comparison of angioplasty and surgical revascularization. In 1993, Weibull et al.[184] demonstrated relative equivalence when PTRA and surgical revascularization were directly compared in a cohort of 58 patients with unilateral RAS. Improved or stable renal function was seen in 83% after PTRA and 72% after surgery.[184] Much of the literature concentrates on renal angioplasty interventions targeted primarily at the treatment of RVH rather than IN. Table 77.5 provides a summary of renal outcomes following PTRA from several studies.[60,145] The complication rates of PTRA are variable. Typical rates of major complications have been reported as 3 to 15%,[60,70,140] and these may include bleeding at the puncture site, pseudoaneurysm of the femoral artery, rupture or thrombosis of the renal artery, dissection of the renal artery or access artery,

the cholesterol emboli syndrome, and radiocontrast nephropathy. Expected mortality rates have been reported to be 1% to 6%.[60,136,145]

In 2000, van Jaarsveld et al.[177] published the results of the Dutch Renal Artery Stenosis Intervention Cooperative (DRASTIC) Study Group, the largest randomized controlled trial to address the use of renal artery angioplasty without stenting. In this study, 106 patients with hypertension who had atherosclerotic renal-artery stenosis and a serum creatinine of 2.3 mg/dl or less were randomly assigned to undergo PTCA (n = 56) or medical therapy (n = 50). RAS was defined as at least 50% stenosis, and patients with a solitary kidney were excluded. Twenty-one percent of the subjects had less than 70% stenosis and only 23% had bilateral RAS. Nine percent of the medical group progressed to total occlusion. Creatinine clearance was better in the PTRA group at 3 months (70 vs. 59 ml/min; p = .03), but the same at 12 months (70 vs. 62 ml/min; p = .11). Twenty-two of the 50 patients in the drug treatment group crossed over to PTRA after 3 months: 14 patients because of persistent hypertension on more than two drugs and eight patients because of an increase of 0.2 mg/dl of the serum creatinine or worsening of the time-activity curve on renal scintigraphy. The results were inconclusive regarding the utility for the treatment of ischemic nephropathy. The study population was small and included many patients who had hemodynamically inconsequential RAS and/or whose whole functioning renal mass was not clearly threatened by the index RAS lesions. Therefore, one would not expect the RAS to cause major renal dysfunction over the follow-up period, thereby lessening the potential benefit of successful revascularization. Even more importantly, the liberal use of rescue revascularization (crossover) followed by an intention-to-treat analysis of the data may have reduced any treatment advantage.

Renal Artery Stenting

Endovascularly deployed stents appear to provide better prospects for restenosis-free long-term patency than angioplasty alone. This is especially true for ostial stenoses which constitute the majority of atherosclerotic stenoses. Stenting achieves higher initial technical success rates, improved immediate patency, and lower restenosis rates in comparison to balloon angioplasty alone. Technical problems with stent placement include malpositioning, embolization of the stent, main renal artery rupture, distal arterial wire perforation, dissection, or branch vessel occlusion. Stents that are coated with and elute antiproliferative medications (such as sirolimus, everolimus, or paclitaxel) have shown success in reducing restenosis rates in coronary arteries.[84,150,167,185] However, there has been only one study of a drug coated "renal" stent, the sirolimus-eluting Genesis stent, which failed to meet its pre-specified performance metrics and work on this platform was abandoned.[190] There is limited data suggesting that drug-eluting coronary stents may have some utility for the treatment of in-stent restenosis but the data remains mixed.[88,191]

Multiple studies on renal artery stenting have been published over the past decade. In the preliminary reports of the U.S. Multicenter Trial, which involved 304 stents placed in 296 renal arteries in 263 patients whose disease was 80% ostial and 98% atherosclerotic, the technical success 95% and the restenosis rate was 32.7% at 6 months. Among 123 patients with serum creatinine above 1.5 mg/dl, renal function improved in 34%, remained stable in 39%, and deteriorated in 27%.[142] In a 1999 review of 10 studies that included 416 stents placed in 379 patients (with 97% of stenoses being atherosclerotic and 80% being ostial), Isles et al.[76] found a 96 to 100% technical success rate and a 16% restenosis at 6 to 12 months. Serum creatinine improved in 26%, stabilized in 48%, and deteriorated in 26% of patients whose renal function was initially impaired (serum creatinine >1.5 mg/dl). In 2000, Leertouwer et al.[94] published a meta-analysis of 14

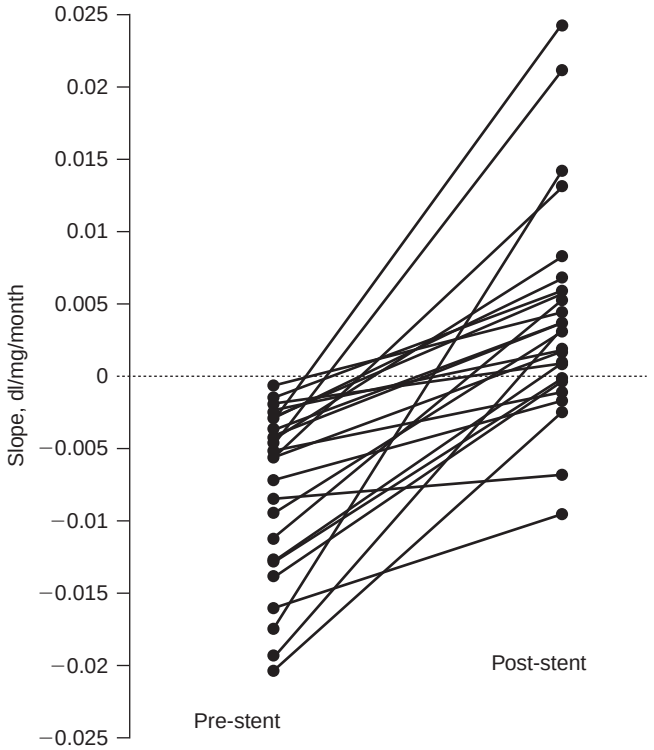

FIGURE 77.7 Slopes of plots of reciprocal of serum creatinine measured before and after renal artery stent deployment in 25 patients with global renovascular disease and chronic renal failure. Negative and positive slopes depict deteriorating and improving renal function, respectively. *(From ref. [182], with permission.)*

studies of stenting in 678 patients compared with ten studies of PTRA in 644 patients. They found that the restenosis rate at 6 to 29 months was 17% after stenting and 26% after PTRA; after stenting, renal function improved in 30%, stabilized in 38%, and worsened in 32%; and the improvement rate was greater after PTRA (38%, $p < .001$). Burket et al.[23] found an early decline in blood pressure after stenting, and a decrease in the number of required medicines to treat hypertension.

Studies by Harden and Watson[65,182] suggest that stenting may improve the outcome of IN, although as is discussed later, a substantial criticism of this work is the absence of a concurrent control group for comparison. The Watson study focused on patients with progressive, but not severe, chronic renal insufficiency and with global high-grade renovascular obstruction.[182] Renal artery stenting was performed in all of the 33 patients studied who had as criteria for inclusion into the analysis progressive renal insufficiency (defined by serum creatinine >1.5 mg/dl [mean, 2.1 mg/dl]), a negative slope of 1/serum creatinine, and more than 70% RAS producing global renovascular obstruction (bilateral renal artery stenosis or unilateral stenosis in the presence of a solitary or single functional kidney). Of 25 patients who had a mean follow-up of 20 months, the mean slope of 1/creatinine improved from −0.0079 to +0.0043 dl/mg per month with preservation of renal size while patient survival was 90%. As shown in Fig. 77.7, stabilization or improvement in renal function was documented in all surviving subjects. There was only one procedure-related complication—a femoral artery hematoma. Although the findings of these studies support the idea of using stenting to treat IN, the lack of a control group limits the strength and interpretability of the conclusions.

More recently two randomized trials have been completed that directly compared medical therapy alone against medical therapy with stenting, the STAR and ASTRAL trials.[1,10] The STAR trial was conducted by a Dutch cooperative group and tested in a cohort of 140 patients whether stenting could reduce by 50% the proportion of patients that experienced a 20% decline in GFR. Unfortunately 28% of patients who were enrolled in the stent arm had no significant renal artery stenosis and were not treated. Not surprisingly, with a substantial false positive rate of enrollment, in addition to what was likely an over-estimation of the likely treatment effect of stenting, the study authors concluded that "confidence bounds…are compatible with both efficacy and harm, so the finding is inconclusive." ASTRAL, published in late 2009, had a much larger enrollment of 806 randomized patients. However ASTRAL also had a high rate of false positive inclusion, approximately 17%, in addition to 5% of subjects in whom stenting was attempted but not completed. There was also selection bias inherent in the study design as patients were entered only if the enrolling center felt that the subject did not definitely require revascularization. Despite this the study demonstrated a trend toward an improvement in the primary endpoint of slope of reciprocal Cr (-0.0713×10^{-3} vs. -0.13×10^{-3} micromole/L/yr, $p = 0.06$). However this difference was neither statistically nor clinically significant, as were the findings of the secondary analyses. From these recent studies we would conclude that: (1) If stenting has an effect on the progression of ischemic nephropathy it is likely modest in size, (2) great caution should be utilized to avoid over-analyzing these results due to the methodologic issues that confound their interpretation: high rates of false + enrollment lack of centralized analysis of critical study measures such as stenosis severity or renal function, and the lack of a consistent, specified medical intervention. Some have criticized the ASTRAL result for an apparently higher than expected rate of complications and lower than expected success rate, however, it is entirely unclear whether the ASTRAL result is better reflective of the "realities of stenting" when compared to single center publications, or whether technical issues were more excessive in this study.

Evolution in technology may modify the future approach to the treatment of renal artery stenosis. Several investigators have now reported retrospective or observational series that suggest that Embolic Protection Devices (EPD) may improve the result of renal artery revascularization, at least as it relates to the preservation of renal function.[47,69,73] Thus far there has been one prospective trial of EPD use, a study that also tested in a two by two factorial design a platelet glycoprotein IIbIIIa inhibitor abciximab, administered in a double-blind fashion.[37] Abciximab overall, and more specifically when administered in conjunction with the EPD, resulted in improved renal function. More surprisingly, the analysis of the embolic debris demonstrated a high rate of platelet-rich emboli captured by the EPD, suggesting that these lesions may be more thrombotic than previously appreciated. Whether more widespread adoption of EPDs or potent platelet inhibitors will generally improve the effect of renal artery stenting is unknown but these results raise the possibility that the net effect of the revascularization procedure is determined by the benefit of improved blood flow balanced by injury due to atheromatous or thrombotic debris.[37]

Currently ongoing is a large prospective, National Institutes of Health–sponsored multicenter randomized trial to test the effect of stenting when added to a background of aggressive medical therapy. Known as CORAL, for Cardiovascular Outcomes in Renal Atherosclerotic Lesions, it began in the spring of 2005

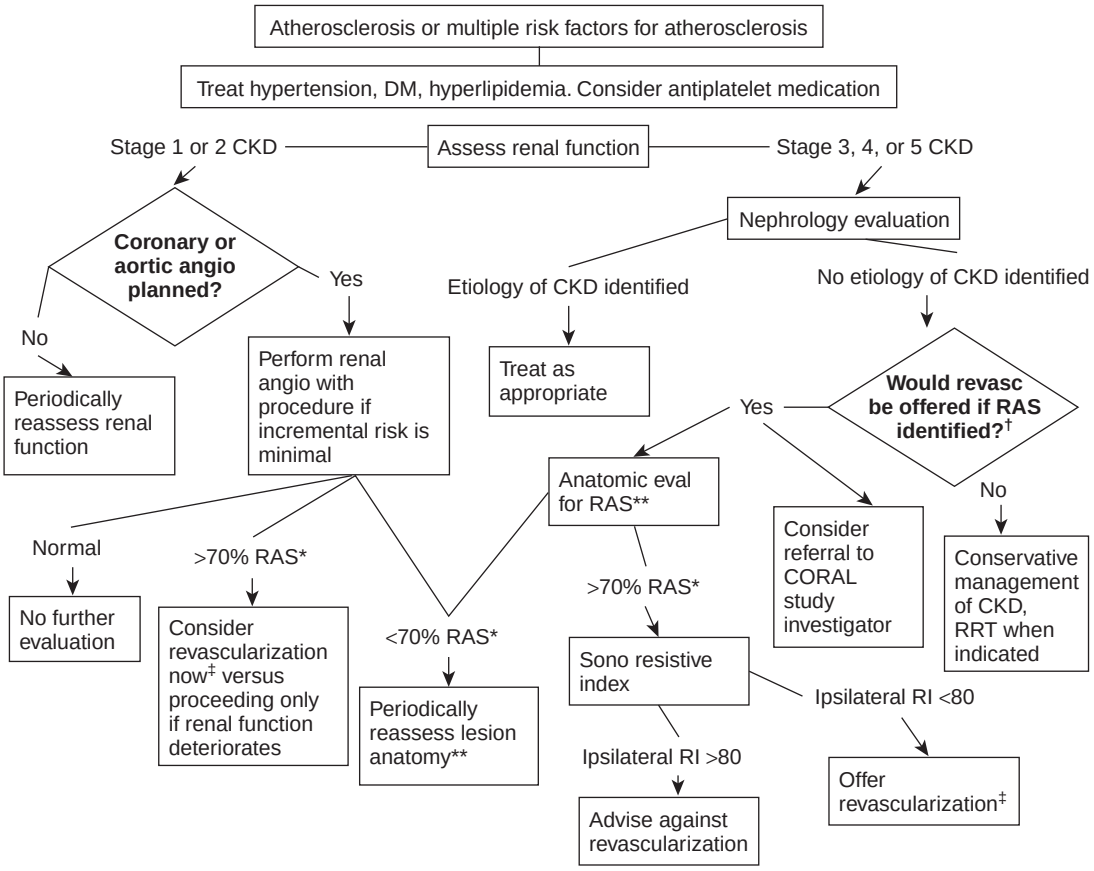

FIGURE 77.8 *60% if sonoduplex is used as diagnostic modality. **Magnetic resonance angiography (MRA) or computed tomography angiography (CTA) are generally tests of choice. Other options are discussed in text. Also consider renal angiography during cardiac catheterization or aortic angiography if either of these procedures is indicated otherwise in these patients. †Very limited life expectancy, patient preference against revascularization, and advanced longstanding chronic renal insufficiency are factors that may persuade against revascularization and would make further evaluation futile. ‡The renal artery revascularization procedure of choice is generally percutaneous transluminal renal artery angioplasty (PTRA) with stenting. Surgical revascularization could be considered if aortic or other intra-abdominal vascular surgical procedure is indicated for other reasons and if perioperative risk is not prohibitive. CKD, chronic kidney disease, with stages as defined by K/DOQI; RRT, renal replacement therapy; RI, resistive index; RAS, renal artery stenosis; revasc, revascularization.

and will include approximately 1000 patients with hypertension and documented significant RAS.[38] Patients are randomized to medical therapy with or without renal artery stenting with follow up for a composite endpoint of cardiovascular and renal events. It is designed to test the hypothesis that renal artery stenting (along with medical therapy) reduces cardiovascular and renal morbidity and mortality.

Recommended Approach

There are many different reasonable approaches and algorithms for the diagnosis and management of patients with IN, and the recommendations that follow and that are summarized in Figure 77.8 remain opinion-based, as data are not sufficient to make definitive recommendations. In patients at high risk for atherosclerosis or in those with known atherosclerosis, renal function should be monitored and anti-atherosclerotic life style and pharmacologic interventions and risk factor reduction should be used. A high degree of suspicion for coexisting coronary artery disease should be maintained. If renal insufficiency is found, appropriate nephrologic evaluation should be undertaken and this should include an assessment for ischemic nephropathy. In many patients an anatomic evaluation of the renal arteries is warranted to further stratify their stage of disease and expected outcome. Duplex ultrasonography is currently the test of choice since it is entirely non-invasive and involves no nephrotoxic contrast agents, if appropriately trained technologists and interpreting physicians are available. MRA is an alternative in centers where experienced ultrasonagraphers are not available but is limited to patients with an estimated GFR of greater than 40 ml/min, due to the risk of nephrogenic systemic sclerosis with administration of gadolinium to patients with impaired renal function. In

patients with mild renal dysfunction a CTA may be *considered*. At other centers MRA without contrast may become an alternative test.

Once one or more renal artery stenoses are identified medical therapy with aspirin or another anti-platelet agent, a statin and an agent to interrupt the renin-angiotensin system such as an ACE or ARB should be instituted. Renal function as assessed by serum creatinine and serum potassium should be followed carefully during institution of such treatment. In addition careful attention to blood pressure control using agents such as calcium antagonists, combination β- α-adrenergic blockers and diuretics are appropriate. During treatment with medical therapy follow-up of lipids, HbA1c (if appropriate) and blood pressure is of great importance, with titration of medications to achieve guidelines-driven outcomes.

The decision to refer for revascularization should be made with circumspection. Critical in the decision include an objective measure of stenosis severity, recognizing that many of the tomographic imaging studies such as CTA and MRA grossly over-estimate lesion severity. As such, if the patient is referred for an invasive assessment, at a minimum the evaluation of the lesion severity should be done objectively and oftentimes requires measurement of a pressure gradient with an 0.014 inch pressure sensing guidewire to discern if the apparent stenosis is of any functional significance. In parallel to the lesion assessment a critical review should be given to potential benefit for revacularization balanced against the expected risks of the specific patient. In general one can expect a greater potential for improvement in renal function in patients with advanced chronic kidney disease, however this is associated with less renal function reserve and a higher probability of dialysis dependence if complications occur or renal function fails to improve. At this time there is little role for captopril-augmented renal scintigraphy, with the possible exception for the evaluation of the occluded renal artery where the scintigram will occasionally demonstrate a viable kidney that contributes significantly to GFR and that may benefit from surgical revascularization. At this time, given the results of ASTRAL that demonstrate either a small or marginal treatment effect, a compelling case could be made for reserving renal artery revacularization to those patients who have clearly failed medical therapy or are willing to participate in a clinical outcomes trial.

SUMMARY

This chapter was intended to provide an intellectual framework that will improve the clinician's understanding of the complex issues involved in the management of patients with ischemic renal disease. By understanding the mechanisms and limits of renal autoregulation, one can appreciate how the kidney compensates for the renal hypoperfusion that RAS causes. The pharmacologic interference of this process may cause a decrease in renal function although this scenario is less frequent than was once supposed. RAS may cause chronic and or even irreversible renal injury via a complicated pathophysiologic process, and this is an important cause of renal morbidity. The diagnosis of ischemic nephropathy is often difficult but important to make because anti-atherosclerotic medical treatments will likely benefit patients and selected patients may benefit from revascularization. A recommended approach to the diagnosis and treatment of RAS is provided, but it should be noted that the results of ongoing trials may soon alter these recommendations.

CHAPTER

78

Pathophysiology and Pathogenesis of Diabetic Nephropathy

Sheldon Chen[1] *and Charbel Khoury*[1] *and Fuad N. Ziyadeh*[2]

[1]Northwestern University, Chicago, U.S.A.

[2]American University of Beirut, Beirut, Lebanon

Diabetic nephropathy is the major cause of end-stage renal disease (ESRD) in the industrialized world. Although the incidence of nephropathy due to type 1 diabetes may not be increasing, type 2 diabetes mellitus, considered 30 years ago a rather benign condition invariably associated with the "normal" aging process, is now the most common single cause of chronic kidney disease in the United States, Japan, and Europe.[1,2] The associated health care costs are massive and not only is diabetic nephropathy a major burden on the quality of life, it also predicts an ominous prognosis despite advances in the medical management of renal and cardiovascular diseases. For instance, the diabetic patient with proteinuria has a two- to fourfold increased risk of morbidity and mortality from cardiovascular diseases.[3] Even with chronic dialysis, the cardiac death rate of diabetic patients is ~50% higher than nondiabetic patients.

The pathophysiology of diabetic nephropathy is complex. Renal injury was initially thought to be caused by hemodynamic alterations (renal hyperperfusion, intraglomerular hypertension, and glomerular hyperfiltration),[4] but there is now clear evidence that these changes are only one aspect of a complex series of metabolic and biochemical alterations caused by disturbed glucose homeostasis.[5] Hyperglycemia is a necessary prerequisite but genetic susceptibility is also crucial for the development of diabetic nephropathy.[6] Several lines of evidence, including familial aggregation, suggest the existence of genes where allelic variation contributes to risk of diabetic nephropathy. Metabolic changes and hemodynamic stress can induce the release of vasoactive peptides, cytokines, and growth factors that can trigger a host of autocrine and/or paracrine effects[7] that eventually mediate the effects of hyperglycemia and nonenzymatically glycated proteins on the functional alterations (hyperperfusion, hyperfiltration) as well as the structural changes (early hypertrophy, excess extracellular matrix deposition, podocyte abnormalities) of diabetic nephropathy.[5,8,9] This chapter will provide a comprehensive review of our current understanding of the pathophysiology of diabetic nephropathy.

EPIDEMIOLOGY

There are approximately 200 million people with diabetes mellitus worldwide, and this number is projected to increase to 366 million by 2030. In the United States, it is estimated that 18.8 million people (or ~6% of the population) have diabetes (ADA statistics webpage found at http://www.diabetes.org/diabetes-basics/diabetes-statistics/), but a significant portion of those with type 2 diabetes have not yet been clinically identified. Up to one third of patients with type 1 diabetes eventually develop nephropathy after ~20 years of diabetes.[10] Among those with type 2 diabetes, the risk of nephropathy is less clear and varies with ethnicity.[1] However, some European studies have suggested that the risk of ESRD in type 2 diabetic patients is almost as high as in type 1 diabetic patients.[2] African Americans, Native Americans, Asians, and Hispanics are more prone to developing both type 2 diabetes and diabetic nephropathy than non-Hispanic whites. The reasons for this difference remain unknown but genetic factors may be implicated. There has been a secular trend of

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00078-1

decreasing prevalence of nephropathy in type 1 diabetic patients,[11,12] presumably because of progressively better management of glycemia and hypertension. Although in type 2 diabetic patients, aggressive early, multi-factorial intervention reduces the frequency of cardiovascular and renal endpoints,[13] there was little evidence of a decreasing incidence of nephropathy in patients with type 2 diabetes.[14–16] As of 2005, however, the incidence of diabetic nephropathy leading to end-stage renal disease seems to be leveling off, but whether that positive trend continues will require additional years of data to confirm[17] (USRDS 2011). The increasing prevalence of type 2 diabetes in the aging population[16] and the better survival of diabetic patients with nephropathy had been the major reasons for the rising numbers of type 2 diabetics with ESRD,[2,18] but incident rates have recently stabilized or are falling in older populations and among whites. The sobering news is that diabetes-related ESRD is increasing among younger minority patients (USRDS 2011). Importantly, the risk of dying from cardiovascular disease is greater than the chance that one may live long enough to develop ESRD. An increasing proportion of diabetic patients can have acute but irreversible renal failure, superimposed on chronic kidney disease, usually after cardiac or septic complications. Administration of radiocontrast media agents or nonsteroidal anti-inflammatory agents may sometimes precipitate renal failure that may not resolve.

According to the US Renal Data System (www.usrds.org, 2004; incidence data from 2002) diabetic nephropathy was the primary diagnosis in 45% of incident patients starting renal replacement therapy (i.e., 148 of 326 patients per million). This was an increase of 221% compared with 1990,[19] (updated for USRDS 2011, incidence data from 2009, diabetic kidney disease accounted for 43% of incident patients, i.e., 154 of 354.8 patients per million). The number of type 2 diabetic patients with ESRD in the United States in 2000 far exceeded that of type 1 (38% and 6% of the total ESRD dialysis population, respectively). This is due to the much higher prevalence of type 2 diabetes in the overall diabetic population (90–95%) as compared with type 1 diabetes (5–10%). Survival of diabetic patients on dialysis is considerably worse than that for nondiabetic patients. Five-year mortality is between 40% and 80% in diabetic patients with ESRD in European countries and the United States. The main causes of death in hemodialyzed diabetic patients are primarily cardiovascular events but infection also plays a significant role.[20,21] Survival rates in dialyzed diabetic patients are much better in Eastern countries such as Japan,[22] presumably related to the lower rate of cardiovascular death in the background population of Japan.

Genetic Risk Factors

The risk of nephropathy is strongly determined by genetic factors and only approximately 30% of patients with type 1 or type 2 diabetes will ultimately develop nephropathy.[23] Genetic factors may directly influence the development of diabetic nephropathy and/or be clustered with genes influencing cardiovascular diseases.[24,25] One support for genetic transmission is an experimental study showing that bone marrow–derived mesangial cell progenitors transmit diabetic nephropathy from donors with type 2 diabetes (*db/db* mice) to naive, normoglycemic recipients.[26] There is ongoing research through genomic screening and candidate gene approaches to better identify genetic loci for diabetic nephropathy susceptibility.[27–30] Although some potential genes have been identified, linkage was only present in defined ethnic subpopulations and not in the majority of patients. An incomplete list of previously implicated genes is shown in Table 78.1. The major problem with such studies is that diabetic nephropathy is a complex disease trait, meaning that several genes are likely involved and the inheritance patterns do not follow simple Mendelian rules. For example, a potential association between polymorphisms in candidate genes and the development and progression of nephropathy has been widely studied.[31–37] These case-control studies are often problematic and clear guidelines for such polymorphism studies have been provided.[38] The complexity of this genetic linkage analysis is exemplified by studies with controversial results investigating the insertion or deletion polymorphism of the angiotensin-converting

TABLE 78.1 Some Genes Implicated in Susceptibility and/or Progression of Diabetic Nephropathy

Gene	Gene Variant
Promoter of RAGE	63-bp deletion (decreased risk)
Histocompatibility antigen	DR3/4
Angiotensin-converting enzyme	D/I
Angiotensinogen	M235T
Aldose reductase	Z + 2 alleles
Transforming growth factor-β1	Leu10Pro, Arg25Pro
Apolipoprotein E	e2 allele
Paraoxonase 1	T107C, Leu54Met
Interleukin-1γ	T105C
Atrial natriuretic peptide	C708T
Glucose transporter 1	Xba1/HacIII
Mannose-binding lectin	YA/YA, XA/YA

RAGE, receptor for advanced glycation end-product.

enzyme (ACE) gene. Discrepancies could be explained by genetic heterogeneity and by small effects in limited cases in most studies (often <200 cases). The current opinion about the role of ACE gene polymorphism is that it may be associated with progression of disease in certain ethnic populations, but it is not a predictor of the development of diabetic nephropathy.[39,40]

The introduction of Genome-Wide Association Studies (GWAS) is projected to bring new insights into the genetics of diabetic nephropathy. After scanning the entire genome, this method tries to identify single nucleotide polymorphisms (SNPs) associated with a particular disease, and thus can pinpoint areas of the genome involved in renal disease for example. So far, 2 GWAS have been conducted on patient populations with diabetic nephropathy.[41] Pezzolesi et al. identified two loci that are significantly associated with renal disease in patients with type 1 diabetes: the FRMD3 (4.1 protein ezrin, radixin, moesin [FERM] domain containing 3) and CARS (cysteinyl-tRNA synthetase). These findings were replicated using samples from the Diabetes Control and Complications Trial (DCCT)/Epidemiology of Diabetes Interventions and Complications (EDIC) study.[42] On the other hand, using a Japanese cohort, Maeda et al. suggest that ELMO1 (engulfment and cell motility 1 gene) and SLC12A3 (solute carrier family 12, member 3) may be associated with type 2 diabetic nephropathy.[43] This was later confirmed by studies on African-American cohorts with type 2 diabetes as well as data from the GoKinD collection which includes Caucasians with type 1 diabetes.[44,45] Because it casts a wide net, GWAS should increase our understanding of the pathology of diabetic nephropathy, and help identify novel therapeutic targets. This powerful method also promises to give clinicians and researchers a better understanding of the differences in disease progression and therapeutic responsiveness, paving the way towards a personalized medical practice.

More recently, the tools of genome-wide association studies have been applied to diabetic nephropathy. This method allows for a comprehensive genetic survey of the entire genome for chromosomal regions that are linked with a specific trait, in this case diabetic nephropathy.[46] A genome scan for diabetic nephropathy in African-Americans identified susceptibility loci on chromosomes 3q, 7p, and 18q.[47] Another scan in Pima Indians, a native American tribe with an alarmingly high incidence of early-onset type 2 diabetes,[48] also identified linkage to diabetic nephropathy on chromosome 7.[49,50] This powerful method, or its derivative technologies, may in the future more clearly identify the genetic risk for developing diabetic nephropathy. However, the genetic findings still need to be sussed out for their functional significance and explained in the larger pathophysiological context.

CLINICAL COURSE OF DIABETIC NEPHROPATHY IN TYPE 1 AND TYPE 2 DIABETES

Five clinical stages characterize the progression of diabetic nephropathy (Fig. 78.1, Table 78.2).[51] These stages are classified on the basis of the values of the glomerular filtration rate (GFR), urinary albumin excretion (UAE), and systemic blood pressure. The discrete structural lesions in the renal parenchyma and vasculature (discussed in subsequent sections) generally become more severe with advancing clinical stages, but the diagnosis of diabetic nephropathy is often made on clinical grounds without the need for renal biopsy except in atypical presentations. The stages are best delineated in the setting of type 1 diabetes because the patient is often young, typically does not have essential hypertension that can cause renal injury, and the onset of diabetes is much more easily pinpointed. In these patients, sustained albuminuria due to diabetic nephropathy rarely develops before the first 10 years of diabetes. On the other hand, if a patient has diabetes for longer than 25 years and has not developed proteinuria, the future risk of developing nephropathy is only about 1% per year.

It should be noted that transient albuminuria can be first detected in human type 1 diabetes when the patient has uncontrolled diabetes or co-existent infections. This feature is not reflective of established diabetic nephropathy because the patient typically reverts to the normoalbuminuric state when the blood glucose is better controlled or an infection is cleared.

The natural history for patients with type 2 diabetes is not as easily characterized as in type 1 patients,[52,53]

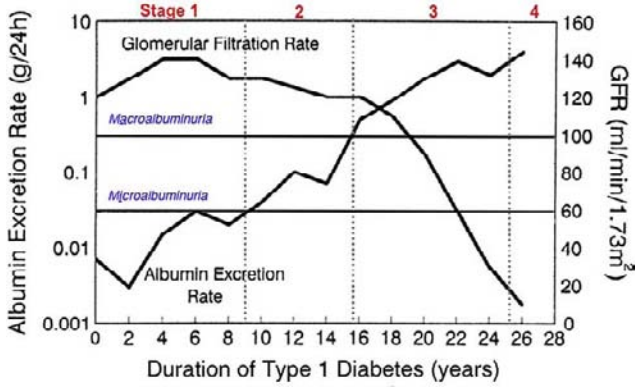

FIGURE 78.1 Five clinical stages characterize the progression of diabetic nephropathy. *(Adapted from Molitch ME. Am J Med 102: 392–398, 1997)*

TABLE 78.2 Clinical Stages of Diabetic Nephropathy

Stage	GFR	UAE	Blood Pressure	Years After Diagnosis
1. Hyperfiltration	Supernormal	<30 mg/d	Normal	0
2. Microalbuminuria	High normal–normal	30–300 mg/d	Rising	5–15
3. Overt proteinuria	Normal-decreasing	>300 mg/d	Elevated	10–20
4. Progressive nephropathy	Decreasing	Increasing	Elevated	15–25
5. ESRD	<15 ml/min	Massive	Elevated	20–30

GFR, glomerular filtration rate; UAE, urinary albumin excretion; ESRD, end-stage renal disease.

because 5% to 20% of these patients have some degree of albuminuria at the time of recognition of diabetes. Unlike type 1 patients, patients with type 2 diabetes commonly have hypertension at presentation and the renal disease in these patients can be attributed to diabetes only in approximately 75% of the cases. A renal biopsy may sometimes be indicated to reach the correct diagnosis. Moreover, due to increased cardiovascular mortality, many type 2 diabetic patients die before they ever progress to ESRD. Nevertheless, longitudinal observations in the Pima Indians have revealed that the course of diabetic nephropathy in type 2 diabetes is very similar to that of type 1 diabetes.[48,54,55] Thus, although it may be debated that diabetic nephropathies due to either type 1 or type 2 diabetes are specific entities, there is convincing evidence that basic pathophysiological mechanisms that eventually lead to nephropathy are essentially similar in types 1 and 2 diabetes.[56–58] However, in type 2 diabetes cases, other noxious factors, being or not related to diabetes mellitus itself, such as hypertension, obesity, dyslipidemia, and macrovascular ischemic renal disease could additionally injure the kidney resulting in complex patterns of nephropathy. The pathophysiological changes prior to the development of type 2 diabetes have been classified as the metabolic syndrome (see subsequent sections).[59]

Stage I

The earliest renal manifestations in type 1 diabetes are nephromegaly and glomerular hypertrophy, which are accompanied by afferent arteriolar vasodilation, renal hyperperfusion (although some find that renal blood flow is reduced[60]), and glomerular hyperfiltration (Fig. 78.1). Microscopically, there is thickening of the glomerular and tubular basement membranes. All these early functional and structural manifestations appear even if the patient is not destined to develop overt diabetic nephropathy. The UAE in this stage is normal (<30 mg/d or <20 μg/min) (Fig. 78.1) but occasionally a transient increase in UAE ("transient microalbuminuria") is present secondary to poor glycemic control or infection. Typically the blood pressure is below the hypertensive range (<140/90 mm Hg). The GFR is increased by 20 to 40% above normal values, with higher levels being frequently achieved when glycemic control is poor. Some studies suggest that patients with more renal hypertrophy or higher degrees of hyperfiltration (GFR >150 ml/min) are at increased risk for the future development of overt nephropathy.[61–64] In patients with type 2 diabetes, this early stage is not readily discernible owing to the increased age but there may be modest degrees of nephromegaly and hyperfiltration.[65]

Stage II

Incipient or latent nephropathy is defined by the appearance of microalbuminuria (UAE of 30–300 mg/day or 20–200 μg/min).[66] Without intervention, UAE increases at the rate of 10% to 20% per year and is almost always accompanied by a steady rise in blood pressure. Hypertension (>140/90 mm Hg) is typically diagnosed one to two years after the appearance of microalbuminuria in type 1 diabetes. Microalbuminuria rarely develops before five years of disease duration (median, 10 years) in type 1 diabetes, but in type 2 diabetes microalbuminuria may be present at the time of diagnosis of hyperglycemia in up to 20% of patients with as many as 40% of patients having elevated blood pressure as well. This may be due to the fact that many of these patients have had impaired glucose tolerance for years before actually being diagnosed with diabetes, or it may reflect another disease causing increased UAE as part of the metabolic syndrome, most notably essential hypertension. Other possible causes of increased UAE in this population include renovascular hypertension, morbid obesity, and sleep apnea. Even during this clinically "silent" phase of the disease, there may be significant mesangial matrix expansion or diffuse glomerulosclerosis, further thickening of the glomerular and tubular

basement membranes, and some degree of podocyte loss. The GFR may remain elevated or may decrease to within the "normal" range (100–120 ml/min) (Fig. 78.1). Longitudinal studies have shown that the patient with microalbuminuria is at greater risk for the development of overt proteinuria (UAE >300 mg/d) compared with patients with normoalbuminuria. For example, type 1 diabetic patients with persistent microalbuminuria have approximately an 80% chance of developing established nephropathy within the ensuing five to seven years.[67,68] In contrast, the percentage of patients with type 2 diabetes who progress to overt proteinuria is significantly lower, in part because of excess mortality due to cardiovascular events.[69] Thus, the predictive value of microalbuminuria in patients with type 2 diabetes is much less clear than in type 1 patients.

Stage III

This stage is characterized by the development of overt proteinuria (total protein excretion >500 mg/day) or macroalbuminuria (UAE >300 mg/d) (Fig. 78.1). In type 1 patients this occurs after an average of 15 years of diabetes. Hypertension is almost always present, and the worse the blood pressure control is, the more rapidly the GFR declines (Fig. 78.4). If a renal biopsy were to be performed, the glomeruli would typically demonstrate diffuse glomerulosclerosis and/or nodular glomerulosclerosis, further podocyte loss with focal areas of foot process effacement, arteriolar hyalinosis in both the afferent and efferent arterioles, and variable degrees of tubulointerstitial fibrosis. Structure–function correlations indicate a highly significant inverse correlation between declining GFR and mesangial expansion.[70] The progressive expansion of the glomerular mesangium causes a reduction in the glomerular filtering surface area. Nephron loss due to tubulointerstitial fibrosis is another major cause of the reduction in GFR. In the untreated patient, the GFR falls at a rate of about 1 ml/min/month, but this rate of fall can vary significantly from patient to patient. As the GFR falls from previously supernormal levels, the serum creatinine may remain in the normal range or be slightly elevated and is therefore not a reliable indicator of the magnitude of disease progression.

Stage IV

After approximately five years of overt nephropathy, untreated patients progress to advanced nephropathy, as characterized by nephrotic-range proteinuria (>3.5 g/d), worsened hypertension that becomes difficult to control, and a progressive decline in GFR (Fig. 78.1). In fact, diabetic nephropathy is the most common cause of the nephrotic syndrome in the adult population. Parenchymal and vascular lesions become more severe. The rate of decline in GFR is steady over a period of months but is variable from patient to patient and depends on the degree of elevation of blood pressure as well as the amount of UAE.

Stage V

The final stage is progressive renal failure reaching ESRD, with the GFR declining to 15 ml/min or lower. The patient may soon need renal replacement therapy to control uremic symptoms or excessive volume expansion. The average time for progression to ESRD from the time of diagnosis of diabetes is about 20 to 25 years, with a more rapid course developing in patients with uncontrolled hypertension and/or heavy proteinuria. Many patients, especially those with type 2 diabetes, never reach ESRD because of the severely increased risk of cardiovascular mortality in this population.

PATHOLOGY OF KIDNEY DISEASE IN DIABETES MELLITUS

Kidney structure is dramatically altered in diabetes in virtually all affected patients (Fig. 78.2, Table 78.3), even those not destined to develop full-blown diabetic nephropathy. The early structural changes include kidney enlargement involving both the tubules and the glomeruli and occurring as early as the first few months after the onset of diabetes.[71] This process involves predominantly hypertrophy (cell enlargement) and, to a much lesser extent, hyperplasia (cellular proliferation).[72–76] The larger glomerular volume and the resultant increase in capillary surface area maintain a higher GFR despite the development of mesangial matrix expansion.

One of the earliest cellular changes in diabetes is mesangial and tubular cell hypertrophy.[76] Insights into the complex mechanisms of growth came mostly from in vitro studies exposing renal cells to high ambient glucose concentrations. After a self-limited and short period of proliferation, glomerular and tubular cells subjected to hyperglycemia *in vitro* or *in vivo* become arrested in the G_1 phase of the cell cycle.[77,78] This G_1-phase arrest is mediated by $p27^{Kip1}$, an inhibitor of cyclin-dependent kinases (CDKI).[78] Another inhibitor, p21, may play a role as well. High glucose, via stimulation of the ERK isoform of the mitogen-activated protein kinases (MAPKs), leads to a posttranscriptional increase in $p27^{Kip1}$ expression because phosphorylation

of serine residues increases the half-life of $p27^{Kip1}$.[79] Deletion of $p27^{Kip1}$ attenuates high-glucose–induced hypertrophy of mesangial cells.[80] In addition, angiotensin II (Ang II) further enhances $p27^{Kip1}$ induction and blockade of Ang II attenuates high-glucose–mediated mesangial cell hypertrophy.[78,81] Treatment of diabetic animals with an ACE inhibitor attenuates $p27^{Kip1}$, but not p21, and reduces renal hypertrophy.[82] Knock out of $p27^{Kip1}$ in mice made diabetic with streptozotocin (STZ) results in less diabetic nephropathy.[83] While cell cycle arrest is essential, it may not be sufficient for the development of hypertrophy. Complementary signals increasing RNA and protein synthesis are needed for the cell to grow. Early in diabetes, renal cells, and especially mesangial cells, activate the mammalian target of rapamycin (mTOR).[84,85] mTORC1 acts mainly on two important downstream targets: the eukaryotic translation initiation factor 4E-binding protein 1 (4EBP1) and the serine/threonine protein kinase p70S6 kinase 1 (S6K1). Phosphorylation of 4EBP1 leads to the release of eIF4E and consequently the initiation of cap-dependent translation of mRNAs. On the other hand S6K1 phosphorylates the 40S ribosomal protein S6, and plays a role in the regulating cellular and organ hypertrophy.[86] In fact inhibition of the mTOR pathway with rapamycin, or the knockdown of S6K1 decrease renal hypertrophy in rodent models of diabetes.[85,87] Moreover rapamycin treatment can reduce basement membrane thickening, mesangial matrix accumulation, as well as renal inflammatory markers, and lead to significantly less albuminuria.[88]

The basement membranes of tubules and glomeruli begin to thicken after two to three years of diabetes (Fig. 78.3). The width of the glomerular basement membrane (GBM) often exceeds 500 nm, or nearly double the control value.[89] There is increased abundance of type IV collagen, laminins, and nidogen/entactin, but other reports have described an increase in the subendothelial content of the novel (restricted) α3(IV) and α4(IV) collagen chains and a relative decrease in the density of the classical (ubiquitous) α1(IV) and α2(IV) collagen chains.[90] There may also be a relative reduction in the other novel α5(IV) collagen chain.[91] Thus, altered assembly of collagen IV chains is one major aspect of the altered composition of the thickened GBM and may partly explain the proteinuria. In fact, thickening of the GBM correlates well with the presence of proteinuria[56,57] and is potentially reversible with insulin therapy and tight glycemic control.[92]

After three to five years of diabetes, expansion of the mesangial regions of the glomerulus begins (Fig. 78.2). The most distinctive lesion of full-blown diabetic glomerulopathy is nodular glomerulosclerosis, frequently termed the "Kimmelstiel-Wilson lesion." Nodules probably form in response to injury produced by microaneurysmal dilation of glomerular capillaries and mesangial lysis. Nodules are present in up to 25% of diabetic patients at postmortem examination. A similar pattern may be seen in other renal diseases, notably light-chain nephropathy and amyloidosis; however, appropriate immunofluorescent staining, electron microscopy, and historical and laboratory information distinguish these conditions from the nodular glomerulosclerosis of diabetes. More prevalent is the diffuse rather than nodular enlargement of the mesangium (diffuse glomerulosclerosis) (Fig. 78.2). Matrix accumulation in the mesangium is the result of increased synthesis and decreased degradation of extracellular matrix molecules, especially fibronectin and the classical collagen chains α1(IV) and α2(IV) and nonfibrillar short-chain collagen VIII.[93] Fibrillary collagens that are not native to the glomerulus (such as collagens type I and III) eventually appear within the expanded mesangium. A small increase in mesangial cell volume may also occur. Mesangial cell proliferation is not considered to be a feature of diabetic nephropathy, although a very modest and self-limited increase in cell number

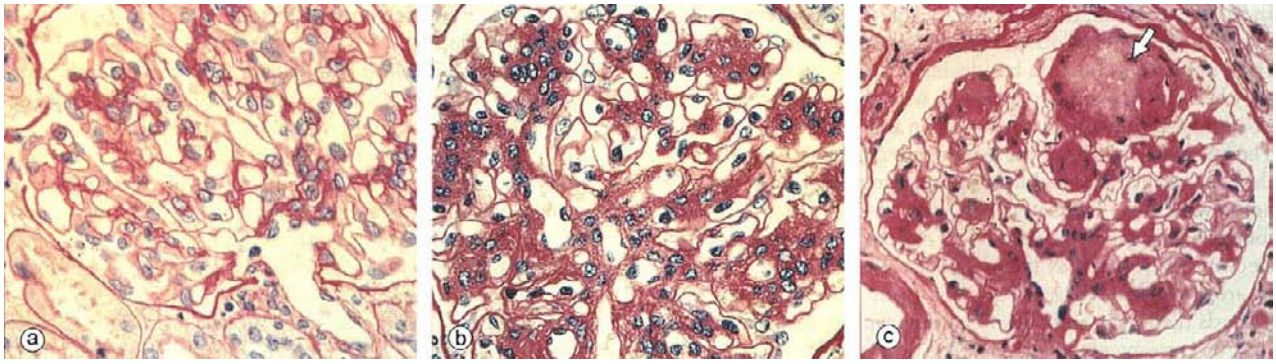

FIGURE 78.2 Appropriate immunofluorescent staining, electron microscopy, and historical and laboratory information distinguish these conditions from the nodular glomerulosclerosis of diabetes. More prevalent is the diffuse rather than nodular enlargement of the mesangium (diffuse glomerulosclerosis). *(From Vora JP, Chattington PD, Ibrahim H. Clinical Manifestations and Natural History of Diabetic Nephropathy. Harcourt Publishers Limited: London, 2000. pp. 6.34.1–6.34.12)*

per glomerulus may perhaps occur as an early accompaniment to glomerular hypertrophy.[76,94] In advanced glomerulosclerosis, mesangial cell number may actually decrease. Globally sclerotic (obsolescent) glomeruli similar to those seen in kidneys with ESRD of any cause can also develop in diabetes. Other glomerular lesions include "capsular drops," which are lens-shaped pieces of sclerosing extracellular matrix adjacent to Bowman capsule, and "fibrin caps," which are homogeneous eosinophilic masses overlying capillary loops.

Although diabetic nephropathy is generally regarded as primarily a glomerular disease, discrete abnormalities of the vasculature and tubulointerstitium also occur.[95,96] One pathognomonic finding is the arteriosclerotic hyalinosis of both the afferent and efferent arterioles. Lesions of the renal tubulointerstitium include chronic interstitial inflammation (with macrophage recruitment), interstitial fibrosis, tubular atrophy, and a predisposition to papillary necrosis. The worsening proteinuria can have adverse effects on the tubules, causing tubular atrophy and inciting interstitial fibrosis. Tubulointerstitial fibrosis is perhaps the best pathologic correlate for the progressive decline in GFR.[95–97] Tubulointerstitial fibrosis and renal arteriosclerosis can be present in patients with type 1 or type 2 diabetes mellitus, but are more prevalent in type 2 diabetic patients. Renal structure is, in fact, heterogeneous in type 2 diabetic patients: only a subset has typical diabetic glomerulopathy, while a substantial proportion has more advanced tubulointerstitial and vascular rather than glomerular lesions, or has normal or near normal renal structure.[98]

THE CENTRAL ROLE OF PODOCYTES IN THE PATHOPHYSIOLOGY OF DIABETIC PROTEINURIA

It is likely that proteinuria is an important predictor of kidney disease as well as of cardiovascular complications.[3,99] In addition, proteinuria is a progression factor because it can aggravate the tubulointerstitial fibrosis and the progression of renal failure.[100] Proteinuria arises because of permeability defects of the glomerular capillary wall that are related to abnormalities in GBM composition and to alterations in the structure and function of the cells lining the GBM (especially the podocytes, and to a lesser extent, the endothelium).[101,102] In diabetic nephropathy there is a marked reduction in the number of anionic moieties such as sialic acid and heparan sulfate proteoglycans (HSPG) in the GBM, and this has been correlated with loss in the charge-permselectivity. Loss of size-permselectivity most likely is due to changes in podocyte function and structure. Podocyte dysfunction is well recognized as a crucial player in the pathogenesis of various progressive nephropathies including

diabetic kidney disease.[103,104] Cross-sectional and longitudinal studies in patients with diabetic nephropathy have described an increase in foot process width in microalbuminuric subjects, and this parameter correlates directly with the UAE.[105] In addition, the number and density of podocytes are markedly reduced (podocytopenia), whether the patient is afflicted with type 1 or type 2 diabetes.[106–109] The decreased number of podocytes per glomerulus in humans is seen early in the course of the disease and is a strong predictor of progressive renal injury.[108,110] Widening or stretching of the remaining podocytes maintains coverage of the GBM but also causes a derangement in the filtration slit diaphragms.[111] Podocytopenia can exacerbate the development of proteinuria because when the GBM is denuded, it comes into contact with Bowman capsule and this promotes synechiae formation, an initial step in the development of glomerulosclerosis.[103] Several experimental studies in diabetic rats have reported a decrease in podocyte number, broadening of the foot processes, and reduction in nephrin protein expression.[112] Consistent with the observed loss of podocytes in diabetes, podocytes can be present in the urine of diabetic patients, especially when the albuminuria progresses from microalbuminuria to macroalbuminuria. Interestingly, treatment with an ACE inhibitor reduces the number of urinary podocytes.[113,114] Nephrin staining,[115] but not CD2AP expression,[116] is extensively reduced in renal biopsy specimens from diabetic patients with nephropathy. When treated with an ACE inhibitor, nephrin expression is restored.[111]

The etiology of podocyte loss in diabetes remains speculative, but two mechanisms can be suggested: cell detachment from the GBM and apoptosis.[104] Loss of cell anchorage to the GBM may result from downregulation of the $\alpha_3\beta_1$ integrin receptor, the principal adhesion complex that attaches the podocyte to the GBM. In fact, the $\alpha_3\beta_1$ integrin is decreased in the podocytes of humans and rats with diabetes.[117,118] Furthermore, high-glucose media in cultured rat or human podocytes decreases the expression of $\alpha_3\beta_1$ integrin;[117,118] this downregulation is perhaps mediated by increased levels of the multifunctional cytokine transforming growth factor-β (TGFβ).[119,120] As will be discussed later, multiple factors in the diabetic state can stimulate the activity of this cytokine, which in turn is responsible for most of the renal manifestations of diabetic kidney disease except perhaps for the proteinuria.[121,122] Addition of Ang II to cultured rat glomerular epithelial cells induces apoptosis of the cells, and this effect is also mediated by the TGFβ system.[123]

There is significant experimental evidence that podocyte-derived vascular endothelial growth factor (VEGF) may mediate the proteinuria of diabetes.[104] Interventional studies in the STZ-diabetic rat or the type 2 diabetic db/db mouse (both models of overexpression of podocyte-derived VEGF) have shown that treatment with neutralizing anti-VEGF antibodies or inhibitors of VEGF signaling significantly ameliorated the albuminuria of diabetes.[124–126] The underlying mechanism is still unclear but it has been postulated that VEGF causes afferent arteriolar vasodilatation via nitric oxide (NO),[127]

increasing plasma flow into the glomerulus, opens the junctions between endothelial cells[128] and maintains endothelial fenestrations,[129] and alters the synthetic program for collagen, integrins, and other matrix components by all three glomerular resident cell types, which can eventually have an impact on protein passage across the glomerular capillary wall.[101,102,129] Research findings provide strong support for an autocrine loop in which the podocyte is a target cell for the effects of podocyte-derived VEGF.[101,104,130]

Serum VEGF levels are significantly increased in patients with type 1[131,132] and type 2[133] diabetes. Perhaps the kidney is one source of serum VEGF. Interestingly, the serum VEGF level and urinary VEGF excretion correlate with the degree of proteinuria among diabetic patients.[131,133] VEGF mRNA and protein are more abundant in the glomeruli, distal tubules, and collecting ducts of diabetic than in normal rats.[134,135] Similar findings are reported in human diabetes.[136,137] Equally important, the expression of VEGF receptors on the glomerular endothelium is elevated in the diabetic kidney.[134,137] In a study on diabetic patients, the extent of VEGF and VEGFR2 staining in the kidney was significantly associated with the presence of marked proteinuria (>2 g/d).[137] Some studies, however, have found a decreased renal VEGF content in advanced diabetic nephropathy with severe glomerulosclerosis (or other severe glomerulopathies).[138,139] This does not necessarily contradict the previous findings because late diabetic glomerulosclerosis with appreciable loss of podocytes may be expected to eventually result in decreased podocyte-derived VEGF expression. Then again, some have found that VEGF mRNA expression is decreased even in early diabetic nephropathy and is associated with peritubular capillary rarefaction.[140] For an in-depth and balanced analysis of the complex field of VEGF as it relates to DN, we refer the reader to a recent review article.[141]

CELLULAR AND MOLECULAR MECHANISMS IN THE PATHOPHYSIOLOGY OF DIABETIC NEPHROPATHY

A host of mediators can be shown to be important in the pathogenesis of diabetic nephropathy (Table 78.4) and these will be reviewed here.

Early Hemodynamic Alterations in the Glomerulus

Altered renal hemodynamics is an early characteristic feature of diabetes in humans as well as animal models.[63,142] It is widely held that glomerular capillary hypertension in diabetes is the major hemodynamic alteration that contributes to progressive glomerular injury.[142,143] The increase in glomerular capillary pressure is accompanied by increased glomerular blood flow, which is caused by afferent arteriolar dilation but with little or no dilation of the efferent arteriole. An imbalance of a variety of vasoactive and growth factors including the renin-angiotensin-aldosterone system (RAAS), atrial natriuretic peptide, insulin-like growth factor-1, endothelin, prostanoids, and eicosanoids has been implicated in diabetic hyperfiltration, but evidence strongly implicates the NO system as the main mediator for afferent arteriolar dilation.[144,145] Three major theories have been put forward to account for the hemodynamic changes in the glomerulus: (1) a primary alteration in vascular function, (2) a primary alteration in tubular function, and (3) a primary growth of the total filtration surface area (part of the hypertrophic response), mediated by endothelial cell proliferation, capillary elongation, and new capillary formation.[146–148]

It has been well characterized that diabetes is associated with impaired autoregulation at the afferent arteriolar level.[149] This vascular theory suggests that vascular smooth cells, mesangial cells, and endothelial

cells are primarily responding to a combination of high-glucose concentrations, local autacoids, and systemic signals to alter the normal autoregulatory response to the prevailing systemic pressure. Studies supporting a primary vascular role include impaired calcium transients in afferent arterioles from diabetic rats.[148,150] Numerous groups have found a persistent altered responsiveness to vasoconstrictors of vascular smooth muscle cells and mesangial cells obtained from diabetic rats.[148,151–155] Some of these studies, using mesangial and vascular smooth muscle cells cultured in high glucose or obtained from diabetic rats, have identified protein kinase C (PKC), reactive oxygen species (ROS), and TGF-β to be important mediators of vascular dysfunction.

A case for tubuloglomerular feedback as the initiating factor has been put forward by Blantz and coworkers.[156,157] These investigators have convincingly demonstrated that increased uptake of glucose and sodium in proximal tubular segments may limit sodium delivery to the macula densa, thus inhibiting tubuloglomerular feedback and preventing constriction of the afferent arteriole. Presumably the enzyme ornithine decarboxylase plays an important role in this pathway.[156] Studies in diabetic animals and patients with salt loading lend further evidence to this hypothesis. NaCl restriction would cause a decrease in GFR in the normal situation; however, in animals with long-standing diabetes and in diabetic humans, salt restriction causes a surprising increase in GFR. This salt paradox could be explained by the further decrease in salt delivery to the macula densa and further afferent arteriolar dilation. However, several studies report unimpaired tubuloglomerular feedback in diabetes;[158,159] one group suggested that enhanced tubuloglomerular feedback may mitigate the increase in GFR.[158] It is likely that much of the discrepant results are accounted for by variations in diabetes induction, degree of hyperglycemia, weight loss, insulin levels, and duration of diabetes. Without a standardized experimental approach it is virtually impossible to interpret the various results.

Regardless of the cause of hemodynamic alterations in diabetes, progressive renal injury eventually ensues. One potential scenario to explain this outcome has been put forward by Kriz and coworkers.[160] With increased glomerular capillary pressure, there is stretching of mesangial cells with loss of tethering to the GBM. Loss of tethering may be contributed by altered integrin expression and growth factor production. This would lead to a ballooning of the capillary loop and denuding of the GBM on the epithelial side. Alterations in GBM composition may also play a role. Dropout of podocytes may ensue due to abnormal stretching of podocytes and loss of adherence to the GBM.[161] Furthermore, abnormal stretch may stimulate TGF-β production by mesangial cells, leading to a sclerotic response.[162,163] This scenario would fit with the glomerular volume increase noted in experimental and human diabetes as well as the diffuse mesangial matrix expansion and podocyte dropout.

Enhanced tubular transport of solutes and water is correlated with glomerular hyperfiltration. The elevation in the glomerular transcapillary hydraulic pressure gradient as well as the increase in *glomerular* plasma flow leads to an increase in GFR. This, in turn, enhances the colloid osmotic pressure in postglomerular capillaries, which can facilitate the reabsorption of water and sodium in proximal tubules. These processes provide a mechanistic link between enhanced tubular transport and the primary abnormality of glomerular hyperfiltration. As an alternative explanation, a primary abnormality in sodium reabsorption has been linked to glomerular hyperfiltration.[157] This explanation suggests that an increase in reabsorption of sodium chloride in the proximal tubule or the loop of Henle leads to an increase in GFR by an intact macula densa mechanism. Diabetes-induced hypertrophy of tubules that mediate stimulated sodium chloride reabsorption could be pivotal in this process, again connecting the structural changes with the hemodynamic adaptation in diabetes.[157] Therefore, both mechanisms could explain the increase in tubular reabsorption that occurs in diabetic nephropathy.

Role of Glucose Uptake and Metabolism

Extracellular hyperglycemia may define the diabetic state but it is the high intracellular glucose concentration that appears to be the critical metabolic abnormality that promotes pathological changes in diabetic nephropathy. Renal cells do not require insulin for glucose uptake but instead rely on a family of transmembrane proteins to facilitate glucose transport across the cell membrane. Glucose diffuses down its concentration gradient, and in diabetes, renal intracellular glucose levels rise in proportion to the degree of hyperglycemia. The most widely expressed glucose transporter is the GLUT-1 isoform, a high-affinity, low-capacity, facilitative transporter that typically would be saturated at or near physiological glucose concentrations.[164] GLUT-1 is normally found in the glomerulus and the tubules, but diabetes changes its distribution and cellular expression. While most tissues downregulate GLUT-1 expression in the face of hyperglycemia to protect cells from excess glucose transport and metabolism, some renal cells such as mesangial cells actually upregulate GLUT-1 gene transcription and protein translation when cultured in high-glucose media.[165] This positive feedback

is an apparent maladaptive response in mesangial cells, because the cells can readily take up more glucose from a diabetic environment, resulting in high intracellular glucose concentration that then initiates signaling cascades, which are integral to the pathophysiology of diabetic kidney disease. In fact, mesangial cells that overexpress GLUT-1 demonstrate avid uptake of glucose even when cultured in normal concentrations of glucose; the cells also behave like wild-type mesangial cells incubated in high glucose in that they increase the synthesis of extracellular matrix proteins such as collagens and fibronectin.[166] Interestingly, several relevant factors in the diabetic state in addition to hyperglycemia can upregulate GLUT-1 expression on the surface of mesangial cells.[167] These factors, which include TGF-β, Ang II, and shear stress, can then stimulate net glucose uptake and intracellular metabolism and therefore promote glucotoxicity.[168]

The Polyol Pathway

Metabolic pathways for intracellular metabolism of glucose are myriad. Activation of the polyol pathway has been shown to be important in the development of some complications of diabetes mellitus such as cataracts, retinopathy, and neuropathy, but its involvement in the development of nephropathy remains much less established. Many of the early, but not late, features of diabetic renal disease can be attributed to activation of the polyol pathway. Aldose reductase, the first and rate-limiting enzyme in this pathway, catalyzes the NADPH-dependent reduction of hexose or pentose sugars to their corresponding sugar alcohols, or polyols.[169] Tissues that do not require insulin for glucose uptake (kidney, lens, retina, and peripheral nerves) become subject to relatively greater loads of intracellular glucose. Increased oxidation of sorbitol to fructose via fructose dehydrogenase is coupled to reduction of NAD^+ to NADH, and a more reduced cytosolic ratio of $NADH/NAD^+$ may result in abnormalities of cellular function, including myo-inositol depletion, ROS generation, PKC stimulation, and even TGF-β production.[170–172] Glomerular hyperfiltration in diabetic rats can be ameliorated by the administration of sorbinil, an aldose reductase inhibitor.[173] In a small randomized trial of type 1 normoalbuminuric diabetic subjects, ponalrestat (a carboxylate-containing aldose reductase inhibitor) reduced renal hyperfiltration.[174] Urinary albumin excretion in diabetic rats has also been reduced by aldose reductase inhibitor therapy.[175,176] Feeding sorbinil to diabetic rats has been reported to decrease the width of the GBM,[177] and the stimulation by high glucose of collagen type IV expression in cultured proximal tubular cells can be abolished with sorbinil, although cellular hypertrophy is not prevented.[178] However, the long-term effects of polyol-pathway inhibition on renal extracellular matrix accumulation have not been uniformly favorable. The aldose reductase inhibitor statil did not reduce the magnitude of glomerulosclerosis in diabetic rats after seven months despite normalization of erythrocyte sorbitol levels with this drug.[179]

The sorbitol pathway may also produce metabolites capable of nonenzymatically glycating intracellular proteins (see subsequent sections), which can be further phosphorylated via novel pathways that are activated in diabetes mellitus. Sorbitol-3-phosphate, fructose-3-phosphate, 3-deoxyglucosone, and other unidentified metabolites are increased in erythrocytes of diabetic subjects and could participate in protein glycation and cross-linking.[180,181] Such studies provide an intriguing pathogenetic link between the products of the polyol pathway (or other pathways of glucose metabolism) and the reactions of nonenzymatic glycation.

The Hexosamine Biosynthetic Pathway

Fructose-6-phosphate can be converted to glucosamine-6-phosphate, with glutamine donating its amido group to become glutamate. The final products of the pathway are uridine diphosphate (UDP)-N-acetyl-glucosamine (GlcNAc) and other nucleotide hexosamines. The amination of fructose-6-phosphate is rate limiting and is catalyzed by glutamine: fructose-6-phosphate amidotransferase (GFAT). Interestingly, high glucose, superoxide production, and Ang II can all stimulate GFAT activity in endothelial or mesangial cell cultures.[182,183] Also, the high-glucose-induced stimulation of TGF-β and fibronectin that is observed in mesangial cells is partly mediated by activation of the hexosamine pathway because treatment of the cells with the GFAT inhibitor azaserine or with GFAT antisense oligonucleotides diminishes this stimulation.[183] The mechanism by which increased flux through the hexosamine pathway induces gene transcription is likely through covalent modification of key transcription factors and signaling molecules.[170] For instance, hyperglycemia-induced mitochondrial superoxide overproduction activates the hexosamine pathway, which stimulates Sp1 activity by post-translational O-linked glycosylation at critical serine or threonine sites;[184] this activation of the Sp1 transcription factor then leads to induction of key prosclerotic factors including TGF-β1 and plasminogen activator inhibitor-1 (PAI-1).[184] The hexosamine pathway can also regulate vascular function by inhibiting endothelial NO synthase (eNOS) via O-linked glycosylation modification of a key signaling enzyme, the Akt/PKB.[185]

Signaling through Protein Kinase C

The signaling pathways that mediate some of the effects of hyperglycemia may involve activation of one or more isoforms of PKC. Based on a series of ^{14}C-radiolabeling experiments, the relationship between hyperglycemia and PKC activation has been ascribed to an increased intracellular metabolism of glucose that promotes the de novo formation of diacylglycerol, the major endogenous activator of the classic and novel isoforms of PKC.[186–190] Interestingly, diacylglycerol synthesis may also be linked to the glucose-induced increase in the ratio of $NADH/NAD^+$ that derives from the polyol pathway.[191] PKC activity, measured by the cytosol-to-membrane shift of various classical PKC isoforms, is increased in mesangial and endothelial cells incubated in high-glucose media.[172,186,192,193] Glomeruli from diabetic rodents also display elevated PKC activity and cytosol-to-membrane translocation of diacylglycerol-sensitive PKC isoforms.[194,195] Increased activity of PKC in glomerular mesangial cells may lead to an increase in extracellular matrix expression, such as fibronectin, laminin and type IV collagen.[186,190]

Specific blockade of one particular PKC isoform *in vivo* has been made possible with the engineering of a safe and orally active PKC-β inhibitor Ruboxistaurin (LY333531). In diabetic rats this compound ameliorates the renal hemodynamic abnormalities, decreases the proteinuria, and prevents the glomerular overexpression of TGF-β and the matrix components, fibronectin and type IV collagen.[196,197] A randomized, double-blind, placebo-controlled, pilot study conducted on patients with type 2 diabetes receiving renin-angiotensin system inhibitors showed that the addition of Ruboxistaurin reduced albuminuria relative to the patients' baseline. However, when comparing the treatment and placebo arms of the trial, the changes in the albumin-to-creatinine ratios were not significant.[198] Other PKC isoforms, particularly PKC-α,[199] may also mediate the renal lesions in diabetes, but this possibility will have to await the design of selective isoform inhibitors. The actual molecular targets downstream of PKC activation remain unclear, but they somehow stimulate other signal transduction pathways (such as MAPKs, PI3Kinases and various growth factors). For instance, markedly elevated ambient glucose levels in mesangial cells can activate p38, a MAPK family member, but they do not significantly affect JNK activity. One member of MAPK family, ERK, is markedly activated in mesangial cells cultured under high-glucose conditions and in glomeruli of diabetic rats, and this activation is mediated through a PKC-dependent mechanism.[200] The activated ERK participates in the induction of TGF-β and the production of extracellular matrix.[201]

Oxidative Stress as a Common Initiator

Generation of ROS has received much attention with regard to the initiation of diabetic microvascular complications, including kidney disease.[202] As espoused by Brownlee, increased ROS generation is a consequence of persistent exposure to high glucose and this process involves increased mitochondrial oxidation as well as decreased scavenging of ROS.[170,184] Glycolysis of intracellular glucose results in production of NADH and pyruvate. Mitochondrial NADH and $FADH_2$ provide energy for ATP production through oxidative phosphorylation via the electron transport chain. Electron transfer through the mitochondrial complexes generates ATP synthase via a proton gradient. With increased electron flux, a high-proton gradient, and a high electrochemical potential difference, superoxide generation is enhanced. In response to elevations in extracellular glucose, aortic endothelial cells generate intracellular ROS primarily via mitochondrial NADH and $FADH_2$ that are generated by the tricarboxylic acid cycle from cytosolic pyruvate.[184] Subsequent superoxide generation initiates DNA strand breaks leading to poly (ADP-ribose) polymerase (PARP)–mediated glyceraldehyde phosphate dehydrogenase (GAPDH) inhibition.[203] Inhibition of GAPDH may then mediate PKC activation, hexosamine formation, advanced glycation end products (AGEs) formation, and NF-κB activation.[170] Studies in human mesangial cells have shown a host of similar changes related to mitochondrial ROS generation.[204] An interesting finding is that high-glucose stimulation of mitochondrial ROS mediates COX-2 upregulation in human mesangial cells.[204]

Oxidative stress has been clearly demonstrated in several animal models of diabetic kidney disease. Markers for this state are often reflected in decrements of glutathione or increased urinary 8-isoprostane. Inhibition of ROS with α-lipoic acid[205] or via overexpression of a cytosolic superoxide dismutase[206] prevents diabetic kidney disease in rodent models. Inasmuch as the accumulated data show that mitochondrial generation of ROS occurs in endothelial cells, this mechanism likely plays an important role in the generalized endothelial dysfunction of diabetes, including the development of albuminuria. Apart from mitochondrial ROS, a membrane-bound NADPH oxidase may potentially contribute to high-glucose-induced ROS production.[151] Studies have identified a novel form of NADPH oxidase, NOX-4, in the kidney,[207] which is upregulated in animal models of diabetic kidney disease.[208] The role of NOX-4 in diabetic kidney disease is starting to be uncovered. Administration of antisense oligonucleotides inhibiting NOX-4 have been shown to decrease glomerular hypertrophy, and resulted in decreased fibronectin

expression in renal cortex and notably in the glomeruli.[209] Moreover, NADPH oxidases have been localized to podocyte, and the NOX-1 and NOX-4 isoforms are upregulated in hyperglycemic milieu both *in vitro* and *in vivo*.[210] The accumulation of ROS from mitochondrial and non-mitochondrial pathways in the podocyte builds up into apoptotic signals such as the p38 MAPK pathway.[211] Accordingly oxidative stress could be contributing to the pathological changes in diabetic nephropathy, including podocyte loss and albuminuria. The subcellular source of ROS in diabetic kidney disease remains to be clarified. Also, the role of inhibition of discrete pathways of ROS generation is an exciting area of research that can help dictate future therapies for diabetic nephropathy.

Nonenzymatic Glycation of Proteins

Glycated proteins arise from a condensation reaction, driven by the ambient glucose concentration, in which a free sugar covalently attaches to a protein at reactive NH_2 groups. Glycation proceeds through the formation of a labile Schiff base adduct, which then undergoes an intramolecular Amadori rearrangement to become a stable glucose-modified protein. The reaction occurs slowly, and the degree and duration of hyperglycemia influence the amount of glycated protein. Amadori-modified proteins may further evolve through a series of spontaneous rearrangement, dehydration, and polymerization reactions to become advanced glycation end products (AGEs). Nonenzymatic glycation can be mediated by a large variety of carbohydrates including glucose, and by methylglyoxal and 3-deoxyglucosone. In fact, methylglyoxal and 3-deoxyglucosone are far more reactive than glucose, forming adducts with amino groups of proteins, nucleic acid, and phospholipids up to several thousand times more readily than glucose. Although the chemical reactions involved are nonenzymatic, the production and detoxification of AGE precursors is actually controlled by enzymatic mechanisms. Thus the accelerated formation of glycated proteins in diabetes may result from increased production and/or decreased degradation. A large body of research has been devoted to understanding the role of glycated proteins in the pathogenesis of diabetic complications.

ROLE OF AMADORI-GLYCATED ALBUMIN

A large clinical study found that type 1 diabetic patients who have nephropathy manifest significantly higher levels of Amadori albumin than subjects without nephropathy.[212] The severity of tissue damage in diabetic nephropathy often parallels the localization of glycated proteins in glomeruli. Albumin modified by Amadori-glucose adducts has been linked to the development of diabetic nephropathy through its ability to activate PKC-β, upregulate the TGF-β system, and stimulate expression of extracellular matrix proteins in glomerular cells.[213–215] When PKC-β activity is specifically blocked by the selective inhibitor LY-379196, the increase in type IV collagen synthesis is prevented to the same degree,[214] consistent with the notion that the β isoform plays a predominant role among the PKC isotypes.[197,216] A putative cell-surface receptor is postulated to transduce the observed actions of glycated albumin.

Chronic administration of Fab fragments of an anti-glycated albumin antibody, A717, significantly lowers the plasma glycated albumin concentration in the diabetic *db/db* mouse and produces significantly less urinary albumin excretion.[217] Glomeruli from A717-treated *db/db* mice also showed considerably less mesangial expansion than control mice; this was associated with attenuation of the augmented mRNA levels for α1(IV) collagen and fibronectin.[217]

ROLE OF ADVANCED GLYCATION END PRODUCTS

The Maillard reaction, resulting in AGE production, alters protein structure and molecular surface composition, and this can profoundly change the affected molecule's biochemical properties and surface topology. Virtually any protein can be affected by glycoxidative modifications but particularly long-lived proteins including matrix and structural proteins or intercellular matrix components are prone to form AGEs.[218] The kidney, however, is not only a target of AGEs but also a culprit, as declining renal function is associated with retention in the plasma of high concentrations of these products.[219]

Glucose is a predominant source of reactive sugars for AGE formation but many other sugar molecules can also condense with proteins such as fructose, threose, glucose-6-phosphate, and glyceraldehyde-3-phosphate to produce different AGEs such as N^{ε}-(carboxymethyl)-lysine (CML) and pentosidine. Pentosidine is a cross-linking molecule that covalently bridges distant lysine and arginine residues by a complex C5-sugar ring thereby linking different proteins together or forming intramolecular covalent bonds. Protein adducts arising from this pathway are accordingly termed "advanced lipoperoxidation end products." Compounds such as malondialdehyde,

hydroxynonenal (HNE)-lysine, or acrolein adducts derived from oxidized hydroxy-aminoacids, L-serine or L-threonine, belong to the glycoxidation class of terminally modified proteins. Lipoxidative and glycoxidative pathways may converge, resulting in the same end product, CML, whereas pentosidine is only formed from carbohydrate precursors. In contrast, AGEs such as imidazolone and pyrraline adducts can also be generated independently from oxidative stress.

In the diabetic kidney, progressive tissue damage is closely related to the deposition of AGEs.[220] In an animal model, cellular and molecular growth events typical for progressive diabetic nephropathy can be almost mimicked by chronic intravenous infusion of CML-albumin.[221] AGEs induce connective tissue growth factor (CTGF) expression in the kidney through a TGF-β-mediated effect;[222] CTGF is known to mediate many of the profibrotic effects of TGF-β.[223] Interestingly, AGEs activate the TGF-β–Smad signaling pathway in mesangial cells by autocrine production of Ang II.[224] Pharmacological interventions using AGE-breaking agents or inhibitors of AGE formation such as aminoguanidine, OPB-9195, ALT-946, pyridoxamine and others have been widely used to prevent AGE-induced end-organ damage.[225]

In 1992, Schmidt and her colleagues first discovered a cellular surface receptor that binds AGE-modified proteins with high affinity, which was subsequently termed "receptor for AGE" (RAGE).[226] Subsequent research identified several additional cell surface molecules capable of binding AGE-modified proteins, including macrophage scavenger receptors (MSRs) type A and B1 (CD36), oligosaccharyl transferase-48 termed "AGE receptor 1" (AGE-R1), 80K-H phosphoprotein (AGE-R2), and galectin-3 (AGE-R3), the scavenger receptor. Among these molecules, RAGE has been best characterized. It is a 35-kD protein belonging to the immunoglobulin superfamily whose gene is located on chromosome 6. RAGE is a transmembrane receptor consisting of 394 amino acids with a single hydrophobic transmembrane domain of 19 amino acids and a C-terminal cytosolic tail of 43 amino acids.[227] The extracellular part consists of a terminal V-type and two distinct C-type domains (V-C-C) where V domains bind ligands and the highly charged cytosolic tail mediates activation of intracellular signal transduction pathways. Various mRNA splice variants have been detected that encode truncated proteins with different biological properties. The receptor can bind different AGE-adducts with high affinity, including CML and pentosidine.[228]

In normal human kidney, RAGE protein is found on glomerular podocytes and tubular epithelia by immunohistochemical techniques. In the presence of AGE ligands, susceptible cells can rapidly upregulate RAGE expression (e.g., in podocytes of diabetic kidney). In contrast, RAGE expression in other glomerular cells is generally less inducible.[229] Cellular expression of RAGE can be induced by AGE ligands as well as in the absence of AGEs, such as during inflammatory tissue remodeling or after direct cytokine stimulation by TNF-β. These experimental observations are on RAGE induction readily explained by the presence of NF-κB and SP-1 binding sites in the promoter region of the RAGE gene.

Activation of RAGE triggers multiple intracellular signal transduction cascades depending on the individual cell type.[230] This can include enhanced intracellular oxidant stress and activation of NF-κB by redox-sensitive signaling pathways.[231] AGEs may also inhibit cellular NO production, which is mediated at least in part by downregulation of eNOS and increased NADP(H) oxidase expression, thus linking RAGE activity to chronic endothelial cell dysfunction. RAGE activation can increase RAGE mRNA transcription directly and thus initiate an auto-amplifying loop. RAGE activation can also induce intracellular generation of hydrogen peroxide, which is dependent on the functional integrity of NADPH oxidase.

In diabetic nephropathy, renal expression of RAGE and VEGF increases considerably, including in podocytes.[134] Experimentally, soluble RAGE (sRAGE) has been used extensively as a tool to block RAGE-dependent effects in cultured cells and in experimental animals. Treatment of diabetic *db/db* mice with sRAGE significantly reduces the albuminuria and the glomerular hypertrophy. On the other hand, homozygous RAGE-null mice rendered diabetic do not develop increased renal VEGF and TGF-β expression, indicating a pivotal role for RAGE-dependent activation of these growth factors in the development of diabetic kidney disease.[124]

Renin-Angiotensin-Aldosterone System

Data from animal studies suggest that local angiotensin-generating systems exist in many tissues including the kidney, and these systems may operate independently of the systemic RAAS.[232] Micropuncture and microdialysis experiments in normal rats have demonstrated that proximal tubular and interstitial fluid contain Ang II concentrations in the nanomolar compared with picomolar range in the systemic circulation. These studies suggest that tubular cells possess a RAAS and can produce Ang II. Significant activation of the proximal tubular RAAS is presumed to occur in the diabetic state. Studies in early STZ-induced diabetes have shown enhanced expression of renin mRNA, which contributes to this local

RAAS activation. It is hypothesized that the increased local production of Ang II could contribute to tubulointerstitial injury in diabetes.

Of particular importance is the observation that systemic application of an ACE inhibitor results in almost complete inhibition of systemic Ang II formation but has only little effect on intrarenal Ang II production. Also of interest is that intact Ang II is intracellularly present in endosomes and is derived from receptor-mediated endocytosis that follows Ang II binding to its putative receptor. This could be an important mechanism because it has been demonstrated in certain cells that Ang II may directly go into the nucleus and could regulate gene transcription.[58]

Ang II is metabolized by peptidases such as aminopeptidase A (APA) into angiotensin III and further into angiotensin IV (Ang IV). Ang IV binds to a specific receptor named AT4. This receptor is widely expressed in the kidney including endothelial, proximal tubular, and distal convoluted tubular cells. Ang IV stimulates PAI-1 expression in proximal tubular and endothelial cells through AT4 receptors. Since PAI-1 reduces extracellular matrix turnover, Ang IV may induce renal fibrosis independently of activation of AT1 and AT2 receptors. Moreover, Ang IV-generating enzymes are upregulated in conditions with presumed high levels of Ang II in the kidney such as diabetic nephropathy, likely shifting more Ang II into the degradation pathway to Ang IV.[233]

Drugs interfering with the RAAS are a mainstay of therapy in preventing the progression of diabetic nephropathy as first reported by Zatz and coworkers in experimentally-induced diabetes.[234] Although initially considered to act solely through normalization of systemic and glomerular hypertension, it is now clear that inhibition of the RAAS has many effects, including antifibrotic and anti-inflammatory mechanisms. In fact, Ang II itself induces in renal cells many proinflammatory and profibrogenic cytokines, chemokines, and growth factors.[58] High glucose stimulates expression of renin and angiotensinogen in mesangial and tubular cells.[235,236] This stimulation results in an increase in local Ang II concentrations that may, in turn, through autocrine and paracrine pathways, induce a whole battery of different cytokines and growth factors. Experimental studies indicate that high-glucose–mediated generation of ROS is important in the upregulation of angiotensinogen in proximal tubular cells.[235]

Inhibition of the RAAS significantly reduces proteinuria in diabetic nephropathy as compared with other antihypertensive classes of medications. Treatment with ACE inhibitors or AT1-receptor antagonists attenuate podocyte foot process broadening in STZ-diabetic rats.[113,114] An AT1-receptor antagonist, but not the calcium channel blocker amlodipine, normalized the reduced nephrin expression in podocytes from spontaneously hypertensive rats with superimposed STZ-induced diabetes.[237] Thus, a local increase in Ang II leads to suppression of nephrin expression in podocytes, and thereby can enhance the ultrafiltration of proteins. Podocytes express AT1 and probably AT2 receptors and could respond to stimulation with Ang II. Transgenic rats with targeted overexpression of the AT1-receptor to podocytes showed pseudocysts in podocytes, followed by foot process effacement and local detachments.[238] These changes subsequently progressed to focal segmental glomerulosclerosis.

Podocytes are also a likely site for Ang II generation. It has been previously shown that high ambient glucose concentration induces Ang II formation in podocytes through upregulation of angiotensinogen expression.[239] Furthermore, proteinuria and the transit of proteins through the ultrafiltration barrier likely activate Ang II formation in podocytes. Finally, mechanical stretch could increase Ang II generation in podocytes.[240] Interestingly, Ang II formation as a consequence of mechanical stress appears to be independent of ACE. In this regard, it has been demonstrated that chymase, an Ang II forming enzyme not inhibited by ACE inhibitors, is upregulated in glomeruli of patients with nephropathy due to type 2 diabetes.[241] This observation suggests that local glomerular formation of Ang II in the diabetic state may be partly independent of ACE and may not be abolished by ACE inhibition alone.

Activation of the RAAS may play an important role in macrophage recruitment. Biopsy studies from patients with diabetic nephropathy and investigations in various animal models have revealed the presence of inflammatory cells, especially mononuclear cell infiltrates, in the glomerular and tubulointerstitial compartments.[242] Monocyte chemoattractant protein-1 (MCP-1) is an important chemokine for macrophages/monocytes, and high glucose has been shown to stimulate MCP-1 expression in mesangial cells. In fact, increases in tubular expression of MCP-1 and RANTES, members of the C-C chemokine subfamily with chemoattractant properties for monocytes/macrophages, have been found adjacent to infiltrating immune cells in renal biopsy specimens from patients with diabetic nephropathy.[243,244] The MCP-1 increase could be relevant in another way that does not involve macrophages. MCP-1 directly stimulates matrix expression in mesangial cells[245] and increases cellular motility in podocytes,[246,247] having the associated effect of making a podocyte monolayer more permeable to albumin. Extrapolated to diabetic nephropathy, these MCP-1 effects may abet the process of mesangial matrix expansion and diabetic albuminuria. The proinflammatory transcription factor NF-κB has been detected mainly in tubular cells in biopsy specimens from 11

patients with type 2 diabetes and overt nephropathy, indicating that proteinuria may have contributed to this activation.[243] Activation of the RAAS may play an important role in this process. In animal models of kidney disease there is upregulation of NF-κB in tubular cells that is inhibited by inhibitors of the RAAS.[58,248] Ang II, through an effect mediated by AT2 and not AT1 receptors, increases the mRNA and protein levels of RANTES in cultured glomerular endothelial cells.[249] Intraperitoneal infusion of Ang II into naive rats for 4 days significantly stimulates glomerular influx of macrophages/monocytes as well as the expression of RANTES mRNA and protein in the glomeruli, mainly in endothelial cells and small capillaries.[249] Ang II also stimulates the chemoattractant cytokines MCP-1 and osteopontin in mesangial and tubular cells, which may play a role in glomerular and tubular inflammation associated with proteinuria.[250]

Aldosterone, working independently from the RAAS, may be involved in the development of diabetic nephropathy.[251] The aldosterone antagonist spironolactone attenuates the enhanced TGF-β1 expression and the increased collagen deposition in rats three weeks after STZ administration.[251] In a preliminary study, Schjoedt and colleagues observed that an increased plasma aldosterone level during long-term treatment with an AT1-receptor blocker is associated with a decline in GFR in patients with nephropathy due to type 1 diabetes.[252] These data demonstrate that aldosterone contributes to the progression of diabetic nephropathy despite blockade of the AT1 receptor. Spironolactone decreases proteinuria in patients with type 2 diabetes and early nephropathy.[253] The more selective aldosterone antagonist, eplerenone, also decreases the microalbuminuria in patients with type 2 diabetes independent of its antihypertensive effect.[254] In addition to direct effects on renal cells, aldosterone also potentiates the Ang II-mediated signal processes such as MAPK activation, indicating that Ang II and aldosterone act in concert.[255]

In summary, there are many deleterious effects of the RAAS in the pathophysiology of diabetic nephropathy. Early treatment with drugs that interfere with RAAS activation, especially ACE inhibitors and AT1 receptor blockers, is a major mainstay in the clinical management of the diabetic patient who is at risk of developing nephropathy.

TGF-β is the Common, Downstream Mediator of Diabetic Nephropathy

The cytokine TGF-β has risen to prominence in the past several years as the principal mediator of progressive renal diseases including diabetic nephropathy. TGF-β has been shown to be the final common pathway or mediator that leads to the hypertrophic and prosclerotic changes in diabetic kidney disease, thus fulfilling all of Koch's postulates as a chief etiologic agent of the disease.[122,256,257] TGF-β stimulates the synthesis of key extracellular matrix molecules including type I collagen, type IV collagen, fibronectin, and laminin.[258] TGF-β also decreases matrix degradation by inhibiting proteases as well as activating inhibitors of those proteases (e.g., PAI-1).[259] Additionally, TGF-β promotes cell−matrix interactions by upregulating integrins, the cell-surface receptors for matrix.[260]

The biologic effects of TGF-β in kidney cells, which include cell hypertrophy and stimulation of extracellular matrix production, closely resemble those of hyperglycemia. Almost all of the molecular mediators and intracellular signaling pathways that have been identified in diabetic kidney injury have also been found to stimulate the renal TGF-β activity as an intermediary step (see also Table 78.4). These include high-glucose concentration;[261] early (Amadori) as well as AGE-modified proteins;[215,262] oxidative stress and overproduction of superoxide by the mitochondrial electron-transport chain;[170,202,263] cyclical stretch/relaxation of mesangial cells in culture;[163] de novo synthesis of diacylglycerol and PKC activation;[192,197] stimulation of MAPK, such as ERK;[201] glucosamine overproduction;[183] and high levels of vasoactive substances such as Ang II,[74,264] endothelin,[265] and thromboxane.[266]

Studies in animal models of both type 1 and type 2 diabetes further implicate TGF-β as an important mediator of diabetic kidney disease. TGF-β1 mRNA and protein levels are increased in both the glomerular and tubular compartments of rat and mouse models of diabetes.[267−269] Of particular significance is the finding of concomitant upregulation of the renal TGF-β type II signaling receptor in tubules and glomeruli.[270,271] In almost all renal cell types studied in tissue culture (except perhaps for podocytes), high ambient glucose has been shown to upregulate the expression and bioactivity of TGF-β; these include proximal tubular epithelial cells, glomerular mesangial and endothelial cells, and interstitial fibroblasts.[75,121,122,272] In all renal cells studied, including podocytes, high glucose also upregulates the TGF-β type II receptor.[271,273]

Human studies have also corroborated the important role that the renal TGF-β system plays in the pathogenesis of diabetic nephropathy.[274,275] Glomerular TGF-β1 mRNA is markedly increased[276] and there is net production of TGF-β1 protein by the kidney in diabetic patients.[277] Interestingly, therapy with an ACE inhibitor protects the kidney through a host of mechanisms that also include the lowering of TGF-β1 production.[278] In fact, a decrease in the circulating TGF-β1 level predicts a better long-term preservation of the GFR.[278]

Blocking the activity of the renal TGF-β system in diabetic animals has provided proof-of-concept that the development of renal disease is due to overactivity of this system in diabetes. Neutralizing monoclonal antibodies to TGF-β prevent the glomerular hypertrophy and attenuate the increase in TGF-β1, α1(IV) collagen, and fibronectin mRNAs in STZ-induced diabetes in mice.[279] Also, the antibody therapy in the *db*/*db* mouse, a model of type 2 diabetes, prevents the mesangial matrix expansion (but without affecting the albuminuria).[121] This latter finding may suggest that diabetic proteinuria, unlike the hypertrophic and prosclerotic renal manifestations of diabetes, is mediated by increased podocyte-derived VEGF rather than by TGF-β.[101,121,124,125]

Hypoxia and Diabetic Nephropathy

Clinical studies have provided evidence that even mild anemia (hemoglobin <13.8 g/dl) increases risk for progression in patients with type 2 diabetes and nephropathy.[280] Moreover, treating anemia early in renal failure with erythropoietin slows the decline of renal function.[281] In practice, however, the benefit of erythropoiesis-stimulating agents has not held up to the scrutiny of several large, prospective, randomized controlled trials such as TREAT which showed no renal benefit and no delay in the progression to ESRD with darbepoetin alfa.[286] The exact mechanisms by which anemia increases the risk for progression of diabetic nephropathy are incompletely understood, but a few suggestions could be made. Anemia likely causes renal hypoxia. It has been described in experimental models of chronic renal injury that hypoxia is an important factor aggravating interstitial fibrosis, partly by the induction of factors such as TGF-β and VEGF. The transdifferentiation of tubular epithelial cells into fibroblasts, an important process contributing to tubular atrophy and interstitial fibrosis, is stimulated by cellular hypoxia and mediated, appropriately enough, by hypoxia-inducible factor-1 (HIF-1), a transcription factor that plays a role in regulating genes critical to the adaptation to low oxygen.[282–284] Certain growth factors and cytokines are stimulated by HIF-1 which itself can be increased by Ang II via activation of AT2 receptors, leading to the suppression of SM-20, a dihydrogenase involved in hydroxylation of HIF-1α.[58] Since hydroxylated HIF-1α is rapidly degraded through the proteasome, the Ang II-mediated decrease in hydroxylation leads to stabilization of this important transcription factor. Thus, hypoxia plus Ang II may induce growth factors and signaling pathways with potentially deleterious effects in diabetic nephropathy. On the other hand, erythropoietin application may have additional effects in addition to correcting anemia, and the mobilization of potential progenitor cells by this treatment has become the focus of active research.[285] Certainly, more experiments are necessary to elucidate how anemia may contribute to the development and progression of diabetic nephropathy. Lastly, any well-meaning attempt to correct anemia for the sake of diabetic nephropathy has to be weighed against the not-inconsiderable risk of stroke, hypertension, other cardiovascular event, and possibly increased mortality that seem to arise from the overzealous use of erythropoiesis-stimulating agents.[286–290]

METABOLIC SYNDROME/OBESITY AND RENAL DISEASE

The metabolic syndrome is increasingly being recognized as a major contributor to cardiovascular diseases among large segments of the population worldwide. Although once relegated to a constellation of risk factors that were not considered to play a major role in kidney diseases, analyses in large population groups have identified the metabolic syndrome as a major risk factor for chronic kidney disease. Conversely, chronic kidney disease has also emerged as a key risk factor for predicting cardiovascular disease even in patients with mild renal dysfunction.

The metabolic syndrome is defined as having at least three of the following five parameters: increased waist circumference, elevated triglycerides, decreased high-density lipoproteins (HDLs), elevated blood pressure, and elevated fasting blood glucose.[291] These values have been derived primarily from the white population and will likely need to be redefined for different ethnic groups. It appears that some Asian populations develop the metabolic syndrome with lesser levels of waist circumference,[292] whereas African Americans may exhibit features of insulin resistance without a correlation with visceral adiposity.[293] Values pertaining to blood pressure and fasting blood glucose may also need to be revised as lower levels of pressure and glucose have been associated with increased cardiovascular risk. Other features such as albuminuria and left ventricular hypertrophy may also be added to the definition.[294] The major outcome of the metabolic syndrome is the increased risk these patients have for developing myocardial infarctions, strokes, and diabetes mellitus.

The recognition that the metabolic syndrome is strongly associated with kidney disease has only been appreciated in the past few years.[295] In 2003, a statistical relationship was found between features of the metabolic syndrome and albuminuria using the Third National Health and Nutrition Survey (NHANES III)

cohort.[296,297] In 2004, Chen et al.[298] found that each component of the metabolic syndrome added to the risk of impaired renal function as estimated by four different GFR formulas that are based on the serum creatinine value. The estimated GFR has also been inversely correlated with the development of cardiovascular disease and poor outcome after a major cardiovascular event.[299,300] In addition, even low levels of albuminuria in patients with left ventricular hypertrophy are associated with increased cardiovascular risk.[294] The interplay between heart and kidney, that chronic kidney disease is adversely influenced by chronic heart disease and vice versa, has recently been promulgated as the cardiorenal syndrome.[301] Therefore, it is apparent that there is a very close relationship between the metabolic syndrome, renal dysfunction, and cardiovascular endpoints. However, the mechanisms linking this triad together remain unclear.

The nature of the kidney lesions associated with the metabolic syndrome has not been clearly established. Studies have found that obese individuals (body mass index [BMI] >30) have large kidneys and glomerulomegaly (reviewed in[295]). This appears to be strikingly uniform such that almost 100% of patients with obesity-related kidney disease exhibit glomerulomegaly.[302] In addition, several studies have demonstrated an altered hemodynamic profile in obesity. Thus, obese patients have increased renal blood flow, increased filtration fraction, and mild glomerular hyperfiltration.[303,304] The close resemblance of obesity-related kidney disease to the early features of diabetic kidney disease is intriguing. However, the pathologic lesion in the former is distinct from diabetic nephropathy as there is typically focal and segmental glomerulosclerosis rather than diffuse mesangial matrix expansion or nodular glomerulosclerosis.[302]

The mediators of kidney disease associated with the metabolic syndrome and obesity have not been identified. Using the NHANES data, the fasting blood glucose and systolic blood pressure are the most closely linked to albuminuria and the development of renal insufficiency.[298] Sleep apnea and hypoxia may also contribute to kidney impairment. It is now recognized that visceral adipocytes are a potent source of deleterious factors that could impact renal function. Visceral adipocytes probably produce all components of the RAAS, and this may contribute to systemic hypertension and altered renal hemodynamics.[305,306] Production of leptin, VEGF, endothelin-1, TGF-β, and PAI-1 by adipocytes[307–309] may also contribute to hypertension, altered glomerular blood flow, glomerulomegaly, focal sclerosis, and albuminuria. Production of adipocyte-derived TNF-α may mediate an inflammatory cascade in the kidney that leads to renal dysfunction. Alternatively, the adipocyte-induced regulation of adiponectin may contribute to endothelial dysfunction and renal injury.[295]

Treatment approaches for the metabolic syndrome are only now being addressed. Weight loss and exercise are important cornerstones and greater attention is required to allow physicians to incorporate behavior-altering regimens into their clinical practice. Apart from behavior modification, attention has been paid to the role of PPAR-γ agonists (glitazones) and inhibitors of the RAAS. The glitazones are able to decrease visceral adiposity by inhibiting adipocyte hypertrophy and proliferation.[310] The recognition that both ACE inhibitors and AT1 receptor blockers are able to decrease insulin resistance and lower hemoglobin A1c may in part be due to adipocyte-derived activation of the RAAS.

REGRESSION

One would assume that the morphological alterations of advanced diabetic nephropathy (e.g., glomerulosclerosis, interstitial fibrosis) are not reversible and represent a one-way road to ESRD. Experimental[311] and clinical studies[312] show, however, that this pessimistic scenario is not necessarily true. Several studies indicate that aggressive blood pressure control with agents that interfere with the RAAS leads to remission of overt proteinuria. Fioretto and colleagues performed serial renal biopsy in eight patients with type 1 diabetes and nephropathy who had undergone a successful pancreas transplantation.[312] These investigators found that sustained euglycemia reversed the morphological alterations of diabetic nephropathy, including increased GBM thickness and mesangial matrix expansion, 10 years after receiving the pancreas transplant. The regression of diabetic nephropathy was convincing, but clearly this process takes time. In addition, Perkins et al.[313] showed that the onset of sustained microalbuminuria does not imply an inexorable progression to nephropathy, at least not in patients with type 1 diabetes. This study provides indirect evidence that aggressive management aimed at various risk factors could lead to remission of albuminuria. Since no renal biopsies were performed in this study, it remained unproven whether morphological changes of diabetic nephropathy were also improved. Although the molecular mechanisms surrounding regression are currently incompletely understood, it is possible that induction of metalloproteinases that may degrade the deposited extracellular matrix play a central role in the healing. Nevertheless, there is light at the end of the tunnel and a better understanding of the complex pathophysiology of diabetic nephropathy will likely improve a multipronged approach to induce regression.

SUMMARY AND OUTLOOK

Only a minority of diabetic patients will ever develop diabetic kidney disease. This has been the major impetus to try to identify those genes that are either predisposing to or protective against the development of diabetic kidney disease. Much remains to be understood about the genetic factors that are at play. Another concept that has emerged is that injury to the kidney in susceptible patients may start before diabetes mellitus has fully manifested. Evidence is emerging that the metabolic syndrome can injure the kidney through many different mechanisms in addition to hypertension and hyperglycemia. Although it has been debated for many years whether hemodynamic or metabolic changes are more important in the development of overt diabetic nephropathy, it is now clear that metabolic events can be triggered by hemodynamic stress and thus these processes are interwoven, depicting two sides of one coin. On a molecular level, metabolic pathways activated by hyperglycemia as well as by proteins altered by high blood glucose such as Amadori products and AGEs are key players in the development of diabetic nephropathy. Oxidative stress that is induced by high-glucose–mediated activation of the mitochondrial electron-transport chain is an early event in the development of diabetic complications. A variety of growth factors and cytokines are then induced through complex signal transduction pathways involving PKC, MAPK, and NF-κB. The cytokine TGF-β has emerged as an important downstream mediator for the development of renal hypertrophy and the accumulation of extracellular matrix components. Activation of the RAAS in different kidney compartments by high glucose, mechanical stress, and proteinuria can cause many of the pathophysiological changes associated with diabetic nephropathy. In fact, it has been shown that Ang II is involved in almost every pathophysiological process implicated in the development of diabetic nephropathy (hemodynamic changes, hypertrophy, extracellular matrix accumulation, growth factor/cytokine induction, ROS formation, podocyte damage, proteinuria, interstitial inflammation, and fibrosis). Consequently, blocking the deleterious effects of Ang II is an essential part of every therapeutic regimen to prevent and treat diabetic nephropathy. There is hope that regression of diabetic nephropathy could be achieved under certain circumstances.

Renal failure is a common complication of patients with advanced cirrhosis. Early studies in patients with cirrhosis focused the attention on a distinctive form of renal failure characterized by progressive azotemia associated with marked abnormalities of the systemic arterial circulation and normal renal histology, a condition later known as hepatorenal syndrome (HRS).[1–4] However, HRS is not the only cause of renal failure in cirrhosis. Patients with cirrhosis may develop renal failure due to a variety of clinical conditions, including bacterial infections (with or without septic shock), gastrointestinal bleeding (with or without hypovolemic shock), administration of non steroidal antiinflammatory drugs (NSAIDs), and intrinsic renal diseases, particularly glomerulonephritis associated with hepatitis B or C infection or alcoholic liver disease.[5] Because the approach to management of renal failure in patients with cirrhosis is different according to the etiology of renal failure, it is essential to establish the cause of renal failure before starting any specific therapy. The aim of this chapter is to review the current approach to renal failure in patients with cirrhosis, with particular emphasis on the pathogenesis, diagnosis, and management.

DEFINITION

The diagnosis of renal failure in patients with cirrhosis is established when serum creatinine increases over 1.5 mg/dL (133 μmol/L) which corresponds to a glomerular filtration rate (GFR) of approximately 30 ml/min.[5–7] Although serum creatinine is the most commonly used GFR marker in cirrhosis, it has some limitations[7,8] Serum creatinine may overestimate GFR mainly due either to decreased creatinine production or reduced muscle mass. Additionally, it is considered that baseline serum creatinine below <1.5 mg/dl does not necessarily exclude renal dysfunction.[9–11] Creatinine clearance also overestimates GFR; more so in those with low GFR.[11] There are no data to indicate that creatinine clearance is better or preferred to serum creatinine concentration as a marker of GFR in patients with cirrhosis. In addition, creatinine clearance is difficult to perform because it depends on the adequate collection of urine volume over 24 hours, which in many cases is inadequate, especially in oliguric patients.[11,12] The estimation of GFR with the Cockcroft and Modification of Diet in Renal Disease (MDRD) equations are based on serum creatinine and therefore have

Seldin and Giebisch's The Kidney, Fifth Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-381462-3.00079-3

not shown to be very useful in cirrhosis.[13–15] The gold standard for measuring GFR in cirrhosis relies on clearance techniques of exogenous markers.[7,8] Use of these techniques allows the precise estimation of GFR, which helps to classify patients with chronic kidney disease according to categories previously defined by the National Kidney Foundation.[16] Inulin has been the most widely used marker as it is completely filtered by the glomerulus without being secreted, reabsorbed, synthesized, or metabolized by the ducts. Thus, after an intravenous infusion and at a stable concentration in healthy subjects, the amount filtered equals to the amount excreted in urine. However, this method is cumbersome, expensive and not available in all settings. Other markers such as radiolabeled compounds (51Cr-EDTA, 99mTc-DPTA and 125I-iothalamate) or iohexol/iothalamate are useful, but there are expensive, they expose the patient to radiation if used repeatedly, and they have not been specifically or adequately studied in cirrhosis.

The above-mentioned limitation of using serum creatinine as a marker of renal function may require that the current definition undergo reassessment. New proposed criteria including the acute kidney injury and chronic kidney disease definitions may be useful in patients with cirrhosis but these need to be properly studied[6] Given the above, serum creatinine concentration is still considered the method of choice to estimate GFR in cirrhosis in clinical practice. Although a single measurement of serum creatinine alone is probably inadequate for identifying and/or quantifying either acute or chronic renal disease in cirrhosis repeated measurements over time may be useful in indicating variations of GFR in clinical practice.

Etiology and Epidemiology

There are several causes of renal failure in cirrhosis due to a variety of clinical conditions (Table 79.1). These etiologies are classified as: (1) renal failure associated with infections, (2) hypovolemia induced renal failure (3) intrinsic renal diseases, (4) hepatorenal syndrome (HRS), and (5) drug-induced renal failure. In patients with cirrhosis and ascites the one year probability of developing HRS ranges between 18-23% at one year and increases up to 40-50 % at three to five years of follow-up.[17,18] (Figure 79.1). A systematic review of 74 studies showed that the overall median mortality in patients with cirrhosis and renal failure was 67%, with a 58% mortality at 30 days and 63% mortality at one year[19]In an analysis of 562 hospitalized patients with cirrhosis and renal failure, the most frequent cause of renal failure in cirrhosis was that associated with bacterial infections (46%), followed by hypovolemia-induced renal failure (32%), HRS (13%), parenchymal nephropathy (9%), drug-induced renal failure (7.5%), mixed causes (8%) and other causes (2%).[19] Patients with intrinsic renal disease had a 73% survival at three months followed by a 46% survival in those with hypovolemia-related renal failure. Those with renal failure associated with infections and HRS had the lowest three-month survival probability, 31 and 15% respectively.[19] (Figure 79.2).

TABLE 79.1 Main Causes of Renal Failure in Patients with Cirrhosis

1. Infections
   - **a.** Spontaneous bacterial peritonitis
   - **b.** Spontaneous bacteremia
   - **c.** Urinary tract infection, pneumonia, skin infections
2. Hypovolemia-induced renal failure
   - **a.** Vomiting, diarrhea
   - **b.** Gastrointestinal bleeding (with or without shock)
   - **c.** Diuretic-induced
3. Hepatorenal syndrome
4. Intrinsic renal diseases
   - **a.** Glomerulopathies – IgA nephropathy, membranous nephropathy, membranoproliferative glomerulonephritis, polyarteritis nodosa, cryoglobulinemia due to viral hepatitis, or alcohol.
   - **b.** Chronic kidney diseases due to diabetes, hypertension or other causes.
5. Drug induced renal failure
   - **a.** Hemodynamically induced—Nonsteroidal anti-inflammatory agents, ACE Inhibitors, Angiotensin receptor blockers
   - **b.** Acute tubular necrosis- Aminoglycosides, Amphotericin B, Tenofovir, Adefovir
   - **c.** Acute interstitial nephritis- penicillin, rifampin and sulfonamides

Approach to Renal Failure in Cirrhosis

It is essential to establish the underlying etiology of renal failure before considering further management. That said, there are no specific tests that secure the diagnosis of the different types of renal failure in cirrhosis. In most cases a detailed clinical history, physical exam and assessment of renal function with a thorough evaluation of urine and serum electrolytes will suffice for establishing the cause (Table 79.2). Renal ultrasonography needs to be performed in order to rule out the existence of abnormalities in renal structure suggestive of chronic kidney disease or urinary tract obstruction. Data on urine biomarkers and renal biopsy in the assessment of renal failure in cirrhosis is limited and therefore cannot be routinely recommended in the workup of renal failure in cirrhosis. Since the diagnosis of HRS cannot be made with a specific test, its confirmation is currently made using criteria to exclude other causes of renal failure that can occur in cirrhosis. So, if after an extensive investigation there is no evidence of infection, hypovolemia, administration of nephrotoxic drugs, or intrinsic renal diseases, then HRS should be considered the cause of renal failure. The diagnosis of HRS is based on specific clinical criteria that aim to exclude other causes of renal failure that are not functional, see (Table 79.3) below.

INFECTIONS AND RENAL FAILURE

Bacterial infections are the most common cause of renal failure in cirrhosis. The pathogenesis seems to be related to an impairment of the systemic arterial vasodilation present in cirrhosis due to bacterial products, cytokines or vasoactive mediators that appear in relation with the infection.[21] This occurs mainly in patients that develop spontaneous bacterial peritonitis (SBP) and spontaneous bacteremia, but may occur with any bacterial infection[18,19,22] It is estimated that bacterial infections are present at admission or during hospitalization in 20-60% of patients.[19,22,23] Of these, most are secondary to SBP, other common causes are urinary tract infection, pneumonia and bacteremia[22,23] which are due to both gram negative bacteria and aerobic gram-positive bacteria.[24] Bacterial infections

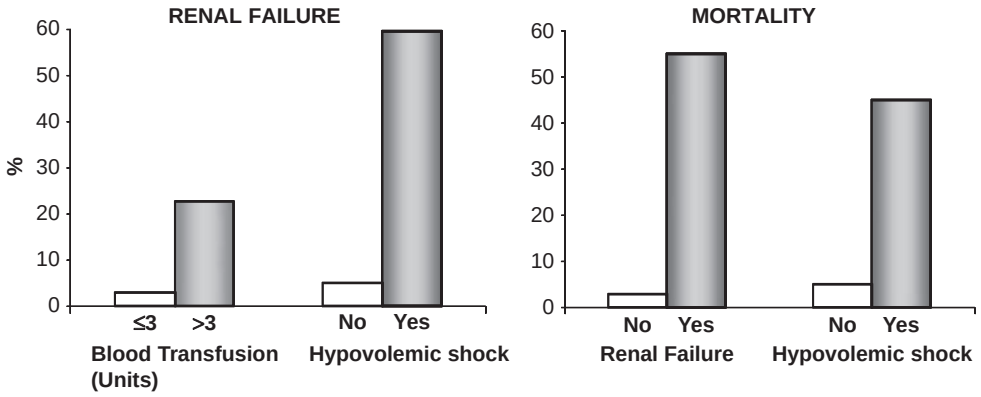

FIGURE 79.3 Renal failure in patients with gastrointestinal bleeding. Left panel: Renal failure according to the number of units of blood transfused and presence or absence of hypovolemic shock (*p < 001). Right panel: In-hospital mortality in patients with cirrhosis and gastrointestinal bleeding according to the development of renal failure and presence or absence of hypovolemic shock (*p < 0.01). *Reproduced with permission from Ref.* [27].

significantly increase mortality in patients with cirrhosis. A meta-analysis of 178 studies estimated that the overall mortality of infected patients with cirrhosis was 38%.[25] The same analysis concluded that the mortality in those with SBP was 43.7% and in those with bacteraemia (1437 patients), the mortality was 42.2%.[25] In any patient with cirrhosis that develops renal failure, the presence of a bacterial infection should be thoroughly sought after. It is important to take into account that signs and symptoms of early bacterial infection may be vague or even absent in some patients with cirrhosis. The mandatory workup consists of a complete blood cell count, liver chemistries, polymorphonuclear cell count in a sample of ascitic fluid, ascitic fluid cultures, urine sediment and culture, abdominal ultrasound, chest X-ray and blood cultures.

HYPOVOLEMIA-INDUCED RENAL FAILURE

Pre-renal renal failure occurs due to a reduction in intravascular volume that causes a drop in renal plasma flow and GFR. In hypovolemia-induced renal failure the major mechanism responsible for renal hypoperfusion is a reduction in intravascular volume which, if severe, may lead to acute tubular necrosis (ATN).[5,6,26] The main causes of hypovolemia in cirrhosis are gastrointestinal bleeding and overdiuresis due to excessive diuretic treatment followed by gastrointestinal fluid losses due to vomiting and/or diarrhea. In most cases, renal function improves after elimination of the precipitating cause and plasma volume expansion. Patients need to be thoroughly questioned about gastrointestinal bleeding, and physical examination should include a rectal exam to rule-out melena, bright red blood per rectum or occult blood if gastrointestinal bleeding is suspected. A naso-gastric tube should be considered if there is a high suspicion of upper GI bleeding. Additionally, if patients were taking diuretics, the type and doses need to be clarified. Patients with cirrhosis and gastrointestinal bleeding require an important reduction in blood volume which in most cases is associated with hypovolemic shock in order to develop renal failure.[27] In moderate to severe cases of GI bleeding (those requiring >3 units of packed red blood cells) there is a 20% chance of developing renal failure. In mild cases this figure drops to less than 5%.[27] When hypovolemic shock develops in patients with cirrhosis and gastrointestinal bleeding there is a 60% probability of developing renal failure and mortality rates are very high (Figure 79.3).

INTRINSIC RENAL DISEASES

Most intrinsic renal diseases are related to common etiologic factors of cirrhosis, including chronic hepatitis B or C infection or alcoholic liver disease. Most encompass kidney diseases secondary to the deposition of circulating immunocomplexes in the glomeruli. The commonest in hepatitis C are membranoproliferative glomerulonephritis, membranous glomerulonephritis and focal segmental glomerular sclerosis.[28] Membranous nephropathy is commonly encountered in patients with hepatitis B and IgA nephropathy in patients with alcoholic cirrhosis.[28] In some patients, the glomerular deposits are mild and do not affect kidney function, whereas in other patients they are so severe that GFR markedly decreases and renal failure develops. In patients with cirrhosis and renal failure due to intrinsic renal diseases, there is usually proteinuria or hematuria. Intrinsic renal disease is considered if there is either proteinuria greater than 500 mg/24-hr, abnormal urine sediment with more than 50 red cells per high power field, or abnormal

renal ultrasound findings in the absence of other causes of renal failure.[6] However some patients with renal failure due to chronic kidney disease may not necessarily meet the definition. Therefore, criteria for this definition are specific but lack sensitivity and thus need to be properly studied.

The role of kidney biopsy in the evaluation of renal failure in cirrhosis is a matter of debate in some centers. Findings demonstrating glomerulosclerosis or significant fibrosis in the renal parenchyma may require the patient receive dialysis or a simultaneous liver–kidney transplant (if being consider for liver transplantation-LT). Limited data indicates that in transvenous renal biopsies in patients with hematuria or proteinuria, various types of lesions may be present. In one retrospective study of 65 patients, renal biopsy showed that glomerular, vascular and tubulointerstitial changes in 77, 69 and 94% of cases respectively.[29] Fibrous endarteritis was the most common renal vascular lesion and pathological changes to different structures were frequently combined. There were no reported complications of transvenous renal biopsy.[29] Another report of 44 liver transplant candidates with renal failure of undetermined etiology that underwent percutaneous renal biopsy revealed that IgA nephropthy and ATN were the most common findings, however there was more than one pathological finding (i.e., interstitial fibrosis, glomerular sclerosis, or membranoproliferative disease) in 64% of patients.[30] A disappointing finding was the development of serious complications (mainly bleeding) requiring intervention in 18% of patients. Therefore the role of renal biopsy in patients with cirrhosis still needs be studied, however a renal biopsy, preferably via transvenous route should be obtained in those patients in whom the diagnosis of HRS is unclear and are being considered for liver transplantation.

HEPATORENAL SYNDROME

HRS is a pre-renal renal failure without any identifiable kidney pathology that occurs in patients with advanced cirrhosis.[31–33] Patients with very advanced liver disease display a profound disturbance in the systemic circulation, characterized by a low arterial blood pressure, high cardiac output and a decreased total systemic vascular resistance. This hemodynamic pattern is due to an intense arterial vasodilation occurring in the splanchnic vascular bed that triggers a neurohormonal response with the activation of the renin- angiotensin-aldosterone system, the sympathetic nervous system and the non-osmotic release of arginine vasopressin (the antidiuretic hormone) aimed at maintaining arterial pressure that eventually leads to vasoconstriction in several vascular beds, particularly the kidneys, decreasing the GFR (Figure 79.4).[5,6] As the disease progresses, splanchnic vasodilation worsens and this creates a vicious cycle that favors further activation of vasoconstrictors (renin, norepinephine and vasopressin) and ongoing renal vasoconstriction that establishes HRS. Although the kidney tries to

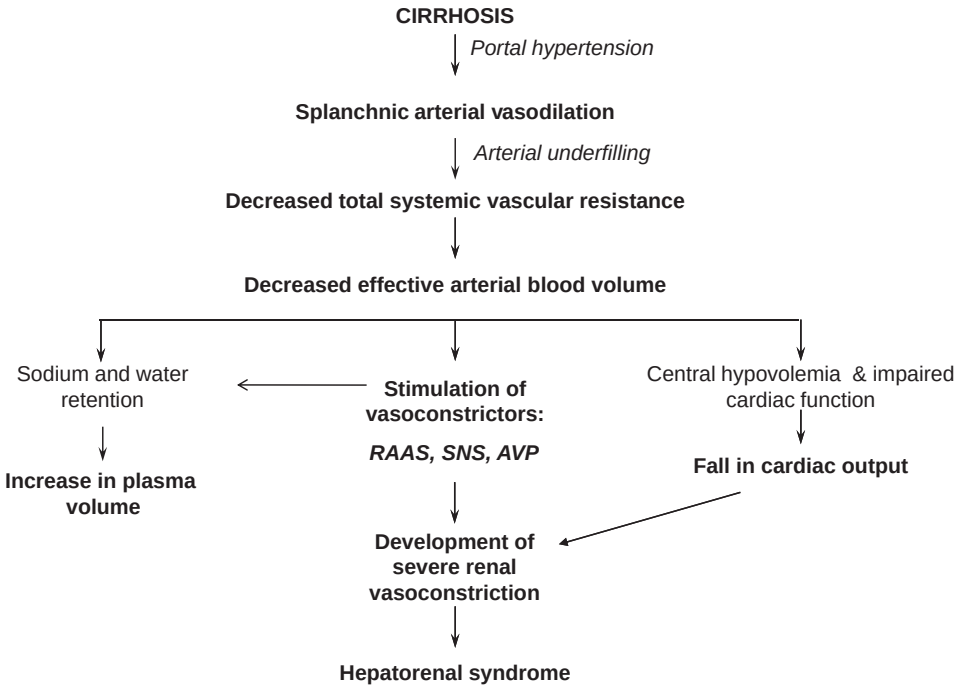

FIGURE 79.4 Proposed pathogenic mechanism of hepatorenal syndrome. Splanchnic vasodilation arising from portal hypertension, an increased plasma volume and a decreased cardiac output seem to play an equally important role in the decreased renal perfusion leading to HRS. The impairment effective arterial blood volume responsible for the activation of vasoconstrictor systems acting on renal circulation is a consequence of both a low systemic vascular resistance causing an abnormal distribution of blood volume and a low cardiac output relative to the markedly dilated arterial bed secondary to cirrhotic cardiomyopathy. (RAAS) Renin-angiotensin-aldosterone system, (SNS) sympathetic nervous system (SNS), and (AVP) arginine vasopressin.

counterbalance the effects of this vasoconstriction with the intrarenal production vasodilators such as prostaglandins, the incessant overproduction of vasoconstrictor factors overcomes their protective role and HRS ensues. In the early stages of cirrhosis there is an increase in cardiac output that compensates for a mild decrease in systemic vascular resistance, but in very advanced cirrhosis there is marked reduction in systemic vascular resistance for which the increased cardiac output cannot compensate for with the development arterial underfilling of circulation. Additionally, in the very advanced stages of cirrhosis cardiac output drops which contributes to decreased effective arterial blood volume and decreased renal perfusion.[34,35] In recent years several studies indicate that adrenal insufficiency (AI) in compensated and decompensated cirrhosis occurs in 26-64% of patients.[36] In those with ascites it might play a role in the pathogenesis of HRS. Normal adrenal function is essential for an adequate response of the arterial circulation to endogenous vasoconstrictors, thus AI could be an important contributory mechanism of circulatory dysfunction associated with renal failure induced by bacterial infections. In one study, adrenal insufficiency was found in 80% of patients with HRS but only in 34% with serum creatinine below 1.5 mg/dL.[37] Another study showed that in patients with cirrhosis, sepsis and adrenal insufficiency treatment with hydrocortisone was associated with a rapid improvement in systemic hemodynamics and a reduction of vasopressor requirements.[38] More studies are needed to clarify the clinical importance of AI in cirrhosis and define the impact of corticosteroid supplementation in patients with liver disease and HRS.

Due to the lack of specific diagnostic markers, the diagnosis of HRS is currently made using criteria to exclude other causes of renal failure that can occur in cirrhosis (Table 79.3).[31–33] There are two types of HRS; in Type 1 HRS renal function deteriorates rapidly with an increase in serum creatinine to a level higher than 2.5 mg/dl in less than two weeks. This type of HRS is associated with a very poor prognosis without treatment with a median survival time of only two weeks if untreated (Figure 79.5).[17,39] In Type 2 HRS there is a steady impairment of renal function and serum creatinine levels usually range between 1.5-2.5 mg/dl. Patients with Type 2 HRS have a median survival time of six months if not transplanted (Figure 79.5).[17,39] Patients with type 2 HRS may go on to develop type 1 HRS, either due to progression of disease or triggering factors such as bacterial infections. Although the differential diagnosis between HRS and ATN remains difficult and the presence of granular casts may be observed in the urine sediments of both HRS and ATN, if renal tubular cells are seen this favors the diagnosis of ATN.[6]

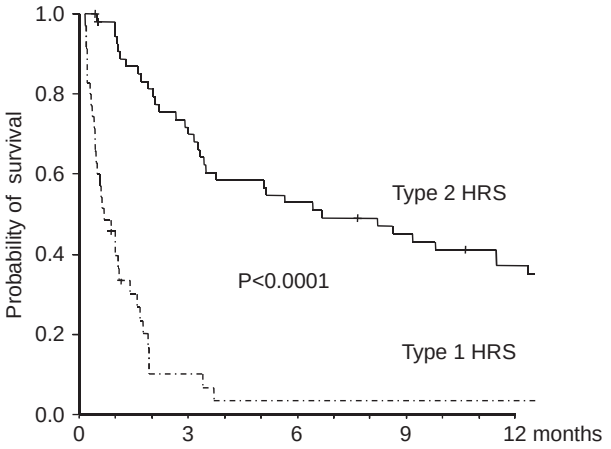

FIGURE 79.5 Probability of survival of patients with cirrhosis according to type of hepatorenal syndrome (HRS). *Reproduced with permission from Ref. [39].*

DRUG-INDUCED RENAL FAILURE

Drug nephrotoxicity in patients with cirrhosis occurs due to medications that cause hemodynamic changes, ATN, and/or acute interstitial nephritis (AIN).[40] Hemodynamically mediated renal failure is mainly caused by NSAIDS and diuretics. These drugs alter the equilibrium between vasodilator and vasoconstrictor factors in the renal circulation. NSAIDs, inhibit the enzymes cycloxygenase-1 and 2 which are responsible for prostaglandin synthesis. Prostaglandins are important renal vasodilators that contribute significantly at maintaining normal renal perfusion. The risk of developing renal failure due to NSAID administration is higher in patients with cirrhosis and ascites and increased activity of the vasoconstrictor systems.[40] Renal failure after NSAID use is followed by a rapid improvement of the GFR to pretreatment values after cessation of the drug in most cases. Diuretic-induced renal failure is usually moderate and reversible after diuretic withdrawal and is related to an imbalance between the fluid loss from the intravascular space caused by diuretic treatment and the passage of fluid from the peritoneal compartment to the general circulation. Drug-induced ATN occurs mainly due to the use of aminoglycosides, amphotericin B or vancomycin. Other drugs used in patients with chronic liver disease undergoing therapy for hepatitis B that may cause renal toxicity are the antivirals adefovir and tenofovir. The specific mechanisms that lead to this toxicity are not completely understood. Thus, it must be taken into account that patients with cirrhosis and renal failure being treated with these drugs may need to switch to

an alternative antiviral such as entecavir. Finally AIN may occur due to antibiotics such as penicillin, rifampin, and sulfonamides as well as with NSAIDs, proton pump inhibitors or allopurinol. In drug-induced AIN there is an inflamatory component that affects the renal tubules and interstitium and occurs as a hypersensitivity reaction to medications. In most cases renal failure will return to normal function after discontinuation of the offending agent.

MANAGEMENT

Successful management of patients with renal failure depends on the prompt recognition of renal failure and of its underlying cause. In general, patients with severe acute renal failure should be admitted to a monitored unit where an appropriate work up and therapy can be performed. If there is any suspicion of an associated bacterial infection, in most cases third-generation cephalosporins are the initial treatment of choice while awaiting cultures.[33] As discussed above, patients with renal failure and severe sepsis may have associated relative AI and may benefit from hydrocortisone administration, however more studies are needed in this area before recommending steroids in this setting. Patients with renal failure and hypovolemia usually respond to volume repletion (saline or colloid) and therapy for gastrointestinal bleeding if present. As mentioned above those with drug- induced renal disease will improve renal function upon discontinuation of the toxic drug. Patients with renal failure that require therapy for large volume ascites or edema should not be treated with spironolactone or furosemide. These patients benefit from large-volume large-volume paracentesis and administration of albumin (8 grams per liter of ascites removed) if necessary (33). Although cirrhotic patients rarely develop renal failure after contrast media for radiological studies, they should undergo standard prophylactic measures such as saline hydration and monitoring of renal function after the procedure.

Patients with Hepatorenal Syndrome

The most important aspect of managing patients with HRS is considering their candidacy for liver transplantation as it is the treatment of choice for individuals with HRS. The main objective of patients with HRS , particularly those awaiting LT, is reversing renal failure in order to provide a successful bridge to transplantation. The best available therapy for HRS other than LT, is the use splanchnic vasoconstrictors plus albumin. Other modalities such as transjugular intrahepatic portosystemic shunts (TIPS), renal replacement therapy and albumin dialysis may be useful in some patients, but data on these approaches is very limited (Figure 79.6).

Vasoconstrictors

The administration of vasoconstrictors is the best medical therapy currently available for the management of HRS. The rationale of this therapy is to improve circulatory function by causing vasoconstriction of the extremely dilated splanchnic arterial bed, which subsequently improves arterial underfilling, reduces the activity of the endogenous vasoconstrictor systems, and increases renal perfusion. The available vasoconstrictors used in HRS are vasopressin analogues (terlipressin) and alpha-adrenergic agonists (noradrenaline or midodrine), which act on V1 vasopressin receptors and α-1 adrenergic receptors, respectively, present in vascular smooth muscle cells (Table 79.4). In most studies, vasoconstrictors have been given in combination with iv albumin to further improve the arterial underfilling (Table 79.4). Most of the published data comes from the use of intravenous terlipressin for type 1 HRS. Non-controlled studies showed response rate of 30-75%.[41–48] Similarly, results from recent randomized controlled studies and systematic reviews indicate that treatment with terlipressin together with albumin is associated with marked improvement of renal function in approximately 40-75% of patients.[49–54]

Although there are no dose-efficacy studies, treatment is typically started with 1 mg/4-6h iv, and the dose is increased up to a maximum of 2 mg/4-6 h after thee days if there is no response to therapy as defined by a reduction of serum creatinine >25% of pre-

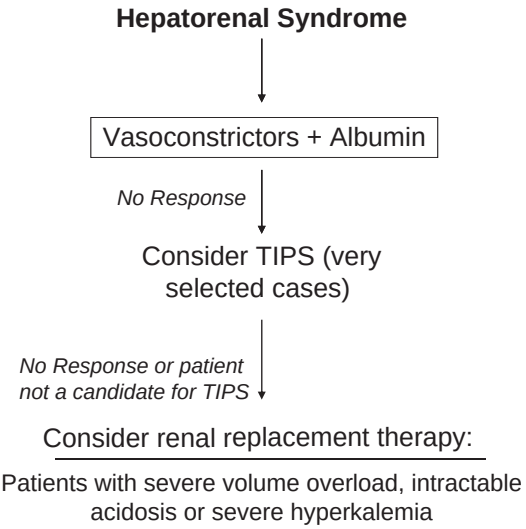

FIGURE 79.6. Management strategy for patients with hepatorenal syndrome.

TABLE 79.4 Pharmacological Therapies for Hepatorenal Syndrome

VASOCONSTRICTORS
Terlipressin: 1 mg/4-6 hrs intravenously; the dose is increased up to a maximum of 2 mg/4-6 h after 3 days if there is no response to therapy as defined by a reduction of serum creatinine > 25% of pre-treatment values. Response to therapy is considered when there is marked reduction of the high serum creatinine levels, at least below 1.5 mg/dl (133 μmol/L). Treatment is usually given from 5-15 days.
Midodrine and Octreotide: 7.5 mg orally three times daily, increased to 12.5 mg three times daily if needed. Octreotide (100 μg subcutaneously three times daily, increased to 200 μg three times daily if needed).
Norepinephrine: 0.5-3 mg/h as continuous intravenous infusion aimed at increasing mean arterial pressure by 10 mmHg. Treatment is maintained until serum creatinine decreases below 1.5 mg/dl.
ALBUMIN ADMINISTRATION
Concomitant administration of albumin together with vasoconstrictor drugs (1 g/kg body weight at day 1 followed by 20-40 g/day).

treatment values. Response to therapy is considered when there is marked reduction of the serum creatinine levels, at least below 1.5 mg/dl, which is usually associated with increased urine output and improvement of hyponatremia. The incidence of ischemic side effects requiring the discontinuation of treatment is of approximately 7%.[55,56] Two randomized studies have shown that the overall population of patients treated with terlipressin and albumin do not have an improved survival compared to that of patients treated with albumin alone.[50,51] Nonetheless, these studies had a low sample size which could have hindered a survival benefit of treatment. In any case, both studies showed that responders in terms of improvement of renal function after therapy had an improved survival compared to non-responders. Recurrence of HRS after withdrawal of therapy occurs in less than 10% of patients and retreatment with terlipressin is generally effective.[55] Factors associated with poor response include a bilirrubin level ≥10 mg/dL, no increase in mean arterial pressure >5 mmHg or lack of a drop in serum creatinine >0.5 mg/dl at day three of therapy.[57] In addition another study showed that patients with baseline serum creatinine <5.6 mg/dL and receiving >3 days therapy achieved HRS reversal.[58] Finally a systematic review of studies concluded that an increase in mean arterial pressure during vasoconstrictor therapy in patients with HRS was strongly associated with a decrease in serum creatinine which suggests that tailoring therapy to increase the baseline mean arterial pressure is beneficial for these patients.[59] This indicates that less severe renal failure (i.e., lower SCr) and an increase in mean arterial pressure during therapy are associated with a good probability of HRS reversal in those patients treated with terlipressin

Alpha-adrenergic agonists (noradrenaline, midodrine) represent an attractive alternative to terlipressin because of their low cost and wide availability[53,54,60–63] (Table 79.4). However, the information on the efficacy and side effects of alpha-adrenergic agonists in patients with type 1 HRS is still limited. A recent controlled study that compared intravenous terlipressin and albumin vs octreotide/midodrine plus albumin in patients with type 1 HRS.[52] showed that improvement of renal function was significantly better in patients receiving terlipressin and albumin (75%) than in patients treated with midodrine and octreotide and albumin (35 %). This trial specifically compared both treatment regimens and the results indicate that terlipressin is superior to octreotide and midodrine and thus a preferred treatment option for patients with type 1 HRS.[52]

There is limited data on use of vasoconstrictors plus albumin for patients with type 2 HRS. However data from uncontrolled studies suggest that they are effective in decreasing serum creatinine levels in these patients. In two controlled studies, patients with type 2 HRS that received terlipressin plus albumin had a response between 67 and 88%, however few were treated with this strategy in both studies (n = 13) and therefore more studies are needed in order to better define the role of vasoconstrictors plus albumin in the management of type 2 HRS.[51,53]

Transjugular Intrahepatic Portosystemic Shunts (TIPS)

The use of portsosystemic shunts for therapy of HRS has been suggested for years, but the applicability in patients with such advanced liver disease is very limited. Two small studies indicate that the transjugular route with and intrahepatic posrtosystemic shunt (TIPS) may improve GFR as well as reduce the activity of the renin-angiotensin-aldosterone system and the sympathetic nervous system in approximately 60% of patients with type 1 HRS.[64,65] However these studies only included patients with moderate liver failure and excluded those with a history of hepatic encephalopathy, Child-Pugh scores ≥12 or serum bilirubin >5 mg/dL. The applicability of TIPS in patients with type 1 HRS is low because TIPS is considered contraindicated in patients with features of severe liver failure, which are common findings in the setting of type 1 HRS. The use of TIPS in type 2 HRS may improve renal function and reduce the risk of progression to type 1 HRS, but these data would require confirmation in specifically designed studies.[66]

Renal Replacement Therapy and other Dialysis Methods

Renal replacement therapy (RRT), mainly hemodialysis, has been used in the management of patients with type 1 HRS, especially in patients candidates to LT, in an attempt to maintain patients alive until LT is performed or spontaneous improvement in renal function occurs.[67] Unfortunately, the potential beneficial effect of this approach has not been demonstrated in randomized studies comparing RRT to other forms of therapy such as vasoconstrictors. Most patients develop side effects during RRT which include severe arterial hypotension, bleeding, and infections that may contribute to death during treatment. Additionally, indications for RRT (severe fluid overload, acidosis or hyperkalemia) are uncommon in type 1 HRS, at least in the early stages. Other methods such as the use of the molecular readsorbent recirculating system (MARS), an alternative of dialysis that clears albumin-bound substances, including vasodilators, is promising but more data is needed in order to consider it as a therapeutic device for HRS.[60] The results of a recent study using a fractionated plasma separation and adsorption extracorporeal liver support system, Prometheus, suggest that this technique improves survival in patients with type 1 HRS and acute-on-chronic liver failure, however these results require confirmation in larger studies.[68]

LIVER TRANSPLANTATION

It is the treatment of choice for patients with cirrhosis and HRS. Unfortunately a drawback of LT as a treatment modality for type 1 HRS is the very high mortality rates in the waiting list many patients exhibit. This limitation is usually overcome by assigning these patients a high priority for transplantation. Since pretransplant renal failure is an independent risk factor of both short-term and long-term post-transplantation patient and graft survival all efforts should be made to improve renal function in order to obtain a better outcome after transplantation.[70] The reversal of both type 1 and 2 HRS before transplantation may help patients not only reach transplantation, but also reduce the relatively high morbidity after LT characteristic of HRS. An analysis of a cohort of patients with type 1 HRS treated with terlipressin and albumin *vs* albumin alone revealed that among those receiving terlipressin plus albumin, the six month survival rates were 100% for patients that underwent LT.[71] Interestingly the group receiving only albumin and that underwent LT had a survival rate was 94% at six months. The survival rate was significantly better (47%) for those achieving a reversal of HRS versus those not achieving a reversal (4%). In the analysis terlipressin did not confer with a significant posttransplant survival benefit because the six-month survival rate for both groups was similar. What is clear is that LT is beneficial for patients with type 1 HRS regardless of the type of treatment they receive. The advantage of using terlipressin in patients undergoing LT relates mainly to its effect of improving renal function which makes taking care of the patients easier while awaiting LT and, most likely, during the post-transplant period. More studies and a longer follow-up period are still needed to determine whether pre-LT therapy of HRS actually will translate into better post-LT outcomes.

Other management strategies when considering LT in patients with HRS include simultaneous liver-kidney (SLK) transplantation and, LT followed by kidney transplantation. Current criteria for SLK include established end-stage renal disease and dialysis, GFR <30 mL/min and proteinuria >3 grs/day with 24 hour urine protein/creatinine ratio >3, and/or acute kidney injury and a requirement for dialysis at least times per week for more than six weeks.[70] After the introduction of MELD score system for organ allocation in the United States there has been an increase in the use of SLK for patients with cirrhosis and renal failure, which has been associated with a decline in survival after SLK compared to the preceding years.[72–74] Moreover, the outcome of patients with HRS treated with SLK is not better than that of patients with HRS treated with LT alone.[72] In addition, this approach uses kidneys that could be used for patients with chronic renal failure without liver disease, who have prolonged waiting times for renal transplantation. All these factors, together with the fact that renal function in HRS patients usually recovers after LT alone, suggest that SLK is not a good approach for the management of patients with HRS. The only exception may be that of patients with HRS who meet the above criteria for SLK.[70] Performance of LT alone followed by kidney transplantation, if necessary has been advocated by some centers. With this approach, kidney transplantation is performed in patients who undergo LT for HRS and require RRT more than 60 days after LT. Data on this approach is limited to only one study and thus more studies are needed in order to consider this strategy acceptable.[75]

PREVENTION

HRS can be prevented in some clinical settings. In the patients with SBP the risk of HRS is substantial, but it may be prevented with the administration of intravenous albumin (1.5 g/kg at diagnosis of infection and 1 g/kg 48 hours later). This measure prevents

worsening of circulatory dysfunction and the subsequent development of HRS. The rationale for albumin administration is to prevent further arterial underfilling and subsequent activation of vasoconstrictor systems, which usually occur in the setting of SBP in patients with cirrhosis.[76] The incidence of HRS in patients with SBP who receive albumin together with antibiotic therapy is 10%, compared with an incidence of 33% in those not receiving albumin.[76] More importantly, there is improved survival in those receiving albumin (10%) versus those not receiving albumin (29%). In patients with very advanced liver disease the long-term administration of norfloxacin orally (400 mg/day) prevents the development of HRS. In patients with ascitic fluid containing under 15 grams of proteins per liter (1.5 grams per deciliter) and associated liver and/or renal function impairment (bilirubin higher than 3 mg/dL, a Child-Pugh score greater than 10, serum sodium lower than 130 mmol/l and/or serum creatinine greater than 1.2 mg/dL) norfloxacin reduces the risk of HRS and improves survival.[77] The reason why norfloxacin prevents this complications is likely related to its ability to prevent bacterial translocation, suppress proinflammatory cytokines, and improve circulatory function.[78,79] A previous study showed that in patients with acute alcoholic hepatitis the use of pentoxifylline, an inhibitor of tumor necrosis factor-α, (400 mg tid orally for 28 days) reduced the incidence of HRS and mortality (8 and 24%, respectively) with respect to a control group (35 and 46%, respectively), however this has not been confirmed inin further studies. Finally, a large study showed that in the setting of acute alcoholic hepatitis the use of N-acetylcysteine for five days plus prednisolone prevented death due to the hepatorenal syndrome. Mortality at six months was higher in the prednisolone only group compared with N-acetylcysteine group (22 *vs* 9%).[80] These results although promising need confirmation.

Autosomal Dominant Polycystic Kidney Disease

Stefan Somlo[1], *Vicente E. Torres*[2], *Michael J. Caplan*[1]

[1]Yale University School of Medicine, New Haven, Connecticut, USA

[2]Division of Nephrology and Hypertension, Mayo Clinic College of Medicine, Rochester, Minnesota, USA

Autosomal dominant polycystic kidney disease (ADPKD) (MIM 173900) is a systemic disorder characterized by age-dependent occurrence of bilateral, multiple renal cysts as well as a variety of extrarenal manifestations. The latter include cysts in the liver bile ducts, pancreatic ducts, seminal vesicles, and arachnoid membrane, as well as noncystic manifestations, such as intracranial aneurysms and dolichoectasias, aortic root dilatation and aneurysms, mitral valve prolapse, and abdominal wall hernias. Over the past several decades, the study of this disease has yielded remarkable progress and insights. The mutated genes and their respective protein products were identified by positional cloning, the occurrence of multiple somatic mutations were implicated in the molecular pathogenesis, a comprehensive array of orthologous gene animal models have been developed, and a much neglected organelle, the primary cilium, has become the focus of investigation not just in this disease but in a whole panoply of structural kidney diseases as well as more diverse biological processes. There has been improved understanding of the clinical disease and the variation it exhibits, and several directed therapeutic clinical trials based on preclinical and bench investigations are beginning to yield results in patients. Still, the goals of understanding the basic disease mechanisms and finding effective treatments remain a work in progress.

CLINICAL FEATURES OF AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD affects between 1 in 400 and 1 in 1000 live births in all ethnic populations worldwide.[1–3] Mutations in either of two genes, *PKD1* or *PKD2*, respectively encoding to protein products called polycystin-1 (PC1) than polycystin-2 (PC2), result in ADPKD. It is the most common single gene disorder that can lead to premature death in man. Approximately 2100 ADPKD patients start renal replacement therapy yearly in the United States. Worldwide yearly incidence rates for end stage renal disease (ESRD) caused by ADPKD in men and women, respectively, are 8.7 and 6.9 per million (1998–2001, United States), 7.8 and 6.0 per million (1998–1999, Europe),[4] and 5.6 and 4.0 per million (1999–2000, Japan).[5] Age-adjusted sex ratios greater than unity (1.2–1.3) suggest a more progressive disease in men than in women. In the United States the incidence of ESRD due to ADPKD has increased by 10.8 percent from 1996–1998 to 2007–2008.[6,7] Similarly, in Denmark ESRD incidence secondary to ADPKD increased from 6.45 per million in 1990–1995 to 7.59 per million in 2002–2007.[8] These trends may be due to improved patient survival before the onset of ESRD.[9] At the same time the age at ESRD in ADPKD patients has increased in both countries.[6,7] In Denmark, age-adjusted male-to-female ratio for onset of ESRD has changed from 1.6 to 1.1, indicating a trend toward similar progression in both genders in recent years.[8]

The diagnosis of ADPKD usually relies on imaging testing (Figure 80.1).[10] Renal ultrasound is commonly used because of cost and safety. Counseling should be done before testing an individual with a family history for the presence of ADPKD. Benefits of testing include certainty regarding diagnosis that may influence family planning, early detection and treatment of disease complications, and identification of genetically unaffected family members for living related-donor renal

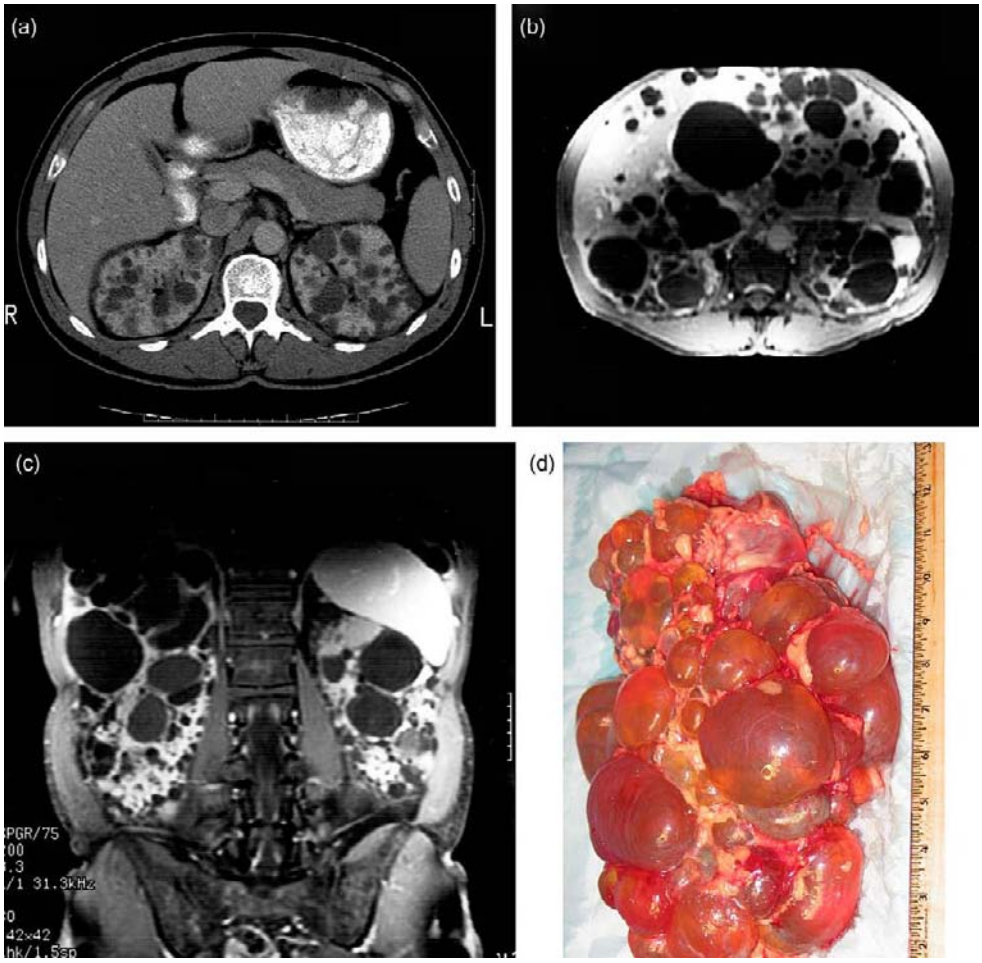

FIGURE 80.1 Radiographic and gross appearance of ADPKD. **a**: Contrast enhanced, axial CT image through the abdomen demonstrating moderate polycystic kidney disease, with numerous bilateral renal cysts, preservation of renal parenchyma, and absence of hepatic cysts. **b,c**: Axial and coronal, gadolinium-enhanced, T1-weighted MR images demonstrating more advanced polycystic kidney and liver disease with marked enlargement of both organs. In both the CT and MR images, cysts appear as hypodense areas within the organ parenchyma. **d**: Nephrectomy specimen from a patient with ADPKD and end-stage renal disease. Cysts permeate the mass of the kidney and the noncystic regions are fibrotic and scarred. *(CT and MRI courtesy of Rex Mahnensmith. Kidney image courtesy of Darren Wallace.)*. See color plate section at the back of the book.

transplantation. The potential for discrimination in terms of health insurability and employment associated with a positive diagnosis has been reduced by the Genetic Information Nondiscrimination Act (GINA) but it does not apply to life, disability or long-term care insurance. Additionally, the psychological burden of knowing affliction by a chronic disease should be considered in the decision to test.

The occurrence and severity of the cystic lesions are highly variable. Cysts have been observed *in utero* and have been detected as incidental findings in 80-year-old patients with otherwise normal blood pressure and kidney function. In genetic terms, the expressivity, or severity, of the phenotype, in this disease is highly variable. By contrast the penetrance is virtually complete if it is expressed as a function of age. Individuals over the age of 30 carrying a causative gene mutation will invariably manifest cysts sufficient for diagnosis when assessed with an appropriately sensitive imaging study. For this reason, the gold standard for diagnosis of ADPKD remains imaging studies of the kidney. The ultrasound criteria, referred to as the modified Ravine criteria,[11] take into account the age-dependent penetrance of the disease by requiring increasing numbers of cysts with increasing age to make the diagnosis. For individuals at 50% risk for the disease (i.e., those with a family history), these criteria include at least two unilateral or bilateral cysts in individuals younger than 30 years; two cysts in each kidney in individuals 30 to 59 years old; and four cysts in each kidney in individuals 60 years or older.[11] In the absence of a family history of ADPKD, bilateral renal enlargement and cysts or the presence of multiple bilateral cysts with hepatic cysts together with the absence of other manifestations

suggesting a different renal cystic disease provide presumptive evidence for the diagnosis of ADPKD.

Revised ultrasound criteria have been proposed to improve the diagnostic performance of ultrasonography in ADPKD[12] (Table 80.1). The presence of at least three (unilateral or bilateral) renal cysts and of two cysts in each kidney have a positive predictive value of 100% in 15 to 39 and 40 to 59 year-old at-risk individuals, respectively. For at-risk individuals ages 60 years and older, four or more cysts in each kidney are required. Although the positive predictive values of these criteria are very high, their sensitivity and negative predictive value are low, particularly when applied to 15- to 59-year-old *PKD2* patients. This is a problem in the evaluation of potential kidney donors where exclusion of the diagnosis is important. Information on the age of ESRD in other affected family members may be helpful in this setting.[13] A history of at least one affected family member with ESRD secondary to ADPKD by age 55 years has 100% positive predictive value for *PKD1*. Conversely, a history of at least one affected family member without ESRD by age ≥ 70 years has 100% positive predictive value for *PKD2*. More strict criteria have therefore been proposed to exclude a diagnosis of ADPKD in an individual at risk from a family with an unknown genotype (Table 80.1). An ultrasound scan finding of normal kidneys or one renal cyst in an individual age 40 years or older has a negative predictive value of 100%. The absence of any renal cyst provides near certainty that ADPKD is absent in at-risk individuals ages 30 to 39 years with a negative predictive value of 98.3%. A negative or indeterminate ultrasound scan result does not exclude ADPKD with certainty in an at-risk individual younger than 30 years of age. In this setting, negative results on magnetic resonance imaging (MRI) or contrast-enhanced computed tomography (CT) provide further assurance, but there are insufficient data to quantify its predictive accuracy. Jointly considering the proposed sonographic criteria, family history information, and findings on high resolution imaging studies routinely obtained during donor evaluations usually allows a determination of disease status in the majority of potential living related kidney donors with high level of certainty.[14]

Genetic testing can be used when the imaging results are equivocal and/or when a definite diagnosis is required in a younger individual, such as a potential living related kidney donor. Prenatal and preimplantation genetic testing are rarely considered for ADPKD.[15] Genetic testing is performed by direct sequence analysis. Direct sequencing yields mutation detection rates of approximately 85%.[16] However, as most mutations are unique and up to one third of *PKD1* changes are predicted to be single amino acid substitution changes, the causative nature of some sequence changes is difficult to prove. Genetic testing can be helpful with *de novo* mutations in the absence of a family history. A unique variant in either *PKD1* or *PKD2* present in the affected child but absent in both parents in the setting of documented maternity and paternity can identify the new mutation.

Natural History of ADPKD

The clinical *sine qua non* for ADPKD is the presence of multiple cysts in both kidneys and the consequent increase in total kidney size. The development of cysts in ADPKD probably starts in the embryo. They

continue to form and grow during the remaining life time. Cyst expansion along with associated inflammation, fibrosis, and tubular dropout results in a loss of filtering nephrons, but glomerular filtration rate remains stable for decades thanks to the compensatory capacity of the kidney. During this often-silent phase, mild polyuria due to impaired urinary concentrating capacity, elevated blood pressure, microalbuminuria, and, occasionally, low-grade proteinuria can develop. When enough filtering nephrons have been lost, the glomerular filtration rate (GFR) begins to fall precipitously. Extrarenal manifestations of the disease are rare in childhood. Cysts in the liver usually start later than in the kidney. Patients may seek medical attention at any point in the course of the disease for renal or extrarenal, cyst-related or non−cyst-related manifestations.

The Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease (CRISP) has provided the best clinical information on how cysts develop and grow. Two hundred and forty-one nonazotemic patients have been followed prospectively with yearly magnetic resonance imaging (MRI) examinations to assess kidney and cyst growth.[17] Total kidney volume and cyst volumes increased exponentially. At baseline, total kidney volume was 1060 ± 642 ml, and the mean increase over three years was 204 ml, or 5.3% per year. The rates of change of total kidney and total cyst volumes, and of right and left kidney volumes, were strongly correlated, suggesting that kidney enlargement was due to cyst enlargement. Baseline total kidney volume predicted the subsequent rate of increase in renal volume and was associated with declining GFR in patients with baseline total kidney volume above 1500 ml after the first three years of follow-up. The association between baseline total kidney volume has become increasingly strong with an extended follow-up of eight years, qualifying total kidney volume as a prognostic biomarker in ADPKD.[18]

Renal Manifestations of ADPKD

Hypertension

Hypertension (BP > 140/90 mmHg) is present in approximately 50% of 20-34 year old ADPKD patients with normal renal function and increases to nearly 100% of patients with ESRD.[19] Its development is accompanied by a reduction in renal blood flow, increased filtration fraction, abnormal renal handling of sodium, and extensive remodeling of the renal vasculature.[20,21]

The association between renal size and prevalence of hypertension has supported the hypothesis that stretching and compression of the vascular tree by cyst expansion causes ischemia and activation of the renin−angiotensin system.[22] Whether the classic, circulating renin-angiotensin system is inappropriately activated is controversial.[23,24] There is stronger evidence for the activation of a local intrarenal renin-angiotensin system. Evidence for the latter includes (1) partial amelioration of the reduced renal blood flow, increased renal vascular resistance and increased filtration fraction in the setting of acute or chronic administration of an ACEI;[21,23,25] (2) shift of immunoreactive renin from the juxtaglomerular apparatus to the walls of the arterioles and small arteries;[26,27] (3) ectopic synthesis of renin in the epithelium of dilated tubules and cysts;[27,28] and (4) ACE-independent generation of angiotensin II by a chymase-like enzyme.[29]

It has been suggested that a primary disruption of polycystin protein function in the vasculature may also play a role in the early development of hypertension and renal vascular remodeling. Supportive evidence includes expression of the respective *PKD1* and *PKD2* gene products in vascular smooth muscle[30−32] and endothelium,[33] and enhanced vascular smooth muscle contractility[34] and impaired endothelial dependent vasorelaxation[35] in heterozygous blood vessels. Recent studies have shown that nitric oxide endothelium-dependent vasorelaxation is impaired in small subcutaneous resistance vessels from patients with normal renal function before development of hypertension.[35−37] Other factors proposed to contribute to hypertension in ADPKD include increased sympathetic nerve activity and plasma endothelin-1 levels and insulin resistance.[38]

The diagnosis of hypertension in ADPKD is often made late. Twenty-four hours ambulatory blood pressure monitoring of children or young adults without hypertension may reveal elevated blood pressures and attenuated nocturnal blood pressure dipping and exaggerated blood pressure response during exercise, which may be accompanied by left ventricular hypertrophy and diastolic dysfunction.[39] Early detection and treatment of hypertension is important because cardiovascular disease is the main cause of death and uncontrolled blood pressure increases the risk for proteinuria, hematuria, faster decline of renal function and morbidity and mortality from valvular heart disease and aneurysms.[2,40,41]

Pain

Pain is the most frequent symptom (~60%) reported by adult patients.[42,43] Acute pain may be associated with renal hemorrhage, passage of stones and urinary tract infections. Some patients develop chronic flank pain without identifiable etiology other than the cysts.

VEGF produced by the cystic epithelium[44] may promote angiogenesis, hemorrhage into cysts and gross hematuria. Rarely, a hemorrhagic cyst can rupture into the subcasular or retroperitoneal space. Symptomatic episodes likely underestimate the frequency of cyst

hemorrhage as over 90% of ADPKD patients have hyperdense (CT) or high signal (MRI) cysts reflecting blood or high protein content. Most hemorrhages resolve within two to seven days. If symptoms last longer than one week or if the initial episode occurs after the age of 50 years, investigation to exclude neoplasm should be undertaken.

Approximately 20% of ADPKD patients have kidney stones.[45–47] Their composition is usually uric acid and/or calcium oxalate. Metabolic factors include decreased ammonia excretion, low urinary pH and low urinary citrate concentration. Urinary stasis secondary to the distorted renal anatomy may also play a role. Stones may be difficult to differentiate from cyst wall and parenchymal calcification, which also occur with increased frequency.

As in the general population urinary tract infections affect females more frequently than males. Most are caused by enterobacteriaciae.[48] CT and MRI are sensitive to detect complicated cysts and provide anatomic definition, but the findings are not specific for infection. Nuclear imaging (^{67}Ga or ^{111}In-labeled leukocyte scans) is useful but false negative and positive results are possible. ^{18}fluorodeoxyglucose (^{18}FDG) positron-emission computed tomography (PET/CT) is currently the most helpful imaging modality to detect a cyst infection, but it is not widely available, is expensive, and currently not approved by the Centers for Medicare and Medicaid Services (CMS) for the diagnosis of infection.[49,50] Cyst aspiration should be considered when the clinical setting and imaging are suggestive and blood and urine cultures are negative.

Renal cell carcinoma is a rare cause of pain in ADPKD. It does not occur more frequently than in the general population, but it may present at an earlier age with frequent constitutional symptoms and a higher proportion of sarcomatoid, bilateral, multicentric, and metastatic tumors.[51] A solid mass on ultrasound, speckled calcifications on CT, and contrast enhancement, tumor thrombus and regional lymphadenopathies on CT or MRI should raise the suspicion for a carcinoma.

Renal Failure

The development of renal failure is highly variable. In most patients renal function is maintained within the normal range, despite relentless growth of cysts, until the 4th to 6th decade of life. By the time renal function starts declining, the kidneys usually are markedly enlarged and distorted with little recognizable parenchyma on imaging studies. At this stage, the average rate of GFR decline is approximately 4.4−5.9 mL/min/year.[52] The mutated gene (*PKD1* or *PKD2*) is a significant determinant of the severity of disease and position of the mutation within *PKD1* and possible modifier genes also contribute to the clinical course of ADPKD (see following sections). Other risk factors for a worse prognosis include male gender (particularly in *PKD2*), black race, first episode of hematuria before the age of 30, onset of hypertension before the age of 35, hyperlipidemia, low HDL, and sickle cell trait.[53–55]

Several mechanisms account for renal function decline. The CRISP study has confirmed previous studies suggesting a strong relationship between renal enlargement and functional decline.[17] CRISP has shown that kidney and cyst volumes are the strongest predictors of renal functional decline. CRISP also found that renal blood flow (or vascular resistance) is an independent predictor of functional decline.[56] This points to the importance of vascular remodeling in the progression of the disease and may account for cases where the decline of renal function seems to be out of proportion to the severity of the cystic disease. Angiotensin II, transforming growth factor-β, and reactive oxygen species may contribute to the vascular lesions and interstitial fibrosis by stimulating the synthesis of chemokines, extracellular matrix, and metalloproteinase inhibitors. Other factors such as heavy use of analgesics may contribute to chronic kidney disease (CKD) progression in some patients.

Extrarenal Manifestations of ADPKD

Polycystic Liver Disease

PLD is the most common extrarenal manifestation. It is associated with both *PKD1* and *PKD2* genotypes. The cysts arise by excessive proliferation and dilatation of biliary ductules and peribiliary glands. Estrogen receptors are expressed in the epithelium lining the hepatic cysts and estrogens stimulate hepatic cyst derived cell proliferation.[57] Bile duct cyst growth is also promoted by growth factors and cytokines secreted into the cyst fluid.[63,219]

Hepatic cysts are rare in children. Their frequency increases with age and may have been underestimated by ultrasound and CT studies. Their prevalence by MRI in the CRISP study is 58%, 85 and 94% in 15 to 24, 25 to 34 and 35 to 46 year old participants.[58] Hepatic cysts are more prevalent and hepatic cyst volume is larger in women than in men. Women who have multiple pregnancies or who have used oral contraceptive agents or estrogen replacement therapy have worse disease suggesting an estrogen effect on hepatic cyst growth.[59,60]

Typically, PLD is asymptomatic, but symptoms have become more frequent as the lifespan of ADPKD patients has lengthened with dialysis and transplantation. Symptoms may result from mass effect or from complications related to the cysts. Symptoms typically

caused by massive enlargement of the liver or by mass effect from a single or a limited number of dominant cysts include dyspnea, early satiety, gastroesophageal reflux, and mechanical low back pain. Other complications caused by mass effect include hepatic venous outflow obstruction, inferior vena cava compression, portal vein compression or bile duct compression presenting as obstructive jaundice.[61]

Symptomatic liver cyst complications include cyst hemorrhage, infection and rarely torsion or rupture. The typical presentation of cyst infection is with localized pain, fever, leukocytosis, elevated sedimentation rate and often elevated alkaline phosphatase.[62] It is usually monomicrobial and caused by enterobacteriaceae. MRI is very sensitive for identifying complicated hepatic cysts. On CT scanning, fluid-debris levels within cysts, cyst wall thickening, intracystic gas bubbles, and heterogeneous or increased density have been associated with infection. Radionuclide imaging and more recently ^{18}F-fluorodoxyglucose PET/CT scanning have been used for diagnosis.[63]

Mild dilatation of the common bile duct has been observed in 40% of patients studied by CT and may rarely be associated with episodes of cholangitis.[64] Rare associations of PLD include congenital hepatic fibrosis,[65] adenomas of the ampulla of Vater,[66] and cholangiocarcinoma.[67]

Cysts in other Organs

Seminal vesicles, pancreas, and arachnoid membrane cysts are present in 40% (males), 5%, and 8% of patients, respectively.[68–73] Seminal vesicle cysts rarely result in infertility.[74] Defective sperm motility is another cause of male infertility in ADPKD.[75] Pancreatic cysts are almost always asymptomatic, with very rare occurrences of recurrent pancreatitis and possibly chance associations of intraductal papillary mucinous tumor or carcinoma reported in ADPKD.[76–78] Arachnoid membrane cysts are asymptomatic, but may increase the risk for subdural hematomas.[70,79] Spinal meningeal diverticula may occur with increased frequency and rarely present with intracranial hypotension due to cerebrospinal fluid leak.[80] Ovarian cysts are not associated with ADPKD.[81,82]

Vascular Manifestations

These include intracranial aneurysms and dolichoectasias, thoracic aortic and cervicocephalic artery dissections, and coronary artery aneurysms. They are caused by alterations in the vasculature directly linked to mutations in *PKD1* or *PKD2*. The respective protein products, PC1 and PC2, are expressed in vascular smooth muscle cells (VSMC).[30–32] *Pkd2*$^{+/-}$ VSMCs from mice exhibit increased rates of proliferation and apoptosis and *Pkd2*$^{+/-}$ mice have an increased susceptibility to vascular injury and premature death when induced to develop hypertension.[83,84] Defective structural integrity of blood vessels occur in mice lacking PC1.[85]

Intracranial aneurysms (ICA) occur in approximately 6% of patients with a negative, and 16% of those with a positive family history of aneurysms.[86,87] They are most often asymptomatic. Focal findings such as cranial nerve palsy or seizure result from compression of local structures. The risk of rupture depends on many factors including the size of the aneurysm. Rupture carries a 35–55% risk of combined severe morbidity and mortality.[88] The mean age at rupture is lower than in the general population (39 years versus 51 years). Most patients with ICA have normal renal function and up to 29% will have normal blood pressure at the time of rupture.

Cardiac Manifestations

Mitral valve prolapse occurs in up to 25% of ADPKD patients on echocardiography.[118,184] Aortic insufficiency may occur in association with dilatation of the aortic root.[89] Although these lesions may progress with time, they rarely require valve replacement. Screening echocardiography is not indicated unless a murmur is detected on examination. Clinically inconsequential pericardial effusions are a common incidental finding in ADPKD.[90]

Diverticular Disease

Colonic diverticulosis and diverticulitis are more common in ESRD patients with ADPKD than in those with other renal diseases.[160,198,297] Whether this increased risk extends to patients prior to ESRD is uncertain.[91] There have been reports of extracolonic diverticular disease.[92] It may become clinically significant in a minority of patients. Subtle alterations in polycystin function that may enhance the smooth muscle dysfunction during aging may underlie the development of diverticula.

Isolated Polycystic Liver Disease

Isolated autosomal dominant PLD (ADPLD; MIM 174050) also occurs as a genetically distinct disease in the absence of renal cysts.[93,94] Like ADPKD, ADPLD is genetically heterogeneous, with two genes identified (*PRKCSH* and *SEC63*) accounting for approximately one-third of isolated ADPLD cases. ADPLD often goes undetected even in first-degree relatives of patients with highly symptomatic polycystic liver disease. As in the case of polycystic liver disease associated with ADPKD, isolated ADPLD is more severe in women than in men. Liver function tests remain normal and when symptoms develop, these are related to mass effects or complications such as cyst hemorrhage or infection. Patients with isolated ADPLD may also be at

increased risk for intracranial aneurysms and valvular heart disease.

CILIA AND THE SPECTRUM OF INHERITED CYSTIC DISEASE

Understanding of the clinical spectrum of polycystic kidney diseases as well as clues to the underlying molecular pathogenesis have been significantly advanced by the discovery over the past decade of the central role of cilia in cyst formation in the kidney. The 'cilia hypothesis' for polycystic disorders has been reviewed extensively (e.g., [95–97]). It is now appreciated that defects in cilia-basal body-centriole-related proteins—i.e., those found in the cilial membrane, cilial axoneme, the basal body or pericentriolar region—are varyingly associated with clinical spectrum of disease that can include cystic kidneys, bile duct and pancreatic duct cysts, retinal degeneration and retinitis pigmentosa, *situs inversus* (incorrect left-right body axis), anosmia, infertility, and hydrocephalus.[95,98]

There are two general classes of cilia: the motile "9 + 2" structures and the non-motile '9 + 0' structures that are also referred to as "primary cilia"[99] (Figure 80.2). In the kidney, the apical surface of every tubular epithelial cell, with the exception of mature intercalated cells, is decorated by a single primary cilium, a hair-like structure enclosed by a membrane continuous with the cell membrane and a containing the central axoneme composed of nine peripheral microtubule doublets without a central pair (hence, 9 + 0). The non-motile primary cilium is rooted in the centrosome, the microtubule organizing center of the cell. The centrosome is composed of a mother and a daughter centriole and a cloud of pericentriolar material around the mother centriole. During interphase, the distal end of the mother centriole known as the basal body gives

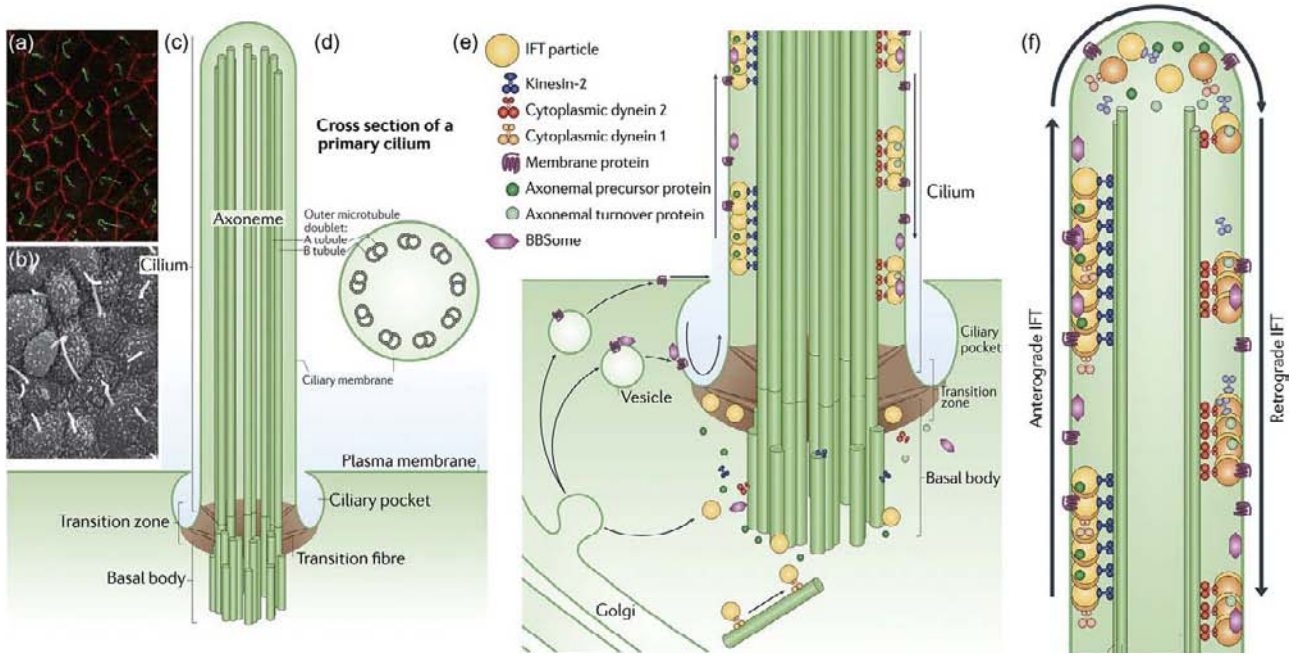

FIGURE 80.2 Structural and functional elements of cilia. **a**: Immunofluorescence image of primary cilia (green) in inner medullary collecting duct (IMCD3) cells; basal bodies, magenta; cell–cell junctions, red. **b:** Scanning electron micrographs of cilia at the mouse embryonic node. **c, d**: Primary cilia differ from motile cilia in that the ciliary axoneme is comprised of nine pairs of microtubules without a central pair (9 + 0). Primary cilium arises from the basal body which is comprised of the centrosome in non-mitotic cells. The base of the cilium has a circumferential invagination of the plasma membrane called the ciliary pocket and is separated from the rest of the cell body by the transition zone. **e**. The transition zone complex, which includes several members of the NPHP, JBTS and MKS protein families, serves to selectively sort proteins that enter and exit the cilium. Proteins pass through the transition zone by either of two processes. Intraflagellar transport (IFT) involves loading of cytoplasmic proteins onto large multiprotein complexes (IFT particles) that move along the outer doublet microtubules beneath the ciliary membrane. Proteins destined for the ciliary membrane (e.g., the polycystins) are synthesized in the endoplasmic reticulum, processed through the Golgi stack and trafficked into vesicles that dock near the ciliary base in a process dependent on the BBSome comprised of proteins associated with BBS. **f**: The IFT particles, comprised of complexes A and B and their cargo, including the BBSome and integral membrane proteins such as polycystins, are moved toward the tip of the cilium by the anterograde motor protein kinesin-2. Once at the tip, the cargo is released and the IFT complexes rearrange so that kinesin-2 is replaced by cytoplasmic dynein-2 which acts as the retrograde motor to carry the particles back to the cell body *(Modified and reprinted by permission from Macmillan Publishers Ltd: Ishikawa H. & Marshall W.F., Ciliogenesis: building the cell's antenna*, Nature Reviews Molecular Cell Biology*, 12:222–234, copyright 2011).*

rise to the primary cilium. Cilia are assembled and maintained by a process called intraflagellar transport (IFT) in which the components of the ciliary axoneme are assembled at the basal bodies into large transport particles called rafts. A region at the base of the cilia composed of transition fibers provides a compartmental demarcation between the cilium and the rest of the cell. Kinesin-2 and cytoplasmic dynein motor proteins mediate the anterograde and retrograde traffic of rafts along the axoneme, respectively. Kinesin-2 forms a heterotrimeric complex composed of two motor subunits KIF3A and KIF3B or KIF3C and a tail-associated nonmotor accessory subunit, KAP3. When the cell prepares to divide in the S-phase, the primary cilium is reabsorbed and each centriole divides into new mother and daughter centrioles that migrate to the poles of the mitotic spindle.

Several lines of complementary evidence converged on cilia as the central organelle in the pathogenesis of ADPKD. Among these were the findings that the PC1 ortholog in *C. elegans* is expressed in cilia[100] and that several mouse models of recessive polycystic kidney disease targeting genes not orthologous to either *PKD1* or *PKD2* exhibited the phenotypic combination of cystic kidney defects and left-right axis abnormalities.[101,102] This is significant because left-right axis determination has been established as a cilia dependent phenotype. The connection was further strengthened when one of these recessive polycystic kidney disease genes, *Tg737* (also called polaris or IFT88), was identified as a component of the intraflagellar transport machinery necessary for ciliary biogenesis.[103] Further direct evidence of the cilia link with ADPKD came with the demonstration of the localization of PC2[104] and PC1[105] in the cilia of kidney epithelia and the discovery that *Pkd2*$^{-/-}$ mice have defects in left-right axis formation.[106] Previous studies in ciliated MDCK cells had shown the mechanical deflection of cilia resulted in cellular calcium transients that could be detected by calcium sensitive fluorescent dyes.[107–109] The discovery that PC1 and PC2 were expressed in cilia coupled with the knowledge that PC2 function as a cation channel (see below)[110] led to the hypothesis that the polycystins were responsible for the cilia-dependent calcium transients observed in cultured cells.[111] This hypothesis was supported by the observation that cells lacking PC1 failed to respond with cellular calcium transients upon deflection of cilia by laminar shear stress under flow.[111] This finding was combined with the discovery that PC2 is required for left-right axis formation led to studies that showed that lateralized PC2-dependent calcium signals played a role in downstream signaling and vertebrate body axis specification.[112] PC2 may be part of a mechanosensory complex that sensed the leftward flow generated by cilial movement in left-right axis formation,[112] although a more complex mechanism for the lateralized nodal calcium signal may be operational.[113]

Subsequently, an ever growing number of genes for human diseases that include cystic changes in the kidney have been identified in their function linked to cilia.[98] These "reverse genetic" discoveries have been complemented by a forward genetic screen using random insertional mutagenesis in zebrafish that resulted in a cystic pronephric kidney phenotype in fish which identified a number of intraflagellar transport related proteins, as well as *Pkd2*, among the target genes.[114] Similarly, in the metanephric mouse kidney, conditional inactivation of the Kif3a component of the heterotrimeric kinesin-2 anterograde motor resulted in loss of cilia and consequent cyst formation during kidney development.[115] Taken together the data support a strong functional connection between defects in cilia structure or function and cyst formation in lumen forming epithelia including kidney tubules, bile ducts and pancreatic ducts.

Recessive Human Ciliopathies

Primary cilia are increasingly implicated in a wide variety of important morphogenic signaling pathways (e.g.,[97,116]) which in turn account for the wide spectrum of clinical features associated with syndromes when cilia function is disturbed.[98,117] Association with cilia, basal body or pericentriolar region has also been reported for the ever expanding groups of genes mutated in recessive "ciliopathy" syndromic disorders with pleiotropic manifestations that include varying degrees and penetrance of kidney cyst formation. These diseases include nephronophthisis (NPHP), Joubert syndrome (JBTS), Meckel-Gruber syndrome (MKS), Bardet-Biedl syndrome (BBS) and oro-facial-digital syndrome (OFD).[118,119] In addition, fibrocystin, the ARPKD gene product is expressed in cilia as well as the apical membrane of distal nephron tubular cells.[120–122]

Subsets of the recessive ciliopathies have coalesced into phenotypic and genetic continuums. NPHP, JBTS, and MKS comprise a phenotypic spectrum roughly proceeding from less severe to more severe, respectively.[118] Manifestations at the NPHP end of the spectrum include kidney and liver fibrosis, kidney cysts and retinal defects. JBTS patients also have cerebellar vermal hypoplasia and cognitive impairment while at the most severe end of the spectrum, MKS patients manifest with occipital encephalocele and are commonly nonviable. BBS shares kidney and retinal defects and in addition is characterized by digital defects, obesity, anosmia and cognitive impairment. Recessive mutations in over thirty genes have been identified among the ciliopathy syndromes.[98,118] Mutations in same genes (e.g., *CEP290*, *NPHP1*, *BBS4*, *MKS1*) give

rise to more than one of clinical syndromes indicating that the phenotypic continuum is mimicked by genotypic overlap. In the most extreme example, mutations in CEP290 has been associated with NPHP, JBTS MKS and BBS.[123] This interrelationship of a spectrum of clinical syndromes with recessive mutations in the same gene likely results from a complex interplay of locus heterogeneity, multiple allelism, modifier gene effects and possibly more complex multigenic inheritance.[98]

Recent work has established that the functional protein complexes composed of the recessive ciliopathy gene products are part of the transition zone and trafficking complexes that determine the molecular composition cilia (Figure 80.2). Mutations in at least nine genes have been associated each with NPHP and JBTS, six genes with MKS, and an additional 14 genes associated with BBS. Extensive cell biological and proteomic analysis has shown that the NPHP, JBTS and MKS associated gene products comprise the transition zone fibers that are critical gatekeepers determining the entrance and exit of components into and out of cilia.[99,124,125] The BBS gene products assemble into the BBSome which functions in the trafficking of integral membrane proteins to and from cilia.[126,127] The other key elements of cilia structure and function are the IFT proteins that, in conjunction with the kinesin and dynein motor proteins, are required to form structurally intact cilia. While mice and fish exhibit polycystic phenotypes with mutations in IFT proteins that result in abnormal or absent cilia, no human diseases with recessive loss of function in IFT genes and absent cilia have been identified possibly because these are embryonically lethal. Taken together, these recent discoveries suggest that recessive ciliopathies result in complex perturbations in the molecular composition of cilia. These findings also define the molecular relationship between the syndromic kidney cystic diseases resulting from ciliopathies with the non-syndromic polycystic kidney diseases, ADPKD and ARPKD. The latter both result from mutations in individual integral membrane proteins that are among the much larger group of client proteins of the BBSome and transition zone complex as they function to determine molecular composition of cilia. Ciliopathy syndromes therefore result from complex perturbations of cilia composition whereas ADPKD and ARPKD result from the discrete absence of individual molecular components of cilia that are not know to otherwise affect delivery or retention of additional ciliary proteins.

GENETICS OF ADPKD

Mutations in at least two genes cause the clinical presentation of ADPKD—a property referred to as genetic heterogeneity. The two genes, *PKD1* located on chromosome 16p13.3 and *PKD2* located on chromosome 4q21, have been isolated by positional cloning.[128–131] The genomic segments occupied by the *PKD1* and *PKD2* genes are of similar size (~45–50 kb), but *PKD1* contains 46 exons that encode ~12 kb of open reading frame, compared to 15 exons and ~3 kb of open reading frame for *PKD2*. Two thirds of the 5′ end of human *PKD1*, both exons and introns, are duplicated multiple times with very high sequence fidelity (>95%) in more proximal regions of chromosome 16.[132–135] *PKD1* accounts for approximately 85% of affected families in European populations, with the remaining 15% resulting from *PKD2* mutations.[136–138] Analysis of the gene locus-dependent clinical phenotypes have highlighted the increased severity of *PKD1*. The mean age of the composite endpoint of death or ESRD is 53 years for *PKD1* and 69.1 years for *PKD2*; both differed significantly from the control population (78 years).[137,139] Given this difference, it is would be expected that the relative prevalence of *PKD2* will increase in patient subgroups stratified based on age of onset of ESRD. In one study, 39.1% of patients reaching ESRD after age 63 had *PKD2* mutations.[140] Using only age of presentation with ESRD as an endpoint, *PKD1* patients have a median age of onset of 54.3 compared with 74.0 for *PKD2* patients.[137,139] The prevalence of hypertension is four-fold lower in *PKD2* compared to *PKD1* and the occurrence of urinary tract infections and hematuria is also reduced in the former compared to *PKD1*.[137,139] The value of these gene locus-based clinical differences in providing specific prognostic information to patients is limited due to the marked intrafamilial and interfamilial variation in clinical manifestations of ADPKD.[141–144]

Molecular Genetic Mechanisms of Cyst Formation in ADPKD

The molecular genetic mechanisms of cyst formation in ADPKD are required to explain two salient clinical features of the disease. The first is to explain why the disease occurs in such a focal manner given that the ADPKD gene mutations are autosomally inherited and all cells in the body carry a mutated allele. The second is to determine the basis of the marked intra-and interfamilial variability in disease severity.

The apparent paradox of the focal nature of ADPKD is highlighted by the observation in microdissection studies of early ADPKD kidneys that localized cystic dilatations occur in kidney tubules that appear otherwise normal despite the presence of the same germline mutation in all the cells.[145] A molecular explanation for this observation has come with the discovery that cyst lining cells from human ADPKD cysts have loss of heterozygosity (LOH) in the chromosomal regions of the

respective *PKD* genes in both kidney tubular[146–149] and bile ductular cysts.[150] The LOH indicates loss of the functional gene from the wild type allele through focal somatic second hit mutations that define cyst formation as a recessive phenotype at the cellular level. The absence of a remnant wild type allele in a subset of cells from a cyst with LOH suggests that the cysts are clonal in origin—i.e., arising from a single cell.[146]

The conclusions from these studies were challenged[151] on the basis of: (1) Immunolocalization studies using anti-PC1 antibodies showing evidence of residual expressed protein in human cysts,[152–155] (2) the relatively low rate of detection of LOH in cysts, (3) the relatively high rate of somatic mutations required to account for the thousands of independent cysts, and (4) the fact that the finding of LOH in cysts established an association, but not a causal link. In retrospect, immunolocalization studies were focused on cellular staining patterns that did not examine cilia expression of the protein; the latter is now thought to be the primary site of PC1 function in ADPKD.[104,105] Additionally, approximately 30% of germline mutations in *PKD1* are predicted to be non-synonymous amino acid substitution mutations[14] which are predicted to yield immunoreactive protein products. If a similar proportion of missense variants occurs among second hit mutations, resulting cysts be positive for PC1 by immunostaining. The relatively low detection rate of LOH in cysts may reflect limitations in comprehensive screening of *PKD1* for pathogenic mutations. Even a decade later, the success rate of *PKD1* mutation detection is still ~85%.[14] When more effective sequence-based mutation detection was applied to cysts from patients with germline *PKD2* mutations, the rate of detection of second hits was the same as the sensitivity of mutation detection suggesting that effectively all cysts had second hits.[156] The rate of somatic mutations required to account for the thousands of cyst that develop in ADPKD are in keeping with the rate of measured HPRT mutation frequencies in kidney epithelial cells ranging from 5×10^{-5} in the first decade to 2.5×10^{-4} after the eighth decade of life.[157]

A variant of the two hit hypothesis was suggested by studies examining kidney cysts from patients with defined *PKD2* mutations. Cyst cells were initially screened for second hit mutations in *PKD2*, followed by screening for *PKD1* mutations in the subset of cysts in which second hit *PKD2* mutations could not be found.[156,158] Evidence of loss of a *PKD1* allele in these latter cysts led to the proposal the trans-heterozygous somatic mutations involving an allele of the *PKD* gene other than the one affected by the germline mutation can give rise to cysts.[156] However, trans-heterozygous mutations are unlikely to be sufficient for cyst formation. Compound heterozygous individuals with bilineal inheritance of a *PKD1* mutation and a *PKD2* mutation show more severe polycystic kidney disease[159] as do trans-heterozygous mice,[160] but the overall severity of phenotype in both man and mouse is within the range observed for individuals with mutations at just one of the gene loci.

Mouse models have established the causal link between second hits in a single *Pkd* gene and cyst formation (Figure 80.3). The occurrence of kidney cysts after embryonic day 14.5 in conventional germline knockout animal models of *Pkd1* and *Pkd2* anticipated a link between homozygous loss of polycystin genes and cyst formation.[161,162] A novel mouse model of *Pkd2* was the first to established a causal relationship between somatic inactivation of the normal allele and cyst formation in adult mice.[163] In this model, a serendipitous modified allele, $Pkd2^{WS25}$, resulted from insertion of a disrupted exon 1 in tandem with the wild type exon1. $Pkd2^{WS25}$ expresses functional PC2 but is prone to genomic rearrangement converting it to either a null or true wild type allele.[163] The dosage of this allele correlates with propensity toward cyst formation and the cyst lining cells in adult mouse kidneys did not express PC2.[163] Subsequently, the conditional Cre-lox system has been used to bypass the embryonic lethality of null mice and achieve homozygous inactivation of *Pkd* genes in a tissue in a selective and temporally controlled manner.[164–168] These studies confirmed that somatic second hit mutations in either *Pkd* gene are sufficient for cyst formation. Similar conditional inactivation approaches have been applied to cilia ablation models targeting genes whose products are required for intraflagellar transport (*Kif3a*, *Ift88*).[115,169] The latter showed that somatic loss of intact cilia also results in a polycystic kidney phenotype. The Cre-lox system offers spatial and temporal control of *Pkd* gene inactivation but has the limitation that inactivation events occur simultaneously in large tracts of cells in either selected nephron segments or along the entire nephron. This is not believed to be the prevalent pattern of inactivation in human disease; in this regard the $Pkd2^{WS25}$ model remains unique in that *Pkd2* inactivation is thought to occur by stochastic mechanism involving individual cells. Interestingly, the molecular events underlying *Pkd2* inactivation in this model are not believed to have a nephron segment specific bias, yet the majority of cysts arise from distal nephron segments.[163,170] More recent mouse studies suggest that collecting duct cyst growth is particularly sensitive to PC1 dosage.[171] These findings have been part of the rationale for the potential benefit of vassopress-2 receptor antagonists in the treatment of ADPKD.[170]

While somatic second hits are sufficient to initiate cyst formation, an increasing number of additional molecular factors affecting progression of polycystic

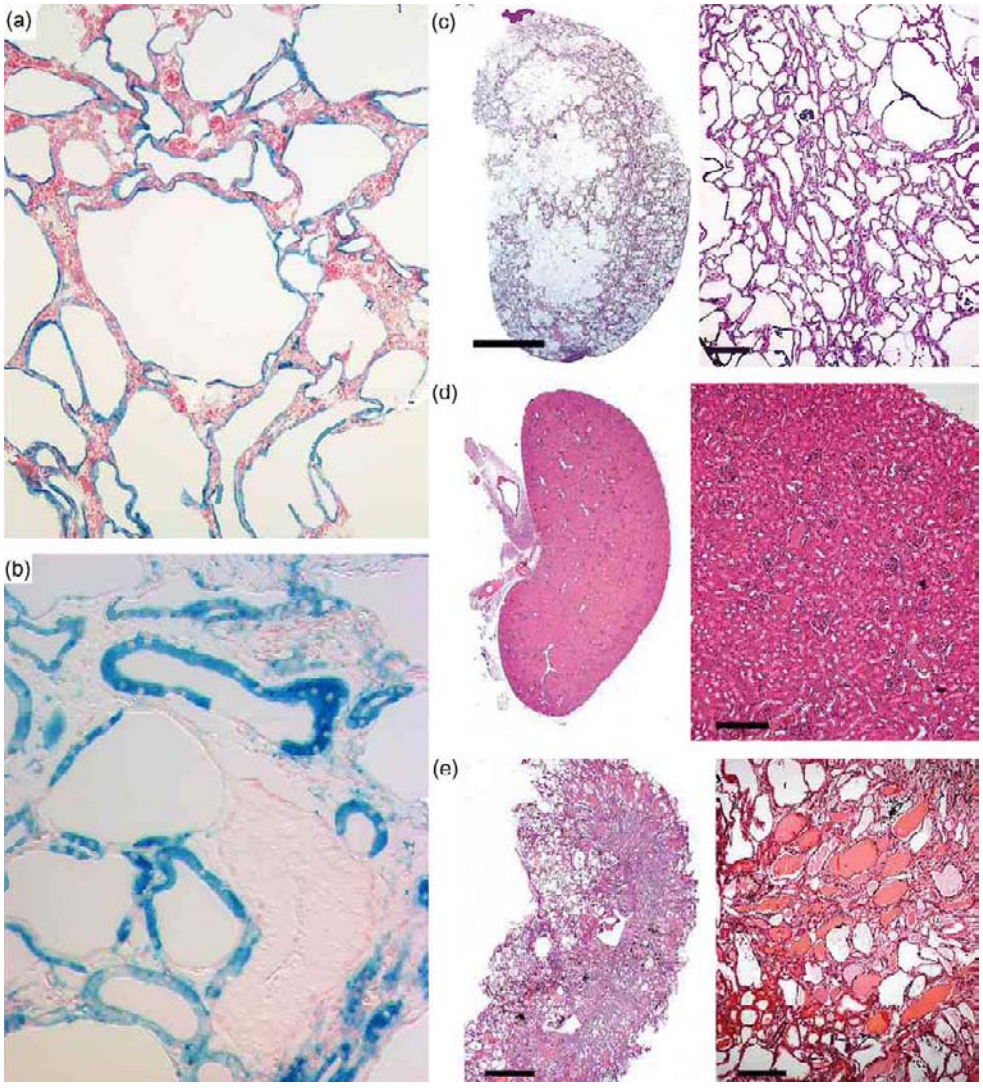

FIGURE 80.3 Mouse models of polycystic kidney disease. **a**: Conditional mouse model of polycystic kidney disease due to homozygous inactivation of Pkd1 in some nephron segments. Cells in the kidney that have undergone inactivation of *Pkd1* are marked by the β-galactosidase expression (blue) from a Cre-recombinase reporter expressing *lacZ*. Tubule segments (*) and glomeruli (*arrowheads*) in which Pkd1 is not inactivated appear normal but are confined to septa between expanding cysts lined by cells stained blue indicating *Pkd1* has been inactivated. **b**: Chimeric mice produced from Pkd1 − / − ES cells aggregated with wild type morulae marked by constitutive lacZ expression show mosaic cyst formation. Cyst lining are comprised of cuboidal wild type cells (*blue staining*) and flat Pkd1 − / − cells that do not express lacZ and are therefore unstained (indicated by arrows). (Images courtesy of Stefan Somlo and Saori Nishio). **c**: Early inactivation of *Pkd1* results in rapidly progressive cyst formation; cystic kidneys postnatal day 19 following inactivation of *Pkd1* on postnatal day 2. **d,e**: Adult inactivation of *Pkd1* results in slowly progressive polycystic kidney disease. Kidneys at 3 months (**d**) following inactivation at 1.5 months show no overt cysts; kidneys at 6 months (**e**) following inactivation at 1.5 months show progressive cyst formation. **d**–**e**: Scale bars, 2 mm (left panels); 100 μm (right panel). *(Modified and reprinted by permission from Macmillan Publishers Ltd: Piontek K et al., A critical developmental switch defines the kinetics of kidney cyst formation after loss of* Pkd1, Nature Medicine, *13:1490–95, copyright 2007.).*

kidney disease have been discovered using *in vivo* model systems. These factors include: (1) The critical role of the timing of second hit mutations with respect to developmental stage, (2) the discovery that reduced dosage of PC1, not just complete absence, is sufficient for graded cystic dilation, (3) the potential role of kidney injury in fostering PKD progression, and (4) the finding that loss of polycystins can exert effects on surrounding cells to promote disease progression. Evidence that timing of polycystin inactivation has a profound impact on the rate of cyst growth came from inducible conditional inactivation mouse models permissive for inactivation of *Pkd* genes either during kidney development or during adult life.[165,169] Using such a model, Piontek et al. showed that inactivating *Pkd1* in the early postnatal period when the mouse kidney is

still undergoing active nephrogenesis resulted in rapid progression of polycystic kidney disease whereas inactivation of *Pkd1* in the post-developmental adult kidney resulted in very slow progression polycystic kidney disease.[165] A similar finding of rapid cyst growth following early inactivation and slow cyst growth following late inactivation was observed in a polycystic model based on cilia ablation following inactivation of *Kif3a*.[169] The discovery of the timing of gene inactivation as a contributing factor to disease progression has led to consideration of the possibility that the majority of somatic second hit mutations in human ADPKD as well as the critical rapid growth phase of cysts occur during embryogenesis.[172] Such a mechanism, if confirmed in patient studies, would potentially have significant implications for the timing of the most effective therapy in ADPKD.

The impact of reduced PC1 dosage, as opposed to complete loss, in polycystic kidney disease has emerged over the past several years. Two animal models expressing hypomorphic (i.e., reduced function) alleles of *Pkd1* showed progressive cyst formation despite the presence of some residual *Pkd1* activity.[173,174] Similarly, loss of the protein bicaudal C results in reduced PC2 expression and cyst formation through de-repression of inhibitory microRNAs.[175] The significant interplay of gene dosage and polycystic kidney disease has, however, best been defined by studies centered on the genes responsible for isolated polycystic liver disease without kidney cysts (ADPLD)—a disease with indistinguishable clinical features from the polycystic liver disease that occurs in ADPKD patients.[176] Heterozygous loss of function mutations in two genes have been identified so far for this dominantly inherited disease: *PRKCSH* and *SEC63*.[177–179] *PRKCSH* encodes the non-catalytic β-subunit of glucosidase II (GIIβ), an *N*-linked glycan processing (glucose trimming) enzyme in the ER.[180–184] The SEC63p protein is highly conserved from yeast to man and functions as part of the ER protein translocation machinery to deliver proteins into and through the ER membrane. The functional unit for this process is the multicomponent translocon (Figure 80.4).[185,186] The activities of the translocon are tightly coordinated with downstream events of protein folding, modification and assembly, thereby providing a direct link between membrane targeting (including the cilial membrane) and protein maturation,[185] and between Sec63p and GIIβ functional pathways.[171,186] While neither protein is expressed in cilia, the connection of these proteins to polycystic kidney diseases is underscored by the finding that *Prkcsh* and *Sec63* conditional mouse models develop kidney cysts in addition to liver cysts by a two hit mechanism when either gene is inactivated in a tissue selective manner.[171] The severity of the polycystic phenotype in the ADPLD gene knockouts can be worsened by reducing the *Pkd1* gene dosage. Increasing *Pkd1* dosage by either genetic or pharmacologic means on the other hand eliminated cyst formation.[171] The ability to modulate severity of polycystic kidney disease in these models by manipulating *Pkd1* dosage establishes PC1 is the rate limiting component of the cystic pathway in both ADPKD and ADPLD. Interestingly, the same study showed that PC1 dosage also affects the severity of the kidney disease Due to mutations in *Pkhd1*, the ARPKD disease gene.[171]

Acute kidney injury following ischemia, nephrotoxin exposure or reduction of renal mass results in markedly augmented progression of cyst formation in animal models based on *Pkd1*, *Pkd2*, *Kif3a* or *Ift88*.[187–192] This is particularly true in adult onset models that otherwise show indolent progression in the absence of injury. These environmental "third hits" have been proposed as an essential part of disease progression in human ADPKD.[193] While it is likely that kidney injury can exacerbate polycystic kidney disease, its contribution to disease progress in human ADPKD is uncertain given that cyst progression also occurs in animal models in the absence of injury.[165,194,195] Finally, evidence is accumulating that there are effects promoting cyst formation that are active in the context of the whole kidney organ and may impact cells that have not lost polycystin expression. Perhaps the most intriguing of these was suggested by a unique chimeric animal model produced by aggregation of $Pkd1^{-/-}$ embryonic stem cells with wild type morulae expressing LacZ as the wild type lineage marker[196] (Figure 80.3). These mice formed kidney cysts commensurate with the degree of $Pkd1^{-/-}$ chimerism. The cyst lining epithelia were mosaic with both $Pkd1^{-/-}$ and $Pkd1^{+/+}$ epithelial cells present in the early stages of cystogenesis. The $Pkd1^{-/-}$ cyst cells appeared flat while the $Pkd1^{+/+}$ cells were cuboidal. Over time, $Pkd1^{-/-}$ cells replaced the $Pkd1^{+/+}$ cells by inducing apoptosis via the c-Jun N-terminal kinase (JNK)-mediated pathway.[196] These findings suggest the possibility that cells that lose PC1 expression induce cystic degeneration followed by programmed cell death in surrounding wild type tubular cells. Another study based on kidney specific inactivation of Pkd1 demonstrated the importance of the immune response mediated by macrophages in the progression of cyst formation in ADPKD.[197] Orthologous gene models of ADPKD based on either *Pkd1* or *Pkd2* show infiltration of alternatively activated macrophages into the pericystic space early in the course of the disease. Pharmacologic depletion of the macrophages markedly slows the rate of growth of kidney cysts in these models.[197] And aggregately, these animal models based on genes orthologous to human ADPKD are providing an increasingly complex and

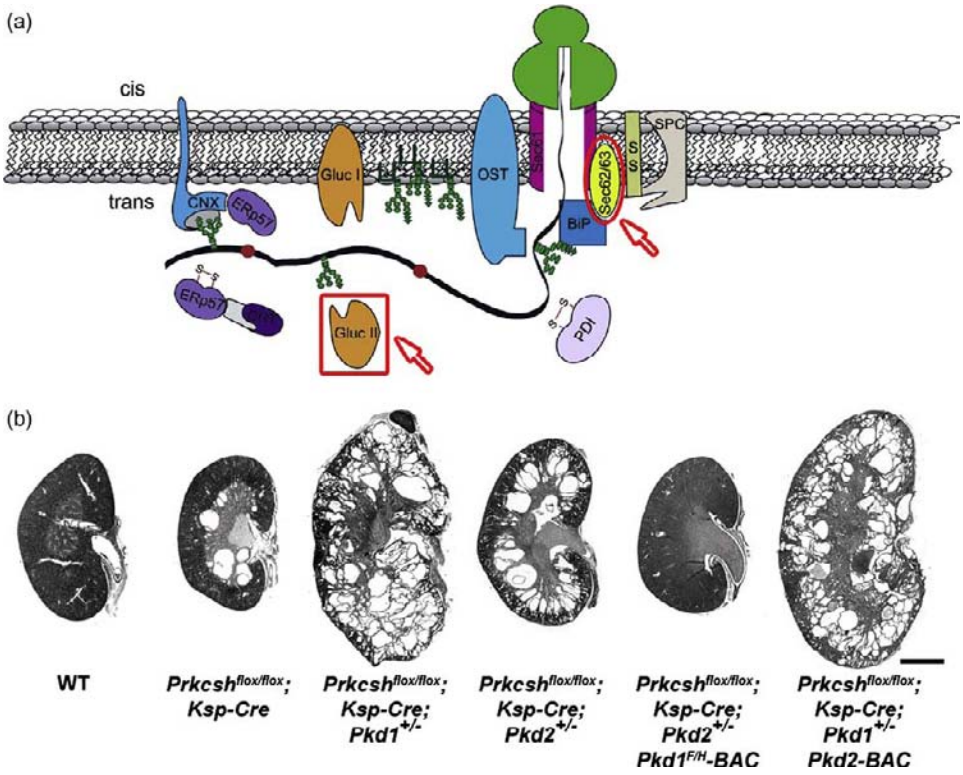

FIGURE 80.4 The inter-relationship of isolated polycystic liver disease (ADPLD) with polycystic kidney disease (ADPKD). **a**: The two known polycystic liver disease gene products, the β subunit of glucosidase-II (GIIβ, indicated as Gluc II, red box) and SEC63 (red oval), are shown in relation to the multicomponent co-translational translocon. GII is an N-linked glycan processing (glucose trimming) enzyme in the ER that plays a major role in regulation of proper folding and maturation of glycoproteins. SEC63 acts as a docking site localizing the ER chaperone BiP to the luminal exit site of the translocon. BiP plays a direct role in gating of the translocation channel and in polypeptide transport via an ATP-dependent reaction that is activated by SEC63. There is a tight interconnection between protein translocation mediated by the multicomponent translocon and protein maturation involving the N-linked glycan processing enzymes, providing a direct link between the functions of the ADPLD gene products. Co-translational maturation events in this pathway include signal peptide cleavage, the transfer and trimming of *N*-linked glycans including the activity of GII, disulfide bond formation, transmembrane domain integration, chaperone binding and protein folding. SPC, signal peptidase complex; SS, signal sequence; PDI, protein disulfide isomerase; OST, oligosaccharyl transferase; Gluc I, glucosidase I; Gluc II, glucosidase II (α and β subunits); CNX, calnexin; CRT, calreticulin. *(Modified and reprinted by permission from Elsevier: ref. [185], copyright 2003.)* **b:** The critical effect of polycystin-1 (PC1) dosage on polycystic disease severity. Inactivation of the APDLD gene *Prkcsh* encoding GIIβ in collecting ducts result in kidney cyst formation due to impaired PC1 biogenesis. The severity of cyst formation is markedly increased by further reducing PC1 with $Pkd1^{+/-}$ background and moderately increased by reducing polycystin-2 (PC2) on the $Pkd2^{+/-}$ background. Over-expression of PC1 using the $Pkd1^{F/H}$-BAC transgene rescues the $Prkcsh^{flox/flox}$;*Ksp-Cre;Pkd2* + / − cystic phenotype; *Pkd2*-BAC has no effect. Ages, P42; scale bar, 2 mm. *(Reprinted by permission from Macmillan Publishers Ltd: Fedeles S et al., A genetic interaction network of five genes for human polycystic kidney and liver diseases defines polycystin-1 as the central determinant of cyst formation,* Nature Genetics, *43:1639–647, copyright 2011.)*

complete picture of the molecular genetic basis for disease progression. These studies also serve to emphasize the importance of using *in vivo* models to validate and refine data obtained from *ex vivo* tissue culture-based systems–ADPKD is after all a disease of three-dimensional organ structure and is most appropriately studied using *in vivo* models.

Molecular Determinants of Disease Progression

Studies have begun to provide clues as to the genetic determinants of disease progression. Interfamilial variation in ADPKD is strongly influenced by gene locus. *PKD1* causes more severe disease than *PKD2*,[139,198] yet the gene products are thought to function in the same genetic and biophysical pathway.[111,199] Either of two explanations can underlie this observed difference: mutation of *PKD1* is inherently a more severe molecular lesion than mutation of *PKD2* or the occurrence of the somatic second hit alterations that precipitate cyst formation more readily affect *PKD1* than *PKD2*. In general, the data support the latter mechanism. Homozygous inactivation of *Pkd1* or *Pkd2*

in the mouse results in similar severity of kidney and pancreatic cystic disease, embryo edema, hemorrhage and embryonic lethality.[161,162] While PC1 is rate limiting in models of dosage reduction, there is an absolute requirement for functional PC2 for PC1 to function normally.[171] Indeed, the *Pkd2*$^{-/-}$ mouse has the additional phenotypic features of randomization of left-right axis formation[106,112] and defects in heart septum formation,[162] neither of which are seen in *Pkd1*$^{-/-}$ mice.[200] Defects of the conotruncus, such as dual outlet right ventricle, have been a variable finding in *Pkd1*$^{-/-}$ mice[201,202] as have defects of bone ossification,[201,203] and vascular integrity.[85] These phenotypes have not been specifically investigated in *Pkd2*$^{-/-}$ mice. In the genetic model organism *Caenorhabditis elegans* (nematode), mutation to either the *Pkd1* ortholog, *lov-1* or the *Pkd2* ortholog, *pkd-2*, results in identical defects in the stereotypical male mating behavior.[204] Doubly mutant *lov-1:pkd-2* worms do not show increased phenotypic severity.[204]

The higher population frequency and increased clinical severity of *PKD1* disease compared to *PKD2* may be explained in large part by a higher frequency, respectively, of germline and somatic mutation affecting *PKD1*. This in turn is certain to be influenced by the four-fold larger coding sequence of *PKD1* compared to *PKD2*. The recent recognition that PC1 is the rate limiting component of the polycystin complex coupled with the significantly higher rate of pathogenic non-synonymous amino acid substitution mutations in PC1 compared to PC2, further suggests that a broader range of mutations in PC1, than in PC2, will result in ADPKD.[14,171] The strongest support for this theory that the frequency of mutation is primarily responsible for the locus specific differences in disease severity comes from the CRISP.[16] At baseline, *PKD1* kidneys had more cysts and were larger than *PKD2* kidneys. However, while the absolute changes in kidney volume were greater for *PKD1* (74.9 mL/year) than for *PKD2* (32.2 mL/year), the relative rates of growth were not significantly different for the two genotypes (5.68% per year vs. 4.82% per year). This suggests that cyst initiation, but not cyst enlargement, is modulated by the disease gene; *PKD1* is more prone to second hits than *PKD2*, but there is no inherent difference in cyst growth potential once second hits occur in either gene.

Most of the several hundred *PKD1* mutations described to date are unique to individual families. This suggests that each mutation essentially arose as a *de novo* event that was fixed in the population since it confers little or no significant reproductive disadvantage.[205] The *de novo* mutation rate for *PKD1* is estimated to range from 1.8×10^{-5} to 6.9×10^{-5} per generation.[206,207] Studies in heterozygous mouse models support these theories. *Pkd2*$^{+/-}$ mice uniformly show loss of PC2 immunoreactivity in cyst linings suggesting that homozygous somatic loss is the underlying cystogenic event; cyst linings in *Pkd1*$^{+/-}$ mice uniformly showed presence of PC2 immunoreactivity allowing for the inference that it was PC1 that was lost in these cysts.[160] In compound heterozygous *Pkd1*$^{+/-}$:*Pkd2*$^{+/-}$ animals, 160 of 171 cysts (93%) showed uniformly positive staining for PC2, 8 (5%) were negative for PC2 and 3 (2%) could not be evaluated. This suggests that in compound heterozygous mice, *Pkd1* was far more often the target of somatic loss *in vivo*.[160]

Genotype-Phenotype Correlations

Genotype-phenotype correlations refer to the association between specific germline mutations (genotype) and the resulting spectrum of disease expression (phenotype). Genotype-phenotype correlations are largely absent in ADPKD with two notable exceptions.[208] The first is the occurrence of contiguous gene deletion syndromes with loss of *PKD1* in conjunction with loss of adjacent *TSC2*, the gene mutated in tuberous sclerosis complex 2. This contiguous gene syndrome results in early onset severe APDKD and clinical features of tuberous sclerosis.[209,210] The second example of genotype-phenotype correlation in ADPKD occurs with recessive inheritance of hypomorphic alleles (i.e., partial, as opposed to complete, loss of function) in either *PKD1*[211,212] or *PKD2*.[213] The phenotype observed in individuals with hypomorphic alleles affecting both copies of the respective *PKD* gene can mimic ARPKD[212] with early-onset polycystic disease manifest by diffuse and more homogeneous, albeit smaller cyst formation.

The marked intrafamilial variation otherwise seen in ADPKD suggest that factors other than the germline mutation determine the course of the disease.[214] This intrafamilial variation was illustrated in a study of dizygotic twins, one of whom developed severe polycystic kidneys *in utero* while the sibling showed a more typical course of adult onset disease.[215] Similarly, in an analysis of age of renal death in 74 parent-offspring pairs, the median difference within the pairs was 0 years, but with a range −26.3 to +27.2 years that followed a normal Gaussian distribution.[216] A systematic analysis of genotype-renal function correlation in 461 affected individuals from 71 ADPKD families with known *PKD2* mutations revealed that the location of *PKD2* mutations did not influence the age of onset of ESRD.[217] This study also found that marked intrafamilial variability in disease severity occurs in *PKD2* as well, with several individuals showing presentation of ESRD before age 50 while affected family members had the typical late onset disease.

Over 90% of mutations in *PKD2* are predicted to be chain terminating loss of function alleles.[14] In *PKD1*, about one third of putative pathogenic variants are predicted to be amino acid substitution or other in-frame variants. Most of the non-truncating mutant alleles are thought to be loss-of-function[218] although missense variants behaving as hypomorphic alleles that result in mild disease expression in the heterozygous state have been identified.[219] Two studies have correlated 5′ location of mutations in *PKD1* with more severe phenotypes. In one study examining 324 patients from 80 families with known *PKD1* mutations, location of the mutations 5′ to the median position correlated significantly with about a 3 year earlier onset of ESRD.[218] In a second study, 51 patients with vascular complications and known *PKD1* mutations were evaluated. The median position of the *PKD1* mutation was significantly further 5′ in the vascular population than in *PKD1* families without vascular complications.[220] Within the vascular population, more severe disease as defined by aneurysmal rupture, early rupture, or more than one vascular case in the family had median mutation locations more 5′ than the *PKD1* vascular population as a whole.[220] These data correspond to a previous report of a smaller number of cases[221] and raises the possibility that the large 5′ extracellular domain of PC1 may act as a dominant factor in aneurysmal complications in ADPKD.

Modifier Effects in ADPKD

Modifier effects, either genetic or environmental, are an alternative explanation to stochastic factors such as second hit timing and frequency for the phenotypic variation seen in ADPKD. The observed intrafamilial variability that argues against strong allelic effects may in fact argue for genetic background effects within families modulating disease expression.[208] A study comparing intrafamilial variation in age to ESRD among siblings to that in monozygotic twins found significant excess variability among the siblings relative to the genetically identical twin pairs.[142] The genetic contribution to intrafamilial disease variability, defined as the proportion of the variance explained by modifier genes (i.e., heritability), was assessed using variance component analysis in two studies. The first examined 406 patients from 66 *PKD1* families and estimated the heritability for creatinine clearance (C_{cr}) among those without ESRD to be 42% and the heritability for ESRD to be 78% among those with ESRD.[222] Although conclusions from this data are limited by power, one possible interpretation that emerges is that genetic factors contribute to differing extents to progression in early stage disease and late stage disease. A second study examined variance of a number of phenotypic traits in 315 affected relatives in 83 *PKD1* families. The heritability for these traits ranged from 18 to 59% of the variance.[223] In this study, modifier genes accounted for 32% of the variance for C_{cr} and 43 to 50% of the variance for age of ESRD,[223] again showing the trend toward more heritability for late stage disease. One putative modifier gene locus was identified in a severely affected *PKD1* family in which affected individuals also carried a heterozygous mutation for HNF-1β,[224] a transcription factor that has been implicated in regulating of *PKD* gene expression.[225,226] A second study analyzing candidate genes as modifiers in a large cohort of ADPKD families identified the canonical Wnt inhibitor Dickkopf 3 as a candidate for modifying ADPKD expression.[227] Much larger studies than these will be required to actually begin to identify modifier loci in genome-wide association studies.[222]

THE PKD GENES AND THEIR PROTEIN PRODUCTS

The *PKD1* and *PKD2* gene products, respectively identified as PC1 (PC1) and PC2 (PC2), were unique and complex when first discovered (Figure 80.5). They have only grudgingly yielded the functional clues that will eventually lead to a full understanding of ADPKD and a successful development of appropriate mechanism-based treatment paradigms.

Polycystin-1

Polycystin-1 (PC1) is an eleven membrane spanning 4302 amino acid protein with a ~3000 amino acid extracellular NH_2-terminus and a ~220 amino acid cytosolic COOH-terminus[129,228] (Fig. 80.5). The extracellular NH_2-terminal domain contains distinct combination protein motifs including leucine-rich repeats, a WSC homology domain, C-type lectin domain, an LDL-A related domain, and 16 immunoglobin-like domains PKD repeats,[129,228,229] a receptor egg jelly (REJ) module containing four fibronectin type III FNIII) domains[230] and a GPCR proteolytic site (GPS motif)[231] within a newly defined GPC autoproteolysis inducing domain (GAIN domain) shift.[232] Additional domains identified either by homology or computational prediction include a PLAT/lipoxygenase homology 2 (LH2) domain between the first and second transmembrane spans[233,234] and a polycystin motif region in the extracellular loop between the sixth and seventh transmembrane spans.[235] The cytoplasmic COOH-terminus of PC1 contains a coiled-coil domain.[236,237] The region of the last five transmembrane spans of PC1 share sequence homology with PC2 (PC2) although there are critical differences in the sequence that suggest that PC1 does not function directly as a channel protein the

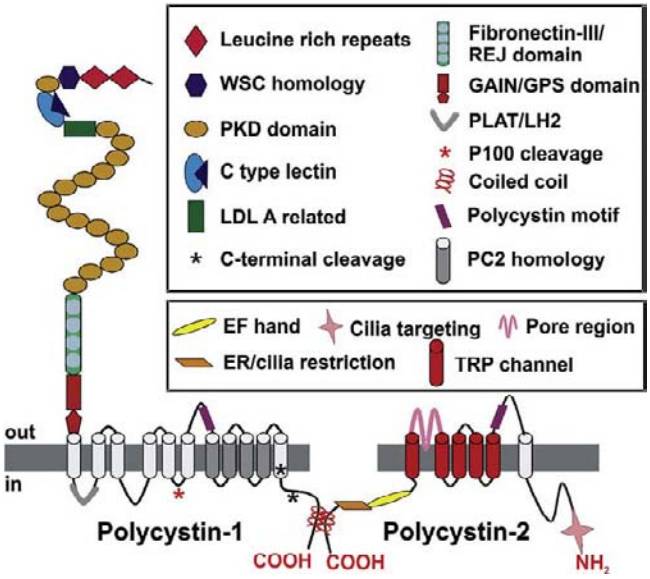

FIGURE 80.5 Schematic representation of the predicted structural domains of polycystin-1 (PC1) and polycystin-2 (PC2). There are a combination of structurally predicted domains and experimentally identified or verified functional domains shown. In PC1, the immunoglobulin-like structure of the PKD domains and the GAIN/GPS domain have been determined by structural studies as have the respective coiled coil domains in the COOH-termini of PC1 and PC2. The interaction of the COOH-terminal coiled coil domains of PC1and PC2 is well established. PC1 undergoes autoproteolytic cleavage at the GPS site to form the extracellular NH_2-terminal fragment and the intramembranous COOH-terminal fragment, which remain noncovalently associated with each other. Additional PC1 cleavage sites have been identified in the COOH-terminus as well as in the intramembranous region. The TRP channel function of PC2 has been shown in several systems to be a nonselective cation channel permeable to Ca^{2+}. The functions of the cilia targeting and the ER/cilia restriction domains in PC2 have defined.

way PC2 does[235] (see Polycystin Channel Function subheading below).

The location and topology of the predicted 11 transmembrane spans of PC1 was demonstrated by experimentally using glycosylation reporter analysis.[238] The NMR solution structure of one the PKD domains, so named because they were first described in PC1, showed the domain to have a β-sandwich fold that belongs to a distinct family uniquely conserved among vertebrate polycystin homologs.[239] Atomic force spectroscopy has shown that PKD domains confer increased tensile strength to the PC1 molecule.[240,241] However, another study found that the PC1 extracellular region is highly extensible and that this extensibility is mainly caused by the unfolding of its immunoglobulin-like PKD domains.[242] Stretching the native PC1 extracellular region results in a sawtooth pattern with equally spaced force peaks resulting from the sequential unfolding of individual PKD domains and domains refold after mechanical force unloading. The tensile properties of the PKD domains is altered by naturally occurring missense mutations found in patients.[243] The PKD domains, along with the WSC homology domain, C-type lectin domain, an LDL-A related domain are thought to be involved in protein-protein or protein-carbohydrate interactions which have led to speculation that PC1 could serve as a receptor for unknown ligands. A mechanosenory role in flow sensation has also been proposed for PC1.[111] PC1 signaling events might be regulated through force driven unfolding/refolding events with or without associated ligand interactions.

PC1 has broad tissue expression, including kidney, brain, heart, bone, and muscle.[244–246] Its expression is developmentally regulated with high levels of expression in developing mouse tissues that subsequently decline.[244,246] The subcellular localization of PC1 in tissues has been difficult to establish likely due to a combination of very low abundance of the native protein and limitations of the antibody reagents. Several studies identified PC1 in the plasma membrane of kidney tubule cells, particularly in the distal nephron segments including collecting ducts.[33,152,247] Within these segments, PC1 appeared at the lateral membrane at sites of intercellular adhesion[248] and at desmosomes.[249] Over-expressed, epitope-tagged full length PC1 has been localized in the lateral membrane.[250] Similar lateral location of a PC1–PC2 complex was reported in kidney tissue overexpressing PC1 as a transgene,[251] although a similar pattern was not reported in epitope tag knockin model.[246] Following the paradigm shift resulting from the discovery of the role of primary cilia in ADPKD and related disorders, much of the emphasis on the subcellular localization of native PC1 has shifted to primary cilia of epithelial cells from the kidney[105,111] and other tissues.[246] Most recently, PC1 has been found to be a component in urinary exosome-like vesicles, whose potential role in the functioning of polycystin signaling and ADPKD is just beginning to be explored.[252]

PC1 Homologous Proteins

With the advent of the sequencing of the human and mouse genomes, four genes encoding proteins structurally related to PC1 have been identified in mammals. PKDREJ contains REJ and GPS motifs in the extracellular part and the PLAT/LH2 domain in the first intracellular loop.[253,254] PKDREJ is only expressed in mammalian testis and mature sperm where it is localized to the plasma membrane and may contribute to transmembrane signaling[255] and controls the timing of fertilization through effects on sperm motility and exocytotic competence.[256] PKD1L1 has two PKD domains,

as well as REJ and GPS motifs in the extracellular region, a PLAT/LH2 domain in the first loop, and a coiled-coil domain in the C-terminal cytoplasmic tail.[257] *Pkd1L1* knockout mice develop defects in left right axis determination,[258] a cilia based phenotype also observed in *Pkd2* knockout mice,[106,112] but absent from *Pkd1* null embryos.[200] Unlike in kidney tissues where PC1 and PC2 are thought to form a receptor channel complex in primary cilia, evidence suggests that in the cilia of the embryonic node responsible for left-right axis determination, Pkd1L1 and PC2 form the signaling complex required for left-right patterning.[259,260] The PKD1L2 and PKD1L3 protein products contain the combination of GPS and PLAT/LH2 domains that uniquely identify all PC1 family members.[235] In addition, both have a C-type lectin domain; PKD1L2 also contains PKD and REJ domains. PKD1L2 and PKD1L3 have transient receptor potential (TRP; see section on PC2 below) ion channel signatures in the last five transmembrane spans that are conserved with PC2 family members suggesting that, unlike PC1, they may possess cation channel functions. A complex of PKD1L3 and a PC2 homolog, PKD2L1, has been identified as a candidate sour taste receptor.[261–263] In addition, this complex has been proposed to function as cerebrospinal fluid chemosensory system that selectively triggers action potentials in response to decreases in extracellular pH.[261] Finally, an overexpression mouse model for Pkd1L2 shows a complex myopathic neuromuscular phenotype[264] that may be related to its function as a cation channel. This data emerging from studies of homologous proteins suggests the possibility that permuted combinations of PC1 and PC2 homologs confer tissue and developmental stage specific functions to polycystin complex and may suggest a broader role for these novel signaling complexes in vertebrate organisms. Understanding the bases for the function of any of these putative receptor-channel complexes may shed considerable mechanistic insight into the functioning of the PC1/PC2 complex that is central to ADPKD.

PC1 Cleavage

The complexity and potential diversity of PC1 function is further amplified by a series of proteolytic events yielding fragments in both the extracellular and intracellular compartments. PC1 undergoes autoproteolytic cleavage at the GPS motif within the GAIN domain to produce an NH_2-terminal fragment (NTF) comprised of the first extracellular domain and a COOH-terminal fragment (CTF) containing the eleven membrane spans and the cytosolic tail[232,265,266] (Figure 80.5). This cleavage process requires an intact REJ module and GAIN domain and likely occurs early in the biosynthetic pathway, probably at the level of the endoplasmic reticulum (ER). The NTF and CTF remain non-covalently associated with each other and functional GPS cleavage is required for PC1 to be able to stimulate spontaneous tubulogenesis of MDCK cells in three dimensional matrix culture.[265] GPS cleavage is conserved in proteins evolutionarily related to PC1[267] and has been reported as an essential step for folding, trafficking, and bioactivity of non-polycystin proteins.[268] The crystal structure of the GAIN domain, which includes the GPS motif at its COOH-terminal region, has recently been solved in two distantly related adhesion-GPCRs which share this domain with the PC1 related proteins in higher organisms.[232] The GPS cleavage process is thought to be necessary for proper trafficking of PC1[269] and for autoinhibitory function in adhesion-GPCRs. GPS cleavage deficient knockin mice show a partial rescue of the *Pkd1* null phenotype suggesting that uncleaved PC1 may behave as hypomorphic allele.[270]

A second intra-membranous cleavage product of PC1 results in the P100 intramembranous fragment with six membrane spanning domains.[271] P100 acts to reduce store operated calcium entry through a mechanism involving the ER calcium sensor protein STIM1.[271] The cytoplasmic tail of PC1 is also cleaved. Two processes have been described that liberate different sized fragments, both of which traffic to the nucleus and affect gene transcription.[272,273] These processes are discussed in detail in the section on C-terminal Cleavage below.

Interactions

The most significant biochemical interaction for PC1 remains its association with PC2. PC1 and PC2 interact through their respective COOH-termini[236,237,274–276] (Figure 80.5). The structural data suggest a stoichiometry of one PC1 molecule and three PC2 molecules in the complex.[276,277] The interaction depends on the integrity of the coiled coil domains in the COOH-termini of PC1 and PC2[237,275] and has been demonstrated using full length PC1 and PC2 constructs. All known pathogenic predicted truncating mutations in either gene result in loss of this interaction.[278] The recognition of this interaction soon after the discovery of the genes led to the hypothesis that PC1 may serve a receptor function that controls the channel activity of PC2 as part of the polycystin signaling complex.

Several other associated complexes for PC1 have been defined although their roles in the pathogenesis of ADPKD are less clear (reviewed in[279]). The extracellular domains of PC1 are capable of *in vitro* homotypic interactions via their PKD domain repeats that may mediate intercellular or intermolecular adhesion as part of polycystin function.[280] In *C. elegans*, the β-subunit of ATP synthase (ATP-2) co-localizes in cilia and

interacts with the PLAT/LH2 domain of the nematode PC1 homolog, LOV-1.[234] Casein kinase II also interacts with LOV-1 and this interaction may regulate trafficking of the *C. elegans* PC2 homolog into cilia in a phosphorylation dependent manner.[281] Interaction with the COOH-terminal domain of PC1 inhibits degradation and results in re-localization of regulators of G protein signaling (RGS7),[282] perhaps fitting with a postulated role for PC1 as an atypical G-protein coupled receptor.[283,284] The cytoplasmic tail of PC1 also interacts with tuberin, the tuberous sclerosis complex 2 (*TSC2*) gene product[285] (see mTOR). PC1 interacts with intermediate filament components including vimentin, cytokeratin 8 and 18 and desmin.[286] PC1 has also been shown to co-localize and complex with the intercellular adhesion molecules E-cadherin and β-catenin suggesting a possible role in stabilization of adherens junctions and the maintenance of the differentiated polarized state of epithelia in kidney tubules.[287,288] PC1 may mediate communication with the extracellular matrix as suggested by co-localization with α2, β1 integrin[289] and interaction with αv,β3 integrin via the COOH-terminal region of the β3 integrin.[290] This diversity of interacting partners highlights the likelihood that PC1 and PC2 (see below) serve a broad array of cellular and tissue functions, not all of which will be related to polycystic kidney disease.

Polycystin-2

From the time of its discovery, polycystin-2 (PC2) was hypothesized to be a cation channel most likely functioning in calcium-based signaling events.[131] PC2 is a 968 amino acid integral membrane protein with six membrane spans and intracellular NH_2- and COOH-termini (Figure 80.5). It belongs to the transient receptor potential (TRP) channel family. TRP channels constitute a family of channel proteins found throughout metazoan evolution that generally function as receptor gated sensory channels. The mammalian TRP channels encompass at least 28 different proteins that are grouped into six subfamilies based the complement of structural motifs in their respective cytosolic NH_2^- and COOH-termini (reviewed in[291,292]). The polycystins belong to the TRPP subfamily and PC2 is also called TRPP2. The last five transmembrane spans bear a strong TRP channel signature and the region between S5 and S6 (transmembrane segments 5 and 6) contains the putative pore region.[235] In addition, the large first extracellular loop between S1 and S2 contains a polycystin motif of unknown function that is highly conserved in all PC1- and PC2-related proteins.[235] The cytoplasmic tail contains a putative calcium binding EF-hand.[131,274,293] The EF hand binds calcium[293] and may have a role in modulating channel activation and inhibition.

PC2 is widely expressed in tissues, particularly the kidney, heart, ovary, testis, vascular smooth muscle, and small intestine.[294,295] In the kidney, PC2 is expressed in all nephron segments, with the possible exception of the thin limbs of the loops of Henle. PC2 is not expressed in the glomerulus. As with PC1, expression in the distal nephron segments may be more robust than in the proximal segments.[163] A domain in the COOH-terminus functions to restrict the membrane location of PC2 to the ER and cilia.[296] At a subcellular level, there is general agreement that both native and heterologously over-expressed PC2 is strongly expressed in the ER membrane of both cultured cells[251,278,296–299] and tissues.[110] The plasma membrane localization of PC2 has been the subject of debate (reviewed in[300]). Native PC2, but not heterologously over-expressed protein, has been reported on the plasma membrane both by anti-native protein antibodies[249,299] and by channel physiology.[301] It has also been proposed that PC2 requires co-assembly with PC1 to traffic to the cell membrane and co-expression of both polycystins results in appearance of a novel plasma membrane cation channel activity.[111,278] Conversely, studies using the C-terminal fragment of PC1 suggested a possible reciprocal role for PC2 in the cellular distribution of PC1.[269,302] There is consensus and strong evidence to show that PC2 is localized to the primary cilia in kidney tissues and cultured epithelial cells.[104,105,112] Native and over-expressed PC2 can be detected in the primary cilium.[303] The NH_2-terminus domain of PC2 containing an RVxP amino acid motif has been identified as both necessary and sufficient for cilia location of type 2 membrane proteins including PC2.[303,304] Trafficking of PC2 to cilia is independent of PC1.[303]

PC2 Homologous Proteins

Two homologs of PC2, PKD2L1 (or PCL) and PKD2L2, have been identified in the mammalian genome.[254,303,305,306] PKD2L1 is expressed in striated muscle (heart and skeletal), brain, spleen, and testis,[306] whereas PKD2L2 is expressed only in testis.[254] PKD2L1 has been shown to function in conjunction with PKD1L3 in sensing sour taste and cerebrospinal fluid pH.[261–263] PC2 is highly conserved in metazoan evolution and homologs have been identified in sea urchin, *C. elegans*, *Drosophila melanogaster* and zebrafish. In sea urchin, the PC2 homolog associates with suREJ3, the PC1 homolog, and both localize to acrosomal region of spermatozoa suggesting a possible role in the ionic channel events that accompany the acrosome reaction during fertilization.[307] In *C. elegans*, mutations in the PC2 homolog result in defects in location-of-vulva and response behavior in the male worms that is indistinguishable from the phenotype seen in LOV-1 (PC1

homolog) mutants.[204] As in mammalian systems, PC2 shows strong expression in the ER membrane and the cilia membrane in *C. elegans*. However, there is little sequence conservation of the cystolic NH_2^- and COOH termini from mammals to invertebrates (*C. elegans* and *Drosophila*) and there appear to be differences in the phosphorylation pattern[281] and trafficking signals[303] with mammalian protein. The PC2 homolog in *Drosophila* is expressed in sperm and knockout in fly results in sperm that retain normal backward motility and ability to fertilize but lose hyperactivation and directed movement required for reaching the female storage organs.[308–310] Flies with a loss of function PC2 allele showed reduced contractility of the visceral smooth muscle cells through a mechanism that requires cooperativity with the ryanodine receptor in regulating intracellular calcium homeostasis.[311] In mammalian systems, PC2 directly interacts with and regulates the activity of the ryanodine receptor[312] and alters smooth muscle cell calcium homeostasis.[83] Finally, zebrafish have proven to be a valuable vertebrate genetic model of polycystic kidney disease. Zebrafish have a pronephric kidney as well as left-right body axis asymmetry and knockdown or mutation of the PC2 homolog in fish results in cystic dilation of the pronephric tubule as well as abnormalities of left-right body axis formation.[114,313,314]

Channel Function

PC2 functions as non-selective cation channel permeable to calcium.[110,278,299,315] The initial studies used a variety of biophysical systems to characterize the channel and this may account for qualitative differences in the channel properties described for PC2. The systems used include co-expressed PC1 and PC2 in CHO-K1 cells studied by patch clamping,[278] the outer membrane of human placental syncytiotrophoblasts and reconstituted purified protein studied in lipid bilayers,[315] ER vesicles prepared from cells overexpressing wild type or mutant PC2 fused to lipid bilayers[110] or epithelial cells in culture treated with chemical chaperones and studied by patch clamp technique.[299] While the channel is non-selective for cations, it does pass calcium and most investigators believe that *in vivo* PC2 function is calcium-based second messenger signaling.[316] PC2 channel activity is stimulated by physiological concentrations of calcium and is inhibited by higher concentrations of calcium that may be achieved locally as a result of PC2 channel activity.[110,315] The critical role of the channel activity in the *in vivo* functioning of PC2 was demonstrated by a pathogenic patient mutation altering a single amino acid (D511V) that resulted in isolated loss of channel activity.[110,317] Aside from biophysical studies, the *in vivo* cellular effects of polycystins have been evaluated by monitoring changes in cellular calcium using fluorescent indicator.[110,111] PC2 can function as an ER calcium release channel.[110] Phosphorylation of PC2 at a casein kinase 2 site, serine 812, modulates channel activity[318] and has a role in trafficking of PC2 between ER, Golgi and plasma membrane compartments.[319] The function of PC2 as a putative mechanosensory channel in cilia[107,111] is discussed in the section on cellular calcium signaling below.

Interactions

The functional association of PC2 with PC1 was discussed in previous sections. PC2 associates with a number of calcium channel proteins. PC2 homomultimerizes with itself via its COOH terminus[236,320,321] as a predicted tetramer.[322] PC2 forms functional heteromeric channels through interaction with at least two other TRP channels, TRPC1[323,324] and TRPV4.[325] In keeping with its putative role in regulating cellular calcium homeostasis via intracellular calcium pools, PC2 interacts directly with the inositol 1,4,5-trisphosphate receptor (IP_3R)[326–328] and also regulates the activity of the ryanodine receptor through direct interaction.[312] PC2 interacts with the ER t-SNARE protein syntaxin-5 which acts to inactivate the channel.[329] Additionally, the mitotic centrosomal kinase Aurora A binds and phosphorylates PC2 at serine 829 and reduces the endoplasmic reticulum calcium release activity of PC2.[330]

Protein interaction screens have yielded several putative PC2 binding partners potentially involved in cytoskeletal interactions. PC2 binds Hax-1 which in turn associates with the F-actin-binding protein cortactin suggesting a link between PKD2 and the actin cytoskeleton.[331] The COOH-terminus of PC2 interacts with CD2AP[332] which also interacts directly with the actin cytoskeleton.[333] PC2 interacts with tropomyosin-1, troponin-1 and alpha-actinin, components of the actin microfilament complex.[334–336] Yeast two hybrid screening also identified mDia1/Drf1 (mammalian Diaphanous or Diaphanous-related formin 1 protein) as a PC2-interacting protein.[337] PC2 and mDia1 co-localize prominently at the mitotic spindles of dividing cells suggesting an association with microtubule cytoskeleton components.

Clues as to regulation of PC2 trafficking have also begun to emerge from studies of associated proteins. In addition to the previously noted co-assembly of PC1 and PC2, a novel interacting protein PIGEA-14 (chibby homolog 1) has been identified that plays a role in PC2 trafficking.[297] PIGEA-14 co-expression with PC2 resulted in translocation of both proteins to the trans-Golgi network, suggesting role for PIGAE-14 in regulating the intracellular location of PC2. PC2 has been proposed to bind to phosphofurin acidic cluster sorting protein (PACS)-1 and PACS-2 via an acidic

cluster in the COOH-terminal domain of PC2 that also contains the serine 812 phosphorylation site.[319] The phosphorylation of PC2 regulates the binding of these adapter proteins that in turn are required for the routing of PC2 between ER, Golgi and plasma membrane compartments.[319] In an attempt to unify the mechanisms of ADPKD with those for autosomal recessive polycystic kidney disease (ARPKD),[338,339] association between PC2 and the *PKHD1* (ARPKD) gene product fibrocystin[340,341] has been investigated. Fibrocystin and PC2 co-localize and co-immumoprecipitate suggesting that they may exist in the same complex[342] and this complex may also include the kinesin-2 anterograde cilia transport motor which may mediate fibrocystin dependent regulation of PC2 channel function.[343] Although direct association was not shown, the *klp-6* gene product in *C. elegans* encoding a kinesin-3 family member functions in the same genetic pathway as the polycystins (i.e., male mating behavior) and is required for localization and function *C. elegans* homolog of PC2 in cilia.[344]

CELLULAR PATHWAYS AFFECTED BY POLYCYSTINS

Anyone inspired to seek a quick primer on the arcane alphabet soup of signaling pathways might consider beginning their quest by perusing the literature documenting the list of cellular activities that may be susceptible to the eclectic influences of the polycystin proteins. This ever-lengthening roster includes the Wnt, mTOR, MAPK-ERK, and AP-1 cascades, and also involves the participation of most of the cell's arsenal of second messenger systems including cAMP, calcium, G proteins and G protein coupled receptors[345] (Figure 80.6). Much remains to be learned concerning the relative importance of the polycystins in modulating the activities of each these pathways and the relative importance of each these pathways in preventing or defining the pathophysiology associated with ADPKD. The number and variety of these pathways testifies to the complexity of the interwoven network of signaling mechanisms that control epithelial morphogensesis and the maintenance of luminal architecture and highlight the central position that the polycystins must occupy in this web.

Wnt Signaling

The canonical Wnt signaling pathway plays a central role in controlling cell proliferation and differentiation.[346] Aberrant Wnt signaling during embryogenesis can lead to axis duplication or dysgenesis of critical body structures,[347,348] and excessive Wnt signaling activity is associated with the malignant transformation and metastatic potential of neoplasms.[349] At the heart of the Wnt pathway is the multifunctional β-catenin protein, which is both a key constituent of the epithelial intercellular adhesive apparatus and an arbiter of a transcriptional pathway that profoundly influences cell proliferation and differentiation.[350,351] The adhesive junctions that alert epithelial cells to the proximity of their neighbors are mediated by the transmembrane calcium-dependent adhesion molecule E-cadherin.[352] The cytoplasmic COOH-terminal tail of E-cadherin binds to several soluble cytosolic proteins, including α-catenin, β-catenin and p120, which together link E-cadherin clustered at sites of cell-cell contact to the subcortical cytoskeleton, which in turns allows cells to exploit their intercellular adhesive junctions in order to organize their membranes into polarized domains.[353] The pool of β-catenin protein that is not bound to E-cadherin is able to enter the nucleus, where it binds to and activates the TCF transcription factor.[346] Many of the genes whose expression is controlled by TCF stimulate cell division, including c-myc, c-jun and cyclin D1.[354] Thus, sequestration of β-catenin at sites of cell-cell contacts prevents it from activating a transcriptional program that results in proliferation. In contrast, loss of cell-cell contact liberates E-cadherin-bound β-catenin, freeing it to pursue its pro-proliferative agenda.

Before β-catenin can enter the nucleus, however, it must negotiate a major hurdle in the form of the cytoplasmic Axin/GSK3/APC complex.[355] The primary purpose of this protein assembly is to capture and phosphorylate free β-catenin and, by so doing, doom it to degradation by the proteasome. Activation of the canonical Wnt signaling cascade leads to inhibition of the GSK3 kinase and hence to an increase in the size of the pool of β-catenin that is free to enter the nucleus and activate TCF-mediated transcription.[346] The Wnt ligands are a family of secreted polypeptides that bind to cell surface receptors composed of a transmembrane protein called Frizzled and a second transmembrane co-receptor that can be any one of several different members of the family of LDL receptor related (LRP) proteins. Ligation of Frizzled by a Wnt protein leads to activation of its cytosolic partner protein Disheveled, which interacts with the Axin/GSK3/APC complex to prevent it from targeting β-catenin for proteasomal destruction.[346] Stimulation of the Frizzled receptor can also elicit several β-catenin-independent effects, including transient elevations in cytosolic calcium concentrations and activation of c-jun kinase (jnk). These additional consequences of Frizzled activation are collectively referred to as non-canonical Wnt signaling.[356,357] Non-canonical Wnt signaling is intimately involved in the establishment of planar cell polarity[357] (see following sections).

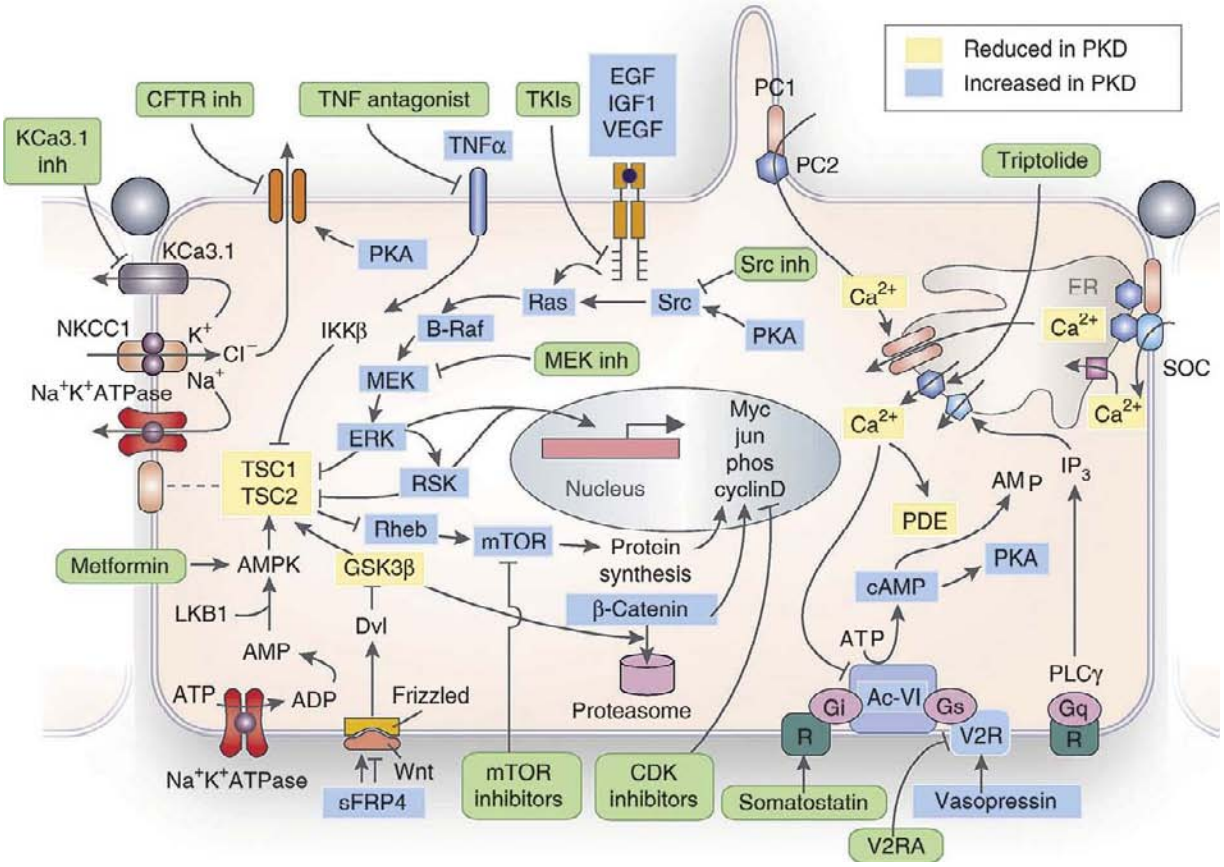

FIGURE 80.6 Signaling pathways associated with polycystin protein functions and PKD. PC1 and PC2 function has been implicated in the up-regulation (blue boxes) or down-regulation (yellow boxes) of a variety of cellular signaling pathways that play important roles in cell growth and differentiation. In the cilium, the polycystin complex appears to participate in flow- or ligand-stimulated calcium entry. Intracellular endoplasmic reticulum (ER) calcium stores are also subject to regulation by the polycystins. Increased concentrations of cAMP, activation of ErbB receptors, and up-regulation of EGF, IGF1, VEGF, and TNF have been described in cells or kidneys with defective polycystin function. Increased cAMP levels contribute to cystogenesis by stimulating chloride and fluid secretion. Activation of tyrosine kinase receptors by ligands present in cystic fluid may contribute to stimulation of MAPK/ERK signaling. Phosphorylation of TSC2 by ERK may lead to the dissociation of TSC2 and TSC1 and lead to the activation of Rheb and mTOR. Up-regulation of TNF or down-regulation of AMPK signaling may also stimulate mTOR signaling through inhibition of the TSC2/TSC1 complex. Activation of AMPK may also blunt cystogenesis through inhibition of CFTR and ERK. Up-regulation of Wnt signaling stimulates mTOR and β-catenin signaling. ERK and mTOR activation promotes G1/S transition and cell proliferation through regulation of cyclin D1. These effects of mutations in polycystin provide the rationale for treatment with V2 receptor antagonists, somatostatin, triptolide; tyrosine kinase, src, MEK, TNF , mTOR, or CDK inhibitors; metformin, and CFTR or KCa3.1 inhibitors (green boxes). AC-VI, adenylate cyclase 6; AMPK, AMP kinase; CDK, cyclin-dependent kinase; ER, endoplasmic reticulum; MAPK, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; PC1, polycystin-1; PC2, polycystin-2; PDE, phosphodiesterase; PKA, protein kinase A; R, somatostatin sst2 receptor; TSC, tuberous sclerosis proteins tuberin (TSC2) and hamartin (TSC1); V2R, vasopressin V2 receptor; V2RA, vasopressin V2 receptor antagonists. *(Reprinted by permission from Macmillan Publishers Ltd: Harris P.C. & Torres V.E., Autosomal dominant polycystic kidney disease: the last 3 years,* Kidney International, *76:149–168, copyright 2009.)*

Several lines of evidence indicate that the polycystin proteins participate in modulating Wnt signaling and that perturbations of Wnt signaling can lead to renal cystic disease. Studies of genetically manipulated mouse models reveal that either kidney-specific inactivation of the APC gene or expression of constitutively active β-catenin both result in the development of renal cysts that closely resemble those found in ADPKD.[358,359] PC1 can be co-immunoprecipitated in a complex that includes E-cadherin and β-catenin,[287,288,360] indicating that the potential exists for PC1 to exert a direct influence over the stability or extent of membrane bound pool of β-catenin. Overexpression studies employing membrane tethered constructs incorporating the C-terminal of PC1 offer conflicting results. One such study suggests that the membrane tethered C-terminal tail of PC1 can activate Wnt signaling reporters,[361] whereas another study employing similar construct did not detect this activity.[362] The basis for this discrepancy remains to be elucidated. Recent results indicate that the expression of genes associated with activation of the Wnt

pathway is elevated in cystic renal tissue derived from the excised kidneys of ADPKD patients, as compared to the expression levels detected in normal-appearing non-cystic tissue derived from the same kidneys.[363]

A seminal study on inversin, the protein encoded by the gene mutated in nephronophthisis type II, illustrates a fascinating paradigm through which a polypeptide associated with a renal cystic disease can influence signal transduction through both the canonical and non-canonical Wnt pathways. Inversin marks Disheveled for degradation in the proteasome, thus turning off canonical Wnt signaling by preventing Disheveled from inhibiting GSK3.[364] Inversin also enhances manifestations of planar cell polarity that are under the control of the non-canonical Wnt pathway. As discussed in a later section, cleavage of the PC1 COOH-terminal tail releases a fragment that is capable of activating jnk and therefore may be similarly capable of upregulating the non-canonical Wnt pathway.[272] Finally, as discussed below in greater detail, a cleaved COOH-terminal fragment of PC1 can interact directly with the TCF transcription factor and, through this interaction, prevent the TCF transcription factor from activating the expression of genes under the control of the Wnt pathway.[365] Thus, both inversin and PC1 may act through distinct but analogous mechanisms as molecular switches that control the relative strengths of the canonical and non-canonical Wnt signaling pathways. Taken together, these diverse observations suggest that a failure to suppress canonical Wnt signaling and to activate non-canonical Wnt signaling constitutes a plausible mechanism that could account for at least some of the pathogenesis of PKD.[187] In this context, however, it is important to note two recent studies whose results are not consistent with this model. Analysis of mitotic spindle axis, a parameter thought to be related to planar cell polarity, finds that it is not perturbed in advance of cyst formation in mouse models of ADPKD.[366] Furthermore, a study found that the cells lining the cysts that develop in mouse models of ADPKD that have been engineered to express a Wnt/TCF reporter *in vivo* did not demonstrate elevated levels of TCF transcription activity.[367] It remains to be determined whether activation of TCF-mediated transcription is involved in early phases of cyst formation and is terminated by the time that cysts are evident.

Cellular Calcium

PC2 belongs to the TRP family of ion channel proteins.[368] PC2 can function as a non-selective calcium-permeable cation channel at the endoplasmic reticulum and perhaps at the plasma membrane as well.[110,278,315] The importance of the channle activity is suggested by the fact that the disease causing non-synonomous D511V mutation abrogates PC2 channel activity.[110] Functional studies demonstrate that PC2 expression enhances the release of calcium from intracellular stores.[110] PC2 can physically interact directly with the IP3 receptor and, perhaps by virtue of this association, can alter the kinetics of cytoplasmic calcium transients induced by IP3 and by agonists of receptors that signal through IP3.[326]

Seminal studies of MDCK cells performed by Praetorius and Spring illuminated an entirely new perspective on the potential function of the primary cilia that grace the apical surfaces of renal epithelial cells. These investigators found that primary cilia can serve a mechanosensory function and that bending them induces transient elevations of cytosolic calcium concentrations.[107–109,369] Subsequent research using cell lines that lack expression of the polycystin proteins as well as antibodies directed against these proteins' extracellular domains suggests that the PC2 channel activity, as well as polcystin-1 receptor activity, is required for induction of calcium transients in response to ciliary bending.[111] Taken together, these studies gave rise to the hypothesis that cilia on apical surface kidney epithelia sense flow via the PC1/PC2 complex and this flow signal is important in establishing and maintaining kidney tubule lumen morphology *in vivo*. More recently, PC2 has been shown to inhibit the activity of stretch-activated ion channels in smooth muscle cells, indicating a possible role of PC2 in pressure sensing.[370]

The binding of EGF to its receptor initiates elevations in cytosolic calcium concentrations that appear to require participation of the channel activity of PC2.[301] The mechanism responsible for this EGF effect on PC2 channel activity appears to involve a protein called mammalian diaphanous-related formin 1 (mDia1), a member of the formin family of actin and microtubule regulatory proteins whose activity is modulated by the RhoA small GTPase. The mDia protein binds to PC2 and exerts a membrane potential-dependent block on its channel activity. The binding of EGF to its receptor appears to activate RhoA, which in turn releases mDia from PC2 and relieves the associated block of the PC2 channel.[371]

A role for PC2 in governing the size and properties of intracellular calcium stores is suggested by the observation that vascular smooth muscle cells isolated from mice heterozygous for inactivation of the PC2 gene exhibit reduced size of the releasable intracellular calcium pool as well as reduced capacitative calcium entry.[83] PC1 may also modulate the properties of intracellular calcium stores. Over-expression of PC1 in MDCK cells may inhibit capacitative calcium entry and speed calcium re-uptake by the endoplasmic reticulum.[372] While the relationship between these effects of

the polycystins on intracellular calcium stores and the pathophysiology of cystic disease remains to be determined, it is clear that through their involvement in modulating intracellular calcium levels the polycystins impact a physiologically critical second messenger pathway that influences almost every aspect of cellular behavior.

Cyclic AMP

A large body of evidence indicates that fluid secretion into cyst lumens makes use of the same machinery and mechanisms that drive fluid secretion by the well-studied secretory epithelia of the airway, the small intestinal crypt and the shark rectal gland. Chloride accumulates in the cytosol above its electrochemical equilibrium through secondary active transport mediated by a basolateral Na,K,2Cl co-transporter. An apical conductive pathway allows chloride to travel passively down its electrochemical gradient into the cyst lumen and the resultant lumen-negative potential causes sodium to follow paracellularly. The osmotic gradient created by this NaCl transport draws water into the cyst lumen, presumably contributing to the expansion of cyst volume.[373,374] Several studies demonstrate that cAMP levels are elevated in cyst epithelial cells and furthermore that cAMP stimulates cyst fluid and electrolyte secretion.[375,376] The identification, through both functional and cell biological experiments, of CFTR as the apical chloride channel involved in cyst fluid secretion provides a molecular explanation for cAMP's pro-secretory effects.[377,378] The CFTR channel opens in response to protein kinase A-dependent phosphorylation and thus the channel is activated in response to elevations in cytoplasmic cAMP.[379] *In vivo* support for the role of CFTR as a mediator of cyst expansion has come from preclinical studies that showed some efficacy for CFTR inhibitors in reducing cyst formation in an orthologous gene model of *Pkd1*.[380] Additionally, case reports of families in which ADPKD coexists with cystic fibrosis have suggested that individuals with both diseases manifest a milder form of ADPKD,[381,382] although this anecdotal evidence has been challenged.[383] It has also been shown that cAMP acts as a mitogen in ADPKD renal epithelial cells and that this effect may be mediated through stimulation of the B-Raf/MEK/ERK signaling cascade, which is discussed in greater detail later in the chapter.[376,384]

While the involvement of CFTR in cyst fluid secretion provides a plausible connection between cAMP and the production of cyst fluid, it does not explain why cyst epithelial cells manifest high cytosolic cAMP concentrations. It is possible that the perturbations in cytosolic calcium levels discussed in the preceding section may in part account for cAMP dysregulation in cyst cells. Several isoforms of both adenylate cyclase and phosphodiesterase, which generate and degrade cAMP, respectively, are subject to positive or negative regulation by calcium. In fact, recent evidence indicates that the primary cilium contains a cAMP signaling complex that includes two calcium-sensitive isoforms of adenylyl cylclase, AC5 and AC6. This complex also includes protein kinase A as well as A kinase anchoring protein 150, which acts as a scaffold on which components of the cAMP signaling network assemble. This complex interacts with PC2. Loss of PC2 expression or of its channel activity leads to dis-inhibition of AC5 and AC6, resulting in elevated levels of cAMP.[385]

Finally, the polycystin proteins may directly or indirectly alter the activities of G-protein coupled receptors that signal through cAMP. Expression and activity of the V2 vasopressin receptor, for example, is elevated in a number of animal models of PKD.[375,386] As noted in a later section, this fact is being exploited through the development of V2 receptor antagonists as potential therapeutic agents that can potentially slow or prevent cyst fluid accumulation by reducing cytosolic cAMP levels.[386]

G-Protein Coupled Receptor Signaling

While their effects on V2 receptor activity suggest that the polycystins may influence G-protein coupled receptors, other studies suggest that PC1 may itself function as a non-traditional G-protein coupled receptor. The COOH-terminal tail of PC1 contains a short sequence that is capable of activating purified trimeric G proteins.[387] Furthermore, the ability of a membrane tethered construct of the PC1 COOH-terminal tail to activate c-jun kinase and the AP-1 pathway depends upon the involvement of trimeric G-proteins.[284] Expression of PC1 is apparently sufficient to initiate activation of $G\alpha$ subunits and dissociation of the $G\beta$ and γ polypeptides, as detected through measurement of the activities of ion channels whose open probabilities are modulated by $\beta\gamma$ interactions.[283] The presence of PC2 prevented PC1 from exerting this effect on G-proteins. The expression of the membrane tethered C terminal tail of PC1 has been found to activate $G\alpha q$ and thus to increase the activity of phospholipase C (PLC). Increased PLC activity leads to the generation of IP3 and consequently to elevations in cytosolic calcium levels which, in turn, can lead to the activation of the calcium-dependent calcineurin/NFAT-dependent transcription pathway.[388] The NFAT transcription factor governs the expression of genes involved in cell growth and differentiation.[389] Activation of the calcium-sensitive phosphatase calcineurin by sustained elevation of cytosolic calcium levels results in dephosphorylation of NFAT, leading to its nuclear accumulation. Recently, PC1 was shown to bind $G\alpha_{12}$ and

modulate the activity of Gα12/JNK apoptosis pathway.[390] Mutations in $G\alpha_{12}$ or PC1 that eliminate interaction between these proteins also abrogated the PC1 dependent inhibition of $G\alpha_{12}$ stimulated apoptosis.[391]

Thus, PC1 appears to possess the capacity to modulate the activities of trimeric G-proteins and their downstream effectors in much the same manner as traditional seven transmembrane domain G-protein coupled receptors. The nature of the stimuli or ligands that regulate this capacity of PC1 and the relationship of this capacity to the major physiological functions of PC1 remain to be determined.

Mitogen Activated Protein Kinase/Extracellular Regulated Kinase

The mitogen activated protein kinase/extracellular regulated kinase (MAPK/ERK) cascade couples extracellular signals received by a variety of surface receptors, through the activation of small G proteins and the involvement of a variety of adaptors, to the successive phosphorylation of Raf (MAP kinase kinase kinase), MEK (MAP kinase kinase) and MAP kinase/ERK. Activated MAPK/ERK can modulate protein translation and can enter the nucleus to regulate the activities of transcription factors and the cell cycle. The MAPK/ERK pathway receives input from and influences a variety of other signaling pathways, including those associated with G-protein coupled receptors, calcium, cAMP, PKA, PKC, EGF receptor (and other receptor tyrosine kinases) and integrins.[392]

In renal epithelial cells the MAPK/ERK cascade influences a variety of morphogenetic phenomena, including cell spreading, branching and tubulogenesis.[393] In wild type subconfluent cells, PC1 associates with focal adhesion contacts and promotes cell spreading through a mechanism that involves both the ERK cascade as well as the focal adhesion kinase, FAK. The absence of PC1 impedes spreading.[394] Furthermore, the MAPK/ERK cascade is found to be activated in a number of animal models of PKD[384,395] including orthologous gene models for *Pkd1* and *Pkd2*.[166] Studies in cultured human ADPKD cells suggest that ERK activation may be attributable to the high levels of cAMP present in their cytosols, which acts through protein kinase A to activate the MAP kinase kinase kinase B-Raf;[384,396] however, such B-RAf dependent activation was not observed in vivo models based on *Pkd1* and *Pkd2*.[166] It is also worth noting that in the absence of PC2 there is a dramatic increase in the quantity of ERK detectable in the nucleus, suggesting that both of the polycystin proteins participate in providing tonic suppression of the activity of the MAPK/ERK cascade.[397] Clearly, the MAPK/ERK pathway is intimately related to a variety of processes that control epithelial growth and morphogenesis. In light of the numerous observations that the MAPK/ERK cascade is excessively active in a variety of cell and animal models of PKD, efforts are underway to test the potential of inhibitors of the relevant MAPK/ERK cascade kinases to prevent the aberrant cell proliferation and differentiation associated with renal cystic disease.[398]

mTOR

The mTOR (mammalian target of rapamycin) protein is a kinase whose activation leads to increased protein translation and cell growth.[399] Proteins that inhibit the formation of the mRNA cap structure are phosphorylated and inactivated by mTOR. In addition, mTOR phosphorylates and activates ribosomal S6 kinases, which act to enhance the translation of mRNAs that encode proteins involved in translation. Thus, any signal that upregulates mTOR activity produces an enhancement of the cell's capacity to synthesize protein and consequently to increase its size. The mTOR pathway is stimulated by cell surface receptors that signal through PI3 kinase to activate the AKT kinase. Activated AKT phosphorylates the tuberous sclerosis complex, composed of the TSC1 and TSC2 proteins (hamartin and tuberin). The TSC complex acts as a GTPase activating protein (GAP) for the small G protein Rheb. When in the GTP bound state, Rheb acts to enhance mTOR function. Phosphorylation of the TSC complex by AKT inhibits its GAP activity, resulting in elevated levels of GTP bound Rheb and thus in elevated levels of active mTOR kinase.[400]

Since activation of mTOR prepares the cell for additional growth, it is perhaps not surprising that dysregulation of the mTOR pathway that leads to inappropriately high levels of mTOR activation are associated with a variety of neoplastic syndromes. Loss of the TSC complex and its associated Rheb GAP activity, for example, results in loss of suppression of mTOR. Tuberous sclerosis is the hereditary disease caused by inactivating mutations in the genes encoding tuberin and hamartin, and it is characterized by the development of multiple hamartomas as well as renal cysts.[401] It is interesting to note that the TSC2/tuberin gene lies extremely close to the PC1 gene and the two genes have an associated contiguous gene deletion syndrome.[210] Furthermore, PC1 interacts with tuberin through its C-terminus[285,402] and it has been suggested that tuberin may play a role in controlling the trafficking of newly synthesized PC1 to the cell surface. Phosphorylation of TSC2 by ERK leads to dissociation of the TSC1/TSC2 complex and loss of its Rheb GAP activity.[403] This phosphorylation appears to be prevented by PC1.[404] The interaction between PC1 and tuberin also appears to protect tuberin from inactivating phosphorylation by AKT.[405] Thus, the interaction between PC1 and tuberin maintains the Rheb GAP

capacity of the TSC1/TSC2 complex and contributes to the suppression of mTOR activity.

Administration of rapamycin markedly slows cyst development in studies of the Han:SPRD rat model of PKD, suggesting the possibility that inappropriate activation of the mTOR pathway is associated with or in part responsible for the excessive proliferation of renal epithelial cells that characterizes PKD.[406,407] Further support for this hypothesis is provided by studies demonstrating that downstream effectors of the mTOR pathway are inappropriately activated in cyst lining cells.[285] These studies also extend the beneficial effects of rapamycin to two mouse models of polycystic disease.[408] Taken together, these data suggest under normal circumstances the polycystin proteins exert a potentially significant inhibitory influence on the strength of mTOR signaling. It is possible that loss of this mTOR suppression could be responsible for at least some of the hyperplastic component of PKD pathophysiology and human clinical trials using inhibitors of mTOR in ADPKD have been completed (see Prospects for Therapy in ADPKD).

Cell Cycle

As has been noted at several points throughout this chapter, in our current conception of ADPKD the disease is thought to arise, at least in part, as a consequence of inappropriate and excessive proliferation of renal epithelial cells. The clear implication of this model is that ADPKD is associated with the absence of growth suppressive factors that act as brakes on progression through the cell cycle. The nature of these growth suppressive influences is manifold and varied, probably reflecting both direct and indirect consequences of perturbations in the expression or function of the various gene products implicated in renal cystic diseases. In fact, much of the discussion presented in the preceding sections on signaling pathways testifies to the validity of this statement. Essentially all of the signaling pathways that are touched by the polycystin proteins, including Wnt, MAPK/ERK, mTOR, calcium and cAMP are major strands of the intricate net of control elements in which the cell cycle is entangled.

Both of the polycystin proteins themselves exert growth suppressive effects when heterologously expressed, and their absence is associated with increased proliferation. Expression of the full length PC1 protein, for example, activates the JAK-STAT pathway.[194] This in turn leads to upregulation of $p21^{waf1}$, which induces cell cycle arrest. The expression of p21 is reduced by Id2,[409] a helix-loop-helix protein that binds to the COOH-terminal tail of PC2 in a manner that appears to be dependent upon a phosphorylation event presided over by PC1.[410] The absence of either polycystin protein can thus result in the translocation of Id2 to the nucleus, where it can suppress p21 and activate the cell cycle. PC2 null cells derived from the kidneys of $Pkd2^{WS25/-}$ mice proliferate significantly more rapidly than cells derived from the same animals in which the $Pkd2^{WS25}$ allele has undergone recombination to produce a wild type allele.[397] Transfection of a cDNA encoding PC2 into the null cells slows their proliferation to wild type levels. Perhaps somewhat surprisingly, the PC2 null cells manifest unusually extensive branching morphogenesis and tubule formation. This effect is also reversed by expression of wild type PC2. Transfection of these cells with a cDNA encoding the D511V human pathogenic mutant form of PC2 lacking channel activity does not suppress the hyperproliferative phenotype but does reduce tubulogenesis. Thus, the channel activity of the PC2 protein appears to be involved in at least some aspects of growth regulatory functions. PC2 also contributes to growth suppression through a direct physical interaction with eukaryotic translation elongation initiation factor 2a (eIF2a). This translation factor is a substrate for an activating phosphorylation by pancreatic ER-resident eIF2a kinase (PERK). By binding to both eIF2a and PERK, PC2 acts as a signaling scaffold that enhances eIF2a's phosphorylation and consequently decreases cell proliferation.[411]

Finally, it is becoming increasingly clear that the presence of an intact cilium and the appropriate organization of its associated proteins play an important role in regulating the cell cycle.[412] Loss of the cilium appears to be associated with inappropriate cell proliferation in a variety of models. Much remains to be learned about the mechanisms through which the cilium and the receptors expressed within its ensheathing membrane influence the cell cycle. It is interesting to note in this context, however, that in Chlamydomonas several members of the NIMA-related expressed kinases family (Neks) localize to the flagellum.[413,414] The Neks are involved in cell cycle regulation, and mutations in Nek1 and Nek8 account for the pathology found in two mouse models of renal cystic disease.[415]

C-Terminal Cleavage

Until fairly recently, the prevailing view of signal transduction from the cell surface to the nucleus held that extracellular signals received by plasma membrane receptors must undergo an obligate translation into the language of the intracellular second messenger systems before they could exert any influence on events in the nucleus. Revelations from studies of the Drosophila Notch protein and a variety of other transmembrane receptors have led to the definiation of a new signaling paradigm known as regulated

intramembranous proteolysis (RIP). During the course of its postsynthetic processing Notch undergoes proteolytic cleavages that release its extracellular domain, which remains attached to the transmembrane segment via non-covalent interactions. This preparatory cleavage permits Notch to become the substrate for a subsequent intramembraneous cleavage event mediated by γ-secretase that is initiated by the binding of Notch to its ligand Delta, a transmembrane constituent of the plasma membranes of neighboring cells. The fragment released through this final cleavage travels to the nucleus, where it influences transcriptional activities that play a key role in cell fate determination.[416,417] Thus, the C-terminal tail of a membrane protein can itself act as a direct messenger that can carry a signal from the surface to the nucleus without any need for the intercession of traditional second messenger molecules. It has now become clear that such cleavage events are quite common, playing critical roles in a variety of physiological processes, including the unfolded protein response, cholesterol metabolism and the adaptation of pancreatic islet cells to changes in extracellular glucose concentrations.[418]

Both PC1 and fibrocystin undergo cleavages that release COOH-terminal tail fragments capable of entering the nucleus and modulating activities therein.[272,273,419] Two C-terminal tail cleavage fragments have been reported for PC1.[273] The larger of these is approximately 200 amino acid residues in length, apparently comprising the entire extent of the protein's predicted C-terminal tail.[272] This fragment's production is dependent upon the activity of the γ-secretase protease,[365] and it includes the amino acid motif previously identified as a G-protein activation sequence, which is rich in basic residues and appears to be capable of serving as an autonomous nuclear localization motif. Expression of a protein corresponding to this fragment in transfected cells leads to activation of jun kinase and the AP-1 pathway.[272] This fragment can also act as an inhibitor of canonical Wnt signaling by virtue of its ability to bind directly to the TCF transcription factor and impede TCF's interaction with the p300 transcriptional co-activator complex.[420] The cleaved C terminal tail also interacts with the CHOP-10/GADD153 transcription factor and similarly prevents its interaction with p300.[365,421] CHOP is activated as a final step in the endoplasmic reticulum/unfolded protein response pathway and induces the expression of genes that activate apoptotic pathways.[422] Apoptosis has been described in cyst lining epithelial cells and may contribute to cyst formation.[168,410,423–426] Expression of the PC1 tail fragment reduces CHOP activity, as well as the level of apoptotis in *Pkd1*$^{-/-}$ cultured epithelial cells.[365]

The smaller fragment of the PC1 C terminal tail encompasses roughly 17 kDa and does not include the nuclear localization signal that has been identified in the larger fragment. This fragment can interact with STAT6 and the coactivator P100 and is apparently translocated into nuclei by virtue of these associations.[273] The 17 kDa fragment directly activates STAT6, and it activates STAT3 through a mechanism that is dependent upon STAT phosphorylation activated by growth factors or cytokines. The activation of the STAT transcription factors is pro-proliferative and pro-apoptotic. It has been suggested that accumulation of the 17 kDa PC1 fragment in the nucleus may contribute to ADPKD pathogenesis, while inhibition of STAT activity may dramatically slow cyst development.[427,428]

The relationship between these two fragments is currently unclear. It is possible that the smaller fragment is the product of a secondary cleavage of the larger fragment. It is also possible that these fragments arise through separate cleavage mechanisms that respond to and transduce distinct messages. Nuclear accumulation of the PC1 COOH-terminal tail is detected in the renal epithelial cells of transgenic mice that over-express PC1, of mice that manifest kidney specific agenesis of cilia, as well as of wild type mice that have been subjected to ureteral ligation.[272] These data suggest that cleavage and nuclear translocation of the PC1 COOH-terminal tail is suppressed by intact cilia function. Absence of cilia or loss of flow appears to initiate both of the reported PC1 COOH-terminal tail cleavages.[272,273] It is interesting to note that the 17 kDa fragment appears to increase proliferation and apoptosis, whereas the larger fragments appear to suppress these processes. This observation prompts the as yet untested speculation that the two cleavage fragments may participate in distinct phases of the renal epithelial response to injury. According to this model, the early phases of the injury response, which involve apoptosis of epithelial proliferation to replace lost or damaged cells may be mediated at least in part by activation of the cleavage that produces the 17 kDa fragment. Activation of the production of the larger cleavage fragment may accompany the later phases of repair and may serve as a break to prevent repairative proliferation and apoptosis from becoming excessive and potentially pathogenic.

The observations that polcystin-1 and fibrocystin are substrates for COOH-terminal tail cleavage raise a large number of interesting and potentially important questions. Where within the cell do the cleavage events occur? What proteolytic enzymes are responsible? Where are the cleavage sites within the primary structures of PC1 and fibrocystin, and what are the sequence parameters that determine their susceptibility to cleavage? Is the NH_2-terminal GPS cleavage a

prerequisite for PC1 COOH-terminal tail cleavage? How does PC2 expression stimulate PC1 C-terminal tail cleavage?[429] Finally, and perhaps most importantly, do mutations that prevent the cleavage produce a phenotype in cultured renal epithelial cells and in renal tubules *in vivo*? Future research into these and other questions related to COOH-terminal tail cleavages are likely to shed important light on the normal physiological functions of the PC1 and fibrocystin proteins. These studies may also suggest new pathways that can be exploited in the continuing search for novel strategies applicable to the development of therapeutics for renal cystic diseases.

PROSPECTS FOR THERAPY IN ADPKD

A better understanding of pathophysiology and availability of animal models has facilitated the identification of an growing number of potential therapeutic targets and development of preclinical trials. Some candidate drugs are now being tested in clinical trials (Figure 80.6). These include vasopressin V2 receptor antagonists, somatostatin analogs, mTOR inhibitors, c-Src inhibitors and triptolide. The following summarizes the current status of preclinical and clinical trials of various drugs classified by their likely mechanism of action:

Intracellular Calcium Homeostasis and Signaling

Triptolide, the active diterpene in the traditional Chinese medicine Lei Gong Teng, induces cellular calcium release through a PC2−dependent pathway, arrests growth of *Pkd1*$^{-/-}$ cells, and reduces cyst burden in embryonic and kidney-specific conditional *Pkd1* knockout mice.[430,431] TRPV4 activation increases $[calcium]_i$ in *pck* cholangiocytes and inhibits B-Raf and Erk1/2 signaling, cell proliferation, and cyst growth in 3-dimensional-culture. The TRPV4 activator *GSK1016790A* inhibits renal cyst growth and fibrosis.[432] Calcimimetics are allosteric activators of the calcium sensing receptor (CaR). The calcimimetic *R-568* inhibits cyst growth and fibrosis in Cy/+ rats[433] (when administered between 34 and 38 weeks of age) and in *pcy* mice,[434] but had no effect at the concentrations tested on cyst growth in *pck* rats and *Pkd2*$^{WS25/-}$ mice.[435] By coupling to Gq proteins, CaR activates phospholipase C-protein kinase C and mobilizes calcium from intracellular stores. By coupling to Gi proteins, it inhibits adenylyl cyclase-cAMP signaling. The beneficial effects of calcimimetics on PKD are thought to be due to downregulation of cAMP signaling. Inconsistencies in different animal models or at different stages of the disease in the same animal model may be due to the R-568-induced hypocalcemia offseting its effect on intracellular calcium and cAMP.[436] Indeed, inhibition of cyst growth in these studies is associated with a reduction in renal cAMP, whereas cAMP levels remain unchanged when no effect on cyst growth is detected.

Cyclic AMP Signaling

The effect of vasopressin, via V2 receptors, on cAMP levels in the collecting duct, the major site of cyst development in ADPKD, and the role of cAMP in cystogenesis provide a strong rationale for preclinical trials of vasopressin V2 receptor (VPV2R) antagonists. One of these drugs, OPC-31260, has marked effects in terms of reduced levels of cAMP and inhibition of cyst development in models of ARPKD, ADPKD, and nephronophthisis.[386,437,438] Recently, an antagonist with high potency and selectivity for the human VPV2R (tolvaptan) has also been shown to be an effective treatment in the *pck* rat model of ARPKD[439] and the Pkd2 mouse model of ADPKD (V. Torres, unpublished observations). These drugs have no effect on liver cysts, consistent with the absence of VPV2R in the liver. High water intake by itself also exerts a protective effect on the development of PKD in pck rats likely due to suppression of vasopressin.[440] Furthermore, genetic elimination of vasopressin in *pck* rats by breeding these animals with Brattleboro rats yields animals born with normal kidneys that remain relatively free of cysts unless an exogenous VPV2R agonist is administered.[441]

Two three year phase 2 clinical trials with tolvaptan in 63 ADPKD patients have been completed. These trials show this drug to be relatively safe and well tolerated by ADPKD patients. A prospectively designed analysis of annual total kidney volume (TKV) and thrice annual estimated glomerular filtration rate (eGFR) measurements in these patients randomly matched (1:2) to historical controls by gender, hypertension, age and baseline TKV or eGFR shows significant reductions in rates of growth in kidney volume (1.7 versus 5.8% per year) and decline in GFR (−0.71 versus −2.1 mL/min/1.73 m^2 per year).[442] Limitations of the study include small number of patients and utilization of historical controls. A larger, double-blind, placebo controlled trial is currently on-goinig and will be completed in 2012.[443]

Somatostatin acting on SST2 receptors inhibits cAMP accumulation not only in the kidney but also in the liver. Octreotide, a synthetic metabolically stable somatostatin analog, halts the expansion of hepatic cysts from *pck* rats *in vitro* and *in vivo*. Similar effects were observed in the kidneys of the *pck* rat.[444] These observations are consistent with the inhibition of renal growth in a pilot study of long-acting octreotide for human ADPKD[445] and provided support for further clinical trials for ADPKD and ADPLD.[446−448] The latter have shown inhibition of kidney growth and a mean annualized 5% reduction in liver volume.

Limitations of the studies are small number of patients insufficient to adequately assess safety and short duration (6–12 months). Further studies are ongoing. Small-molecule phosphodiesterase activators were shown to to reduce cAMP and inhibit cyst growth in an *in vitro* PKD model.[449] At present the efficacy of these compounds may be limited by their lack of selectivity and potential toxicity *in vivo*.

Chloride Driven Fluid Secretion

Fluid accumulation in the cysts requires chloride secretion by the cystic fibrosis transmembrane conductance regulator (CFTR). CFTR and other transporters required for chloride secretion have received attention as potential therapeutic targets for ADPKD. CFTR inhibitors slow cyst growth in an MDCK cell culture model, in metanephric kidney organ cultures, and in conditional *Pkd1* knockout mice.[380,450] Metformin inhibits MDCK cyst growth and cystic disease in conditional *Pkd1* knockout mice, in part by inhibiting AMPK dependent phosphorylation and activation of CFTR.[451] PPARγ agonists inhibit the expression and apical localization of CFTR, vasopressin-stimulated Cl^- secretion via CFTR in the MDCK cells, and renal and hepatic cyst growth in pck rats.[452,453] Other transporters in addition to CFTR are required for chloride driven fluid secretion into the cysts, the Na-K-2Cl cotransporter for chloride entry at the basolateral cell membrane and Na-K-ATPase and KCa3.1 for recycling of sodium and potassium out of the cell. A KCa3.1 inhibitor, TRAM-34 (an analogue of clotrimazole), inhibits forskolin stimulated transepithelial chloride secretion in filter-grown polarized monolayers of MDCK, NHK, and ADPKD cells, as well as MDCK and ADPKD cell cyst formation and enlargement in collagen gels.[454,455]

Tyrosine Kinase Receptors

Evidence from several laboratories supports an important role of the epidermal growth factor (EGF)/transforming growth factor-alpha (TGF-α)/EGF receptor (EGFR or ErbB1) axis in promoting tubular epithelial cell proliferation and cyst formation.[456] Pharmacologic inhibition of EGFR tyrosine kinase activity inhibits the development of cystic disease in bpk and orpk mice, two autosomal-recessive models of rapidly progressive cystic disease, and in Han:SPRD rats, an autosomal dominant model of slowly progressive renal cystic disease.[457] They had no effect, however in the *pck* rat, an orthologous model of ARPKD, probably because Erb-B2 but not EGFR (Erb-B1) is overexpressed in this model.[458,459] The expression of VEGF and VEGF receptors (VEGFR) is upregulated in the renal and hepatic cystic epithelium. VEGFR-1 and VEGFR-2 ribozyme treatment inhibits cystogenesis and improves renal function in Han:SPRD rats.[460] The VEGF receptor inhibitor SU-5416 reduces cystic development of the liver, but has no effect on renal cyst growth in $Pkd2^{WS25/-}$ mice.[461] Another study suggests that SU-5416 inhibits hepatic cystogenesis in conditional *Pkd2* but not *Pkd1* knockout mice.[462] In contrast with these results, administration of an anti-VEGF antibody (B20.4.1) worsens the cystic disease in Han:SPRD rats[463] and administration of a VEGFR-2 antibody (DC101) at 2 and 4 days of age results in renal cyst formation in CD1 mice.[464]

Src Kinase Inhibitors

Cyclic AMP and receptor tyrosine kinase signaling converge in the activation of c-Src, a nonreceptor tyrosine kinase. c-Src activity is increased in polycystic kidney disease. The Src inhibitor SKI-606 retards cyst growth *pck* rats and *bpk* and *Pkd1* heterozygous mice probably through inhibition of the MAPK (Ras/Raf/MEK/ERK) pathway.[459,465]

Inhibitors of MAPK (Ras/Raf/MEK/ERK) Signaling

PLX5568, a selective small molecule inhibitor of Raf kinases, attenuates cyst enlargement in vitro and in Han:SPRD Cy+/− rats without improving kidney function, presumably due to increased renal fibrosis.[466] Sorafenib, a Raf kinase inhibitor that has activity against receptor tyrosine kinases, including VEGFR and PDGFR, has been found to inhibit cAMP-dependent activation of B-Raf and MEK/ERK signaling, cAMP and/or EGF induced cell proliferation, and growth of human ADPKD cell derived cysts in collagen gels.[467] A MEK inhibitor (PD184352) decreased cyst growth in the slowly progressive *pcy* mouse model of nephronophthisis,[468] whereas a different MEK inhibitor (U0126) failed to affect cystic progression in an acute perinatal *Pkd1* conditional knockout mouse at doses sufficient to reduce phospho-ERK1/2 in cystic kidneys.[166]

mTor Inhibitors

Patients with the contiguous PKD1-TSC2 gene syndrome exhibit a more severe form of PKD than those with ADPKD alone.[469] This observation suggests a convergence of signaling pathways downstream from PC1 and tuberin. mTOR activation in polycystic kidneys and an interaction between PC1 and the tuberous sclerosis protein tuberin have been reported.[285] Preclinical trials of mTOR inhibitors in rodent models of PKD have been mostly encouraging, but differences between rat and mouse studies cast doubt on whether doses of mTOR inhibitors necessary for effectiveness in PKD are feasible in the clinical setting. Tolerated doses and blood levels are much lower in rats than in mice. At doses and blood levels achievable in humans, sirolimus and everolimus are effective in Han:SPRD rats, a

rat model of PKD mainly affecting proximal tubules,[285,406,407,470–472] but not in an orthologous model affecting distal nephrons and collecting ducts.[473] At doses and blood levels higher than those achievable in humans, they are consistently effective in multiple orthologous and non-orthologous mouse models.[408,474,475]

The results of clinical trials have been mostly discouraging, possibly because blood levels capable to inhibit mTOR activity in peripheral blood mononuclear cells are not sufficient to inhibit mTOR activity in the kidney.[476] A randomized, open label, placebo controlled, eighteen month trial (SUISSE) of sirolimus in 100 ADPKD patients with a mean estimated creatinine clearance of 92 ml/min and kidney volumes of 907 (sirolimus) and 1003 (placebo) ml showed no effect on kidney volume or GFR.[477] Doses of sirolimus were low due to toxicity and patient retention was excellent (96% in the sirolimus group). A six-month cross-over trial (SIRENA) of sirolimus in 21 patients with a mean GFR of 77 ml/min/1.73 m^2 and kidney volume of 1874 ml showed less increase in cyst volume on sirolimus compared to placebo, but no effect on GFR.[478] Sirolimus blood levels were higher than in the SUISSE study, but patient retention (71%) was lower. Finally, a randomized, double blinded, placebo controlled, two year trial of everolimus in 433 patients with a mean eGFR of 55 ml/min/1.73 m^2 and kidney volumes of 2028 (everolimus) and 1911 (placebo) ml shows inhibition of kidney growth but a greater decline in eGFR.[479] Limitations of this trial included advanced stage of CKD (6.3% in CKD stage IV) and low patient retention (67% in the everolimus group). All together, these results cast doubt on the role of sirolimus and everolimus in the management of the renal cystic disease in ADPKD, but do not negate completely the importance of mTOR activation in its pathogenesis, nor the possibility that other strategies targeting this pathway could be successful.

Cytokines and Cytokine Receptors

TNFα is one of many cytokines found found in cyst fluids.[480–482] TNF-α, TNFR-I and TNF-α converting enzyme are over-expressed in cystic tissues. The administration of TNF promotes cyst formation in *Pkd2*$^{+/-}$ mice, whereas etanercept had an inhibitory effect.[483] An inhibitor of TNF-α-converting enzyme was shown to ameliorate the polycystic disease in the *bpk* mouse, a recessive non-orthologous model of PKD.[484] The aggravation of PKD by TNFα may be due to its enhancement of the expression of FIP2, a protein that physically interacts with PC2 and prevents its transport to the plasma membrane and primay cilium.[483] Alternatively, TNFα activates IKKβ (inhibitor of κB kinase-β), which physically interacts and phosphorylates hamartin, suppressing TSC1-TSC2 function and activating mTOR.[485]

Arachidonic Acid Signaling

A number of studies have focused on the role of arachidonic acid metabolites and their inhibitors on the progression of PKD. Prostaglandin E2 (PGE2) accumulates in cyst fluids and enhances cAMP production and growth of MDCK cysts in collagen gels.[486] PGE2 may act on four different G protein coupled receptors named E-prostanoid (EP) receptors 1–4. EP2 and EP4 are coupled to G stimulatory proteins and stimulate cAMP formation. EP3 is coupled to G inhibitory protein, inhibits cAMP formation, induces Rho activation and actin polymerization, and antagonizes AVP action. EP1 activation induces inositol 3-phosphate formation and calcium release. Recently, the effects of PGE2 on cAMP formation and cystogenesis, in a three-dimensional cell-culture system of human epithelial cells from normal and ADPKD kidneys, have been shown to be mediated by EP2 receptor activation, thus suggesting a possible role for EP2 receptor antagonists in the treatment of ADPKD.[486] PLA, COX-1 and COX-2 activities and the production of prostacyclin, thromboxane A2 and PGE2 are higher in cystic than wild-type kidneys. Endogenous and steady-state *in vitro* levels of prostanoids were 2–10 times higher in diseased compared with normal kidneys. The administration of the COX-2 inhibitor NS-398 reduced cystic expansion by 18%, interstitial fibrosis by 67%, macrophage infiltration by 33%, cell proliferation by 38%, and presence of oxidized LDL by 59% compared to controls, but had no protective effect on renal function.[487] The production of 20-hydroxyeicosatetraenoic acid (20-HETE), an endogenous cytochrome P450 metabolite of arachidonic acid with mitogenic properties, is markedly increased in microsomes from *bpk* compared to wild-type mice.[488] Daily administration of HET-0016, an inhibitor of 20-HETE synthesis, reduced kidney size by half and doubled survival. Transfection of principal cells isolated from wild-type mice with the cytochrome P450 peptide Cyp4a12 induced a four- to five-fold increase in cell proliferation, which was completely abolished when 20-HETE synthesis was inhibited. These observations suggest that 20-HETE contributes to the proliferation of epithelial cells in the formation of renal cysts and provide another potential target for intervention.

AMP-Activated Protein Kinase (AMPK)

AMPK is an intracellular energy sensor that decreases energy-consuming processes such as secretion, and growth when cellular AMP levels are high and ATP levels are low. AMPK activation inhibits growth through different pathways includeing

inhibition of mTOR and stimulation of the p53/p21 axis. mTORC1 inhibition by AMPK is dependent on Lkb1 signaling from intact cilia and is independent of PC2.[489] AMPK activation also decreases epithelial fluid secretion by directly inhibiting CFTR. Metformin activates AMPK and inhibits the growth of MDCK cysts in collagen gels and renal cyst growth in conditional *Pkd1* knockout mice.[451]

Signal Transducers and Activators of Transcription (Stats)

STATs are a family of transcription factors activated by cytokines and some growth factors that control cell growth, differentiation, and apoptosis. PC1 affects the activity of several STAT transcription factors (STAT1, STAT3, STAT6). STAT3 inhibitors (the anti-parasitic drug pyrimethamine and S3I-201) inhibit cyst formation and growth in conditional *Pkd1* knockout mice.[490] Curcumin, a natural product derived from the plant curcuma longa, inhibits forskolin-induced MDCK cell proliferation, MDCK cystogenesis *in vitro*, and cyst growth in embryonic metanephric organ cultures[491] and conditional *Pkd1* knockout mice,[492] possibly by blocking STAT3 signaling among other mechanisms.

Peroxisome Proliferator Activated Receptors (PPARs)

PPARs are a family of transcription factors that belong to the nuclear receptor superfamily. PPARs form heterodimers with the 9-cis retinoic acid receptor, RXRα. Activation of PPAR:RXRα by PPAR ligands and/or RXRα ligands results in a conformational change, allowing the heterodimers to bind peroxisomal proliferator response elements (PPREs) in target genes and modulate gene transcription. PPARγ is activated by its natural ligands, e.g. prostaglandin J2 and fatty acid derivatives, by conjugated linoleic acid, and by synthetic ligands such as the thiazolidinediones (pioglitazone, troglitazone, and rosiglitazone). Activation of PPARγ causes cell cycle withdrawal by mechanisms that include reduced expression of protein phosphatase 2A, increased phosphorylation, decreased DNA binding and transcriptional activity of the E2F/DP transcription factors, and repressed transcription and enhanced proteasome-dependent degradation of cyclin D1, promotion of terminal differentiation, and induction of apoptosis. Pioglitazone administered to pregnant mice inhibits renal cyst growth, cardiac abnormalities, and subcutaneous edema of $Pkd1^{-/-}$ embryos.[202] Administration of conjugated linoleic acid reduced macrophage infiltration, interstitial inflammation, and interstitial fibrosis in male Han:SPRD Cy +/− rats.[493] N-(4-hydroxyphenyl) retinamide (HPR), a synthetic derivative of retinoic acid, inhibited the growth of ADPKD derived cysts in a three-dimensional collage matrix.[494] Rosiglitazone attenuated PKD progression and prolonged survival in Han:SPRD rats.[495] Pioglitazone inhibited renal and hepatic cyst growth and fibrosis in the *pck* rat model of ARPKD.[453,496] This effect was associated with downregulation of ERK, mTOR and TGFβ signaling and with reduced expression and apical localization of CFTR. Contrary to these favorable results, pioglitazone had no significant effect on cyst growth in *Pkd1* knockout mice.[497]

Histone Deacetylases (HDACs)

Acetylation of histones by histone acetyl transferases increases accessibility of transcription factors to gene promoter regions whereas deacetylation by HDACs has the opposite effect. HDACs also deacetylate specific transcription factors to decrease their DNA binding activity. HDAC1 deacetylates p53 repressing *PKD1* gene transcription.[498] Polycystin signaling increases intracellular calcium and activates protein kinase C which directly or indirectly phosphorylates HDAC5, disrupts its association to myocyte enhancer factor 2C (MEF2C), and releases this transcription factor to affect transcription.[499] HDACs also regulate cellular functions through transcription-independent mechanisms.[500] HDAC6 deacetylates α-tubulin and regulates the stability of microtubules and cilia disassembly during the cell cycle. EGF-induced nuclear localization of β-catenin is regulated by HDAC6-dependent also deacetylates of β-catenin which is important for EGF-induced β-catenin nuclear localization. Valproic acid, an inhibitor of of class I HADCs (HDAC1, HDAC2, HDAC3 and HDAC8) and trichostatin A (TSA), an inhibitor of class II HDACs (HDAC4, HDAC5, HDAC6, HDAC7, HDAC9 and HDAC10) suppress cyst formation and retard renal failure in *Pkd1* and *Pkd2* knockout mice.[499,501]

Cyclins and Cyclin Dependent Kinases (CDK)

Roscovitine (Seliciclib, CYC202), a CDK inhibitor, inhibits cystogenesis and improves renal function in in two non-orhtologous mouse models of PKD (*jck* and *cpk*), acting through transcriptional regulation, blockade of the G1/S phase in the cell cycle, and inhibition of apoptosis.[502] Like PC1, roscovitine increases the levels of p21, which is downregulated in PKD.[503] In polycystic liver disease the expression of miR15a expression is decreased, while that of its target, the cell-cycle regulator cell division cycle 25A (Cdc25A), is upregulated.[504] Cdc25A is a phosphatase that plays an essential role in cell cycle progression by activating CDKs. Menadione lowers the levels of Cdc25A and other cell cycle proteins and inhibits renal and hepatic cyst growth in both *pck* rats and $Pkd2^{WS25/-}$ mice.

Other Targets

Sphingolipids and glycosphingolipids regulate many cellular processes, including proliferation, apoptosis and modulation of cell signaling pathways. Glucosylceramide (GlcCer) and lactosylceramide (LacCer) are elevated by approximately 2–3 fold in ADPKD patients and may stimulate proliferation via the activation of MAPK. The GlcCer synthase inhibitor Genz-123346 suppresses mTOR signaling, induces G1/S cell cycle arrest, and inhibits cystogenesis in mouse models orthologous to human autosomal dominant PKD (*Pkd1* conditional knockout mice) and nephronophthisis (*jck* and *pcy*), but the exact mechanism of action of this drug in PKD is not well understood.[505]

In planning for clinical trials for ADPKD, the use of renal function as the primary outcome becomes an issue. The natural history of ADPKD is characterized by decades of normal renal function, despite progressive enlargement and cystic transformation of the kidneys. By the time the GFR starts to decline, the kidneys are markedly enlarged, distorted, and unlikely to benefit from some treatments that may have been beneficial earlier in the course of the disease. On the other hand, early interventional trials would require unrealistic periods of follow-up if renal function was to be used as the primary outcome. The results of CRISP[17] have shown that the rate of renal growth is a good predictor of functional decline and justify the use of kidney volume as a surrogate marker of disease progression in clinical trials for ADPKD. The continued identification of targets for therapy coupled with the developement of appropriate outcomes for study endpoints portends continued advancement toward developing effective therapy for ADPKD.

CHAPTER

81

Renal Physiology and Disease in Pregnancy

Kirk P. Conrad and S. Ananth Karumanchi

The urinary system, volume homeostasis, body fluid composition, and osmoregulation are all profoundly altered in normal pregnancy. There are also marked changes in systemic hemodynamics involving cardiac output and blood pressure. Knowledge of these physiological adaptations permits earlier detection and facilitates management of renal disease and hypertension during pregnancy. In the fifth revision of this chapter, the authors revise and update the previous edition coauthored with Marshall Lindheimer, former senior and an original author of the chapter. As before, space limitations lead us to refer on occasion to previous editions of the book especially for details from the older literature.

ANATOMICAL CHANGES

Information about renal anatomy during normal pregnancy is limited, but it appears that the kidney becomes larger. Autopsy studies are obviously scarce, but in one unique and large series[1] combined kidney weights of normotensive women dying during or shortly after gestation were higher than normal values for nonpregnant individuals. However, details about the cause of death, which could have affected kidney weights, were limited. Renal weight also increases during pregnancy in rats, the evidence suggesting that this is due to increased water content, as renal dry weights are similar in gravid and nonpregnant rats.[2,3] In one study in which renal biopsy specimens were obtained from normal gravidas (usually during cesarean section), the light microscopic appearance was described as similar to that in nonpregnant subjects [cited in[4]]. But data from both autopsy material[1] and renal biopsies performed in the last trimester on 12 normal gravidas[5] suggested that glomerular size, but not number of cells, may be increased in pregnant women. Detailed descriptions of the kidneys of normal pregnant women or animals using electron microscopic or immunofluorescence techniques are not available.

Starting in the first trimester, overall renal dimensions—length, width, and thickness—increase and peak during the third trimester at 1 cm above prepregnant values.[6] These changes, documented by ultrasonography and pyelography, translate into an overall increase in renal volume of ~50% by the end of pregnancy[6] (Figure 81.1). Both renal parenchymal and pelvicalyceal volumes enlarge, although the latter typically begins to rise somewhat later during the second trimester. Renal parenchymal volume enlarges most likely due to increases in both vascular and interstitial fluid volume; there is little evidence for cellular hyperplasia or hypertrophy.[7] Renal size and volume estimated by ultrasonography or pyelography in the immediate puerperium are also increased.[4,6] Of interest, roentgenograms performed shortly after delivery and repeated six months later demonstrated that renal length had decreased ~1 cm between the two exams [cited in[4]]. The well-documented dilation of the upper ureter, renal pelvis, and major and minor calyces, which affects the vast majority of gravidas at term, is particularly prevalent on the right side.[7–13] Consequently, urinary stasis and hydronephrosis (either with or without calyceal clubbing) are common physiological occurrences in human pregnancy[14] (Figure 81.2), and usually do not reflect pathologic obstruction. Although the more severe signs of this physiological obstruction resolve at least by 6 weeks after delivery, evidence for urinary stasis persists in many women at 12 weeks postpartum.

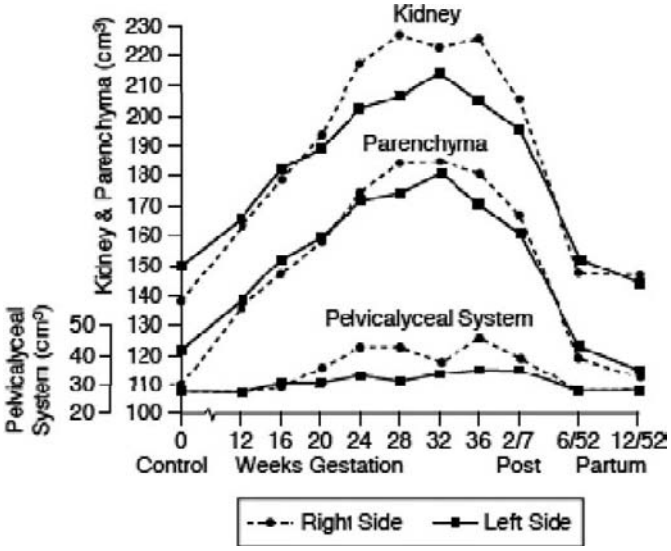

FIGURE 81.1 Quantitative determination by nephrosonography of total renal and pelvicalyceal volumes, as well as the calculated difference of the two, parenchymal volume, in 34 primigravid women throughout pregnancy and in the postpartum period. The volumes were calculated by the ellipsoid formula, volume = length x width x thickness x 0.5233. 2/7, 6/52, and 12/52 designate day 2, and weeks 6 and 12 postpartum, respectively. *[Reproduced with permission from Ref.[6]]*

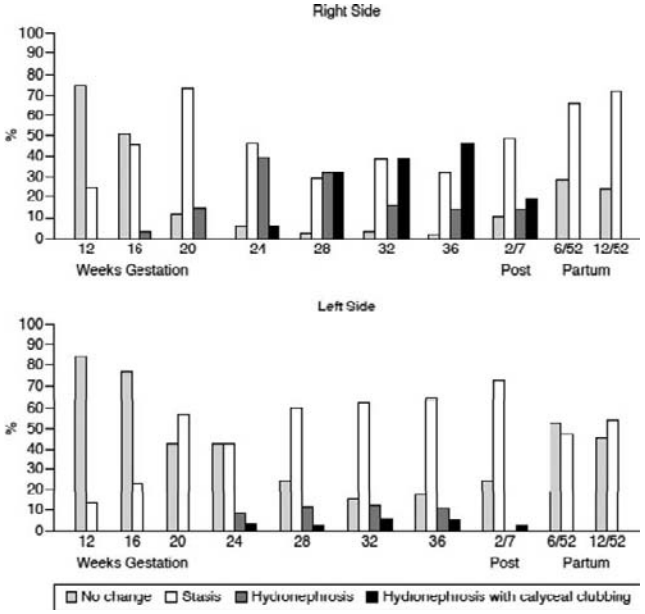

FIGURE 81.2 Qualitative determination by nephrosonography of the right and left upper urinary tracts throughout pregnancy and the postpartum period in the same women as described in Figure 81.1. The percentage of women experiencing changes by nephrosonography is displayed on the ordinate. No change, absence of visible urine in the renal pelvis seen on both longitudinal and/or transverse planes; urinary stasis, slight separation of the renal pelvis observed on both longitudinal and/or transverse planes; hydronephrosis, marked dilation and wide separation of the renal pelvis seen on both longitudinal and/or transverse planes; hydronephrosis with calyceal clubbing, dilation of the renal pelvis accompanied by filling and clubbing of the major and minor renal calyces. 2/7, 6/52, and 12/52 designate day 2, and weeks 6 and 12 postpartum, respectively. *[Reproduced with permission from Ref.[14]]*

The causes of the ureteral dilation are controversial. Both humoral changes and mechanical obstruction have been implicated. Smooth muscle relaxation occurs in several organs during pregnancy, and some authors reported ureteral dilation in nonpregnant humans and animals administered estrogen–progestin derivatives.[9] Ureteral dilation may occur in primates with placentas that secrete hormones but absent fetuses,[4,9] and ultrasonography shows that the ureter dilates before the uterus has enlarged sufficiently to cause obstruction[10,14]; nor is the dilation relieved by prolonged catheterization.[4,9]

The obstructive theory is supported by the observations of marked exacerbation of intraureteral pressure when third trimester gravidas were in a supine or standing position, and significant amelioration upon removal of the obstructive influence of the gravid uterus by placing the subject in the lateral decubitus or knee–chest position, or by cesarean delivery of the fetus.[15] Moreover, the increased pressure was noted only above the pelvic brim.[15,16] These data are supported by the elegant studies of Dure-Smith,[12] who combined *in vivo* and postmortem observations and concluded that ureteral dilation stops at the level of the true bony pelvic brim where the ureter crosses the iliac artery (Figure 81.3). At that junction, one may see a pyelographic filling defect, called the "iliac sign" (Figure 81.3). Although compelling, the data are not conclusive, because Waldeyer's sheath, a connective tissue enveloping the ureters as they enter the true pelvis, hypertrophies during pregnancy and could restrict hormone-induced dilatation below the pelvic brim.

A related theory is that dilation of the ovarian and uterine veins (especially those on the right) during pregnancy obstructs the ureters.[4,8,9,12] The "ovarian vein syndrome" (ureteral colic ascribed to obstruction secondary to enlargement of the ovarian vein) was described in a patient taking oral contraceptives, an observation that combines the humoral and obstructive theories.

Also supporting obstruction as a cause of the physiological dilation is the occurrence of an "overdistention" syndrome in late gestation.[8,17,18,19] This clinical entity caused by exaggerated ureteral dilation is characterized by marked hydronephrosis, abdominal pain, increases in serum creatinine, and in some cases, hypertension.[17,18,20] Some of these patients were successfully managed with ureteral stents, which were removed postpartum without recurrence of signs and

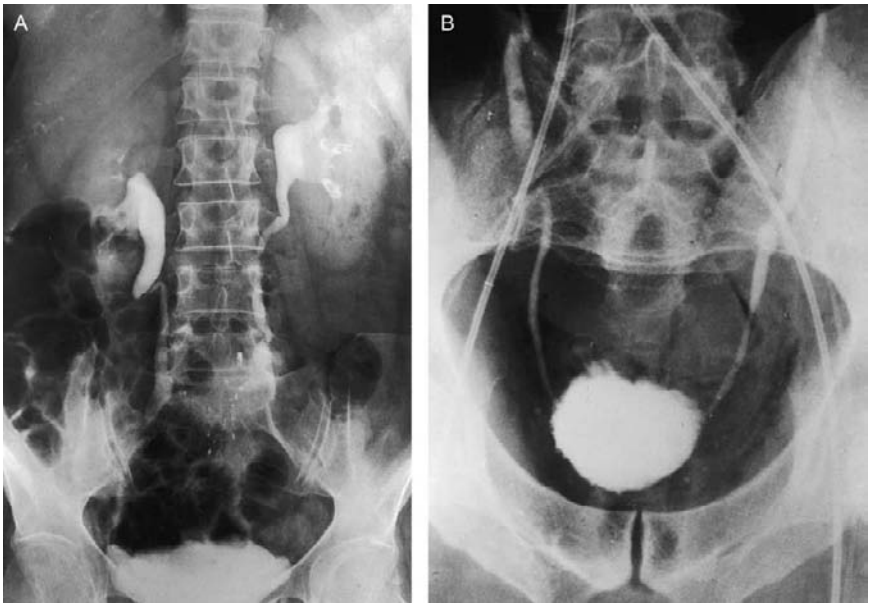

FIGURE 81.3 Intravenous pyelogram (A) demonstrating dilatation of the ureters during pregnancy. Note the sharp cutoff of the ureter at the pelvic brim where it crosses the iliac artery (the iliac sign). Postmortem injection studies (B) showing the relationships of the ureters and iliac arteries at the pelvic brim. The genesis of the iliac sign is shown on the right. *[From Ref.,[12] with permission]*

symptoms.[21] Perhaps the most serious consequences of physiological obstruction during pregnancy are acute urinary retention and nontraumatic rupture of the ureter, but whether these entities reflect extreme instances of physiologic ureteral dilatation or underlying pathology is not clear.[17]

There are other clinical ramifications to the anatomical changes in the urinary tract during pregnancy. First, acceptable norms of kidney size increase by 1 cm if assessed during pregnancy or immediately postpartum, and reductions in renal length noted several months after delivery need not be ascribed to pathological decrements in renal parenchymal mass. Second, ureteral dilation and urinary stasis may contribute to the propensity of women entering pregnancy with benign asymptomatic urinary tract infection to develop frank pyelonephritis (see below). Third, ureteral dilation may result in a higher frequency of vesicoureteral reflux, further predisposing to symptomatic infection, but the presence of increased reflux in gravid women is disputed.[9,16] Finally, the dilated urinary tract may contain substantial urine volumes that can introduce errors in the collection of timed urine volume. This eventuality may be minimized, however, by having the patient hydrated and positioned in lateral recumbency for 1 h prior to starting and again before completing the collection. A modest diuresis minimizes the dead-space error and concurrently ensures that any residual urine in the urinary tract or bladder is dilute and of recent origin.

Ureteral dilation mostly abates by the 12th postpartum week, and therefore imaging of the urinary tract should be deferred to this point, if possible. However, minor but significant dilation may persist in as many as 11% of parous women who have no history of urinary tract infection. This, again, suggests that obstruction may be a significant cause of changes in the ureter during pregnancy.[8,9]

RENAL HEMODYNAMICS

Several carefully conducted serial studies in pregnant women, in which glomerular filtration rate (GFR) and effective renal plasma flow (ERPF) were measured by renal clearances of inulin and *p*-aminohippurate, were conducted during the 1950s and early 1960s. The results convincingly showed that both GFR and ERPF increase during pregnancy, but there was considerable controversy regarding the time course of these changes [reviewed in[9,22–24]]. All concurred that renal hemodynamics rose during the first trimester; the discrepancies concerned late pregnancy, i.e., whether peak increments in GFR and/or ERPF were sustained until term. These divergent results most likely reflect a number of methodological pitfalls, then unappreciated, which can confound the results of renal function tests performed during pregnancy. These potential problems are reviewed in detail elsewhere,[9,22] and here we highlight two of them: the need to impose a high urine flow with hydration, because the dilated ureter introduces dead-space errors, and to position the subject in lateral recumbency. The latter is particularly important in late

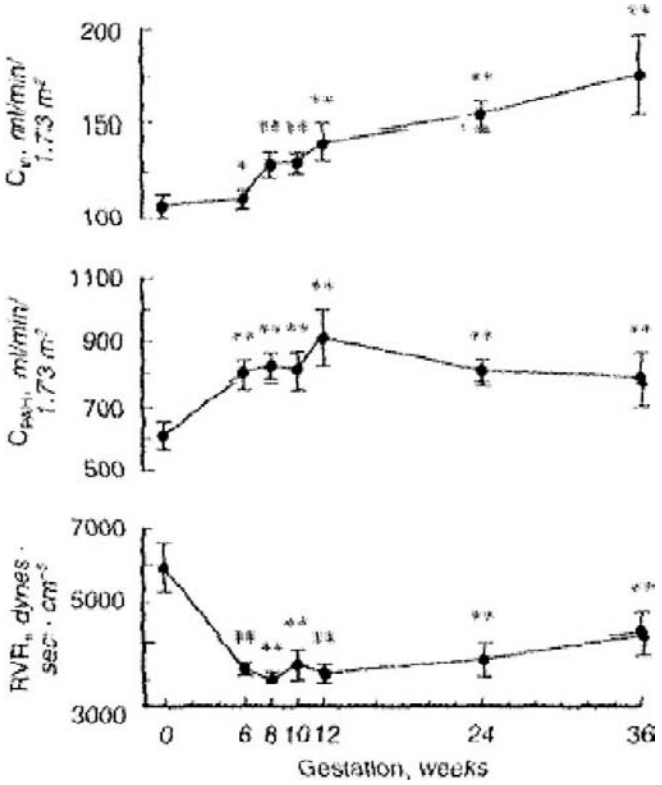

FIGURE 81.4 Renal hemodynamic changes throughout early human pregnancy. Ten women were studied in the midfollicular phase of the menstrual cycle and weeks 6, 8, 10, 12, 24 and 36 of gestation. Renal plasma flow and GFR increased significantly in association with a decrease in renal vascular resistance by week 6 gestation. C_{In}, inulin clearance; C_{PAH}, *p*-aminohippurate clearance; RVR, renal vascular resistance. $^{*}P < 0.05$, $^{**}P < 0.001$ vs midfollicular. Note that authors normalized renal function by body surface area. However, because gestational changes in renal plasma flow and glomerular filtration are functional and not anatomical in nature, such normalization will underestimate true values. *[From Ref.[26] with permission]*

pregnancy, because an upright or supine posture may lead to marked decrements in GFR or ERPF.[9,25]

More recently, investigators reexamined the time course of renal hemodynamic changes in pregnancy, often combining serial 24-h endogenous creatinine clearances with both inulin and *p*-aminohippurate renal clearances and focusing on the first and last few weeks of gestation [22,23,26–31;24] (Figure 81.4). In some studies, nonpregnant control data were obtained prior to conception and postpartum. Although not all are methodologically flawless, they provide important information summarized as follows: GFR normally increase during the luteal phase of the menstrual cycle,[27,29] continue to rise early in pregnancy, reaching peaks 40–65% above nonpregnant levels by the second trimester. These increments are maintained at least until the 36th gestational week after which a modest decrease in GFR may occur.[28,29] Three months postpartum, GFR values are similar to those measured before pregnancy.

ERPF also increases in the luteal phase of the menstrual cycle and then markedly during gestation reaching values 50–85% above prepregnancy levels during the initial two trimesters[22,23,27,30,31] (Figure 81.4); Near term, however, ERPF seems to decrease ~25%, although it still remains considerably above nongravid values. In general, filtration fraction decreases early in gestation and returns to or towards nonpregnant levels in the last trimester.[22,32]

Given the tremendous increase in GFR and ERPF, the question arises as to whether renal vasodilation is maximal during pregnancy, or whether gravidas possess a "renal functional reserve" similar to that observed during protein loading in nonpregnant subjects. The results of several studies are equivocal. Amino acid infusions consistently increase GFR further in pregnant women, but results of high protein meals are inconclusive.[33–36] Finally, glycine infusions increase GFR in gravid rats.[37]

Mechanisms of Renal Hemodynamic Changes During Pregnancy

Our understanding of mechanism(s) underlying the gestational rise in ERPF and GFR continues to evolve. In part due to both ethical and logistical concerns, most studies designed to determine mechanisms of gestational changes in renal function have utilized animal models as there are several species also known to manifest increases in GFR and ERPF during pregnancy [referenced in[2,9]]. Thus, by applying the renal micropuncture technique to Munich-Wistar rats during midgestation, the period when ERPF and GFR are maximally increased in this species, Baylis[38] demonstrated the gestational rise in single nephron GFR (SNGFR) to be secondary to an increase in glomerular plasma flow, the latter due to a decline in renal vascular resistance. In her rat model, transglomerular hydrostatic pressure difference remained unchanged because there were comparable decreases in both afferent and efferent arteriolar resistances. Plasma oncotic pressure was not significantly different between nonpregnant and midterm pregnant rats and thus not involved in altering SNGFR. Because the animals were in filtration equilibrium, only a minimum value for the ultrafiltration coefficient, K_f could be calculated, which was similar between nonpregnant and midterm pregnant rats; nevertheless, this determinant of glomerular ultrafiltration most likely contributed little to the gestational rise in SNGFR in the gravid rat model. To summarize, SNGFR rises mainly because glomerular plasma flow increases in the gravid rat model.[38]

Whether similar mechanisms occur in pregnant women is unknown as glomerular dynamics cannot be

directly measured. Moreover, human glomeruli may be in filtration disequilibrium, a condition in which alterations in ERPF are predicted to have less impact on GFR.[39] Nevertheless, the parallel increases in ERPF and GFR suggest a similar mechanism governing the rise in GFR in gravid women.

Using an indirect approach, investigators measured the fractional clearance of neutral dextrans ($C_{dextran}/C_{inulin}$) in normal pregnant women serially studied throughout early and late gestation followed by retesting 6 weeks postpartum.[31,40,41] Such data can be analyzed by mathematical models, which incorporate clearance values and plasma oncotic pressures to predict glomerular capillary pressure, the ultrafiltration coefficient (K_f) and glomerular capillary membrane porosity. Permselectivity to neutral dextrans was altered during gestation (Figure 81.5), and the theoretical analysis of the sieving curves, using two different models, suggested that hyperfiltration during pregnancy was mainly due to increments in ERPF with a minor contribution from decreased glomerular oncotic pressure (the latter being greater during late gestation). Membrane porosity appeared to be altered, but comparable to micropuncture studies in rats, there was no evidence of increased glomerular capillary pressure in human pregnancy (Figure 81.5). It should be emphasized, however, that this approach is theoretical in nature being dependent on several assumptions that may or may not be valid.

Further insight into the causes of the altered renal hemodynamics during pregnancy arose from studies in a rat model. Conrad adapted methodologies developed by Gellai and Valtin for measurement of renal function in chronically instrumented, conscious rats and applied them to pregnancy.[42,43] Because physiology is markedly perturbed by anesthesia and surgical stress and the effects of anesthetics and surgical stress can differ in the nonpregnant and pregnant states, studies in chronically instrumented, conscious animals are an essential first step in the investigation of mechanisms underlying maternal circulatory adaptations to pregnancy. Thus, when the same chronically instrumented, conscious rats were serially studied before, during, and after pregnancy, both renal vasodilation and hyperfiltration were observed throughout most of gestation, making it an excellent model to explore the mechanisms underlying these changes.

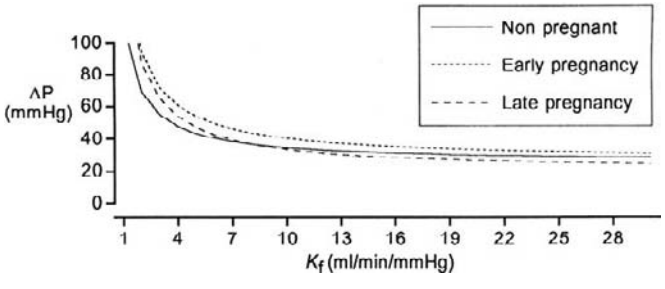

FIGURE 81.5 Theoretical relationship between ultrafiltration coefficient (K_f) and the transglomerular pressure difference (ÄP) in normal pregnancy. Note that over a large range of K_f values, chosen to include those we would expect in humans, there is little change in the ÄP when results during early pregnancy, late gestation, and the nonpregnant state are compared to each other. *[From Ref.[31] with permission]*

The Role of Extracellular Volume

Extracellular and plasma volumes dramatically increase during pregnancy (although most studies suggest after the peak in ERPF and GFR). *Acute* expansion of plasma volume by 10–15% failed to increase the GFR, SNGFR, or glomerular plasma flow in virgin female Munich-Wistar rats.[44] Because volume expansion can suppress tubuloglomerular feedback activity, it could mediate the gestational increases in glomerular plasma flow and SNGFR.[45] However, tubuloglomerular feedback activity was not suppressed in gravid Munich-Wistar rats, rather the mechanism was reset to the higher SNGFR of pregnancy suggesting that volume expansion of pregnancy is actually perceived as "normal." This conclusion supports the "arteriolar underfilling" hypothesis, which states that a *primary* reduction in systemic vascular resistance precedes *secondary* vascular filling during pregnancy; however, the two events are tightly linked and virtually inseparable, although some investigators have discerned a temporal dissociation.[46,47] (Also, see the section Significance of the Volume Changes During Pregnancy.)

Whether *chronic* volume expansion can raise ERPF and GFR to pregnancy levels is difficult to test. Most instances of chronic volume expansion that occur naturally are pathological in nature, for example, congestive heart failure or cirrhosis, and these are conditions where renal function is usually reduced rather than elevated. However, in the rare condition of primary mineralocorticoid excess, which is associated with volume expansion, GFR increases but not to the same degree as observed in pregnancy. Interestingly, chronic administration of either arginine vasopressin (AVP) or oxytocin to chronically instrumented rats permitted water *ad libitum* expands total body water and reduces plasma osmolality (P_{osm}), as well as markedly increases ERPF and GFR.[48,49]Thus, it is possible that chronic volume expansion contributes to the initiation and/or maintenance of elevated ERPF and GFR during pregnancy. Another possibility is that vascular filling consequent to primary arteriolar vasodilation in the kidneys and elsewhere may be permissive for the rise of GFR, in parallel with ERPF.

Maternal Factors in Early Renal Circulatory Adaptations

Mating female rats with vasectomized males produces pseudopregnancy—a condition physiologically mimicking the first half of rat gestation, but in the absence of fetoplacental development. This state reproduces the increases in ERPF and GFR that are observed during early pregnancy.[50,51] Thus, maternal factors alone can induce changes in the renal circulation.

Davison and Noble[29] reported that the 24-h endogenous creatinine clearance increased by 20% during the luteal phase of the menstrual cycle in women. Other investigators corroborated this finding either by using the renal clearance of creatinine,[52,53] 51Cr-EDTA,[53,54] or inulin.[27,55] Furthermore, ERPF measured by the renal clearance of PAH or [^{125}I] hippuran was noted to be increased in two studies[27,54] but not in another.[55] Thus, increases in ERPF and GFR are observed in the luteal phase, albeit to a lesser degree compared to pregnancy. This observation may shed light upon underlying mechanisms, because several hormones that increase during the luteal phase of the menstrual cycle rise even further in early pregnancy (e.g., the ovarian hormones, progesterone, and relaxin, see below).

Sex Steroids

Neither acute nor chronic administration of *estrogen (s)* to humans or laboratory animals influences ERPF or GFR, although the hormone can clearly increase blood flow to other nonreproductive and reproductive organs.[56–60] On the other hand, *progesterone* (or possibly progesterone metabolite(s)[61,62]) may contribute to renal circulatory changes in pregnancy. Chesley and Tepper administered 300 mg/d of progesterone intramuscularly to 10 nonpregnant women for 3 1/2 days and observed a 15% increase in C_{IN} and C_{PAH}. They speculated that longer administration of the hormone might produce larger increases in GFR and ERPF akin to normal gestation.[57] Atallah et al. who studied nine nonpregnant women demonstrated that a rise in circulating progesterone from 7 to 30 ng/mL was associated with a significant rise in endogenous C_{cr} (15%; 103–118 mL/min) 4 h after an i.m. injection of 200 mg of the steroid.[63] By extrapolation, they suggested that pregnancy levels of serum progesterone, which are considerably higher, could account for the 40–65% gestational increase of GFR. Of further interest, studies in male subjects in whom renal function was measured either 3 h after i.m. administration of 310 mmol progesterone or 3 days after 155 mmol progesterone i.m. twice daily revealed significant increases in ERPF (~15% and irrespective of dietary sodium intake), but GFR was unchanged.[64] Finally, subcutaneous injection of 2 mg/kg/d progesterone to intact female rats for 3 days produced a 26% increase in GFR; however, ERPF was not measured in this study.[63] Thus, data from both humans and animals suggest a contribution of progesterone (or its metabolites) to the gestational rises in ERPF and GFR, although definitive evidence is lacking.

Peptide Hormones

Prolactin surges in both pseudopregnant and pregnant rats during the first half of gestation coinciding with the increases in ERPF and GFR. Whether prolactin (or later in pregnancy, *placental lactogen* acting via the same receptor) actually contributes to the increase in renal hemodynamics and GFR during early gestation remains controversial and requires further study.[65]

Relaxin is another hormonal candidate underlying the gestational changes in renal function. In gravid rats and women circulating relaxin arises from the corpus luteum.[66] Human chorionic gonadotropin (hCG) is a major stimulus for relaxin secretion during pregnancy in women.[66]

There was compelling, albeit, circumstantial evidence for considering relaxin a potential mediator of renal vasodilation and hyperfiltration during pregnancy. (i) Circulating relaxin concentrations rapidly increase after conception in women[66] coinciding with the large increases in GFR and ERPF during the first trimester,[29,67]and refs cited above). (ii) Circulating relaxin is detectable during the luteal phase of the menstrual cycle[66,68–70] corresponding with the transient 10–20% increase in GFR and ERPF at that time,[27,29,52–55] and see section *Maternal Factors in Early Renal Circulatory Adaptations*, above. (iii) The early gestational rise in relaxin coincides with another physiological adaptation in human pregnancy, i.e., changes in osmoregulation.[71] These osmoregulatory changes were recapitulated by administering hCG to women in the luteal phase, but not to men suggesting the intermediary role of an ovarian hormone.[72–74] Furthermore, administration of synthetic human relaxin to ovariectomized rats for 7 days produced a significant decline in P_{osm} without changing plasma AVP concentration similar to the osmoregulatory changes noted in normal pregnancy.[75] (iv) Chronic administration of relaxin was reported to reduce blood pressure, [[76] but not confirmed in[77]] and vasoconstrictor responses in the mesenteric circulation of spontaneously hypertensive rats,[76,78] while acute administration increased coronary blood flow and reduced platelet aggregation through nitric oxide (NO) and cGMP,[79,80] thereby implicating a cardiovascular role for the hormone.

Although ERPF and GFR may rise in gravid rats as early as gestational day 5, before circulating relaxin is measurable, there is a jump in renal function between gestational days 8 and 12, when circulating relaxin concentrations surge.[42,66] (The modest increases in GFR

and ERPF that occur during rat gestation before circulating relaxin is detectable on gestational[9] or during pseudopregnancy when circulating relaxin is also undetectable seem to be mediated by other, as yet, undiscovered mechanisms.) Supporting the hypothesis that relaxin mediates the renal circulatory changes of pregnancy, Danielson and colleagues reported that long-term administration of porcine relaxin (pRLX) or of recombinant human relaxin (rhRLX) to chronically instrumented, conscious nonpregnant female rats increased both ERPF and GFR to midgestational levels when renal function peaks in this species.[42,81] The renal circulatory response to relaxin was not contingent upon the ovaries,[81] and intriguingly, was also noted in male rats.[82] Short-term administration of rhRLX to conscious nonpregnant rats also increased GFR and ERPF within 1–2 h.[83] Moreover, myogenic reactivity of small renal arteries isolated from relaxin-treated rats was significantly reduced[84] and comparable to reductions previously reported in small renal arteries isolated from midterm pregnant rats.[85] This phenomenon of reduced myogenic reactivity of small renal arteries has served as a faithful *in vitro* bioassay for the renal vasodilatory changes induced by pregnancy or relaxin treatment of nonpregnant rats.[84,85] Finally, by administering relaxin-neutralizing antibodies or removing circulating relaxin by ovariectomy and maintaining pregnancy with exogenous administration of sex steroids in physiological amounts, the gestational renal hyperfiltration, vasodilation, and reduced myogenic reactivity of small renal arteries isolated from midterm pregnant rats were completely abolished.[86] These experimental manipulations also circumvented the osmoregulatory adaptations of pregnancy.[86] Thus, relaxin is critical to the renal circulatory and osmoregulatory changes of midterm pregnant rats. It may also contribute to these pregnancy adaptations in women.[87]

Endothelium-Derived Relaxing Factors

Endothelium-derived relaxing factors including vasodilatory *prostaglandins* (PGs) and NO have been hypothesized to mediate the gestational increases of ERPF and GFR. The potential intermediary role of PGs has been investigated in gravid animal models and humans. Gestational rises in ERPF and/or GFR were unaffected by administration of PG synthesis inhibitors to chronically instrumented, conscious gravid rats or rabbits.[88–90] Moreover, vasodilatory PG synthesis *in vitro* was not to increased in renal tissues from pregnant animals.[91,92] Although intravenous PG infusion is not physiologically equivalent to locally produced hormone, intravenous infusion of prostacyclin to male human volunteers did not significantly change either ERPF or GFR.[93] In related studies, the cyclooxygenase inhibitor, indomethacin, raised systemic vascular resistance by *only* 5% in pregnant women without significantly affecting either mean arterial pressure or cardiac output, and this increase was trivial compared to the overall decrease in systemic vascular resistance of ~40% observed during normal pregnancy.[94] Similarly, another cyclooxygenase inhibitor, meclofenamate, did not significantly augment systemic vascular resistance in conscious, gravid guinea pigs.[95] Taken together, the results do not support a significant role for vasodilatory PGs in the elevation of ERPF, GFR, and cardiac output, as well as the reduction in both renal and systemic vascular resistances during pregnancy.

Guanosine 3′,5′′-cyclic monophosphate (cGMP) and NO: cGMP, a second messenger of NO may participate in the renal vasodilation and hyperfiltration of pregnancy.[65,96] Because extracellular levels generally reflect intracellular production, plasma levels, urinary excretion, and "metabolic production rate" of cGMP were investigated in conscious rats. All of these variables were increased throughout pregnancy and pseudopregnancy.[65,96,97] Comparable elevations in urinary excretion and plasma concentration of cGMP were reported for human gestation.[98–100] The 24-h urinary excretion of nitrate and nitrite (NO_x), the stable metabolites of NO, also increased during pregnancy and pseudopregnancy in rats consuming a low-NO_x diet, paralleling the rise in urinary cGMP excretion.[97] This gestational rise in urinary NO_x excretion was prevented by chronic administration of nitro-L-arginine methyl ester (L-NAME), an inhibitor of NO synthase, implicating NO as the source. Plasma concentrations of NO_x were also higher in pregnancy, and NO-hemoglobin was detected only in the red blood cells from pregnant, but not from nonpregnant, rats by electron paramagnetic resonance spectroscopy.[97] These results demonstrated that endogenous NO production is increased in gravid rats. Although the tissue source(s) of the gestational increase in NO production was not identified, the possibility that vascular tissues contributed was raised. Plasma levels and urinary excretion of NO_x were also reported to be increased in gravid ewes.[101] Unfortunately, the situation of NO biosynthesis during normal human pregnancy (and in women with preeclampsia) remains controversial.[98,102]

The renal circulation contributes to the overall maternal vasodilatory response of pregnancy. Renal vascular resistance reaches a nadir, and ERPF and GFR peak during midgestation in rats.[42] In chronically instrumented conscious, midterm pregnant and virgin control rats *acutely* administered L-arginine analogs, which inhibit NO synthase, GFR, ERPF, and effective renal vascular resistance converged in the two groups of animals.[102,103] In other words, compared to virgin control rats, the gravid animals responded more

robustly to short-term infusion of NO synthase inhibitors, resulting in a larger decline in GFR and ERPF, and a greater rise in effective renal vascular resistance. Consistent with these *in vivo* data was the inhibition of myogenic reactivity in small renal arteries *ex vivo* isolated from midterm pregnant compared to virgin control rats, which was restored to virgin levels by addition of NO synthase inhibitors to the bath or endothelial removal.[85]

A critical role for NO in renal vasodilation, hyperfiltration, and reduced myogenic reactivity of small renal arteries was also established for relaxin-treated nonpregnant rats again by using L-arginine analogs.[81,84] Thus, NO serves a critical role in the renal circulatory changes of both pregnant and relaxin-treated nonpregnant rats. Although pregnancy and relaxin administration to nonpregnant rats, both elicit renal vasodilation, hyperfiltration and reduced myogenic reactivity of small renal arteries that is dependent upon NO (*vide supra*), unexpectedly the urinary excretion of cGMP and NO metabolites is only increased during pregnancy.[81,96,97] Ironically, therefore, the increased production of cGMP and NO metabolites described initially in rat pregnancy, and which stimulated further interrogation of this vasodilatory pathway, may not be either of vascular origin or of hemodynamic consequence.

Of additional interest is that in one report,[104] but not in another,[105] vasodilatory PGs fulfilled a compensatory role maintaining relative renal hyperfiltration and vasodilation in gravid rats compared to virgin controls during *chronic* NO synthase blockade. In other words, in the setting of chronic NO synthase inhibition, renal function converged in the two groups of rats after short-term infusion of PG synthesis with meclofenamate.[104] PG blockade alone, however, did not affect renal function in conscious virgin or pregnant rats.[88,89,104]

Endothelin and the Endothelial ET_B Receptor Subtype

Paradoxically, *endothelin* (ET) plays a critical role in the renal vasodilation and hyperfiltration of pregnant and relaxin-treated nonpregnant rats. ET is widely recognized as a potent vasoconstrictor through interactions with ET_A and ET_B receptor subtypes on vascular smooth muscle.[106] However, ET also increases intracellular calcium in endothelial cells, thereby stimulating synthesis of prostacyclin, NO, and possibly other relaxing factors through an endothelial ET_B receptor subtype.[107–110] Specific blockade of the ET_B receptor subtype in chronically instrumented, conscious male rats with the pharmacologic antagonist, RES-701-1, induced profound renal vasoconstriction.[111] This unexpected finding indicates a major contribution of endogenous ET in maintaining low renal vascular tone through a RES-701-1 sensitive, endothelial ET_B receptor subtype and tonic stimulation of endothelium-derived relaxing factors and/or restraint of ET production.[107–112] RES-701-1 appears to be relatively selective for the "vasodilator" ET_B receptor subtype on the endothelium.[113] In summary, the RES-701-1 sensitive, endothelial ET_B receptor subtype maintains low renal vascular tone in normal conscious rats most likely through tonic stimulation of NO. However, with ET infusion or in pathophysiological states, ET-mediated vasoconstriction may predominate in the kidney.[113]

A logical extension of these observations in nonpregnant rats is that the endothelial ET_B receptor–NO vasodilatory mechanism is accentuated during pregnancy, thus mediating gestational renal vasodilation and hyperfiltration.[114] Indeed, short-term infusion of RES-701-1 to conscious virgin and gravid rats completely abrogated gestational renal vasodilation and hyperfiltration, thereby producing a convergence of GFR, ERPF, and effective renal vascular resistance in the two groups of animals.[114] As well, the inhibited myogenic reactivity of small renal arteries *ex vivo* isolated from gravid rats was reversed by addition of RES-701-1 or of a mixed $ET_B + ET_A$ antagonist (SB209670), but not a specific ET_A receptor antagonist (BQ123) to the bath.[85] These observations were analogous to those using inhibitors of NO synthase (*vide supra*). Subsequently, the NO/cGMP pathway was suggested to transduce the vasodilatory action of endogenous ET in the renal circulation of pregnant rats.[85,114]

The essential role of the endothelial ET_B receptor subtype in mediating inhibited myogenic reactivity of small renal arteries isolated from pregnant rats was corroborated in the ET_B receptor-deficient rat.[115] Finally, a critical role for the endothelial ET_B receptor subtype in mediating renal vasodilation, hyperfiltration, and reduced myogenic reactivity of small renal arteries was also established for relaxin-treated nonpregnant rats.[82,84]

Vascular Matrix Metalloproteinase-2

Jeyabalan and coworkers[116] proposed that relaxin enhances vascular gelatinase activity during pregnancy that, in turn, mediates renal vasodilation, hyperfiltration, and reduced myogenic reactivity of small renal arteries ultimately through activation of the endothelial ET_B receptor–NO pathway (Figure 81.6). The hypothesis that vascular gelatinase activity plays a pivotal role was founded upon the confluence of several observations: first, the essential role of relaxin, the endothelial ET_B receptor, and NO in pregnancy-mediated renal vasodilation as described above; second, the publications reporting stimulation of matrix metalloproteinase (MMP) expression by relaxin in fibroblasts;[117,118] and third, the ability of vascular MMPs, such as MMP-2, to

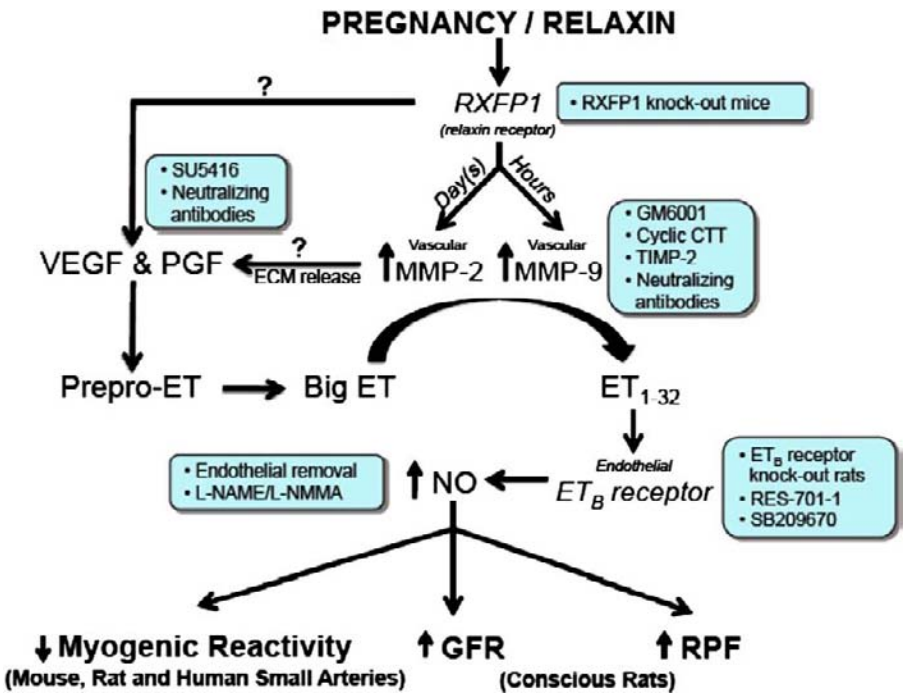

FIGURE 81.6 **Working model for the sustained vasodilatory effect of relaxin.** Depicted are the postulated roles of VEGF and PlGF in mediating the vasodilatory actions of relaxin to be further tested in this grant proposal. The precise localization of VEGF and PGF in the relaxin vasodilatory pathway is currently unknown. Relaxin may increase expression of angiogenic growth factor(s) in the arterial wall and/or release them from the extracellular matrix via MMP-9 or -2. Inhibitors of pregnancy- and/or relaxin-induced vasodilation are shown in the boxes. ET, endothelin; MMP, matrix metalloproteinase; ECM, extracellular matrix; RBF, renal blood flow; GFR, glomerular filtration rate; RFXP, relaxin/insulin-like family peptide receptors; SU5416, vascular endothelial growth factor receptor tyrosine kinase inhibitor; GM6001, a general MMP inhibitor; cyclic CTT, a specific peptide inhibitor of MMP-2; TIMP-2, tissue inhibitor of MMP; RES-701-1, a specific ET_B receptor antagonist; SB209670, a mixed ET_A and ET_B receptor antagonist; L-NAME, nitro-L-arginine methyl ester; L-NMMA, N^G-monomethyl-L-arginine. Note that RFXP2 knockout (in mice), STT (control peptide for cyclic CTT), heat inactivated TIMP-2, BQ-123 (a specific ET_A receptor antagonist), phosphoramidon (an inhibitor of the classical ET-converting enzyme), D-NAME and isotype-matched IgGs (controls for neutralizing antibodies) did not affect the sustained vasodilatory responses to relaxin. *[Reproduced from Ref.[127] with permission]*

hydrolyze big ET at the gly–leu bond to yield ET_{1-32} with activation of ET receptors.[119,120]

The best (if not the only) approach to testing the potential role of MMP-2 in mediating renal vasodilation, hyperfiltration, and inhibited myogenic reactivity of small renal arteries mediated by pregnancy or relaxin is to block MMP-2 production or its activity. Accordingly, short-term infusion of gelatinase inhibitors abrogated relaxin-mediated renal vasodilation and hyperfiltration in conscious rats; moreover, the inhibited myogenic reactivity of small renal arteries isolated from pregnant or relaxin-treated nonpregnant rats was reversed by gelatinase inhibitors *in vitro*.[116] In contrast, there was no effect of the traditional ET-converting enzyme inhibitor, phosphoramidon, which inhibits the processing of big ET to ET_{1-21}.[116] In small renal arteries harvested from relaxin-treated nonpregnant and mid-term pregnant rats, MMP-2 activity is increased by ~50% relative to nonpregnant control arteries.[116,121] Thus, vascular gelatinase activity is not only part of the relaxin-endothelial ET_B receptor–NO vasodilatory pathway, but it is a major locus of regulation by relaxin in this species, because neither endothelial NO synthase nor ET_B receptor abundance is increased by relaxin or pregnancy,[122,123] but not all investigators agree.[124–126]

It is unlikely that vascular MMP-2 and endothelial ET_B receptor–NO are components of separate vasodilatory pathways acting in parallel. If this was the case, then one might predict that after inhibition of either vascular MMP-2 or the endothelial ET_B–NO pathway, compensation of one for the other should be observed. However, no compensation or even partial compensation was noted: each and every inhibitor of the ET_B receptor,[82,84,85,114] NO synthase,[81,84,85,103] or MMP[116] completely abolished the renal circulatory changes during pregnancy or relaxin treatment of nonpregnant rats. Nevertheless, experimental confirmation of a common vasodilatory pathway shared by vascular gelatinase activity and the endothelial ET_B receptor–NO vasodilatory pathway was obtained. That is, small renal arteries isolated from relaxin-treated, ET_B receptor-deficient rats showed upregulation of vascular MMP-2 activity, but failed to show inhibition of myogenic reactivity. This dissociation of the biochemical

and functional consequences of relaxin administration in small renal arteries harvested from ET_B receptor-deficient rats, when taken in the context of the other results (*vide supra*), strongly suggests that vascular gelatinase is in series with, and upstream of, the endothelial ET_B receptor–NO signaling pathway.[116]

To summarize, during pregnancy relaxin accentuates the endothelial ET_B receptor–NO renal vasodilatory pathway by increasing vascular MMP-2 activity (via increases in MMP-2 mRNA and protein[121]). A more recent study also suggests the participation of vascular endothelial growth factor (VEGF) and placental growth factors (PlGF) in the renal vasodilatory pathway of relaxin.[127] Interestingly, higher doses of gelatinase inhibitors also decreased GFR and ERPF, and elevated arterial pressure when administered to control rats, albeit less so than in relaxin-treated rats,[116] whereas phosphoramidon was again without effect.[116] These results suggest that vascular gelatinase activity rather than the traditional ET-converting enzyme may be the main physiological mechanism for big ET processing (and consequent vasodilation) at least in the renal circulation of rats. Possibly, the colocalization of MMP-2 and associated proteins in the caveolae of endothelial cells with the ET_B receptor and eNOS facilitates this interaction (Figure 81.6).

Other factors in addition to relaxin are likely to contribute to gestational renal vasodilation and hyperfiltration especially during late pregnancy, when circulating levels of placental hormones are particularly high. For example, placental growth hormone may contribute.[128] In addition, local factors within the kidneys themselves may participate. Mesangial cell expression of iNOS, the angiotensin (AT)-2, and relaxin receptors was reported to increase during midgestation in rats.[129] Moreover, upregulation of the *n*NOSβ isoform in the renal cortex of midterm pregnancy rats was noted.[130] Intriguingly, Morgan and colleagues observed increased histidine decarboxylase and histamine production in the superficial cortical zone of pregnant mice.[131] Finally, increased renal production of epoxyeicosatrienoic acid may also play a role in renal vasodilation and hyperfiltration of pregnancy.[132]

To conclude, evidence from both animal and human studies suggests that renal hyperfiltration in pregnancy is secondary to increased RPF, the latter resulting from profound decreases in renal vascular resistance. There has been considerable progress in identifying mechanisms responsible for gestational renal vasodilation, and those most promising so far were reviewed in detail above. Of importance, whatever the primary vasodilatory stimulus, it must be a powerful one, for the pregnancy-induced rise in GFR is not restricted to women with two normally functioning kidneys but occurs also in subjects with previously hypertrophied single kidneys (following uninephrectomy) and in transplant recipients.[133,134]

Significance of the Changes in Renal Hemodynamics During Pregnancy

The GFR increase during pregnancy has important clinical consequences. Production of creatinine changes little, so that increases in creatinine clearance lead to a reduction in its plasma level.[4,9,135] This is also true of urea, which may be decreased even further by enhanced protein synthesis. Therefore, levels of creatinine and urea nitrogen decrease from a mean of 0.7 and 12 mg/dl (62 and 4.3 mmol/L), respectively, in the nonpregnant state, to 0.5 and 9 mg/dL (44 and 3.2 mmol/L).[4,9] The implication of these observations is that values considered normal in nonpregnant women may reflect compromised renal function during pregnancy. Concentrations of serum creatinine and urea nitrogen exceeding 0.8 and 13 mg/dL (80 mmol/L and 5 mmol/L), respectively, should alert the clinician to evaluate renal function further.

The augmented filtered load consequent to increased GFR also contributes to the glucosuria, aminoaciduria, and enhanced urinary excretion of water-soluble vitamins that occur during normal pregnancy.[9,23] Urinary protein excretion may double as well, but the greatest increments seem to occur in late gestation, long after changes in renal hemodynamics are maximal.[22,32] Also, there are still discrepancies about whether there are increases in albuminuria during pregnancy, but the majority of studies suggest so.[22,41] It should be borne in mind, though, that many factors affect urinary protein excretion in addition to glomerular filtration, including the pore size and number of fixed charges in the glomerular filtration barrier, and tubular reabsorption rates, a topic discussed elsewhere in this text.

There are also changes, usually increments, in the renal excretion of various low-molecular weight proteins and enzymes during pregnancy. Whether the alterations result from increased filtration and/or changes in tubular handling, or even in production is unclear (see Ref.[22]) for further details and citations). The increments in urinary glucose, amino acids, and proteins mentioned above also have pathophysiological consequences, i.e., the nutrient content of the urine is increased, which may predispose pregnant women to symptomatic urinary tract infection.[4,9] Finally, awareness that the normal limit of urinary protein excretion is increased during gestation to 300 mg/24 h suggests that this event will also occur and may even be exaggerated in women with preexisting kidney disorders, so that increased proteinuria during pregnancy

does not necessarily signify progression or exacerbation of their disease.

RENAL TUBULAR FUNCTION

Glucose, Other Sugars, and Water-Soluble Vitamins

Glucosuria may occur normally during pregnancy. In one study, 30 women with normal glucose tolerance were evaluated serially beginning early in gestation and continuing through the sixth postpartum week (reviewed in Ref.[23]). Daily urinary excretion of glucose was measured by a sensitive and specific enzymatic assay, an important methodological consideration, because excretion of many other reducing substances also increases during pregnancy. All subjects excreted <100 mg/24 h when not pregnant, but during gestation this value was exceeded in 26 women (86%) ranging up to 500 mg in 12, between 0.5 and 1.0 g in 4, and exceeding 1 g/24 h in 10 others. Glucosuria was intermittent and not necessarily related to blood glucose levels or gestational stage. A comparable high incidence of glucosuria in normal pregnancy was reported by others (reviewed in Ref.[9]). Gestational glucosuria reverts to normal within 1 week postpartum.[136]

Renal tubular handling of glucose, including the transport maximum (T_m), threshold, and splay of the titration curve were evaluated during pregnancy. Many reports had weaknesses in experimental design, but there were exceptions. With exquisite attention to methodology, Welsh and Sims[137] assessed the T_m of glucose in normal nonpregnant subjects, nonglycosuric pregnant women, and normoglycemic glycosuric gravidas. The T_m of glucose was lower in the latter group in comparison to the nonglycosuric pregnant subjects, and the authors proposed that gestational glucosuria resulted from increased GFR, and hence filtered load, in women with a low T_m for glucose. Fifteen years later, Davison and colleagues[138] suggested that both the T_m and fractional reabsorption of glucose decrease in all pregnant women. In their study, renal glucose reabsorption was measured in subjects with normal carbohydrate metabolism during and after gestation. Care was taken to avoid extremely high plasma glucose concentrations during infusions, which can affect renal hemodynamics. All women demonstrated lower fractional reabsorption of glucose during pregnancy compared to after delivery. Those most severely glycosuric in pregnancy had the lowest fractional reabsorption rates both during and after gestation; however, they were not glycosuric postpartum because GFR and the filtered load of glucose had decreased substantially. Said otherwise, even if the splay in the glucose titration curve increases or the glucose T_m decreases slightly, the striking gestational increment in GFR and consequent filtered load of glucose remains the major cause of glucosuria in pregnancy.

Gravid rats may also display glucosuria. Renal micropuncture studies in this species reveal that proximal tubular glucose reabsorption is actually enhanced, commensurate with the increment in filtered load; thus, the increased urinary glucose is due mainly to decreased distal tubular reabsorption, and perhaps to changes in epithelial permeability causing backleak in Henle's loop.[139]

Excretion of other sugars, including lactose, fructose, xylose, and fucose, but not arabinose, also increases during pregnancy [citations in Ref.[9]]; lactosuria is present in 50% of gravidas by the end of gestation, when excretion may be as much as 10-fold higher than nongravid women. During pregnancy, certain oligosaccharides are excreted in the urine not found in the urine of nonpregnant women, and thus, they are suspected to be of mammary origin. It should be emphasized, however, that the excretion of these sugars combined is minimal compared to that of glucose, and consequently, they do not amount to a significant nutrient loss to the mother.

The renal excretion of several water-soluble vitamins is also increased during pregnancy including nicotinic, ascorbic, and folic acids.[9] Plasma folate levels actually decrease in pregnancy, and the increased urinary excretion may be largely due to reduced tubular reabsorption rather than enhanced filtered load.

Amino Acids

Urinary excretion of many amino acids rises during pregnancy. In fact, urinary histidine concentration was once used as a method to detect pregnancy, and its disappearance from the urine was noted in preeclampsia.[9] The most detailed studies are by Hytten and Cheyne,[140] who conducted serial measurements in 10 women from early pregnancy through the eighth postpartum week. Renal excretion of glycine, histidine, threonine, serine, and alanine increased early in gestation and urinary losses became substantial near term. In contrast, increments in urinary excretion of lysine, cystine, taurine, tyrosine, phenylalanine, valine, and leucine occurred during the first half of pregnancy, but declined thereafter, and the urinary excretion of asparagine, glutamic acid, and arginine was unchanged during gestation. It is noteworthy that gestational aminoaciduria can reach $\sim$2 g/day, a loss that could adversely affect fetal growth, if protein intake is suboptimal. In some subjects, urinary glycine and histidine excretion exceeded 50% of the filtered load, suggesting a role for inhibition of tubular reabsorptive process. However, these data

reflect 24-h renal clearance measurements, and the little information concerning threshold or T_m during short-term infusion studies is inconclusive.[9]

Uric Acid

Although uric acid production has been described as unchanged during pregnancy,[4,9,22] more recent evidence disputes this conclusion.[141] In either case, gravidas excrete considerably more urate than when they are not pregnant.[22,142,143] The renal clearance of uric acid, typically 6–12 mL/min in nonpregnant women, rises to 12–20 mL/min during pregnancy, and consequently, plasma concentrations decline at least 25% and are only 2.5–4.0 mg/dL in many pregnant women.[9,144] In most centers, 5–5.5 mg/dL is considered to be the normal upper limits for pregnancy,[145] but the upper limit is different depending on the stage of gestation.[144] Circulating urate tends to be higher in women with multiple gestations,[146] displays circadian rhythm with higher and lower levels at morning and night, respectively,[147] and the normal range may be subject to racial variations.[148]

Whereas both the filtered load and absolute tubular reabsorption of urate increase during gestation, most investigators have documented increments in fractional excretion, i.e., the C_{urate}/C_{inulin} ratio is greater in pregnancy than in the nonpregnant state (reviewed in Refs[9] and[22]). However, there have been only two well-monitored serial studies in which investigators determined urate concentrations with specific enzymatic assays, and the results vary. In one study, no difference in fractional clearance of urate during and after pregnancy was reported,[149] whereas in the other,[143] C_{urate}/C_{inulin} increased during the first two trimesters but returned to nonpregnant values in the third.

The peak in renal clearance of urate and the nadir in plasma concentration are observed in early gestation; subsequently, C_{urate} declines and plasma urate levels rise near term.[9,22,143,149] It is not clear whether these findings are confounded by postural artifacts,[9] nonrenal metabolic effects in relation to the oxidant/antioxidant balance during gestation,[141] or possibly by inadvertent inclusion of women with subclinical preeclampsia. In this regard, decrements in the C_{urate}/C_{inulin} or increments in P_{urate} concentrations may precede the clinical manifestations of preeclampsia.[9,22,150]

Potassium Secretion

There are few data on body potassium stores in pregnancy. One study suggests that body stores decline early in gestation and then rise to values ~100 mEq above prepregnancy levels.[151] These findings are consistent with the theoretical considerations that pregnant women should lose potassium in their urine, because they eat and excrete normal quantities of sodium, but manifest very high levels of aldosterone and other potent mineralocorticoids (see below). Furthermore, they develop bicarbonaturia at substantially lower plasma bicarbonate levels than do nonpregnant women. Observations that plasma and serum potassium levels decrease 0.2–0.3 mEq/L between gestational weeks 10 and 28 are also consistent with this formulation.[152]

A more traditional view, however, is that pregnant women do not waste potassium but undergo a cumulative retention of ~350 mEq of the cation, most of which is stored in the products of conception, as well as in the organs of reproduction (Table 81.1).[9,152] Moreover, in striking contrast to nonpregnant women, gravidas are resistant to the kaliuresis provoked by the combination of exogenous mineralocorticoids and a high-sodium diet[153] (Figure 81.7). This remarkable capacity to conserve potassium in the face of high concentrations of potent mineralocorticoids such as aldosterone and deoxycorticosterone (DOC), and the delivery of substantial quantities of sodium to distal nephron sites, may be secondary to the increased circulating levels of progesterone during pregnancy, a view supported by studies in both humans[152,153] and animals[154] but not accepted by all.[155]

Resistance to the kaliuretic influence of mineralocorticoids may benefit gravid women with certain potassium-wasting diseases. On the one hand, excessive potassium loss of primary aldosteronism may be easier to control in gestation (Figure 81.8).[4,9,152,156] On the other, if the kidneys resist kaliuretic stimuli, women with underlying disorders that impair their ability to excrete potassium may be jeopardized by gestation. Finally, there is a rare disorder in which the renal

TABLE 81.1 Storage of Minerals During Pregnancy

Storage site	Sodium, mEq	Potassium, mEq	Calcium, g
Fetus	290	154	28.00

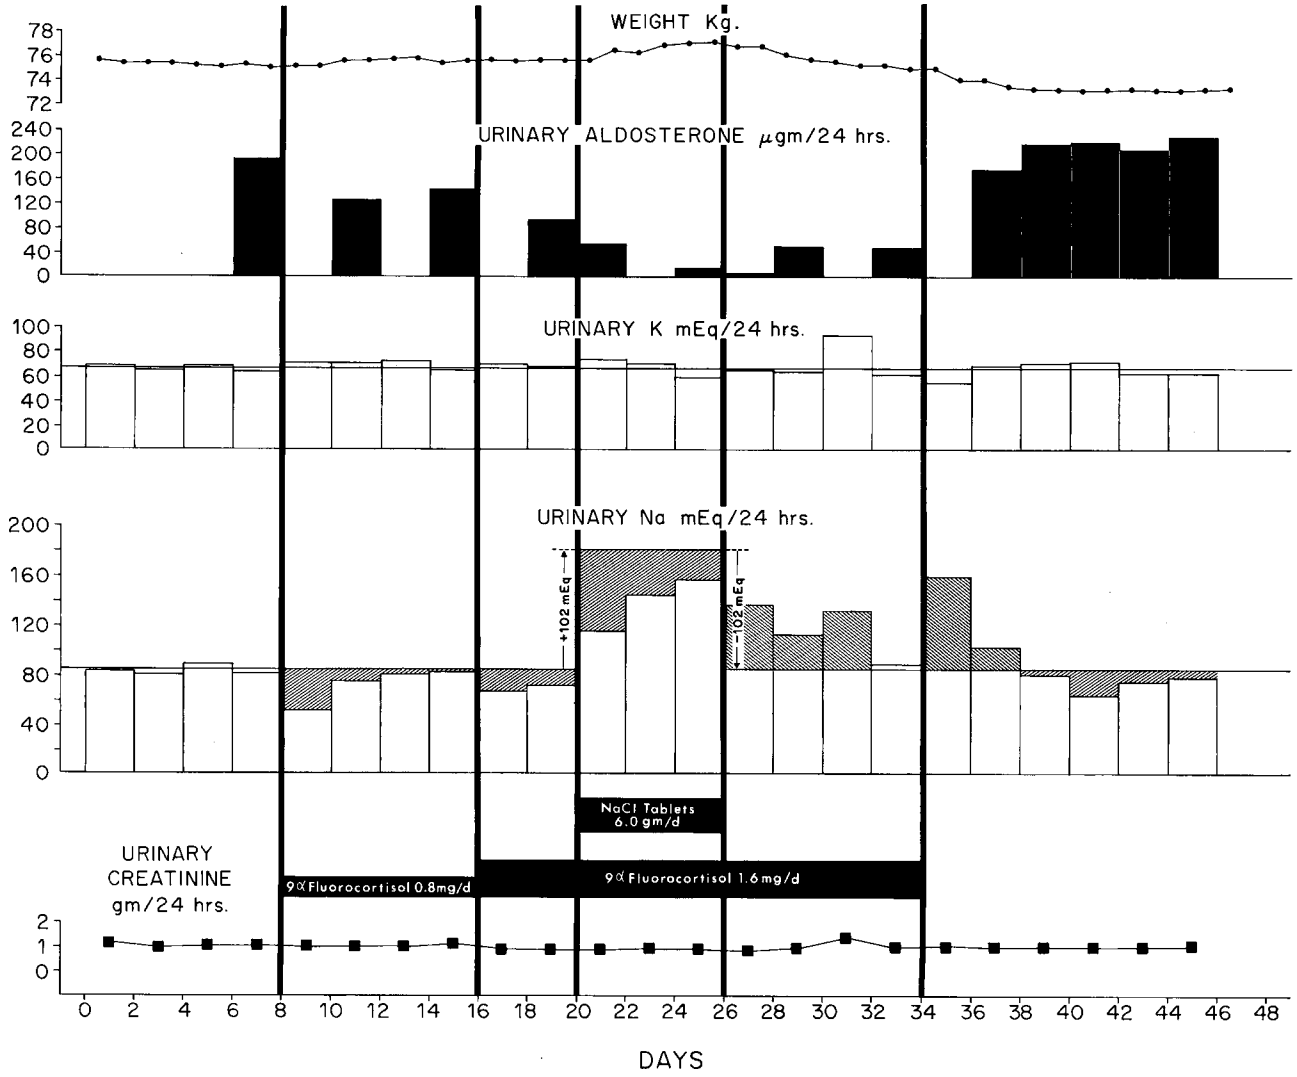

FIGURE 81.7 Effect of a mineralocorticoid (Florinef acetate) in a normal 19-year-old pregnant woman. Oral ingestion of this potent corticoid led to sodium retention, but no kaliuresis was observed even when dietary sodium chloride was abruptly increased during days 20–26 of the study. The high baseline aldosterone excretion is normal for pregnancy. The heavy vertical lines delineate the different treatment periods, and the horizontal lines are the arithmetic means of urinary sodium and potassium excretions during pretreatment (control) days. Note that a kaliuresis occurred only on day 31, but the increased creatinine excretion (asterisk) suggests a collection or measurement error. *[From Ref.,[153] with permission]*

mineralocorticoid receptor is genetically altered in a manner that hormones antagonizing the salt-retaining actions of corticoids become agonist in nature.[157] During pregnancy, progesterone levels increase 100-fold, and women heterozygous for the disorder manifest severe hypertension, renal potassium wasting, and marked hypokalemia, but suppressed aldosterone levels.

Regulation of Acid–Base Balance

Acid–base balance is affected by pregnancy. Blood levels of hydrogen ion decline 2–4 nmol early in gestation, a decrement that is maintained throughout pregnancy,[4,9,158] and arterial (or arterialized capillary) blood pH is typically 7.42–7.44 in gravidas, as compared with 7.38–7.40 in nonpregnant women. This mild alkalemia is respiratory in origin, because pregnant women hyperventilate (believed to be a central effect of progesterone effect), and consequently, their arterial PCO_2 decreases from a nonpregnant mean of 39 to 31 torr during gestation.[4,9,158] Supporting the causal role of progesterone are data showing that arterial PCO_2 also falls 3–4 torr during the luteal phase of the menstrual cycle.[159] These decrements in PCO_2 are compensated by decreases in plasma bicarbonate levels

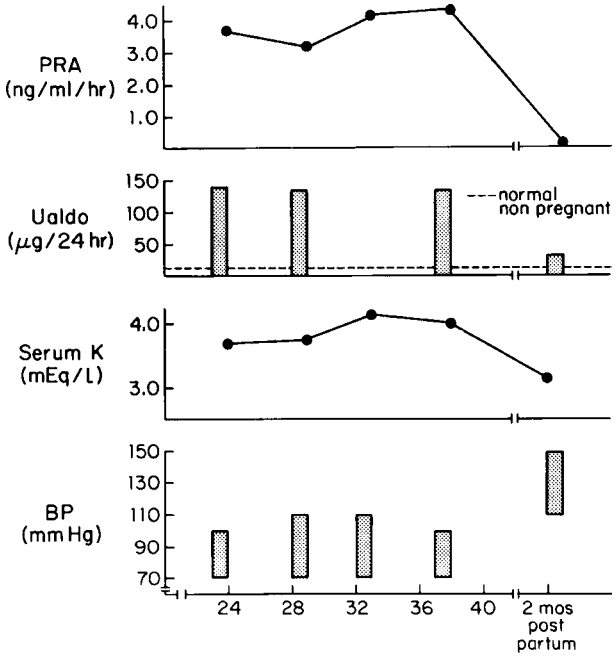

FIGURE 81.8 Plasma renin activity (PRA), urine aldosterone excretion, serum potassium, and blood pressure during pregnancy and 2 months postpartum in a woman with primary aldosteronism. Hypertension and hypokalemia disappeared during pregnancy. *[From Ref.,[156] with permission]*

of ~4 mEq/L, normal values in gestation ranging from 18 to 22 mEq/L,[4,9,158] thereby establishing a blood pH that is only slightly alkalotic.

There have been few studies addressing renal bicarbonate reclamation and regeneration during pregnancy. Lim et al.[158] infused a hypertonic bicarbonate solution in women during the third trimester. The bicarbonate titration curve from that study is shown in Figure 81.9 (left). Despite large filtered loads of bicarbonate, reabsorption continued to increase, and even when plasma levels reached 31 mEq/L, reabsorption virtually matched the filtered load. These results were unexpected, because pregnant women are hypocapnic and have increased extracellular volumes, conditions that should lead to an exaggerated "splay" in the titration curve and/or a decrease in the apparent T_m for bicarbonate. However, a small but persistent bicarbonate leak was noted at lower plasma bicarbonate concentrations during pregnancy than postpartum (Figure 81.9, right). This modest bicarbonaturia was occasionally present at plasma bicarbonate levels as low as 15–16 mEq/L.

Urinary acidification as well as titratable acid and ammonium excretion have been measured in gravid women after being challenged with both acute and chronic administration of NH_4Cl.[4,9,158,160] The results were comparable to those of nonpregnant control subjects. It is noteworthy that the decrement in urine pH and the increases in titratable acid and ammonium excretion occurred even though blood pH decreased only slightly from 7.44 to 7.40. Thus, substantial bicarbonate regeneration can already be demonstrated at a pH higher than in nonpregnant women, and in fact it starts when values are still alkaline relative to the nonpregnant state. Distal hydrogen secretory capacity, as measured by the increment in urinary PCO_2 during the bicarbonaturia that accompanied the hypertonic bicarbonate loading, appeared to be intact during pregnancy.[158] Finally, the decrease in blood pH during exercise is similar in the pregnant and nonpregnant states.[161]

OSMOREGULATION AND RENAL WATER HANDLING

Osmotic Thresholds for AVP Release and Thirst

P_{osm} decreases 8–10 mOsm/kg during normal gestation.[4,9,71,73,74] This decline, which starts in the luteal phase of the menstrual cycle,[27,162] continues through conception and reaches a nadir about gestational week 10, after which it is maintained until term. Only about 1.5 mOsm/kg of the fall can be accounted for by decreases in urea concentration, most of the change resulting from a decline in the concentrations of plasma sodium and its attendant anions.[71] Thus, pregnancy is characterized by a true decrease in effective P_{osm}.

A decrease in P_{osm} of such magnitude in a nonpregnant subject would suppress antidiuretic hormone secretion and result in a state of massive and continuous water diuresis, which does not happen in pregnant women. Rather, gravidas are able to maintain the new, lower P_{osm} within a narrow range, and water loading or fluid restriction, respectively, lead to appropriate dilution and concentration of their urine.[163] These events are made possible because osmotic thresholds for both AVP secretion and thirst decrease by 8–10 mOsm/kg each during gestation, decrements which are already demonstrable during gestational weeks 5–8 and are sustained through term[72,164,165] (Figure 81.10). It should be emphasized that parallel declines in both the osmotic thresholds for AVP release and thirst are required, in order to maintain the new steady state P_{osm} within a narrow range. That is, P_{osm} would rise in the face of persisting circulating levels of AVP at the lower P_{osm} of gestation, if the subject is not simultaneously stimulated to drink water; conversely, considerable polydipsia would be required to maintain a lower P_{osm} in the absence of AVP secretion.

The metabolism of AVP also changes in gestation, hormonal disposal rates rising four-fold between early

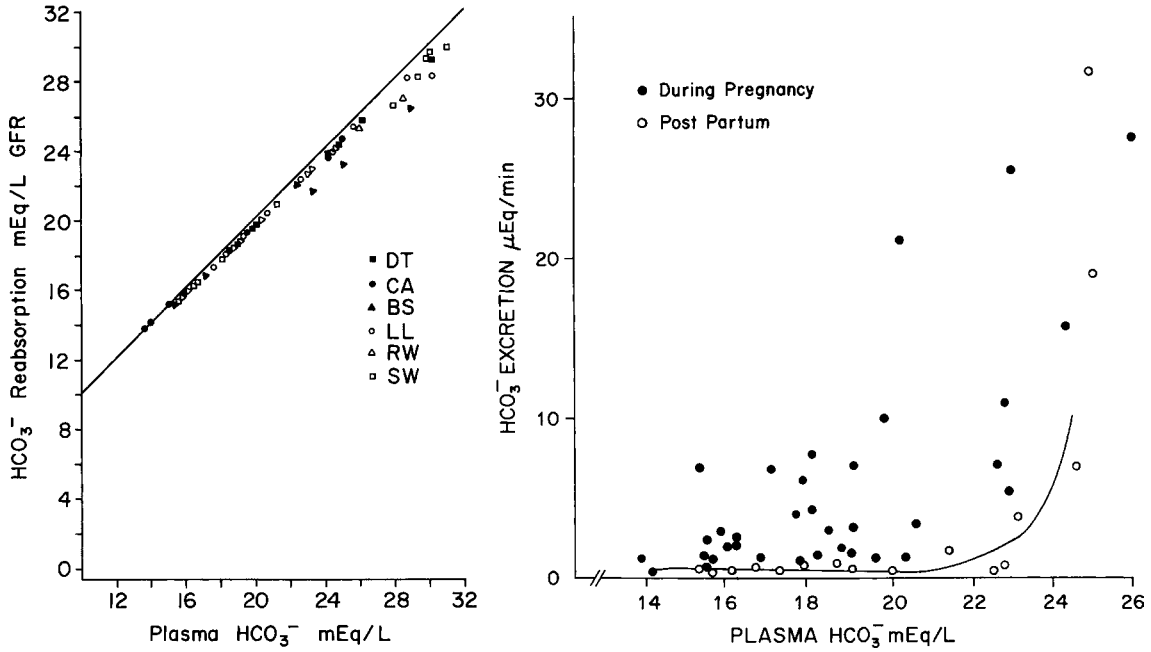

FIGURE 81.9 **Left:** Bicarbonate titration curves in six third-trimester women during slow infusion of 5% $NaHCO_3$ solution. The infusion inadvertently ran faster for a period of 30 min in 1 subject (BS), the only volunteer who displayed a wide splay. **Right**: Bicarbonate excretion as a function of plasma HCO_3 levels in pregnant women (filled circles) and two subjects restudied after delivery (open circles). $THCO_3$ is lower in the pregnant women (mean 18.9 mEq/L), but even when surpassed, the bicarbonaturia is still trivial. *[From Ref.,[158] with permission]*

and midgestation.[164,165] This rather striking increase in the metabolic clearance rate (MCR) of AVP parallels the marked increase in both placental trophoblastic mass and circulating levels of cystine aminopeptidase (vasopressinase).[165,166] Thus, the rise in MCR of AVP is likely due to the extremely high circulating vasopressinase emanating from the placenta, a concept supported by studies showing that the metabolic clearance of 1-deamino 8-D-AVP (DDAVP, Desmopressin), the AVP analogue resistant to inactivation by vasopressinase, does not change in pregnancy[164] (Figure 81.11).

The cause of the osmoregulatory changes in pregnancy is obscure. hCG,[72,167] constitutive NOS,[124,168] and relaxin[75,81] have each been suggested to play etiologic roles. Of further interest, decrements in P_{osm} do not occur in every species[74]; they do so, however in rodents (along with decreases in the osmotic thresholds for AVP release and drinking), and the rat has become the model in which to explore mechanisms responsible for changes that occur in humans.[73,74,169–173] In this latter model, injection of hCG yielded equivocal results (Barron and Lindheimer, unpublished observations), but relaxin lowers P_{osm}, as well as the osmotic threshold for AVP release.[75,81] These data suggest that the osmoregulatory effects of hCG in premenopausal women, ineffective in males, is through stimulation of ovarian relaxin secretion. This hypothesis remains to be explored.

Of interest is a group of investigators[174] that ascribed the decreased P_{osm} in pregnancy to the decreased "effective" circulating volume of pregnancy (so-called "nonosmotic" release mechanism, see below). Ohara et al. suggested that plasma AVP is detectable at low P_{osm} during pregnancy due to nonosmotic release, and gravid rats also manifest upregulation of aquaporin-2 (AQ2) mRNA and protein in apical membranes of the collecting duct, thus abetting water retention and lower body tonicity. However, the mechanism underlying increased AQ2 expression is uncertain, because circulating AVP, although detectable despite the lower P_{osm}, are not elevated above nonpregnant values (as in congestive heart failure). As discussed below, others have accumulated evidence against decreased or "underfill" of the arterial circulation as an explanation for the control of vasopressin secretion during pregnancy. We note here that the observations of Ohara et al may be paradoxical, insofar as an increase in AQ2 might be expected to blunt the animals ability to excrete a water load, yet gravid rats excrete water as well as or better than virgin controls.[172]

Significance of the Osmoregulatory Changes

The physiological significance of the changes in body tonicity, as well as in the osmotic threshold for AVP release and thirst is unclear. They may represent an

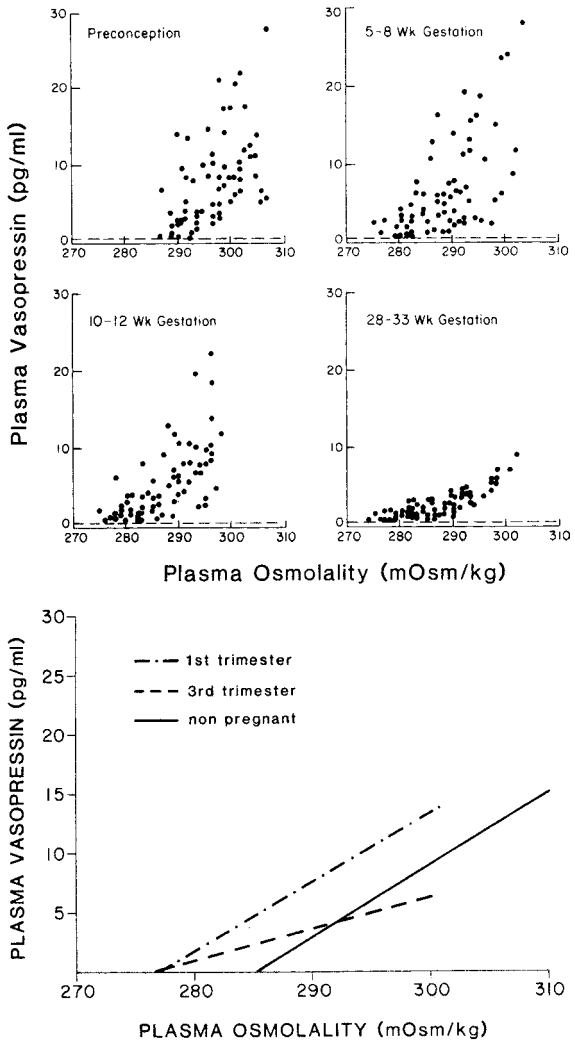

FIGURE 81.10 Relationships of P_{AVP} to P_{osm} during serial hypertonic saline infusions in eight volunteers starting before conception and completed postpartum. Each point in A–D represents individual plasma determinations, and data from the postpartum period, which were similar to these before conception, are not shown. Highly significant mean regression lines from the early pregnancy, the third trimester, and nonpregnant periods demonstrate the marked decrease in the abscissal intercept (which is the apparent osmotic threshold for AVP release) during gestation. The decreased slope ($\Delta P_{AVP}/\Delta P_{osm}$) in the third trimester is discussed in the text. Finally, the osmotic thresholds for thirst in both pregnant and nonpregnant subjects (not shown) were consistently 2–5 mOsm/kg above that for hormone release, and were thus ~10 mOsm/kg lower during pregnancy. *[Modified from Ref.[72]]*

epiphenomenon secondary to hormonal changes of pregnancy, but it is noteworthy that they may facilitate the increments in intravascular and extracellular volume that occur in pregnancy. Some believe the "physiological hypervolemia" of gestation optimizes fetal development, and in this respect, hypoosmolality results in a need for less solute per liter of extracellular water retained, certainly an advantage when sodium is scarce. Another idea is that the retention of water during pregnancy, which is distributed mainly to the intracellular space, creates a reservoir for maintaining extracellular and intravascular volume when water is scarce.

One very clinically relevant consequence of the altered osmoregulation in pregnancy is related to the striking increase in the MCR of AVP. In the past, women with central diabetes insipidus (DI) required increasing amounts of AVP administration during pregnancy. This is no longer the case since virtually all patients are currently managed with DDAVP,[175] which escapes metabolism by circulating placental vasopressinase (*vide supra*). Still there are patients with partial central DI and sufficient hormone secretory capacity to escape detection when nonpregnant, whose disease is unmasked by the marked increase in AVP disposal rates of pregnancy.[176,177] More frequent and dramatic, however, is another syndrome called "transient DI of pregnancy," which presents during the second half of gestation and remits postpartum.[73,74,177–179,180] It is important to recognize this entity as women may become dangerously hypernatremic especially if they undergo cesarean sections using general anesthesia or are water restricted in the delivery suite.[181] These patients have markedly high levels of circulating vasopressinase that may still be above those of normal gestation when measured during the first week of the puerperium.[179,182] Others may have subclinical central DI, their pituitary gland unable to respond to the increases in MCR of AVP during pregnancy. Polyuria in these women is usually unresponsive to large doses of AVP (pitressin), but they concentrate their urine rapidly when treated with DDAVP[179] (Figure 81.12). Some of these patients have hepatic dysfunction usually associated with preeclampsia, but in a few the DI has been associated with acute fatty liver of pregnancy. Thus, it is tempting to speculate that failure of the liver to inactivate vasopressinase, coupled with continuous placental production of large quantities of the enzyme, are causal. Consistent with this reasoning is documentation in one patient of excessive pitocin requirements during labor (vasopressinase destroys oxytocin as well as AVP).[175]

The ability to excrete water during pregnancy can be altered in other ways as well. Changing from lateral recumbency to a supine position decreases urine flow, and quiet standing may be more antidiuretic in pregnant than nonpregnant subjects (reviewed in Refs[4,9,71]). The effect of supine posture is independent of circulating levels of antidiuretic hormone, since it has been noted in a pregnant patient with central DI.[4,9] It should be underscored, however, that these "nonosmotic" influences on water handling are not sufficient, of themselves, to explain the gestational decline in P_{osm}.

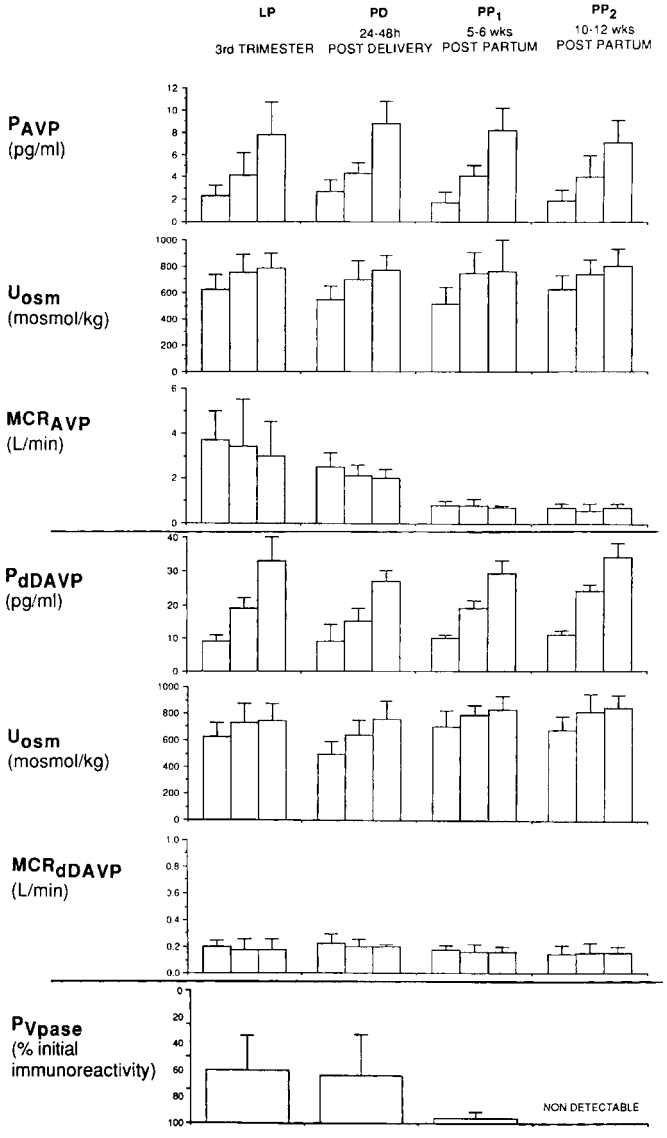

FIGURE 81.11 Plasma levels and metabolic clearance rates (MCRs) of AVP and DDAVP (1-deamino-8-D-AVP) measured serially starting in the third trimester, then 24–48 h postpartum, as well as 5–6 and 10–12 weeks after delivery. Above each bar is one SD. P_{Vpase} = plasma vasopressinase levels. *[From Ref.,[164] with permission]*

No single body position is maintained all day, and in addition the posturally induced antidiuresis rarely retards urine flow sufficiently to account for the chronically reduced P_{osm} (and thus the decreased plasma sodium levels[9,71]) observed in pregnancy.

Nonosmotic Stimulus for AVP Secretion in Pregnancy

The relative contribution of nonosmotic factors to the regulation of AVP secretion during pregnancy is uncertain, but in the nonpregnant human, volume is an important determinant of AVP release: hypovolemia stimulates, whereas hypervolemia blunts hormone secretion. In gestation, absolute blood volume increases markedly, but how the "effective volume" is sensed is a subject of considerable speculation, ([183–186] and discussed below). In this respect, the pregnant rat, which also undergoes a 40–50% increase in plasma volume near term, resets its volume-sensing, vasopressin secretory mechanisms such that the increased volume is sensed as normal.[45,170,187,188] Hypovolemia may decrease the osmotic thresholds for hormone release and thirst (see the chapters by Robertson, MacKnight et al., and Fitzsimons, Vol. 2), and some have ascribed the osmoregulatory changes in human pregnancy to an "underfilling" of the dilated intravascular space, ([184–186] and see below). However, expansion of the central volume by head-out water immersion during the first or last trimester had no effect on either the reduced tonicity or the decreased osmotic thresholds in pregnant women,[167] and P_{osm} could not be restored by overexpansion of volume (produced by administration of exogenous mineralocorticoids) maintained throughout gestation in rats.[170]

Urine Concentration and Dilution

Studies of maximum urinary concentrating capacity (U_{max}) during gestation are reviewed elsewhere[4] [see also Table 81.2 of the first edition of this text,[4] which summarizes data from 255 women in seven publications]. However, there are only three reports that include nonpregnant controls whose mean U_{max} is sufficiently high for valid comparisons. Urine osmolality was lower in the pregnant women in each of these studies, but not significantly so (probably due to the limited number of subjects). In any case, the differences from nonpregnant controls were too small to be of biological significance.

Urinary dilution, too, seems unchanged or only minimally affected by gestation.[4,9] Pregnant women excrete water loads as well as when not pregnant,[163] and gravid rats seem to excrete water more efficiently than virgin controls.[172] The latter observation is of special interest because of the apparent paradoxical observation that AQ2 mRNA and protein are upregulated in the gravid rat.[174] Immunohistochemistry of medullary tissue suggested that the increase in protein was mainly in apical membranes, which should have blunted the animal's ability to excrete water (as would have small undetectable increases in P_{AVP}, which the authors postulated as causing the upregulation). However, this apparent paradox may be resolved, if during the imposition of water loading, the mechanism (s) responsible for the basal increase in AQ2 expression during pregnancy are superseded.[189]

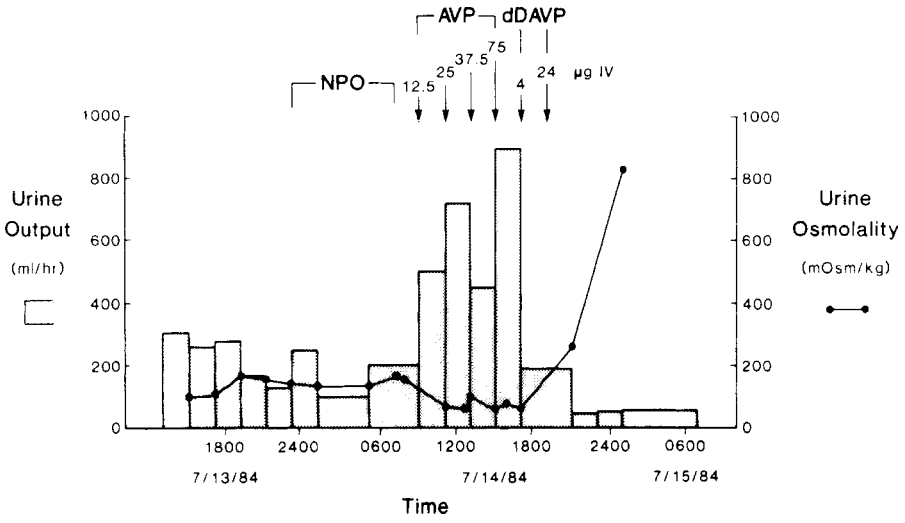

FIGURE 81.12 Urine volume and U_{osm} on postpartum day 6 in a patient who developed DI late in pregnancy and whose polyuria increased in the puerperium (~25 L/24 h). She was unable to concentrate her urine during fluid restriction (NPO), and P_{AVP} was undetectable despite a P_{Na} of 153 mEq/L. DDAVP therapy, however, increased U_{osm} to 800 mOsm/kg. The authors also measured a P_{AVP} of 240 pg/mL 30 min after the last AVP dose (when several thousand pg/mL should have been circulating), but demonstrated that this radioimmunoassay material was not bioactive and probably represented fragments. Finally, vasopressinase level measured 12 days postpartum was 10-fold higher than in women at term. See text for definitions of abbreviations. *[From Ref.,[179] with permission]*

TABLE 81.2 Analysis of Weight Gain

	Increase in Weight, g			
Tissues and Fluids Accounted for	**10 weeks**	**20 weeks**	**30 weeks**	**40 weeks**
Fetus	5	300	1500	3400
Placenta	20	170	430	650
Amniotic fluid	30	350	750	800
Uterus	140	320	600	970
Mammary gland	45	180	360	405
Blood	100	600	1300	1250
Extracellular extravascular fluid	0	30	80	1680
Total	340	1950	5020	9155
Total weight gained	650	4000	8500	12500
Weight not accounted for	310	2050	3480	3345

When investigating urinary diluting capacity in humans, one should be aware that supine posture can interfere with this test. Therefore, studies aimed at detecting minimal urine osmolality or maximum free water clearance should be performed with the patient lying on her side. However, while lateral recumbency is the preferred position for prenatal measurement of most renal functional parameters, this posture interferes with tests of U_{max}. For example, Davison et al.[71] demonstrated that U_{osm} actually decreased in patients dehydrated for 12 h when they assumed a lateral decubitus position for an additional 3 h, but increased when the test was repeated with the subjects sitting quietly. These observations may be explained by fluid mobilization from the extremities during bed rest, which results in either volume suppression of antidiuretic hormone release or in a mild osmotic diuresis. These results demonstrate the importance of upright posture, such as quiet sitting, when tests of maximum urine concentrating ability are performed during pregnancy.

VOLUME HOMEOSTASIS

Factors controlling volume homeostasis in pregnancy are incompletely understood and controversial. At one time, authorities believed that pregnant women retained salt excessively, thus predisposing them to develop hypertension. Sodium intake was curtailed and at times diuretics were prescribed prophylactically. More recently, the gravida was considered a subtle sodium waster, and supplemental salt was even advocated as a means of avoiding preeclampsia (reviewed in Refs.[4,9,150] A third view, to which we subscribe, is that renal sodium handling is similar in pregnant and nonpregnant women. This section summarizes current views on sodium handling and volume homeostasis in normal pregnancy.

Weight Gain

Healthy primigravidas gain ~12 kg during gestation, whereas multiparous women gain about 1 kg less. Most of this gain (~9.5 kg) occurs after the 20th gestational week.[190] Not all of the increase can be accounted for by the products of conception, reproductive tissues, or total body water (discussed below), but 4–6 kg of the added weight may be accounted for by increments

in maternal fat stores.[151,183,190,191] The gain of 12 kg cited above was recorded in pregnant women without any edema or with only leg swelling.[4,190] However, 15% of normal pregnant women may develop generalized edema (including swelling of fingers and face). Their weight gain averaged 14.5 kg, of which 4.9 kg was due to increase in the extracellular-extravascular compartments.

The value of 12 kg is well above averages reported in the older literature. Most surprising, however, is that in the past practitioners tended to regard published averages as upper limits of permissible weight gain, and many pregnant women have been admonished for excessive weight gain and their salt or calorie intake, or both, needlessly restricted. It should be emphasized that some women gain little weight while others may gain twice the average, and gestation proceeds uneventfully in both.

Alterations in Fluid Volume

Most of the weight added in pregnancy represents fluid retention. Total body water has been measured during pregnancy using deuterium, the stable isotope of oxygen [O^{18}], and by bioelectrical impedance.[151,190–194] The results suggest total accumulations of 6–9 L, although they vary due to methodological differences. Of interest, in a serial study starting before conception, Forsum et al.[151] noted higher increments in body fat than other investigators.

The volume of water accumulated in the extracellular compartment remains uncertain due largely to the lack of an ideal tracer for use in pregnant women. Reported estimates vary widely, and there is poor correspondence in those subjects in whom both extracellular and total body water were measured simultaneously. Reports in which thiocyanate was used as the tracer and the gain in extracellular space calculated as 6–7 L appear the most reasonable, since when added to the estimated 1.8–2.5 L of accrued intracellular water, the total approximates that measured directly with deuterium oxide.[4,150,190] Nonetheless, more research in this area will be needed before definitive conclusions can be reached.

Intravascular volume increases during pregnancy due mainly to increases in plasma water and a small increment in red blood cell mass (Table 81.2).[4,9,150,183,195] Plasma volume has been measured in pregnant women by several methods, but usually with Evans blue dye.[9,26,150,195,196] In the earlier literature, values were recorded as increasing until gestational week 30 and then declining. Such studies were in error, because late in gestation the indicator may not attain complete mixing within 10 min, if the subject is positioned in a supine or sitting position. Subsequent studies were performed serially, with the gravidas positioned in lateral recumbency for each measurement, and increases in plasma volume started in the first trimester, accelerated in the second, peaked near gestational week 32, and remained elevated until term.[195,197,198] The maximal gain averages 1,100–1,300 mL, although larger increments may occur when there are multiple fetuses.

Studies in animal models demonstrate increases in both plasma and red cell volume during pregnancy.[2,187] Of interest is an observation that plasma volume increases during early rat gestation even when the animals have a "zero" sodium intake, suggesting that some of the gain can be from internal redistribution of salt and water under this dietary condition.[199,200]

Since expansion of the plasma volume accounts for only 20–30% of the increase in extracellular space, increases in interstitial fluid must be substantial. In his analysis of the distribution of body water during pregnancy, Hytten[190] suggested the following: in women with no edema or leg edema only (~80% of normal gravidas), increments in interstitial fluid average 2.5 L at term, whereas in normotensive women with generalized edema the increase in interstitial fluid reaches ~5 L at term. In normal pregnant women, both with and without edema, the greatest accrual of interstitial fluid occurs in the third trimester, thus lagging somewhat behind the increment in plasma volume.

The mechanisms explaining interstitial fluid volume increases are incompletely understood. Unfortunately, there are but sporadic and/or conflicting data from both animal models and humans.[183,195] Plasma albumin decreases 0.5–1.0 g/dL during pregnancy, but its concentration in interstitial fluid may fall even further; thus, paradoxically, the oncotic pressure difference favors retention of fluid within the capillaries.[195,201,202] However, pregnancy is a vasodilated state (see below), and precapillary resistance is decreased, capillary hydrostatic pressure elevated, and, if the capillary ultrafiltration coefficient is unaltered[203] or higher, more fluid will enter the interstitium, especially if interstitial compliance is increased. In the steady state, there would also be enhanced return of fluid to the intravascular compartment and increased removal of protein through the lymphatics.

There is also speculation that some of the interstitial changes during gestation are due to alterations in the properties of connective tissue ground substance.[4,9,183,190] Thus, although low-molecular weight substances (e.g., cellular nutrients) diffuse readily through this material, fluid is "complexed" and poorly mobilized by diuretics. Furthermore, alterations in interstitial compliance, mediated through humorally induced changes in mucopolysaccharides,

could conceivably influence blood pressure. Data in favor of such a hypothesis are sparse (reviewed in Refs[4,9,183,190]) but provocative, and await further study.

On the one hand, the normal gain in interstitial volume during pregnancy may reduce the safety margin for edema formation in pathological states,[183] thus explaining why previously healthy gravidas may develop pulmonary edema when tocolytic therapy or the development of preeclampsia provokes additional fluid retention. On the other, there is the theoretical advantage of providing a large pool of interstitial fluid, which can be mobilized into the intravascular space when sudden depletion occurs, for example, by hemorrhage. Finally, increased fluid filtration across the capillary may protect the gravida from circulatory overload whose total blood volume is already increased.

In summary, pregnancy is characterized by the accumulation of >7 L of fluid, which is stored not only in the products of conception but also in the maternal intracellular, plasma, and interstitial compartments. In essence, there is maternal "physiologic hypervolemia." However, the volume receptors apparently reset to the hypervolemic state, thus sensing it as normal, and with imposition of salt restriction or diuretic therapy, the maternal response is similar to that observed in salt-depleted nonpregnant subjects (see below).

Renal Sodium Handling

A pregnant woman accrues ~950 mEq of sodium (Table 81.1), which is distributed between the products of conception and the maternal extracellular space (see above). This positive balance occurs gradually throughout gestation with the third trimester being the period of most rapid accumulation; however, the quantity retained is too small to be detected by conventional balance techniques. Renal sodium handling is the primary determinant of volume homeostasis, thus a brief review of the hemodynamic and humoral changes of normal gestation, which might influence urinary sodium excretion follows.

Circulating levels of many antinatriuretic hormones, mainly mineralocorticoids (e.g., aldosterone and DOC) increase during gestation, often markedly (see the previous edition, and Refs,[9,150,195] which provide reviews and monographs with detailed bibliographies). In this regard, the renin–angiotensin system is the control mechanism most studied,[9,195,204] and Figure 81.13 summarizes a detailed study by Wilson et al.[205] in which plasma renin substrate, activity (Plasma renin activity), and urinary sodium and potassium excretion were measured throughout gestation. Note the sequential increases in plasma renin substrate and activity, which start early in gestation. Salt excretion (reflecting intake) was similar during gestation and in the postpartum period, suggesting that inadequate sodium intake does not account for these rises. Moreover, despite these high circulating levels of plasma renin substrate and activity, the renin–angiotensin system responds appropriately to provocative maneuvers, e.g., circulating levels decrease after saline infusion or during a high salt diet, or rise further after the administration of diuretics or when dietary sodium is restricted.[9,195,206–211] Furthermore, inhibition of aldosterone biosynthesis causes a diuresis and subtle signs of volume depletion, the salt loss already apparent when aldosterone excretion, though decreasing, is still considerably above nonpregnant levels.[212] Thus, the renin–angiotensin system does not function autonomously during pregnancy as some have presupposed. Rather, the high circulating levels of aldosterone, which often exceed those measured in nonpregnant patients with primary aldosteronism, are appropriate in pregnancy responding to homeostatic demands.

Nevertheless, physical factors do seem to have a greater influence on renal handling of salt during pregnancy then they do in the nonpregnant state including the antinatriuretic potential of the upright or supine position, and perhaps the vascular changes in the uterus especially in late gestation which has been likened to an arteriovenous shunt.[4,9,150] In pregnancy, therefore, the supine and upright positions are markedly antinatriuretic, and quiet standing may cause greater reductions in sodium excretion in pregnant than in nonpregnant women.[4,9,150] Thus, bed rest in the lateral recumbent position is helpful in the rare instances when a diuretic appears necessary.

Postural influences may also underlie the circadian rhythms of solute and water excretion in pregnant women. Recumbent gravidas typically display patterns of urine flow, creatinine clearance, and aldosterone and electrolyte excretion similar to those of nonpregnant subjects (i.e., daytime peaks and nighttime nadirs). However, ambulation results in more striking changes during pregnancy than in the nonpregnant state, and excretory peaks frequently occur at night (reviewed in Refs[4,9]). On the other hand, nighttime excretion of sodium and solute-free water may be greatest early in pregnancy when postural effects are minimal, suggesting that humoral, rather than mechanical factors are responsible for these changes.[4,9]

Many hormones and autocoids change during pregnancy, which can theoretically enhance renal sodium excretion. These include increased circulating levels of oxytocin, melanocyte stimulating hormone, progesterone, natriuretic peptides, vasodilating PGs, and NO

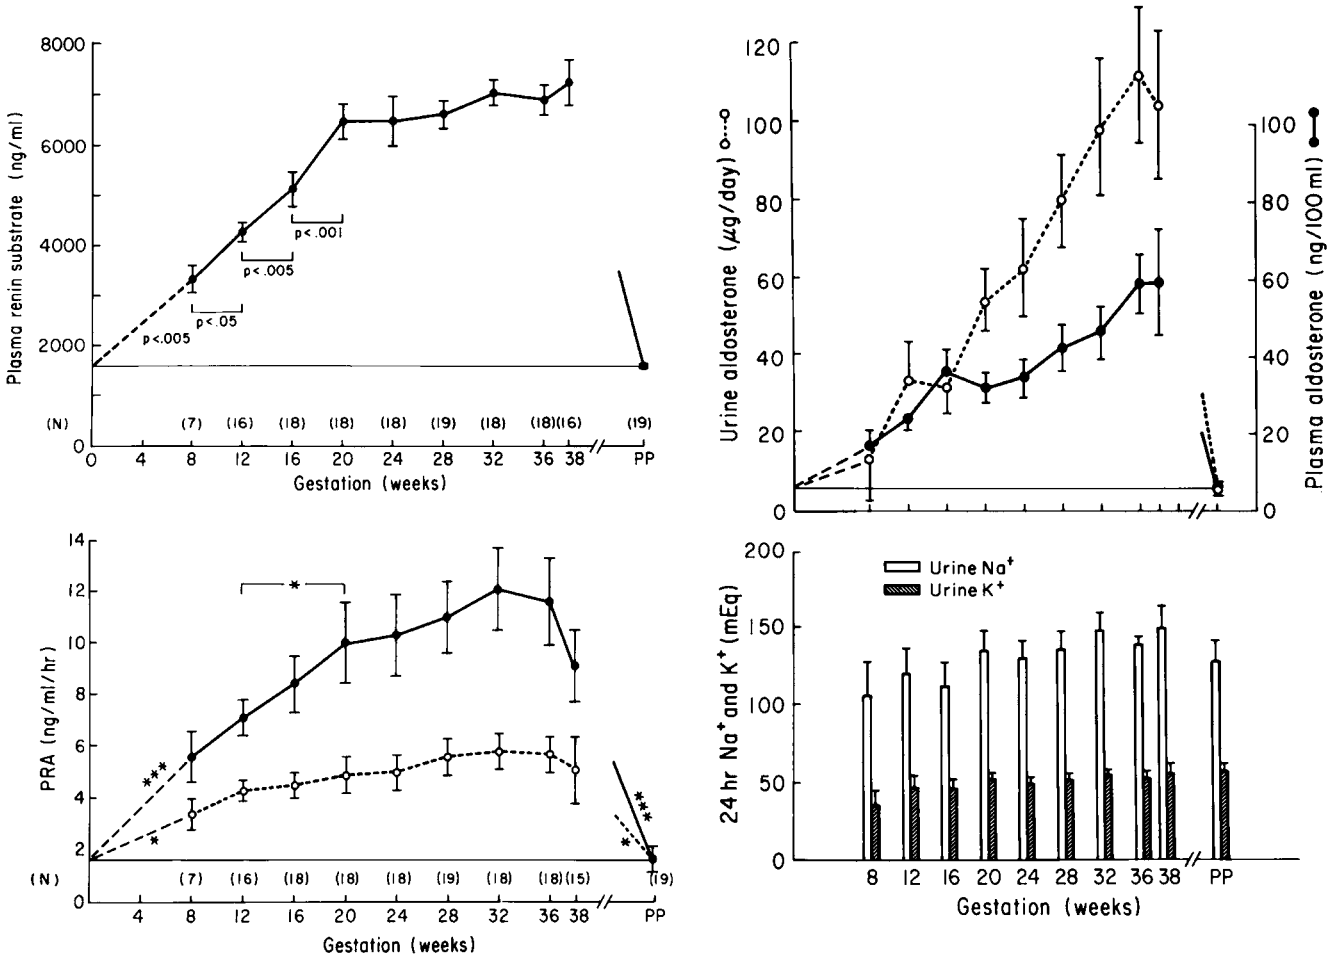

FIGURE 81.13 Sequential changes in plasma renin substrate (A), activity (B), and plasma and urine aldosterone (C) during pregnancy, all related to urine sodium excretion. Dashed line in B represents values normalized to the postpartum substrate levels. *[From Ref.,[156] with permission]*

(for literature reviews see Chapter 100 in the first edition and Refs[9,195,213]). Progesterone levels increase markedly even over those observed during the luteal phase of the menstrual cycle, and binds with higher affinity than aldosterone to the mineralocorticoid receptor prompting investigators to question how aldosterone functions in face of such high circulating levels of progesterone.[214] One possibility may be that progesterone actually contributes to antinatriuresis, as it is the major source of DOC production during pregnancy.[215–218] Because renal steroid 21-hydroxylase activity (the enzyme that converts progesterone to DOC) may be particularly high in pregnancy, a considerable portion of maternal DOC may be produced in the vicinity of the renal receptors whose stimulation enhance sodium reabsorption.[218]

There is considerable literature devoted to the various natriuretic factors and Na^+–K^+ ATPase inhibitors in pregnancy, but their influence on renal sodium excretion during pregnancy is also obscure. In particular, the production of atrial natriuretic peptide (ANP) exceeds increases in metabolic clearance, so that circulating levels are increased.[213,219–221] However, the increments in P_{ANP} are quite modest in relation to the marked increases in extracellular volume that occurs in normal pregnancy. Finally, the renal resistance to the natriuretic effects of atrial peptides described in animal models[222–225] does not seem to occur in human gestation.[221]

Perhaps, the major factor of importance when considering renal salt handling during pregnancy is the profound increase in GFR. Thus, every day more than 10,000 additional milliequivalents of sodium are filtered that must be reabsorbed by the renal tubules, a quantity which greatly exceeds the salt-retaining effects of large amounts of aldosterone, DOC, or estrogens administered experimentally. Quantitatively, the increase in filtered load of sodium is so enormous that

one might anticipate that it would render gravidas more vulnerable to salt and volume depletion. Thus, on the one hand, gravid rats tolerate sodium restriction and adrenalectomy more poorly than do the virgin controls[9,226] but, on the other, all pregnant species including humans are in positive sodium balance, and as noted, many women exhibit edema at some point of their gestation.

Effects of Acute and Chronic Sodium Loads

Whether salt-retaining or salt-losing influences predominate during gestation might be clarified by testing the capacity of pregnant and nonpregnant subjects to excrete saline loads. In the older literature, most studies lack nonpregnant controls.[4,9,150] An exception is that of Chesley and colleagues,[227] who infused 3% saline (410 mEq Na over 30 min) and observed that pregnant subjects excreted the administered sodium as well as the nonpregnant controls despite the fact that they were tested in the supine position and moderately sodium restricted prior to the test. These results, however, were disputed by Weinberger et al.,[211] who observed that gravid subjects given 2 L of isotonic saline over 4 h excreted significantly less sodium than comparably treated nonpregnant controls. More recently, in an extensive and meticulously conducted study in which dietary sodium intake was controlled, and the subjects were evaluated serially during the second and third trimesters and again postpartum, Brown et al.[228] confirmed the original observations of Chesley and coworkers.[227] A similar conclusion was reached in an animal study, in which term pregnant rats excreted acute sodium loads as well as, or better than, virgin littermate controls; however, the animals were anesthetized.[229]

Acute imposition of sodium loads does not necessarily relate to the homeostatic processes involved in sodium balance that occur over the course of an entire gestation. Consequently, several investigators conducted metabolic balance studies in an attempt to assess salt handling over a more prolonged period during pregnancy. Some authors concluded that gravidas have an impaired ability to conserve sodium and may show signs of volume depletion when dietary salt content is too low, whereas others stated that pregnant and nonpregnant subjects withstood challenges to sodium balance in a comparable fashion (reviewed in Refs[4,9]). Bay and Ferris[206] reported that pregnant women achieved balance as rapidly as nonpregnant controls while consuming diets containing as little as 10 mEq of sodium daily. Urinary sodium excretion decreased to similar values in pregnant and nonpregnant subjects 5–7 days after the low salt diet was instituted. These data, however, may lead to different conclusions from those reached by the authors when the following factors are considered: the small daily positive balance of 3–6 mEq in late gestation is too small to be detected by routine metabolic studies, and gravidas appear to excrete all their ingested sodium. Moreover, when gravid subjects are salt restricted, the increased sodium demands of pregnancy should make them resemble patients with cirrhosis or congestive heart failure who virtually eliminate sodium from their urine. Hence, the dietary restriction of 10 mEq daily in the report by Bay and Ferris should have revealed discernible differences in sodium balance between pregnant and control subjects. However, the gravidas in this study actually excreted 1–2 mEq more than the nonpregnant women, failed to gain the 1–2 lb of weight expected during a 7-day period in late gestation, and actually lost >2 lb. Also, plasma aldosterone increased to levels, which are considered high even for pregnant women. Thus the data of Bay and Ferris actually support conclusions contrary to the one they made, i.e., some salt-restricted pregnant women are prone to subtle sodium wasting, and others may achieve balance by invoking compensatory mechanisms such as adrenal steroid production.

In summary, there is a positive, cumulative salt balance during gestation, which amounts to a few milliequivalents of sodium daily. There are many physiological changes during pregnancy that impact sodium balance including the rise in GFR, the effects of physical factors, altered plasma levels of both antinatriuretic and natriuretic hormones, etc., but to what degree each contributes to the overall renal handling of sodium during pregnancy remains uncertain. On the one hand, the vast array and complexity of changing factors during pregnancy that affect sodium balance may render gravid women particularly susceptible to pathological outcomes should a component(s) of this intricate control system be amiss, e.g., the appearance of generalized edema and even obscure hypokalemia occasionally encountered in otherwise normal gravidas. On the other, the vast array and complexity of changing factors in pregnancy may be advantageous and evolutionarily conserved because of the inherent redundancy of mechanisms that can compensate one for the other, in the event that one or more should fail.

Significance of the Volume Changes During Pregnancy

On the one hand, the physiological hypervolemia may be a suboptimal response to the general arterial vasodilation of pregnancy, the so-called “underfill” or “primary arterial dilation” theories. On the other, the volume changes may be a primary event arising from the marked increase in antinatriuretic factors such mineralocorticoids, the so-called “overfill” theory.

However, an intermediate possibility is that volume-sensing mechanisms are continually reset as gestation progresses, and as such, the increments in absolute volume are "sensed" as normal ("normal-fill"). These contrasting hypotheses, previously mentioned in the section on osmoregulation, are clarified further below (see Ref.[183] for extensive review).

Evidence supporting the "underfill" theory is detailed by Schrier[184–186,230] and Duvekot[231] and their respective colleagues, and includes the marked activation of the renin–angiotensin system, substantiated not only by an increase in all of its circulating components (Figure 81.13) but also by the observation that pregnant women manifest exaggerated increases in aldosterone release in response to low-dose infusion of angiotensin II.[232] There is also evidence that the gestational decline in systemic vascular resistance precedes intravascular volume expansion, thus supporting the "primary arterial vasodilation" theory,[26,47,231,233] and administration of angiotensin-converting enzyme (ACE) inhibitors early in pregnancy evokes exaggerated decrements in blood pressure.[230] Finally, as noted, adrenalectomy, sodium restriction, or both, are tolerated more poorly in pregnant animal models.[226]

The "overfill" theory is supported by increases in renal hemodynamics and GFR, *absolute* increments in extracellular and intravascular volumes, elevation in the levels of circulating natriuretic factors and inhibitors of Na^+–K^+ ATPase,[195,213,220,221] and by a report of increased sodium excretory capacity in response to saline infusions.[211] Gravidas also appear more susceptible to complications of volume overload, especially those with underlying cardiac or renal disorders, or those receiving tocolytic therapy with sympathomimetic agents. In addition, they seem to tolerate blood loss better than do nonpregnant women. Finally, the mean circulatory filling pressure measured in gravid rodents has been consistently described as high normal or increased[234–238] as discussed further in Ref.[183]

Evidence for "normal-fill" is supported by animal experiments demonstrating the relationship between intravascular volume depletion and AVP release (detailed in the section on osmoregulation and Refs[74,167,170,187]). Also studies in rats and humans using indices of proximal tubular function such as fractional lithium and free water clearances suggest that sodium and water reabsorption by this nephron segment are unaltered.[239,240] Moreover, with water loading both species dilute their urine normally or better than nonpregnant controls.[71,163,172] Of note here is that failure to dilute the urine normally and excrete water and sodium are major pathophysiological features of hyponatremic patients with cirrhosis or cardiac failure, the prototypic diseases in which absolute extracellular and intravascular volumes are increased while "effective circulating volume" is low. Pregnancy, however, is a physiological condition, and thus salt and water excretory responses to acute sodium and water loads are comparable in pregnant and nonpregnant populations consistent with the concept that pregnancy is a "normal-fill" state (see Refs cited above and[9,227–229]). Finally, as detailed elsewhere,[183,241] circulatory performance during gestation (including the adequate response to exercise) is further evidence that gravidas "sense" their intravascular volume as normal.

In summary, disputes surrounding the true nature of the volume accrual in pregnancy as noted above are yet to be settled, and it may be that all views are correct with each being apropos depending on the stage of gestation, e.g., early primary vasodilation[26,46,47,231,233] followed by rapid compensation to normal-fill, and in some cases, overfill during late gestation due to a predominance of antinatriuretic influences such as physical factors at that time. Settling these controversies should perhaps be a priority, because understanding how the pregnant woman "senses" her volume changes may have wider implications for our understanding and management of gravidas with cardiac disease and hypertensive disorders such as preeclampsia.

RENAL DISORDERS AND GESTATION

This section surveys renal and obstetrical outcomes in pregnancies associated with kidney disease, including acute problems (e.g., urinary tract infection and sudden renal failure), as well as the natural history of gestation in women with chronic renal parenchymal disorders. Once, women in the latter category were advised against conception, while many who had already conceived had their gestations terminated, regardless of renal functional status. Data collected during the past three decades, albeit primarily retrospective, has led to a more rational and optimistic approach to counseling these patients, as well as to guidelines for managing their gestations. Of note, most women with chronic kidney disorders but preserved, or only mildly compromised renal function, can anticipate successful pregnancy outcomes with minimal risk of accelerating their disease.

Patient Evaluation

The approach to gravid women with renal problems is similar to that in nonpregnant populations, although tests which utilize ionizing radiation or radiochemicals should obviously be deferred until after pregnancy unless deemed crucial. Exposures to #5 rads do not

appear to harm the fetus.[242] The effect of the enhanced GFR, as well as alterations in acid-base parameters, and osmoregulation, on normal ranges of circulating creatinine, urea nitrogen, bicarbonate, sodium, and osmoles; blood pH and CO_2 tension were discussed in the previous section and will not be repeated here. Ammonia loading to determine the kidney's ability to excrete protons and achieve a minimal urine pH is rarely performed in pregnancy,[158,197,243] and gravidas may be more susceptible to NH_4Cl-induced nausea than nonpregnant women. When assessing GFR by endogenous creatinine clearance the lower limits of normal should be increased by ~30%. Of note, other endogenous proteins easily measured in clinical labs have recently suggested as better markers of GFR than creatinine levels. One, especially, Cystatin-C has been recommended for use in pregnant women, but its validity for use in pregnancy has been recently questioned.[244,245] Finally, when timed urines are neither practical (e.g., decisions during labor) nor reliable use of the Cockcroft–Gault formula based on preconception body weight can be utilized.[246]

Most, but not all, investigators[247] detect increases in urinary protein excretion in pregnancy.[31,134,248] Accepting the relative imprecision and variabilities of the methods used by hospital laboratories (as well as the fact that certain proteins remain undetected by some and not by other tests), 300 mg/day should be considered the upper limit of protein excretion in pregnancy. There are limited data on normal limits and validity of protein and/or albumin creatinine ratios in gestation. As previously discussed, the fate of urinary albumin excretion is disputed.[22,31,248–256] Even if it does rise, the increments are quite small, and thus use of nonpregnant upper limits of normal is probably permissible. Urine albumin excretion may have predictive value in relation to pregnancy outcome in women with diabetes, and those at high risk for preeclampsia but more research is needed here.

One should recall that as many as 5% of healthy adolescents and young adults manifest postural proteinuria, and this may become apparent or be first detected during pregnancy, especially near term when gravidas tend toward lordosis, a posture that augments urinary protein excretion. Finally, studies of tubular proteinuria, as well as enzymuria in either normal gravidas or those with renal disorders have sporadically appeared [summarized in Refs[4,22,257]]. These measurements are yet to be proved useful in the detection and management of renal disorders in pregnant women.

There have been few attempts to quantitate the urine sediment in pregnancy. Whether or not there is an increase in leukocyturia is unclear, but excretion of red blood cells definitely rises, so that 1–2/RBC per high-power field, considered abnormal in nonpregnant patients is probably acceptable in gravidas.[9,150,160,258] One should be aware, though, that microscopic and even gross hematuria may complicate otherwise uneventful gestations. When this occurs, the differential diagnosis includes all causes of urinary tract bleeding in nonpregnant populations, but often a cause cannot be found and the bleeding subsides postpartum. In some cases, the hematuria may be due to the rupture of small veins around the dilated renal pelvis,[259] the bleeding recurring with subsequent pregnancies. When faced with *de novo* hematuria in a pregnant woman, we follow up the urinalysis with ultrasonographic or magnetic resonance imaging (MRI), deferring more extensive investigations to the postpartum period.

Renal Biopsy

There are few indications to perform percutaneous renal biopsies in pregnant women, although the procedure has the same morbidity as that reported in nonpregnant patients.[260] In 1987, Packham and Fairley[261] described their large experience with renal biopsy during gestation and suggested that most pregnant women with undiagnosed hematuria and/or proteinuria should have antepartum biopsy, claiming that such a policy has important relevance for management and prognosis. We believe that their indications are too broad, and recommend the procedure in only the following instances[260]: (a) sudden deterioration of renal function with no obvious cause present, because certain forms of rapidly progressive glomerulonephritis may respond to aggressive treatment such as steroid pulses and perhaps plasma exchange; and (b) symptomatic nephrotic syndrome remote from term. For the latter, some might consider a therapeutic trial of steroids, but we prefer to determine first whether the lesion is one likely to respond to this treatment before exposing the gravida to it. On the other hand, proteinuria alone in a normotensive woman with well-preserved renal function who has neither marked hypoalbuminemia nor intolerable edema would lead us to examine the patient at more frequent intervals and defer biopsy to the postpartum period. This is because prognosis is determined primarily by the patient's functional status, as reflected in the serum creatinine level or its clearance, and by the presence or absence of hypertension (see below). Our approach to gravidas presenting with asymptomatic microscopic hematuria alone and no pathological findings by ultrasonography is similar. Finally, renal biopsy should not be performed after gestational week 32, because at this stage the decision to deliver is usually made rapidly and independent of biopsy results.

Urinary Tract Infection

Infections of the urinary tract represent the most frequent renal problem encountered during gestation.[9,150,262–264] Although the prevalence of asymptomatic bacteriuria, which ranges between 2% and 10%, is similar to that in nonpregnant populations [exceptions are gravidas with sickle cell trait and diabetes in whom higher rates have been observed[262]], the natural history of covert urinary tract infections differs from that in nongravid women. In the latter, the situation is quite benign, whereas during pregnancy progression to overt cystitis or pyelonephritis occurs in up to 40% of affected gravidas.[9,262–265] It has also been claimed that asymptomatic bacteriuria is associated with increased incidence of anemia, hypertension, and intrauterine growth retardation, as well as "preterm/low-birthweight" infants, but data supporting these assertions are lacking or equivocal.[9,150,262,266–269]

The pathophysiological basis for the increased morbidity noted above can be traced to two of the "physiological" changes in the urinary tract detailed in the preceding sections. There is urinary stasis and ureteral dilatation (sometimes obstructive in origin), and the urine of gravidas has a high nutrient content which supports growth better than that of nonpregnant subjects. Consequently, most authorities believe that all gravidas should be screened at their initial prenatal visit, and women with confirmed positive cultures should be treated, guided by the antibiotic sensitivity of the isolated microorganisms.[9,262,264] Indeed, detection and therapy of asymptomatic infections seems to prevent approximately two-thirds of potential antepartum pyelonephritis.[262] Other investigators,[270–272] however, question the sensitivity and cost-effectiveness of routine screening and suggest that testing be limited to women with a history of recurrent urinary tract infection.

The incidence of bacteriuria increases to ~17% immediately after delivery but decreases again to about 4% if the urine is cultured on day 3 postpartum[273]

Symptomatic Infections

Cystitis or pyelonephritis complicates about 3% of all pregnancies.[262,264] Universal screening for covert bacteriuria does not seem to have decreased the incidence of acute cystitis (1–2%), but appears to be responsible for the decrement in the potentially more serious complication, acute pyelonephritis. Its incidence, once nearly 3%, is now less than 1%, a decline ascribed to prompt treatment once asymptomatic bacteriuria is detected.[262]

Cystitis seems to be a distinct entity with little relationship to covert bacteriuria. The latter is unusual after gestational week 12, whereas most bouts of cystitis appear in the second trimester in women with previously negative screening cultures. Furthermore, it is easier to eradicate, and has a lower recurrence rate, than asymptomatic bacteriuria.[262,264]

Acute pyelonephritis is a potentially more threatening disorder in pregnancy. Most instances, ~70% related to preexisting asymptomatic bacteriuria, but the offending organism may be newly acquired. About 10% of these symptomatic infections in the initial trimester, and the remainder equally divided between the last two trimesters.[262,264] The infecting organisms parallel those cultured in women with asymptomatic bacteriuria (>90% gram-negative rods, primarily *E. coli*).[262–264,272,274] Of importance, gestation seems to decrease tolerance to these pathogens, and gravidas with acute pyelonephritis seem more prone to shock and respiratory distress syndrome, as well as renal, hematological, and liver function abnormalities.[9,262,264,275] Symptomatic infections of the kidney have also been implicated in the etiology of congenital abnormalities, premature delivery, fetal growth retardation, and intrauterine death.[9,150] It is noteworthy that while the infectious attack appears to have little effect on the renal function of nonpregnant patients, acute pyelonephritis in pregnant women may result in transient but marked decrements in GFR.[262,264]

Perinephric abscess, renal carbuncle, and renal cortical abscess are unusual events in pregnancy, but should be considered in cases of occult or resistant infection.[9,262] This is especially true in the immediate puerperium, when focus on uterine and abdominal sources of infection frequently leads physicians to ignore the possibility of the complications noted above.

Management

As of 2011, most authorities would prescribe 7–10 days of antibiotics to treat covert bacteriuria. Such regimens eradicate bacteriuria in 70% of these asymptomatic patients and cure >90% of women with cystitis.[262,264] Shorter courses, currently under investigation, include single dose therapy,[276] an approach, that if proven successful will minimize toxicity, and perhaps identify patients at increased risk for recurrent asymptomatic bacteriuria (the latter who then may benefit from suppressive therapy).[262,264] Also, in 2006 a large WHO randomized trial testing the use of dip sticks to detect significant bacteriuria followed by single day therapy to eradicate it was underway.

While cystitis is treated on an outpatient basis, acute pyelonephritis is preferably treated in a hospital setting, In the latter respect, though, scattered reports claiming successful outpatient management periodically appear.[264,277] Most gravidas with upper tract infections respond with defervescence within 48–72 h,[262,264] but in contrast to gravidas with cystitis or covert bacteriuria, these women have a propensity

toward relapse. Thus, while patients with cystitis or asymptomatic infection warrant a 7–10-day course of the appropriate antibiotic, those with acute pyelonephritis should be treated with therapeutic doses for 2–3 weeks. Subsequently, they should receive continuous suppressive therapy during the remainder of gestation, as well as during the first postpartum weeks, since up to 60% of these patients will have recurrent pyelonephritis if left untreated.[262,264] Some authorities,[274] however, claim that frequent surveillance for recurrent infection, and institution of prompt treatment only when significant bacteriuria is identified, is as effective as suppressive therapy.

Acute Renal Failure

The incidence of acute renal failure (ARF) of sufficient severity to require dialytic therapy is <0.01% in industrialized nations.[278–280] This represents a substantial decline from frequencies reported during the 1960s[278] and is due most likely to liberalization of abortion laws, more aggressive antibiotic therapy, and improvement of prenatal care. Furthermore, maternal mortality associated with ARF, once almost 20%, is now unusual.[278,280,281] These reassuring statistics, however, do not apply to poorer and less industrialized nations, where obstetric patients comprise up to 25% of referrals to dialysis centers, and where ARF continues to cause substantial maternal and fetal mortality.[278,280]

Septic Abortion

Before elective pregnancy termination was legalized, estimates of illegal (usually nonsterile) abortions in the United States were as high as 1 million annually.[278] Approximately 5% of these women became critically ill, and septic shock frequently complicated by renal failure was a leading cause of maternal death. Most of these events took place during the initial trimester, giving ARF in pregnancy a bimodal distribution: one peak in early gestation comprising most cases of septic abortion, and a second after gestational week 35, mainly due to placental abruption, bleeding, and preeclampsia. In countries where access to sterile pregnancy terminations has increased, the initial peak has virtually disappeared.[278,280,281]

The presentation of women with sepsis-related ARF, especially when due to clostridia, can be quite dramatic. Onset may be sudden, from several hours to 1–2 days after the attempted abortion, associated with an abrupt rise in temperature (>40°C), often with vomiting and diarrhea (which may be bloody). Muscle pain may be present, most intensely in the upper limbs, thorax, and abdomen; the latter leading at times to erroneous diagnosis of an intraabdominal inflammatory process (especially when a history of induced abortion is denied or not sought for). Vaginal bleeding may be absent, and clostridia organisms are difficult to culture or detect in the smear, besides being also normally present in the female genital tract. Progression to shock may be rapid, and the patients can manifest a peculiar bronze color due to association of jaundice (secondary to hemolysis) with cutaneous vasodilatation, cyanosis, and pallor. Other features include severe anemia, marked leukocytosis, and severe thrombocytopenia (as part of an intravascular coagulopathy). Hypocalcemia also occurs, and has been reported to be of sufficient severity to provoke tetany. An abdominal roentgenogram may demonstrate air in the uterus or abdomen secondary to gas-forming organisms and/or perforation. Death occurs rapidly in a small percentage of patients, but most respond to antibiotics and volume resuscitation, and survival depends largely on management of the renal failure. (The roles of hyperbaric oxygen, antitoxin, and exchange transfusion, as well as controversies concerning a conservative approach versus early surgical intervention to remove the infected uterus are discussed in most obstetric texts, and in Refs.[278,280,282]

Other Pregnancy-Related Causes

Volume depletion complicating hyperemesis gravidarum, severe vomiting associated with pyelonephritis, and uterine hemorrhage due to a variety of causes (including placenta previa, abruption, failure of the postpartum uterus to contract, lacerations, and perforations) all cause ARF mainly of the tubular necrosis variety.[278,280] Failure to estimate blood loss correctly because the hemorrhage is "concealed" behind the placenta contributes to the development of renal failure in these patients, and such judgment errors can be minimized by the judicial and rapid use of ultrasonic techniques. ARF associated with preeclampsia is discussed in the final section of this chapter.

Cortical Necrosis

Renal cortical necrosis, which was once more frequent in obstetric than in nonpregnant populations,[278,280,283–285] is now rare, its incidence in industrial nations being 1 in 80,000.[279] It presents more commonly in late gestation, when it is often associated with placental abruption and less commonly following retention of a dead fetus. Abruptio placentae should be considered when ARF develops suddenly between gestational weeks 26 through 30, as 45% of the patients in one series[286] had concealed hemorrhage.

Cortical necrosis may involve the whole renal cortex causing irreversible renal failure, but most cases associated with gestation are of the incomplete or "patchy" variety. The latter is characterized by an initial episode

of severe oliguria-anuria, lasting longer than uncomplicated tubular necrosis, followed by a variable return of function.[280,286]

The reason why gravidas are prone to develop cortical necrosis more readily than nonpregnant women is unclear. Many of the patients are older multiparas whose renal biopsies contain evidence of nephrosclerosis, suggesting a kidney vulnerable to whatever the inciting factor may be.[278] There may be severe and prolonged "selective" renal vasospasm causing endothelial damage and local activation of coagulation factors and/or potent vasoconstrictors. Of interest, the Sanarelli-Shwartzman reaction is produced more readily in gravid or postpartum animals than in their nonpregnant controls.[287]

Pregnancy-Specific Complications

There are two very uncommon forms of ARF peculiar to gestation. One is associated with acute fatty liver of pregnancy, and the second, of unknown etiology, occurs postpartum.

Renal failure in association with acute fatty liver is seen mainly near term but can occur shortly after midgestation.[1,9,278,280,288] The earliest manifestations of fatty liver are nausea and vomiting, important clues that may be overlooked or considered functional because the patient is pregnant. Laboratory data will confirm the presence of jaundice and other evidence of hepatic dysfunction.[278,280,289] There is an early rise in ammonia levels, which should be sought for, especially in lethargic patients. Evidence of disseminated intravascular coagulation includes decreased levels of antithrombin III.[289] Serum urate levels are also elevated, often out of proportion to the degree of renal dysfunction.[278] Ultrasonography and computed tomography of the liver also aid in establishing the diagnosis.[278]

The cause of acute fatty liver in pregnancy is unknown. Some signal its frequent association with preeclampsia.[278,290] Reversible urea cycle enzyme abnormalities resembling those in Reye's syndrome have been described.[291,292] Also of interest are women developing acute fatty liver of pregnancy or the microangiopathic hemolytic anemia associated with severe liver abnormalities associated with preeclampsia (see "HELLP syndrome" under preeclampsia below) who harbor a long chain 3-hydroxy acyl-Co-A dehydrogenous deficiency or carry mutations of the enzyme's gene resulting in deficiencies in the fetus.[293,294]

The hepatic lesion, characterized by deposition of fat microdroplets within the hepatocytes is described elsewhere in detail.[1,278,290] The kidney lesion is mild and nonspecific, and the cause of renal failure is obscure. It may be due to hemodynamic changes akin to the "hepatorenal syndrome" in some patients, or to the coagulopathy in others. Of importance, whereas mortality rates for both mother and fetus once exceeded 70% in this disease, and the frequency of accompanying ARF was 60%, these are much less frequent now. Maternal deaths average <10%, and renal dysfunction, when present, is usually mild and rarely requires dialysis.[278] These improved prognoses have been ascribed to earlier recognition of milder forms of the disease, followed by aggressive management, which includes prompt termination of the pregnancy.[278,290]

This second pregnancy-specific condition is characterized by the onset of renal failure in the puerperium after an uneventful gestation and termed *Idiopathic postpartum renal failure*. This disorder was first delineated as a specific clinical entity in the late 1960s.[295–298] By the late 1990s, only several hundred cases had been reported (under a variety of names, including irreversible postpartum renal failure, postpartum hemolytic–uremic syndrome, postpartum malignant nephrosclerosis, and late postpartum intravascular coagulation with ARF).[278,280,295,296,298] Using strict diagnostic criteria, the syndrome is defined by its onset between 1 day and several weeks after delivery. The patient presents with oliguria, or at times anuria, and progresses rapidly to azotemia, often with evidence of microangiopathic hemolytic anemia or a consumption coagulopathy. In the earliest descriptions, blood pressure was often normal, whereas the later literature stressed presentation with severe accelerated hypertension. Extrarenal manifestations have also been described. They involve the cardiovascular (cardiac dilatation and congestive heart failure) and central nervous systems (lethargy, convulsion), and are often disproportionate to the degree of uremia, hypertension, or volume overload.

The cause of this syndrome is unknown. Hypotheses have included an antecedent viral infection, retained placental fragments, or drugs such as ergotamine compounds, oxytocic agents, or oral contraceptives prescribed shortly after delivery. Since some women manifested hypocomplementemia, immunologic causes have been also postulated. Other theories include deficiency of PG production, decreased antithrombin III levels, and endothelial dysfunction perhaps secondary to deficits in NO-dependent endothelium relaxing factor. The pathophysiology of postpartum renal failure has been compared to those disorders currently listed under the "thrombotic microangiopathies" category, including hemolytic–uremic syndrome, thrombotic thrombocytopenic purpura, and for some the hemolysis, elevated liver enzymes, and low platelet (HELLP) syndrome, and even preeclampsia (see below), all disorders characterized by disseminated intravascular coagulation.[297,299] Of interest in this respect is a report of HLA-identical sisters, one of whom developed

postpartum renal failure and the other hemolytic–uremic syndrome associated with contraceptive pill ingestion.[300] Finally, postpartum renal failure has further been compared to the generalized Shwartzman reaction, which, as noted above, develops more readily in pregnant animals.[278,287]

Renal pathology in idiopathic postpartum renal failure has been described in two general categories: changes in the glomerular capillaries resembling those in the hemolytic–uremic syndrome and arteriolar lesions reminiscent of malignant nephrosclerosis or scleroderma.[1,278,301] Immunofluorescence staining shows nonspecific changes: fibrin-like material often present in the mesangium, glomerular capillary walls, and arterioles, and C3 deposits are common, but presence of other immunoglobulins has been rare and inconsistent. It has been suggested that glomerular lesions resembling thrombotic microangiopathy are more apt to be noted in specimens obtained early in the course of the disease, while those demonstrating accelerated nephrosclerosis are seen in biopsy material taken after the disorder becomes chronic. An increased incidence of postbiopsy bleeding has also been reported.[278,280]

Prognosis is guarded, as most women have either succumbed, required chronic dialysis, or have survived with severely reduced renal function. However, rare instances of recovery have been recorded.[278,280] Treatment is aimed at controlling the accelerated hypertension, in conjunction with the usual supportive management for ARF. There are reports of success with early use of anticoagulant therapy such as heparin and fibrinolytic agents (reviewed in Ref.,[254]but the data are not convincing. Similarly, antiplatelet therapy, infusion of fresh blood products including concentrates of antithrombin III, or plasma exchange (used in a variant of postpartum renal failure associated with circulating lupus anticoagulant or antiphospholipid antibodies[302,303] have been advocated and remain to be proven successful[278] Finally, due to a report implicating retained placental fragments with this syndrome, dilatation and curettage may be considered in selected cases.[278]

Miscellaneous Causes

ARF has been provoked by intraamniotic saline administration, amniotic fluid embolism, as well as by diseases or accidents unrelated to the gestation.[278] These include drug ingestion, bacterial endocarditis, and incompatible blood transfusions. Sudden renal failure during gestation has been caused by obstruction secondary to the enlarged uterus,[278,280] various nephritides, collagen disorders,[278,280] and rarely sarcoidosis.[304] The obstructive causes associated with the enlarged uterus, including the overdistention syndrome were described above. Finally, gravidas with underlying renal disease and acute infectious pyelonephritis may be more susceptible to develop acute tubular necrosis, even though they have normal or adequate renal function.[278,280,305] This is especially true when their gestation is complicated by superimposed preeclampsia or another cause of increased blood pressure.[306]

Treatment

Management of ARF during gestation or in the puerperium is similar to that in nonpregnant subjects, but certain points pertinent to obstetric ARF deserve emphasis. As noted, uterine hemorrhage in late pregnancy may be concealed and the blood loss frequently underestimated. Thus, it is important that blood be replaced early, and even that patients be slightly overtransfused in order to forestall the development of acute tubular or cortical necrosis. Either peritoneal dialysis or hemodialysis can be used in obstetric renal failure as detailed elsewhere.[307–311] The former modality is preferred on theoretical grounds, because alterations in fluid and solute levels are more gradual, thus less likely to precipitate hypotension and/or premature contractions.[308–310] If hemodialysis is utilized, the above problems can be minimized by daily treatment for shorter time periods, avoiding high flux technology. Since urea, creatinine, and probably other metabolites that accumulate in uremia cross the placenta, dialysis should be undertaken early in pregnancy, with the aim of maintaining the blood urea nitrogen at <50 mg/dL (18 mmol/L)[308–310,312] In essence, the advantages of early dialysis for nonpregnant patients are even more important for pregnant subjects and make the argument for "prophylactic dialysis" compelling. If the conceptus is near maturity, it should probably be delivered as soon as the mother's condition has been stabilized.

CHRONIC PARENCHYMAL RENAL DISEASE

As noted, the prognosis for pregnant women with chronic renal disease is considerably more optimistic now than two decades ago, a change brought about by a series of studies, primarily retrospective, which date from 1980.[305] These studies, which comprise the gestational history (and in some substantial postpartum follow-ups) of over 1,000 patients whose renal disease was confirmed by biopsy (literature reviewed in Refs[313–316]) permit the following guidelines:

Prognosis, in general, is based on the degree of renal insufficiency at conception, the patients being arbitrarily placed in three categories, those with "mild," "moderate," or "severe" renal dysfunction.

1. Normotensive patients whose function at conception is intact or only mildly decreased, (serum creatinine ≥ 1.4 mg/dL or 125 μmol/L) usually do well (>95% live births, >75% of neonates with weights adequate for gestational age). In addition, gestation has few or no adverse effects on the natural history of their underlying kidney disorder (Figure 81.14[317]). This generalization, however, has to be tempered for certain specific disorders that appear more sensitive to gestation, such as lupus nephropathy and perhaps membranoproliferative glomerulonephritis. There is controversy as to whether or not gestation adversely influences the natural history of IgA nephropathy, focal segmental glomerulosclerosis (FSGS), and reflux nephropathy.[305,318] Authorities agree, however, that women with scleroderma and polyarteritis nodosa (primarily those patients with renal involvement) do very poorly in pregnancy, and counsel such patients against conception or suggest termination to those already pregnant (see below).

Hypertension prior to conception is a substantial risk factor for mother and fetus even when renal function is preserved.[305,314,315,319,320] Controlling the blood pressure leads to pregnancy outcomes similar to those in normotensive women with mild renal dysfunction.[321]

2. The renal prognosis of women whose kidney function is moderately or impaired (serum creatinine ≥ 1.5 mg/dL or ≥ 133 μmol/L) is poorer, but fetal outcome is still quite good (≥90% live births).[316,318] Over one-third of these patients experience renal functional deterioration during pregnancy or in the immediate puerperium which may not revert postpartum, and may at times progress rapidly to end-stage disease. There is also a substantial incidence of severe hypertension (and/or superimposed preeclampsia), and blood pressures can be hectic, and difficult to control.

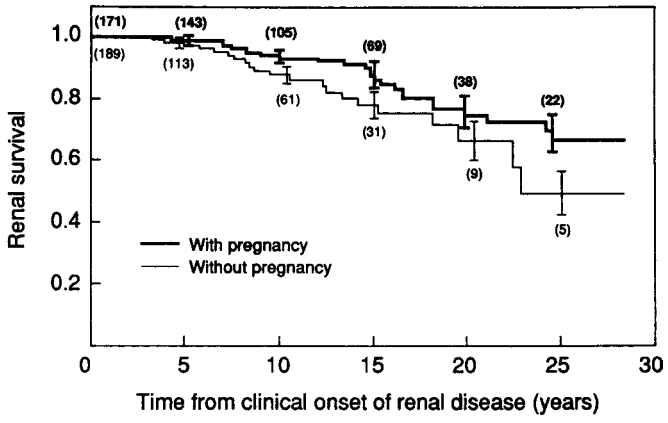

FIGURE 81.14 Kidney survival in women with preexisting chronic glomerulonephritis comparing those who subsequently underwent pregnancies (thick line) compared to those who did not. *[From Ref.,[313] with permission]*

3. Women with severe renal dysfunction [defined here as having a serum creatinine level ≥ 3 mg/dL (≥ 275 μmol/L)] are often infertile.[309,310] Even when conception occurs, the success rate is low while maternal morbidity is substantial.[308–310,314,315] These are two compelling reasons to discourage pregnancy in such patients.

Finally, we emphasize that the guidelines enumerated above, as well as the discussions of specific diseases that follows, are based primarily on retrospective data. Most of them were obtained from patients with mild disease and there is very little information on pregnant women with moderate and severe renal dysfunction. Thus, confirmation of our views will require large prospective observational trials.

Pathophysiology

Renal Hemodynamics

Pregnant patients with intact or only mildly decreased renal function usually manifest increments in GFR and ERPF often similar to those in normal gravidas[305] [Figure 81.15[170]]. Increases also occur in women with a single kidney due to uninephrectomy and in transplant recipients.[133,134,322] Renal adaptation in the latter two groups is of interest because their GFR and ERPF have already increased substantially prior to conception, due to compensatory morphologic and functional hypertrophy. Increases in renal function, however, appear restricted to patients with only mild dysfunction and GFR does not increase during pregnancy when creatinine levels exceed 1.4 mg/dL (124 μmol/L).[133,134,314,322]

Proteinuria

Urinary protein excretion may increase markedly in pregnant women with parenchymal renal disease.[305] The increments occur most frequently in the second half of pregnancy and do not seem to parallel the changes in renal hemodynamics. In one series[305] which comprised 121 gestations in 89 women the development of, or increase in, abnormal proteinuria was common and occurred in nearly half of all pregnancies. It was severe (≥3 g/24 h) in 39 of the proteinuric women, many of whom manifested substantial edema. Appearance of nephrotic-range proteinuria was associated with virtually every type of renal disease, with the exception of interstitial nephritis, and presented for the first time during gestation in a substantial number of women. Of importance is that these degrees of protein loss were usually well tolerated, had little or no influence on the course of the pregnancy or the natural history of the renal disorder, and fetal outcome was good.

Volume Homeostasis

There are sparse data on how renal disease affects the alterations in volume homeostasis and osmoregulation that occur during normal gestation. Of interest, though, is a report[323] suggesting that both blood and plasma volume appear to expand normally even when renal function is moderately decreased, but is markedly attenuated in patients with severe dysfunction.

Blood Pressure

The incidence of hypertension including superimposed preeclampsia associated with pregnancy in women with preexisting kidney disease is universally described as increased, but the specific influence of gestation on the blood pressure in these patients is difficult to assess[310,324] For instance, in one series, where renal function was preserved prior to conception, hypertension complicated 23% of the pregnancies, but blood pressure had been elevated prior to conception in about half the cases. The increments often occurred late in gestation, when it was difficult to distinguish superimposed preeclampsia from an exacerbation of the kidney disease.[325] There are also claims that women with certain specific disorders, such as IgA nephropathy, may have a greater propensity to manifest hypertension during pregnancy (see below). Finally, as noted above, hypertension frequently accelerates or complicates pregnancy when preconception function is moderately or severely compromised.[316] Such patients, of course, have a substantial incidence of high blood pressure prior to conception, and in this respect 79% of the women with moderate and 86% of those with severe insufficiency described by Cunningham et al.[323] developed superimposed preeclampsia.

Specific Disorders

The focus of this text is physiology and pathophysiology. Thus, the section that follows is but a selective summary of gestation in relation to a number of specific renal diseases (Table 81.3); the reader is referred to Ref.[314] regarding more detailed discussions that focus on management.

Glomerulonephritis

Acute poststreptococcal glomerulonephritis during gestation is quite unusual, and the reports in which the diagnosis seems to have been verified are characterized by complete recovery of maternal renal function and a successful pregnancy.[9,150,326,327] Also, a history of "healed" glomerulonephritis in the past has little influence on pregnancy.[9]

Women with most forms of chronic glomerulonephritis (a vague classification encompassing many morphologically distinct entities) have a good renal and fetal prognosis during pregnancy when kidney function is preserved and hypertension is absent or well controlled.[9,305,314,315] There are some exceptions, however: Membranoproliferative glomerulonephritis (where transplacental passage of nephritic factors has been documented[328]) is said by some to be affected

TABLE 81.3 Pregnancy in Women with Underlying Disorders

Renal Disease	Effects
Diabetic nephropathy	Most frequent nephropathy encountered in pregnancy. Gestation does not seem to accelerate functional loss; asymptomatic bacteriuria more frequent; higher incidence of nephrotic-range proteinuria and hypertension after midgestation.
Chronic glomerulonephritis focal glomerulosclerosis (FGS)	Increased incidence of high blood pressure late in gestation, but no adverse effect if renal function is preserved and hypertension absent before gestation. Some disagree, stressing the physiological coagulation changes in pregnancy exacerbate these diseases, especially IgA nephropathy, FGS, and membranoproliferative glomerulonephritis.
SLE	More problems than in most glomerular diseases, but prognosis is more favorable if disease is in remission 6 mo before conception. Poorest maternal and fetal outcomes associated with antiphospholipid antibodies or with lupus anticoagulant.
Scleroderma and periarteritis nodosa	Associated with maternal deaths and poor fetal outcome; reactivation of quiescent scleroderma can occur during pregnancy or puerperium; therapeutic abortion should be considered.
Chronic pyelonephritis (infectious tubulointerstitial disease)	Bacteriuria in pregnancy may lead to acute exacerbations but otherwise is well tolerated. Frequent urine cultures recommended; chronic suppressive antibiotic therapy may be necessary.
Reflux nephropathy	Some controversy; most agree that these patients do well when function is preserved. Frequent urine cultures necessary.
Polycystic kidney disease	Pregnancy uneventful when function preserved; increased tendency for late pregnancy hypertensive complication.
Urolithiasis	The "physiologic" ureteral dilation and stasis of pregnancy do not seem to affect natural history, but infections can be more frequent. Stents have been successfully placed during gestation.
Previous urologic surgery	Other urogenital tract malformations may be present; urinary infections increase, functional decrements have been observed; and cesarean section may be necessary to avoid disruption of the continence mechanism if artificial sphincters or neourethras are present.

adversely by gestation, but data in the literature appear to us inconclusive. The prognosis of IgA nephropathy is disputed.[314,315] There are claims that gestation provokes accelerated declines in maternal renal function as well as the *de novo* appearance of hypertension, and that both these complications may not remit postpartum. These concerns, however, are not born out by case–control and/or long-term follow-up studies that comprise ~300 patients, published by Jungers and Abe and their respective colleagues.[315,329,330]

Focal Glomerulosclerosis

Another glomerular disease whose prognosis in pregnancy is disputed is FSGS, perhaps because this disorder may have many etiologies, and data are quite limited (#100 patients described in the literature). In one report, hypertension, at times severe, was present in three quarters of the patients and persisted postpartum in 20% these women.[331] Proteinuria increased in most instances, while functional deterioration was recorded in 45% of the patients. On the other hand, it appears that those patients who are normotensive and have preserved renal function prior to conception do well.[314,315] Obviously, considerably more data are required to resolve the dispute.

Collagen Disorders

Systemic lupus erythematosus (SLE) is the most common collagen disorder affecting women of childbearing age.[332] The pregnancy prognosis for women with SLE and renal involvement is complex and is further complicated by the fact that the natural history of this disease is unpredictable whether or not gestation is present.[332,333,334,335,336] An older literature, limited and anecdotal, stressed the adverse affects of pregnancy, but more recently Hayslett,[337] reviewing the results of nine series (comprising 200 patients) published during or after 1980, came to more positive conclusions. When renal function is preserved, the best outcomes are in patients whose systemic disease has been in remission for six or more months before conception. Prognosis is poorer, however, if the disease had been active more recently, presents *de novo* during gestation (where it may be confused with preeclampsia), when there is preexisting hypertension, greater degrees of renal dysfunction, or if a circulating lupus

anticoagulant or antiphospholipid antibody is present. The literature regarding placental transmission of maternal autoantibodies, their relationships to the increased frequency of spontaneous abortion, placental and fetal pathology (especially congenital heart block), and a neonatal lupus syndrome, as well as the poor fetal prognosis associated with circulating lupus anticoagulants and antiphospholipid antibodies, are beyond the scope of this chapter are discussed in Ref.[332]

Contrasting SLE, where gestational prognosis is usually sufficiently benign when kidney function is preserved or only mildly compromised, the outcome of pregnancy in patients with renal scleroderma and periarteritis nodosa is very poor, often because of the associated hypertension which can be malignant in nature.[9,332] Not only is fetal prognosis dismal but most of the reported cases in the older literature, albeit anecdotal and selective, describe maternal deaths. More recently, however, there are descriptions of successful pregnancies (still anecdotal) in patients treated with ACE inhibitors, but the latter drugs are relatively contraindicated for use in pregnancy.[315,332] Thus, we continue to counsel against conception in these last two entities and suggest pregnancy termination when the disease is present in the first trimester.

Diabetes

Diabetic nephropathy is the most common renal disease encountered in obstetric practice. Most reports focus on pregnant women with overt disease, there being only limited data regarding those who have microalbuminuria before conception or early in pregnancy.[338–346,343,347,348–350] There is little evidence of pregnancy adversely affecting the long-term renal prognosis of diabetics whose preconception renal function is preserved, which is surprising given that nephrotic-range proteinuria and hypertension complicate two-thirds of these gestations. However, there is evidence, albeit limited, of rapid functional deterioration in women entering pregnancy with moderate or greater dysfunction.[351,352] Of interest is a report noting that hypothyroidism appears *de novo* during gestation in a significant number of nephrotic diabetics.[353]

Fetal outcome, described as poor in the older literature[9] is presently quite good, 95% of the pregnancies ending successfully. However, there is high incidence of preterm deliveries, often due to termination early in the third trimester, as this is the period when the increases in hypertension and proteinuria occur, and are difficult to differentiate from superimposed preeclampsia.

Miscellaneous Glomerular Diseases

The literature regarding minimal change disease, though limited to less than 200 patients, is quite favorable.[305,315,354] There is also limited experience with membranous nephropathy, but again most patients with preserved renal function do well, though, not surprisingly they have a high incidence of nephrotic-range proteinuria.[9,305,314,315,354] An adverse effect of pregnancy on familial Mediterranean fever with amyloidosis, even when preconception function appears preserved or minimally compromised, has been suggested.[355] The literature regarding vasculitides such as Wegener's granulomatosis, Henoch–Schönlein purpura with renal involvement, and Goodpasture's syndrome is selective and anecdotal.[315,356,357] Regarding the latter disorder is a case report where the disease improved during pregnancy, in which the authors postulated that the placenta, which may share some key antigens with the glomerular basement membrane, provided a large absorptive surface for the autoantibody.[358] Finally data relating to vasculitides like Wegener's granuloses is both limited and anecdotal.[359,360]

Reflux Nephropathy and Other Tubulointerstitial Disorders

Reflux nephropathy is a disease that begins during childhood and thus is present in a substantial number of pregnant women. The natural history of this disorder during pregnancy was once disputed, but two reports[318,361] comprising 697 pregnancies in 290 women with reflux nephropathy were consistent with the dictum that when renal function is preserved and hypertension absent, these gestations do well. However, these patients are prone to urinary tract infection and require special attention during gestation, including frequent urine cultures and prompt treatment when signs of urinary tract infection occur.

Concerning tubulointerstitial disease, most are infectious in nature, and gestational outcome relating to the patient's functional status prior to conception.[305] There are few data concerning renal tuberculosis, which in the older literature appeared to be unaffected by gestation.[9]

Finally, some women who have had major urinary tract reconstructive surgery, especially diversion, may develop reflux during pregnancy.[362] Since such patients have a high incidence of bacteriuria, and the risk of developing obstruction grows as the uterus enlarges, it is gratifying that most authors have reported fairly benign and successful pregnancies (reviewed in Ref.[362]).

Hereditary Disorders

Autosomal Dominant Polycystic Kidney Disease: Patients with polycystic kidney disease have a greater propensity to develop *de novo* late gestational

hypertension or preeclampsia, but pregnancy outcomes are favorable when renal function is preserved and hypertension prior to conception absent.[363,364] There is, however, an increased risk of upper urinary tract infections which can be virulent at times.[365] Also, one group of investigators[363] noted that multiple pregnancies (defined as >three) lead to an earlier onset of kidney failure. However, this may only reflect the influence of pregnancy in women who already had moderate or greater renal dysfunction when they conceived (which is more likely to be the case in older multigravidas).

Though pregnancy does not appear to influence the natural history of the renal disorder, it may have effects on other organs. Liver cysts are said to be larger or more prevalent in parous women, and enlargement of the cysts (increasing their chance of rupturing) may occur during pregnancy.[366] Finally, routine preconception screening of the intracerebral vasculature should be reserved for patients with family histories of clustering for intracranial aneurysms or subarachnoid hemorrhage.[292]

Hereditary Nephritis: This is primarily an X-linked dominant disease (where the majority of carrier females manifest only mild degrees of urinary abnormalities), but ~15% of affected patients have an autosomal dominant or recessive variety.[367,368] Thus, in most women, the disease is clinically silent, but there are exceptions. In addition, the disorder may manifest for the first time during pregnancy (due to observation of hematuria and/or proteinuria when a urinalysis is performed as part of routine prenatal care). However, renal function is usually well preserved and these pregnancies do well, but there is an interesting report of two sisters with the disease, each of whom developed rapidly progressive crescentic glomerulonephritis during their respective pregnancies.[369] Finally, there are variants of hereditary nephritis associated with thrombocytopenia and thrombocytopathy.[367] Such patients are at risk for excessive bleeding during delivery.

Miscellaneous: Patients with *cystinosis* have usually progressed to end-stage renal disease by adolescence, but may conceive while receiving renal replacement therapy. Angiomyolipomas and renal aneurysms may be present in patients with *tuberous sclerosis*, and since the former may bleed and the later rupture during gestation, screening and appropriate interventions are warranted prior to a planned pregnancy.[370] Similarly, women with *von Hippel–Lindau* disease should be screened for silent pheochromocytomas, present in ~25% of such patients, as activation during gestation and especially at delivery has been described.[371,372]

Urolithiasis

The incidence of urolithiasis in pregnancy varies by geographic location, the best estimate being 1 in 1,500 pregnancies [reviewed in Ref.[373]]. This estimate, however, may be too low, due to under-reporting of the disease. Many patients remain undiagnosed until their disease is symptomatic, and in others the symptoms are quite subtle, such as repeat urinary tract infections, and urolithiasis is not considered in the differential diagnosis.

There does not appear to be any increase in either the appearance or recurrence of nephrolithiasis during gestation.[374] This is surprising because normal pregnant women are markedly hypercalciuric and their urinary supersaturation ratios for calcium oxalate and brushite are substantially increased[373,375,376] [Figure 81.16[169]]. There are also increases in magnesium and citrate excretion, but the increments are not enough to counter the strikingly elevated supersaturation ratios.[376] In essence, the combination of supersaturation with the physiologic dilatation, stasis, and perhaps obstruction of the urinary tract, raises the question why stone disease is not more prevalent in

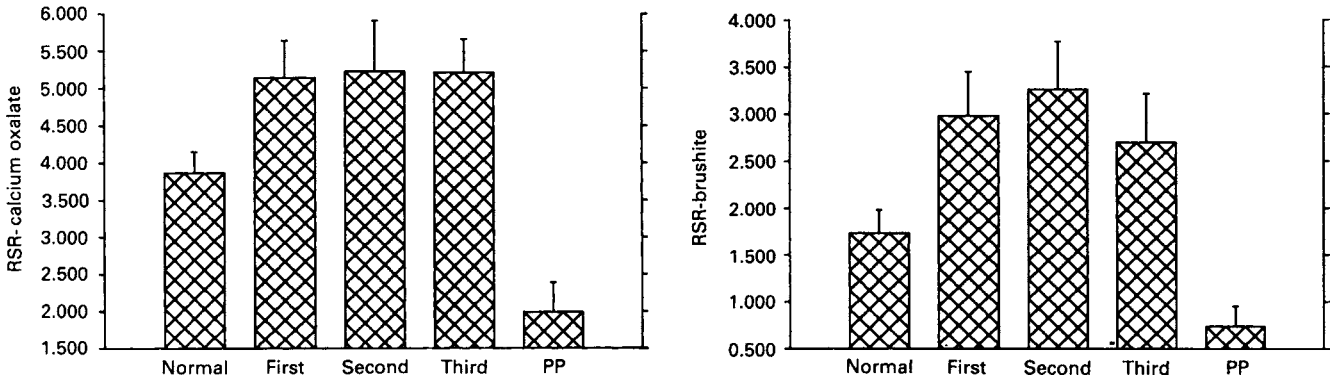

FIGURE 81.16 During pregnancy the relative supersaturation ratios for calcium oxalate (A) and brushite (B) exceed those measured postpartum (PP), as well as values in a population of healthy women (normal) ($p < 0.01$; for both comparisons). *[From Ref.,[376] with permission]*

pregnancy. The answer may be that there is an even greater increment in the urinary excretion of several potent glycoproteins that inhibit stone formation such as nephrocalcin (which inhibits crystal aggregation and growth) and Tamm–Horsfall protein (which decreases aggregation), as well as smaller increases in urinary citrate and magnesium.[373,375,376] In this respect, there is evidence that increments in urinary inhibitors of pathological crystalluria are present as early as the eighth gestational week.[375]

The disease in pregnant women resembles that in nonpregnant patients, ~89% presenting with flank pain, and a similar percentage display either microscopic or macroscopic hematuria.[377] The majority of stones passed during pregnancy contain calcium salts, but some are infective in origin ("struvite").[373] The older literature stressed the dramatic complications associated with obstruction and/or infection, but subsequent studies suggested that gestation has little influence on the course of urolithiasis, with the exception of possible increments in urinary tract infection, and that rates of spontaneous abortion and premature labor may be increased.[373]

The above synopsis relates primarily to women with noninfectious calcium oxalate stones, whose renal function is usually preserved and whose course is relatively benign in the pregnant state. Little is known of the natural history of the more serious "struvite" stones during pregnancy. Similarly, experience with cystinuria is quite limited. One should strive to ensure adequate hydration, especially in early pregnancy when gravidas are frequently nauseous, and to consider withholding *d*-penicillamine during the first 12 gestational weeks.[378]

When nephrolithiasis is suspected, an ultrasound examination of the urinary tract is in order, but when complications suggest the need for surgical intervention, pregnancy should not be a deterrent to the performance of pyelography ([242,373,379] Operative procedures such as open lithotomy and percutaneous nephrostomy, both rigid and flexible ureteroscopy (direct vision) have all been performed during pregnancy, but more currently, placement of a ureteral stent has made it possible to manage gravidas through term with a less invasive technique.[21,291,373,380] Experience with lithotripsy is anecdotal and this procedure should probably be avoided in pregnant women.[381]

Management of Chronic Renal Disease in Pregnancy

Management guidelines similar in most aspects to nonpregnant patients is beyond the scope of this text devoted to physiology and pathophysiology. The reader is referred to reviews elsewhere, especially concerning hemodialysis in pregnancy [382,383 310], Of interest, the kidney, being the source of erythropoietin, makes its replacement necessary, often at creatinine levels when such therapy would not be necessary in the nonpregnant state. The initiation of renal replacement therapy at higher levels of dysfunction that such treatments would be started in nongravid women is also is advocated by some to facilitate better control of volume and electrolytes, and perhaps fetal development. The placenta hydroxylates Vitamin D, while dialysis depletes phosphorous, and one must watch for hypercalcemia, and the fact that pregnancy is a hypercoagulable state may make anticoagulation more difficult. Antihypertensive therapy is discussed below.

Transplantation

The first successful pregnancy in a renal allograft recipient appears to have been reported in 1963,[384] with thousands of such successes noted since. It is estimated that one in every 50 women of childbearing age who have functioning kidney transplants conceive.[322] Often the women were unaware that transplantation had reversed the relative infertility associated with end-stage renal disease[385] and had not been practicing contraception, indicating a failure of physicians to counsel these patients appropriately.

In an extensive literature review published in 1994, Davison (Ref.[386] contains 98 citations) documented 3382 gestations in 2049 gravidas with transplanted kidneys (many more were probably unreported). Most of these patients had received azathioprine and prednisone, experience with cyclosporine, tacrolimus, and mycophenolate being quite limited[309,310,387] (though currently data on women receiving newer immunosuppressants is increasing thanks to effective registries[386,387,388–391,392]). Approximately 35% of these gestations did not proceed beyond the first trimester (but the spontaneous abortion rate of 15% was similar to that in normal pregnant populations). However, of the pregnancies that continued beyond the initial trimester 93% succeeded, both the renal prognosis and the gestational outcome paralleling those with preexisting kidney disease (discussed above). Here, too, the better the renal function prior to conception, the more favorable the outcome. Not surprisingly, the prognosis was better when the allograft came from a living donor.

The success rate may be high but there are many maternal and fetal problems to be dealt with. The incidence of ectopic gestations (which reaches ~0.4%) and hypertension (~30%) are increased, and steroid-induced hyperglycemia, leukopenia, septicemia, uterine rupture, allograft rejection, liver function abnormalities, and maternal death have all been described.[309,322] Women transplanted after renal failure

due to diabetic nephropathy harbor considerable vascular disease and are at particular risk although those with combined renal pancreas-transplant may fare better.[309,322,393,394] Problems for the fetus and neonate include increased incidence of congenital anomalies, premature births, and growth restriction. Serious infections, thrombocytopenia, hypoadrenalism, and hepatic insufficiency affecting the neonate have also been reported.[322]

Most renal allografts recipients experience increments in renal hemodynamics during pregnancy, though smaller than those observed in normal gestation.[134,322] (This occurs despite the presence of but a single functioning kidney, which invariably has undergone some degree of chronic rejection.) Renal volume also increases.[395] On the other hand, functional declines are reported in ~15% of the pregnancies.[322] They occur mainly in late gestation and are transient in nature (rarely due to obstruction).[322,396] The loss, however, may persist, especially when prepregnancy GFR is already compromised.[397] Urinary protein excretion also rises, often to abnormal levels, but in most instances the increase is functional in nature and not related to the health of the allograft.

There is controversy about the effect of pregnancy on long-term allograft survival. In 1993 Salmela et al.[398] suggested that pregnancy might jeopardize the long-term health of the renal allograft. Their small but well designed case–control study showed that women who conceived, even well-preserved renal function, had a lower 10-year graft survival rate (69 versus 100%, $p < 0.005$). This report sent "shock waves" throughout the transplant community, but such alarm proved premature.[399] First, the difference appears due be due mainly to the highly unusual outcome in their control group, who in these same 10 years had no graft failures. In fact the 10-year graft survival statistics of most centers covering all transplant recipients resemble (or may even be poorer than) those of the group of women with allografts who subsequently underwent pregnancy studied by Salmela et al.[398] In addition, their report is at odds with a body of evidence reported both prior to and after their article, which seems to establish that pregnancy has little or no effects on long-term renal allograft survival.[399–405]

Preconception counseling, management of the gestations, and the status of the various immunosuppressive regimens are beyond the scope of this chapter and are discussed in detail elsewhere.[309,387,400] Most recently the American transplantation Association convened a consensus group and issued a report[392] As noted, the natural history of pregnancy in allograft recipients whose immunosuppressive regimens include cyclosporine and even newer drugs is just emerging, the early data seem to support the optimistic conclusions Davison arrived at in his extensive review of the precyclosporine era discussed above[309,387]

Concluding Perspectives

The text devoted to chronic renal disorders stressed that gestation seems well tolerated in of most renal diseases or in allograft recipients[401–405] provided that kidney function was preserved, and hypertension absent or well controlled. Nevertheless, urinary tract infections and preeclampsia seem to occur more often in such patients. In addition gestation did not seem to affect the natural history of their underlying kidney disorder, with certain exceptions. On the other hand, women with greater degrees of renal dysfunction prior to conception have a poorer renal and fetal prognosis. All gravidas with renal disease require close prenatal surveillance, including monitoring of blood pressure and renal function (serum creatinine levels or its clearance). When function deteriorates at any stage of gestation, reversible causes (e.g., urinary tract infection, obstruction, and subtle dehydration) must be considered, but if hypertension accompanies the decrease in GFR, the outlook for the pregnancy is more guarded.

One issue omitted from the discussion of chronic renal disorders was the provocative hypothesis that the increase in glomerular filtration accompanying gestation could have adverse effects on the course of the kidney disease. There is concern, based on evidence derived from animal models, that the hyperfiltration in the residual (intact) nephrons of patients with renal disease (or those with a single kidney after uninephrectomy) is accompanied by increments in glomerular capillary pressure and/or increased mesangial processing of macromolecules that lead to focal glomerular sclerosis and progressive loss of renal function. Hyperfiltration occurs during normal gestation, in gravidas who have renal disease with minimal dysfunction, and in those with single kidneys after uninephrectomy but, fortunately, it does not seem to lead to glomerular injury.

Several long-term follow-up studies have failed to detect increased renal functional loss when women with chronic disorders who had been pregnant were compared to those not known to have conceived.[313,315,330] Davison[406] has performed periodic inulin and *p*-aminohippurate clearances over a span of 17 years in a limited group of parous and nonparous women with and without a variety of renal problems. A small decrease in renal hemodynamics, possibly attributable to pregnancy, occurred in women with a single kidney, and those with chronic renal disease. On the other hand, as noted above, several long-term follow-up studies of 29 women who donated kidneys for transplantation and subsequently

had 39 pregnancies, failed to detect changes in GFR, urinary sediment, or the appearance of hypertension in these donors.[407] Thus the increases in renal hemodynamics seem well tolerated and are not a reason to discourage conception. This opinion is strengthened by data from rat and rabbit animal models though rats with adriamycin nephropathy develop hypertension during gestation.[2,408–416] Finally, preliminary results from pregnant women with underlying kidney disorders, whose authors combine the sieving characteristics of infused dextran with mathematical modeling to assess determinants of ultrafiltration, also suggest that there are no increases in glomerular capillary pressure[31]

HYPERTENSION

The remainder of this chapter is devoted to the hypertensive disorders of pregnancy. Hypertension, the most common medical disorder complicating pregnancy (~5–10% of all gestations) can be a challenging medical problem.[417] Moreover, the hypertensive disorders of pregnancy, primarily the pregnancy-specific disease preeclampsia, remain major causes of morbidity and mortality for mother, fetus, and newborn especially in developing countries. The sections that follow will briefly review the striking alterations of systemic hemodynamics in normal pregnancy, followed by an overview of the classification and diagnosis of the hypertensive disorders of pregnancy with the main focus on preeclampsia, because this disease remains the most potentially ominous of the more common hypertensive disorders encountered during pregnancy. Due to space considerations as well as to the focus of this text (the physiology and pathophysiology of the kidney), we will discuss in more detail the renal alterations associated with high blood pressure in pregnancy, while summarizing the disease effects on other organ systems and management considerations. Readers seeking more details on these topics are referred to the second edition of Chesley's Hypertensive Disorders in Pregnancy,[32] a comprehensive multiauthored text, published in 2009.

CARDIOVASCULAR CHANGES IN NORMAL PREGNANCY

Arterial pressure decreases during normal human pregnancy, the decrements beginning during the luteal phase of the menstrual cycle, continuing after conception, and by midgestation, diastolic levels are ~10 mm Hg below nonpregnant levels. Thereafter, most reports show arterial pressure increasing, gradually approaching nonpregnant levels near term,[27,418–421] and a small increase may occur in the immediate postpartum period.[422] Cardiac output also increases during the luteal phase of the menstrual period, rising further after conception, and peaking some 30–50% above midfollicular values by the end of the first or beginning of the second trimester.[26,27,47,231,423–426] In fact, this early, marked rise in cardiac output is anticipatory in nature, because blood flow and oxygen delivery exceed demands as reflected by the narrowing of the difference in oxygen content between arterial and mixed-venous blood in humans and conscious rats [[427] and citations therein]. Despite some discordance in the older literature, load-independent left ventricular contractility appears to be unaltered during pregnancy.[428–430] A marked decline in systemic vascular resistance initiates the increase in cardiac output and fall in arterial pressure. In essence, normal pregnancy is a profoundly vasodilated state.

Accompanying the early fall in systemic vascular resistance is a rise in arterial compliance.[425,431] The temporal coordination of these two events ensures the maintenance of cardiovascular homeostasis during pregnancy by (i) minimizing the decline in diastolic pressure, (ii) minimizing energy expended by the heart on pulsatile oscillatory work, (iii) preserving steady shear-type (or minimizing oscillatory shear-type) stress at the blood–endothelial interface, and (iv) accommodating increased vascular volume.[425,432] Theoretically, failure or reversal of these compliance changes during pregnancy in the face of the marked massive increase in stroke volume could cause endothelial dysfunction, thereby affecting blood pressure regulation and producing hypertension.[426,433]

The systemic hemodynamic and arterial compliance changes during normal pregnancy in women are also observed in several animal models including sheep,[434,435] rabbits,[436] guinea pigs,[437,438] rats[427,439] and baboons.[46] Of note, long-term relaxin administration to chronically instrumented, conscious rats recapitulates the increase in cardiac output and arterial compliance and reduction in systemic vascular resistance observed during midterm pregnancy in this species.[77,432,440] Thus, in addition to mediating the renal circulatory changes of pregnancy in rats (see section Renal Hemodynamics), relaxin also contributes to the boarder cardiovascular changes in systemic hemodynamic and arterial properties during pregnancy in this species. Whether the hormone plays a similar role in gravid women is presently unknown.

The hormone(s) and distal vasodilatory effector pathway(s) responsible for maternal vasodilation during pregnancy remain uncertain and may vary according to animal species (and possibly by organ circulation and vessel size). Investigators have

emphasized the endothelium in the vascular changes of pregnancy (see section Renal Hemodynamics). Of interest, is that immunoneutralization of relaxin prevented the systemic hemodynamic and global arterial compliance changes during midgestation in conscious rats.[441] Another candidate, calcitonin gene-related peptide (CGRP) hormone, rises in the blood during pregnancy in women.[442] CGRP is a potent vasodilator, and it may contribute to the systemic (and renal) vasodilator responses to pregnancy.[443] Recent evidence also shows increased endothelial angiotensin (AT)-2 receptor expression and AT-2-mediated relaxation of aorta during late pregnancy in rats.[444] Consistent with a potential role of the AT-2 receptor, the midterm decline in systolic blood pressure in midterm pregnant mice was prevented by administration of an AT-2 receptor antagonist.[445] The endothelium produces pressor and vasodilator hormones and autocoids such as PGs, NO and hyperpolarizing factors. Despite initial enthusiasm, the evidence that has emerged is not supportive of a major role for vasodilatory PGs in either women[93,94] or gravid animal models.[88–92,95] However, there is evidence to support a role for NO[102] and hyperpolarizing factors.[102,446,447] An overall refractoriness to the major vasopressors, alpha-adrenergic and vasopressinergic agonists and angiotensin II, has been a consistent finding during pregnancy in women and gravid animal models [reviewed in[22,89,102,241]]. Whether this refractoriness is inherent to the vascular smooth muscle and/or mediated by endothelial vasodilatory factors has not been clearly defined. Interestingly, relaxin administration to conscious, nonpregnant rats mimics pregnancy in this regard, insofar as the renal and systemic vasoconstrictor responses to angiotensin II are attenuated.[77,81,89,103]

Despite the profound decrease in systemic vascular resistance, only a modest decline in arterial pressure is observed during normal pregnancy in both humans and gravid animal models.[27,418,419,421,448] The decline in systemic vascular resistance is mostly offset by a comparable rise in cardiac output, thereby maintaining arterial pressure. (This viewpoint assumes that early pregnancy is a condition of arterial "underfill" or "normal-fill" initiated by primary vasodilation of nonreproductive organs—see section Significance of the Volume Changes During Pregnancy.) At least 4 mechanisms contribute to this reciprocal rise in cardiac output: (i) increased heart rate, (ii) elevated stroke volume, (iii) reduction in ventricular afterload by virtue of the profound decline in systemic vascular resistance and increase in arterial compliance, and (iv) augmentation of active venous tone and/or reduction of passive venous compliance[431] that maintains or even increases left ventricular end diastolic volume or preload[47,233,423,424] despite the marked decline in systemic vascular resistance. As mentioned above, the increase in arterial compliance also buffers the decline in diastolic blood pressure, and this overall cardiovascular picture is recapitulated by administration of relaxin to nonpregnant female (and to male) rats[77,432,440] [and most likely humans, reviewed in[449]].

As pregnancy progresses beyond the first trimester and the expansion of blood volume accelerates, then increases in venous volume are likely to play a larger role in maintaining or increasing the ventricular end diastolic volume, possibly allowing for restoration of the active venous tone and/or reduced passive venous compliance towards nonpregnant values or even for a complete reversal, i.e., reduced active venous tone and/or increased passive venous compliance, in order to accommodate the massive increase in vascular volume at this time. Regrettably, very few studies have focused on the changes in venous function and associated mechanisms, thereby limiting our understanding of the cardiovascular system during normal pregnancy.[450] Finally, ventricular remodeling, so-called "eccentric hypertrophy" also occurs with advancing gestation, thereby contributing to the maintenance of end diastolic volume without increasing end diastolic pressure, and hence cardiac work.[104]

Clinical Significance of the Physiological Decrease in Arterial Pressure During Pregnancy

The physiological decrease in arterial pressure in human pregnancy has clinical implications. The definition of hypertension during gestation has remained 140/90 mm Hg in both contemporary texts and working group recommendations[451,452] but one should consider suspect diastolic levels of 75 mm Hg in the second, and 85 mm Hg in the third trimester, and/or systolic values of 120 mm Hg in mid- and 130 mm Hg in late pregnancy.[419,453,454] In this regard, data from two large epidemiologic studies (comprising >30,000 pregnancies) reveal that diastolic pressures of $\geq$85 mm Hg at any stage of gestation are associated with significant increases of fetal mortality,[453] and there are significant increments in both perinatal mortality and growth restriction when mean arterial pressure exceeds 90 and 95 mm Hg during the second and third trimesters, respectively.[419]

Diagnosis and Classification

Measurement of Blood Pressure

The have been controversies on how measure blood pressure during gestation. These include the positioning of the patient during the measurement (lateral recumbency versus sitting), and which sound should constitute diastolic levels (Korotkoff IV [K_4], muffling,

or V [K_5], disappearance. It is now apparent that the lower levels recorded when the subject lies on her side is merely the difference in hydrostatic pressure when the cuff is positioned substantially above the left ventricle. In addition, an older view that because of their hyperdynamic circulations gravidas often manifest large differences between K_4 and K_5, the latter approaching zero, has been disproved, and K_5 has been established is the sound closest to true diastolic pressure.[455–458] Regarding the definition of hypertension, whether in absolute numbers, (usually 140/90 mm Hg (K_5)), or as increases in pressure (15 mm Hg diastolic and 30 mm Hg systolic, respectively, even when the final value is below 140/90 mm Hg), both had their advocates and through the late 1990s. However, epidemiological data establishing that outcomes are similar no matter what the magnitude of the rise, provided values remain below 140/90 mm Hg, have led to consensus groups to define only $\geq$140/90 mm Hg as the definition of hypertension in pregnancy.[452,459] Nevertheless the National High Blood Pressure Education Program (NHBPEP), stresses that patients with blood pressures below this cutoff who have experienced a 15 and/or 30 mm Hg in diastolic and systolic levels, respectively, be managed as high-risk patients. Of further note these disputes regarding the definition of hypertension are one reason for a host of discordant finding in such areas as epidemiology and outcome research, now hopefully resolved.[460]

Classification

A review of the literature reveals an assortment of terms and schemes, some quite complex and detailed, used to describe the hypertensive disorders of pregnancy. Toxemia, estosis, pregnancy-induced hypertension (PIH), pregnancy-associated hypertension, and preeclamptic toxemia are all utilized to classify the disorder we label as preeclampsia. The reader may be even more confused when the same term (e.g., PIH) is used to include different disorders by various authors. The terminology used in this chapter is that recommended by the Working Group[461] of NHBPEP, modified from that originally proposed by the American College of Obstetricians and Gynecologists' Committee on Terminology in 1972, which is concise and practical. In it, blood pressure in pregnancy is considered in only four categories:

1. Preeclampsia–eclampsia
2. Chronic hypertension of any cause
3. Preeclampsia superimposed on chronic hypertension
4. Gestational hypertension

Preeclampsia (pure or superimposed, categories 1 and 3) poses the greatest threat to fetal survival and is the disorder most often associated with severe maternal complications (including fatalities). The majority of women in the second category have essential hypertension, usually mild in intensity, and their pregnancies usually remain uncomplicated and end successfully. On occasion, however, the high blood pressure is due to specific causes including endocrine tumors, renal artery stenosis, and renal disease,[1,9,48,150,152,462] and some of these women with secondary forms of hypertension do poorly during gestation. Thus, pheochromocytoma, though rare, may present for the first time during gestation and is especially lethal when unsuspected, whereas when diagnosed it can be managed to a successful outcomes, either surgically or pharmacologically (with alpha blockade) depending on the stage of pregnancy.[48,462] Cushing's syndrome, also quite rare, has been associated with exacerbations of the hypertension during pregnancy and poor fetal outcomes,[48,463] and the serious maternal risks associated with scleroderma and periarteritis nodosa were stressed in a previous section. However, not all forms of secondary hypertension have a poor prognosis during gestation. For example, pregnancy may ameliorate the kaliuresis associated with primary aldosteronism[152] (also see Figure 81.7). Finally, both angioplasty and stent placement has been successfully performed on pregnant women with renal artery stenosis.[48]

Gestational hypertension (category 4) is characterized by mild, to moderate, elevation of blood pressure after midgestation, usually near term (though rarely the levels may be higher. The cause of this entity is unclear, but there is evidence that transient hypertension of pregnancy occurs in women destined to have essential hypertension later in life (analogous to women with gestational hyperglycemia who eventually develop type II diabetes).[325] Blood pressure returns to normal during the immediate puerperium,(at which point some relabel the entity "transient hypertension") but these women often have hypertension in subsequent pregnancies. There is an entity entitled late postpartum hypertension, in which women with normotensive gestations develop high blood pressure (usually mild) during a period that ranges from two weeks to six months after delivery.[464,465] Blood pressure remains labile for months but returns to normal values by the end of the first postpartum year. Little is known of this entity, which like transient hypertension of pregnancy, may be a predictor of essential hypertension later in life. Finally, a rare group of patients with activating mineralocorticoid receptor mutations that result in an exaggerated sensitivity to the usually weak mineralocorticoid effect of progesterone have been described.[157] They manifest salt sensitive

hypertension, accompanied by hypokalemia, but virtually undetectable aldosterone levels, most marked during pregnancy as progesterone levels rise.

Preeclampsia–Eclampsia

Epidemiology

Studies designed to determine the incidence of the hypertensive complications of pregnancy, particularly preeclampsia, have several problems. As noted, the presence of diverse classification schemes can be confusing. Equally important, it is very difficult to distinguish clinically between preeclampsia, essential or secondary hypertension, renal disease, and combinations of these separate entities. First, presence of normal blood pressure early in gestation does not necessarily differentiate preeclampsia from other forms of hypertension, as many women with essential hypertension experience decrements in blood pressure to normal values during the first half of pregnancy. Also diseases such as lupus nephropathy, and more rarely pheochromocytoma, as well as an accelerated phase of essential hypertension (actually unusual in pregnancy) may all mimic preeclampsia. These problems are well illustrated by reports in which the etiology of hypertension complicating gestation was established by renal biopsy [nine series cited in Ref.[325]]. In our own study[325] 176 women were biopsied, usually for suspected preeclampsia (Table 81.4). This diagnosis was correct in only 85% of the primiparas and was wrong in most of the multiparas (underscoring the need for caution in interpreting reports in which patients diagnosed as preeclamptic and/or "toxemic" are multiparous).

TABLE 81.4 Renal Pathology in 176 Hypertensive Patients[a]

Diagnosis	No. of Patients	Primigravidas	Multiparas
Preeclampsia[b]	96	79	17
With nephrosclerosis	13	6	7
With renal disease	3	1	2
With both	2	1	1
Nephrosclerosis	19	3	16
With renal disease	4	2	2
Renal disease	31	12	19
Normal histology	8	0	8

[a]*Biopsy material (obtained between 1958 and 1976) was considered adequate if it contained eight glomeruli for light microscopic analysis and three for electron microscopic analysis.*

[b]*Only glomerular endotheliosis on biopsy.*

Several other problems, ranging from selected populations to discrepancies between the data and discharge diagnoses are discussed in detail by Ness and Roberts.[466] Thus, the epidemiological literature must be approached with the above reservations in mind, and careful attention should be paid to the different definitions of normalcy, methods used to measure blood pressure, and the quality of the data analyzed.

In view the above limitations it is not surprising that the incidence of preeclampsia in the literature range from 5% to 30%.[9,150,418,419,421,461,467] Of interest, however are data from a number of carefully conducted prospective trials which have mainly focused on normotensive nulliparas (a population where the incidence of preeclampsia is three to five fold higher than in multiparas[150,468,469] reveal the following. Preeclampsia was consistently diagnosed in 4–7% of the "placebo controls," and about twice as many women developed gestational hypertension (ranging from 6–17%).[454,470–472]

There are specific populations at "high risk" to develop pure or superimposed preeclampsia. These include women with diabetes, multifetal gestation, preexisting chronic hypertension or renal disease, and those with a history of preeclampsia in a previous gestation (especially prior to gestational week 36), whose incidence averages 20%.[319] Women with trisomy 13 fetuses also have more preeclampsia, the potential cause of which is discussed below. Presence of nonimmune hydrops fetalis and alpha thalassemia are also associated with more preeclampsia, often before midpregnancy.[9,150]

Finally, the rate of eclampsia has fallen almost 30-fold from the incidence published in the first half of the twentieth century, and is now less the 1 per 1000 births. This no doubt reflects improvement in prenatal care whereby practitioners detect and terminate the pregnancies at-risk in timely fashion, a policy reflected, in part, by an almost two-fold increase in the diagnosis of "severe" preeclampsia during the same period.[150,466]

Clinical Spectrum

Recognition and differentiation of preeclampsia (both "pure"' or superimposed) from other causes of high blood pressure in pregnancy has implications regarding the management of hypertensive gravidas, as this is the disorder most likely to cause serious maternal and fetal complications. However, a precise diagnosis may not always be possible, in which case therapy should be directed toward a presumptive diagnosis of the more serious disorder preeclampsia.

Preeclampsia, characterized by hypertension, proteinuria, edema, and at times coagulation and/or liver function abnormalities, or both, occurs mainly in

nulliparas, usually after the 20th gestational week, and most frequently near term.[9,150,473] The earlier the onset, the less likely it is to be "pure" preeclampsia, and the higher the probability that one is dealing with disease superimposed on underlying essential hypertension or a renal disorder.

Attempts have been made to categorize preeclampsia as "mild" or "severe." The latter is usually defined on the basis of diastolic and systolic levels (≥110 and 160 mm Hg, respectively), the appearance of nephrotic proteinuria, sudden oliguria, or neurologic symptoms (e.g., headache or hyperreflexia), as well as by laboratory tests demonstrating thrombocytopenia and/or abnormal liver function. Since a woman with seemingly mild disease (for instance a teenage gravida with a blood pressure of 140/90 mm Hg and minimal proteinuria) can suddenly convulse, designations such as mild and severe could be misleading. In fact, *de novo* hypertension alone in a third trimester nullipara is sufficient reason to manage such patients as if they were preeclamptics. Of final note, early preeclampsia (onset <34 weeks) is associated with greater morbidity than term preeclampsia.[474] In this respect some suggest subdividing preeclampsia into two groups, in regard to clinical management.[475] This may be misleading, however, as all preeclampsia is potentially explosive.

The eclamptic convulsion, the most dramatic and life-threatening complication of preeclampsia, was once associated with a maternal mortality of 30%, with cerebral hemorrhage as the leading cause of death,[9,150] but improved and aggressive obstetrical management have decreased the occurrence of convulsions and made maternal deaths extremely unusual. Eclampsia is usually preceded by various premonitory signs including headache, visual disturbances, severe epigastric pain, a sensation of constriction of the thorax, apprehension, excitability, hyperreflexia, and hemoconcentration. However, the convulsion can occur suddenly and without warning in a seemingly stable patient with only minimal elevations of blood pressure. It is the capricious nature of this disorder that underlies the need for early hospitalization of women with suspected preeclampsia.

There is a deceptively benign variant of preeclampsia whose initially mild clinical presentation may be misleading. The patient presents with borderline thrombocytopenia, and slightly abnormal liver function tests, normal or minimally elevated blood pressure, and little or no renal dysfunction. However, this form of preeclampsia may rapidly become life threatening when within 24–48 h there is progression to a syndrome characterized by hemolysis with marked evidence of both liver and coagulation abnormalities (transaminases and lactic dehydrogenase increasing to >1,000 IU/dL, platelet counts decreasing to <40,000/mL, with the presence of schistocytes on the blood smear. This complication, termed the HELLP syndrome, constitutes an emergency requiring termination of the pregnancy.[297] Furthermore, although postpartum recovery is usually rapid, the disease could persist for almost a week and some of these patients have undergone plasma exchange.

Finally, there is an uncommon disorder labeled late postpartum eclampsia (hypertension and convulsions that occur 48 h to several weeks after delivery).[476–478] Some of the patients have typical manifestations of preeclampsia and/or eclampsia prodroma, but prophylactic therapy had not been started because of lack of postpartum education, or their presentation at emergency rooms where caregivers are unfamiliar with gestation-related problems.[478] A similar syndrome has been reported in patients administered bromoergocryptine, a drug once utilized to suppress lactation,[479–481] but the evidence for this association was never compelling.

Pathogenic Mechanisms

The etiology of preeclampsia remains unknown, and some[468] suggest the disease has heterogeneous causes. There is evidence of a familial factor, with suggestions that preeclampsia may be inherited as a recessive condition (perhaps with maternal–fetal genotype interactions), or as a dominant one with 50% penetrance.[150,482] There are also ongoing investigations on the roles of angiotensinogen gene polymorphism[483,484] and the gene for 5,10 methylene tetrahydro reductase, an association also linked to hyperhomocysteinemia.[485,486] Detailed discussions of the genetics of preeclampsia can be found in reference.[487] More recently, a small Dutch genetic study suggested that polymorphism in the STOX1 (a member of the winged helix gene family), a paternally imprinted gene has been linked to preeclampsia within a small Dutch cohort.[488]

Considerable research is currently focused on the role of the placenta in the pathogenesis of preeclampsia. This includes determining the mechanisms of pathological changes that occur during the development of the blood supply to the placenta (see below), said to result in a relative hypoxemic environment and to lead to the production of cytokines that enter the maternal circulation and injure the vascular endothelium.[489] Other research focuses on the immune response at the maternal–fetal interface. For instance, placental tissue from preeclamptic pregnancies may express less HLA-G (a nonclassical HLA antigen expressed in normal placental tissues, which may modulate the maternal response to the immunologically "foreign" placenta).[490] Other evidence of pathogenic immune mechanisms include the disease's propensity for nulliparous pregnancies followed by normotensive

subsequent gestations (except if conception is with a new partner), a decreased prevalence in women who have received blood transfusions, required long periods of cohabitation before conceiving, and frequent oral sex, as well description of changes in the placental vasculature that resemble those in the blood vessels in allograft rejection.[491,492] Finally, investigators seeking insight into the cause of preeclampsia have studied a host of factors of placental origin(with a recent emphasis on angiogenic factors, see below).[493]

Pathophysiology of Preeclampsia

Preeclampsia is more than hypertension; it is a systemic disorder with both maternal and fetal manifestations. The disease in the mother includes vasospasm, alterations in many hormonal and autocoid systems which regulate blood pressure and volume control, and coagulation changes. Its physiopathology may also include the failure of mechanisms that deal with oxidative stress, the presence of a proinflammatory state, and an imbalance between pro- and antiangiogenic events. What is important to note is that many of the "nonhypertensive" manifestations of preeclampsia can be life threatening even when hypertension is quite mild.

Blood Pressure

Hypertension in preeclampsia, characteristically labile, represents a reversal the vasodilation of normal pregnancy and is due to increases in peripheral vascular resistance. These are so striking, that blood pressure rises even though cardiac output often falls. There is also a reversal of the resistance of the vasculature to pressor substances characteristic of normal pregnancy (discussed above), the vessels of preeclamptic women being actually hyperresponsive to a variety of pressor peptides and amines, especially to angiotensin II.[156,204] Loss of pressor resistance to the latter may be documented months before the appearance of overt disease.[494]

The cause of the altered vascular reactivity in preeclampsia has been sought for decades but remains obscure. Research has focused on changes in the ratio of vasodilating and vasoconstricting prostanoids (or frank increments in the latter),[495,496] and on the vasoconstricting potential of circulating pressor hormones (angiotensin II and ET), brought about by a number of possible scenarios. These include upregulation of receptors,[156,204,497] loss of resistance by a vasculature damaged by cytokines[489,498] or lipid peroxidases,[489,499] or inhibition of adaptive increments in the production of NO synthase as well as the NO-dependent and independent endothelium-derived relaxing factor.[500,501] Still other investigators focus on gestational alterations in calciotropic hormones, insulin metabolism, and the body stores of calcium and magnesium.[156,502] Most recently agonistic autoantibodies to the angiotensin I receptor have been detected in the blood of preeclamptic (see below) As of 2005, all the above postulates were still unproven.

The Heart

Data describing cardiac performance in preeclampsia is conflicting. This is due to several reasons. First, the investigators often failed to define precisely the study populations and included multiparous women, as well as patients with chronic hypertension and renal disease, all labeled preeclamptics. Many reports describe term and/or intrapartum protocols and the subject studied had often received magnesium sulfate and/or a variety of antihypertensive medications, as well as intravenous solutions of variable solute content. Also, the same data (especially the echocardiographic studies) may be interpreted differently by various groups. Finally, all findings may be correct, reflecting only that the hemodynamic parameters of preeclampsia change as the disease progresses.

Cardiac Performance: Pulmonary edema is a complication of severe preeclampsia, yet the literature is unclear as to whether the disease directly affects the heart or not (reviewed in[429]). In one study[429] focusing on proteinuric nulliparas and appropriately selected pregnant postpartum controls (both groups were restudied one month postpartum), load-independent left ventricular contractility was normal in all groups. Of importance was that if traditional approaches (rather than the load-independent indices) were utilized, some would have interpreted the echocardiographic findings as showing decreased contractility.

A survey of studies designed to determine systemic hemodynamic changes in preeclampsia reveals results that range from high output−low resistance to a low output−high resistance state.[22] This wide and inconsistent spectrum relates both to the problems cited above, and in some instances reflect experimental artifact. We will focus on selected reports where data permits us to focus on nulliparous preeclamptics.

Easterling et al.,[503] in a serial study, using noninvasive echocardiographic techniques, observed an exaggeration of the normally increased cardiac output throughout gestation, as well as greater decreases in peripheral vascular resistance in women who became preeclamptic. The exaggerated Increase in cardiac output, but not the excessive decrement in peripheral vascular resistance, has recently been confirmed in an even larger serial study by Boslo and colleagues.[504] In an a group of term nulliparous preeclamptics (said to have received minimal fluid) Mabie et al.[505] found cardiac output to be normal or slightly increased, while pulmonary capillary wedge pressure (PCWP) was

usually normal. Perhaps the most carefully controlled studies were those by Visser and Wallenburg,[506] in which proteinuric hypertensive women and a small group of normotensive pregnant controls were studied prior to any therapeutic interventions. Using Swan-Ganz pulmonary artery thermodilution techniques they convincingly demonstrated low cardiac output and markedly increased peripheral resistance and low normal PCWP in untreated preeclamptics. They further showed that the profile was variable when subjects had been treated, though on average their cardiac output was similar to that in normotensive gravidas, while peripheral vascular resistance was considerably improved (though still significantly elevated).

The observations described above have several interpretations. The first relates to the heterogeneity of the study designs and populations, with a call for further and more precise research. The second is the intriguing possibility that the older literature "missed" the natural history of cardiac performance in patients destined to develop preeclampsia; an early preclinical period characterized by an exaggeration of the normal increase in cardiac output in gestation as well as an exaggerated decrease in peripheral vascular resistance (the anticipated autoregulatory response). This is followed by a "crossover" to a decreased cardiac output-high peripheral resistance state when the disease manifests near term. If confirmed, though, this would be surprising, given that the increased pressor responsiveness of preeclampsia is detectable at midgestation.[494]

Finally, Hibbard et al. combining echography and modeling techniques studied both preeclamptics and chronic hypertensives with superimposed preeclampsia.[433] They confirmed the decrease in arterial compliance in preeclampsia, demonstrating that a component of the decrease was due to the disease, (in addition to the due to increased blood pressure). They further demonstrated that the first harmonic of the input impedance spectrum was higher, while the data suggested that characteristic impedance was also higher

Liver and Coagulation Abnormalities

Preeclampsia is associated with activation of the coagulation system, although abnormalities are undetectable clinically in most patients.[507] Thrombocytopenia, rarely severe, is the most common finding recorded, whereas increases in platelet activation and size, as well as decrements in their life span, and worsening of the hypercoagulability of normal pregnancy (e.g., reduced antithrombin III, protein S, and protein C) can be detected by special testing in many patients with normal thrombocyte counts.[507] Rarely, however, preeclamptic patients develop evidence of a severe life-threatening coagulopathy, as evidenced by the ominous HELLP syndrome discussed above. Finally, the causes of thrombocytopenia and the hypercoagulability of normal gestation are still unclear.[156,507]

Preeclampsia also affects the liver.[1,508,509] Manifestations of liver involvement include elevation of transaminase and lactic dehydrogenase levels, usually of a mild degree.[510] In fact, preeclampsia is probably the most common cause of mild liver functional abnormalities in pregnancy. However, as described above, the liver can also be the focus of the disease, severe liver failure and disseminated intravascular coagulation combining to threaten both maternal and fetal well-being.[297]

The gross and microscopic hepatic changes in preeclampsia are detailed in the extensive autopsy series of Sheehan and Lynch.[1] In that series the liver appeared normal 40% of the time, and there were occasional petechiae (on the surface or in sections) in another 20%. In the remaining 40%, however, there were confluent petechiae and obvious infarcts. Also described were subcapsular hematomas, some of which had ruptured and were the immediate cause of death. On the other hand, a more recent study in which the liver was assessed laparoscopically, hematomas were quite unusual.[104] Microscopically, there are two characteristic lesions. One is a periportal lesion, manifesting as hemorrhage into the hepatic cellular columns, and the second is the presence of infarction.[1] Also, of interest, also, are results from liver biopsies performed during laparoscopy showing intracellular fatty changes in all patients with preeclampsia, irrespective of the severity of the disease.[104] (Nevertheless, both autopsy and laparoscopy studies are by their nature quite selective). Finally, acute fatty liver of pregnancy, a disorder frequently associated with preeclampsia, was discussed in the ARF section above.

Central Nervous System

Eclampsia, the convulsive phase of preeclampsia, remains a leading cause of maternal death, the proximate causes including disseminated intravascular coagulation-like syndromes, pulmonary edema, aspiration and sepsis, and especially cerebral hemorrhage and edema.[1,150,466] Knowledge of its etiology, however, remains incomplete. Some, noting fibrin deposition in brain at autopsy, relate its cause to the coagulation changes associated with preeclampsia. To others[511] the disease is merely a form of hypertensive encephalopathy, a concept difficult to accept as the convulsion can occur suddenly in women whose systolic levels are consistently below 140 mm Hg. However, vasoconstriction in preeclamptic women can be selective. For example, investigators have demonstrated ultrasonographically the presence of severe cerebral vasospasm in patients with minimal evidence of

peripheral vasoconstriction.[512] They have also suggested that the cause of eclampsia may be heterogeneous, as some patients manifest normal cerebral vascular indices, while others (especially those with mean arterial pressures that exceed the brain's autoregulatory capacity) demonstrate high pressure indexes, and/or perfusion, akin to hypertensive encephalopathy.[513,514] On the other hand, phase contrast velocity imaging techniques combined with MRI consistently fail to demonstrate any changes in cerebral perfusion in severe preeclampsia or eclampsia.[515]

Reports based on cranial axial tomography and MRI (the latter, the preferred diagnostic test) vary but often describe transient abnormalities consistent with localized hemorrhage or edema.[515,516] The edema is said to be vasogenic, and fully reversible, though a recent study has noted "cytotoxic" edema and infarction in up to one forth of the patients.[517] These data, as well as those in the perfusion studies described above are not always easy to interpret; however, as many of the patients had been treated with antihypertensive drugs, magnesium infusions, and especially with considerable fluid administration, raising the possibility that many of these findings may be iatrogenic. Of interest is a disorder termed "reversible posterior leukoencephalopathy syndrome," observed in patients with a variety of medical disorders and in three women with postpartum eclampsia.[518] The disease is life threatening and characterized by accelerated hypertension, severe headaches, altered mental status, cortical blindness, and convulsions, but appears to be reversible with aggressive diuresis and rapid reduction of blood pressure. Review of this article suggests the eclamptic women had been grossly volume overloaded.

The best descriptions of gross and microscopic pathology are in autopsy series of Sheehan and Lynch,[1] as most of these necropsies were performed within two hours of death, thus eliminating most of the postpartum changes that might confound interpretation. Of interest, there was little evidence of brain edema, which led the authors to conclude that cerebral edema was a late, perhaps postseizure event, and not a cause of the convulsion. The major finding was gross evidence of cerebral hemorrhage, not surprisingly present in 60% of the subjects expiring within 48 h of the convulsion. There were also varying degrees of smaller hemorrhages and petechiae observed with the naked eye, and more numerous on histological sections. The petechiae were cited as evidence of vascular disturbances produced by local ischemia. Sheehan & Lynch[1] have produced a series of photomicrographs that we highly recommend to the reader).

The Placenta

Abnormal placentation is believed by many to be the major culprit in the pathophysiology of preeclampsia, if not its proximate cause. This is because uteroplacental ischemia has been used to develop several animal models believed to mimic the disease in humans,[519] and because delivery remains the most successful and probably the only definitive cure in preeclamptic women. Furthermore, the incidence of preeclampsia is increased in women with hydatiform disease (a rapidly growing placenta in the absence of a fetus), and in multifetal gestations (increased placental mass).[9,150] Finally, abnormalities in placentation, which occur between 10 and 20 weeks gestation, may represent the earliest evidence of pathology leading to the disease (reviewed in Ref.[520]), even though maternal signs of preeclampsia do not appear until the late third trimester.

Normal placentation involves the transformation of the spiral arteries from thick-walled, muscular arteries, into sac-like, flaccid uteroplacental vessels that permit delivery of greater volumes of blood at a lower blood pressure than before. This transformation is believed to be accomplished primarily by invasion of trophoblast cells which destroy and replace the endothelium of maternal vessels, and then invade their medial elastic and muscular layers, a process that ensures that the fetus is adequately supplied with oxygen and nutrients. However, in women destined to develop preeclampsia, invasion of the spiral arteries by endovascular trophoblast is incomplete, and it may occur in the decidual but not in the myometrial segments[521] (Figure 81.17). These changes may be focal or diffuse, the result being that many spiral arteries remain muscular, with thick-walled vessels, and blood flow to the placenta is compromised.

Reasons for the failure of spiral artery remodeling are obscure. Of interest are studies by Fisher and associates[520,522] which suggest that in preeclampsia the cytotrophoblast cells fail to mimic a vascular adhesion phenotype and to express adhesion molecules believed to be critical to the process of trophoblastic invasion.[520,522] Differentiation of trophoblasts along the invasive pathway involves alteration in expression of a number of different classes of molecules, including cytokines, adhesion molecules and extracellular matrix molecules, metalloproteinases and class Ib major histocompatibility complex molecule, HLA-G.[523–525] During normal differentiation, invasive trophoblasts alter their adhesion molecule expression from those that are characteristic of epithelial cells (integrin α_6/β_4, α_v/β_5 and E-cadherin) to those of endothelial cells (integrin α_1/β_1, α_v/β_3, PECAM, and VE-cadherin) a process referred to as "pseudovasculogenesis"[526] (Figure 81.17) Both

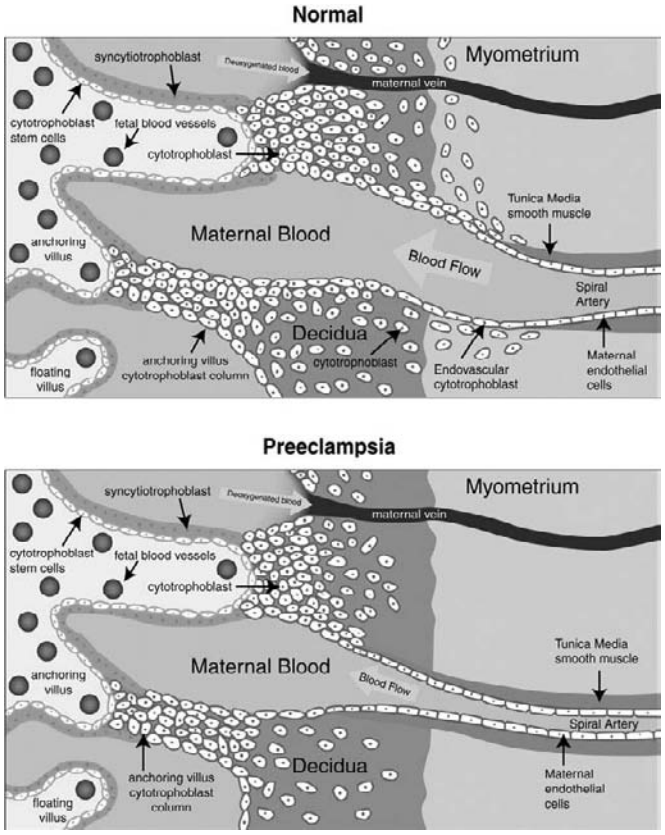

FIGURE 81.17 Cartoon depicting the changes in uteroplacental arteries that take place during normal and preeclamptic gestations. During the process of uterine vascular invasion, the cytotrophoblasts differentiate from an epithelial phenotype to an endothelial phenotype, a process referred to as "pseudovasculogenesis" (Upper Panel). In preeclampsia, cytotrophoblasts fail to adopt an invasive endothelial phenotype. Instead, invasion of the spiral arteries is shallow and they remain small caliber, resistance vessels (Lower Panel). *[Reproduced from Ref.[666] with permission]*

in vitro and *in vivo* studies show that trophoblasts obtained from patients with preeclampsia fail to undergo these alterations of adhesion molecules and pseudovasculogenesis.[522,527] The molecular pathways that regulate pseudovasculogenesis may involve a vast array of transcription factors, growth factors and cytokines.[528]

Another morphologic change in the placentas of preeclamptic women, though believed to be less specific, is an arteriolar lesion termed acute atherosis.[150,520] It is characterized by fibrinoid necrosis of the arterial wall, accumulation of fat-laden macrophages, and perivascular mononuclear cell infiltrates.

Finally, research efforts are in progress to link abnormal placentation early in preeclampsia with circulating markers to predict its occurrence and to explain why symptoms do not occur until late in gestation. The reader is referred to several reviews on the subject [489,520,529]), The reduced placental perfusion may also explain the increased incidence of fetal growth retardation associated with preeclampsia.

Circulating Factors and Endothelial Dysfunction

The increase in blood pressure in preeclampsia has been attributed to generalized endothelial dysfunction that disrupts the appropriate control of vascular tone,[530] Similarly, increased glomerular vascular permeability, and coagulopathy are ascribed to abnormal endothelial expression of procoagulants, while liver dysfunction to hepatic ischemia. In these respects there are considerable data to support the theory that the maternal response in preeclampsia is secondary to generalized endothelial dysfunction. These include studies demonstrating increases during preeclampsia in circulating fibronectin, Factor VIII antigen, and thrombomodulin, all markers of endothelial cell injury decreased production of endothelium-derived vasodilators (e.g., prostacyclins), increased production of vasoconstricting ETs, and enhanced vascular reactivity to angiotensin II.[494,531–535] Of note the characteristic renal lesion of the disease, described in Figure 81.19 is primarily limited to endothelial cells.[325] Finally, serum from preeclamptic women causes endothelial activation in human umbilical vein endothelial cell culture studies *in vitro*.[536]

Identification of circulating factors of placental and/or maternal origin that mediate endothelial dysfunction has been and continues as an area great research activity. There have been reports of alterations in levels of cytokines/growth factors/chemicals such as TNF-α, IL-6, IL-1α, IL-1β, Fas ligand, oxidized lipid products, neurokinin-B and asymmetric dimethylarginine.[537–540] However, there is no evidence that any of these molecules are etiologic. One interesting hypothesis for which some evidence exists, involves excessive exportation" of bits of trophoblastic material from the diseased placenta into the circulation causing the generalized microangiopathy.[541]

Increased sensitivity to angiotensin II, a consistent feature of preeclampsia, may be secondary to increased bradykinin (B2) receptor upregulation in preeclamptic patients.[317] In this respect there is *in vitro* data demonstrating that heterodimerization of B2 receptors with angiotensin II type I receptors (AT1), forms an AT1/B2 heterodimer that shows increased responsiveness to angiotensin. II. It is unclear however whether these alterations observed are of pathophysiological significance or just epiphenomena. Recent studies from the laboratory of a co-author of this chapter (S.A.K.)[542] and others[543,544] have demonstrated an increased placental expression and secretion of sFlt-1 (soluble fms-like tyrosine kinase 1, see below), a naturally occurring circulating VEGF antagonist in patients with preeclampsia. Importantly, when administered exogenously to

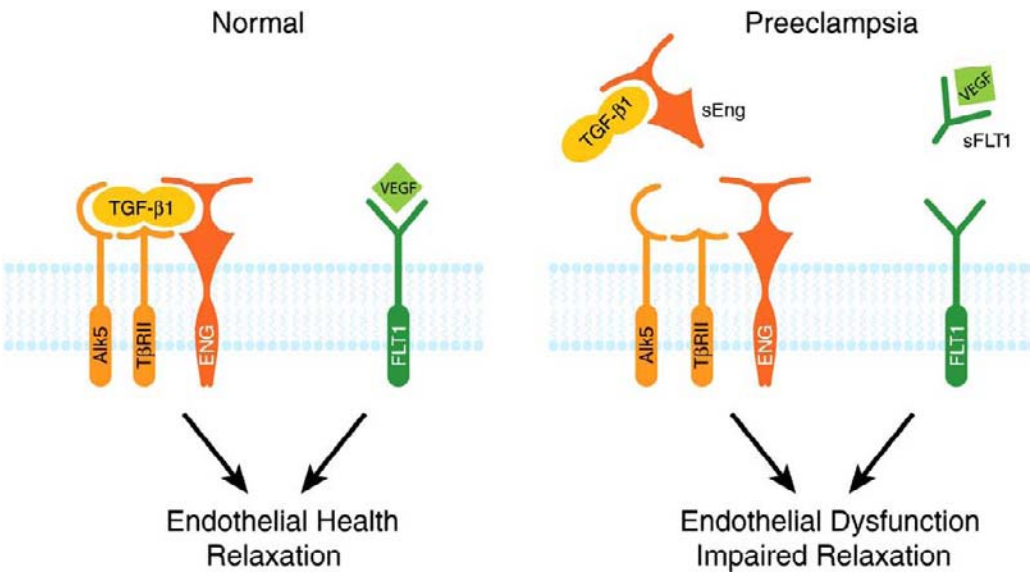

FIGURE 81.18 sFlt1 and sEng causes endothelial dysfunction by antagonizing VEGF and TGF-β1 signaling. There is mounting evidence that VEGF and TGF-β1 are required to maintain endothelial health in several tissues including the kidney and perhaps the placenta. During normal pregnancy, vascular homeostasis is maintained by physiological levels of VEGF and TGF-β1 signaling in the vasculature. In preeclampsia, excess placental secretion of sFlt1 and sEng (two endogenous circulating anti-angiogenic proteins) inhibits VEGF and TGF-β1 signaling respectively in the vasculature. This results in endothelial cell dysfunction, including decreased prostacyclin, NO production, and release of procoagulant proteins. *[Reproduced with permission from Refs[666,667]]*

Capillary lumina are encroached by swollen endothelial and mesangial cells (arrow). **B**: Electron micrograph in the area of a vacuolated tuft demonstrating obliteration of the capillary space. There are also clusters of lysosomal structures which contain myelin-like figures and collections of lipids, most marked in mesangial cells. *(Courtesy of Dr. B.H. Spargo)*

rats, sFlt-1 alone has been shown to be sufficient to induce a preeclampsia-like phenotype.[542] This work has generated considerable enthusiasm for sFlt1 as an important mediator in preeclampsia.

Alterations in Pro and Antiogenic Factors Normal Pregnancy and Preeclampsia

Perhaps the more plausible explanations of genesis of at least two phenotypes of preeclampsia, hypertension and proteinuria are events that lead to an imbalance of pro and anti-angiogenic factors in the circulation of pregnant women. sFlt1 is an anti-angiogenic molecule which antagonizes both VEGF and PlGF. VEGF is important in both angiogenesis (the growth of new blood vessels) and in the maintenance of endothelial cell health in the basal state. Although the function of PlGF is still ill-defined, it appears to act synergistically with VEGF, and may be necessary for wound healing and angiogenesis in ischemic tissues.[545,546] VEGF has a family of receptors, the most important of which are Flt1 (VEGFR1) and Flk1 (VEGFR2).[547] sFlt1 is a truncated form of the Flt1 receptor (see Figure A). It includes the extracellular ligand-binding domain, but not the transmembrane and intracellular domains; it is secreted (hence "soluble") and antagonizes VEGF and PlGF in the circulation by binding and preventing their interaction with their endothelial receptors[548] Although sFlt1 is made in small amounts by other tissues (endothelial cells and monocytes), the placenta seems to the major source of circulating sFlt1 during pregnancy as evidenced by the dramatic fall in circulating concentrations of sFlt1 after the delivery of the placenta.[542]

Circulating sFlt1 levels are increased, while free (unbound) PlGF and free VEGF levels are suppressed, in women with preeclampsia.[542] The increase in sFlt1 precedes the onset of clinical disease by at least five weeks[549–552] and appears to be more pronounced in severe and early-onset preeclampsia.[551,553] In several studies, decreased free PlGF levels were observed before 20 weeks gestation in women who developed preeclampsia later in pregnancy,[551,553–555] though not all investigators have confirmed this finding.[556] Although reduction in free PlGF may be predominantly explained by increased sFlt1 production, some data suggest the fall in PlGF may actually precede the rise in sFlt1, implicating other mechanisms such as decreased PlGF production.[557] Since free PlGF is readily filtered through an intact glomerulus, urinary PlGF is significantly decreased in preeclampsia and measurements of urinary PlGF can also be used for the prediction of preeclampsia.[558]

In vitro studies confirm that excess placental sFlt-1 production induces an anti-angiogenic state in the serum of preeclamptic women that can be rescued by exogenous VEGF and PlGF.[542] Excess sFlt-1 alone, when administered to pregnant rats, induced albuminuria, hypertension and renal pathological changes of glomerular endotheliosis by antagonizing circulating VEGF and PlGF and inducing endothelial dysfunction.[542] Furthermore, a significant percentage of cancer patients receiving VEGF signaling antagonists develop hypertension and proteinuria.[559,560] Even a 50% reduction of renal VEGF production in genetically modified mice resulted in glomerular endotheliosis and proteinuria.[561] These data suggest that excess circulating sFlt-1, by neutralizing VEGF and PlGF, may play a causal role in the pathogenesis of the maternal syndrome in preeclampsia (Figure 81.18).

The role of sFlt-1 in preeclampsia is supported by two clinical studies in a patient population considered high risk for the development of preeclampsia. The genes for sFlt1 and Flt-1 are carried on chromosome 13, and the incidence of preeclampsia in mothers who carry fetuses with trisomy 13 is in fact greatly increased, as compared with all other trisomies or with control pregnant patients.[562] In a more recent study where blood samples were obtained from women with trisomy 13 (in the majority the pregnancy was terminated or ended prior to the final trimester) the ratios of sFlt1/PlGF levels compared to other trisomies or control pregnant women measured during the second trimester were comparable to those observed in pregnant women who subsequently develop preeclampsia.[563] These data suggest a molecular explanation for the increased risk of preeclampsia observed in these patients. Finally, circulating concentrations of sFlt1 were recently reported to be higher in the first versus second pregnancies this accounting for the increased risk of preeclampsia among nulliparous women.[564]

The discussions in this section are detailed because as of 2011 the role of angiogenic factors has become the most exciting research area in the enigmas that historically surrounded understanding preeclampsia.[565] However, there are still unanswered questions to the sFlt-1 story. Although hypoxia of cytotrophoblasts has recently been shown to be a potent inducer of sFlt1 production,[566] the precise mechanisms of excess sFlt-1 production by the preeclamptic placenta are not known. Importantly, the role of sFlt-1 in normal placental development and in placental pseudovasculogenesis is not clear. No coagulation or liver function abnormalities or brain abnormalities (eclampsia) were reported in sFlt-1-treated animals. Finally, sFlt1 may not be altered in some preeclamptic women especially in those labeled mild preeclamptics.[567] Therefore, additional synergistic factors that are elaborated by the placenta may yet be identified that play a role in the pathogenesis of the generalized endothelial

dysfunction noted in preeclampsia. Derangements in other angiogenic molecules have also been observed recently. Levels of endostatin, an anti-angiogenic factor, are also elevated in preeclampsia.[568]

Soluble endoglin (sEng), another anti-angiogenic protein, has also been implicated in the pathogenesis of preeclampsia (see Figure 81.18). The role of this protein in producing preeclampsia phenotypes was evaluated based on the hypothesis that sEng may impair transforming growth factor-beta 1 (TGF-β1) binding to its cell surface receptors and decreasing endothelial NO signaling.[569] sEng is placental in origin, is present in the sera of pregnant women, is elevated in preeclamptic individuals and correlates with disease severity.[570,571] Administration of both sFlt1 and sEng using an adenoviral expression system in rats produces a severe preeclampsia-like animal model with hypertension, proteinuria, glomerular endotheliosis, features of HELLP syndrome and small for gestational age (SGA) pups.[569] The role of sEng in early placentation and its regulation is still not yet known.

Agonistic Antibodies Against AT1 Receptors

Patients with preeclampsia have also been reported to have circulating autoantibodies against the angiotensin receptor -1 (AT1-AA).[572] These autoantibodies are agonistic to the AT1 receptor and have been hypothesized to participate in angiotensin II-induced hypertensive changes noted in preeclamptic patients in preeclamptic patients and in "shallow" placental implantation.[573,574] These autoantibodies have been also shown, *in vitro* to stimulate NADPH oxidase from both trophoblasts and vascular smooth muscle cells, the implication being the antibodies being the antibodies are responsible for the substantial increase in circulating reactive oxygen species in the in preeclampsia.[575] Recently, direct pathogenic role for AT1-AA in preeclampsia has been noted in animal models.[576] However, these antibodies have also been encountered in other examples of vascular injury such as vascular rejection,[577] suggesting that they may be secondary to the generalized microangiopathy of preeclampsia. As of 2011 we could locate no information on the temporal relationship of these autoantibodies with the appearance of preeclampsia. It was also unclear at that time, whether these antibodies synergize with other proteins, such as sFlt-1, to induce systemic endothelial dysfunction or whether they are simply a consequence of the diffuse endothelial injury. Finally, the source of the antigen responsible for these antibodies has not yet been identified.

Oxidative Stress and Inflammation

Oxidative stress, the presence of active oxygen species in excess of available antioxidant buffering capacity, is a prominent feature of preeclampsia. Oxidative stress is known to damage proteins, cell membranes, and DNA and is a potential mediator of endothelial dysfunction. It has been hypothesized that in preeclampsia factors responsible for oxidative stress of placental origin are transferred to the systemic circulation, resulting in oxidative damage to the vascular endothelial cells throughout the body. Proponents of this theory, focus on oxidative stress itself as the link between the placenta and maternal end-organ disease.[578,579]

There are many reports that document increased markers of oxidative stress in both the placentas and circulation of preeclamptic patients.. These include decreased expression of enzymatic antioxidants, abnormally high superoxide generation,, higher levels of lipid peroxidation, and increased production and secretion of isoprostanes, all in the placenta.[580–585] Maternal serum markers include increases in peroxynitrite, protein carbonyls.[586] There are also Increases in volatile organic compounds in alveolar breath,[587] though this is disputed.[588,589]

Animal models and human trials also suggest a role for oxidative stress. One of the major animal models of preeclampsia is produced by infusion of L-NAME (L-nitro-arginine methylester), an inhibitor of NO synthesis, into pregnant rats. This produces a preeclampsia-like syndrome with hypertension, proteinuria, and thrombocytopenia[590,591] A UK study showed that deficiency of selenium, a trace element with antioxidant properties, was associated with an increased risk of preeclampsia.[592] But the most clinically relevant insights come from human trials: if oxidative stress is a key element in preeclampsia, antioxidant treatment might be expected to be beneficial. A randomized controlled trial by Chappell et al randomized showed that supplementation with vitamin C and E decreased preeclampsia in high-risk pregnant women (OR 0.4). PAI-1 and PAI-2, markers of endothelial activation, were also decreased in the treatment group.[593] Similarly, treatment with the antioxidant lycopene was found to decrease the risk of preeclampsia by almost 50% in a small randomized trial.[594] Unfortunately, large randomized controlled trials did not show an effect of antioxidants, vitamin C and vitamin E on the risk of preeclampsia.[595,596] In summary, the data reviewed suggest that oxidative stress while noted in preeclampsia, may not play an important role in the pathogenesis of disease.

The Kidney in Preeclampsia

Renal Morphology

Preeclampsia is accompanied by characteristic morphological alterations in the kidney termed

"glomerular endotheliosis." Detailed descriptions of the renal lesions of preeclampsia, an historical review, a precise of several disagreements in the literature, including whether or not preeclampsia causes focal glomerular sclerosis, and a more complete bibliography can be found elsewhere.[1,473] It is noteworthy that the best information has come from analysis of tissues obtained at necropsy between 1930 and 1950, and renal biopsy series liberally performed from the late 1950 through the mid-1970s. More recently, reasons to perform renal biopsies have become more stringent, with few indications for use of this procedure in routine preeclamptics, either prepartum or in the puerperium (see section on renal disease). The more recent literature, therefore, has focused on more atypical variants of the disease, as biopsies have been performed weeks, and even months following the index pregnancy. We believe that many of these reports have only managed to confuse our understanding of the morphological picture of the disorder, and therefore focus on the older literature in the summary that follows.

The kidneys from women dying after eclampsia are pale and enlarged compared to those of gravidas dying from accidents or other causes, but the variance is such that the differences are not significant.[1] The glomeruli are large and swollen, but not hypercellular. This is due to swelling of the intracapillary cells (mainly endothelial, but mesangial as well), which encroach on the capillary lumina giving the appearance of a bloodless glomerulus (Figure 81.19). This change varies with the severity of the lesion but is usually widespread, involving most of the capillaries in nearly all glomeruli, and the swelling may be of sufficient magnitude that the tuft herniates into the initial segment of the proximal tubule, a phenomenon termed "pouting".[1,325,473,597] On occasion, the mesangium is severely affected, its expanded matrix and enlarged cells extending into the peripheral capillary loops between the endothelial cells and the basement membrane and creating the illusion of "double contours" or "tramtrack." Thrombosis and fibrin-like material, as well as foam cells may be present, and epithelial crescents have been described in rare instances[1,9,325,473,597]

The characteristic glomerular changes of preeclampsia most evident on ultrastructural examination (Figure 81.19) include extensive swelling and vacuolization, primarily of the endothelial cells and to a lesser extent of the mesangial cells, without significant changes elsewhere. The enlarged and reactive cells, which have increased amounts of vacuolated cytoplasm, narrow the capillary lumen and even appear to obliterate it, but result in only moderate widening of the lobular stalks even when mesangial involvement is prominent. Impressive lysosomal changes, especially in material obtained after delivery when the disease is in regression, can also be seen. The basement membrane is not thickened, but may appear so on light microscopy because of the fibrils produced by endothelial and mesangial cells.

Variable densities of amorphous, extracellular debris separate the swollen cells where the capillary lumina are severely narrowed. Occasionally, small subendothelial deposits (thought to represent accumulation of protein) and tactoids of fibrin or a fibrin-like material may be seen. These aberrations may in part be due to the accumulation of several basement membrane proteins including laminin, type IV collagen, tenascin, fibronectin and its receptor, and a proteoglycan in the glomeruli of preeclamptics.[598,599] Moreover, renal biopsies obtained after a prolonged postpartum interval may reveal large cytoplasmic cholesterol clefts in addition to lipid-containing vacuoles.[325,473,597]

Mesangial proliferation, granulated epithelial cells, and nonspecific tubular changes have been described (cited in refs.,[166,167]but this has not been consistent during the 30-year experience at our institution, which includes several hundred biopsies.[325,473,597] Starting in the 1980s there have been more and more reports describing FSGS in association with preeclampsia, some authors claiming that this lesion is a consequence of the disease,[600–605] which would alter the benign prognosis of pure preeclampsia (see above). Presence of FSGS might also suggest that clinicians have not been sufficiently aggressive in controlling the rise in blood pressure, or have utilized antihypertensive agents that failed to decrease glomerular pressure, which might conceivably be high during this disease. Interpretation of our own biopsy material (reviewed in[473,597]) suggests that FSGS, when present, antedated pregnancy or was due to hemodynamic factors present earlier in gestation, conclusions that are consistent with the benign remote prognosis of pure preeclampsia[150,325] (see below). This is because the FSGS lesion, if present, would not likely disappear spontaneously.

Glomerular endotheliosis, which can be superimposed on other preexisting renal lesions, has not been observed by us in biopsies from nonpregnant patients. But others have described similar lesions in a number of nongravid subjects with a variety of glomerular diseases, as well as in certain pregnant women with placental abruption (cited in refs.[9,597]). More recently glomerular endotheliosis has been described in a few renal biopsies from normal third trimester gravidas, but the degree of endothelial swelling was trivial, and even borderline.[5] In the same study, the lesion in preeclamptics was fully developed and glomerular volume markedly increased. Thus we believe, that the glomerular lesion in its fully developed form is distinctive, and that it reverses rapidly after delivery,

the glomeruli resuming a normal appearance within 2–3 weeks.[9,325,473,597] Nevertheless, some authors have attributed abnormalities seen years after the putative disease to residua of the preeclamptic lesion.[9,325,597]

The significance of immunoglobulins and fibrin deposits in the glomerular lesion of preeclamptic patients is disputed, and is discussed in detail elsewhere.[325,473,597] Some authors reported that IgG, IgM, and fibrin are invariably present, but such deposits were found less often by others, including us. Of interest, however, is a report by Packham et al.,[606] in which biopsies performed prior to delivery contained substantially more fibrin deposition than those obtained in the immediate puerperium, suggesting that mobilization of the deposits postpartum occurs more rapidly than was originally appreciated.[606]

Functional Changes

Both GFR and ERPF decrease in preeclampsia.[9,22,150,219] In most studies the former falls more than the latter (32% v 24% in 23 studies reviewed in reference,[94]so that the filtration fraction also decreases. Since the decrement in filtration is <25% and lower in mild cases, the GFR of preeclamptics often remains above values in nonpregnant women, despite morphological evidence of ischemia and an obliterated urinary space. In fact, the decrement may not be appreciated if one is not aware of norms for pregnancy. However, while functional decrements are usually mild or moderate and reverse rapidly after delivery, an occasional preeclamptic patient may progress to ARF, especially when treatment or intervention is neglected, and the long range renal and cardiovascular prognosis of these latter cases is poorer than that associated with acute tubular necrosis in general.[306]

The mechanism(s) responsible for the compromised renal function are unknown. The inciting event may relate both to factors that evoke general vasoconstriction in preeclampsia, and to the morphological changes in the kidney (especially glomerular endotheliosis) described above. Irrespective of the proximal cause, renal vascular resistance is high, which accounts for the reduced renal blood flow. As for the GFR, indirect calculations of renal afferent and efferent arteriolar and of venous resistances suggest that the increment in total renal vascular resistance is primarily due to an increase in the afferent arteriolar resistance.[22,41] This is not unexpected, as the decrement in filtration fraction, albeit consistent is small. Under these circumstances it is tempting to speculate that a reduction in the ultrafiltration coefficient is the explanation for the fall in GFR. In this respect, elegant morphometric studies of renal biopsies in combination with theoretical modeling,[602] and preliminary data from protocols in which glomerular permselectivity to dextrans are used to estimate ultrafiltration coefficient,[607] suggest similar conclusions.

The fractional and absolute clearances of urate also decrease in preeclampsia, and consequently plasma levels of this solute increase [in pregnancy values exceeding 4.5 mg/dL (268 μmol/L) are suspect, while values exceeding 5 mg/dL (297 μmol) are definitely abnormal].[9,22,150] Decrements in urate clearance tend to occur earlier and are more profound than that in GFR, so that the urate/inulin or urate/creatinine clearance ratio is also decreased.

The reasons for the rise in circulating urate and the fall in its renal clearance are also obscure. Certainly, all the changes can be ascribed to decrements in fractional urate clearance. Of interest are studies in the older literature (reviewed in reference[22] and[41]), in which probenecid administration normalized plasma urate levels in preeclamptics, but had little or no effect in normal pregnant women, suggesting that hyperuricemia was primarily due to enhanced tubular reabsorption. Finally, studies whose authors attempted to determine whether there is increased urate production in preeclamptic women yielded conflicting results.[22] Interesting in this respect are recent reports which note that placental xanthene oxidase/dehydrogenase activity may be increased in preeclampsia.[141,608] Finally, recent rodent studies suggest that hyperuricemia may play a pathogenic role by contributing to the vascular damage and hypertension.[609]

Abnormal proteinuria almost always accompanies preeclampsia, and the diagnosis is suspect without this sign (although increased protein excretion may appear later in the course of the disease). The proteinuria may be minimal or severe, is usually nonselective in nature, and its magnitude correlates roughly with the severity of the renal lesion as well as with poor fetal outcome.[325] Of interest, too, is that preeclampsia is the most common cause of nephrotic proteinuria in pregnancy.[325]Tubular proteinuria may also occur in preeclampsia,[22] which is surprising in view of the noninvolvement of the tubules in the morphologic lesion.

Fluid Volumes and Sodium Excretion

Edema was once considered the hallmark of preeclampsia, and salt restriction and/or diuretics figured prominently in preventing or managing the disorder. However, even when interstitial fluid volumes are markedly increased, plasma volume is smaller compared to normal gestation, and severe disease can occur even in the absence of edema (the "dry preeclamptic) [reviewed in[150,195,610,611]]. The reasons for the decrement in plasma volume (which is associated with hypoalbuminemia and hemoconcentration) is unclear, as the decrease precedes any evidence of

hypertension.[160] One major postulate attributes most of the change to increases in capillary permeability.[195,202,203,610] In addition, both proteinuria and liver involvement would be expected to contribute to the hypoalbuminemia.

The ability to excrete sodium may be impaired in preeclamptics but the degree to which this occurs varies.[9,150,195,207,227,610] The reason for the decreased sodium excretory capacity is also poorly understood [reviewed in references[195] and[610]]. The renin–angiotensin–aldosterone system is suppressed or unchanged, while ANP levels are increased and its metabolic clearance unchanged.[195,204,213,219,610] Finally, a literature devoted to cellular sodium transport, including several membrane pumps or their inhibitors, has shed little light on these problems and is reviewed elsewhere.[9,195,610]

Prediction, Prevention, and Remote Prognosis

Prediction

Investigators have sought to identify markers that could provide clues to the cause of preeclampsia (or at least improve its management), to predict the risk of its appearance later in gestation, or to differentiate it from more benign hypertensive complications of pregnancy. In the past a decline in fractional urate clearance, a positive "cold pressor" response, enhanced sensitivity to infused angiotensin II, and demonstration of a rise in blood pressure upon turning from a lateral recumbent to a supine posture (the "roll over" sign) were all heralded as promising tests.[150,612] More recently, studies have focused on autacoids, circulating lipids, oxidant and antioxidant activity, markers of endothelial dysfunction, a host of cytokines, hormones, and circulating proteins (especially those of placental origin such as chorionic gonadotropin, activin, and inhibin), the isoelectric point of albumin, urinary excretion of albumin, and so on.[468,498,612] Unfortunately, the sensitivity and positive predictive value of all these tests are at best modest.

The recent focus on the role of circulating angiogenic proteins in the pathogenesis of preeclampsia, has also raised hope that measurement of these molecules in serum or urine may serve as a screening tool.[550] In retrospective studies, serum sFlt-1 has been reported to have sensitivity of 83% and specificity of 95% between 28 and 32 weeks of pregnancy in predicting preterm preeclampsia[549] Similarly measurement of sFlt-1 between 32 and 36 weeks of pregnancy has been reported to have a 70% sensitivity and 97% specificity for term preeclampsia.[549] A number of studies have also investigated serum PlGF and found that alterations in PlGF occur even as early as first trimester in women destined to develop preeclampsia.[551,554,557,613,614] Recently, a more promising screening strategy has evolved by measuring urinary PlGF levels.[558] In a cross sectional study representing a secondary analysis of stored specimens from a completed prevention trial, Levine et al reported that at 21–32 weeks of gestation, urinary PlGF concentration in the lowest quartile (<118 pg/mL) was highly predictive of the development of preterm preeclampsia (odds ratio:22.5) and modestly predictive of term preeclampsia (odds ratio:2.2). The ability of sEng to predict preeclampsia has also been evaluated in several studies and found to be particularly useful in early-onset preeclampsia.[570,615] Recently, Kusanovic et al. reported a remarkable performance of delta and slope of PlGF:sEng ratio, (from early pregnancy and midtrimester) with a positive LR of 55.6 (95% CI 36.4–55.6) and 89.6 (95% CI 56.4–89.6), respectively for predicting early-onset preeclampsia.[616] Poon et al. evaluated 7,797 women with singleton pregnancies, during gestational weeks 11–13 using several biomarkers and uterine artery Dopplers. This yielded very good results using an algorithm developed by logistic regression that combined the logs of uterine pulsatility index, mean arterial pressure, PAPP-A, serum free PlGF, body mass index and presence of nulliparity or previous preeclampsia. At a 5% false positive rate, the detection rate for early preeclampsia was 93.1%.[617]

In addition to being useful in the prediction of preeclampsia before the onset of clinical symptoms, angiogenic factors may also prove useful in diagnosing the disease and in distinguishing it from other hypertensive disorders of pregnancy, such as gestational hypertension and chronic hypertension.[618,619] These findings have also been now confirmed on clinical grade automated assays.[620–622] In summary, measurement of circulating angiogenic proteins for the diagnosis and prediction of preeclampsia is still at an early stage but is rapidly evolving. Large prospective trials demonstrating clinical utility are needed.

Prevention

Interventions that could prevent preeclampsia or abort the disease at an early preclinical stage would revolutionize prenatal care. Sodium restriction and/or prescription of prophylactic diuretics were once popular strategies. They were then discarded but were revived in 1985 when a metaanalysis of ~7000 randomized patients suggested that saluretic agents did indeed reduce the incidence of preeclampsia.[623] A careful analysis of the results, however, reveals that there is no difference in the incidence of proteinuric hypertension, the seemingly positive results having been the ability of diuretics to decrease edema or to induce a small decrease in blood pressure.

In the 1990s two new approaches were advocated, each based on plausible hypotheses. The first approach, administration of low-dose aspirin (60−100 mg/day) starting after the gestational week twelve, was based on the postulate that hypertension and coagulation abnormalities in preeclampsia were due to an imbalance in the production of vasodilating and vasoconstricting PGs. The dose of aspirin chosen would inhibit platelet thromboxane synthesis but spare prostacyclin production. Initially, an extremely favorable metaanalysis, primarily based on small series led physicians to routinely prescribe low-dose aspirin prophylactically.[624,625] This optimism proved premature, as a number of large randomized, placebo-controlled trials (several aimed at "high-risk" populations as defined in the epidemiology section above), which included over 30.000 women, have revealed but small effects of aspirin to reduce the incidence of preeclampsia. [454,625,626,627] More recently, a large Cochrane metaanalyses concluded that low-dose aspirin had a modest effect in preventing preeclampsia with a relative risk of preeclampsia of 0.90 (95% CI 0.84−0.97) for aspirin-treated patients.[628] Aspirin prophylaxis should be considered as primary prevention for preeclampsia only in women at high baseline risk in whom the absolute risk reduction will be greatest.

The second approach consisted of dietary calcium supplementation starting in early gestation, based on observations that preeclamptic women are hypocalciuric,[502] and that the incidence of the disease may be greater among populations in which dietary calcium is low,,[629] and on a hypothesis that alterations in calciotropic hormone levels play a role in the genesis of the hypertension.[624,625] Here, too, initial reports were very encouraging, several metaanalyses noting marked and significant reductions in the incidence of preeclampsia (very reminiscent of the aspirin saga) (reviewed in references[624,625]). Again, a carefully conducted, large randomized, and blinded trial comprising >4500 women failed to detect any effects of calcium supplementation on either the incidence of preeclampsia or of improved fetal outcome.[472] The negative results in North America may relate to the virtual absence of severely calcium-deficient diets in that population, in contrast to deficiencies in deprived populations in certain developing nations. More recently in a recent WHO prospective study in women who live in endemic areas of calcium deficiencies, calcium supplementation seems to protect them from adverse pregnancy outcomes including the development of severe preeclampsia.[469]

Are there other promising trials? Enthusiasm for fish oil or its ingredient eicosapentaenoic acid (which are actually surrogates for aspirin in their effects on PGs) appears to have waned.[624,625] However, investigators are contemplating or have started new trials, again based on plausible hypotheses. These include combinations of dietary supplements of L-arginine (the precursor of NO), antioxidants (e.g., vitamin C), and magnesium. Despite the essentially negative results discussed above there are populations where "prophylactic" strategies may improve outcomes. These include subjects with a history of early-onset preeclampsia or who have metabolic abnormalities or risk factors associated with vascular thrombosis. Screening may reveal hyperhomocysteinemia, lupus anticoagulant, antiphospholipid antibodies, activated protein C resistance (factor V Leiden), and protein S deficiency.[630] The presence of these findings increases the likelihood that a preeclampsia-like syndrome will occur in subsequent gestations, and to some is an indication to consider prophylactic treatment with heparin and/or low-dose aspirin.

Remote Prognosis

There is controversy regarding the interpretation of studies designed to determine the remote cardiovascular prognosis of women who experienced preeclampsia or eclampsia. This is not surprising, for as noted, a diagnosis of preeclampsia is suspect when clinical criteria alone are used, although its reliability improves if the population analyzed had their disease when nulliparous, had convulsed (eclampsia), or the diagnosis was confirmed by renal biopsy. Second, data from preeclamptics compared to follow-up information from matched normotensive deliveries lead to different conclusions than those in which the preeclamptic women were compared to the expected prevalence in the general population, matched for race and age at the time of the remote examination. These issues are discussed further below.

In the older literature Chesley[150] reviewed 53 publications with follow-up information on 2637 eclamptics and estimated the prevalence of remote hypertension to be 24% (but the range was enormous).[150] Perhaps the most complete long-term survey after eclampsia is that of Chesley et al.,[150,631] who periodically reexamined 267 of 270 women who survived eclampsia during the years 1931 to 1951. The last report included the years 1973 and 1974,[631] at which time the clinical course of some of these patients had been followed for 40 years! The remote mortality rate in Caucasian women who convulsed during their first gestation was not greater than that of age-matched unselected women from several large epidemiological surveys. In white women who had eclampsia as multiparas and in all black women (this group comprised only 26 patients), the remote mortality was two to five times higher than expected. The prevalence of late

hypertension was also increased in women who had eclampsia as multiparas, which seemed to account for the increment in remote deaths. In contrast, prevalence of hypertension or the distribution of systolic and diastolic blood pressure levels in eclamptic primiparas was similar to that reported for the general population of women in the epidemiological surveys. Prevalence of hypertension was also greater in eclamptic primiparas who manifested high blood pressure in subsequent gestations compared to those who remained normotensive in all later pregnancies. Chesley et al.[150,473] concluded that eclampsia is neither a predictive sign nor a cause of essential hypertension, and that hypertensive pregnancies that follow eclampsia may indicate the probability of later hypertension, but do not cause it. Similar conclusions were reached by Bryans,[632] who studied a group of eclamptic black women, (follow-up averaging 14 years), and by Sibai et al[633] (posteclamptic follow-up seven years).

With preeclampsia, however, the findings are different. A survey of the older literature (reviewed in reference[150,634]) and a number of more recent publications (the latter often combining small numbers of eclamptics with large series of preeclamptic women) consistently reveal an increased remote prevalence of hypertension in women who had preeclampsia.[635–637] It has even been suggested that preeclampsia may have caused the remote hypertension.[634] Of interest in these studies are the following: First, the development of hypertension is far more frequent in women who preeclampsia as multiparas. Second, in the one study where diagnosis was confirmed by renal biopsy (see Table 81.4) two differing outcomes were noted depending upon how the control population was selected.[325] Prevalence of remote hypertension was increased if the authors used age- and race-matched normotensive gravidas as the controls, but was unchanged if they compared the outcome in biopsy-proven preeclamptics to that of age- and race-matched unselected women from the National Survey. Further inspection of the data revealed that the control group of normotensive delivering women had a very low prevalence of remote hypertension, suggesting that normotensive delivery "selects" a population without risk factors for future cardiovascular disease. A number of studies in both the older and more recent literature are consistent with this view.[150,638] However, although favoring the above formulation, we recall a 1964 publication which may some day prove prescient: Epstein[634] followed the clinical course of women with "toxemia" and a group with normotensive deliveries and like others using such controls he observed a higher incidence of remote hypertension in both nulliparous and multiparous preeclamptics. In addition, however, he also measured blood pressure in 74 of the "toxemic" women's siblings, and they displayed a lower prevalence of hypertension, suggesting that the long-term hypertension noted in preeclamptics may have been due to a persistent subtle renal injury.

Women with history of preeclampsia, have also been reported to have increased incidence of dyslipidemias and insulin resistance.[639,640] There are also epidemiological surveys suggesting increased cardiovascular events (including coronary events and strokes) in women with a history of preeclampsia,[474,641,642] that in one study was found uniquely in women with "early" preeclampsia..[474] However, it is unknown whether these represent baseline risk factors in these women at risk for premature preeclampsia or whether they develop as a consequence of preeclampsia More recently it was observed that women with a history of preeclampsia have a slightly higher baseline sFlt-1 concentrations than women with a history of normal pregnancy.[579] Patients with preeclampsia are said to have a decreased long-term incidence of malignancies[643] a provocative observation that is disputed by some.[644] Finally, recurrent preeclampsia has also been associated with increased risk for end-stage renal disease and hypothyroidism in later years, although the absolute risk is relatively low.[645,646]

Management

As already noted this text is devoted to physiology and pathophysiology, and space considerations limit detailed discussions of therapy. The following overview regarding the treatment of preeclampsia–eclampsia and chronic hypertension in pregnancy outlines in brief the management of these conditions and underscores some of the unresolved controversies in this area. For a more comprehensive discussion of treatment the reader is referred to several chapters[48,647,648] in a contemporary text as well as to a report on High Blood Pressure in Pregnancy, issued by the US NHBPEP in 2000[322] as well as periodic updates that are based on that report and published by the American College of Obstetrics and Gynecology.

Preeclampsia–Eclampsia

Due to its capricious and at times explosive nature, suspicion of preeclampsia is sufficient grounds to recommend hospitalization. This approach will diminish the incidence of convulsions, minimize diagnostic error, and improve fetal outcome. Near term, induction of labor is the therapy of choice, whereas attempts to temporize should be made if pregnancy is at an earlier stage.[461] If the latter decision is made, several antihypertensive agents considered safe in pregnancy are available (Table 81.5).[461,648,649] Delivery is indicated at

TABLE 81.5 Drugs for Chronic Hypertension in Pregnancy

Drug (Food and Drug Administration Risk)*	Dose	Concerns or Comments
Preferred agent Methyldopa (B)	0.5–3.0 g/d in two divided doses	Drug of choice according to NHBEP working group; safety after first trimester well documented, including 7-year follow-up evaluation of offspring
Second-line agents† Labetalol (C)	200–1200 mg/d in 2–3 divided doses	May be associated with fetal growth restriction and neonatal bradycardia
Nifedipine (C)	30–120 mg/d of a slow-release preparation	May inhibit labor and have synergistic interaction with magnesium sulfate; small experience with other calcium-entry blockers
Hydralazine (C)	50–300 mg/d in 2–4 divided doses	Few controlled trials, long experience with few adverse events documented, useful only in combination with sympatholytic agent; may cause neonatal thrombocytopenia
β-receptor blockers (C)	Depends on specific agent	May cause fetal bradycardia and decrease uteroplacental blood flow, this effect may be less for agents with partial agonist activity; may impair fetal response to hypoxic stress; risk for growth retardation when started in first or second trimester (atenolol)
Hydrochlorothiazide (C)	25 mg/d	Majority of controlled studies in normotensive pregnant women rather than hypertensive patients, can cause volume depletion and electrolyte disorders; may be useful in combination with methyldopa and vasodilator to mitigate compensatory fluid retention
Contraindicated ACE Inhibitors and AT1-receptor antagonists (D)‡		Leads to fetal loss in animals; human use associated with fetopathy, oligohydramnios, growth restriction, and neonatal anuric renal failure, which may be fatal

U.S. Food and Drug Administration classification.
†*We omit some agents (e.g., clonidine, α-blockers) because of limited data on use for chronic hypertension in pregnancy.*
‡*We would classify in category X during second and third trimesters.*
Note: No antihypertensive drug has been proven safe for use during the first trimester. Drug therapy is indicated for uncomplicated chronic hypertension when diastolic blood pressure is ≥100 mm Hg (Korotkoff V). Treatment at lower levels may be indicated for patients with diabetes mellitus, renal disease, or target organ damage.
NHBPEP, National High Blood Pressure Education Program.

any stage of pregnancy if severe hypertension remains uncontrolled for 24–48 h or at the appearance of certain "ominous" signs such as clotting or liver abnormalities, decreasing renal function, signs of impending convulsions (headache, epigastric pain, and hyperreflexia), or evidence of fetal jeopardy (as evidenced by severe growth retardation and the results of fetal testing).

There is some confusion and even controversy regarding "aggressive" versus "conservative" management of preeclamptic women very remote from term. Contemporary texts stress that such patients warrant termination of their pregnancies, citing a literature that attests the low yield of successful outcomes and, more important, substantial risk of maternal morbidity. Recently, however, this practice has been questioned, the authors proposing an expanded role for "conservative" management of the women, even when they manifest severe disease.[624,650–654] Review of these reports reveals that the case for the conservative approach may be more apparent then real. For example, one group temporizes only as long as blood pressure is reasonably controlled and "ominous" signs and symptoms are absent, precisely what we and others have recommended for decades when suggesting criteria for terminating pregnancy in the face of severe disease (see above). Of interest in this respect is a randomized trial where the investigators[653] assigned patients for either termination or "conservative" management after labeling their disease as severe based on a traditional classification pattern (level of blood pressure and degree of proteinuria), rather than the evolution of the clinical picture over a defined period of time. The positive results in the "conservative" arm are a cogent reminder that when managing women with hypertension in pregnancy we do not treat the diagnosis but the evolving disease.

There is another group which stresses an even more radical form of "conservative" management, a policy that we strongly question. Visser et al.[654] would continue temporization even when patients develop early evidence of the HELLP syndrome (see above). Scrutiny of their results suggests they were inadequately controlled, that there was substantial fetal loss even though they studied patients up to gestational week 34, and that there was evidence of increased maternal

bleeding episodes. Their approach appears too risky to us, and we continue our recommendations that physicians continue to be vigilant, aggressively terminating pregnancies complicated by early-onset preeclampsia using the clinical criteria noted by us above, as well as those by Sibai et al.,[653] who paradoxically entitled their criteria "conservative management." Finally, it should be noted that all of the studies above took place in tertiary care centers with maternal–fetal medicine intensive care units, facilities not readily available to most practitioners.

Sudden Escalating Hypertension and Imminent or Frank Eclampsia

There are controversies on when to treat rapidly rising blood pressure near term or during delivery (usually associated with the presentation of pure or superimposed preeclampsia). There is further debate on how aggressive treatment should be. We adhere to the NHBPEP recommendations,[461] which state that diastolic levels $\geq$105 mm Hg require treatment (though some contemporary texts still recommend $\geq$110 mm Hg). Certain circumstances, such as a teenager whose recent diastolic levels were 70 mm Hg or lower, or any patient demonstrating cerebral signs such as excruciating headache, confusion, or somnolence,[518] warrant treatment at lower levels (Table 81.6).

In the past there was an acrimonious debate about prevention and management of the eclamptic convulsion. Some considered parenteral magnesium the therapy of choice, while others condemned this approach, labeled the drug as ineffective and archaic, and suggested other agents such as phenytoin and diazepam. Still others questioned whether any therapy other than blood pressure control was needed for prophylaxis (see reference,[624,625,655] and previous edition of this text). Several reports of randomized trials appear to have resolved these controversies. In one[656] comprising 1680 patients intravenous magnesium sulfate proved superior to both diazepam and phenytoin in preventing *recurrent* seizures. In another,[657] scheduled to evaluate 4500 women, by comparing magnesium sulfate to phenytoin as *prophylaxis*, the trial was halted after 2123 women had been randomized because seizures were only occurring in the phenytoin arm. In a third,10,141 women underwent a placebo-controlled trial of magnesium, and prophylactic magnesium more than halved the eclampsia rate.[658] Thus magnesium has been demonstrated as the therapy of choice once a convulsion has occurred, and the drug is superior to phenytoin or placebo in preventing eclampsia. (These, and other trials are further reviewed in systematic analyses[627,659] (Table 81.6).

Controversies still exist. Magnesium especially intravenously, is not without hazard, and some contend its risks outweigh those with "mild" preeclampsia and it should be reserved for those with "severe disease" only.[660,661]Trials to settle these questions are needed.

Chronic Hypertension

Most pregnant women with chronic hypertension have the "essential" variety, and their disease is

TABLE 81.6 Drugs for Urgent Control of Severe Hypertension in Pregnancy

Drug (Food and Drug Administration Risk)*	Dose and Route	Concerns or Comments†
Labetalol (C)	20 mg i.v., then 20–80 mg every 20–30 min, up to a maximum of 300 mg; or constant infusion of 1–2 mg/min	Experience in pregnancy less than with hydralazine; probably less risk for tachycardia and arrhythmia than with other vasodilators
Hydralazine (C)	5 mg, i.v. or i.m., then 5–10 mg every 20–40 min; or constant infusion of 0.5–10 mg/h	Drug of choice according to NHBEP working group; long experience of safety and efficacy
Nifedipine (C)	Tablets recommended only: 10–30 mg orally, repeat in 45 min if needed	Possible interference with labor; may interact synergistically with magnesium sulfate
Relatively contraindicated nitroprusside (C)‡	Constant infusion of 0.5–10 μg/kg/min	Possible cyanide toxicity; agent of last resort

*U.S. Food and Drug Administration classification; C indicates that either studies in animals have revealed adverse effects on the fetus (teratogenic, embryocidal, or other) and/or there are no controlled studies in women, or studies in women and animals are not available. Drugs only should be given if the potential benefits justify the potential risk to the fetus.

†Adverse effects for all agents, except as noted, may include headache, flushing, nausea, and tachycardia (primarily caused by precipitous hypotension and reflex sympathetic activation).

‡We would classify in category D: there is positive evidence of human fetal risk, but the benefits of use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).

Note: Indicated for acute increase of diastolic blood pressure $\geq$105 mm Hg; goal is a gradual reduction to 90–100 mm Hg.

i.v., intravenously; i.m., intramuscularly; NHBPEP, National High Blood Pressure Education Program.

frequently mild in nature and of recent origin. Over 85% of these gestations are uncomplicated, though outcomes are poorer than those of normotensive populations.[48,150,419,453,662] Albeit small, there is an increased incidence of placental abruption, ARF, cardiac decompensation, and cerebral accidents in the mother, and of growth retardation and (in midtrimester) death of the fetus.[150,461] Such events are mainly associated with superimposed preeclampsia, whose incidence in chronic hypertensives is ~20%.[319] They also tend correlate with the age of the gravida as well as the duration and degree of control of her high blood pressure, many of these complications occurring in women over the age of 30 or in those with evidence of end-organ damage. Extremely obese women with chronic hypertension are at special risk for cardiac decompensation near term, especially if volume loaded during labor. Echocardiography performed earlier in pregnancy will alert the physician to those patients with early evidence of ventricular dysfunction.

The approach to treatment of women with chronic hypertension is also controversial, as some would treat those with mild hypertension and others would not. In this respect randomized studies are needed to resolve this issue. We follow the NHBPEP recommendations,[461] withholding antihypertensive drugs unless diastolic levels are >100 mm Hg (but at lower levels if there is evidence of end-organ damage or specific risk factors such as underlying renal disease). As of 2006 several trials to decide whether mild-moderate hypertension during pregnancy should be treated, Including if such an approach will decrease the incidence of superimposed preeclampsia were in progress. The reader is referred further to two reviews, one focusing on systematic analyses of antihypertensive drugs in pregnancy,[627] the second more philosophical in nature.[663]

Antihypertensive Therapy

Clinicians considering the prescription of antihypertensive drugs to pregnant women should be aware of the following: There have been only a few large randomized multicenter trials. Most studies have been limited in scope, and frequently performed at the request of and with the support of the pharamacological industry. Most published data are from studies where therapy was started after midgestation, when virtually all the risks of provoking congenital malformations have passed. Finally, there are no rigorous animal testing requirements to be met before human trials are undertaken, including standardized means of evaluating the drug effect on the fetus' ability to withstand hypoxic stress, as well as a more complex analysis of morphologic and physiologic variables in the newborn in animal models. This state of affairs should be kept in mind when reviewing the literature on antihypertensive therapy in pregnancy.[663]

Tables 81.5 and 81.6 summarize the status of the more commonly used antihypertensive drugs during gestation, including their pregnancy risk categories (A−D, through X) as defined by the US Food and Drug Administration (see reference[648]). The central adrenergic inhibitor methyldopa remains the preferred drug choice for us because of its long record of use and apparent safety, including evidence from a 7.5 year follow-up study of infants whose mothers received the drug. Beta adrenergic blocking agents are associated with an increased incidence of fetal growth restriction though the effects are minimal, and many clinicians currently use the combined .alpha and beta adrenergic blocker, labetalol.[627,663] Theoretically there may be synergism between magnesium sulfate and calcium channel blocking agents leading to precipitous decreases in blood pressure. In this respect there have been anecdotal report of maternal respiratory arrest, but increased problems do not seem to have appeared in larger surveys.[664] Other comments concerning these agents can be found in Tables 81.5 and 81.6, and the interested reader is referred to references[648] and[627,663] for details on each drug and a summary of randomized trials. We end with the story of ACE inhibitors to underscore why one must be careful when prescribing drugs to pregnant women.

Both captopril and enalapril were originally listed as category C in the Physician's Desk Reference, a designation in which most drugs prescribed to pregnant women fall. While this classification carries some cautionary remarks, most physicians consider Class C drugs as relatively safe. There were reports citing problems in animal models in the early 1980s, but the ACE inhibitors remained Category C medications until 1992. By then mounting evidence that ACE inhibitors used late in pregnancy were associated with renal failure and death in the neonate resulted in the manufacturers being required to print a "black box" warning on the label, and a change to category D in the PDR in 1992 with a similar classification for angiotensin receptor antagonists. More recent data suggest that infants exposed to ACE inhibitors during first trimester were at increased risk for malformations of the cardiovascular system (risk ratio, 3.72; 95 percent confidence interval, 1.89 to 7.30) and the central nervous system (risk ratio, 4.39; 95 percent confidence interval, 1.37 to 14.02).[665] Physicians are taught to do no harm, a cogent reason for continued conservatism when asked to prescribe drugs in pregnancy.
